The large-scale distribution of the elements in the Earth depends on the affinity of each element for specific compounds or phases. Those elements that alloy easily with iron, for example, are mostly sequestered in the Earth's core; those which form oxides and silicate minerals tend to be concentrated in the Earth's crust and mantle. Although many elements display multiple characteristics depending on the chemical environment, a classification according to geochemical affinity is nevertheless useful. The categories in this classification include atmophile (elements that are gases and concentrate in the atmosphere), lithophile (elements that form silicates or oxides and are concentrated in the minerals of the Earth's crust), siderophile (elements that alloy easily with iron and are concentrated in the core), and chalcophile (elements such as copper which commonly form sulfide minerals if sufficient sulfur is available).

Although geochemists have a good general knowledge of the overall distribution of elements in the core and mantle, much more detailed information is available about the chemical composition of the crust, which is accessible. The crust is actually composed of two major parts with quite different compositions, thickness, and average age: the continental crust and the oceanic crust.

Although all elements are present, the crust is made almost entirely of just nine chemical elements: oxygen, silicon, aluminum, iron, magnesium, calcium, sodium, potassium, and titanium. Oxygen and silicon are by far the most abundant. The most common minerals in the crust are those of the silicate family, in which the basic building block is a silicon atom surrounded by four oxygen atoms in the form of a tetrahedron. The crust is essentially a framework of oxygen atoms bound together by the common cations. *See* CHEMICAL BONDING; SILICATE MINERALS.

A variety of processes act to make the crust chemically heterogeneous on many scales. Many of these processes involve liquid water. Running water physically sorts particles depending on size and density, which are ultimately related to chemical composition. It is also a superb solvent, carrying many elements in solution under different conditions of temperature and pressure, and depositing them when these conditions change. Processes involving water account for many ore deposits, in which extreme concentrations of some elements occur relative to their average abundance in the crust. One example is the circulating hydrothermal solutions in volcanically active parts of the crust, which can leach metals from their normally dispersed state in large volumes of volcanic rocks and deposit them in concentrated zones as the solutions cool and encounter different rock types. Another example is the action of weathering in tropical regions with high rainfall, which can leach away all but the least soluble components from large volumes of rock, leaving behind mineral deposits rich in aluminum or, depending on the original composition of the rocks being weathered, metals such as iron and nickel. *See* ELEMENT (CHEMISTRY); GEOCHEMISTRY; ORE AND MINERAL DEPOSITS; WATER; WEATHERING PROCESSES. [G.Fau.; J.D.MacD.]

Elephant The common name for two living species of mammals in the family Elephantidae, one of several families included in the order Proboscidea. The remaining families contain extinct animals, such as the mammoth. One of the living species (*Loxodonta africana*) is indigenous to Africa, and the other (*Elephas maximum*) ranges throughout Southeast Asia.

These animals are terrestrial and entirely herbivorous. The nostrils and upper lip are elongated into a proboscis, the trunk, which is a powerful and sensitive organ specialized to form a prehensile, food-gathering structure. The upper incisors protrude from the mouth on either side of the trunk as tusks, which continually grow throughout the life of the animal. The hard, thick skin of the elephant is sparsely covered with hair, and serves as an insulator. The eyes are tiny but vision is keen. The tail is short; large columnar legs support the massive body.

Elephants live and travel in herds which were originally composed of several hundred individuals, but the usual number is now around 20 animals, with a mature bull, a number of cows and calves, and some younger bulls. Elephants are at ease in water, and they bathe and roll in the mud as a protective measure since, despite the thickness of the skin, they are sensitive to intense sun and insects.

Bulls reach sexual maturity at the age of 15, while cows mature earlier. The gestation period averages 20–22 months with a single calf being born. Twins are rare. The newborn, which may be 3 ft (0.9 m) tall and weigh 200 lb (90 kg), grows rapidly. *See* MAMMALIA; PROBOSCIDEA. [C.B.C.]

Eleutherozoa One of the two subphyla into which the phylum Echinodermata had been customarily divided. The Eleutherozoa are now best considered as comprising at least two distinct subphyla: (1) the Echinozoa, spherical-bodied forms with meridional symmetry; and (2) the Asterozoa, starshaped forms with radially divergent axes of symmetry. *See* ECHINODERMATA; ECHINOZOA. [H.B.F.]

Elevating machines Materials-handling machines that lift and lower a load along a fixed vertical path of travel with intermittent motion. In contrast to hoisting machines, elevating machines support their loads instead of carrying them suspended, and the path they travel is both fixed and vertical. They differ from vertical conveyors in operating with intermittent rather than continuous motion. Industrial lifts, stackers, and freight elevators are the principal classes of elevating machines.

A wide range of mechanically, hydraulically, and electrically powered machines are classified as industrial lifts (Fig. 1). They are adapted to such diverse operations as die handling and feeding sheets, bar stock, or lumber. In some locations with differences in floor level between adjacent buildings, lifts take the form of broad platforms to serve as floor levelers to obviate the need for ramps. They are also used to raise and lower loads between the ground and the beds of carriers when no loading platform exists. Lifting tail gates attached to the rear of trucks are similarly used for loading or unloading merchandise on sidewalks or roads and at points where the lack of a raised dock would make loading or unloading difficult.

Stackers are tiering machines and portable elevators used for stacking merchandise with basically portable vertical frames that support and guide the carriage, to which is attached a platform, pair of forks, or other suitable lifting device (Fig. 2). Horizontal movement is effected by casters on the bottom of the vertical

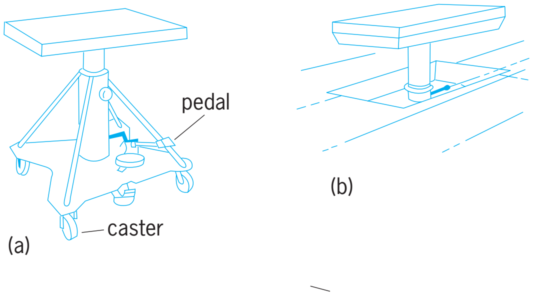

Fig. 1. Examples of industrial lifts, (*a*) Hydraulic elevating work table. (*b*) Hydraulic lift floor leveler.

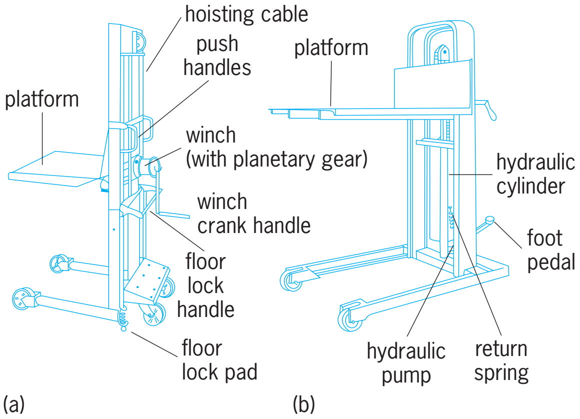

Fig. 2. Two types of electric and hydraulic stackers, (*a*) Hand type, (*b*) Hydraulic foot type.

frame, and can be accomplished manually, or mechanically, by using the same power source as the lifting mechanism. These casters are usually provided with floor locks bolted in position during the elevating or lowering operation. Used in conjunction with cranes, stackers are widely applied to the handling of materials on storage racks and die racks.

Examples of industrial elevators range from those set up temporarily on construction jobs for moving materials and personnel between floors to permanent installations for mechanized handling in factories and warehouses. Dumbwaiters are a type of industrial elevator; they carry parts, small tools, samples, and similar small objects between buildings, but are not permitted to carry people. The most common and economical elevator employs electric motors, cables, pulleys, and counterweights. *See* MATERIALS-HANDLING EQUIPMENT. [A.M.P.]

Elevator A platform or enclosure that is raised and lowered in a vertical hoistway to transport freight or people. The term elevator can also encompass all of the hoisting equipment, motor, cables, and accessories. *See* ELEVATING MACHINES.

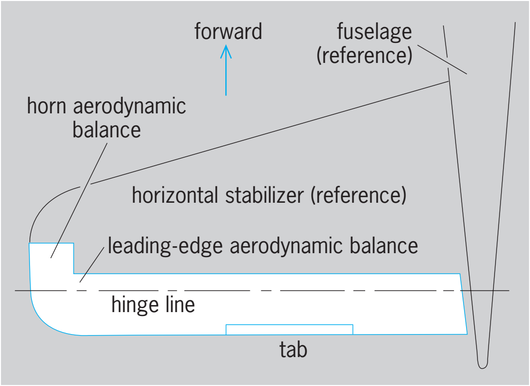
The closed passenger car of a modern elevator rests inside a steel frame. The car and the car frame ride up and down on steel rails in an elevator shaft or hoistway. Guide shoes or rollers on the frame keep the car in place on the rails. Most elevators also have a heavy weight, called a counterweight, attached to the other end of the steel hoisting ropes that pass over the driving machine pulley. The counterweight offsets much of the weight of the car and passengers, thereby reducing power requirements.

The typical elevator control system is made up of a speed-sensing device known as a governor, a clamping device (safety) mounted under each end of the car frame that grips the guide rail when tripped, a tension sheave (pulley) in the pit, and a steel rope. *See* GOVERNOR.

Control devices are also built into the door and its control circuit. When the doors open, control circuits prevent the car from moving away from the landing, but permit releveling if the car moves as passengers enter or leave the elevator (load changes).

In modern elevators, microprocessor computer systems control elevator position, direction of travel, speed, door operation, passenger waiting time, flight time, energy consumption, and system diagnostics. Modern elevators include Braille buttons and voice announcements of the floors to help the sight-impaired. [C.DiT.]

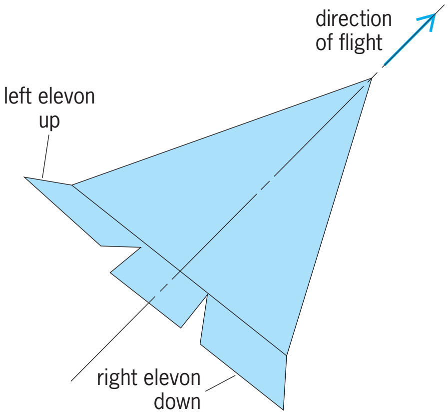
Elevator (aircraft) The hinged rear portion of the longitudinal stabilizing surface or tail plane of an aircraft used to obtain longitudinal- or pitch-control moments. The angular setting of the elevator is controlled by the human or automatic pilot through the flight-control system. A typical elevator control surface is shown in the illustration. *See* FLIGHT CONTROLS.



Elevator control surface (left-hand side).

The elevator is used to perform pitching maneuvers, or maneuvers in which the aircraft's plane of symmetry is not disturbed. These maneuvers include airspeed adjustments and acceleration normal to the flight path (pull-ups or push-downs). The elevator also serves to adjust the aircraft's attitude with respect to the ground for takeoff and landing. [M.J.A.]

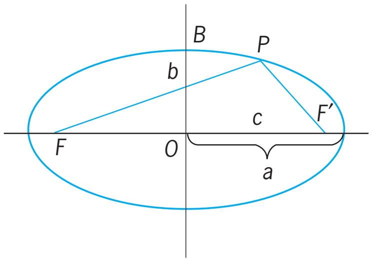
Elevon A movable surface at the trailing edge of a tailless airplane that provides pitch and roll control. Elevons hinged on each side of the rear wing surface (see illustration) nose the airplane up or down, and roll one wing up and the other down. The term elevon is derived from elevator and aileron, and, in effect, elevons provide the same control as conventional elevators and ailerons. An example of an airplane employing elevons is the orbiter vehicle for the space shuttle. *See* AILERON; ELEVATOR (AIRCRAFT); SPACE SHUTTLE; TAIL ASSEMBLY.



Elevons on the trailing edge of a delta wing.

When the elevons on both sides of the wing are deflected upward, they combine to produce a nose-up pitching moment on the wing and, hence, on the tailless airplane. If the elevon on the right wing is deflected upward and the one on the left wing downward, the differential movement does not result in any pitching moment, since the nose-up and nose-down pitching moments produced by the two elevons cancel each other. However, the lift on the right wing decreases, and that on the left wing increases; the combined effect produces a moment on the airplane tending to roll it to the right. Deflecting the elevons in the opposite directions causes the wing to roll to the left, and deflecting both elevons downward produces a nose-down moment. *See* AIRPLANE; WING. [B.W.McC.]

Ellipse A member of the class of curves that are intersections of a plane with a cone of revolution. The ellipse is obtained when the plane cuts all the elements of one nappe, and does not go through the apex. In the illustration, denote the distance between two points F, F' of a plane by $2c$, $c > 0$, and let $2a$ be a constant, with $a > c$. The ellipse with foci F and F' and major axis $2a$ is the locus of points P of the plane such that $PF + PF' = 2a$, where PF denotes the distance of P and F. This suggests the following construction of an ellipse. Put pins at F and F', and slip over them a loop of thread of length $2a + 2c$, pulling the thread taut with a pencil. If the pencil is moved, keeping the thread taut, its point traces an ellipse. *See* CONIC SECTION.



An ellipse, as described in the text.

The midpoint of F, F' is the center O of the ellipse, and the chord through O perpendicular to the major axis is the minor axis, whose length is denoted by $2b$. If B is a point in which the minor axis intersects the ellipse, then $BF = BF' = a$, and so $c^2 = a^2 - b^2$. The ratio $c/a = \epsilon < 1$ is the eccentricity of the ellipse. *See* ANALYTIC GEOMETRY. [L.M.Bl.]

Ellipsometry A technique for determining the properties of a material from the characteristics of light reflected from its surface. The materials studied include thin films, semiconductors, metals, and liquids.

When an electromagnetic wave passes through a medium, it causes the electrons associated with the atoms of the medium to oscillate at the frequency of the wave. As a result, the wave is slowed so that its velocity in the medium is less than its velocity in empty space. Another result may be a transfer of energy from the wave to the electrons, thereby causing the amplitude of the wave to decrease as it penetrates into the material. These two processes are described phenomenologically by the complex refractive index. *See* ABSORPTION OF ELECTROMAGNETIC RADIATION; REFRACTION OF WAVES.

When an electromagnetic wave is incident on a medium, only part of it is transmitted into the medium. The fraction reflected depends on the complex refractive index, the angle of incidence, and the polarization state of the wave. For multilayers with different complex refractive indices, the fraction also depends on the layer thicknesses. The two basic types of polarization are parallel, designated p, and perpendicular, designated s. These terms refer to the orientation of the electric vector with respect to the plane of incidence, which is defined by the directions of the incident and reflected waves. The (intensity-independent) ratios of the amplitudes and phases of the reflected and incident p- and s-polarized electric fields are described by the complex reflectances r_p and r_s. *See* POLARIZATION OF WAVES; POLARIZED LIGHT; REFLECTION OF ELECTROMAGNETIC RADIATION.

The (also intensity-independent) ratio of the p- to the s-polarized component of such a wave is termed the polarization state. Simple examples include linear polarization, where the p- and s-polarized components are in phase, and circular polarization, where the p- and s-polarized amplitudes are equal but the phases differ by 90°. The geometric terms refer to the locus of the p and s (or y and x) components of the electric field when plotted in the complex plane. The general polarization state is elliptical.

Since the complex reflectances r_p and r_s depend on the properties of the medium, the medium can be investigated by determining its reflectance for either p- or s-polarized light, that is, by determining the ratio of reflected and incident intensities $I_{\text{refl}}/I_{\text{inc}} = R = |r|^2$. This is the objective of reflectometry. Alternatively, because r_p and r_s are different, the complex reflectance ratio $\rho = r_p/r_s$, which is equal to the ratio of reflected and incident polarization states, can also be determined. This is the objective of ellipsometry. The ratio ρ is traditionally expressed in terms of angles ψ and Δ as in the equation below.

$$\rho = \frac{r_p}{r_s} = \tan\psi\, e^{i\Delta}$$

Because it deals with complex, intensity-independent quantities, an ellipsometric measurement is analogous to an impedance measurement. This gives ellipsometry certain advantages relative to reflectometry, such as higher accuracy and higher information content in a single measurement. A standard experimental approach, now used almost exclusively in spectroscopic applications, is to determine ρ by establishing a known state of polarization for the incident beam, for example, by passing it through a fixed linear polarizer, then determining the polarization state of the beam after reflection by passing it through a rotating linear polarizer, called an analyzer. The rotating analyzer essentially unrolls the polarization ellipse, allowing the azimuth angle of its major axis and its minor-major axis ratio to be determined by the phase and amplitude of the alternating-current component of the detected intensity. *See* ALTERNATING-CURRENT CIRCUIT THEORY; ELECTRICAL IMPEDANCE.

The primary application of ellipsometry is materials analysis, particularly the nondestructive analysis of thin films in semiconductor technology. Developing applications include the real-time monitoring and control of dynamic processes such as material deposition and etching. Spectroellipsometry, where the complex refractive index is measured and analyzed as a function of wavelength, has almost exclusively replaced reflectometry in materials analysis. Deposition and etching involve kinetic ellipsometry, where single-wavelength data are monitored as a function of time. *See* FILM (CHEMISTRY); INTEGRATED CIRCUITS; NONDESTRUCTIVE EVALUATION; SEMICONDUCTOR HETEROSTRUCTURES; VAPOR DEPOSITION. [D.E.As.]

Elliptic function and integral In a certain sense, elliptic integrals are the simplest integrals not expressible in terms of elementary functions; elliptic functions arise as the inverse functions of certain elliptic integrals.

Let R be a rational function of x and y, and set $I = \int R(x,y)dx$. I can be expressed in terms of elementary functions if y^2 is a polynomial of degree 2 or less in x. If y^2 is a polynomial of degree 3 or 4 in x, I cannot in general be expressed in terms of elementary functions and is called an elliptic integral. The standard elliptic functions are analogous to trigonometric functions. Trigonometric functions may be defined as the inverse functions of certain integrals of the form I; they satisfy differential equations, are periodic functions, and may alternatively be obtained as the "simplest" periodic functions. The standard elliptic functions are the inverse functions of certain elliptic integrals; they satisfy differential equations of order 1 and degree 2, are doubly periodic functions, and may alternatively be obtained as the "simplest" doubly periodic functions.

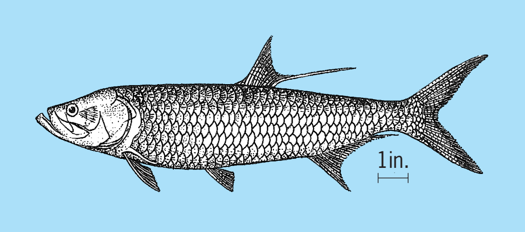
In geometry elliptic functions or integrals arise in determining the length of an arc of an ellipse, hyperbola, or lemniscate, the surface of an ellipsoid, geodesics on quadrics of revolution, parametric representations of plane cubic curves or, more generally, curves of genus 1, conformal representation problems, and other problems. There are applications to differential equations (Lamé's equation, diffusion equation, and others) in analysis, and there are applications in a great variety of problems in number theory. In the physical sciences elliptic functions or integrals appear in potential theory both through conformal representations and in the potential of an ellipsoid, in the theory of elastica, the pendulum, in rigid body motion, in Green's functions in heat conduction and diffusion theory, and many other problems. [A.Er.]

Elm Any species of *Ulmus*, a genus of hardwood trees in the Northern Hemisphere, with simple, serrate, deciduous leaves. The American or white elm (*U. americana*) is the most important species. It ranges from the eastern half of the United States westward as far as the base of the northern Rockies and southward through central Texas to the Gulf of Mexico. The tree is also found in southern Canada.

The tree was very popular as a shade tree, perhaps better adapted as a street tree than any other species because the upper branches spread, joining with elms across the street to form an arch. Once abundant, the elm has been severely attacked by the lethal Dutch elm disease imported from Europe. The future of the species is uncertain. [A.H.G./K.P.D.]

Elopiformes A primitive order of soft-rayed, teleost fishes, including the tarpons, bonefishes, and their relatives, that was formerly included in the Clupeiformes. The elopiforms have a single dorsal fin composed of soft rays only (see illustration).

The most important characteristic of the order involves the occurrence in early development of a leptocephalous larval stage. This larva is translucent, ribbonlike, and strongly toothed; eventually it passes through a marked transformation to adult form. This developmental pattern characterizes only two other orders of teleosts, the Notacanthiformes (spiny eels and halosaurs) and the Anguilliformes (true eels), groups which are therefore believed to be descendants of elopiforms. *See* ANGUILLIFORMES; CLUPEIFORMES; NOTACANTHIFORMES.



Tarpon (*Megalops atlantica*). 1 in. = 2.54 cm. (*After G. B. Goode, Fishery Industries of the United States, Sect. 1, 1884*)

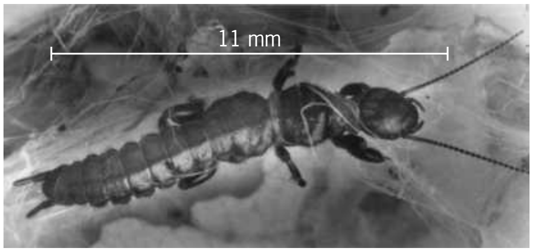
The elopiforms have a well-represented paleontological history since the Jurassic, on all continents. They were especially abundant in the Cretaceous. Extant forms are classified in 2 families, 4 genera, and 12 species. Most inhabit tropical to temperate shore waters of all oceans, but tarpons invade rivers, sometimes for long distances. *See* ACTINOPTERYGII; TARPON; TELEOSTEI. [R.M.B.]

Embedded systems Computer systems that cannot be programmed by the user because they are preprogrammed for a specific task and are buried within the equipment they serve. The term derives from the military, where computer systems are generally activated by the flip of a switch or the push of a button. The continual increase in the densities of ever-smaller microprocessors, on silicon chips that fit on a thumbnail, and the attendant decreases in their costs, has pushed the concept of embedded systems well beyond the original military applications. Embedded systems are also used in industrial, automotive, consumer, and medical applications.

Most embedded microprocessors are of the CISC (complex-instruction-set computer) type, and most of these are used in applications where low cost is paramount and performance is secondary, such as consumer products. The later-generation microprocessors have wider bus widths, up to 64 bits, and thus can do more computations. *See* MICROPROCESSOR.

Since about 1990, microprocessors of the RISC (reduced-instruction-set computer) type have appeared, with much greater computational capability and at greater cost. RISC processors are used mostly in those embedded applications where performance is primary and low cost is secondary. They are used in engineering workstations, where the computational burdens of high-resolution graphics require such processors. *See* COMPUTER-AIDED ENGINEERING; COMPUTER GRAPHICS; COMPUTER SYSTEMS ARCHITECTURE. [R.Al.]

Embioptera A peculiar order of silk-spinning, orthopteroid insects related to termites, commonly called the embiids or web spinners. This order comprises about 1000 species which are chiefly tropical in distribution. The body is linear and supple (see illustration). The legs are short with three-segmented tarsi. The forelegs are adapted for spinning silk, and the hindlegs for reverse locomotion. Metamorphosis is incomplete. The females are neoteinic and wingless (apterous). Males are usually winged (alate), but in certain genera and species they are apterous. The wings are subequal and elongate. The wings are flexible when in repose and folded over the back, but are stiffened when extended for flight by the blood pressure in the saclike veins. Flight is a poorly directed, whirling flutter.

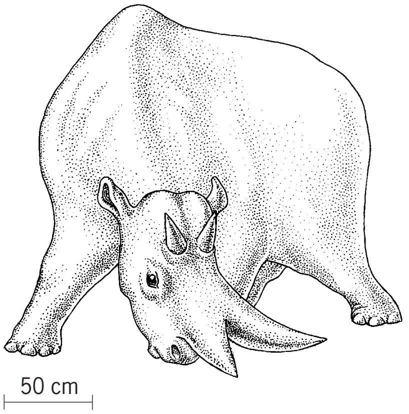


Body form of a typical emblid (*Pararhagadochir trachelia*). (*From E. S. Ross, Insects Close Up, University of California Press, 1953*)

The silk galleries, which constitute a safe shelter for all embiid activities except adult dispersal, radiate on or in the food supply which also constitutes the habitat and consists of bark, lichens, moss, dead leaves, or grass. Many individuals, usually the brood of one female, may occupy one gallery system. *See* INSECTA; ORTHOPTERA. [E.S.R.]

Embolism The sudden blocking of an artery or vein by a clot or other substance which has been brought to its place by the blood current. The material carried in the circulation in this process is an embolus. Emboli may be composed of thrombi, fat, air, tumor cells, masses of bacteria or parasites, bone marrow, amniotic fluid, or atheromatous material from the vessel wall. With complete obstruction of a vessel by an embolus an infarct may result. *See* INFARCTION. [R.A.V.]

Embrithopoda An order established for the unique mammal *Arsinoitherium*, which has been found only in early Oligocene deposits in northern Egypt. This animal was of rhinoceros size with a large body and short pillarlike legs (see illustration). There were two huge, scimitarlike horns over the nose and two much smaller, peglike horns over the eyes. The exact relationship of this exotic order to other orders is not clear, but similarities to both the uintatheres, or Dinocerata, and Hyracoidea have been interpreted by some authorities as evidence of kinship. *See* DINOCERATA; MAMMALIA. [M.C.McK.]



***Arsinoitherium*, the early Oligocene embrithopod from Egypt. (*After C. R. Knight*)**

Embrittlement A general set of phenomena whereby materials suffer a marked decrease in their ability to deform (loss of ductility) or in their ability to absorb energy during fracture (loss of toughness), with little change in other mechanical properties, such as strength and hardness. Embrittlement can be induced by a variety of external or internal factors, for example, (1) a decreasing or an increasing temperature; (2) changes in the internal structure of the material, namely, changes in crystallite (grain) size, or in the presence and distribution of alloying elements and second-phase particles; (3) the introduction of an environment which is often, but not necessarily, corrosive in nature; (4) an increasing rate of application of load or extension; and (5) the presence of surface notches.

Low-temperature embrittlement results from a competition between deformation and brittle fracture, with the latter becoming preferred at a critical temperature. For a material to be useful structurally, it is desirable that this critical temperature be below the minimum anticipated service temperature; in most cases, this is room temperature. At high temperatures, internal structural changes that lead to intergranular embrittlement can occur. Embrittlement usually occurs in the creep temperature range, a temperature at which deformation can occur under very low stresses; and the two processes are believed to be connected.

In many metals, particularly structural steels, annealing or heat treating in certain temperature ranges sensitizes the grain boundaries in such a way that intergranular embrittlement subsequently occurs during service. To reduce the brittleness, the steel undergoes an annealing treatment called tempering, which, while decreasing the strength, usually increases the toughness. The exception to this trade-off occurs when the steel is tempered at 1000°F (538°C). This can lead to a mode of intergranular fracture called temper embrittlement; such a process has led to catastrophic failures in turbines, rotors, and other high-strength steel parts. In other metals, there are less specific but similar types of embrittlement resulting from critical heat treatments. *See* HEAT TREATMENT (METALLURGY); TEMPERING.

Metals can fracture catastrophically when exposed to a variety of environments. These environments can range from liquid metals to aqueous and nonaqueous solutions to gases such as hydrogen.

If a thin film of a liquid metal is placed on the oxide-free surface of a solid metal, the tensile properties of the solid metal will not be affected, but the fracture behavior can be markedly different from that observed in air. Although many different liquid metals are capable of inducing embrittlement in a variety of solid metals, some of the more common couples, many of which have important engineering and design consequences, are mercury embrittlement of brass, lead embrittlement of steel, and gallium embrittlement of aluminum.

Stress corrosion cracking can occur when a metal is stressed and simultaneously exposed to an environment which may be, but is not necessarily, corrosive in nature. Both stress and environment are required; if only one of these elements is present, the metal usually displays no embrittlement. *See* CORROSION.

Hydrogen embrittlement is a form of embrittlement often considered to be a type of stress corrosion cracking. Hydrogen atoms can enter a metal, causing severe embrittlement, again with little effect on other mechanical properties. This phenomenon was originally observed, and is most critical in, steels, but it is not documented to occur in titanium and nickel alloys, and may lead to cracking in other alloy systems as well.

Factors such as notches and the rate of application of stress can modify the response of a material to a specific type of embrittlement. In general, notches or surface flaws always enhance embrittlement, both by acting as a stress raiser and by providing a preexisting crack. [I.M.B.]

Embryobionta One of the two plant subkingdoms, the other being the Thallobionta. The Embryobionta are here considered to include eight divisions, the Rhyniophyta, Bryophyta, Psilotophyta, Lycopodiophyta, Equisetophyta, Polypodiophyta, Pinophyta, and Magnoliophyta. The Rhyniophyta are represented only by Paleozoic fossils, but the other seven divisions have both modern and fossil representatives. See the separate articles on each division.

The Embryobionta differ from the green algae (Chlorophyta) and from most Thallobionta in that the normal life cycle of the Embryobionta shows a well-marked alternation of generations in which the sporophyte (spore-producing, typically diploid) generation always begins its development as a parasite on the gametophyte (gamete-producing, typically haploid) generation. The young sporophyte is called an embryo.

The more primitive divisions of Embryobionta have the gametes produced in multicellular sex organs (archegonia and antheridia), in contrast to the unicellular oogonia and antheridia of the Thallobionta in general. In the more advanced divisions (Pinophyta and Magnoliophyta) of Embryobionta, the antheridia and archegonia are highly modified or entirely suppressed, in conformity with the general reduction of the gametophyte generation.

All divisions of Embryobionta except the Bryophyta have specialized conducting tissues (xylem and phloem) in the sporophyte. With the exception of most bryophytes, they also commonly have a characteristic stomatal apparatus which controls the opening and closing of numerous tiny pores (stomates) in the leaves and stems in response to environmental conditions. These specializations, together with the progressive reduction of the gametophyte in the more advanced divisions, reflect the progressive evolutionary adaptation of the Embryobionta to life on dry land instead of in the ancestral water. The Embryobionta are therefore often called the land plants, in spite of the fact that many of them, such as the water lilies, have returned to an aquatic habitat. The seven divisions of Embryobionta which characteristically have xylem and phloem have sometimes been treated as a single comprehensive division under the name Tracheophyta. *See* PLANT KINGDOM; THALLOBIONTA. [A.Cr.]

Embryogenesis The formation of an embryo from a fertilized ovum, or zygote. Development begins when the zygote, originating from the fusion of male and female gametes, enters a period of cellular proliferation, or cleavage. Cells of the embryo subsequently give rise to the tissues and organs of the body in a temporal and spatial pattern that creates a functional, multicellular organism.

Following cleavage, the cells of the animal embryo rearrange into three germ layers: an outer ectoderm, a middle mesoderm, and an inner endoderm. Cells, responding to intrinsic and extrinsic factors, eventually segregate from the germ layers and organize into the rudiments of the tissues and organs of the body. These rudiments alter the size and the shape of the embryo, endowing the body with its axial symmetry. Cellular growth and differentiation are the principal processes that transform the rudiments into functional tissues and organs. Once the organs and organ systems are formed, further development consists primarily of growth. *See* GERM LAYERS. [M.J.Ca.]

Major features of embryogenesis in flowering plants include the formation of root and shoot apical meristems; differentiation of primary vascular tissue; the transition from a heterotrophic zygote to an embryo capable of independent growth and development; and preparations for desiccation, dormancy, and germination. *See* APICAL MERISTEM; CELL DIFFERENTIATION; DEVELOPMENTAL BIOLOGY; EMBRYOLOGY; EMBRYONIC DIFFERENTIATION; EMBRYONIC INDUCTION. [D.W.Me.]

Embryology The study of the development of an organism, commencing with the union of male and female gametes. Embryology literally means the study of embryos, but this definition is restrictive. An embryo is an immature organism contained within the coverings of an egg or within the body of the mother. Strictly speaking, the embryonic period ends at metamorphosis, hatching, or birth. Since developmental processes continue beyond these events, the scope of embryology is customarily broadened to encompass the entire life history of an organism. Embryology may, in this wider context, consider the mechanisms of both asexual reproduction and regeneration.

Animals. The production of male and female gametes is commonly considered to be the first phase in animal development. The differentiating gametes arise from diploid stem cells in the gonads. Cell division by meiosis reduces the number of chromosomes carried by a mature gamete to one-half that present in the stem cell. *See* GAMETOGENESIS.

The union of gametes (spermatozoon and ovum), representing the second phase of development, creates a diploid zygote with the potential to form an entire organism. Two events must occur for successful fertilization: the ovum must respond to contact with the spermatozoon by making preparations for further development, an event called activation, and the haploid nucleus of the spermatozoon must combine with the haploid nucleus of the ovum, an event called amphimixis.

Fertilization is the typical method to initiate development, but it is not the only method. In a few animals, the ovum develops independently by parthenogenesis, that is, without the participation of a spermatozoon.

A period of cell proliferation, converting the unicellular zygote into a multicellular embryo, represents the third phase of development. Cleavage is a modified form of cell division by mitosis, distinguished by little or no growth between the divisions. The cells of the embryo, or blastomeres, become progressively smaller at the end of each division, so the embryo maintains the relative size and shape of the zygote. Small, fluid-filled spaces form between the cleaving blastomeres, and these spaces eventually coalesce to create an internal cavity, or blastocoele. Upon the appearance of a blastocoele, the cells of an embryo are referred to collectively as the blastoderm. *See* BLASTULATION.

The fourth phase of development is poorly delineated from cleavage, because the cells of the embryo continue to divide. Gastrulation is distinguished from cleavage by extensive cell rearrangements that lead, in most animals, to the establishment of three germ layers: an outer ectoderm, a middle mesoderm, and an inner endoderm. Endodermal and mesodermal cells of the blastoderm migrate to the inside of the embryo, while ectodermal cells remain on the surface, where they spread to completely cover the body.

Control of development passes from the cytoplasm to the nucleus immediately prior to gastrulation. Responding to cytoplasmic cues, the nuclei begin to specify the production of proteins that make the cells qualitatively different from one another. In a few invertebrates, the transfer of control from cytoplasm to nucleus actually fixes the developmental fate of a cell. In most other organisms, and particularly in vertebrates, the determination of cell fate is not finalized until the blastoderm has rearranged into the three germ layers. *See* CELL LINEAGE; GASTRULATION; GERM LAYERS.

The organization of cells into the tissues and organs of the body, constituting the fifth phase of development, is closely allied with gastrulation. Blastodermal rearrangements during creation of the germ layers shift cells into new positions and bring about new intercellular relationships. The developmental fate of a cell can, to a considerable degree, be the consequence of its new position. The influence exerted by one group of cells over the developmental fate of a neighboring group is called induction. Induction occurs by the transmission of chemical substances, called inducing agents.

Differentiation, or the process by which a cell becomes specialized, correlates to a reduction in the amount of genetic information that is expressed. Determination, or the fixation of a developmental fate, occurs when a cell has such a limited amount of usable genetic information that it must commit to a terminal pathway of differentiation. *See* CELL DIFFERENTIATION.

Cellular differentiation is just one aspect of morphogenesis, or the development of form. Morphogenesis must be considered at all levels of organization, ranging from the individual cell to the whole organism. Such a broad perspective complicates the formulation of general theories of development. Presently, no comprehensive theory exists, but there are some embryologists who anticipate that a theory is possible once activities of the DNA molecule have been fully integrated into the topic of development. *See* ANIMAL MORPHOGENESIS; REPRODUCTION (ANIMAL). [M.J.Ca.]

Plants. Reproductive development in multicellular plants is generally divided into three phases: gametogenesis, fertilization, and embryogenesis. The zygote produced by the fusion of male and female gametes divides to form a multicellular embryo with meristematic regions that ultimately produce the adult plant.

Development of the cell in flowering plants begins with a diploid megasporocyte located within the nucellar tissue of an immature ovule. This megasporocyte undergoes meiosis to form a tetrad of four haploid megaspores. In the most common pattern of development, three of these megaspores degenerate, leaving a single functional megaspore that undergoes several postmeiotic mitoses to form a mature megagametophyte (embryo sac) composed of seven cells and eight haploid nuclei. One of these haploid cells is the egg cell.

Development of the male gametes begins with numerous diploid cells (microsporocytes) located within the anthers of an immature flower. Each microsporocyte undergoes meiosis to form a tetrad of four haploid microspores, which then separate and enlarge to form mature pollen grains. Each microspore divides unequally to form a large vegetative cell, and a small generative cell located within the cytoplasm of the vegetative cell. The generative cell divides again, in either the maturing pollen grain or the elongating pollen tube, to form two genetically identical male gametes, the sperm cells.

The zygote is produced as part of a unique process known as double fertilization. One of the male gametes fuses with the egg cell to form the diploid zygote, while the other male gamete fuses with two polar nuclei, located near the center of the embryo sac, to form a triploid endosperm nucleus. Following double fertilization, the zygote develops into an embryo composed of two parts, the embryo proper and the suspensor. The embryo proper ultimately differentiates into the mature embryo, whereas the suspensor degenerates during later stages of development and is not usually present at maturity.

Flowering plants can be divided into two groups, monocots and dicots. In most dicots, the endosperm tissue is gradually absorbed by the developing embryo and is not present in the mature seed. Nutrients required for the germination of dicot seeds are generally stored in the embryonic leaves known as cotyledons. In contrast, most mature monocot seeds contain a significant amount of starchy endosperm tissue that serves as a source of nutrients for the germinating seedling.

Two important regions of the mature embryo are the root and the shoot apical meristems. The entire shoot system (stems, leaves, and flowers) of the adult plant forms from cells that are located in the shoot apical meristem of the mature embryo. The root apical meristem that is formed during embryogenesis becomes active during the early stages of germination and ultimately produces the entire root system of the adult plant. *See* APICAL MERISTEM; ROOT (BOTANY).

The final stages of embryogenesis in angiosperms include maturation, desiccation, and preparation for seed dormancy.

Different patterns of embryo development are found in gymnosperms and in the more primitive vascular and nonvascular plants. Double fertilization and the development of a nutritive endosperm tissue are features unique to the angiosperms. The haploid microgametophyte (germinating pollen grain) in most gymnosperms contains two male gametes, but only one of these participates in fertilization. The nutritive function served by the endosperm tissue in angiosperms is served in gymnosperms by the large haploid megagametophyte. Early divisions of the zygote are also different in gymnosperms; the zygote typically undergoes a series of free nuclear divisions during the earliest stages of embryogenesis, and multiple embryos often arise from a single zygote through a process known as polyembryony. Even more striking differences in embryogenesis are found in ferns and mosses, where the haploid or gametophytic phase of the life cycle is much more extensive.

Several major differences also exist between embryogenesis in plants and animals. Plant cells are surrounded by a cell wall that limits the contact and movement between adjacent cells. Embryogenesis in plants therefore proceeds without the morphogenetic movements that are characteristic of animal development. Morphogenesis in plants is also not limited to embryo development, but occurs throughout the life cycle. The mature plant embryo is therefore not simply a miniature version of the adult plant. *See* PLANT MORPHOGENESIS. [D.W.Me.]

Embryonated egg culture Embryonated eggs are among the most useful and available forms of living animal tissue for the isolation and identification of animal viruses, for titrating viruses, and for quantity cultivation in the production of viral vaccines. The embryo proper, chorioallantoic membrane, yolk sac, allantoic sac, or amniotic sac may be inoculated in hen eggs of various ages, so that a wide choice of types of tissue is available to fit the characteristics of the virus under study or for special studies. The chorioallantoic membrane is frequently used; in some infections, such as smallpox, vaccinia, and herpes simplex, characteristic lesions are produced which in some cases may resemble those in the natural host. *See* ANIMAL VIRUS. [J.L.Me.]

Embryonic differentiation The process by which specialized and diversified structures arise during development of the embryo. The process involves (1) an increase in the number of cell types, and (2) an increase in morphological heterogeneity through the arrangement of cells into increasingly complex structural patterns in the form of tissues and organs. *See* HISTOGENESIS.

Differentiation begins in most organisms with fertilization of an egg with a sperm, after which the relatively large egg divides into many smaller cells called blastomeres. The blastomeres receive unequal portions of the cytoplasmic materials of the egg and are therefore initially somewhat different from each other. At the end of cleavage, the blastomeres are organized into a blastula, commonly either a hollow ball of cells or a flattened two-layered disk of cells. The cells of the blastula lie in different relative positions from those that will be occupied by their descendants in the adult organism. By a process known as gastrulation, they move to their approximate final positions and are arranged into three basic layers, called germ layers. However, only two layers form in the simpler multicellular organisms. The outer layer is the ectoderm, from which arise the nervous system and the epidermal layer of the skin. The innermost germ layer, the entoderm, forms the epithelial lining of the digestive tract and contributes the essential tissue of associated organs. In all but the most primitive animals a third germ layer, the mesoderm, is formed by cells which come to lie in the area between the other two layers. In higher animals the mesoderm gives rise to most of the cells of the organism, such as those found in the muscles, skeleton, blood, connective tissue, kidneys, gonads, and certain other organs. The molding of groups of embryonic cells into such diverse tissues and organs proceeds through a variety of morphogenetic processes, such as migration, aggregation, dispersion, delamination, folding, and differential local growth of cells. *See* BLASTULATION; GASTRULATION; GERM LAYERS.

Underlying the visible structural diversification of the embryo is the more fundamental and concomitant process of cellular differentiation (chemodifferentiation), by which embryonic cells are transformed into the highly specialized cells of the adult.

The mechanisms by which the course of cellular differentiation is realized are not precisely known. The factors involved may, however, be divided into two classes: (1) intrinsic, those operating within the cell, and (2) extrinsic, those brought to bear upon the cell from outside. Both classes of factors play a role in the differentiation of every cell. However, the relative importance of these factors varies considerably from one cell strain to another and also within the same cell at different stages in its development.

The fertilized egg begins development with a rich endowment, consisting of a nucleus with a set of paternal and maternal chromosomes together with a complexly organized cytoplasm. The activation of the egg by the sperm sets off a chain of actions and reactions that progressively transform the physical and chemical constitution of each descendant cell. The emergence of new cell characteristics may be attributed to an oscillating interaction between the intrinsic gene makeup of the cell and the surrounding cytoplasm. The dynamic imbalance existing between these interacting components drives the cell along its path of differentiation. In certain kinds of invertebrate embryos, interactions within each separate cell seem sufficient for guiding differentiation to its terminal state. Such embryos exhibit mosaic development. By contrast, in the embryos of vertebrates and certain invertebrates such as echinoderms, influences from adjacent cells are an essential part of the differentiation process. These embryos show regulative development. *See* CELL LINEAGE; DEVELOPMENTAL BIOLOGY; EMBRYONIC INDUCTION. [C.L.Ma.]

Embryonic induction In the early development of many tissues and organs of complex, multicellular organisms, the action of one group of cells on another that leads to the establishment of the developmental pathway in the responding tissue. The groups of cells which influence the responding cells are termed the inducing tissue. Since specific inducing tissues cannot act on all types of cells, those cells which can respond are referred to as competent to react to the action of a specific inducer stimulus.

Embryonic induction is considered to play an important role in the development of tissues and organs in most animal embryos, from the lower chordates to the higher vertebrates.

Perhaps the first major induction phenomenon occurs during the final stages of gastrulation of most animal embryos. Following fertilization, the egg divides to form a multicellular blastula-stage embryo. The cells of the blastula then undergo a series of movements which generate a more complex embryo, the gastrula, which contains three major groups of cells: ectoderm, mesoderm, and endoderm. The mesoderm actually arises as cells move from the surface of the embryo to the inside. Once inside, they induce the cells which reside over them, the surface ectoderm cells, to develop into the neural tube. The neural tube eventually forms the central nervous system. The first induction event of early embryogenesis is called primary embryonic induction. The migratory cells which invaginate from the surface and induce the development of the neural tube are termed the embryonic organizer. The first step in the sequence of events termed primary embryonic induction is the acquisition by the mesoderm of neural inducing activity. Proteins such as fibro blast growth factor and activin, which belong to a category of so-called peptide growth factors, play key roles in programming the mesoderm cells to induce overlying ectoderm to differentiate into neural structures. *See* GASTRULATION.

The development of a large number of tissues and organs is influenced by embryonic inductions. Various eye structures (lens, optic cup, and so on), internal ear structures, as well as several tissues (for example, vertebral cartilage) emerge from cells which were acted upon by inducer tissues. *See* NERVOUS SYSTEM (VERTEBRATES).

Limbs, kidney, nasal structures, salivary glands, pancreas, teeth, feathers, and hair are organs which require inductive stimuli. It is not known whether a single common mechanism underlies each of those inductions. Many scientists believe that inductive interactions are mediated by cell-cell contacts; that is, the developmental information which is transferred from the inducing tissue is thought to reside at the cell surface of that tissue. Perhaps the surface of the responding tissue recognizes the signal molecules present on the surface of the inducing tissue. In other instances, a secreted protein might move among various cells or tissues and exert its effects on competent cells.

The principles of animal development also apply to plants. A greater role is, however, usually played by the diffusion of small-molecular-weight signal molecules rather than cell-cell contacts or protein growth factors. The earliest stages of plant embryo development involve groups of cells acquiring the competence to respond to inductive signals. Later in development, inductive signaling also becomes important. For example, in flowering plants the distance between nodes along the stem elongates, and lateral buds form below the shoot apex. The buds are believed to develop in response to a concentration gradient of signal molecules which exists along the stem. Thus, a process which is analogous to embryonic limb bud formation in animals is played out, and both plant and animal inductions can be conceptualized in similar terms. *See* CELL DIFFERENTIATION; DEVELOPMENTAL BIOLOGY; EMBRYOLOGY; PLANT MORPHOGENESIS. [G.M.M.]

Emerald The medium- to dark-green gem variety of the mineral beryl, crystallizing in the hexagonal system. A flawless emerald with good color is one of the most sought after and highly prized of all precious gems. Emerald is restricted in its occurrence, and only infrequently are exceptional stones found; most emeralds are flawed and cloudy, and few stones command high prices.

In contradistinction to beryl and its other gem varieties, emeralds have only been found in mica schists or metasomalized limestones. The most outstanding occurrences include the Muzo and El Chivor mines in Colombia. Noteworthy occurrences in mica schists include Tokovoja in the Ural Mountains, where emerald occurs with the beryllium minerals chrysoberyl (and its gem variety alexandrite) and phenakite; Habachtal, Austria; Transvaal, South Africa; and Kaliguman, India. The ultimate source of an emerald can often be assessed by a study of its inclusions. *See* BERYL; GEM. [P.B.M.]

Emergency medicine The medical specialty that comprises the immediate decision making and action necessary to prevent death or further disability under emergency conditions. It is based primarily in hospital emergency departments, but with extensive responsibilities for supervising emergency medical systems outside the hospital (paramedics).

Prehospital care is professional emergency care delivered before the patient reaches the hospital. Care is provided by paramedics and emergency medical technicians. Paramedics are technicians trained in techniques such as electric shock for defibrillation of the heart, insertion of a tube into the trachea to assist respiration, and the use of intravenous drugs normally administered by physicians. They operate under the supervision of an emergency physician, usually by radio communication. Emergency medical technicians (EMTs) are trained in first aid, give no medication, seldom communicate with a doctor, and often receive very little medical supervision.

Trauma is physical injury, whether minor or major; it does not include medical emergencies due to other causes. In major trauma (usually caused by vehicular or industrial accidents, stabbing or gunshot wounds, or falls) the best care requires rapid transport to the hospital. Proper treatment of trauma requires prompt assessment by qualified paramedics, who may have to immobilize the neck to prevent spinal cord injury, protect the breathing passages, or administer intravenous fluid to replace blood lost by hemorrhage. Further evaluation and treatment by a qualified emergency physician must take place immediately upon arrival at the emergency department or trauma center. Trauma care has also been revolutionized by the advent of computerized tomographic x-ray. *See* COMPUTERIZED TOMOGRAPHY.

Burns are a very serious injury because the protective barrier of the skin is destroyed, leading to massive loss of body fluids, development of shock, and invasion by bacteria. Patients with major burns are best treated in specialized burn centers and should be taken there promptly. Burn mortality has dropped significantly because of prompt intravenous administration of very large volumes of fluid to replace body fluid losses, and the use of antibiotics. *See* BURN.

Cardiac arrest occurs when the heart suddenly goes into an abnormal rhythm so that it does not pump blood; it is the chief cause of death in heart attack. Cardiac arrest tends to occur in the first few hours of heart attack, often before the patient has even decided to go to the hospital, and sometimes is not preceded by any symptoms. If treated by defibrillation (electric shock to the heart) within the first 6 min, it is reversible. Otherwise, death is certain. Therefore, to save lives, emergency medical service programs must deliver paramedics to the patient's side within 6 min of the arrest.

Innumerable poisonings occur every year in the United States, involving thousands of products. Poison centers have been established in every state, where trained physicians and pharmacologists equipped with electronic and on-line references provide emergency telephone consultation. Poison centers have greatly improved the quality of care in poisoning cases. [M.Ca.]

Emery A natural mixture of corundum with magnetite or with hematite and spinel. Because the mixture is very intimate and appears to be quite homogeneous, it was considered to be a single mineral species until the middle of the 19th century. The aggregate has a gray-to-black color and is extremely tough and difficult to break. The specific gravity varies from 3.7 to 4.3, depending upon the relative amounts of the constituent minerals. The hardness is about 8 (Mohs scale), less than that of pure corundum which is 9, and is more dependent upon the physical state of aggregation than on the percentage of corundum. *See* CORUNDUM.

Although synthetic abrasives have replaced emery in many of its earlier uses, it is still used as an abrasive and polishing material by lapidaries and in the manufacture of lenses, prisms, and other optical equipment. Emery wheels, emery paper, and emery cloth are used not only by lapidaries but also by machinists in the grinding and polishing of steel. *See* ABRASIVE; GRINDING; MAGNETITE. [C.S.Hu.]

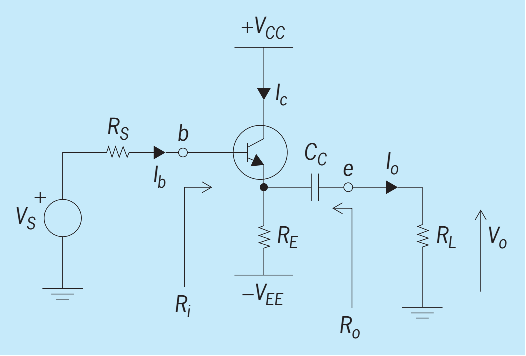
Emission spectrochemical analysis A technique conducted by monitoring and measuring the spectrum of light caused to be emitted by the material to be analyzed. In general, there are many ways in which to conduct an emission spectrometric measurement; the differences among approaches result mainly from the choice of location within the electromagnetic spectrum at which to observe emitted radiation. However, emission spectrochemical analysis traditionally refers to those analytical determinations based on radiation in the visible through vacuum ultraviolet region of the electromagnetic spectrum (wavelengths about 800 to 100 nanometers). The technique is used principally to detect (qualitative analysis) and determine (quantitative analysis) metals and some nonmetals. Under optimum conditions, as little as 10^{-10} gram of an element per gram of sample can be determined.

The steps in emission spectrochemical analysis are: vaporization and atomization of sample; excitation of atomic vapor; resolution of emitted radiation; and observation and measurement of resolved radiation. *See* SPECTROSCOPY. [A.T.Z.]

Emissivity The ratio of the radiation intensity of a nonblack body to the radiation intensity of a blackbody. This ratio, which is usually designated by the Greek letter ϵ, is always less than or just equal to one. The emissivity characterizes the radiation or absorption quality of nonblack bodies. Published values are readily available for most substances. Emissivities vary with temperature and also vary throughout the spectrum. For an extended discussion of blackbody radiation and related information *see* HEAT RADIATION.

A spectral emissivity of zero means that the heat radiator emits no radiation at this wavelength. Strongly selective radiators, such as insulators or ceramics, have spectral emissivities close to 1 in some parts of the spectrum, and close to zero in other parts. Carbon has a high spectral emissivity throughout the visible and infrared spectrum, exceeding 0.90 in certain portions; thus carbon is a good blackbody radiator. Tantalum is the only metal with a spectral emissivity greater than 0.5 in the visible spectrum. All other metals have a lower spectral emissivity. Tungsten is a relatively good emitter, with a spectral emissivity of 0.43–0.47 within the visible region of the spectrum. *See* BLACKBODY. [H.G.S.; P.J.W.]

Emitter follower A circuit that uses a common-collector transistor amplifier stage with unity voltage gain, large input resistance R_i, and small output resistance R_o (see illustration). In its behavior, the emitter follower is analogous and very similar to the source follower in metal-oxide-semiconductor (MOS) circuits. Many electronic circuits have a relatively high output resistances and cannot deliver adequate power to a low-resistance load, or do suffer unacceptable voltage attenuation. In these cases, an emitter follower acts as a very simple buffer. Widely used, it is often found as the last stage of a multistage amplifier so that the circuit is better able to drive a low-resistance load. *See* AMPLIFIER. [R.Sc.]



Schematic diagram of an emitter follower circuit.

Emotion An umbrella concept in the common language, typically defined by instantiation by reference to a variety of mental and behavioral states. These range from lust to a sense of liking, from joy to hostile aggression, and from esthetic appreciation to disgust. Emotions are usually considered to be accompanied by some degree of internal, frequently visceral, excitement, as well as strong evaluative components. Emotions are also often described as irrational, that is, not subject to deliberative cogitation, and as interfering with normal thought processes.

These latter qualities are often exacerbated in the emotional behavior and expression seen in clinical cases. The expression of strong emotions is typically considered to be symptomatic of some underlying conflict, and even the positive emotions are used as indices of unusually strong attachments and atypical earlier experiences. Sigmund Freud introduced the concept of repression to describe a defense mechanism against the occurrence of strong emotional experiences. From the psychoanalytic point of view, what is repressed is not the emotion itself, since the very concept of emotion implies conscious experience, but rather the memory of an event which, if it became conscious, would lead to strong conflicts and emotional consequences. Many other defense mechanisms, such as rationalization and compulsive or obsessive neurotic symptoms, are also seen as serving the purpose of avoiding conscious conflict and emotional sequelae. *See* PSYCHOANALYSIS. [G.M.]

Emphysema A disorder of pulmonary inflation characterized by enlargement and destruction of the air spaces. The key element in this definition is the word destruction for it implies the irreversible loss of a given area of the pulmonary parenchyma. Certain variants of this condition do not necessarily imply irreparable destruction of pulmonary tissue but rather overdistention of air spaces, and consequently are not properly classified as emphysema.

Generalized emphysema probably has many causes; most share chronic bronchiolitis as a factor. Narrowing at this level would cause retention of air, leading to dilatation and rupture of alveolar septa. Increasing attention is being given to heavy cigarette smoking and air pollution as contributing factors. Given the dilatation of the air spaces, the total air space in the lungs is increased. However, the lungs cannot be properly emptied and are functionally impaired.

Emphysema, if widespread, will cause very serious limitation in physical activity. Many cases, however, are compatible with long survival. Complications of severe emphysema include right heart failure (cor pulmonale), respiratory acidosis, and rupture of bullae with development of pneumothorax.

The important variants of emphysema are as follows. Centrilobular emphysema affects predominantly respiratory bronchioles without involvement of the more peripheral elements. In diffuse vesicular emphysema, the most common form, all elements of the respiratory unit (respiratory bronchiole, alveolar ducts, alveolar sacs, and alveoli) are dilated. Senile emphysema was formerly applied to barrel-chested elderly people; however, functional impairment is, in most cases, inconspicuous. This condition is also known as aging lung. *See* BRONCHIAL DISORDERS. [V.E.G.]

Empirical method The empirical method is generally characterized by the collection of a large amount of data before much speculation as to their significance, or without much idea of what to expect, and is to be contrasted with more theoretical methods in which the collection of empirical data is guided largely by preliminary theoretical exploration of what to expect. The empirical method is necessary in entering hitherto completely unexplored fields and becomes increasingly less purely empirical as the acquired mastery of the field increases. Successful use of an exclusively empirical method demands a high degree of intuitive ability in the practitioner. [P.W.Br./G.Ho.]

Emulsion A dispersion of one liquid in a second immiscible liquid. Since the majority of emulsions contain water as one of the phases, it is customary to classify emulsions into two types: the oil-in-water (O/W) type consisting of droplets of oil dispersed in water, and the water-in-oil (W/O) type in which the phases are reversed. The continuous liquid is referred to as the dispersion medium, and the liquid which is in the form of droplets is called the disperse phase.

A stable emulsion consisting of two pure liquids cannot be prepared; to achieve stability, a third component, an emulsifying agent, must be present. Generally, the introduction of an emulsifying agent will lower the interfacial tension of the two phases. A large number of emulsifying agents are known; they can be classified broadly into several groups. The largest group is that of the soaps, detergents, and other compounds whose basic structure is a paraffin chain terminating in a polar group. Some solid powders can act as emulsifiers by being wetted more by one phase than by the other. Whichever phase shows the greater wetting power will become the dispersion medium. Many naturally occurring emulsions, such as milk or rubber latex, are stabilized by proteins. Egg yolk proteins stabilize mayonnaise and salad dressing. Certain hydrophilic colloids such as gum arabic or gelatin also stabilize water-in-oil emulsions by a similar mode of action.

Emulsions may be prepared readily by shaking together the two liquids or by adding one phase drop by drop to the other phase with some form of agitation, such as irradiation by ultrasonic waves of high intensity. In industry, emulsification is accomplished by means of emulsifying machines.

The breaking of emulsions is necessary in many industrial operations, for example, in the separation of water-in-oil emulsions in the petroleum industry and in product recovery from emulsions produced by the steam distillation of organic liquids. Emulsions may be broken by (1) addition of multivalent ions of charge opposite to the emulsion droplet, (2) chemical action (addition of acids to emulsions stabilized by soaps), (3) freezing, (4) heating, (5) aging, (6) centrifuging, (7) application of high-potential alternating electric fields, and (8) treatment with ultrasonic waves of low intensity. *See* COLLOID; DETERGENT; SOAP. [G.S.M.; W.O.M.]

Enargite A mineral having composition Cu_3AsS_4. In some places enargite is a valuable ore of copper. The mineral has perfect prismatic cleavage, metallic luster, and grayish-black color. The hardness is 3 on Mohs scale, and the specific gravity is 4.44. Enargite is one of the rarer copper ore minerals and it has been mined in Yugoslavia, Peru, the Philippines, and the United States at Butte, Montana, and Bingham Canyon, Utah. Probably the largest deposit is at Chuquicamata, Chile. [C.S.Hu.]

Encalyptales An order of the true mosses (subclass Bryidae) that grow in dull, dark tufts on soil or soil-covered rock, generally in calcareous areas. The Encalyptales consist of a single family and two genera, the better known being *Encalypta*, the extinguisher moss, so called because of its long calyptra of candlesnuffer form.

Encalyptales are characterized by broad, papillose leaves and erect capsules covered by very long calyptrae. The stems are erect and simple or forked with folded, incurved leaves. Leaves are broadly acute to rounded and often abruptly short-pointed to hair-pointed with a strong midrib ending at or beyond the leaf tip. The sporophytes are terminal, with elongate setae, and erect, cylindric, and ribbed capsules. The operculum is long-rostrate, and the peristome variable in structure. The spores are often large and quite various in sculpturing. *See* BRYIDAE; BRYOPHYTA; BRYOPSIDA; POTTIALES. [H.Cr.]

Endangered species A species that is in danger of extinction throughout all or a significant portion of its range. “Threatened species” is a related term, referring to a species likely to become endangered within the foreseeable future. The main factors that cause species to become endangered are habitat destruction, invasive species, pollution, and overexploitation.

Habitat destruction is the single greatest threat to species around the globe. Natural habitat includes the breeding sites, nutrients, physical features, and processes such as periodic flooding or periodic fires that species need to survive. Humans have altered, degraded, and destroyed habitat in many different ways. Logging around the world has destroyed forests that are habitat to many species. This has a great impact in tropical areas, where species diversity is highest. Although cut forests often regrow, many species depend upon old-growth forests that are over 200 years old; these forests are destroyed much faster than they can regenerate. Agriculture has also resulted in habitat destruction. In the United States, tallgrass prairies that once were home to a variety of unique species have been almost entirely converted to agriculture. Housing development and human settlement have cleared large areas of natural habitat. Mining has destroyed habitat because the landscape often must be altered in order to access the minerals. Finally, water development, especially in arid regions, has fundamentally altered habitat for many species. Dams change the flow and temperature of rivers and block the movements of species up and down the river. Also, the depletion of water for human use (usually agriculture) has dried up vegetation along rivers and left many aquatic species with insufficient water.

The invasion of nonnative species is another major threat to species worldwide. Invasive species establish themselves and take over space and nutrients from native species; they are especially problematic for island species, which often do not have defensive mechanisms for the new predators or competitors. Habitat destruction and invasion of nonnative species can be connected in a positive feedback loop: when habitat is degraded or changed, the altered conditions which are no longer suitable for native species can be advantageous for invasive species. In the United States, approximately half of all endangered species are adversely affected by invasive species.

Pollution directly and indirectly causes species to become endangered. In some cases, pesticides and other harmful chemicals are ingested by animals low on the food chain. When these animals are eaten by others, the pollutants become more and more concentrated, until the concentration reaches dangerous levels in predators and omnivores. These high levels cause reproductive problems and sometimes death. In addition, direct harm often occurs when pollutants make water uninhabitable. Agriculture and industrial production cause chemicals such as fertilizers and pesticides to reach waterways. Lakes have become too acidic from acid rain. Other human activities such as logging, grazing, agriculture, and housing development cause siltation in waterways. Largely because of this water pollution, two out of three fresh-water mussel species in the United States are at risk of extinction. *See* ACID RAIN; WATER POLLUTION.

Many species have become endangered or extinct from killing by humans throughout their ranges. For example, the passenger pigeon, formerly one of the most abundant birds in the United States, became extinct largely because of overexploitation. This overexploitation is especially a threat for species that reproduce slowly, such as large mammals and some bird species. Overfishing by large commercial fisheries is a threat to numerous marine and fresh-water species. *See* FISHERIES CONSERVATION.

Efforts to save species focus on ending exploitation, halting habitat destruction, restoring habitats, and breeding populations in captivity. In the United States, the Endangered Species Act of 1973 protects endangered species and the ecosystems upon which they depend. Internationally, endangered species are protected from trade which depletes populations in the wild, through the Convention on International Trade in Endangered Species (CITES). Over 140 member countries act by banning commercial international trade of endangered species and by regulating and monitoring trade of other species that might become endangered. For example, the international ivory trade was halted in order to protect elephant populations from further depletion.

Typically, the first step is identifying which species are in danger of extinction throughout all or part of their range and adding them to an endangered species list. In the United States, species are placed on the endangered species list if one or more factors puts it at risk, including habitat destruction or degradation, overutilization, disease, and predation. Florida and California contain the most endangered species of all the contiguous 48 states. Hawaii has more endangered species than any other state. Hawaii, like other islands, has a diversity of unique species that occur nowhere else in the world. These species are also highly susceptible to endangerment because they tend to have small population sizes, and because they are particularly vulnerable to introduced competitors, predators, and disease.

For many endangered species, a significant captive population exists in zoos and other facilities around the world. By breeding individuals in captivity, genetic variation of a species can be more easily sustained, even when the species' natural habitat is being destroyed. Some species exist only in captivity because the wild population became extinct. For a few species, captive individuals have been reintroduced into natural habitat in order to establish a population where it is missing or to augment a small population. Depending on the species, reintroduction can be very difficult and costly, because individual animals may not forage well or protect themselves from predators. *See* ECOLOGY; EXTINCTION (BIOLOGY). [L.H.W.]

Endocrine system (invertebrate)

The chemical integrating system in animals that lack a vertebral (spinal) column. An endocrine system consists of those glandular cells, tissues, and organs whose products (hormones) supplement the rapid, short-term coordinating functions of the nervous system. Almost all of the information about invertebrates pertains to the more highly evolved groups that will be discussed below, the annelids, echinoderms, mollusks, and most particularly two classes of arthropods, the insects and crustaceans. Several of the hormones in invertebrates are neurohormones, that is, they are produced by nerve cells. *See* NEUROSECRETION.

Insects. Increase in linear dimensions of an insect can only occur at periodic intervals when the restricting exoskeleton is shed during a process known as molting. Once an insect becomes an adult, it ceases to molt. The orderly sequence of molts that leads from the newly hatched insect to the adult is controlled by three hormones. The brain produces a neurohormone which stimulates a pair of glands in the prothorax, the prothoracic glands, causing release of the molting hormone, ecdysone. A third hormone, the juvenile hormone, produced by a pair of glands near the brain, functions during the juvenile molts to suppress the differentiation of adult tissues. Juvenile hormone permits growth but prevents maturation. *See* ECDYSONE.

Two neurohormones with antagonistic actions are involved in regulating the water content of insects. One, the diuretic hormone, promotes water loss by increasing the volume of fluid secreted into the Malpighian tubules, the excretory organs. The second, the antidiuretic hormone, acts to conserve water by causing the wall of the rectum to increase the volume of water resorbed from its lumen while lowering the excretion rate from the Malpighian tubules.

Bursicon, a protein neurohormone, is responsible for the tanning and hardening of the newly formed cuticle. During the development of some insects, a period of arrested development occurs, termed the diapause. The mechanisms controlling the onset and the termination of diapause are largely unknown. However, in some insects there is evidence for a hormone, proctodone, that reinitiates development. A very few species of insects, most notably the stick insect (*Carausius morosus*), have the ability to change color. This insect becomes darker at night and lighter by day as a result of the rearrangement of pigment granules within the epidermal cells. Darkening is due to a hormone produced in the brain.

Crustaceans. Higher crustaceans have a structure, the sinus gland, which in most stalk-eyed species lies in the eyestalk and is the storage and release site of a molt-inhibiting hormone. The Y-organs, a pair of structures found in the anterior portion of the body near the excretory organs, are the source of the crustacean molting hormone, crustecdysone. Chemically, crustecdysone is very similar to the ecdysone from insects; both substances can cause molting in crustaceans and insects. The sinus gland is a neuroendocrine structure, but the Y-organs are nonneural.

Crustacean pigment cells (chromatophores) are under hormonal control, as in insects. The active substances are released from the sinus glands and the postcommissural organs, which lie near the esophagus. Substances have been found that cause dispersion of the pigment within the chromatophore, as well as substances with the opposite action. *See* CHROMATOPHORE.

The compound eye of crustaceans has three retinal pigments. The movements of these pigments with illumination level control the amount of light impinging on the photosensitive cells. A substance has been found that causes the migration of these pigments toward the light-adapted positions and another substance that causes migration toward dark-adapted positions.

The pericardial organs, which are found near the heart, are neuroendocrine organs that cause an increase in the amplitude of the heart beat. The sinus gland contains the hyperglycemic hormone, which causes a rise in blood glucose.

Annelids. Strong evidence for hormones in annelids has been obtained from studies of the reproductive system. One substance that has been found in some marine annelids inhibits maturation of the gametes. This substance was thought to have been produced by the brain, but studies show that another structure, the infracerebral gland, which lies ventral to the brain, may be involved.

Echinoderms. The radial nerves of starfishes contain two substances that are required for the maintenance of a normal reproductive cycle. One, the shedding substance, induces spawning. The second, shedhibin, inhibits the former.

Mollusks. The best-established endocrine organs in mollusks, the optic glands, occur in the octopus and squid. They are a pair of small structures, found near the brain, that produce a substance which causes gonadal maturation. The optic glands in turn are regulated by inhibitory nerves from the brain. There is also some evidence that a portion of the nervous system (the pleural ganglia) may secrete a hormone that affects water balance. Removal of the pleural ganglia from a freshwater snail results in swelling of the animal due to the influx of water. [M.F.]

Endocrine system (vertebrate) A system of chemical communication among cells. The classical vertebrate endocrine system consists of a group of discrete glands that secrete unique products (hormones) into the bloodstream. These products travel in the blood to distant sites or targets where they cause specific physiological responses. Thus endocrine glands differ from exocrine glands, in that they lack ducts and deliver their secretions in the bloodstream. The classical definition of an endocrine system has become harder to apply with the discovery of scattered cells rather than discrete glands that act as endocrine organs, of endocrine cells that affect themselves (autocrine effect) or nearby targets (paracrine effect) by diffusion through extracellular fluids rather than the bloodstream, and of neurons that secrete hormones (neurosecretion). All of these mechanisms, however, allow for chemical intercellular communication and can be considered part of the endocrine system. *See* NEUROSECRETION.

One important function of the endocrine system, along with the nervous system, is to maintain homeostasis, that is, a constancy of the internal environment of an organism. Thus an organism reacts and adjusts physiologically to changes in its external environment. The roles of the endocrine and nervous systems in maintaining homeostasis are many, complementary, and overlapping. *See* HOMEOSTASIS; NERVOUS SYSTEM (VERTEBRATE).

Nature of hormones. Hormones are the products of endocrine cells. They are either proteinlike or steroidal. Peptide hormones are produced by protein synthetic mechanisms directed by the genes of the endocrine cells. They are stored in endocrine cells in secretory granules that bud off the endoplasmic reticulum and Golgi membranes, where protein synthesis occurs. The granules leave the cell by endocytosis and enter the bloodstream. Steroid hormones, on the other hand, are produced from cholesterol by a number of well-characterized, enzyme-catalyzed steps. Cholesterol is thus converted stepwise to various steroid families: the hormones of the adrenal cortex (cortisol and aldosterone), the estrogens (estradiol) from the ovary, and the androgens (testosterone) from the testis. Steroid hormones diffuse across the endocrine cell plasma membrane to enter the circulation. *See* HORMONE; PROTEIN; STEROID.

Since in most cases the blood carries hormones throughout the body, there must be a system by which only certain tissues respond to each hormone. This is accomplished by receptors, which are binding sites either on the surface of the target cell or within its nucleus. Receptors are high-molecular-weight proteins; the structure of some, such as the insulin receptor, is known. In general, peptide hormones cannot cross the plasma membrane, so their receptors are located there, whereas steroid hormones do pass through the plasma membrane of their targets and bind to nuclear receptors, probably located in the deoxyribonucleic acid (DNA).

In order for peptide hormones to stimulate physiological changes within the target cell, the "message" must be passed from the hormone-receptor complex of the plasma membrane to the interior of the cell. This process of signaling across the plasma membrane is accomplished by so-called second messengers of which the best known is adenosine 3′,5′-cyclic monophosphate (cyclic AMP). Steroid hormones, of course, have no need for second messengers since they are lipid-soluble and pass readily through the plasma membrane and into the cell. *See* CELL MEMBRANES; SECOND MESSENGERS.

Once hormones are bound with their receptors and have stimulated their target cells, physiological responses occur. This may involve such biochemical processes as conversion of an inactive form of an enzyme into an active one, stimulation of critical enzymatic pathways, increase in transport of glucose or amino acids into cells, or synthesis of new proteins. These events may result in overall changes in cell or organ function, metabolism, growth, or even the behavior of the organism.

The endocrine system is regulated by control mechanisms, the means by which homeostasis is achieved. The most common relationship between the hormone and its target is one of negative feedback, whereby the response to the hormonal stimulus turns off the original stimulus. For example, the endocrine pancreatic beta cells produce insulin in response to high blood sugar levels. Insulin is released into the blood, where it causes its target cells to take up glucose, thus reducing blood sugar. When blood glucose concentration falls, the secretion of insulin is turned off. The system is turned back on when the blood glucose content gradually increases again. *See* CARBOHYDRATE METABOLISM; INSULIN.

Pituitary gland and hypothalamus. The pituitary gland, or hypophysis, is located near the base of the brain. It secretes many hormones and controls the function of other endocrine glands. The production and release of the various pituitary hormones are regulated in turn by small peptide-releasing hormones from the hypothalamus of the brain. These factors are produced by neurosecretory neurons and travel to the adenohypophysis (anterior lobe of the pituitary) by way of a portal blood system. The releasing hormones stimulate specific cells of the adenohypophysis to produce and release their hormones. Generally speaking, each of the adenohypophysial hormones is affected by a separate releasing hormone. Thus, the hypothalamic thyrotropin-releasing hormone stimulates the synthesis and release of thyroid-stimulating hormone (thyrotropin) by the adenohypophysis. Other adenohypophysial hormones include adrenocorticotropic hormone, which stimulates the production of steroid hormones by the adrenal cortex; growth hormone, which stimulates protein synthesis and growth in many cells; prolactin, which stimulates the production of milk by the mammary glands and is important in many other functions; follicle-stimulating hormone, which induces growth of the follicles of the ovary prior to ovulation; and luteinizing hormone, which induces ovulation. The release of both follicle-stimulating and luteinizing hormones is governed by gonadotropin-releasing hormone.

Other hypothalamic hormones do not reach the pituitary by way of the bloodstream; instead they travel down the long axons of the neurosecretory cells into the neurohypophysis (posterior lobe of the pituitary). Oxytocin acts upon the mammary glands of female mammals to cause milk release in response to suckling by the young, and stimulates the uterus to contract at the end of pregnancy to aid in expulsion of the offspring. Vasopressin (or antidiuretic hormone) is important in water conservation by the kidney tubules and also produces an increase in blood pressure. *See* PITUITARY GLAND.

Thyroid gland. The thyroid gland lies in the neck region of mammals. It produces two closely related hormones, triiodothyronine and thyroxine. These both increase the metabolic rate of an organism, and increase enzyme activity and protein synthesis. The thyroid hormones act along with growth hormone to promote cell growth and development. Thyroid hormones are peptides but their three-dimensional structures may be similar to those of steroid hormones. Thus they are unusual in their ability to pass through the plasma membrane of their target cells and bind to nuclear receptors.

The control of hormone secretion by the thyroid (as well as by the adrenal cortex and gonads) involves more complex feedback relationships. These endocrine glands are affected by the levels of hormones from the adenohypophysis. In the case of the thyroid gland, thyrotropin-releasing factor from the hypothalamus stimulates the release of thyroid-stimulating hormone by the adenohypophysis. In response, the thyroid secretes thyroxine and triiodothyronine. High blood levels of the thyroid hormones inhibit the secretion of both thyrotropin-releasing factor (long-loop feedback) and thyroid-stimulating hormone (short-loop feedback). *See* THYROID GLAND.

Calcium regulation. The parathyroid glands derive their name from the fact that in mammals they are embedded within the thyroids. These small glands are essential for life, as they regulate the concentration of calcium ion in blood and other extracellular fluids. If calcium is too low, the animal goes into tetanic convulsions and dies, whereas if calcium is too high, abnormal calcification and stone formation can occur. Parathyroid hormone is a protein hormone that raises the blood calcium levels (hypercalcemia). The hormone acts upon bone to cause the release of calcium and phosphate, and upon the kidney to increase the reabsorption (conservation) of calcium and excretion of phosphate.

Vitamin D is now recognized as a steroidlike hormone, although it does not originate from an endocrine gland. It is synthesized from precursors present in the diet or produced after exposure of skin lipids to ultraviolet light. Vitamin D plays roles in calcium conservation by the kidney and in bone mineralization, but its most important function is to enhance calcium transport across intestinal cells and thus conserve dietary calcium. *See* VITAMIN D.

Calcitonin is a newly recognized peptide hormone produced by thyroid cells in mammals (different cells from those that produce thyroid hormones) and from the ultimobranchial glands of nonmammalian vertebrates. Calcitonin is hypocalcemic and acts by inhibiting calcium loss from bone. Of the three calcium-regulating hormones, it appears to be the least important. *See* PARATHYROID GLAND.

Carbohydrate regulation. Insulin and glucagon are peptide hormones produced by endocrine cells of the pancreatic islets. Insulin is produced by the pancreatic beta cells and is the only hormone that decreases blood sugar (glucose) levels. It acts on its target cells (skeletal muscle, fat cells) to increase the uptake of glucose, amino acids, and fatty acids. Once taken into cells, glucose is used in metabolic reactions or stored as glycogen, a large carbohydrate. Insulin also causes the conversion of amino acids to proteins and fatty acids to fats in the target cells. In the absence of insulin, as in diabetes mellitus, the target cells cannot take up glucose, and thus the body must utilize amino acids and fats as energy sources. These processes result in the accumulation of toxic metabolic products which eventually disrupt the acid-base balance, leading to coma and death. *See* DIABETES.

Glucagon, in contrast, is a hyperglycemic hormone. It is a small peptide from the pancreatic islet alpha cells that acts upon liver cells to cause the conversion of glycogen to glucose by activation of key enzymes in a complex metabolic pathway.

Many other hormones elevate blood sugar levels. For example, epinephrine (adrenalin), an amino acid derivative from the adrenal medulla, acts by the same pathway as glucagon to convert glycogen to glucose, except that the targets of epinephrine are skeletal and heart muscle. Epinephrine is secreted in times of stress and serves to prepare the body for an emergency by increasing the availability of energy in the form of glucose and by increasing the heart rate and blood pressure.

Growth hormone, a large protein hormone from the adenohypophysis, is secreted in response to low blood sugar levels. This hormone elevates blood sugar by blocking the uptake of glucose by cells and by favoring the utilization of fats rather than glucose as an energy source.

Many of the adrenal cortical hormones, such as cortisol, are known collectively as glucocorticoids, because they also elevate blood glucose levels. These steroid hormones favor the production of glucose from proteins and fats rather than glycogen (gluconeogenesis). Glucocorticoids also exert an anti-inflammatory action, which makes them useful for treatment of arthritis and other diseases. *See* ADRENAL GLAND.

Salt and water regulation. Several hormones affect the ability of the kidney to conserve or excrete salts and water. The antidiuretic hormone (vasopressin) promotes water reabsorption by the kidney tubules, so that the organism excretes less water. The secretion of vasopressin is regulated by hypothalamic neurosecretory neurons that are sensitive to the concentration of salts in the extracellular fluids. In the absence of vasopressin, an individual excretes great volumes of dilute urine, leading to severe dehydration (diabetes insipidus).

Salt excretion is regulated mainly by two hormones that act in opposition. Aldosterone is an adrenal cortical steroid that promotes the reabsorption of sodium by the kidney tubules and thus decreases its excretion in the urine. In contrast, atriopeptin (atrial natriuretic factor), a peptide that originates in heart muscle, acts upon the kidney to increase the excretion of sodium in the urine. *See* OSMOREGULATORY MECHANISMS.

Reproductive hormones. Probably the best-studied endocrine glands are the gonads, the testes of the male and the ovaries of the female. The gonads are regulated by the follicle-stimulating hormone and luteinizing hormone from the adenohypophysis. In the male, follicle-stimulating hormone stimulates the initiation of sperm formation by the testis tubules, and luteinizing hormone acts on the nearby Leydig cells of the testis to produce testosterone, the principal male sex hormone. Testosterone acts by a paracrine mechanism to cause the final maturation of sperm, and by way of the blood to stimulate development of the male reproductive system and secondary sex characteristics. *See* TESTIS.

In the female, follicle-stimulating hormone stimulates the growth of the ovarian follicles at the beginning of each reproductive cycle. As the follicles grow, they produce estradiol. Increasing levels of estradiol cause feedback inhibition of gonadotropin-releasing hormone. High levels of estradiol also have an unusual positive feedback effect upon the hypothalamus and adenohypophysis to cause a surge in the secretion of luteinizing hormone, which results in ovulation. The corpus luteum, a remnant of the ovulated follicle, produces both estradiol and the second major female sex hormone, progesterone. Progesterone is necessary for the maintenance of a quiescent uterus during pregnancy, and both estrogen and progesterone are important in the regulation of the female reproductive cycle. Estradiol is also essential for the growth and maturation of the female reproductive system and secondary sex characteristics. In both males and females, the sex hormones affect reproductive behavior. *See* OVARY; REPRODUCTIVE BEHAVIOR.

Other hormones. There are many other factors that act in various ways to achieve homeostasis or intercellular communication, such as a large number of peptides found in both gastrointestinal cells and the brain. These were recognized for many years as gastrointestinal hormones which aid in secretion of digestive juices and motility of the gastrointestinal tract. Their function in the brain appears to be different, and there is evidence that they act in pain reception or analgesia, as factors that stimulate or curb appetite, or in memory or other functions. This field of neuropeptide hormones is in its infancy and serves to emphasize the close relationship between the endocrine and nervous systems in intercellular communication. [N.B.C.]

Endocrinology The study of the glands of internal secretion, the endocrine glands, and the hormones which they synthesize and secrete. These glands are ductless; the hormones are secreted directly into the blood to be carried to the target tissue or organ. The hormones, or chemical messengers, are highly specific and their action may be selective or generalized. *See* ENDOCRINE SYSTEM (VERTEBRATE); HORMONE. [S.P.P.]

Endocytosis The process by which animal cells internalize particulate material (such as cellular debris and microorganisms), macromolecules (such as proteins and complex sugars), and low-molecular-weight molecules (such as vitamins and simple sugars). Cells engage in at least three different types of endocytosis: phagocytosis where cells engulf particulate material, receptor-mediated-endocytosis of macromolecules, and potocytosis of small molecules.

Some of the essential nutrients that a cell needs are scarce in the environment. The cells overcome this problem by expressing high-affinity receptors, or binding sites, on the membrane surface. Each type of receptor is specific for either macromolecules or molecules. These endocytic receptors are capable of concentrating their ligand at the cell surface before carrying it into the cell, thus increasing the efficiency of uptake.

In all three endocytic pathways the internalization step begins with the invagination of plasma membrane and the conversion of this membrane into a closed vesicle called an endosome. Each of the pathways has its own set of molecules that control internalization. These molecules assemble at the cell surface and physically deform the membrane into the shape of a vesicle. The vesicle, the endosome, then detaches and migrates to other locations within the cell. The same cell-surface assemblage of molecules also attracts endocytic receptors that are moving around on the cell surface, causing them to cluster over the site of internalization. Receptor clustering, which is essential for efficient uptake, is sometimes stimulated by ligand binding.

Endosomes that are generated by the phagocytic and receptor-mediated endocytic pathways often fuse with lysosomes that contain many different hydrolytic enzymes. Small molecules, by contrast, do not need further processing, so during potocytosis they are delivered directly to the cytoplasm. *See* CELL MEMBRANES; LYSOSOME.

Phagocytosis. Phagocytosis is a receptor-mediated process where the receptors function as adhesive elements that bond the plasma membrane to the particle. The adhesive interaction of the phagocytic receptors with the membrane stimulates invagination. A critical molecule in this activity is actin, the same protein that provides power for muscle contraction. Surface membranes contain actin-binding proteins that link the phagocytic receptor to the actin cytoskeleton of the cell. Thus, when a particle binds to its endocytic receptor, a signal cascade is initiated that stimulates the recruitment of actin filaments to the site of phagocytosis. *See* CYTOSKELETON; PHAGOCYTOSIS; SIGNAL TRANSDUCTION.

Receptor-mediated endocytosis. The clathrin-coated pit is a segment of cell membrane that is specialized for receptor-mediated endocytosis. Each pit can be recognized by the presence of a polygonal lattice on the cytoplasmic surface of the membrane. This lattice shapes the plasma membrane into a coated vesicle that immediately uncoats and fuses with endosomes. The endosome functions as a switching area that directs membrane and content molecules to specific locations within the cell.

Potocytosis. Potocytosis uses membrane proteins that are anchored by lipid rather than protein as endocytic receptors. The lipid anchor causes the attached proteins to migrate in the plane of the membrane and cluster in a membrane specialization called a caveola. Clustering ensures that any ligand bound to these receptors will be concentrated in this location. When caveolae close, they create a tiny compartment of uniform size that is sealed off from the extracellular space. When the ligand dissociates from its receptor, it reaches such a high concentration that it naturally flows through water-filled membrane channels into the cell.

The closed caveolar compartment appears to be a unique space for the cell. It is transient, does not merge with other organelles, and can selectively concentrate extracellular molecules or ions and deliver them to the cytoplasm. In addition to importing molecules, cells can also use this space to store and process incoming or outgoing messengers that affect cell behavior. *See* CELL (BIOLOGY); CELL PERMEABILITY. [R.G.W.A.]

Endodermis

The single layer of plant cells that is located between the cortex and the vascular (xylem and phloem) tissues. It has its most obvious development in roots and subaerial stems. The endodermis has many apparent functions: absorption of water, selection of solutes and ions, and production of oils, antibiotic phenols, and acetylenic acids.

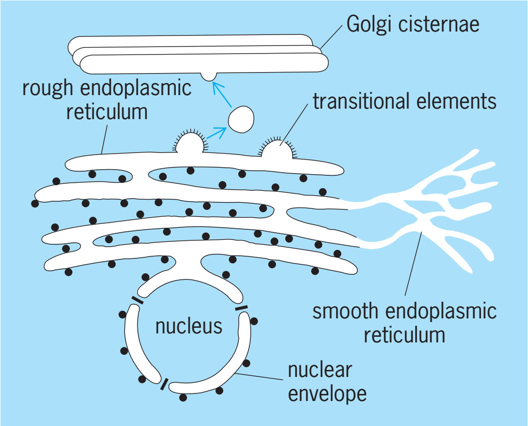
The endodermis has been found to have extra sets of chromosomes as compared with cortical and other cells in the plant. In some plants the chromosome numbers may be so high in the endodermis that four sets of chromosomes may occur in each endodermal cell. The larger amount of nuclear material and nucleic acid in the cells of the endodermis may in part account for the great capacity of endodermal cells to produce large amounts of chemical substances, such as acetylenic oils, high in caloric energy. *See* CORTEX (PLANT); HYPODERMIS. [D.S.V.F.]

Endoplasmic reticulum

An intracellular membrane system that is present in all eukaryotic cells. In most cells the endoplasmic reticulum is thought to consist of only one continuous membrane enclosing only a single space. However, in protozoa, some unicellular algae, and possibly some fungi, the endoplasmic reticulum occurs as separate, multiple vesicles. *See* CELL MEMBRANES.

Several morphologically and functionally distinct domains of this continuous membrane system can be distinguished. At the level of the nuclear pores, the inner nuclear membrane is continuous with the outer nuclear membrane; both membranes together are referred to as the nuclear envelope. The outer nuclear membrane in turn is continuous with the rough endoplasmic reticulum, which contains specialized regions, termed transitional elements, and is continuous with the smooth endoplasmic reticulum. The two membranes of the nuclear envelope enclose the perinuclear space. The rough and smooth endoplasmic reticula and the transitional element enclose a space called the intracisternal space, or lumen. Both intracisternal and perinuclear spaces form a single compartment. All nucleated cells contain at least a nuclear envelope, but the amount of smooth and rough endoplasmic reticula varies greatly among different cell types. *See* CELL NUCLEUS.

The term rough endoplasmic reticulum is based on the morphologic appearance of attached ribosomes, which are absent from smooth endoplasmic reticulum. (Ribosomes are also associated with the outer nuclear membrane; in fact, the outer nuclear membrane and the rough endoplasmic reticulum appear to be functionally equivalent.) Another morphologic distinction is the organization of the rough endoplasmic reticulun in interconnected flattened sacs (called cisternae), whereas the smooth



Nuclear envelope, connected to the rough and smooth endoplasmic reticulum. The rough endoplasmic reticulum is linked to the cis cisternae of the Golgi complex by vesicles that shuttle between the two compartments.

endoplasmic reticulum forms a tubular network (see illustration). *See* RIBOSOMES.

The rough endoplasmic reticulum is the site of translocation of secretory and lysosomal proteins from the cytosol to the intracisternal space, and of integration into the membrane of integral membrane proteins. Except for integral membrane proteins of chloroplast, mitochondria, and peroxisomes, essentially all other integral membrane proteins are integrated into the endoplasmic reticulum and either remain there (resident endoplasmic reticulum membrane proteins) or are subsequently distributed to other cellular membranes.

The signal hypothesis was formulated to explain how these proteins are targeted to and then translocated across or integrated into the endoplasmic reticulum membrane. Its tenets are that all polypeptides targeted to this membrane contain a discrete sequence (termed the signal sequence), that a complex machinery recognizes this sequence, and that recognition triggers the opening of a proteinaceous channel through which the polypeptide passes across the membrane. In the case of membrane proteins, the existence of an additional topogenic sequence, the so-called stop-transfer sequence, was postulated. This sequence is thought to trigger opening of the channel to the lipid bilayer to abort translocation and thus integrate the protein into the lipid bilayer.

The rough endoplasmic reticulum also contains numerous enzymes, most of which are involved in the modification of the nascent protein chain on the cisternal side. Thus the main function of the rough endoplasmic reticulum and the outer nuclear membrane is to serve as a port of entry of secretory, lysosomal, and integral membrane proteins and as the site of their initial modification. *See* CYTOCHEMISTRY.

Secretory and lysosomal proteins as well as those integral membrane proteins that are not residents of the endoplasmic reticulum are next transported to the cis Golgi cisternae. The transitional elements represent sites of transport from the rough endoplasmic reticulum. Coated vesicles carrying proteins to be transported form at these sites and, after uncoating, eventually fuse with the cis Golgi cisternae. *See* GOLGI APPARATUS.

Smooth endoplasmic reticulum contains enzymes for phospholipid biosynthesis, steroid biosynthesis, and drug detoxification. *See* CELL (BIOLOGY); CELL ORGANIZATION; ENZYME. [G.B.B.]

Endopterygota A division (also known as Holometabola) of the subclass Pterygota, including those insects that undergo complete metamorphosis during their life cycle. That is, individual development goes through four distinct stages: egg, larva (trophic), pupa (reconstructive), and adult (reproductive). The larval and adult stages often live in very different adaptive zones and have very different life forms, necessitating a quiescent pupal stage in which extensive restructuring takes place. Internalization of the developing wings and the advent of the pupa combine to form a key general adaptation that breaks the constraining linkage between trophic and reproductive life forms, allowing each to evolve for its own special function. This adaptation probably accounts for the rapid rise of the Endopterygota to a dominant position among the insects from the Permian to the present.

The division Endopterygota comprises a large majority of all insects, distributed in the orders Coleoptera, Neuroptera, Strepsiptera, Mecoptera, Siphonaptera, Trichoptera, Lepidoptera, Diptera, and Hymenoptera. It is thought to be monophyletic. *See* EXOPTERYGOTA; INSECTA; PTERYGOTA. [W.L.Bro.]

Endorphins A family of endogenous morphinelike peptides present within the central nervous system. The term endorphin is generic, referring to all the opioid peptides, while specific peptides are given individual names, such as the enkephalins and β-endorphin. Their discovery has greatly enhanced the understanding of the mechanism of action of opiate drugs and how the perception of pain is modulated within the central nervous system. *See* OPIATES; PAIN.

Morphine, codeine, and their many synthetic and semisynthetic analogs are effective pain killers that act through specific recognition sites, or receptors, localized on the surface of neurons within selected brain regions. These receptors have been extensively characterized, and a number of different subtypes have been identified which vary in their specificity for various opiates and opioid peptides and in the actions they mediate. The existence of these highly specific receptors implied that morphine was mimicking endogenous compounds within the brain with morphinelike actions, which have since been termed endorphins. *See* MORPHINE ALKALOIDS.

The first endorphins to be isolated were the enkephalins, two pentapeptides differing only in their fifth amino acid, which is either methionine or leucine. Since the initial description of the enkephalins, a number of opioid peptides have been reported that all share either the structure of methionine (Met) enkephalin or leucine (Leu) enkephalin as their first five amino acids. The major genes for these peptides have been identified. β-Endorphin is perhaps the most interesting peptide; it is cogenerated with important, nonopioid hormones.

The enkephalins are distributed unevenly throughout the brain, with very high levels in the basal ganglia, the thalamus, and the periaqueductal gray. In addition, there are high concentrations of enkephalins in the adrenal medulla, where they are co-released with norepinephrine in response to stress, among other stimuli. The dynorphins and α-endorphin are located within the central nervous system with a distribution similar to that of the enkephalins. *See* STRESS (PSYCHOLOGY).

β-Endorphin has been identified in only a single group of cells within the hypothalamus. Its highest levels are in the pituitary gland. Within the pituitary, both ACTH and β-endorphin are derived from the same precursor protein and are located within the same cells. Stimuli that release ACTH, a stress hormone which in turn induces the adrenal gland to release steroids, also co-release β-endorphin at the same time. Thus, stressful stimuli that release ACTH and norepinephrine also release both β-endorphin from the pituitary and enkephalins from the adrenal into the blood. This is particularly intriguing in view of the decreased perception of pain reported under periods of stress, such as combat. *See* ENDOCRINE SYSTEM (VERTEBRATE).

All the endorphins can modulate the intensity of pain despite the fact that they act through different classes of opiate receptors. However, the presence of high concentrations of endorphins in brain regions unrelated to pain perception clearly demonstrates that the full range of actions of these compounds within the brain is not yet fully understood. Furthermore, their systemic hormonal role remains uncertain. *See* NERVOUS SYSTEM (VERTEBRATE). [G.Pas.]

Endotoxin A biologically active substance produced by bacteria and consisting of lipopolysaccharide, a complex macromolecule containing a polysaccharide covalently linked to a unique lipid structure, termed lipid A. All gram-negative bacteria synthesize lipopolysaccharide, which is a major constituent of their outer cell membrane. One major function of lipopolysaccharide is to serve as a selectively permeable barrier for organic molecules in the external environment. Different types of gram-negative bacteria synthesize lipopolysaccharide with very different polysaccharide structures. The biological activity of endotoxic lipopolysaccharide resides almost entirely in the lipid A component. *See* CELL MEMBRANES; LIPID; POLYSACCHARIDE.

When lipopolysaccharides are released from the outer membrane of the microorganism, significant host responses are initiated in humans and other mammals. It is generally accepted that lipopolysaccharides are among the most potent microbial products, known for their ability to induce pathophysiological changes, in particular fever and changes in circulating white blood cells. In humans as little as 4 nanograms of purified lipopolysaccharide per kilogram of body weight is sufficient to produce a rise in temperature of about 3.6°F (2°C) in several hours. This profound ability of the host to recognize endotoxin is thought to serve as an early warning system to signal the presence of gram-negative bacteria.

Unlike most microbial protein toxins (which have been termed bacterial exotoxins), endotoxin is unique in that its recognized mode of action does not result from direct damage to host cells and tissues. Rather, endotoxin stimulates cells of the immune system, particularly macrophages, and of the vascular system, primarily endothelial cells, to become activated and to synthesize and secrete a variety of effector molecules that cause an inflammatory response at the site of bacterial invasion. These mediator molecules promote the host response which results in elimination of the invading microbe. Thus, under these circumstances lipopolysaccharide is not a toxin at all, but serves an important function by helping to mobilize the host immune system to fight infection. *See* CYTOKINE; IMMUNOLOGY.

Even though endotoxin stimulation of host cells is important to host defense against infection, overstimulation due to excess production of endotoxin can lead to serious consequences. Endotoxin-induced multiple-organ failure continues to be a major health problem, particularly in intensive care; it has been estimated that as many as 50,000 deaths annually occur in the United States as the result of endotoxin-induced shock.

Immunization of humans with endotoxin vaccines to protect against endotoxin shock has not been considered practical. Efforts to provide immunologic protection against endotoxin-related diseases have focused upon development of antibodies that recognize the conserved lipid A structure of endotoxin as a means of passive protection against the lethal effects of this microbial product. *See* BACTERIA; MEDICAL BACTERIOLOGY; VACCINATION. [D.C.M.]

Energy The ability of one system to do work on another system. There are many kinds of energy: chemical energy from fossil fuels, electrical energy distributed by a utility company, radiant energy from the Sun, and nuclear energy from a reactor. The units of energy include ergs, joules, foot-pounds, and foot-poundals. Work and heat have the same units as energy, but are entirely different physical concepts. *See* HEAT; WORK.

Any particle or system of particles subject to conservative forces has two kinds of energy, potential energy and kinetic energy. Potential energy is the energy due to position or configuration, and kinetic energy is the energy due to motion.

Energy is conserved for all isolated mechanical systems. This is because if a system A is isolated, there is no other system B that it can give any energy to, and its total energy must remain constant. This system A can convert kinetic energy to potential energy, and it can convert one form of potential energy to another, but the total energy must remain the same. The meaning of conserved total energy is that the system has the same value of total energy at all times. *See* CONSERVATION OF ENERGY.

In 1905 A. Einstein showed that at high velocities near the speed of light important modifications must be made in physical concepts. One particularly radical idea which he advanced was that space and time are not independent, but rather are two aspects of the same object, a space-time manifold. This necessitated a reexamination of the concept of energy and led to the conclusion that the inertia, or mass m, depends upon its energy through the mass-energy relation shown below, where c is the

$$E = mc^2$$

speed of light in vacuum. Furthermore, energy and momentum conservation become joined in a single four-momentum conservation law in special relativity. *See* INTERNAL ENERGY; RELATIVITY. [B.DeF.]

Energy conversion The process of changing energy from one form to another. There are many conversion processes that appear as routine phenomena in nature, such as the evaporation of water by solar energy or the storage of solar energy in fossil fuels. In the world of technology the term is more generally applied to operations of human origin in which the energy is made more usable; for instance, the burning of coal in power plants to convert chemical energy into electricity, the burning of gasoline in automobile engines to convert chemical energy into propulsive energy of a moving vehicle, or the burning of a propellant for ion rockets and plasma jets to provide thrust.

There are well-established principles in science which define the conditions and limits under which energy conversions can be effected, for example, the law of the conservation of energy, the second law of thermodynamics, the Bernoulli principle, and the Gibbs free-energy relation. Recognizable forms of energy which allow varying degrees of conversion include chemical, atomic, electrical, mechanical, light, potential, pressure, kinetic, and heat energy. In some conversion operations the transformation of energy from one form to another, more desirable form may approach 100% efficiency, whereas with others even a "perfect" device or system may have a theoretical limiting efficiency far below 100%. *See* ENERGY SOURCES. [T.Ba.]

Energy level (quantum mechanics) One of the allowed values of the internal energy of an isolated physical system. This energy is not free to vary continuously above its minimum value, as predicted by classical mechanics, but is constrained to lie among a set or spectrum of particular values. This spectrum may consist of both an isolated discrete portion and a continuous component of restricted range. The term energy level usually refers to one of the allowed values in the discrete set.

The primary indication for the existence of discrete energy levels came from the study of the spectrum of emissions of energetically excited atomic systems. Historically, the most important such spectrum is that of the simplest atom, hydrogen, a system of one proton and one electron bound together by their electromagnetic attraction. Within the framework of classical physics, the structure of the hydrogen atom poses fundamental problems. The first is the existence of a stable ground state: An electron in orbit around a proton is in constant acceleration, and therefore, according to Maxwell's classical electromagnetic theory, should continuously radiate away energy. Furthermore, the radiation emitted as the atom decays to a lower energy state should form a continuous spectrum of frequencies. However, the hydrogen atom both possesses a stable ground state and emits radiation at only a discrete set of frequencies.

In 1913 N. Bohr made a fundamental advance by postulating that the angular momentum of the electron-proton system could take on only a discrete set of values. The angular momentum is said to be quantized. A consequence is that the excitation energies of the hydrogen atom also have a discrete spectrum. Bohr made the further postulate that the atom decays from an excited level, E_k, only by making a transition to a lower energy level, E_j, emitting a single light quantum (photon) in the process. The energy, E_γ, of this photon is given by the conservation of energy, $E_\gamma = E_k - E_j$. Although Bohr's postulates are in many ways without real foundation, they were later justified and extended by the development of quantum mechanics. *See* ATOMIC STRUCTURE AND SPECTRA.

The quantization of the allowed energy values that occurs in quantum mechanics has analogs for other physical quantities as well, such as angular momentum. The basic reason why such quantization occurs for bound systems of particles in quantum mechanics but not in classical mechanics is that in quantum mechanics particles have associated wavelike attributes, specifically a wave function which encodes the dynamical state of the particle. (This is the content of wave-particle duality.) The wave function of a bound state satisfies an equation similar in many ways to the equation describing waves on a guitar string or drumhead of finite extent. Such musical instruments produce only certain specific notes, or frequencies, for a given length of string or size of drumhead. In other words, the frequencies are quantized. Similarly, the modes of oscillation of the wave function for a quantum system of finite extent are also quantized, leading to discrete energy levels, and so forth. An unbound quantum system, however, is analogous to a string of infinite length, which can play a continuous range of notes.

Energy levels are of great importance for many systems other than simple atoms such as hydrogen. For instance, they determine the interactions and binding of molecules in chemistry and biochemistry, the stability or decay of nuclei, and the macroscopic properties of solids, such as the optical properties of dyes or semiconductors. The observed spectroscopy of the energy levels of a system can also elucidate the properties of a new force, just as the study of hydrogen led to the development of quantum mechanics and quantum field theory. [J.M.R.]

Energy metabolism Energy metabolism, or bioenergetics, is the study of energy changes that accompany biochemical reactions. Energy sustains the work of biosynthesis of cellular and extracellular components, the transport of ions and organic chemicals against concentration gradients (osmotic work), the conduction of electrical impulses in the nervous system, and the movement of cells and the whole organism. Sunlight is the ultimate source of energy for life. Photosynthetic cells use light energy to produce chemical energy and reducing compounds, used to convert carbon dioxide into organic chemicals such as glucose. The energy from the oxidation of carbohydrates, fats, and proteins sustains the biochemical reactions required for life.

The main sources of chemical energy for most organisms are carbohydrates, fats, and protein. Energy content is expressed in calories or joules. The nutritional calorie, or kilocalorie (kcal), in foodstuffs is equivalent to 1000 calories. The energy content per gram of carbohydrate is 4 kcal (16 J); protein, 4 kcal (16 J); and fat, 9 kcal (36 J). The metabolism of foodstuffs yields chemical energy and heat.

Energy is defined as the ability to do work, and metabolism represents the biochemical reactions that a cell can perform to produce energy. The most important thermodynamic parameter in bioenergetics is the free energy change, ΔG, occurring at constant temperature and pressure (the usual conditions for chemical reactions inside the cell). The Gibbs free energy change is defined as the free energy content of the final state minus the free energy content of the initial state.

All feasible reactions occur with a negative free energy change; the final state has less free energy than the initial state; that is, $\Delta G < 0$ (process is exergonic). If the free energy of the final state is more than that of the initial state, ΔG is positive and the reaction is not feasible without the input of energy; $\Delta G > 0$ (process is endergonic). When the free energy change is zero, the reaction or process is at equilibrium; $\Delta G = 0$ (process is isoergonic). *See* FREE ENERGY.

The complete oxidation of one mole of glucose to carbon dioxide and water is associated with the liberation of free energy. Energy is released in a stepwise fashion and is coupled to the biosynthesis of adenosine triphosphate (ATP) from adenosine diphosphate (ADP) and inorganic phosphate (P_i). The reaction of ATP with water to produce ADP and P_i results in the liberation of a large amount of energy (30 kJ, or 7 kcal per mole). Such compounds are said to be energy-rich and to possess a high-energy bond. Lipmann's law is the cornerstone of energy metabolism: ATP serves as the common currency of energy exchange in living systems (animals, plants, and bacteria). The ATP-ADP couple receives and distributes chemical energy in all living systems. Creatine phosphate is an energy-rich compound found in vertebrate muscle and brain; it is a storage form of chemical energy and can energize the regeneration of ATP from ADP. Such a reaction occurs in vigorously exercising skeletal muscle when ATP is expended to produce contraction. *See* ADENOSINE DIPHOSPHATE (ADP); ADENOSINE TRIPHOSPHATE (ATP). [R.Ros.]

Energy sources Sources from which energy can be obtained to provide heat, light, and power. Sources of energy have evolved from human and animal power to fossil fuels, uranium, water power, wind, and the Sun.

The principal fossil fuels are coal, lignite, peat, petroleum, and natural gas; other potential sources of fossil fuels include oil shale and tar sands. As fossil fuels become depleted, nonfuel sources and fission and fusion sources will become of greater importance since they are renewable. Nuclear power is based on the fission of uranium, thorium, and plutonium, and the fusion power is based on the forcing together of the nuclei of two light atoms such as deuterium, tritium, or helium-3. *See* COAL; NATURAL GAS; NUCLEAR POWER; OIL SAND; OIL SHALE; PETROLEUM.

Nonfuel sources of energy include wastes, water, wind, geothermal deposits, biomass, and solar heat. *See* BIOMASS; GEOTHERMAL POWER; SOLAR ENERGY; WATERPOWER; WIND POWER.

Fuels which do not exist in nature are known as synthetic fuels. They are synthesized or manufactured from varieties of fossil fuels which cannot be used conveniently in their original forms. Substitute natural gas is manufactured from coal, peat, or oil shale. Synthetic liquid fuels can be produced from coal, oil shale, or tar sands. Both gaseous and liquid fuels can be synthesized from renewable resources, collectively called biomass. These carbon sources are trees, grasses, algae, plants, and organic waste. Production of synthetic fuels, particularly from renewable resources, increases the scope of available energy sources.

Energy management includes not only the procurement of fuels on the most economical basis, but the conservation of energy by every conceivable means. Whether this is done by squeezing out every Btu through heat exchangers, or by room-temperature processes instead of high-temperature processes, or by greater insulation to retain heat which has been generated, each has a role to play in requiring less energy to produce the same amount of goods and materials. [G.C.G.]

Energy storage The general method and specific techniques for storing energy derived from some primary source in a form convenient for use at a later time when a specific energy demand is to be met, often in a different location.

In the past, energy storage on a large scale had been limited to storage of fuels. For example, large amounts of natural gas and petroleum are routinely stored. On a smaller scale, electric energy is stored in batteries that power automobile starters and a great variety of portable appliances. In the future, energy storage in many forms is expected to play an increasingly important role in shifting patterns of energy consumption away from scarce to more abundant and renewable primary resources.

An example of growing importance is the storage of electric energy generated at night by coal or nuclear power plants to meet peak electric loads during daytime periods. This is achieved by pumped hydroelectric storage, that is, pumping water from a lower to a higher reservoir at night and reversing this process during the day, with the pump then being used as a turbine and the motor as a generator.

Off-peak electric energy can also be converted into mechanical energy by pumping air into a suitable cavern where it is stored at pressures up to 80 atm (8 megapascals). Turbines and generators can then be driven by the air when it is heated and expanded.

The development of advanced batteries (such as nickel-zinc, nickel-iron, zinc-chloride, and sodium-sulfur) with characteristics superior to those of the familiar lead-acid battery could result in use of battery energy storage on a large scale. For example, batteries lasting 2000 or more cycles could be used in installations of several-hundred-thousand-kilowatt-hour capacity in various locations on the electric power grid, as an almost universally applicable method of utility energy storage. Batteries combining these characteristics with energy densities (storage capacity per unit weight and volume) well above those of lead-acid batteries could provide electric vehicles with greater range. *See* BATTERY.

Ceramic brick "storage heaters" that store off-peak electricity in the form of heat have gained wide acceptance for heating buildings in Europe, and the barriers to their increased use in the United States are more institutional and economic than technological.

Solar hot-water storage is technically simple and commercially available. However, the use of solar energy for space heating requires relatively large storage systems, with water or rock beds as storage media, and difficulties can arise in integrating this storage with existing buildings while keeping costs within acceptable limits. *See* SOLAR ENERGY; SOLAR HEATING AND COOLING.

Heat or electricity may be stored by using these energy forms to force certain chemical reactions to occur. Such reactions are chosen so that they can be reversed readily with release of energy; in some cases the products can be transported from the point of generation to that of consumption. For example, reactions which produce hydrogen could become attractive since hydrogen could be stored for extensive periods of time and then conveniently used in either combustion devices or in fuel cells. *See* FUEL CELL.

Electrical energy can be stored directly in the form of large direct currents used to create fields surrounding the superconducting windings of electromagnets. In principle such devices appear attractive because their storage efficiency is high. However, the need for maintaining the system at temperatures approaching absolute zero and, particularly, the need to physically restrain the coils of the magnet when energized require expensive auxiliary equipment (insulation, vacuum vessels, and structural supports). *See* SUPERCONDUCTING DEVICES.

Storage of kinetic energy in rotating mechanical systems such as flywheels is attractive where very rapid absorption and release of the stored energy is critical. However, research indicates that even advanced designs and materials are likely to be too expensive for utility energy storage on a significant scale, and applications will probably remain limited to systems where high power capacity and short charging cycles are the prime consideration. [F.K.; T.R.S.]

Engine

A machine designed for the conversion of energy into useful mechanical motion. The principal characteristic of an engine is its capacity to deliver appreciable mechanical power, as contrasted to a mechanism such as a clock, whose significant output is motion. By usage an engine is usually a machine that burns or otherwise consumes a fuel, as differentiated from an electric machine that produces mechanical power without altering the composition of matter. Similarly, a spring-driven mechanism is said to be powered by a spring motor; a flywheel acts as an inertia motor. By definition a hydraulic turbine is not an engine, although it competes with the engine as a prime source of mechanical power. *See* ENERGY CONVERSION; HYDRAULIC TURBINE; MOTOR; PRIME MOVER; WATERPOWER.

Traditionally, engines are classed as external or internal combustion. External combustion engines consume their fuel or other energy source in a separate furnace or reactor. A further basis of classification concerns the working fluid. If the working fluid is recirculated, the engine operates on a closed cycle. If the working fluid is discharged after one pass through boiler and engine, the engine operates on an open cycle. The commonest types of engine use atmospheric air in open cycles both as the principal constituent of their working fluids and as oxidizer for their fuels. *See* DIESEL ENGINE; GAS TURBINE; INTERNAL COMBUSTION ENGINE; NUCLEAR REACTOR; ROTARY ENGINE; STEAM-GENERATING FURNACE; STIRLING ENGINE; TURBINE PROPULSION. [D.L.An.; F.H.R.]

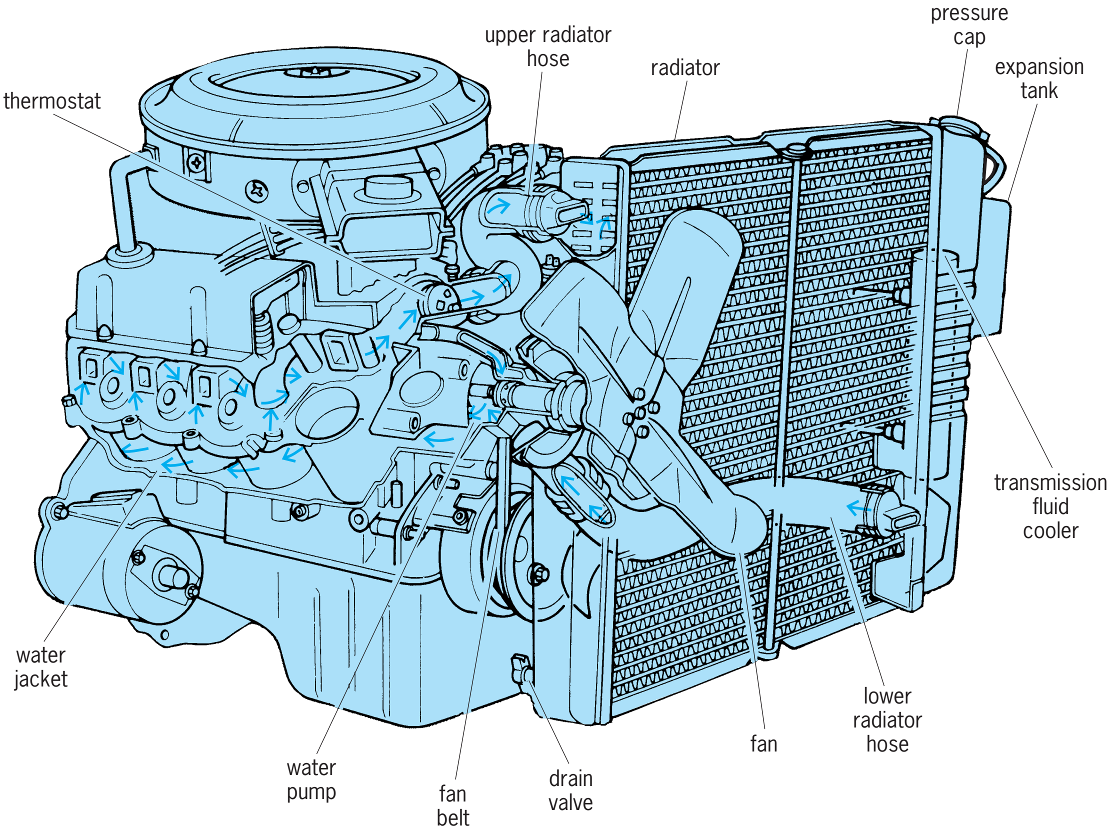
Engine cooling

A cooling system in an internal combustion engine that is used to maintain the various engine components at temperatures conducive to long life and proper functioning. Gas temperatures in the cylinders may reach 4500°F (2500°C). This is well above the melting point of the engine parts in contact with the gases; therefore it is necessary to control the temperature of the parts, or they will become too weak to carry the stresses resulting from gas pressure. The lubricating oil film on the cylinder wall can fail because of chemical changes at wall temperatures above about 400°F (200°C). Complete loss of power may take place if some spot in the combustion space becomes sufficiently heated to ignite the charge prematurely on the compression stroke. *See* INTERNAL COMBUSTION ENGINE.

A thin protective boundary of relatively stagnant gas of poor heat conductivity exists on the inner surfaces of the combustion space. If the outer cylinder surface is placed in contact with a cool fluid such as air or water and there is sufficient contact area to cause a rapid heat flow, the resulting drop in temperature produced by the heat flow in the inside boundary layer keeps the temperature of the cylinder wall much closer to the temperature of the coolant than to the temperature of the combustion gas.

If the coolant is water, it is usually circulated by a pump through jackets surrounding the cylinders and cylinder heads. The water is circulated fast enough to remove steam bubbles that may form over local hot spots and to limit the water's temperature rise through the engine to about 15°F (8°C). In most engines in automotive and industrial service, the warmed coolant is piped to an air-cooled heat exchanger called a radiator (see illustration). The airflow required to remove the heat from the radiator is supplied by an electric or engine-driven fan; in automotive applications the airflow is also supplied by the forward motion of the vehicle. The engine and radiator may be separated and each placed in the optimum location, being connected through piping. To prevent freezing, the water coolant is usually mixed with ethylene glycol. *See* ANTIFREEZE MIXTURE; ETHYLENE GLYCOL; HEAT EXCHANGER.

Engines are often cooled directly by a stream of air without the interposition of a liquid medium. The heat-transfer coefficient between the cylinder and airstream is much less than with a liquid coolant, so that the cylinder temperatures must be much greater than the air temperature to transfer to the cooling air the heat flowing from the cylinder gases. To remedy this situation and to reduce the cylinder wall temperature, the outside area of the cylinder, which is in contact with the cooling air, is increased by finning. The heat flows easily from the cylinder metal into



Cooling system of a V-8 automotive spark-ignition engine. The arrows show the direction of coolant flow through the engine water jackets and cooling system. (*Ford Motor Co.*)

the base of the fins, and the great area of finned surface permits heat to be transferred to the cooling air. *See* HEAT TRANSFER.
[A.R.R.; D.L.An.]

Engine lubrication In an internal combustion engine, the system for providing a continuous supply of oil between moving surfaces during engine operation. This viscous film, known as the lubricant, lubricates and cools the power transmission components while removing impurities, neutralizing chemically active products of combustion, transmitting forces, and damping vibrations. *See* INTERNAL COMBUSTION ENGINE; LUBRICANT.

Automotive engines are generally lubricated with petroleum-base oils that contain chemical additives to improve their natural properties. Synthetic oils are used in gas turbines and may be used in other engines. Probably the most important property of oil is the absolute viscosity, which is a measure of the force required to move one layer of the oil film over the other. If the viscosity is too low, a protecting oil film is not formed between the parts. With high viscosity too much power is required to shear the oil film, and the flow of oil through the engine is retarded. Viscosity tends to decrease as temperature increases. Viscosity index (VI) is a number that indicates the resistance of an oil to changes in viscosity with temperature. The smaller the change in viscosity with temperature, the higher the viscosity index of the oil. *See* VISCOSITY.

Small two-stroke cycle engines may require a premix of the lubricating oil with the fuel going into the engine, or the oil may be injected into the ingoing air-fuel mixture. This is known as a total-loss lubricating system because the oil is consumed during engine operation.

Most automotive engines have a pressurized or force-feed lubricating system in combination with splash and oil mist lubrication. The lubricating system supplies clean oil cooled to the proper viscosity to the critical points in the engine, where the motion of the parts produces hydrodynamic oil films to separate and support the various rubbing surfaces. The oil is pumped under pressure to the bearing points, while sliding parts are lubricated by splash and oil mist. After flowing through the engine, the oil collects in the oil pan or sump, which cools the oil and acts as a reservoir while the foam settles out. Some engines have an oil cooler to remove additional heat from the oil. *See* WEAR.
[D.L.An.]

Engine manifold An arrangement or collection of pipes or tubing with several inlet or outlet passages through which a gas or liquid is gathered or distributed. The manifold may be a casting or fabricated of relatively light material. Manifolds are usually identified by the service provided, such as the intake manifold and exhaust manifold on the internal combustion engine. Some types of manifolds for handling oil, water, and other fluids such as engine exhaust gas are often called headers. In the internal combustion engine, the intake and exhaust manifolds are an integral part of multicylinder engine construction and essential to its operation. *See* INTERNAL COMBUSTION ENGINE.

The engine intake manifold is a casting or assembly of passages through which air or an air-fuel mixture flows from the air-intake or throttle valves to the intake valve ports in the cylinder head or cylinder block. In a spark-ignition engine with a carburetor or throttle-body fuel injection, the intake manifold carries an air-fuel mixture. In an engine with port fuel injection or in a diesel engine, the intake manifold carries only air. For the diesel engine, the air should be inducted with a minimum of pressure drop. The purpose of the intake manifold is to distribute the air or air-fuel mixture uniformly to each of the cylinders and to assist in the vaporization of the fuel.

The engine exhaust manifold is a casting or assembly of passages through which the products of combustion leave the exhaust-valve ports in the cylinder head or cylinder block and enter the exhaust piping system. The purpose of the exhaust manifold is to collect and carry these exhaust gases away from the cylinders with a minimum of back pressure.

Some automative spark-ignition engines have an air-distribution manifold as part of the exhaust-emission control system. This manifold distributes and proportions air to the individual exhaust ports through external tubing or integral passageways. [D.L.An.]

Engineering Most simply, the art of directing the great sources of power in nature for the use and the convenience of people. In its modern form engineering involves people, money, materials, machines, and energy. It is differentiated from science because it is primarily concerned with how to direct to useful and economical ends the natural phenomena which scientists discover and formulate into acceptable theories. Engineering therefore requires above all the creative imagination to innovate useful applications of natural phenomena. It seeks newer, cheaper, better means of using natural sources of energy and materials.

The typical modern engineer goes through several phases of career activity. Formal education must be broad and deep in the sciences and humanities. Then comes an increasing degree of specialization in the intricacies of a particular discipline, also involving continued postscholastic education. Normal promotion thus brings interdisciplinary activity as the engineer supervises a variety of specialists. Finally, the engineer enters into the management function, weaving people, money, materials, machines, and energy sources into completed processes for the use of society.

For articles on various engineering disciplines *see* CHEMICAL ENGINEERING; CIVIL ENGINEERING; ELECTRICAL ENGINEERING; INDUSTRIAL ENGINEERING; MANUFACTURING ENGINEERING; MARINE ENGINEERING; MECHANICAL ENGINEERING; METHODS ENGINEERING; MINING; NUCLEAR ENGINEERING. [J.W.B.]

Engineering design Engineering is concerned with the creation of systems, devices, and processes useful to, and sought by, society. The process by which these goals are achieved is engineering design.

The process can be characterized as a sequence of events as suggested in Fig. 1. The process may be said to commence upon the recognition of, or the expression of, the need to satisfy some human want or desire, the "goal," which might range from the detection and destruction of incoming ballistic missiles to a minor kitchen appliance or fastener.

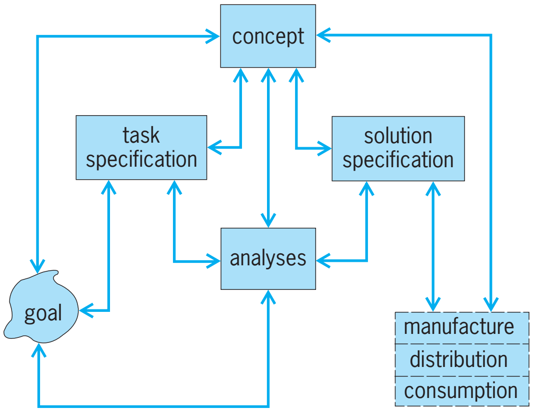


Fig. 1. Engineering design process.

Concept formulation. The first obligation of the engineer is to develop more detailed quantitative information which defines the task to be accomplished in order to satisfy the goal, labeled on Fig. 1 as task specification. At this juncture the scope of the problem is defined, and the need for pertinent information is established. Generation of ideas for possible solutions to the problem is the creative stage, called the concept formulation. When great strides in engineering are made, this represents ingenious, innovative, inventive activity; but even in more pedestrian situations where rational and orderly approaches are possible, the conceptual stage is always present. The concept does not represent a solution, but only an idea for a solution. It can only be described in broad, qualitative, frequently graphical terms. Concepts for possible solutions to engineering challenges arise initially as mental images which are recorded first as sketches or notes and then successively tested, refined, organized, and ultimately documented by using standardized formats.

Concepts are accompanied and followed by, sometimes preceded by, acts of evaluation, judgment, and decision. It is in fact this testing of ideas against physical, economic, and functional reality that epitomizes engineering's bridge between the art of innovation and science. The process of analysis is sometimes intuitive and qualitative, but it is often mathematical, quantitative, careful, and precise.

Production considerations can have a profound influence on the design process, especially when high-volume manufacture is anticipated. Evolutionary products manufactured in large numbers, such as the automobile, are tailored to conform with existing production equipment and techniques such as assembly procedures, interchangeability, scheduling, and quality control. New techniques such as those associated with space exploration, where volume production is not a central concern, factor into the engineering design process in a very different fashion.

Similarly, the design process must anticipate and integrate provisions for distribution, maintenance, and ultimate replacement of products. Well-conceived and executed engineering design will encompass the entire product cycle from definition and conception through realization and demise and will give due consideration to all aspects.

Hierarchy of design. An adequate description of the engineering design process must have both general validity and applicability to a wide variety of engineering situations: tasks simple or complex, small- or large-scale, short-range or far-reaching. That is to say, there is a hierarchy of engineering design situations.

Systems engineering occupies one end of the spectrum. The typical goal is very broad, general, and ambitious, and the concepts are concerned with the interrelationships of a variety of subsystems or components which, taken together, make up the system to accomplish the desired goal. *See* SYSTEMS ENGINEERING.

Time–worker-power resource dynamics. Another dimension of the dynamics of the engineering design process is the elapse of time and expenditure of worker-hours in the evolution of an engineering design project. Figure 2 plots time as the abscissa and resources (worker-power or dollars) as the ordinate. The various stages of the engineering design process are set out in time sequence from left to right.

Goal refinement, task specification, and first-order concept and analyses iterations are conducted by one to a few engineers in the early stages to establish the feasibility of the idea and to block out possible approaches. This is usually called the advanced design stage.

As the design concept becomes more specific and substantive, more and more engineers, technicians, and draftsmen become involved in the project. In projects of significant size, the problem of coordinating and integrating the efforts of the many participants of different talents and skills becomes itself a major consideration. *See* PERT.

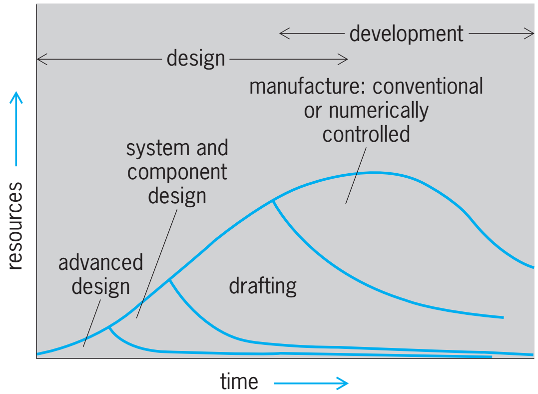

Fig. 2. Elapse of time and resources in an engineering design project, showing various stages in sequence.

Use of the computer in design. The use of the computer, both analog and digital, in the engineering design process has increased. Where economically justified, the overall engineering design process for a product is mechanized via computer programming. *See* Computer; Computer-aided design and manufacturing; Computer storage technology; Multiaccess computer.

The speed, memory, and accuracy of the computer to iteratively calculate, store, sort, collate, and tabulate have greatly enhanced its use in design and encouraged the study, on their own merits, of the processes and subprocesses exercised in the design process. These include optimization or sensitivity analysis, reliability analysis, and simulation as well as design theory. *See* Digital computer.

Optimization analyses, given a model of the design and using linear and nonlinear programming, determines the best values of the parameters consistent with stated criteria and futher studies the effects of variations in the values of the parameters.

Reliability is a special case of optimization where the emphasis is to choose or evaluate a system so as to maximize its probability of successful operation, for example, the reliability of electronics. *See* Circuit (electronics).

Simulation, as of dynamic systems, is mathematical modeling to study the response of a design to various inputs and disturbances. The analog computer has been widely used for simulation through its physical modeling of the mathematic analytical relationships of the proposed design. *See* Analog computer; Simulation.

Decision theory deals with the general question of how to choose between a great number of alternatives according to established criteria. It proposes models of the decision process as well as defining techniques, that is, programs or algorithms, of calculation by which to make choices. *See* Decision theory.

Graphical input/output. In many fields of design—notably architecture; design of airplanes, automobiles, and ships; and almost all mechanical design—the designer works largely in visual terms. A way has been found to set up the computer to interpret drawings. Moreover, the computer has become an active partner in the act of drawing, so that it can provide a certain superskill in preparing the drawing once the human operator has made intentions clear. *See* Computer graphics. [R.W.M.]

Engineering drawing

Engineering drawing A graphical language used by engineers and other technical personnel associated with the engineering profession. The purpose of engineering drawing is to convey graphically the ideas and information necessary for the construction or analysis of machines, structures, or systems. *See* Computer graphics; Drafting; Graphic methods; Schematic drawing.

The basis for much engineering drawing is orthographic representation (projection). Objects are depicted by front, top, side, auxiliary, or oblique views, or combinations of these. The complexity of an object determines the number of views shown. At times, pictorial views are shown. *See* Descriptive geometry; Pictorial drawing.

Engineering drawings often include such features as various types of lines, dimensions, lettered notes, sectional views, and symbols. They may be in the form of carefully planned and checked mechanical drawings, or they may be freehand sketches. Usually a sketch precedes the mechanical drawing.

Many objects have complicated interior details which cannot be clearly shown by means of front, top, side, or pictorial views. Section views enable the engineer or detailer to show the interior detail in such cases. Features of section drawings are cutting-plane symbols, which show where imaginary cutting planes are passed to produce the sections, and section-lining (sometimes called cross-hatching), which appears in the section view on all portions that have been in contact with the cutting plane.

In addition to describing the shape of objects, many drawings must show dimensions, so that workers can build the structure or fabricate parts that will fit together. This is accomplished by placing the required values (measurements) along dimension lines (usually outside the outlines of the object) and by giving additional information in the form of notes which are referenced to the parts in question by angled lines called leaders.

Layout drawings of different types are used in different manufacturing fields for various purposes. One is the plant layout drawing, in which the outline of the building, work areas, aisles, and individual items of equipment are all drawn to scale. Another type of layout, or preliminary assembly, drawing is the design layout, which establishes the position and clearance of parts of an assembly.

A set of working drawings usually includes detail drawings of all parts and an assembly drawing of the complete unit. Assembly drawings vary somewhat in character according to their use, as design assemblies or layouts; working drawing assemblies; general assemblies; installation assemblies; and check assemblies.

Schematic or diagrammatic drawings make use of standard symbols which indicate the direction of flow. In piping and electrical schematic diagrams, symbols are used. The fixtures or components are not labeled in most schematics because the readers usually know what the symbols represent. *See* Schematic drawing; Wiring diagram.

Structural drawings include design and working drawings for structures such as building, bridges, dams, tanks, and highways. Such drawings form the basis of legal contracts. Structural drawings embody the same principles as do other engineering drawings, but use terminology and dimensioning techiques different from thoses shown in previous illustrations. *See* Nomograph. [C.J.B.]

Engineering geology

Engineering geology The application of education and experience in geology and other geosciences to solve geological problems posed by civil engineering works. The branches of the geosciences most applicable are surficial geology, petrofabrics, rock and soil mechanics, geohydrology, and geophysics, particularly exploration geophysics and earthquake seismology.

The terms engineering geology and environmental geology often seem to be used interchangeably. Specifically, environmental geology is the application of engineering geology in the solution of urban problems; in the prediction and mitigation of natural hazards such as earthquakes, landslides, and subsidence; and in solving problems inherent in disposal of dangerous wastes and in reclaiming mined lands.

Another relevant term is geotechnics, the combination of pertinent geoscience elements with civil engineering elements to formulate the civil engineering system that has the optimal interaction with the natural environment. [W.R.J.]

Enopla

Enopla A class of the phylum Rhynchocoela which is divided into the orders Hoplonemertini (free-living) and

Bdellonemertini or Bdellomorpha (symbiotic). In both orders the mouth is anterior to the brain, the nervous system is inside the body wall musculature, and the vascular system is well developed. *See* Anopla; Bdellonemertini; Hoplonemertini; Rhynchocoela. [J.B.J.]

Enoplida An order of nematodes having the cuticle of the cephalic region doubled or formed into a cap or helmet. The helmet results from the infolding of the cuticle over the extreme anterior end of the esophagus. The stoma may possess armature in the form of teeth or movable jaws. Even though the stoma is surrounded by esophageal tissue, the anterior portion of the movable jaws is of cheilostomal origin. The well-developed esophagus is nearly cylindrical, and the esophagointestinal valve is prominent. The five esophageal glands are located in the posterior region of the esophagus; however, the orifices for these glands are located anterior to the nerve ring. The dorsal and two anterior subventral glands open at the base of the stoma or through the stomatal teeth. The amphid apertures may be transverse slits or elongate ovals. The cephalic sensilla are most often in two whorls: an anterior circumoral whorl of 6 and a posterior whorl of 10 ($6 + 4$); in some taxa this whorl is clearly separated into the ancestral state of a circlet of 6 and one of 4. A single medioventral excretory cell is usually present; the orifice is generally at the level of or anterior to the nerve ring. Medioventral supplementary organs may be present on males. The male spicules are paired and accompanied by a gubernaculum. Caudal glands and a cuticular spinneret are found in males and females.

There are two enoplid superfamilies, Enoploidea and Oxystominoidea. The Enoploidea are free-living marine nematodes comprising small to very large species in five well-defined families: Leptosomatidae, Lauratonematidae, Phanodermatidae, Thoracostomopsidae, and Enoplidae. While the feeding habits are largely unknown, it has been postulated that the group is predaceous or omnivorous. The group is almost exclusively marine in habitat, but a few species have been reported from brackish water or soils. Oxystominoidea contain species that maintain the most ancestral of characters known in the phylum. They are separated from other Enoplida by not having the lip region (=cephalic region) set off by a groove. *See* Nemata. [A.R.M.]

Enstatite The name given to the magnesian end member ($MgSiO_3$) of the orthorhombic pyroxene solid-solution series. The mineral is usually yellowish-gray, becoming greenish with a little iron present, and transparent in thin sections.

Enstatite is an important mineral in the upper mantle of the Earth, and coexists with clinopyroxene, garnet, olivine, and plagioclase. Enstatite, clinopyroxene, and garnet rocks called eherzolites are common in certain alpine mountain terrains and as nodules in some diamond-bearing rocks called kimberlites. *See* Pyroxene. [G.W.DeV.]

Enteropneusta A class of Hemichordata with approximately 70 species commonly known as acorn worms. They are free-living, solitary animals with a very soft cylindrical body lacking external appendages. The size is highly variable, from 1 in. to 8 ft (2.5 cm to 2.5 m), and the color ranges from white to shades of violet. The body is covered with cilia and mucus and is always divided into proboscis, collar, and trunk. Sometimes the animal smells like iodoform, and sometimes it shows luminescence.

The acorn worms usually live in shallow waters, buried in the sandy or muddy bottoms, but some species occur at depths of more than 9900 ft (3000 m). The proboscis and collar (the acorn) are used in excavating burrows. During this activity, water, slime, sediment, and organic particles enter the mouth and pass into the gut. Seawater is filtered and expelled through the gill slits, while the organic matter and sediment are retained to be digested.

The trunk is differentiated into four regions: the branchial region, externally recognized by two longitudinal rows of dorsal gill pores; the genital region, characterized by the gonads, which occur dorsolaterally; the hepatic region, distinguishable by a darker color and sometimes by the presence of external sacculations. The final region, the abdominal, is simply tubular with a terminal anus.

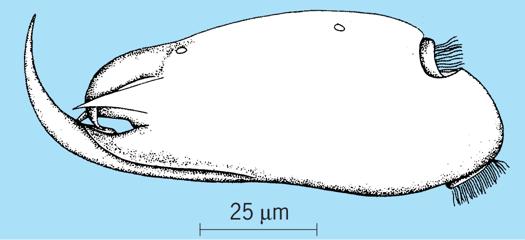
The sexes are distinct. Each gonad opens externally in a pore through which the gametes are shed. Either the eggs are relatively yolky and develop directly, with a free-swimming larval stage that hatches into a miniature acorn worm, or they lack yolk and develop through a planktonic tornaria larval stage. Only one species (*Xenopleura vivipara*) is viviparous, and only one (*Balanoglossus capensis*) reproduces asexually, but all enteropneusts have strong regeneration power. *See* Hemichordata. [J.B.]

Enterovirus One of the two subgroups of human picomaviruses. Enteroviruses include the polioviruses, the coxsackieviruses, and the echoviruses. They are small (17–28 nanometers in diameter), contain ribonucleic acid (RNA), and are resistant to ether. The enteroviruses multiply chiefly in the alimentary tract. The polioviruses, most echoviruses, and a number of the coxsackieviruses can be grown in cell cultures of monkey origin, as well as in human cells.

Enteroviruses are widespread during summer and fall in temperate climates, but may circulate throughout the year in tropical areas. The majority of enterovirus infections are benign and inapparent. However, when these viruses invade tissues other than the enteric tract, serious diseases may result, as when poliovirus invades the spinal cord or when some of the coxsackievirus types invade the heart muscle. *See* Animal virus; Coxsackievirus; Echovirus; Picornaviridae; Poliomyelitis; Rhinovirus. [J.L.Me.]

Enthalpy For any system, that is, the volume of substance under discussion, enthalpy is the sum of the internal energy of the system plus the system's volume multiplied by the pressure exerted by the system on its surroundings. The sum is given the special symbol H primarily as a matter of convenience because this sum appears repeatedly in thermodynamic discussion. Previously, enthalpy was referred to as total heat or heat content, but these terms are misleading and should be avoided. Enthalpy is, from the viewpoint of mathematics, a point function, as contrasted with heat and work, which are path functions. Point functions depend only on the initial and final states of the system undergoing a change; they are independent of the paths or character of the change. For change in enthalpy with pressure or temperature *see* Thermodynamic principles; Entropy; Thermodynamic processes. [H.C.W.; W.A.S.]

Entodiniomorphida An order of the Spirotrichia. These are strikingly different-looking ciliates, covered with a smooth, firm pellicle. They are devoid of external ciliature except for the adoral zone of membranelles and, occasionally, one or two other tufts or zones of other specialized cilia (see illustration). Internal organization of the body is very specialized and complex. These organisms are considered to be highly evolved.



***Ophryoscolex*, an entodinomorphid.**

Entodiniomorphids occur exclusively as endocommensals of herbivorous mammals, either in the rumen and reticulum of ruminants or in the colon of certain higher mammals. *See* Ciliophora; Protozoa; Spirotrichia. [J.O.C.]

Entomology, economic The study of insects that have a direct influence on humanity. Though this includes beneficial as well as harmful species, most attention is devoted to the latter and how they become pests and are controlled. The emphasis on managing harmful insects reflects the immediacy and seriousness of pest problems, particularly the destruction of food and the transmission of disease. These are highly visible problems, whereas the benefits gained from useful insects are not so clearly understood, nor so well documented economically.

Central to the definition of a pest is determination of the economic threshold. Any insect population, when introduced into a favorable environment, increases numbers until reaching an environmental carrying capacity. In pest insects, there exists a density above which the insect population interferes with human health, comfort, convenience, or profits. When this economic threshold is reached, a decision must be made to utilize some control measure to prevent further increase in numbers. Often, the presence of even a single insect is sufficient to warrant control measures, for instance, when that insect is a flea harboring the plague bacillus, or a mosquito capable of transmitting malaria. Also, consumer expectations in most markets are for insect-free produce, so that the economic threshold can be very low on items that people eat. However, economic thresholds may be higher for insects that damage only the inedible portions of crop plants such as the leaves of beans, tomatoes, and apple trees. In any case, knowledge of the amount of injury which is due to different densities of insects is an important prerequisite for efficient management.

Pest management. Management of insect pests begins with prevention. Many of the United States' most noxious insects have been imported from overseas: most domestic cockroaches, the gypsy moth, Japanese beetle, corn borer, housefly, cabbageworm, and codling moth are just a few. Some North American insects have spread elsewhere too—the Colorado potato beetle to Europe and the fall webworm to Japan. To stem the flow of insect invasions, the federal government's Animal and Plant Health Inspection Service maintains inspection facilities for the examination of all incoming shipments of plant or other material that may harbor pests.

Once a pest is established, its spread can sometimes be slowed by an efficient system of local quarantines, early detection, and local eradication. A widely used eradication method is the application of synthetic chemical insecticides. Insecticides were once regarded as a panacea for pest problems, but the development of resistant strains of major insect pests, together with the rising cost of materials and application, has led to recognition that insecticides are more efficiently utilized in a program integrating them with other techniques in a framework of total crop management. *See* Insecticide.

Another method is biological control, in which insects have had their numbers checked by natural enemies. Economic entomologists have effectively reduced densities of several pests by releasing parasites or predators. Natural enemies that are mobile and relatively restricted in diet do the best job of biological control. *See* Insect control, biological.

Crop rotation is a standard agronomic practice that often reduces damage due to insects. Rotation of alfalfa or soybeans with corn reduces populations of corn rootworms, wireworms, and white grubs. The physical disruption of autumnal plowing and disking destroys many insects that could overwinter in stubble or on the soil surface.

The cleanup of breeding and gathering sites is useful, especially in management of medically important insects, many of which have evolved resistance to the commoner insecticides. In general, the most successful programs of insect pest management rely on integrated control or the use of several methods in concert to control a complex of pests.

Beneficial insects. It has been estimated that the dollar value gained from a single insect, the honeybee, equals the loss from damage plus cost of control for all pests combined. Honeybees are managed for their honey and beeswax, but their most valued service is pollination of crop plants. Bees of many species are the chief pollinators, though wasps, flies, moths, butterflies, and beetles pollinate as well. *See* Pollination.

Silk is produced by larvae of the silkworm, an insect so thoroughly domesticated that it cannot climb its food plant, mulberry, with its degenerated legs. The silkworm apparently no longer survives in the wild. Many uses of silk have been taken over by less expensive synthetic materials.

Other insects may be equally beneficial, but their value is not so easily calculated. Foremost among these are predatory insects of several orders. These predators may prevent other insects from ever reaching an economic threshold and thus becoming pests. Innumerable insect species are scavengers, quietly but efficiently breaking down the remains of dead plants and animals. A lack of scavenging insects would, however, result in a great increase of decomposing organic material lying about. Plant-eating insects have been set to beneficial use when their diets consist mainly of unwanted weeds.

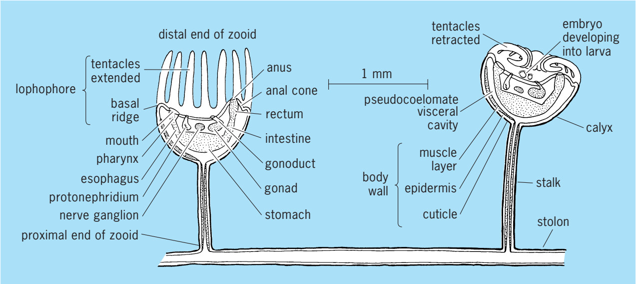
Certain rare and showy butterflies and beetles are sought after so that they have considerable economic worth. Conservation of rare and endangered insects incurs some expense as well. Habitat management to conserve rare insects is a valid and growing concern of economic entomologists.

Finally, insects have rendered invaluable service to science, and thus to humanity, as easily reared experimental animals for investigation of basic principles of genetics, biochemistry, development, and behavior. *See* Insecta. [D.J.Hor.]

Entoprocta A phylum of sessile, aquatic, often colonial invertebrates having a looped gut with both mouth and anus situated inside a circlet of tentacles, a pseudocoelomate body cavity, and no hardened skeleton. The phylum is divided into two orders, Loxosomatida (or Solitaria), with about 100 species, and Pedicellinida (or Coloniales), with about 30. No fossils are known.

Entoprocts are mainly marine, and may be encountered as small colonies on seaweeds and bryozoans near low tidemark. The colonies consist of threadlike, creeping stolons and erect zooids arising at intervals from them (see illustration). Noncolonial forms have similar zooids but lack the stolons. Each zooid is goblet-shaped, consisting of a basal stalk supporting a rounded or pyriform viscera-containing dilatation, the calyx.

The entoprocts feed on particles filtered from the surrounding water. Long lateral cilia drive water inward between the tentacles, while shorter cilia on the inner face convey particles trapped in mucus down the tentacles. These frontal tracts join an annular ciliated groove, which dips into the mouth.



Morphological features of an entoproct zooid, in vertical cross section.

Entoprocts reproduce asexually and sexually. Dispersal is by means of sexually produced larvae. Zooids may be unisexual or hermaphroditic. Gonads are paired, with the ducts uniting before opening into the coelom. Fertilization is internal. [J.S.R.]

Entropy

Entropy A function first introduced in classical thermodynamics to provide a quantitative basis for the common observation that naturally occurring processes have a particular direction. Subsequently, in statistical thermodynamics, entropy was shown to be a measure of the number of microstates a system could assume. Finally, in communication theory, entropy is a measure of information. Each of these aspects will be considered in turn. Before the entropy function is introduced, it is necessary to discuss reversible processes.

Reversible processes. Any system under constant external conditions is observed to change in such a way as to approach a particularly simple final state called an equilibrium state. For example, two bodies initially at different temperatures are connected by a metal wire. Heat flows from the hot to the cold body until the temperatures of both bodies are the same. It is common experience that the reverse processes never occur if the systems are left to themselves; that is, heat is never observed to flow from the cold to the hot body. Max Planck classified all elementary processes into three categories: natural, unnatural, and reversible. Natural processes do occur, and proceed in a direction toward equilibrium. Unnatural processes move away from equilibrium and never occur. A reversible process is an idealized natural process that passes through a continuous sequence of equilibrium states.

Entropy function. The state function entropy S puts the foregoing discussion on a quantitative basis. Entropy is related to q, the heat flowing into the system from its surroundings, and to T, the absolute temperature of the system. The important properties for this discussion are:

1. $dS > q/T$ for a natural change.
   $dS = q/T$ for a reversible change.
2. The entropy of the system S is made up of the sum of all the parts of the system so that $S = S_1 + S_2 + S_3 \cdots$. *See* HEAT; TEMPERATURE; THERMODYNAMIC PRINCIPLES.

Nonconservation. In his study of the first law of thermodynamics, J. P. Joule caused work to be expended by rubbing metal blocks together in a large mass of water. By this and similar experiments, he established numerical relationships between heat and work. When the experiment was completed, the apparatus remained unchanged except for a slight increase in the water temperature. Work (W) had been converted into heat (Q) with 100% efficiency. Provided the process was carried out slowly, the temperature difference between the blocks and the water would be small, and heat transfer could be considered a reversible process. The entropy increase of the water at its temperature T is $\Delta S = Q/T = W/T$. Since everything but the water is unchanged, this equation also represents the total entropy increase. The entropy has been created from the work input, and this process could be continued indefinitely, creating more and more entropy. Unlike energy, entropy is not conserved. *See* CONSERVATION OF ENERGY; THERMODYNAMIC CYCLE; THERMODYNAMIC PROCESSES.

Degradation of energy. Energy is never destroyed. But in the Joule friction experiment and in heat transfer between bodies, as in any natural process, something is lost. In the Joule experiment, the energy expended in work now resides in the water bath. But if this energy is reused, less useful work is obtained than was originally put in. The original energy input has been degraded to a less useful form. The energy transferred from a high-temperature body to a lower-temperature body is also in a less useful form. If another system is used to restore this degraded energy to its original form, it is found that the restoring system has degraded the energy even more than the original system had. Thus, every process occurring in the world results in an overall increase in entropy and a corresponding degradation in energy. [W.F.J.]

Measure of information. The probability characteristic of entropy leads to its use in communication theory as a measure of information. The absence of information about a situation is equivalent to an uncertainty associated with the nature of the situation. This uncertainty is the entropy of the information about the particular situation. *See* INFORMATION THEORY. [F.H.R.]

Environment

Environment The sum of all external factors, both biotic (living) and abiotic (nonliving), to which an organism is exposed. Biotic factors include influences by members of the same and other species on the development and survival of the individual. Primary abiotic factors are light, temperature, water, atmospheric gases, and ionizing radiation, influencing the form and function of the individual.

For each environmental factor, an organism has a tolerance range, in which it is able to survive. The intercept of these ranges constitutes the ecological niche of the organism. Different individuals or species have different tolerance ranges for particular environmental factors—this variation represents the adaptation of the organism to its environment. The ability of an organism to modify its tolerance of certain environmental factors in response to a change in them represents the plasticity of that organism. Alterations in environmental tolerance are termed acclimation. Exposure to environmental conditions at the limit of an individual's tolerance range represents environmental stress. *See* ADAPTATION (BIOLOGY); ECOLOGY; PHYSIOLOGICAL ECOLOGY (ANIMAL); PHYSIOLOGICAL ECOLOGY (PLANT).

Abiotic factors. The spectrum of electromagnetic radiation reaching the Earth's surface is determined by the absorptive properties of the atmosphere. Biologically, the most important spectral range is 300–800 nanometers, incorporating ultraviolet, visible, and infrared radiation. Visible light provides the energy source for most forms of life. Light absorbed by pigment molecules (chlorophylls, carotenoids, and phycobilins) is converted into chemical energy through photosynthesis. Light availability is especially important in determining the distribution of plants. Photosynthetic organisms can exist within a wide range of light intensities. Full sunlight in the tropics is around 2000 μmol photons $\cdot$ m^{-2} $\cdot$ s^{-1}. Photosynthetic organisms have survived in locations where the mean light is as low as 0.005% of this value. *See* INSOLATION; PHOTOSYNTHESIS; SOLAR RADIATION.

In addition to providing energy, light is important in providing an organism with information about its surroundings. The human eye, for example, is able to respond to wavelengths of light between 400 and 700 nm—the visible range. Within this range, sensitivity is greatest in the green part of the spectrum. This is the portion of the spectrum that plants absorb least, and so is the principal part of the spectrum to be reflected.

Temporal variation in light also provides an important stimulus. Life forms from bacteria upward are able to detect and respond to daily light fluctuations. Such a response may be directly controlled by the presence or absence of light (diurnal rhythms) or may persist when the variation in light is removed (circadian rhythms). In the latter case, regulation is through an internal molecular clock, which is able to predict the daily cycle. Such circadian clocks are normally reset by light on a daily basis. Processes controlled by circadian clocks range from the molecular (gene expression) to the behavioral (for example, sleep patterns in animals or leaf movements in plants). *See* PHOTOPERIODISM.

Ultraviolet radiation has the ability to break chemical bonds and so may lead to damage to proteins, lipids, and nucleic acids. Damage to DNA may result in genetic mutations. The ozone layer in the stratosphere is responsible for absorbing a large proportion of ultraviolet radiation reaching the outer atmosphere. As ozone is destroyed by the action of pollutants such as chloroflurocarbons, the proportion of ultraviolet radiation reaching the surface of the Earth rises.

Water is ubiquitous in living systems, as the universal solvent for life, and is essential for biological activity. Many organisms have evolved the ability to survive prolonged periods in the total absence of water, but this is achieved only through the maintenance of an inactive state. Water availability remains a primary environmental factor limiting survival on land. Primitive land organisms possess little or no ability to conserve water within their cells and are termed poikilohydric. Examples include amphibians and primitive plants such as most mosses and liverworts. These are confined to places where water is in plentiful supply or they must be able to tolerate periods of desiccation. Lichens can survive total water loss and rapidly regain activity upon rewetting. Such organisms must be able to minimize the damage caused to cellular structures when water is lost. Dehydration causes irreversible damage to membranes and proteins. This damage can be prevented by the accumulation of protective molecules termed compatible solutes.

Homeohydric organisms possess a waterproof layer that restricts the loss of water from the cells. Such waterproofing is never absolute, as there is still a requirement to exchange gas molecules and to absorb organic or mineral nutrients through a water phase. Water conservation allows organisms to live in environments in which the water supply is extremely low. In extremely arid environments, behavioral adaptations may allow the water loss to be minimized. Animals may be nocturnal, emerging when temperatures are lower and hence evaporation minimized. Cacti possess a form of photosynthesis, crassulacean acid metabolism (CAM), that allows them to separate gas exchange and light capture. *See* GROUND-WATER HYDROLOGY; OSMOREGULATORY MECHANISMS; PLANT-WATER RELATIONS.

Temperature is a determinant of survival in two ways: (1) as temperatures decrease, the movement of molecules slows and the rate of chemical reactions declines; (2) temperature determines the physical state of water.

The slowing of metabolic activity at low temperatures is illustrated in reptiles. Such poikilothermic animals, unable to maintain their internal temperature, are typically inactive in the cold of morning. They bask in the sun to increase their body temperature and so become active. High temperatures will cause the three-dimensional structure of proteins to break down, preventing the organisms from functioning. Organisms adapted to extremely high temperatures need more rigid proteins that maintain their structure. Temperature also affects the behavior of cell membranes, made up of lipids and proteins in a liquid crystalline state. At low temperatures, the membrane structure becomes rigid and liable to break. At high temperatures, it becomes too fluid and again liable to disintegrate. In adapting to different temperatures, organisms alter the composition of the lipids in their membranes, whose melting temperature is thereby changed. This outcome also applies to storage lipids. Hence, cold-water fish are a useful source of oils, whereas mammals, with their higher body temperature, contain fats. The effect of temperature on membranes is thought to be a key factor determining the temperature range that an organism is able to survive.

The effect of temperature on the physical state of water is essential to determining the availability of that water to organisms. Poikilothermic organisms may find that the water in their cells begins to freeze at low temperatures. Certain species can survive total freezing through the prevention of ice crystal formation altogether which would otherwise damage cellular structures. To survive low temperatures, cells must be able to survive desiccation, and so low-temperature tolerance involves the formation of compatible solutes. High temperatures increase the rate of evaporation of water. Hence, where water supply is limiting, an organism's ability to survive high temperatures is impaired.

Mammals and birds, homeothermic organisms, are able to regulate their internal temperature, limiting the effects of external temperature variations. Temperature still acts as an environmental constraint in such organisms, however. Cooling is achieved through sweating and hence loss of water. Heat is produced through the metabolism of food, and hence survival in cold climates requires a high metabolic rate. *See* CRYPTOBIOSIS; HIBERNATION AND ESTIVATION; THERMOREGULATION.

The atmosphere on Earth is thought to be determined to a large extent by the presence of life. At the same time, organisms have evolved to survive in the atmosphere as it is. The atmospheric constitutents with the most direct biological importance are oxygen (O_2) and carbon dioxide (CO_2). Oxygen makes up approximately 20% of the atmosphere and is due to the occurrence of oxygenic photosynthesis. This process involves the simultaneous uptake of CO_2 to make sugars. Aerobic respiration involves the reverse of this process, the release of CO_2 and the uptake of O_2 to form water. Hence, the current atmosphere represents the balance of previous biological activity. For most terrestrial organisms, neither CO_2 nor O_2 is limiting in the atmosphere; however, the need to get either or both of these gases to cells may represent a limitation on size or on the ability to tolerate water stress. Limitation of either gas may be important in aquatic environments, where the concentration of each is significantly lower.

Nitrogen is also required by all organisms but cannot be used by most in the gaseous form. Nitrogen fixation, the conversion of N_2 gas into a biologically useful form, occurs in some species of bacteria and cyanobacteria or may be caused by lightning.

Atmospheric gases are important in determining the climate and the light environment. Absorption of electromagnetic radiation by the atmosphere determines the spectrum of light reaching the Earth's surface. Absorption and reflectance of infrared radiation by greenhouse gases such as CO_2 and water vapor regulate temperature. *See* PHOTORESPIRATION; RESPIRATION.

Among other environmental factors determining the range and distribution and form of organisms are mechanical stimuli such as wind or water movement, and the presence of metals, inorganic nutrients, and toxins in the air, soil, or food.

Biotic factors. The biotic environment of an individual is made up of members of the same or other species. Intraspecific interactions involve the need to breed with other individuals, to gain protection through living in a group, and to compete for resources such as food, light, nutrients, and space. The optimal population density depends on the availability of resources and on the behavior, size, and structure of the organism. Interspecific interactions may also be positive or negative. For example, symbiotic relationships involve the mutual benefit of the individuals involved, whereas competition for resources is deleterious to both. Although predation exerts a negative influence on the population as a whole, the success of an individual may be enhanced if a predator removes one of its conspecific competitors.

Humans alter their environment in ways that exceed the impact of all other organisms. For example, the release of greenhouse gases into the atmosphere contributes to climate alterations over the entire planet. This in turn has impacts on the distribution of all other species. The release of pollutants into the environment brings organisms into contact with stresses to which they were not previously exposed. This causes the evolution of new varieties, eventually perhaps new species, adapted to the polluted environments. *See* AIR POLLUTION; BIOSPHERE; HUMAN ECOLOGY; WATER POLLUTION.

For any given organism, it is often possible to identify a factor in the environment that limits survival and growth. The limiting factor may change through time. Such a change may cause the organism to be at the limit of or outside its tolerance range for that or another environmental factor. In such cases, the organism is said to suffer stress. If the stress to which an individual is exposed is extreme, it may result in irreversible damage and death. Exposure to moderate stress, however, results in a period of acclimation within the organism that allows it to adjust to the new conditions. Organisms exposed gradually to new conditions usually have a higher chance of survival than those exposed suddenly. *See* POPULATION ECOLOGY.

Where a particular environmental factor (or combination of factors) dominates the growth and development of organisms, it is often found that the adaptations and gross features of the landscape will be the same, even when the actual species are different. Thus, mediterranean vegetation is found not only around the Mediterranean Sea but also in California and South Africa, where the conditions of hot dry summers and warm wet winters occur. Regions with similar environmental conditions are classed as biomes. The occurrence of such global vegetation types clearly illustrates the role played by the environment in determining the form and function of individual species. [G.J.]

Environmental engineering The division of engineering concerned with the environment and management of natural resources. The environmental engineer places special attention on the biological, chemical, and physical reactions in the air, land, and water environments and on improved technology for integrated management systems, including reuse, recycling, and recovery measures.

Environmental engineering began with consideration of the need for acceptable drinking water and for management of liquid and solid wastes. Abatement of air and land contamination became new challenges for the environmental engineer, followed by toxic-waste and hazardous-waste concerns. The environmental engineer is also instrumental in the mitigation and protection of wildlife habitat, preservation of species, and the overall well-being of ecosystems.

The principal environmental engineering specialties are air-quality control, water supply, wastewater disposal, stormwater management, solid-waste management, and hazardous-waste management. Other specialties include industrial hygiene, noise control, oceanography, and radiology. *See* AIR POLLUTION; AIR POLLUTION, INDOOR; HAZARDOUS WASTE; WATER POLLUTION; WATER SUPPLY ENGINEERING. [R.A.Cor.]

Environmental fluid mechanics The study of the flows of air and water, of the species carried by them, and of their interactions with geological, biological, social, and engineering systems in the vicinity of a planet's surface. The environment on the Earth is intimately tied to the fluid motion of air (atmosphere), water (oceans), and species concentrations (air quality). In fact, the very existence of the human race depends upon its abilities to cope within the Earth's environmental fluid systems.

Meteorologists, oceanologists, geologists, and engineers study environmental fluid motion. Weather and ocean-current forecasts are of major concern, and fluid motion within the environment is the main carrier of pollutants. Biologists and engineers examine the effects of pollutants on humans and the environment, and the means for environmental restoration. Air quality in cities is directly related to the airborne spread of dust particles and of exhaust gases from automobiles. The impact of pollutants on drinking-water quality is especially important in the study of ground-water flow. Likewise, flows in porous media are important in oil recovery and cleanup. Lake levels are significantly influenced by climatic change, a relationship that has become of some concern in view of the global climatic changes that may result from the greenhouse effect (whereby the Earth's average temperature increases because of increasing concentrations of carbon dioxide in the atmosphere). *See* AIR POLLUTION; GREENHOUSE EFFECT; WEATHER FORECASTING AND PREDICTION.

Scales of motion. Environmental fluid mechanics deals with the study of the atmosphere, the oceans, lakes, streams, surface and subsurface water flows (hydrology), building exterior and interior airflows, and pollution transport within all these categories. Such motions occur over a wide range of scales, from eddies on the order of centimeters to large recirculation zones the size of continents. This range accounts in large part for the difficulties associated with understanding fluid motion within the environment. In order to impart motion (or inertia) to the atmosphere and oceans, internal and external forces must develop. Global external forces consist of gravity, Coriolis, and centrifugal forces, and electric and magnetic fields (to a lesser extent). The internal forces of pressure and friction are created at the local level, that is, on a much smaller spatial scale; likewise, these influences have different time scales. The winds and currents arise as a result of the sum of all these external and internal forces.

Governing equations. The foundations of environmental fluid mechanics lie in the same conservation principles as those for fluid mechanics, that is, the conservation of mass, momentum (velocity), energy (heat), and species concentration (for example, water, humidity, other gases, and aerosols). The differences lie principally in the formulations of the source and sink terms within the governing equations, and the scales of motion. These conservation principles form a coupled set of relations, or governing equations, which must be satisfied simultaneously. The governing equations consist of nonlinear, independent partial differential equations that describe the advection and diffusion of velocity, temperature, and species concentration, plus one scalar equation for the conservation of mass. In general, environmental fluids are approximately newtonian, and the momentum equation takes the form of the Navier-Stokes equation. An important added term, neglected in small-scale flow analysis, is the Coriolis acceleration, $2\Omega \times V$, where Ω is the angular velocity of the Earth and V is the flow velocity. *See* CONSERVATION LAWS (PHYSICS); CONSERVATION OF ENERGY; CONSERVATION OF MASS; CONSERVATION OF MOMENTUM; CORIOLIS ACCELERATION; DIFFERENTIAL EQUATION; DIFFUSION; FLUID-FLOW PRINCIPLES; NAVIER-STOKES EQUATION; NEWTONIAN FLUID.

Fortunately, not every term in the Navier-Stokes equation is important in all layers of the environment. The key to being able to obtain solutions to the Navier-Stokes equation lies in determining which terms can be neglected in specific applications. For convenience, problems can be classified on the basis of the order of importance of the terms in the equations utilizing nondimensional numbers based on various ratios of values. *See* DIMENSIONLESS GROUPS.

Measurements. Because of the scales of motion and time associated with the environment, and the somewhat random nature of the fluid motion, it is difficult to conduct full-scale, extensive experimentation. Likewise, some quantities (such as vorticity or vertical velocity) resist direct observations. It is necessary to rely on the availability of past measurements and reports (as sparse as they may be) to establish patterns, especially for climate studies. However, some properties can be measured with confidence.

Modeling. There are two types of modeling strategies: physical and mathematical. Physical models are small-scale (laboratory) mockups that can be measured under variable conditions with precise instrumentation. Such modeling techniques are effective in examining wind effects on buildings and species concentrations within city canyons (flow over buildings). Generally, a large wind tunnel is needed to produce correct atmospheric parameters (such as Reynolds number) and velocity profiles. Mathematical models (algebra- and calculus-based) can be broken down further into either analytical models, in which an exact solution exists, or numerical models, whereby approximate numerical solutions are obtained using computers. *See* WIND TUNNEL. [D.W.P.]

Environmental geology The branch of geology that deals with the ways in which geology affects people. Examples of the effect of geology on human civilizations include (1) the ways that fertile soils develop from rocks and how these soils can become polluted by human activities; (2) how rocks and soils move down-slope to destroy roads, houses, and other human constructions; (3) sources of surface and subsurface water supplies and how they become polluted; (4) why floods occur where they do and how human activities affect floods; (5) locations of earthquakes and volcanic eruptions and the dangers they pose; (6) location of mineral resources such as copper, oil and gas, and uranium, and how mining these resources can pollute the environment; (7) how human activities can pollute the atmosphere and cause global warming, sea-level rise, and ozone depletion. *See* AIR POLLUTION; EARTHQUAKE; SOIL CONSERVATION; VOLCANO; WATER POLLUTION. [H.Bl.]

Environmental management The development of strategies to allocate and conserve resources, with the ultimate goal of regulating the impact of human activities on the surrounding environment. "Environment" here usually means the natural surroundings, both living and inanimate, of human lives and activities. However, it can also mean the artificial landscape of cities, or occasionally even the conceptual field of the noosphere, the realm of communicating human minds.

Environmental management is a mixture of science, policy, and socioeconomic applications. It focuses on the solution of the practical problems that humans encounter in cohabitation with nature, exploitation of resources, and production of waste. In a purely anthropocentric sense, the central problem is how to permit technology to evolve continuously while limiting the degree to which this process alters natural ecosystems. Environmental management is thus intimately intertwined with questions regarding economic growth, equitable distribution of consumable goods, and conserving resources for future generations. Environmental managers fall within a broad spectrum, from those who would limit human interference in nature to those who would increase it in order to guide natural processes along benign paths. Participants in the process of environmental management fall into seven main groups: (1) governmental organizations at the local, regional, national, and international levels, including world bodies such as the United Nations Environment Programme and the U.N. Conference on Environment and Development; (2) research institutions, such as universities, academies, and national laboratories; (3) bodies charged with the enforcement of regulations, such as the U.S. Environmental Protection Agency; (4) businesses of all sizes and multinational corporations; (5) international financial institutions, such as the World Bank and International Monetary Fund; (6) environmental nongovernmental organizations, such as the World Wildlife Fund for Nature; and (7) representatives of the users of the environment, including tribes, fishermen, and hunters. The agents of environmental management include foresters, soil conservationists, policymakers, engineers, and resource planners.

Some common themes of environmental management are bilateral and multilateral environmental treaties; design and use of decision-support systems; environmental policy formulation, enactment, and policing of compliance; estimation, analysis, and management of environmental risk; management of recreation and tourism; natural resource evaluation and conservation; positive environmental economics; promotion of positive environmental values by education, debate, and information dissemination; and strategies for the rehabilitation of damaged environments.

The need to improve management of the environment has given rise to several new techniques. There is environmental impact analysis, which was first formulated in California and is codified in the U.S. National Environmental Policy Act (NEPA). Through the environmental impact statement, it prescribes the investigatory and remedial measures that must be taken in order to mitigate the adverse effects of new development. It is intended to act in favor of both prudent conservation and participatory democracy. Another technique is environmental auditing, which uses the model of the financial audit to examine the processes and outcomes of environmental impacts. It requires value judgments, which are usually set by public preference, ideology, and policy, to define what are regarded as acceptable outcomes. Audits use techniques such as life-cycle analysis and environmental burden analysis to assess the impact of, for example, manufacturing processes that consume resources and create waste. [D.Ale.]

Environmental radioactivity Radioactivity that originates from natural and anthropogenic sources, including radioactive materials in food, housing, and air, radioactive materials used in medicine, nuclear weapon tests in the open atmosphere, and radioactive materials used in industry and power generation.

Natural radioactivity, which is by far the largest component to which humans are exposed, is of both terrestrial and extraterrestrial (cosmic) origin. About 340 nuclides are known in nature, of which 70 are radioactive and are found mainly among the heavy elements. Three nuclides which are responsible for most of the terrestrial component are potassium-40, uranium-238, and thorium-232.

The average person in the United States receives 80–180 mrem/year (0.8–1.8 millisieverts/year) from natural sources of ionizing radiation, depending on the organ considered. Most of this dose originates from radioactive materials in the Earth's crust. The external dose due to cosmic rays is an average of about 28 mrem/year (0.28 mSv/year), a value that increases with altitude due to reduced shielding of cosmic radiation by the atmosphere. The human body is also exposed to radionuclides in food and water. Potassium-40 is the most important of these, with radium-226 and radium-228 of perhaps less importance from the point of view of the dose delivered.

There are wide deviations from the average doses. Thus, at one extreme, miners working underground in the presence of radioactive ore can be exposed to such high levels of atmospheric radon that they develop lung cancer. There are also geographical areas where the levels of natural radioactivity are unusually high. Six types of anomalies that can be important from the point of view of population exposure are: monazite sands and other placers, alkaline intrusives and granites of the Conway type in New Hampshire, bauxites and intensely weathered soils, uraniferous phosphate rock (and soils), ground waters enriched in radium and radon, and black shales and related organic accumulations. The natural radioactive environment can also be altered by human activities, such as building construction, combustion of fossil fuels, aircraft travel, medical procedures, nuclear weapons testing, and nuclear power plants.

Although various national and international regulatory organizations have proposed guidelines that limit the per capita dose received by individuals in the general population to 170 mrem/year (1.7 mSv/year), it has become evident that nuclear power plants can be routinely operated so that the general population will not be exposed to more than 1% of this limit. *See* NUCLEAR POWER; NUCLEAR REACTOR; RADIOACTIVE WASTE MANAGEMENT; RADIOACTIVITY. [M.E.]

Environmental test The evaluation of a physical system (engineering product) in conditions which simulate one or more of the environments that may harm the system or adversely affect its performance. In addition to the evaluation of a finished product, environmental testing can play an important role throughout a product's design/development cycle to ensure that the materials and manufacturing processes employed can meet the stresses imposed by the environment in which the product is likely to operate. By not waiting until a finished product is evaluated, manufacturers can use environmental testing to eliminate costly redesigns late in the design/development cycle.

Because it is necessary to precisely control the environmental factors which define the test (for example, temperature, vibration level, or altitude), environmental testing is typically conducted in specially designed facilities, or environmental chambers. Some environmental chambers can generate extremely high and low temperatures and humidity levels. Others can simulate corrosive environments such as salt sprays. Products and equipment intended for military use are often subjected to the harshest and most variable of environmental conditions. The military has pioneered the creation of well-documented standards and specifications for the evaluation and testing of any products or equipment which it will purchase.

Civilian organizations, such as the Society of Automotive Engineers, publish standards for automotive and aerospace equipment. In addition, nearly 100 countries have adopted the International Organization for Standardization (ISO) 9000 series of standards for quality management and quality assurance. These standards are implemented by thousands of manufacturing and service organizations, both public and private. Of the ISO 9000 family standards, ISO 9003 covers quality assurance obligations of the manufacturer in the areas of final inspection and testing. Among the guidelines provided by ISO 9003 are those dedicated to (1) developing procedures to inspect, test, and verify that final products meet all specified requirements before they are sold; (2) developing procedures to control and calibrate the testing equipment; (3) ensuring that every product is identified as having passed or failed the required tests. ISO 9003 will have a significant impact upon the standardization of environmental testing in both civilian and military endeavors.

An incomplete but representative list of environmental tests requiring dedicated test chambers includes tests for altitude, dust, explosiveness, flammability, fungus, humidity, icing, acoustic vibration, overpressure, rain, salt fog, sand, temperature, and wind. Tests typically not requiring chambers but still utilizing dedicated mechanical testing equipment include acceleration, fatigue cycling, transportation simulation, shock, and vibration. [R.A.He.]

Environmental toxicology A broad field of study encompassing the production, fate, and effects of natural and synthetic pollutants in the environment. The breadth of this field depends on the definition of environment. It can be defined as narrowly as the home and workplace or as broadly as the entire Earth and its biosphere. Environmental toxicology is truly an interdisciplinary science. The effects of a pollutant on the environment depend on the amount released (the dose) and its chemical and physical properties. Pollutants can be grouped according to their origin and effects.

Pollution from nutrients is generally a problem of aquatic systems. Carbon, nitrogen, and phosphorus are essential nutrients and, when present in excess, can result in an overstimulation of microbial and plant growth. Nutrients enter the environment in runoff from fertilized agricultural areas, and in effluents from municipal and industrial waste and decaying plant material. *See* EUTROPHICATION.

Pathogenic bacteria and protozoa can be a major source of pollution in areas that receive untreated sewage, items from ocean dumping, and improperly discarded hospital waste. Toxic metabolites of fungal origin (mycotoxins) are also potential pollutants. *See* AFLATOXIN.

Forest fires, volcanic eruptions, and dust storms can be major sources of suspended materials. These materials can also originate in runoff from agricultural areas, construction and mining sites, and roads and other paved areas. Truck and automobile exhaust and industrial discharge to the atmosphere are also sources of suspended solids.

Metabolic processes and natural combustion and thermal activity (such as forest fires and volcanoes) can release large amounts of gaseous by-products to the atmosphere. However, natural inputs are minor compared to atmospheric pollutants due to human activity. Although most anthropogenic air pollution is produced by the various forms of transportation, emission from stationary sources of fuel combustion (for example, factories and power plants) are responsible for the greatest amount of hazardous materials released. *See* AIR POLLUTION; GREENHOUSE EFFECT.

All living organisms require certain metals for physiological processes. These elements, when present at concentrations above the level of homeostatic regulation, can be toxic. In addition, there are metals that are chemically similar to, but higher in molecular weight than, the essential metals (heavy metals).

Organic solvents are used widely and in large amounts in industries, laboratories, and homes. They are released to the atmosphere as vapor and can pose a significant inhalation hazard. Improper storage, use, and disposal have resulted in the contamination of surface and ground waters and drinking water. *See* WATER POLLUTION.

The pesticides represent an important group of materials that can enter the environment as pollutants. They are highly toxic, and many nontarget organisms can suffer harmful effects if misuse or unintended release occurs. *See* PESTICIDE.

Coal and petroleum-derived materials and by-products are major environmental pollutants. Widespread use has led to enormous releases to the environment of distillate fuels, crude oils, runoff from coal piles, exhaust from internal combustion-fired power plants, industrial emissions, and emissions from municipal incinerators. The toxicity of polycyclic aromatic hydrocarbons is perhaps one of the most serious long-term problems associated with the use of petroleum. They accumulate in soil, sediment, and biota, and at high concentrations can be acutely toxic. *See* FOSSIL FUEL.

Polychlorinated biphenyls (PCBs) are produced by the chlorination of biphenyl, giving rise to mixtures of up to 210 possible products. They have been used worldwide in electrical equipment, vacuum pumps, hydraulic fluids, heat-transfer systems, lubricants, and inks. The related polybrominated biphenyls (PBBs) have been used as fire retardants. Major sources of polychlorinated biphenyls have included leaks from waste disposal facilities, vaporization during combustion, and disposal of industrial fluids. Their use has been largely restricted or eliminated. Environmental concentrations are decreasing, but with their persistence they remain significant pollutants. Chlorinated dibenzo-*p*-dioxins and dibenzofurans are formed during the heating of chlorophenols, and have been identified as potential contaminants in the herbicide 2,4,5-T. They can be formed during the incineration of municipal wastes, polychlorinated biphenyls, or plant materials treated with chlorophenols. *See* ENVIRONMENTAL ENGINEERING; POLYCHLORINATED BIPHENYLS; TOXICOLOGY. [J.T.O.]

Enzyme A catalytic protein produced by living cells. The chemical reactions involved in the digestion of foods, the biosynthesis of macromolecules, the controlled release and utilization of chemical energy, and other processes characteristic of life are all catalyzed by enzymes. In the absence of enzymes, these reactions would not take place at a significant rate. Several hundred different reactions can proceed simultaneously within a living cell, and the cell contains a comparable number of individual enzymes, each of which controls the rate of one or more of these reactions. The potentiality of a cell for growing, dividing, and performing specialized functions, such as contraction or transmission of nerve impulses, is determined by the complement of enzymes it possesses. Some representative enzymes, their sources, and reaction specificities are shown in the table.

Characteristics. Enzymes can be isolated and are active outside the living cell. They are such efficient catalysts that they accelerate chemical reactions measurably, even at concentrations so low that they cannot be detected by most chemical tests for protein. Like other chemical reactions, enzyme-catalyzed reactions proceed only when accompanied by a decrease in free energy; at equilibrium the concentrations of reactants and products are the same in the presence of an enzyme as in its absence. An enzyme can catalyze an indefinite amount of chemical change without itself being diminished or altered by the reaction. However, because most isolated enzymes are relatively unstable, they often gradually lose activity under the conditions employed for their study.

Chemical nature. All enzymes are proteins. Their molecular weights range from about 10,000 to more than 1,000,000. Like other proteins, enzymes consist of chains of amino acids linked together by peptide bonds. An enzyme molecule may contain one or more of these polypeptide chains. The sequence

Some representative enzymes, their sources, and reaction specificities

Enzyme	Some sources	Reaction catalyzed
Pepsin	Gastric juice	Hydrolysis of proteins to peptides and amino acids
Urease	Jackbean, bacteria	Hydrolysis of urea to ammonia and carbon dioxide
Amylase	Saliva, pancreatic juice	Hydrolysis of starch to maltose
Phosphorylase	Muscle, liver, plants	Reversible phosphorolysis of starch or glycogen to glucose-1-phosphate
Transaminases	Many animal and plant tissues	Transfer of an amino group from an amino acid to a keto acid
Phosphohexose isomerase	Muscle, yeast	Interconversion of glucose-6-phosphate and fructose-6-phosphate
Pyruvic carboxylase	Yeast, bacteria, plants	Decarboxylation of pyruvate to acetaldehyde and carbon dioxide
Catalase	Erythrocytes, liver	Decomposition of hydrogen peroxide to oxygen and water
Alcohol dehydrogenase	Liver	Oxidation of ethanol to acetaldehyde
Xanthine oxidase	Milk, liver	Oxidation of xanthine and hypoxanthine to uric acid

of amino acids within the polypeptide chains is characteristic for each enzyme and is believed to determine the unique three-dimensional conformation in which the chains are folded. This conformation, which is necessary for the activity of the enzyme, is stabilized by interactions of amino acids in different parts of the peptide chains with each other and with the surrounding medium. These interactions are relatively weak and may be disrupted readily by high temperatures, acid or alkaline conditions, or changes in the polarity of the medium. Such changes lead to an unfolding of the peptide chains (denaturation) and a concomitant loss of enzymatic activity, solubility, and other properties characteristic of the native enzyme. Enzyme denaturation is sometimes reversible. *See* Amino acids; Protein.

Many enzymes contain an additional, nonprotein component, termed a coenzyme or prosthetic group. This may be an organic molecule, often a vitamin derivative, or a metal ion. The coenzyme, in most instances, participates directly in the catalytic reaction. For example, it may serve as an intermediate carrier of a group being transferred from one substrate to another. Some enzymes have coenzymes that are tightly bound to the protein and difficult to remove, while others have coenzymes that dissociate readily. When the protein moiety (the apoenzyme) and the coenzyme are separated from each other, neither possesses the catalytic properties of the original conjugated protein (the holoenzyme). By simply mixing the apoenzyme and the coenzyme together, the fully active holoenzyme can often be reconstituted. The same coenzyme may be associated with many enzymes which catalyze different reactions. It is thus primarily the nature of the apoenzyme rather than that of the coenzyme which determines the specificity of the reaction. *See* Biological oxidation; Coenzyme.

The complete amino acid sequence of several enzymes has been determined by chemical methods. By x-ray crystallographic methods even the exact three-dimensional molecular structure of a few enzymes has been deduced. *See* X-ray crystallography.

Classification and nomenclature. Enzymes are usually classified and named according to the reaction they catalyze. The principal classes are as follows.

Oxidoreductases catalyze reactions involving electron transfer, and play an important role in cellular respiration and energy production. Some of them participate in the process of oxidative phosphorylation, whereby the energy released by the oxidation of carbohydrates and fats is utilized for the synthesis of adenosine triphosphate (ATP) and thus made directly available for energy-requiring reactions.

Transferases catalyze the transfer of a particular chemical group from one substance to another. Thus, transaminases transfer amino groups, transmethylases transfer methyl groups, and so on. An important subclass of this group are the kinases, which catalyze the phosphorylation of their substrates by transferring a phosphate group, usually from ATP, thereby activating an otherwise metabolically inert compound for further transformations.

Hydrolases catalyze the hydrolysis of proteins (proteinases and peptidases), nucleic acids (nucleases), starch (amylases), fats (lipases), phosphate esters (phosphatases), and other substances. Many hydrolases are secreted by the stomach, pancreas, and intestine and are responsible for the digestion of foods. Others participate in more specialized cellular functions. For example, cholinesterase, which catalyzes the hydrolysis of acetylcholine, plays an important role in the transmission of nervous impulses. *See* Acetylcholine.

Lyases catalyze the nonhydrolytic cleavage of their substrate with the formation of a double bond. Examples are decarboxylases, which remove carboxyl groups as carbon dioxide, and dehydrases, which remove a molecule of water. The reverse reactions are catalyzed by the same enzymes.

Isomerases catalyze the interconversion of isomeric compounds.

Ligases, or synthetases, catalyze endergonic syntheses coupled with the exergonic hydrolysis of ATP. They allow the chemical energy stored in ATP to be utilized for driving reactions uphill.

Specificity. The majority of enzymes catalyze only one type of reaction and act on only one compound or on a group of closely related compounds. There must exist between an enzyme and its substrate a close fit, or complementarity. In many cases, a small structural change, even in a part of the molecule remote from that altered by the enzymatic reaction, abolishes the ability of a compound to serve as a substrate. An example of an enzyme highly specific for a single substrate is urease, which catalyzes the hydrolysis of urea to carbon dioxide and ammonia. On the other hand, some enzymes exhibit a less restricted specificity and act on a number of different compounds that possess a particular chemical group. This is termed group specificity.

A remarkable property of many enzymes is their high degree of stereospecificity, that is, their ability to discriminate between asymmetric molecules of the right-handed and left-handed configurations. An example of a stereospecific enzyme is L-amino acid oxidase. This enzyme catalyzes the oxidation of a variety of amino acids of the type R—CH(NH$_2$)COOH. The rate of oxidation varies greatly, depending on the nature of the R group, but only amino acids of the L configuration react. *See* Stereochemistry. [D.W.]

Enzyme inhibition The prevention of an enzymic process as a result of the interaction of some substance with an enzyme so as to decrease the rate of the enzymic reaction. The substance causing such an effect is termed an inhibitor. Enzyme inhibitors are important as chemotherapeutic agents, as regulators in normal control of enzymic processes in living organisms, and as useful agents in the study of biochemistry. *See* Antibiotic; Chemotherapy; Enzyme.

Inhibitors have been classified as competitive, noncompetitive, and uncompetitive. The effect of a competitive inhibitor is to bind only free enzyme. This can be reversed by sufficiently increased substrate concentrations, so that essentially all of the enzyme is bound into an enzyme-substrate complex. Since both noncompetitive and uncompetitive inhibitors interact with the enzyme-substrate complex, their effects are not nullified by increased concentrations of substrate. An uncompetitive inhibitor exerts less effect (as percent of control) at low than at high substrate concentrations, since less of the enzyme is in the form of the enzyme-substrate complex, with which it interacts. A noncompetitive inhibitor, which reacts with both free enzyme and the enzyme-substrate complex, exerts comparable effects at all substrate concentrations. [W.Sh.]

Eocanthocephala An order of the Acanthocephala characterized by the presence of a small number of giant subcuticular nuclei which are similar to the embryonic nuclei. Body spines may or may not be present and the chief lacunar vessels are dorsal and lateral. Proboscis hooks are few in number and arranged in circles. Eggs are ellipsoidal and thin shelled. These worms are parasitic in cold-blooded vertebrates (turtles, fish). The cystacanth occurs in crustaceans. *See* ACANTHOCEPHALA. [D.V.Mo.]

Eocene The second oldest of the five major worldwide divisions (epochs) of the Tertiary Period (Cenozoic Era), the interval of time (epoch) extending from the end of the Paleocene Epoch to the beginning of the Oligocene Epoch; the middle epoch of the older Tertiary (Paleogene of some authors, Nummulitic of earlier French authors). *See* CENOZOIC; OLIGOCENE; PALEOCENE; TERTIARY.

The Paleocene/Eocene boundary has been formally defined at the 5.2-ft (1.6-m) level in the Dababiya Quarry section approximately 22 mi (35 km) south of Luxor in the Upper Nile Valley, Egypt. This level coincides with a global carbon isotope excursion associated with significant climatic warming and biotic changes and is about 1 million years older than the base of the classic Ypresian Stage, normally considered the oldest stage of the Eocene. There are varying opinions regarding what to do with the associated stage boundaries. The most prevalent proposes retaining the Ypresian Stage in its present position, with an estimated age for its base of about 54 Ma, and insert the Sparnacian Stage as the lowest stage of the newly redefined Eocene.

Eocene strata are widespread throughout the world and on the deep ocean floor. They include the common sedimentary types and vary from terrestrial, to marginal (estuarine), to normal marine pelagic origin. Igneous activity, while not as extensive as in the later part of the Cenozoic, was notable in some areas such as East Greenland, Oregon, Washington, and British Columbia.

Early Paleogene temperatures, including those of high latitudes, were the warmest of the Cenozoic; peak warming occurred in the early Eocene. The Earth was in a greenhouse state, with partial pressure of carbon dioxide (pCO_2) levels in the early Eocene estimated to have been six times higher than present-day values. During the late Paleocene to the early Eocene, deep-sea temperatures at high southern latitudes warmed by some 7–9°F (4–5°C), from about 50–52°F (10–11°C) to about 57–61°F (14–16°C), while surface temperatures increased by some 9–11°F (5–6°C), with maximum temperatures in excess of 68°F (20°C). At low latitudes, surface water temperatures remained relatively constant and comparable to values of the present-day ocean. Superimposed on this long-term trend was a relatively abrupt (<10,000 years) 2.5–3% drop in $\delta^{13}C$ (the difference in isotopic ratios $^{12}C/^{13}C$ between a sample and a standard) and concomitant marine productivity that has been associated, in turn, with a major turnover (extinction of almost 50%) of the deep-sea benthic (bottom-dwelling) forminiferal fauna. This drop in $\delta^{13}C$ has been identified both in marine organisms and in mammalian bone enamel and paleosol carbonates in terrestrial sections in the Big Horn Basin of the western interior of North America and in the type Sparnacian (that is earliest Eocene) in the Paris Basin. *See* EXTINCTION (BIOLOGY); GEOLOGIC THERMOMETRY; PALEOSOL.

The diversification of life seen in the Paleocene continued in the Eocene, a reflection of the poleward expansion of the tropics, particularly during early Eocene time. In the oceanic realm, microplanktonic animals (foraminiferans) and plants (calcareous nannoplankton) flourished and diversified, as did true bony fishes and siphonate gastropods. In shallow, tropical waters the so-called larger foraminiferans extended their geographic range to latitude 50° north, but the latter group disappeared at the end of the Eocene owing to cooling temperatures. Indeed, microplanktonic animals and plants experienced a gradual but inexorable decline in diversity starting in the late middle Eocene. Succeeding Oligocene faunas and floras were much reduced in diversity and much more uniformly distributed. *See* FORAMINIFERIDA.

On land, subtropical floras extended as far north as southern England and the North American Pacific coast of Puget Sound and southern Alaska. Indeed, the floras of southern England resembled those of modern-day China, Malaysia, and Australia. In the humid interior, thick and extensive mud deposits (the Green River Shale) in Colorado contain a beautifully preserved freshwater fish fauna eagerly sought after by fossil collectors.

Europe was separated from the Eurasian land mass east of the Urals by a north-south seaway extending from the Arctic to the Tethys Sea—the Turgai Straits. Following the elimination of the elevated corridor that allowed transatlantic poleward migration between Europe and North America in late early Eocene time, middle and late Eocene time witnessed the development of extensive endemic animal evolution. Bats, flying lemurs, creodont carnivores, artiodactyls (cloven-hoof mammals, such as cattle, deer, and camels) and perissodactyls (odd-toed, hoofed mammals, such as rhinoceroses and horses), notoungulates (predominantly South American), and edentates reflect the diversification of primitive placental forms. The massive, rhinoceroslike herbivores called titanotheres and uintatheres appeared alongside the small early progenitors of the modern horse, *Hyracotherium* (known popularly as *Eohippus*). *See* MAMMALIA; PERISSODACTYLA.

In the Eocene, some mammals turned toward life in the sea; sea cows appeared in the middle Eocene, while the earliest whales (zeuglodonts) appeared in the North Atlantic–Gulf of Mexico region and the aquatic ancestors of the proboscideans appeared in the late Eocene. [W.A.Ber.]

Eocrinoidea A medium-sized class of primitive, brachiole-bearing, blastozoan echinoderms of the class Crinozoa that ranged from the Early Cambrian to the Middle Silurian, although few eocrinoids survived past the Middle Ordovician. About 32 eocrinoid genera have been described from North America, Europe, North Africa, and Australia. Eocrinoids are the most diverse class of echinoderms known from the Cambrian with about 15 genera, and different members appear to have been ancestral to nearly all of the more advanced brachiole-bearing echinoderm classes that appeared in the Early or Middle Ordovician.

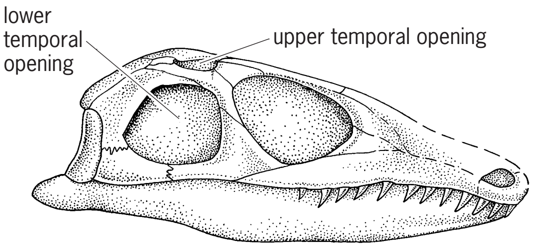
Eocrinoids have a globular, conical, or flattened theca or body, with many irregularly arranged to partly organized, imbricate or adjacent plates. Most Cambrian genera have sutural pores on the plate margins, apparently for respiration. Many early eocrinoids have a multiplated, cylindrical to slightly inflated holdfast for attaching the theca to objects lying on the sea floor. Holdfasts apparently evolved into a true columnal-bearing stem in late Middle Cambrian eocrinoids. Eocrinoids typically have two to five short ambulacral grooves radiating from the mouth on the summit to many long, erect, biserial brachioles that were used for feeding. Most eocrinoids were attached, low- to medium-level suspension feeders that used the brachioles to collect small food particles drifting by the theca. *See* CRINOZOA; ECHINODERMATA. [J.Sp.]

Eolian landforms Topographic features generated by the wind. The most commonly seen eolian landforms are sand dunes created by transportation and accumulation of wind-blown sand. Blankets of wind-deposited loess, consisting of fine-grained silt, are less obvious than dunes, but cover extensive areas in some part of the world.

Where abundant loose sand is available for the wind to carry, sand dunes develop. As soon as enough sand accumulates in one place, it interferes with the movement of air and a wind shadow is produced which contributes to the shaping of the pile of sand.

Dunes advance downwind by erosion of sand on the windward side and redeposition on the slip face. Dunes may have a variety of shapes, depending on wind conditions, vegetation, and sand supply. The fine silt and clay winnowed out from coarser sand is often blown longer distances before coming to rest as a blanket of loess mantling the preexisting topography. Thick deposits of loess are most often found in regions downwind from glacial outwash plains or alluvial valleys. *See* Dune; Loess; Sand. [D.J.E.]

Eosuchia The oldest, most primitive, and only extinct order of lepidosaurian reptiles; they are clearly ancestral of the other two orders (Rhynchocephalia and Squamata). They have a typical diapsid skull, with at most a partial reduction of the lower arcade. Tooth implantation is subthecodont.



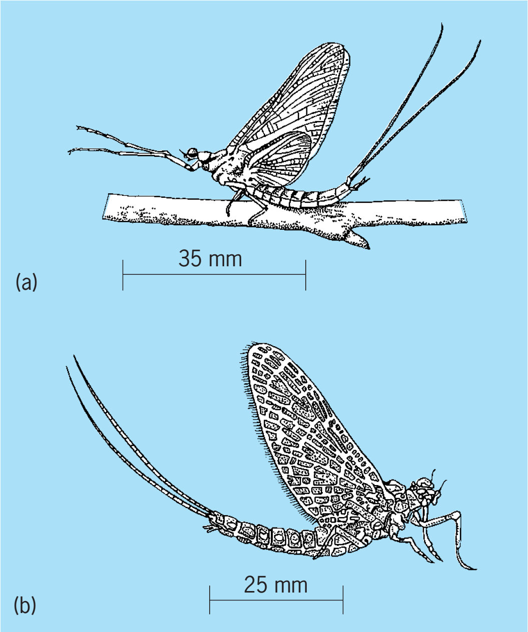
Lateral view of *Youngina* skull, Upper Permian to Lower Triassic. (*After A. S. Romer, Vertebrate Paleontology, 3d ed., University of Chicago Press, 1966*)

Of the four suborders, the oldest is the Younginiformes, including forms such as *Youngina* (see illustration). These, ranging from the Middle Permian to the Lower Triassic and found mainly in South Africa, were small unspecialized lizard-like reptiles. The Prolacertiformes, also terrestrial, range throughout the Triassic. They include forms in which a reduction of the lower temporal arcade and other features indicate a transition toward the Squamata (lizards). The Thalattosauria include a few marine reptiles from the Middle Triassic. The Choristodera include only one genus, *Champsosaurus*, a much later reptile (Upper Cretaceous to Lower Eocene), which had amphibious habits and seems to have been an eosuchian offshoot. *See* Lepidosauria; Reptilia; Squamata. [A.J.C.]

Ephedrales An order of the class Ginkgoopsida having about 35 species in the genus *Ephedra*. These plants are mostly of arid regions. They include freely branched, low shrubs with reduced, scalelike leaves and green photosynthetic twigs. The species are dioecious (seldom gynodioecious). The genus is known from Asia to Europe, in northern Africa, in the United States and Mexico, and from Bolivia to Patagonia. It is not known in the fossil record. *See* Ginkgoopsida; Pinophyta; Plant kingdom. [T.A.Z.]

Ephemeris A table of data, especially astronomical data, that depend on the time, usually arranged with values of the time in the left-hand column. A lunar ephemeris, for example, may give the right ascension and declination of the Moon for every hour of a particular year. *The American Ephemeris and Nautical Almanac* is an annual volume published by the Nautical Almanac Office, U.S. Naval Observatory, with ephemerides of the Sun, Moon, planets, and satellites, and other astronomical data. [G.M.C.]

Ephemeroptera An order of insects commonly known as mayflies. They are aquatic and live in clean, fresh waters during their immature, or nymphal, lives. Nymphs are adapted to aquatic environments ranging from ponds to mountain streams. Most mayfly nymphs are vegetarians, and most species are present throughout the year as nymphs. As immature insects, they constitute a year-round basic food supply for carnivores of their communities, especially for fishes, and trout in particular. Nymphs and adults are models for artificial bait flies (see illustration).



Ephemeroptera. (*a*) Mayfly, adult male, *Hexagenia* sp., in usual resting position. (*b*) Mayfly nymph, *Isonychia* sp. (*After A. H. Morgan, Field Book of Ponds and Streams, copyright 1930 by G. Putnam's Sons*)

Mayfly nymphs are distinguished from all other aquatic insects by the paired tracheal gills on the back of each of the first seven abdominal segments. The body ends in two or three finely segmented tailpieces. The mouthparts are highly interesting examples of adaptations for scraping, cutting, and crushing the various plant cells, which are the chief food.

As subadults, mayflies have the general adult form and useless mouthparts. They are clothed by a thin, furry, grayish skin which accounts for the common name, duns. The adult has transparent wings, shining body, and useless mouthparts; the males generally have extremely large eyes, which may be divided, and long front legs. This stage is brief, lasting from a few hours to several days. In a few mayflies, the legs of the female, and those of the male, except for the front ones, are nonfunctional and the brief adult life is spent entirely in flight. The quivering of the tailpieces during the mating flight gave them the name spinners. Thousands join in the twilight mating swarms, rhythmic dancing flights unequaled by other insects. *See* Insecta. [A.H.M./L.Ber.]

Epicaridea A suborder of the Isopoda which are parasitic on various crustaceans, mainly marine forms. The females are sometimes modified so strongly as to leave almost no indication of their isopod nature. The female pierces the host's skin with the aid of styliform mandibles to suck blood. The dwarf male attaches to the female, from which it takes nourishment, and retains its isopod structure.

The suborder is divided into two tribes, the Cryptoniscina and Bopyrina. The Cryptoniscina live on Entomostraca and are protandrous hermaphrodites. The cryptoniscium larva attaches to a suitable female, develops testes without any change in its external appearance, and acts as a male. After the death of the host, it metamorphoses into a female, ultimately undergoing anatomical degradation that leaves it a mere bulky sac distended with developing embryos.

The Bopyrina are dioecious, but it has been shown experimentally in some forms that the cryptoniscium is ambipotent, and a presumptive young male removed from the female develops into either a female or intersex. The tribe includes three families: Bopyridae, Entoniscidae, and Dajidae. *See* ISOPODA. [S.M.S.]

Epicycloid A curve traced by a point *P* on a circle with radius *r* and center *O*′ that rolls on the convex side of a fixed circle with radius *R* and center *O* (see illustration). The term is also occasionally applied to the curve generated by a point on the prolongation of the radius of a circle as the circle rolls on a straight line, It is a cardioid when the rolling circle has the same radius as the fixed circle. *See* CARDIOID. [L.M.Bl.]

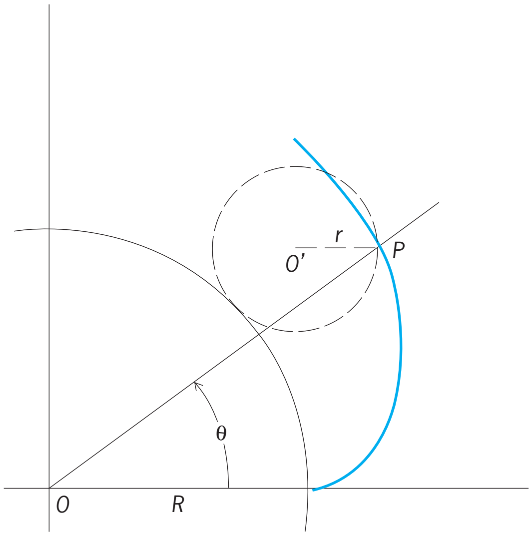


Diagram of an epicycloid.

Epidemic The occurrence of cases of disease in excess of what is usually expected for a given period of time. Epidemics are commonly thought to involve outbreaks of acute infectious disease, such as measles, polio, or streptococcal sore throat. More recently, other types of health-related events such as homicide, drownings, and even hysteria have been considered to occur as "epidemics."

Confusion sometimes arises because of overlap between the terms epidemic, outbreak, and cluster. Although they are closely related, epidemic may be used to suggest problems that are geographically widespread, while outbreak and cluster are reserved for problems that involve smaller numbers of people or are more sharply defined in terms of the area of occurrence. For example, an epidemic of influenza could involve an entire state or region, whereas an outbreak of gastroenteritis might be restricted to a nursing home, school, or day-care center. The term cluster may be used to refer to noncommunicable disease states.

In contrast to epidemics, endemic problems are distinguished by their consistently high levels over a long period of time. Lung cancer in males has been endemic in the United States, whereas the surge of lung cancer cases in women in the United States represents an epidemic problem that has resulted from increase in cigarette smoking among women in general. A pandemic is closely related to an epidemic, but it is a problem that has spread over a considerably larger geographic area; influenza pandemics are often global.

Disease and epidemics occur as a result of the interaction of three factors, agent, host, and environment. Agents cause the disease, hosts are susceptible to it, and environmental conditions permit host exposure to the agent. An understanding of the interaction between agent, host, and environment is crucial for the selection of the best approach to prevent or control the continuing spread of an epidemic.

For infectious diseases, epidemics can occur when large numbers of susceptible persons are exposed to infectious agents in settings or under circumstances that permit the spread of the agent. Spread of an infectious disease depends primarily on the chain of transmission of an agent: a source of the agent, a route of exit from the host, a suitable mode of transmission between the susceptible host and the source, and a route of entry into another susceptible host. Modes of spread may involve direct physical contact between the infected host and the new host, or airborne spread, such as coughing or sneezing. Indirect transmission takes place through vehicles such as contaminated water, food, or intravenous fluids; inanimate objects such as bedding, clothes, or surgical instruments; or a biological vector such as a mosquito or flea. *See* EPIDEMIOLOGY; INFECTIOUS DISEASE; PUBLIC HEALTH. [R.A.Go.]

Epidemic viral gastroenteritis A clinical syndrome characterized by acute infectious gastroenteritis with watery diarrhea, vomiting, malaise, and abdominal cramps with a relatively short incubation period (12–36 h) and duration (24–48 h). A viral etiology is suspected when bacterial and parasitic agents are not found. In the United States, no etiologic agent can be found in 70% of the outbreaks of gastroenteritis. Most of these may be due to viral agents, such as the Norwalk, Snow Mountain, and Hawaii agents, astroviruses, caliciviruses, adenoviruses, nongroup A rotaviruses, and paroviruses. Epidemics are common worldwide and have occurred following the consumption of fecally contaminated raw shellfish, food, or water, although the virus may be spread by airborne droplets as well. Epidemics are most frequent in residential homes, camps, institutions, and cruise ships. Many individual cases of mild diarrhea may in fact occur in epidemics for which the source of the infection cannot be found. Epidemic viral gastroenteritis is distinct from rotavirus diarrhea, a seasonal disease in winter that is the most common cause of diarrhea in young children, and affects virtually all children in the first 4 years of life. Since the diarrhea is often mild and of short duration, attention should be given to rehydration therapy and prevention by identification of the source. Fatalities have been associated with severe dehydration and loss of fluids and electrolytes in the stool. *See* ANIMAL VIRUS; DIARRHEA; INFANT DIARRHEA. [R.G.]

Epidemiology The study of the distribution of diseases in populations and of factors that influence the occurrence of disease. Epidemiology examines epidemic (excess) and endemic (always present) diseases; it is based on the observation that most diseases do not occur randomly, but are related to environmental and personal characteristics that vary by place, time, and subgroup of the population. The epidemiologist attempts to determine who is prone to a particular disease; where risk of the disease is highest; when the disease is most likely to occur and its trends over time; what exposure its victims have in common; how much the risk is increased through exposure; and how many cases of the disease could be avoided by eliminating the exposure.

In the course of history, the epidemiologic approach has helped to explain the transmission of communicable diseases, such as cholera and measles, by discovering what exposures or host factors were shared by individuals who became sick. Modern epidemiologists have contributed to an understanding of factors that influence the risk of chronic diseases, particularly cardiovascular diseases and cancer, which account for most deaths in developed countries today. Epidemiology has established the causal association of cigarette smoking with heart disease; shown that acquired immune deficiency syndrome (AIDS) is associated with certain sexual practices; linked menopausal estrogen use to increased risk of endometrial cancer but to decreased risk of osteoporosis; and demonstrated the value of mammography in reducing breast cancer mortality. By identifying personal characteristics and environmental exposures that increase the risk of disease, epidemiologists provide crucial input to risk assessments and contribute to the formulation of public health policy.

Epidemiologic studies, based mainly on human subjects, have the advantage of producing results relevant to people, but the disadvantage of not always allowing perfect control of study conditions. For ethical and practical reasons, many questions cannot be addressed by experimental studies in humans and for which observational studies (or experimental studies using laboratory animals or biomedical models) must suffice. Still, there are circumstances in which experimental studies on human subjects are appropriate, for example, when a new drug or surgical procedure appears promising and the potential benefits outweigh known or suspected risks. *See* DISEASE; EPIDEMIC.

Descriptive epidemiologic studies provide information about the occurrence of disease in a population or its subgroups and trends in the frequency of disease over time. Data sources include death certificates, special disease registries, surveys, and population censuses; the most common measures of disease occurrence are (1) mortality (number of deaths yearly per 1000 of population at risk); (2) incidence (number of new cases yearly per 100,000 of population at risk); and (3) prevalence (number of existing cases at a given time per 100 of population at risk). Descriptive measures are useful for identifying populations and subgroups at high and low risk of disease and for monitoring time trends for specific diseases. They provide the leads for analytic studies designed to investigate factors responsible for such disease profiles.

Analytic epidemiologic studies seek to identify specific factors that increase or decrease the risk of disease and to quantify the associated risk. In observational studies, the researcher does not alter the behavior or exposure of the study subjects, but observes them to learn whether those exposed to different factors differ in disease rates. Alternatively, the researcher attempts to learn what factors distinguish people who have developed a particular disease from those who have not. In experimental studies, the investigator alters the behavior, exposure, or treatment of people to determine the impact of the intervention on the disease. Usually two groups are studied, one that experiences the intervention (the experimental group) and one that does not (the control group). Outcome measures include incidence, mortality, and survival rates in both the intervention and control groups. [V.L.E.]

Epidermal ridges Minute corrugations of the skin. They compose a sculpturing, termed dermatoglyphics, which characterizes the palmar and plantar surfaces of all primates. These areas lack hair and sebaceous (oil) glands, but sweat glands are numerous. In certain kinds of monkeys, a portion of the undersurface of the tail bears similarly specialized skin.

The ridges over the human hand as a whole, in young adult males, average 0.48 mm in breadth. They are slightly narrower in females, 0.43 mm. Ridges serve two functions: (1) They increase security of contact with objects, in the manner of the milling of a tool handle. Ducts of sweat glands open on the summits of ridges, and moistening of the skin augments the security of contact. (2) They enhance the sense of touch. In passing the fingers or palm over an object for judging its texture, the slight displacement of ridges heightens stimulation of the underlying nerve endings.

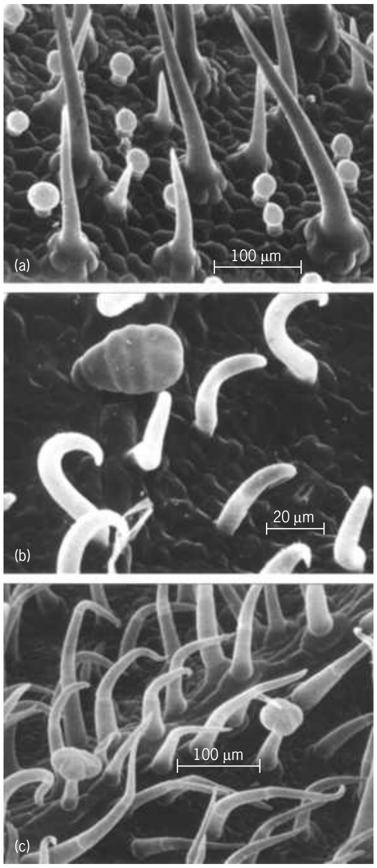
The characteristics of individual ridges and their collective configurations are not ordinarily studied by direct inspection of the skin. Instead, they are examined in prints, usually impressions of the inked surface, made for the purpose of record, or natural imprints made by chance contact. *See* FINGERPRINT. [H.Cu.]

Epidermis (plant) The outermost layer (occasionally several layers) of cells on the primary plant body. Its structure is variable; this article singles out five structural components of the tissue: (1) cuticle; (2) stomatal apparatus (including guard cells and subsidiary cells); (3) bulliform (motor) cells; (4) trichomes; and (5) root hairs.

Leaves, herbaceous stems, and floral organs usually retain the epidermis through life. Most woody stems retain it for one to many years, after which it is replaced. In roots it is usually short-lived. *See* LEAF; PERIDERM.

Cutin is a mixture of fatty substances characteristically found in epidermal cells. It impregnates the outer cell walls and occurs as a continuous layer (cuticle) on the outer surface. The cuticle covers the surfaces of young stems, leaves, floral organs, and even apical meristems. Waxes appear as a deposit on the outside of the cuticle in many plants; the bloom on purple grapes and plums is an example. Most often the waxes are present in small quantity, but the leaves of some plants may be almost white with wax (*Echeveria subrigida*). The waxes of a few species are of great commercial value in the manufacture of polishes for floors, furniture, automobiles, and shoes. Other substances, such as gums, resins, and salts, usually in crystalline form, may be deposited on the outside of the cuticle.

The apertures in the epidermis which are surrounded by two specialized cells, the guard cells, are known as stomata. The singular form, stoma, is derived from the Greek word for mouth. However, some authorities prefer to include both aperture and guard cells within the concept of stoma. The apertures of stomata are contiguous with the intercellular space system of underlying tissues and thus permit gas exchange between



Trichomes. (*a*) Unicellular and glandular (colleters) hairs of the geranium (*Pelargonium*), (*b*) Unicellular-hooked and uniseriate, club-shaped hairs of the bean (*Phaseolus*). (*c*) Uniseriate and glandular hairs of the tomato (*Lycopersicon*).

internal cells and the external environment. The opening and closing of the stomatal aperture is caused by relative changes in turgor between the guard cells and surrounding epidermal cells.

Bulliform (motor) cells are large, highly vacuolated cells that occur on the leaves of many monocotyledons but are probably best known in grasses. They are thought to play a role in the unfolding of developing leaves and in the rolling and unrolling of mature leaves in response to alternating wet and dry periods.

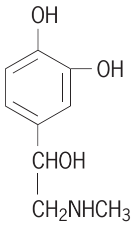
Appendages derived from the protoderm are known as trichomes; the simplest are protrusions from single epidermal cells. Included in the concept, however, are such diverse structures as uniseriate hairs, multiseriate hairs (*Begonia, Saxifraga*), anchor hairs, stellate hairs, branched (candelabra) hairs, peltate scales, stinging hairs, and glandular hairs (see illustration). Cotton and kapok fibers are unicellular epidermal hairs.

Root hairs are thin-walled extensions of certain root epidermal cells. They develop only on growing root tips and may arise from any epidermal cell, or from specialized cells known as trichoblasts. The life of a given root hair is usually numbered in days. *See* Root (botany); Secretory structures (plant). [N.H.B.]

Epidote The group name for a family of minerals of general composition $Ca_2(Fe^{3+}, Al, Mn^{3+})Al_2O[SiO_4][Si_2O](OH)$ that occur widely in metamorphic and igneous rocks. Epidote [octahedral ferric iron (Fe^{3+}) dominant] and clinozoisite [aluminum (Al) dominant] represent the most common compositions among the epidote group; a third composition, piemontite [manganese (Mn^{3+}) dominant], is less abundant. Allanite refers to compositions displaying significant rare-earth (such as lanthanum or cerium) substitution for calcium (Ca^{2+}), with corresponding replacement of Fe^{3+} by ferrous iron (Fe^{2+}). A fifth member, zoisite, is equivalent to clinozoisite, but it has a different crystalline system. Rare epidote-clinozoisites abundant in chromium (Cr), vanadium (V), and lead (Pb) and allanites rich in fluorine (F), beryllium (Be), and phosphorus (P) also exist. *See* Crystal structure; Solid solution.

Epidote group minerals, particularly epidote and clinozoisite, are common and widespread in regional- and contact-metamorphic rocks, both as primary and secondary (that is, alteration) minerals. They occur together as individual grains, as intergrowths, or as zoned crystals. Epidote and (clino)zoisite are found in aluminous limestones with grossularite, anorthite, microcline, quartz, and calcite; in mafic schists and gneisses with hornblende, albite, and chloritoid; in actinolite greenschists with chlorite, sphene, albite, quartz, calcite, and magnetite; in hornfels with diopside, actinolite, grossularite, and albite; in glaucophane schists; in quartzites; and in slates. Approximate depth-temperature conditions of their formation range from 5–25 km (3–15 mi) and 300–500°C (570–1020°F; low-grade) to 5–25 km (3–15 mi) and 450–650°C (840–1200°F; medium-grade). However, their stabilities are also sensitive to the pressure of oxygen in the rock during metamorphism. *See* Metamorphic rocks. [P.S.D.]

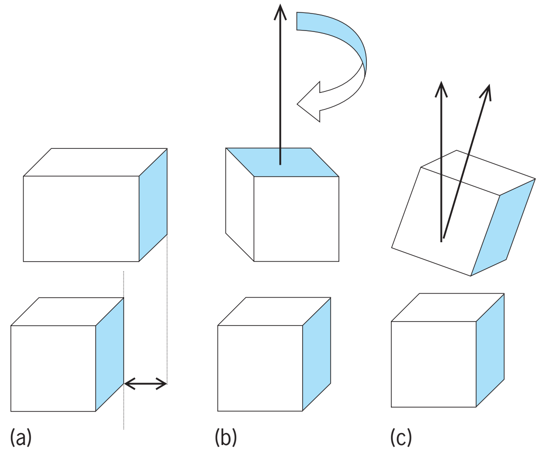
Epinephrine A hormone which is the predominant secretion from the adrenal medulla; also known as adrenalin, it has the structure shown. Epinephrine is a sympathomimetic substance; that is, it acts on tissue supplied by sympathetic nerves, and generally the effects of its action are the same as those of other nerve stimuli. Conversely, the stimulation of the splanchnic or visceral nerves will cause the rapid release of the hormone from the medullary cells of the adrenal gland. Thus, epinephrine plays an important role in preparing the organism to meet conditions of physiologic emergency.



When injected intravenously, epinephrine causes an immediate and pronounced elevation in blood pressure, which is due to the coincident stimulation of the action of the heart and the constriction of peripheral blood vessels. The chief metabolic changes following the injection of epinephrine are a rise in the basal metabolic rate and an increase of blood sugar. These effects of epinephrine are transitory. *See* Adrenal gland; Carbohydrate metabolism. [C.H.L.]

Epitaxial structures Epitaxial interfaces in solids are a special class of crystalline interfaces where the molecular arrangement of one crystal on top of another is defined by the crystallographic and chemical features of the underlying crystal. The term "epitaxy" was introduced to describe the importance of having parallelism between two lattice planes with similar networks of closely similar spacing. Epitaxial phenomena are important to study and understand, as they occur widely in nature (such as oxidation) and are the foundation by which modern semiconductor devices are grown and fabricated. *See* Crystal growth.

Epitaxial interfaces are a subset of a class of interfaces where lattice planes achieve a correspondence across an interface. If the matching is not perfect, such a correspondence can be achieved by a number of ways, including dilation and contraction of lattice planes; rotation of overgrowth (epilayer relative to the orientation of the substrate) until a set of closely matched lattice spacing can be found; and tilting of the epilayer with respect to the substrate (see illustration).



Matching of lattice planes between the substrate and the epitaxial layer by (*a*) expansion or contraction of lattice plane, (*b*) in-plane rotation, and (*c*) tilting (out-of-plane rotation).

The extent to which epitaxial films are mechanically stable due to coherency stresses is governed not only by the extent of lattice misfit but also by the strength of the chemical bond between the epilayer and the substrate. This property of adhesion is manifested by the extent to which the overlayer wets the substrate. Extremely thin layers that are only a few atoms thick can be produced. Such thin layers form the microstructural foundation for the fabrication of quantum wells, which are extremely important in semiconductor device applications. *See* Quantized electronic structure (QUEST). [K.Ra.]

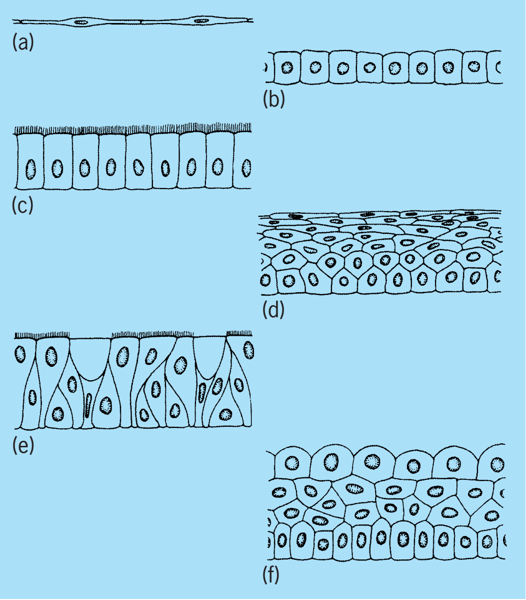
Epithelium One of the four primary tissues of the body, which constitutes the epidermis and the lining of respiratory, digestive, and genitourinary passages. The major characteristic of epithelium is that the cells are close together, separated by a very small amount of intercellular substance. Epithelium may be derived from any of the three primary germ layers of the very early embryo—ectoderm, entoderm, or mesoderm. With very few exceptions, epithelium is free of blood vessels.

The functions of epithelium are varied and include (1) protective function, by completely covering the external surface (including the gastrointestinal surface—and the surface of the whole pulmonary tree including the alveoli); (2) secretory function, by secreting fluids and chemical substances necessary for digestion, lubrication, protection, excretion of waste products, reproduction, and the regulation of metabolic processes of the body; (3) absorptive function, by absorbing nutritive substances and preserving water and salts of the body; (4) sensory function, by constituting important parts of sense organs, especially of smell and taste; and (5) lubricating function, by lining all the internal cavities of the body, including the peritoneum, pleura, pericardium, and the tunica vaginalis of the testis.

The forces which hold the epithelial cells together are not satisfactorily understood. The intercellular substance between the cells, also called cement substance, is undoubtedly important. The interdigitation of adjacent cell surfaces and the occurrence of intercellular bridges in certain cells may also be important in holding the cells together. Finally, in certain cells local modifications of contiguous surfaces and the intervening intercellular substances, which together form the terminal bars, may be effective in the same way.

The outstanding property of the arrangement of most of the epithelium of the body is the economy of space achieved in the face of a broad exposure of the cell surfaces. The efficiency is achieved by the presence of numerous folds, which may be gross or microscopic and temporary or permanent. A part must also be attributed to the surface specialization of the epithelial cells themselves, such as their minute, fingerlike processes. Another specialization of the surface or epithelial cell is the occurrence of motile cilia. *See* Cilia and flagella.

Classification of epithelia is based on morphology, that is, on the shape of the cells and their arrangement (see illustration):

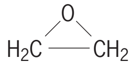


Cellular arrangements in epithelial tissues. (*a*) Squamous. (*b*) Cuboidal. (*c*) Columnar. (*d*) Stratified squamous. (*e*) Pseudostratified. (*f*) Transitional.

I. Single-layered.
  A. Squamous (mesothelium, descending loop of Henle in the kidney)—thin, flat.
  B. Cuboidal (duct, thyroid, choroid plexus)—cubelike.
  C. Columnar (intestine), sometimes ciliated (Fallopian tube, or oviduct)—tall.
II. Multiple-layered or stratified.
  A. Squamous (skin, esophagus, vagina)—superficial cells thin and flat, deeper cells cuboidal and columnar.
  B. Columnar (pharynx, large ducts of salivary glands), sometimes ciliated (larynx)—two or more layers of tall cells.
III. Pseudostratified (male urethra), sometimes ciliated (respiratory passages)—all cells reach to basement membrane but some extend toward the surface only part of the way, while others reach the surface.
IV. Transitional (urinary bladder)—like stratified squamous in the fully distended bladder; in the empty bladder, superficial cells rounded, almost spherical.

An important property of epithelium is the ability of its cells to glide over surfaces. This allows replacement of dead cells to take place in the normal state, while presenting a closed surface to the external environment; replacement is especially important in wound repair. Gliding ability is also manifested normally in the movement of cells which slide over each other in transitional epithelium, for example, when the urinary bladder is being distended or contracted. *See* Gland. [I.G.]

Epoxide A member of a class of three-membered ring cyclic ethers that are also known as oxiranes or alkylene oxides. The basic structure of an epoxide is analogous to that of the first member, ethylene oxide, shown below.



See Ethylene oxide.

Epoxides are made primarily by select oxidation reactions of alkenes; however, another classical preparation results from the ring closure of halohydrins by way of intramolecular nucleophilic displacement; that is, the reaction occurs within the same molecule, the alkoxide ion displacing the halogen to form a ring. The interest in epoxides results from their ease in preparation, and their usefulness as a reactive functional group that can give a variety of products after treatment with either electrophilic or nucleophilic reagents, or on occasion after treatment with oxidizing (for example, periodic acid) and reducing (for example, titanocene dichloride) agents. The ease of opening of the strained three-membered ring epoxides with attack of reagents in a stereospecific manner gives one or two stereochemical products (when applicable), usually in good yield. Epoxides are also used to prepare monomers, prepolymers, polymers, and copolymers. *See* Alkene; Electrophilic and nucleophilic reagents; Heterocyclic compounds.

Poly(ethylene oxide), $(CH_2CH_2O)_n$, was one of the first polymers to be prepared in the laboratory. The use of numerous epoxides (as monomers, or for the synthesis of other epoxide monomers or prepolymers) in polymer synthesis has been quite extensive, and these polyethers have been prepared by both cationic and anionic polymerization techniques. The molecular weights of resulting polyethers generally range from 500 to 10,000, usually because of interfering chain-transfer reactions. An especially interesting synthesis is the opening of propylene oxide to give optically active poly(propylene oxides). Epoxides are used in the preparation of copolymers. *See* Copolymer; Furan; Polyether resins; Polymerization.

Epoxides are promoters; that is, they are easy to polymerize, and their polymerization causes more difficult cyclic ethers such as tetrahydrofuran to polymerize. Epichlorohydrin has also been used for the preparation of prepolymers by condensations with the sodium salt of bisphenols. The epichlorohydrin/bisphenol A and other epoxide prepolymers have been used for the preparation of epoxy resins (thermosets), which are crossed-linked (3D) polymers, linear polymers that are connected by cross-linked molecular units. They are insoluble, infusible, and intractable, and sometimes are called epoxy resins. For example, a low-molecular-weight epoxy prepolymer can be treated and cross-linked with a polyamine or smaller molecules such as diethylenetriamine, or crossed-linked by the addition of carboxylic acid anhydrides, such as maleic anhydride. Other polymers can also be incorporated or can participate in the cross-linking process, and include phenolics, ureas, and melamines. The products resulting from these prepolymer techniques are used for surface coating materials, molding, pipes, laminating, repair of damaged automobile bodies, manufacture of articles reinforced with glass fibers, durable and tough epoxy resin adhesives (glues), and many other applications. [C.F.B.]

Epsomite A mineral with the chemical composition $MgSO \cdot 7H_2O$. Epsomite, or epsom salt, occurs in clear, needle-like, orthorhombic crystals. More commonly it is massive or fibrous, although crystals from salt lakes on Kruger Mountain near Orville, Washington, are reported to be several feet long. Fracture is conchoidal. Luster varies from vitreous to silky. Hardness is 2–2.5 on Mohs scale and specific gravity is 1.68. The mineral has a salty bitter taste and is soluble in water. Epsomite is found as a capillary coating in limestone caves and in coal or metal mine galleries. It is also found associated with gypsum and in thin layers in salt deposits of oceanic origin or from salt lakes. [E.C.T.C.]

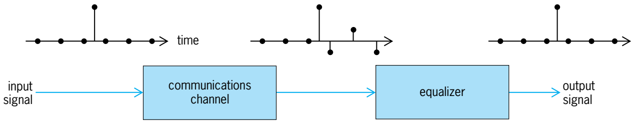
Epstein-Barr virus An antigenically distinct member of the herpesvirus group of viruses, whose genome is DNA. EB virus is the cause of one benign disease (infectious mononucleosis), and is associated with certain types of cancer; however, the great majority of EB virus infections are clinically inapparent. The virus was detected initially by electron microscopy in a small proportion of cells in continuous lymphoblastoid cell lines derived from Burkitt's lymphoma (but particles have not been seen in cells of the tumor itself). The virus also has been detected in cell lines derived from nasopharyngeal carcinomas, a type of cancer found with high frequency in persons from southern China. The virus is found in peripheral blood leukocytes from normal individuals and from patients with infectious mononucleosis. *See* Infectious mononucleosis; Lymphoma.

If EB virus is indeed confirmed as having a role in the development of human malignancies, then one major question to be resolved is how a virus so ubiquitous can be involved in so wide a variety of responses. However, it should be recalled that many virus infections (for example, polio virus, hepatitis viruses, certain of the arboviral encephalitides) have a wide spectrum of outcomes, ranging from inapparent infection to severe syndromes. *See* Animal virus; Oncology. [J.L.Me.]

Equalizer An electronic filter that modifies the frequency response (amplitude and phase versus frequency) of a system for a specific purpose. Equalizers typically realize a more complicated frequency response in which the amplitude response varies continuously with frequency, amplifying some frequencies and attenuating others. An equalizer may have a response fixed in time or may be automatically and continuously adjusted. However, its frequency response is usually matched to some external physical medium, such as an acoustic path or communication channel, and thus inherently needs to be adjustable.

Equalizers can be used in many applications. In music and sound reproduction, equalizers can compensate for artifacts of the electrical-to-sound conversion or for unwanted characteristics of the acoustic environment such as sound reflections or absorption. Sound-recording and sonar systems can use equalizers to reduce unwanted interference. Most analog recording and playback devices, such as audio and video tape recorders, incorporate equalizers to compensate for the undesirable aspects of the recording medium, such as high-frequency roll-off, as well as to reduce noise and maximize dynamic range. *See* Electrical interference; Electrical noise; Sonar; Sound recording.

Equalization is also used to enhance the performance of systems that communicate or record digital signals (streams of bits). All communications and recording systems utilize a physical medium, such as wires; coaxial cables; radio, acoustic, or optical-fiber waveguides; or magnetic and optical recording media. These media cause distortion; that is, the output signal is different from the input signal. For example, on radio or acoustic channels there are often multiple paths from transmitter to receiver, each having a slightly different delay and superimposed at the receiver. An equalizer is an electrical device that compensates for this distortion, reversing the effect of the channel and returning a waveform approximating the input signal. The channel output signal in response to a particular input signal (. . . ,0, 0, 1, 0, 0. . .) may differ from the input, but the equalizer output reproduces the channel input, at least to close approximation (see illustration). *See* Distortion (electronic circuits).



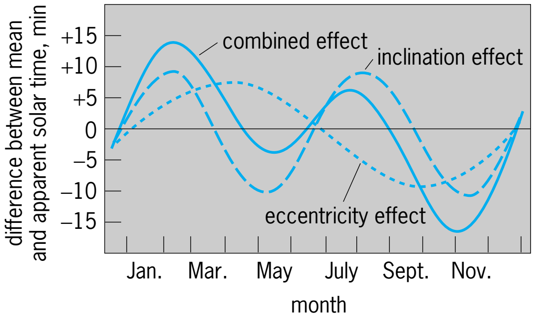
Communications channel with an equalizer placed at the output. The equalizer recovers an accurate replica of the channel input signal.

If the characteristics of the channel are well known, the equalizer can be fixed, or nonadaptive. More commonly, the detailed characteristics of a channel are not known in advance. For example, an equalizer may be required to compensate for any length of wire, from very short up to a maximum. In other cases, the channel may be varying with time, as is characteristic of the radio channel from a fixed transmitter to a moving vehicle. An adaptive equalizer is able to adjust itself to compensate. Adaptive equalizers are important for achieving high bit rates in telephone computer modems, and also for digital communications over radio channels. *See* Data communications; Modem. [D.G.M.]

Equation of time The annual, cyclic variation between mean solar time shown on uniformly running clocks and apparent solar time displayed on sundials.

In the course of the Sun's daily east-to-west transit of the sky, the Sun crosses the meridian, an imaginary line running from north to south that passes overhead and divides the sky into equal halves. An observer in the middle of a time zone generally thinks of noon as being the moment that the Sun reaches the meridian. This event, however, corresponds to noon recorded by mechanical or electronic clocks on only four dates each year (approximately April 16, June 14, September 1, and December 25). On all other dates the Sun reaches the meridian either early or late, with the extremes being 16.3 min early around November 3 and 14.3 min late around February 12. This difference is the equation of time, and results from the combined effects of Earth's axis of rotation being tipped 23° relative to Earth's orbital plane and the elliptical rather than circular shape of the orbit. *See* Meridian.

The elliptical orbit brings the Earth closest to the Sun in January. This proximity, as J. Kepler discovered in the sixteenth century, causes the Earth to move more rapidly in its orbit than in July, when the Earth is farthest from the Sun. The changing orbital speed varies the Sun's apparent rate of motion along the ecliptic and is in part responsible for the equation of time. *See* Celestial mechanics; Kepler's laws.



Graph of the equation of time, showing how the equation results from combining the effects of the inclination of the Earth's axis and the eccentricity of its orbit. (*After B. M. Oliver, The shape of the analemma, Sky Telesc., 44:20–22, July 1972*)

Slightly more influential is Earth's tipped axis, which varies the Sun's position north and south of the celestial equator according to the season. Around the time of the spring and autumn equinoxes the Sun moves at a steep angle relative to the celestial equator. Its daily motion projected onto the equator is less than at the solstices, when the Sun travels parallel to the equator. This situation also creates a departure between the Sun's actual position and that of a mean Sun moving uniformly along the celestial equator. The effects of the inclination of the Earth's axis and the eccentricity of its orbit are combined (see illustration). [D.D.C.]

Equations, theory of The branch of mathematics concerned with finding facts concerning the roots of algebraic equations and finding methods for obtaining them. The most important type of algebraic equation is the polynomial equation in one unknown which is an expression of the form $f(x) = a_nx^n + a_{n-1}x^{n-1} + \cdots + a_1x + a_0 = 0$, where x is called the unknown, or variable; n is a positive whole number; and the a_1, with $i = 0, 1, \ldots, n$, are constants, or fixed numbers, called coefficients of the equation. The left member of the equation is called a polynomial in one variable of degree n. A root of such an equation is a number which, when substituted for the variable x, makes the left member zero. For example, 3 is a root of the equation $x^3 + 2x^2 - 13x - 6 = 0$. In addition, systems of equations in one or more variables are considered, and here the problem is to find values for the variables which simultaneously satisfy each equation of the system. *See* Linear systems of equations; Polynomial systems of equations.

The topics covered in a systematic study of the theory of equations can be placed in the following principal subdivisions: properties of a polynomial which do not depend on the particular number system containing the coefficients of the polynomial; factorization of polynomials; equations with coefficients which are rational, real, or complex numbers; determination of bounds for real roots, and systematic methods for approximating real roots of equations; the solution of quadratic, cubic, and quartic equations by radicals.

The factorization of a polynomial $f(x)$ depends on the particular number field F under consideration. For example, the polynomial $x^5 - {}^1\!/_2x^4 - x^3 + {}^1\!/_2x^2 - 2x + 1$, having coefficients which are rational numbers, factors as

$$(x^2 + 1)(x^2 - 2)\left(x - {}^1\!/_2\right)$$

over the rational numbers, as

$$(x^2 + 1)(x - \sqrt{2})(x + \sqrt{2})\left(x - {}^1\!/_2\right)$$

over the real numbers, and as

$$(x + i)(x - i)(x - \sqrt{2})(x + \sqrt{2})\left(x - {}^1\!/_2\right)$$

over the complex numbers. A polynomial $f(x)$ with coefficients in F is irreducible over F if it cannot be expressed as a product of polynomials of lower degree. Every polynomial can be expressed in essentially one way as a product of irreducible factors, although there is no general algorithm which enables one to obtain this expression.

The fundamental theorem of algebra states that a polynomial equation with complex coefficients has a complex root. From this it follows immediately that a polynomial of degree n with complex coefficients factors into n linear factors over the complex numbers.

Polynomial equations of degree 2, 3, and 4 are solvable by radicals. This means that there are formulas which give the roots in terms of the coefficients of the equation and that these formulas involve only the rational operations and the operation of extraction of roots. By use of the Galois theory of equations, it can be proved that for $n > 4$ there cannot exist a formula involving only rational operations and root extractions for expressing the roots of every polynomial equation of degree n in terms of the coefficients. *See* Determinant; Matrix theory. [R.A.Be.]

Equator The great circle around the Earth, equally distant from the North and South poles, which divides the Earth into Northern and Southern hemispheres. It is the greatest circumference of the Earth because of centrifugal force from rotation, and resultant flattening of the polar areas.

The Earth's rotational axis is vertical to the plane of the Equator, and because the inclination of the axis is $66^1\!/_2{}^\circ$ from the plane of the ecliptic, the plane of the Equator is always inclined $23^1\!/_2{}^\circ$ from the ecliptic.

The celestial equator in astronomy is equally distant from the celestial poles and is the great circle in which the plane of the terrestrial Equator intersects the celestial sphere. *See* Astronomy; Mathematical geography. [V.H.E.]

Equatorial currents Ocean currents near the Equator. The westward trade winds that prevail over the tropical Atlantic and Pacific oceans drive complex oceanic circulations characterized by alternating bands of eastward and westward currents. The intense currents are confined to the surface layers of the ocean; below a depth of approximately 100 m (330 ft) the temperature is much lower, and the speed of ocean currents is much slower. The westward surface currents tend to be divergent—they are associated with a parting of the surface waters—and therefore entrain cold water from below. The water temperature rises as the currents flow westward, so that temperatures are low in the east and high in the west, except between 3 and 10°N where eastward surface currents create a band of warm water across the Pacific and Atlantic oceans. The distinctive sea surface temperature pattern in which surface waters are warm in the west and cold in the east, except for the warm band just north of the Equator, reflects the oceanic circulation. A dramatic change in this pattern every few years during El Niño episodes, when the temperature of the eastern tropical Pacific Ocean rises, is associated with an intensification of the eastward currents and a weakening (sometimes reversal) of the westward currents. *See* El Niño.

The South Equatorial Current flows westward in the upper ocean, has its northern boundary at approximately 3°N, and attains speeds in excess of 1 m/s (3.3 ft/s) near the Equator. It is directly driven by the westward trade winds and has its origins in the cold, northwestward-flowing Peruvian coastal current. Because the Coriolis force deflects water parcels to their right in the Northern Hemisphere and to their left in the Southern Hemisphere, this current is divergent at the Equator. As a consequence, cold water from below wells up along the Equator. *See* Coriolis acceleration; Upwelling.

The North Equatorial Countercurrent flows eastward immediately to the north of the South Equatorial Current. The boundary between these two currents is a sharp thermal front that is clearly evident in satellite photographs. The front can literally be a green line, hundreds of yards wide, because of the abundance of phytoplankton. This current, which is counter to the wind, is driven by the torque (curl) that the wind exerts on the ocean. To its north is a colder westward current known as the North Equatorial Current. *See* OCEAN WAVES; PHYTOPLANKTON.

The Equatorial Undercurrent, which in the Pacific Ocean was originally known as the Cromwell Current, is an intense, narrow, eastward, subsurface jet that flows precisely along the Equator across the width of the Pacific. Its core, where speeds can be in excess of 1.5 m/s (5 ft/s), is at an approximate depth of 100 m (330 ft); its width is approximately 200 km (120 mi). A similar current exists in the Atlantic Ocean. In the Indian Ocean it is often present along the Equator, in the western part of the basin during March and April when westward winds prevail over that region. Such winds (including the trade winds over the Pacific and Atlantic oceans) pile up warm surface waters in the west while exposing cold waters to the surface in the east. *See* ATLANTIC OCEAN; INDIAN OCEAN; PACIFIC OCEAN. [S.G.P.]

Equilibrium of forces In a mechanical system the condition under which no acceleration takes place. Newtonian mechanics today is based upon two definitions which modify, but are essentially equivalent to, Newton's three fundamental laws. These definitions postulate the action of forces on particles. A particle is defined as a conceptual volume element that has mass and is sufficiently small to have point location. A body is defined as a system of particles. To develop the mechanics of a body, these definitions are applied to each of its particles and their influences summed. *See* ACCELERATION.

The law of motion is that, in a newtonian frame of reference (with few exceptions, a frame of reference fixed with respect to Earth is considered to be newtonian), a particle of mass m acted on by resultant force $\mathbf{F}$ has acceleration $\mathbf{a}$ in accordance with the equation $\mathbf{F} = km\mathbf{a}$. Therein, k is a positive constant whose value depends upon the units in which $\mathbf{F}$, m, and $\mathbf{a}$ are measured. The action-reaction law states that when one particle exerts force on another, the other particle exerts on the one a collinear force equal in magnitude but oppositely directed.

A body acted upon by force is in equilibrium when its constituent particles are in equilibrium. The forces exerted on its particles (and therefore on the body) are either internal or external to the body. An internal force is one exerted by one particle on another in the same body. An external force is one exerted on a particle or the body by a particle not of the body. *See* DYNAMICS; KINETICS (CLASSICAL MECHANICS); STATICS. [N.S.F.]

Equine infectious anemia A lentivirus-induced disease of the horse family with an almost worldwide distribution. It is characterized by recurring fever, platelet reduction, weight loss, edema, and anemia. Although death can occur, there is usually an eventual cessation of clinical signs. However, host defenses are unable to completely eliminate the virus, and the animal remains a persistently infected inapparent carrier.

The equine infectious anemia virus is in the *Lentivirus* genus of the family Retroviridae. Although it is closely related to the human immunodeficiency viruses (HIV-1, HIV-2), its genetic organization is the least complex of this group of viruses.

Equine infectious anemia virus infects only members of the horse family. The mechanical transfer of blood between animals by large blood-feeding insects (mainly horse flies and deer flies) is probably the most important mechanism of natural transmission. However, the virus can be efficiently transmitted by humans if sterile techniques are not observed during veterinary procedures.

Clinical responses to equine infectious anemia virus infection can range from an extremely severe disease resulting in death to an absence of obvious signs. However, when disease occurs it is usually observed shortly after exposure to the virus (incubation periods of 10–45 days are common) and consists of fever, platelet reduction (thrombocytopenia), lethargy, loss of appetite, and petechial hemorrhages. Most horses survive this acute episode but in many cases progress to the chronic form of the disease, characterized by recurring fever, thrombocytopenia, anemia, weight loss, edema, and hemorrhage. Each fever episode is associated with massive amounts of viral replication that occurs predominantly in the mature tissue macrophages of the liver and spleen and results in the release of millions of viral particles into the bloodstream. This extensive replication triggers the release of powerful molecules called cytokines, such as tumor necrosis factor alpha (TNFα), that are normally associated with inflammatory reactions.

Equine infectious anemia virus employs numerous mechanisms to avoid removal by host defenses. These mechanisms range from infecting and possibly compromising the efficiency of a key cell type in the immune system to possessing a surface unit protein with a fundamental structure that confers partial resistance to neutralizing antibodies. Another property of this protein is its ability to withstand considerable alterations in amino acid content without loss of function. This, in combination with a high mutation rate, facilitates the emergence of variants that are completely resistant to the strain-specific neutralizing antibodies produced within the first months of infection. Although additional strain-specific neutralizing antibodies may be generated against these variants, the mutational capabilities of this virus permit still more resistant types to arise. *See* IMMUNITY.

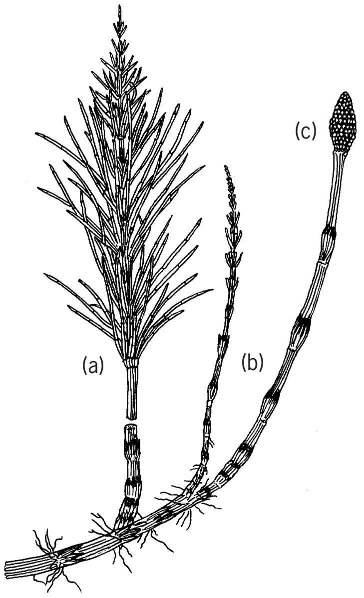
A safe and effective vaccine that rapidly induces protection against all strains of the equine infectious anemia virus is not yet available; this virus is controlled in most areas of the world by serological testing that detects the presence of antibodies against the major core protein of the virus. If a horse tests positive, further transmission of the equine infectious anemia virus can usually be prevented by segregation or quarantine. *See* RETROVIRUS; VIRUS INFECTION, LATENT, PERSISTENT, SLOW. [R.F.Co.; C.J.I.]

Equinox One of the two places in the sky where the ecliptic crosses the celestial equator; or one of the two times of the year when the Sun crosses these points. The ecliptic is the great circle across the sky that marks the mean path of the Sun; the celestial equator is the great circle that is an extension into the sky of the Earth's mean Equator. These two great circles meet at two points, one of which is the vernal equinox and the other the autumnal equinox. The Sun passes the vernal equinox each year about March 20, and the autumnal equinox about September 22. The dates and times drift with the difference between the actual solar years and 365 days, and are corrected by leap years. *See* ASTRONOMICAL COORDINATE SYSTEMS; CALENDAR; TIME.

The term equinox is derived from the Latin for equal nights, indicating that the day and night are of equal duration. However, the actual duration of daylight is several minutes longer on the days of the equinoxes. The equinoctial dates are geometrical constructions in which the Sun is treated as a point; in actuality the top of its disk rises a few minutes ahead of its center. Furthermore, refraction in the Earth's atmosphere makes the Sun appear higher in the sky than it actually is, an effect that also lengthens daylight by several minutes. *See* METEOROLOGICAL OPTICS; REFRACTION OF WAVES. [J.M.P.]

Equisetales An order of the division Spenophyta, subkingdom Embryobionta. The Equisetales, commonly known as horsetails, is represented by a single living genus, *Equisetum*, with about 25 species found both in moist and dry habitats. These plants grow throughout the world, except in Australia and New Zealand. The plants range from herbaceous to shrubby and rarely exceed 3 or 4 ft (0.9 or 1.2 ft) in height, although some tropical species grow much taller.

The plant body is commonly composed of perennial underground stems (rhizomes) with various types of aerial stems (see illustration) in different species. Some of these are perennial, others annual; some are unbranched and reproductive, others



***Equisetum arvense*. (*a*) Sterile shoot. (*b*) Fertile shoot growing from an underground rootstock. (*c*) Cone. (*After E. W. Sinnott and K. S. Wilson*, *Botany*: *Principles and Problems*, *6th ed*., *McGraw-Hill*, *1963*)**

much branched and vegetative. The bushy structure of the latter is suggestive of the common name, horsetail. [P.A.V.]

Equivalent circuit A representation of an actual electric circuit or electronic device by a simple circuit whose behavior is very near to that of the actual circuit over a specified range of conditions. When these conditions are satisfied, the equivalent circuit may be said to constitute a macromodel of the actual circuit. The use of equivalent circuits is important in many of the analysis and design operations associated with electronic circuits. Many electric circuits, for example, active-*RC* (resistance-capacitance) filters, require the use of large numbers of operational amplifiers. In such applications, the use of equivalent circuits greatly simplifies analysis and design operations. *See* CIRCUIT (ELECTRICITY); CIRCUIT (ELECTRONICS); ELECTRIC FILTER; INTEGRATED CIRCUITS; OPERATIONAL AMPLIFIER; TRANSISTOR.

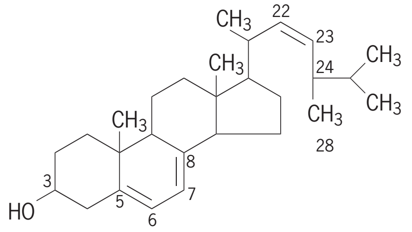
Two of the best-known equivalent circuits are the Thévenin equivalent circuit and the Norton equivalent circuit. The Thévenin equivalent circuit consists of the series connection of a voltage source and a two-terminal circuit; the Norton equivalent circuit consists of the parallel connection of a current source and a two-terminal circuit. In both circuits, the output of the voltage or current source is usually dependent on the electric signals applied to the input terminals. *See* NETWORK THEORY; THÉVENIN'S THEOREM (ELECTRIC NETWORKS). [L.P.Hu.]

Equivalent weight The number of parts by weight of an element or compound which will combine with or replace, directly or indirectly, 1.008 parts by weight of hydrogen, 8.00 parts of oxygen, or the equivalent weight of any other element or compound. For all elements, the atomic weight is equal to the equivalent weight times a small whole number, called the valence of the element. An element can have more than one valence and therefore more than one equivalent weight. *See* ELEMENTS; VALENCE.

The concept of equivalent weight, together with that of gram-equivalent weight, tends to have been abandoned, and relations are expressed in terms of balanced stoichiometric chemical equations and relative numbers of moles reacting. *See* ELECTROCHEMICAL EQUIVALENT; MOLE (CHEMISTRY); STOICHIOMETRY. [T.C.W.]

Erbium A chemical element, Er, atomic number 68, atomic weight 167.26, belonging to the rare-earth group. The naturally occurring element is made up of the six stable isotopes. The rose-pink oxide, Er_2O_3, dissolves in mineral acids to give rose-colored solutions. The salts are paramagnetic and the ions are trivalent. At low temperatures the metal is antiferromagnetic and at still lower temperatures becomes strongly ferromagnetic. For properties of the metal *see* RARE-EARTH ELEMENTS. [F.H.Sp.]

Ergosterol A steroid that belongs to the class of unsaponifiable lipids. It was first isolated from ergot bodies. Ergosterol is a white crystalline compound, insoluble in water and soluble in organic solvents, with the structural formula shown here.



Ergosterol differs from cholesterol by having three positions of unsaturation, at carbon atoms 5-6, 7-8, and 22-23, and containing a methyl group (carbon atom 28) substituted for a hydrogen atom at carbon atom 24. *See* CHOLESTEROL.

Ultraviolet irradiation of ergosterol leads to the formation of calciferol (vitamin D_2). Under controlled conditions, a more than 50% yield of vitamin D_2 can be obtained. The process is used commercially. *see* STEROID; VITAMIN D. [W.J.V.W.]

Ergot and ergotism Ergot is the seedlike body of fungi (molds) of the genus *Claviceps*; ergotism is a complex disease of humans and certain domestic animals caused by ingestion of grains and cereals infested with ergot. Ingestion of these long, hard, purplish-black structures called sclerotia may lead to convulsions, abortion, hallucinations, or death. During the Middle Ages, hundreds of thousands of people are believed to have died from this disease, often referred to as holy fire, St. Anthony's fire, or St. Vitus' dance. Epidemics in humans, although less prevalent in modern times, last occurred in 1951, and the potential danger is always present, as shown by annual livestock losses due to ergot poisoning. There are 32 recognized species of *Claviceps*, most of which infect members of the grass family. Only three species are parasitic on the rushes and sedges. *See* PLANT PATHOLOGY; POISON.

Sclerotia have an unusual chemical makeup. They carry only 10% water by weight, and 50% of the dry weight is composed of fatty acids, sugars, and sugar alcohols, which make the ergot a storehouse of energy. Unfortunately, they also contain the poisonous alkaloids, ranging from 0 to 1.2% of the dry weight.

There are three types of ergotism (gangrenous, convulsive, and hallucinogenic). Their symptoms often overlap; the hallucinogenic form is usually observed in combination with one of the other two. The unusual combination of gangrenous and convulsive symptoms is sometimes observed in the Balkans and areas near the Rhine River.

The hallucinogenic form often includes symptoms of one of the other types. In its more pure form, it is referred to as choreomania, St. Vitus' dance, or St. John's dance. Vivid hallucinations are accompanied by psychic intoxication reminiscent of the effects of many of the modern psychedelic drugs. Early reports state that the disease usually manifested itself in the form of strange public dances that might last for days or weeks on end. Dancers made stiff jerky movements accompanied by wild hopping, leaping, screaming, and shouting. They were often heard conversing with devils or gods, and danced compulsively, as if possessed, until exhaustion caused them to fall unconscious or to lie twitching on the ground. High mortality rates were associated with severe epidemics involving any of the three forms of ergotism. The success with which the disease is controlled in humans has been brought about by (1) agricultural inspection, (2) use of wheat, potatoes, and maize instead of rye, (3) limited control of ergot, (4) reserves of sound grain, and (5) forecasting severe ergot years. The most recent and best-recorded epidemic was in southern France in 1951 when an unscrupulous miller used moldy grain to make flour.

In the early twentieth century two ergot alkaloids (ergotoxine and ergotamine) were isolated. Unfortunately, they caused significant side effects and were not as specific or active as some of the crude aqueous preparations. Shortly after its discovery, ergotamine was found to be effective in the treatment of migraines. Both ergotoxine and ergotamine cause vasoconstriction that can lead to gangrene with chronic use. *See* HEADACHE.

In 1935 a new water-soluble ergot alkaloid, ergonovine, was synthesized. Ergonovine is used to facilitate childbirth by stimulating uterine contractions. Many other important lysergic acid derivatives have been produced by means of semisynthesis. Of these derivatives, LSD-25 (*d*-lysergic acid diethylamide) is the most famous. LSD has been used experimentally, mainly in psychiatry and neurophysiology. *See* PSYCHOTOMIMETIC DRUG.

Through extensive research, many other uses for ergot alkaloids has been found. Ergotamine and dihydroergotamine are used to treat migraines, and methysergine is used in migraine prophylaxis. Dihydroergotoxine is prescribed for hypertension, cerebral diffuse sclerosis, and peripheral vascular disorders. Ergocorine and the less toxic agroclavine have been reported as unusual experimental birth-control agents. The drugs appear to inhibit implantation of the ovum. Several semisynthetic alkaloids are also active implantation inhibitors. [R.L.M.]

Ericales An order of flowering plants, division Magnoliophyta (angiosperms), in the large asterid assemblage (often Asteridae in previous systems of classification). Nearly all of the 24 families assigned to the order have previously been considered members of several orders in the subclass Dilleniidae. Ericales are a diverse group that have general asterid characters: tenuinucellate ovules; flowers with fused sepals, and often, fused petals with the anthers fused at least basally to the petals, even when the petals are apparently free; cellular endosperm formation; and tegumentary tapeta.

The largest families are Ericaceae (1350 species), Primulaceae (1000 species), Myrsinaceae (1000 species), Sapotaceae (800 species), and Balsaminaceae (600 species). The two biggest families are largely temperate herbs (Primulaceae), and the next three are largely tropical trees or herbs (Balsaminaceae). A relationship between the first four families has been known for many years, but the last has nearly always been considered related to the rosid family Geraniaceae.

Familiar plants belonging to Ericales include rhododendrons (*Rhododendron*, Ericaceae), camellias (*Camellia*, also the genus of tea, Theaceae), primroses (*Primula*, Primulaceae), phlox (*Phlox*, Polemoniaceae), and impatiens (*Impatiens*, Balsaminaceae). *See* BLUEBERRY; DILLENIIDAE; MAGNOLIOPSIDA; PLANT KINGDOM. [M.W.C.]

Eriocaulales An order of flowering plants, division Magnoliophyta (Angiospermae), subclass Commelinidae of the class Liliopsida (monocotyledons). The order consists of the single family Eriocaulaceae, with about 1200 species. The Eriocaulales are Commelinidae with a reduced (or no) perianth and with unisexual flowers aggregated into a dense, involucrate head that is elevated above the clustered, basal leaves on a long peduncle. Although the individual flowers are small and inconspicuous, the heads are more or less showy and pollination is usually by insects, in spite of the absence of nectar and nectaries. The order is of negligible economic importance. *See* COMMELINIDAE; LILIOPSIDA. [A.Cr.]

Erosion The result of processes that entrain and transport earth materials along coastlines, in streams, and on hillslopes. Wind and water are common agents through which forces are applied to resistant rocks, soils, or other unconsolidated materials. Erosion types often are designated on the basis of the agent: wind erosion, fluvial (water) erosion, and glacial erosion. Fluvial erosion usually has been regarded as the most effective type in shaping the land surface during recent geologic time. Under certain environmental conditions, however, wind erosion moves considerable quantities of earth materials, as demonstrated during the "dust bowl" years in the United States. Glacial erosion shaped much of the land surface during the Quaternary Period of geologic time. Each type of erosion produces distinctive landforms, contributing to the diversity of terrestrial landscapes. *See* DESERT EROSION FEATURES; EOLIAN LANDFORMS; FLUVIAL EROSION LANDFORMS; GEOMORPHOLOGY; GLACIOLOGY; MASS WASTING; QUATERNARY; STREAM TRANSPORT AND DEPOSITION.

Forces exerted by erosion processes must exceed resistances of earth materials for entrainment and transportation to occur. Environmental conditions determine the magnitude of the forces, the resistances, and the relations among them. Erosion rates are highly variable in time and space due to changing relations between forces and resistances. The major factors governing wind-erosion rates are wind velocity, topography, surface roughness, soil properties and soil moisture, vegetation cover, and land use. The major factors governing fluvial-erosion rates on hillslopes are rainfall energy, topography, soil properties, vegetation cover, and land use. The major factors governing fluvial-erosion rates in stream channels are depth and velocity of water flow, together with the size and cohesiveness of the bed and bank materials. The major factors governing glacial-erosion rates are the depth and velocity of ice flow, together with the hardness of the bed and side-wall materials.

Accelerated erosion by fluvial processes may be the most important environmental problem worldwide because of its spatial and temporal ubiquity. Erosion rates commonly exceed soil-formation rates, causing depletion of soil resources. The effects of erosion are insidious due to the removal of the fertile topsoil horizon, compromising food production. Sediment frequently is transported well beyond the source area to degrade water quality in streams and lakes, harm aquatic life, reduce the water-storage capacity of reservoirs, and increase channel-maintenance costs. *See* SOIL; SOIL CONSERVATION. [T.J.T.]

Errantia A group of 34 families of Polychaeta in which the anterior, or cephalic, region is more or less fully exposed and the body is often long, linear to short, and depressed. The segments of these worms are similar or change gradually. The pharynx is often heavily muscularized and eversible, and its inner walls are fortified with calcified or chitinized plates or jaws. Some families are benthic throughout their life, others are entirely pelagic, and some have pelagic larval and reproductive stages and benthic trophic development. Errantia occur in all seas, at all depths, and in inland seas or lakes. They range in length from a few tenths of an inch (few millimeters) to 6 ft (1.8 m). *See* POLYCHAETA.

There are 6 families of scale bearers and allies: Aphroditidae (9 genera and about 85 species) include the sea mouse (*Aphrodita*) and the giant cold-water *Laetmonice*. Polynoidae (75 genera, 600 species) are in all seas and at all depths. Most are benthic, some are pelagic (*Drieschia, Nectochaeta*), and others are commensal (*Arctonoe, Hesperonoe, Polynoe*); some are known only from abyssal depths (*Macellicephala*). Common genera are *Harmothoe*, *Lepidonotus*, and *Halosydna*. Polyodontidae (8 or 9 genera and about 35 species) are tubicolous and often large-bodied. Some secrete fibers to construct tubes. They are worldwide, occurring chiefly in tropical latitudes. Typical genera are *Eupanthalis, Panthalis*, and *Polyodontes*. Sigalionidae

(10 genera and about 130 species) are worldwide and occur in all latitudes, from littoral to abyssal depths. The best-known genera are *Leanira, Psammolyce, Sigalion, Sthenelais*, and *Thalenessa*. The other 5 families are small: Peisidicidae (1 genus, 3 species); Pareulepidae (1 genus, 8 species); Pisionidae (5 genera, 12 species); Chrysopetalidae (4 genera, 18 species); and Palmyridae (1 genus, 2 species).

There are 3 Amphinomorpha families: Amphinomidae (18 genera and about 120 species) comprise the stinging or fire worms; a burning sensation results from handling them. Common genera are the large, brilliantly colored *Amphinome* and *Hermodice*—the "scorpions of the sea." Euphrosinidae (Fig. 1; 2 genera, 45 species) and Spintheridae (1 genus, 8 species) are short and depressed and are associated with sponges and other colonial animals.

The leaf-bearing and pelagic groups are composed of 8 families. The Phyllodocidae (30 genera, more than 240 species) are often brilliantly iridescent and are highly motile, with arresting colors and ornamentation. They occur in all seas and at all depths. Common genera are *Anaitides, Eulalia, Eteone*, and *Phyllodoce*. The pelagic families allied to the Phyllodocidae are Alciopidae (10 genera, 41 species); Lopadorrhynchidae (2 genera, 5 species); lospilidae (4 genera, 7 species); Pontodoridae (single genus and species); and Typhloscolecidae (3 genera, 14 species). The benthic families are Lacydonidae (3 genera, 6 species), and Tomopteridae, or glass worms (2 genera and about 40 species).

The Hesionidae (22 genera, more than 82 species), and the Pilargidae (6 genera and about 25 species) differ from other depressed; a few are long and linear. Some are free-living; others commensal. The best-known genera are *Hesionie, Leocrates, Oxydromus*, and *Podarke* in the Hesionidae and *Ancistrosyllis* and *Pilargis* in the Pilargidae.

Syllidae comprise the second largest of polychaete families; they have 55–60 genera and more than 400 species. Most occur along intertidal rocky shores among epiphytic plants or animals or in encrusting sponges. They are chiefly foraging predators or scavengers, identified by their long, linear, translucent bodies with articulated cirri (Fig. 2).

Nereidae is known for about 27 genera and more than 360 species. Most are marine, occurring in worldwide seas and at all depths; a few are euryhaline, entering tidal streams or inland seas, or occur in thermal springs and high mountain lakes. Common genera are *Nereis, Neanthes, Ceratocephale, Platynereis*, and *Perinereis*.

Nephtyidae (4 genera and about 85 species) are sometimes called sandworms for their occurrence in intertidal sands, where their highly opalescent colors and rapid movements render them almost invisible. They occur in worldwide seas at all depths. Common genera are *Nephtys* and *Aglaophamus*.

Sphaerodoridae (2 genera and about 18 species) are small, short- to long-bodied, and usually papillated; usually their occurrence is rare.

Glyceridae (3 genera and about 66 species) are characterized by the enormous eversible proboscis used in food capture and forward progression. Closely allied, the family Goniadidae (7 genera and more than 60 species) occurs in all seas and at all depths. *Glycinde, Goniada, Goniadides*, and *Ophioglycera* are worldwide in occurrence.

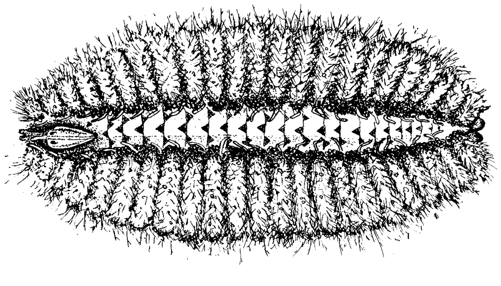


Fig. 1. ***Euphrosine*, of the Euphrosinidae, dorsal view. (*After McIntosh*)**

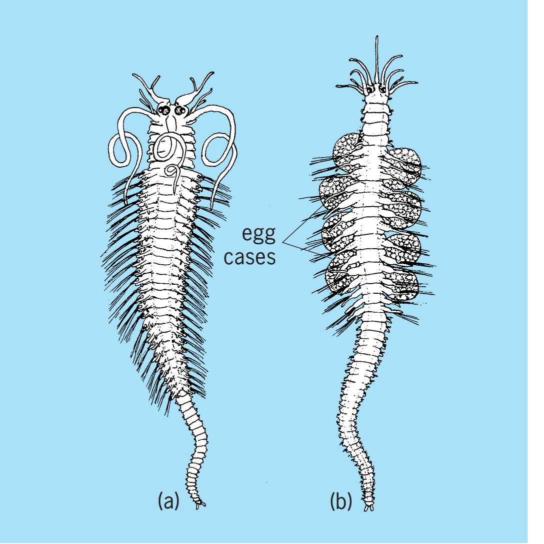

Fig. 2. ***Procerastea* of the Syllidae (Autolytinae). (*a*) Epitokous male, dorsal view. (*b*) Epitokous female with attached egg cases, dorsal view.**

The superfamily Eunicea comprises 6 families. Onuphidae (10 genera and about 100 species) are tubicolous, grazing, herbivorous, scavenging, are worldwide in occurrence, and exist in intertidal to abyssal depths. Eunicidae (7 genera and about 225 species) are mainly from tropical seas; included are the coral-eating *Lysidice*, and a bait worm, *Marphysa*. Lumbrineridae (3 genera and about 130 species) are known in all seas. Arabellidae (9 genera and about 66 species) chiefly include free-living and parasitic species. Lysaretidae (3 genera, 8 species) include large fish-bait worms (*Lysarete* and *Halla*) in tropical regions where they occur. *Iphitime* is an ectoparasite on large crabs. Dorvilleidae (3 genera and about 40 species) are small to minute and are chiefly intertidal in epiphytic growth.

Two parasitic families allied to the Eunicea are the Histriobdellidae, ectoparasites of crayfishes (2 genera, 5 species), and the Ichthyotomidae, parasites of fishes (single genus and species). *See* ANNELIDA. [O.H.]

Erysipelothrix A genus of gram-positive bacteria comprising at least two species, *E. rhusiopathiae* and *E. tonsillarum*. *Erysipelothrix rhusiopathiae* is the more pathogenic and causes disease in a variety of animal species, including humans. It is a rod-shaped organism, 0.3 × 1–2 micrometers, that may form filaments in old cultures and in chronically infected tissues. It occurs in the tonsils of healthy swine and on the surfaces of fish and other aquatic species; it is shed in the urine, oral secretions, and feces of infected animals. Organisms deposited in the soil may survive for years and may be a source of infection for susceptible domestic and wild animals and birds.

Erysipelothrix rhusiopathiae causes disease in swine (erysipelas), turkeys, lambs, and a variety of other domestic and wild mammals and birds. Infections are acquired via skin abrasions, or occur when organisms in the tonsil invade the bloodstream of swine stressed by excessive heat. The organism spreads via contaminated excretions and saliva. Infections in humans are associated with occupational exposure to the organism (veterinarians, butchers, pathologists, fish-handlers). They are usually acquired via minor cuts and abrasions on the hands or arms, leading to a painful local purplish erythema termed erysipeloid. This infection may occasionally lead to invasion of the bloodstream or joints.

Erysipelothrix rhusiopathiae is easily demonstrated microscopically and by culture of blood and tissues of affected animals. Penicillin is the antibiotic of choice for treatment of infected animals or humans. Protective immunity is stimulated by live attenuated strains or by inactivated virulent *E. rhusiopathiae*. *See* MEDICAL BACTERIOLOGY. [J.F.T.]

Escalator A continuously moving stairway and handrail. The escalator (see illustration) transports a continuous stream of passengers from floor to floor. Usually speed is 100 ft/min (0.5 m/s); slope is standardized at 30°. Steps ride on resilient rollers running on tracks; endless roller chains propel the steps, the chains being driven by sprockets and a worm drive. An electric motor at the top of the escalator provides the motive force. The direction of travel can be reversed in accordance with the flow of traffic. [F.H.R.]

Cutaway view of escalator. (*Otis Elevator Co.*)

Escape velocity Minimum speed away from a parent body that a particle must acquire to escape permanently from the gravitational attraction of the parent. Escape velocity is also termed parabolic velocity. *See* ORBITAL MOTION.

Earth retains an atmosphere because the escape velocity is considerably higher than the mean velocity of the gas molecules in its atmosphere. For a space ship to escape from Earth and travel to another planet or orbit about the Sun, it must reach escape velocity. This velocity can be calculated by equating the kinetic energy of the moving body to the work necessary to overcome the gravity at the surface of the parent. For Earth, $v_{\text{escape}} = 11.2 \times 10^3$ m/s. *See* SATELLITE (SPACECRAFT). [R.L.Du.]

Escapement A mechanism in which a toothed wheel engages alternate pallets attached to an oscillating member. The escapement is found principally in timepieces but may be employed wherever oscillating motion is required.

In a mechanical clock or watch, the escapement intervenes between the energy source (spring or elevated weight) and the regulating device (pendulum or balance wheel). It is acted upon by both. The escape wheel is mounted on the same shaft as the last wheel of the gear train, and impulses are delivered from the escape wheel to operate the regulating device. The regulating device, which has a natural period of oscillation, determines the rate at which it will receive these impulses, and thus regulates the rate of going of the timepiece.

The anchor recoil escapement (Fig. 1) is used with a pendulum and takes its name from the shape of its oscillating member and its action. In the position shown, pallet *B* has just received an impulse from the escape wheel, the impulse swinging the pendulum to the left. When pallet *B* has cleared the tooth, allowing the wheel to escape, pallet *C* will be in position to arrest the wheel. Recoil, or momentary reversal of the escape wheel, occurs just after it is arrested because the pendulum has not quite completed its swing. The wheel tooth in contact with pallet *C* will then give the oscillating parts an impulse in the opposite direction.

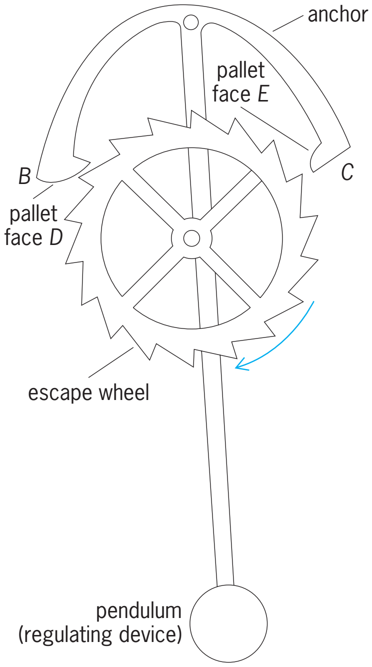

Fig. 1. Anchor recoil escapement.

Modern watches generally employ a detached-lever escapement (Fig. 2), which has banking pins *B* to limit the oscillation of the anchor and its lever. An escapement is termed detached when the regulating device, in this case the balance wheel, is given an impulse during only a small part of its operating cycle. When the fork reaches the end of its swing, it is lightly locked by a wheel tooth and remains stationary until the returning impulse pin *E* causes sufficient recoil of the escape wheel to release the pallet. *See* CHRONOMETER; CLOCK.

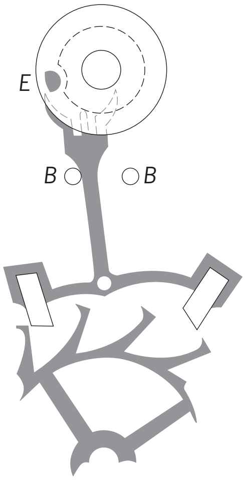

Fig. 2. Detached-lever escapement, often used in modern watches. (*After F. J. Britten, Britten's Old Clocks and Watches and Their Makers, 7th ed., Dutton, 1956*)

Some modern watches employ a light ratchet powered by a vibrating reed at 360 Hz. *See* WATCH. [D.P.Ad.]

Escarpment A long line of cliffs or steep slopes that break the general continuity of the land by separating it into two level or sloping surfaces. Some very high escarpments, or scarps, may form by vertical movement along faults. Often a whole block of land may be forced upward while the adjacent block is downfaulted. *See* FAULT AND FAULT STRUCTURES.

Other types of escarpments form by differential weathering and erosion of contrasted rock types. Less resistant rocks, such as clay or shale, are often eroded from beneath resistant cap rocks, such as sandstone and limestone. With support removed from below, the cap rock fails and the escarpment retreats. Escarpments are often very prominent in arid regions, where hardened weathering products may form extensive cap rocks known as duricrusts.

Some of the largest known escarpments occur on the planet Mars, where erosion has presumably been much slower than on the Earth in reducing primary structural relief. *See* MARS. [V.R.B.]

Escherichia A genus of bacteria named for Theodor Escherich, an Austrian pediatrician and bacteriologist, who first published on these bacteria in 1885. *Escherichia coli* is the most important of the six species which presently make up this genus, and it is among the most extensively scientifically characterized living organisms. *Escherichia coli* are gram-negative rod-shaped bacteria approximately 0.5 × 1–3 micrometers in size. Molecular taxonomic analysis based on the nucleotide sequences of ribosomal ribonucleic acid (RNA) has revealed that *Shigella*, a bacterial genus of medical importance previously thought to be distinct from *E. coli*, is actually the same species.

The natural habitat of *E. coli* is the colon of mammals, reptiles, and birds. In humans, *E. coli* is the predominant bacterial species inhabiting the colon that is capable of growing in the presence of oxygen. The presence of *E. coli* in the environment is taken to be an indication of fecal contamination.

Most strains of *E. coli* are harmless to the humans and other animals they colonize, but some strains can cause disease when given access to extraintestinal sites or the intestines of noncommensal hosts. *Escherichia coli* is the most important cause of urinary tract infections. Women are more susceptible than men; four out of ten women experience at least one urinary tract infection in their lifetime. Urinary tract infections may extend into the bloodstream, especially in hospitalized patients whose defenses are compromised by the underlying illness. This may lead to a type of whole-body inflammatory response known as sepsis, which is frequently fatal. Certain *E. coli* strains can invade the intestine of the newborn and cause sepsis and meningitis. These strains are acquired at birth from *E. coli* which have colonized the vagina of the mother.

Several different strains of *E. coli* cause intestinal infections. In the developing world, the most important of these are the enterotoxigenic *E. coli*, which produce enterotoxins that act on the epithelial cells lining the small intestine, causing the small intestine to reverse its normal absorptive function and secrete fluid. This leads to a dehydrating diarrhea which can be fatal, especially in poorly nourished infants. Therapy consists of oral or, in serious cases, intravenous rehydration. Enterotoxigenic *E. coli* are transmitted by ingestion of fecally contaminated water and food, and are a common cause of diarrheal disease in travelers in developing countries.

An important group of pathogenic *E. coli* in developed countries are the enterohemorrhagic strains, especially the serotype known as *E. coli* O157:H7. These strains are normal in cattle but cause bloody diarrhea in humans. A complication of approximately 10% of cases is a potentially fatal disease known as hemolytic uremic syndrome. The virulence of these strains involves the close attachment of bacteria to epithelial cells lining the colon, resulting in alteration of the epithelial cell structure, and the production of Shiga toxin. The toxin enters the bloodstream after being absorbed in the colon and damages the endothelial cells lining the blood vessels of the colon, resulting in bloody diarrhea. In cases of hemolytic uremic syndrome, the toxin circulating in the blood damages blood vessels in the kidney, resulting in kidney failure and anemia. Enterohemorrhagic *E. coli* are acquired by the ingestion of undercooked beef, uncooked vegetables, or unpasteurized juices from fruits which have been contaminated with the feces of infected cattle. An infection can also be acquired from contact with a human infected with the organism and from contaminated water. Children and the elderly are at greatest risk of developing hemolytic uremic syndrome.

Other strains which are pathogenic in the human colon include the enteroinvasive *E. coli* (including *Shigella*) and the enteropathogenic *E. coli*. Enteroinvasive *E. coli* cause a disease called bacillary dysentery characterized by bloody diarrhea. Enteropathogenic *E. coli* have been associated with protracted diarrhea in infants and can occasionally cause severe wasting. *See* DIARRHEA; TOXIN. [S.L.M.]

Esker A sinuous ridge composed predominantly of sand and gravel deposited by glacial meltwater. Eskers vary in degree of continuity, and range in size from a few meters (1 m = 3.3 ft) to tens of meters high and from a few meters to a hundred or more kilometers long. They have steep ice-contact slopes and were deposited in channels confined by ice. Most eskers generally parallel the direction of ice flow, and while most follow valleys and have a normal down-drainage slope, some trend up a regional or local slope. [W.H.J.]

Esophagus A section of the alimentary canal that is interposed between the pharynx and the stomach. Because of divergent specializations in the various vertebrates, the esophagus cannot be described in general terms and is not always distinguishable.

In humans it is a tube running the full length of the neck and the thorax, held in its position ventral to the vertebral centra by a tunica adventitia of loose connective tissue. It has an inner lining of folded mucous membrane with an exceptionally thick lamina propria, a submucosa of elastic and collagenous connective tissue, and two layers of muscle. The musculature is striated in the anterior third of its length, unstriated in the posterior third, and variably intermixed in the middle. It is supplied with autonomic nerve fibers.

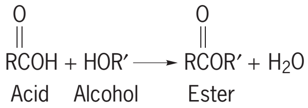
Although normally collapsed, the human esophagus is capable of considerable distension during the rapid passage of swallowed material, under which condition the folds of mucous membrane and lamina propria are temporarily smoothed out. Numerous microscopic esophageal glands open into the lumen, extending their compound tubules out into the submucosa.

In humans the transition from the esophagus to the stomach occurs quite abruptly at the diaphragm. The pharynx narrows posteriorly like a funnel and the foregut may thereupon enlarge, but much of what appears to be stomach may have an esophageal character histologically. *See* DIGESTIVE SYSTEM. [W.W.B.]

Essential oils Volatile, fragrant oils obtained from plants. Essential oils are distinguished from those known as fixed oils, which are mainly triglycerides of fatty acids. Essential oils have been obtained from over 3000 plants and are designated and defined by the plant species and sometimes the geographical location. The sources of these oils are diverse, including flower petals (for example, rose and jasmine), spices (cinnamon and ginger), pine oil and turpentine, and citrus fruit peels. Compounds present in the juice that may contribute to the distinctive flavor of a fruit or berry are not, strictly speaking, components of the essential oil. Chemically, essential oils are extremely complex mixtures containing compounds of every major functional-group class. The oils are isolated by steam distillation, extraction, or mechanical expression of the plant material; often only certain parts, such as roots, buds, leaves, or flower petals, are used.

Essential oils have been produced and used for flavoring, incense, and medicinal purposes for many centuries. [J.Mo.]

Ester The product of a condensation reaction (esterification) in which a molecule of an acid unites with a molecule of alcohol with elimination of a molecule of water as shown in the following reaction.



$$\mathrm{R\overset{O}{\overset{\|}{C}}OH + HOR' \longrightarrow R\overset{O}{\overset{\|}{C}}OR' + H_2O}$$

At one time it was thought that esterification was analogous to neutralization, and esters are still named as though they are “alkyl salts” of carboxylic acids.

Esters are generally insoluble in water and have boiling points slightly higher than hydrocarbons of similar molecular weight.

Ethyl and butyl acetates are volatile industrial solvents, used particularly in the formulation of lacquers. Higher-boiling esters such as butyl phthalate are used as softening agents (plasticizers) in the compounding of plastics. The natural waxes of biological origin are largely simple esters. For example, a principal component of beeswax is myricyl palmitate. *See* SOLVENT; WAX, ANIMAL AND VEGETABLE.

Esters of cellulose (cellulose triacetate) are used in photographic film, as a textile fiber (acetate rayon), and several have become important as thermoplastic materials. Cellulose nitrate, called celluloid pyroxylin, forms celluloid, dynamite cotton, and gun cotton. Cordite and ballistite are made from gun cotton. Dimethyl and diethyl sulfates (esters of sulfuric acid) are excellent agents for alkylating organic molecules that contain labile hydrogen atoms, for example, starch and cellulose.

Esters of unsaturated acids, for example, acrylic or methacrylic acid, are reactive and polymerize rapidly, yielding resins; thus, methyl methacrylate yields a polymethyl methacrylate resin (Lucite). Analogously, esters of unsaturated alcohols are reactive and readily react with themselves; thus, vinyl acetate polymerizes to polyvinyl acetate.

Many low-molecular-weight esters have characteristic, fruitlike odors: banana (isoamyl acetate), rum (isobutyl propionate), and pineapple (butyl butyrate). These esters are used to some extent in compounding synthetic flavors and perfumes. *See* ALCOHOL; CARBOXYLIC ACID; DRYING OIL; FAT AND OIL; POLYESTER RESINS. [P.E.F.]

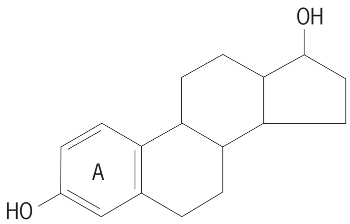
Estimation theory A branch of probability and statistics concerned with deriving information about properties of random variables, stochastic processes, and systems based on observed samples. Some of the important applications of estimation theory are found in control and communication systems, where it is used to estimate the unknown states and parameters of the system.

The estimation problem for dynamic systems may be divided into two parts: parameter estimation and state estimation. The basic difference between a parameter and the state is that the former either does not change at all or changes slowly in time, whereas the latter continuously evolves in time. For example, the state of a satellite is a six-dimensional vector consisting of three position variables and three velocity variables along the axes of an orthogonal coordinate system. The parameters of the satellite are its mass, inertia, and so on. In many control and communication problems, some of the system parameters are not known with desired accuracy. The problem of estimating these parameters from observed data is called parameter identification, though it is basically a problem of estimation. The more general problem of developing a mathematical model of the system from observed data is called system identification. On the other hand, the problem of state estimation is described by names such as signal processing, filtering, and smoothing. The problem belongs to the theory of stochastic processes and is also commonly known as time series analysis. *See* STOCHASTIC PROCESS.

Three basic approaches used for estimation are least-squares, maximum-likelihood, and Bayesian. An estimator is defined as a function of the observations possessing certain desirable properties such as unbiasedness, consistency, and minimum variance. A Kalman filter provides estimates that are optimal in the least-squares, maximum-likelihood and Bayesian sense for a Gauss-Markov model. (A stochastic process is Markov if, given its present state, its future is independent of its past.)

Since their introduction in 1960, Kalman filters and their extensions have found numerous applications. Initially, these filters were developed for space applications such as satellite orbit determination, inertial navigation, Apollo lunar landing module guidance, and so on. The applications to power systems and industrial processes were developed shortly thereafter. Kalman filters have been used for forecasting, water quality prediction, hurricane tracking, aircraft landing systems, and stochastic control. *See* CONTROL SYSTEMS; FLIGHT CONTROLS; GUIDANCE SYSTEMS; PROCESS CONTROL; STATISTICS; SYSTEMS ENGINEERING. [R.K.M.]

Estrogen A substance that maintains the secondary sex characters and organs, such as mammary glands, uterus, vagina, and fallopian tubes, of mammalian females. Naturally occurring substances with this activity are steroid hormones. The principal estrogenic hormone substances are 17(ß)-estradiol (with the structure shown), estrone, and estriol. They are produced and secreted directly into the bloodstream by the ovary, testis, adrenal, and placenta of pregnancy. Two other naturally occurring estrogenic hormones, equilin and equilenin, have been obtained only from the urine of pregnant mares and are apparently peculiar to that species. Stilbestrol, a synthetic compound with considerable estrogenic activity, has been used extensively in medical practice. *See* HORMONE; STEROID. [R.I.D.]



Estrus The period in mammals during which the female ovulates and is receptive to mating. It is commonly referred to as rut or heat. From one estrus period to the next there occurs a series of changes, particularly in the ovary, uterus, and vagina, termed the estrous cycle. With reference to the ovary, the cycle can be divided into a follicular phase, during which the Graafian follicles are ripening, and a luteal phase, during which the corpora lutea develop in the ovulated follicles. During these two phases, mainly estrogen and progesterone, respectively, are secreted, and these hormones control the uterine and vaginal changes. The beginning of the follicular phase is termed proestrus, and the luteal phase metestrus. Following the latter, there is a period of relatively little change, termed diestrus. In species in which the latter is prolonged, it is termed anestrus. *See* ESTROGEN; OVUM; REPRODUCTION (ANIMAL). [A.T.; H.L.H.]

Estuarine oceanography The study of the physical, chemical, biological, and geological characteristics of estuaries. An estuary is a semienclosed coastal body of water which has a free connection with the sea and within which the sea water is measurably diluted by fresh water derived from land drainage. Many characteristic features of estuaries extend into the coastal areas beyond their mouths, and because the techniques of measurement and analysis are similar, the field of estuarine oceanography is often considered to include the study of some coastal waters which are not strictly, by the above definition, estuaries. Also, semienclosed bays and lagoons exist in which evaporation is equal to or exceeds freshwater inflow, so that the salt content is either equal to that of the sea or exceeds it. Hypersaline lagoons have been termed negative estuaries, whereas those with precipitation and river inflow equaling evaporation have been called neutral estuaries. Positive estuaries, in which river inflow and precipitation exceed evaporation, form the majority, however.

Within estuaries, the river discharge interacts with the sea water, and river water and sea water are mixed by the action of tidal motion, by wind stress on the surface, and by the river discharge forcing its way toward the sea. There is a small difference in salinity between river water and sea water, but it is sufficient to cause horizontal pressure gradients within the water which affect the way it flows. Salinity is consequently a good indicator of estuarine mixing and the patterns of water circulation.

Estuarine ecological environments are complex and highly variable when compared with other marine environments. They are richly productive, however. Because of the variability, fewer species can exist as permanent residents in this environment than in some other marine environments, and many of these species are shellfish that can easily tolerate short periods of extreme conditions. Motile species can escape the extremes. A number of commercially important marine torms are indigenous to the estuary, and the environment serves as a spawning or nursery ground for many other species. *See* MARINE ECOLOGY.

The patterns of sediment distribution and movement depend on the type of estuary and on the estuarine topography. The type of sediment brought into the estuary by the rivers, by erosion of the banks, and from the sea is also important; and the relative importance of each of these sources may change along the estuary. Fine-grained material will move in suspension and will follow the residual water flow, although there may be deposition and re-erosion during times of locally low velocities. The coarser-grained material will travel along the bed and will be affected most by high velocities and, consequently, in estuarine areas, will normally tend to move in the direction of the maximum current. [K.R.D.]

Ether One of a class of organic compounds characterized by the structural feature of an oxygen atom linking two hydrocarbon groups, R—O—R′. Ethers are used widely as solvents, both in chemical manufacture and in the research laboratory.

The hydrocarbon radicals R and R′ may be identical (simple ether) or different (mixed ether). They may be aromatic or aliphatic, and the names of the ethers correspond to the hydrocarbon groups present. Thus, CH_3—O—CH_3 is methyl ether, rarely dimethyl ether, and C_6H_5—O—CH_3 is phenyl methyl ether.

Simple ethers may be considered to be the anhydrides of alcohols and are manufactured from alcohols by catalytic dehydration, as in reaction (1), or from olefins by controlled catalytic hydration, as in reaction (2).

$$2\mathrm{ROH} \rightarrow \mathrm{ROR} + \mathrm{H_2O} \tag{1}$$

$$2\mathrm{CH_3CH{=}CH_2} + \mathrm{HOH} \rightarrow \mathrm{(CH_3)_2\,CH{-}O{-}CH(CH_3)_2} \tag{2}$$

Ethers are less soluble in water than are the corresponding alcohols, but are miscible with most organic solvents. Low-molecular-weight ethers have a lower boiling point than the corresponding alcohols, but for those ethers containing radicals larger than butyl, the reverse is true. Inertness at moderate temperatures, an outstanding chemical characteristic of the saturated alkyl ethers, leads to their wide use as reaction media.

The best known of the ethers is ethyl ether, sometimes called diethyl ether or simply ether, $CH_3CH_2OCH_2CH_3$. It is used in industry as a solvent and in medicine as an anesthetic. When ethyl ether is used as a solvent, its high volatility can cause loss. However this volatility is advantageous in that the ether can be readily removed from the concentrated or crystallized product. The toxicity to humans is low, and recovery from overexposure is rapid and complete. It readily forms explosive mixtures with air, and on standing in containers which have been opened, it forms dangerous peroxides.

Several cyclic ethers (epoxides) are of special importance and interest. The simplest of these is ethylene oxide or oxirane (**1**), made industrially by the oxidation of ethylene with air over a silver catalyst. Dioxane or 1,4-dioxane (**2**) is prepared by the catalytic dimerization of ethylene oxide. It is used extensively as an industrial solvent. Furan (**3**), made by the decarbonylation of furfural, is the most important ether obtained from an agricultural source. Most of it is hydrogenated to form the useful solvent tetrahydrofuran (**4**). *See* ETHYLENE OXIDE; FURAN.

(4)

Certain large-ring polyethers, the crown ethers, are able to increase the solubility of alkali metal salts in nonpolar organic solvents. Specific metal complexes are formed by these crown ethers with alkali metal cations, the specificity for a given cation depending upon the hole in the middle of the crown ether structure. *See* HETEROCYCLIC COMPOUNDS. [P.E.F.]

Ethology The study of animal behavior. Modern ethology includes many different approaches, but the original emphasis, as expounded by Konrad Lorenz and Niko Tinbergen, was placed on the natural behavior of animals. This contrasted with the focus of comparative psychologists on behavior in artificial laboratory situations such as mazes and puzzle boxes. Ethologists view the naturalistic approach as crucial because it reveals the environmental and social circumstances in which the behavior originally evolved, and prepares the way for more realistically designed laboratory experiments. The approach goes back to the stress that Charles Darwin placed on hereditary contributions to behavior in all species, including humans. Viewing behavior as a product of evolutionary history has helped to elucidate many otherwise puzzling aspects of its biology and has paved the way for the new science of neuroethology, concerned with how the structure and functioning of the brain controls behavior and makes learning possible.

A central concept in classical ethology is that of the innate release mechanism. If a species has had a long history of experience with certain stimuli, especially those involving survival and reproduction, then to the extent that genes affect the ability to attend closely to such stimuli, natural selection leads to adaptations enhancing responsiveness to them. A common first step in the study of these adaptations was investigation of the development of responsiveness to such stimuli in infancy, focusing on situations that the ethologist knew to be especially relevant to survival. The term innate releasing mechanism, set forth by Tinbergen and Lorenz, eschews notions of innate mental imagery and has proved fertile in understanding how genes influence behavioral development, and in focusing attention of neuroethologists on inborn physiological mechanisms that permit learning while encouraging the infant to attend closely to very specific stimuli, the nature of which varies from species to species according to differences in ecology and social organization.

In birds, such as the herring gull, innate release mechanisms are also better thought of as having evolved to guide processes of perceptual learning, rather than to design animals as though they were automata. Learning is as important in the development of the behavior of many animals as in the human species. Yet as the young organism interacts with social and physical environments with which it has evolved adaptive relationships, the course that learning takes in nature is guided and profoundly influenced by the innate predispositions that the organism brings to bear on dealing with the situation.

Perceptions of the external world provide a basis for both thought and action. It is a fundamental axiom of ethology that each organism's brain is armed with genetically determined programs of action which, in their own way, are as predictable and controlled as the genetic programs for developing anatomical structures such as a brain or a face. Ethologists have shown that it is possible to reconcile the need to modify patterns of action on the basis of experience with the possession of basic patterns of action that are coordinated by the brain, innately controlled, and often distinct from species to species. The concept of the fixed action pattern remains fundamental to understanding the development of the ability to act. Innate "motor programs," generated by the brain, are the natural units out of which behavior emerges during development. Each of these programs designates not a single completely stereotyped action, but a range of options which are limited but sufficient that selection among them allows for adjustments through experience. Close study reveals that sometimes the modifiability of actions lies in the potential flexibility of orientation, timing, and sequencing of actions rather than in the basic patterns or coordinations from which complex actions are built up. Thus nervous systems make some behavioral adjustments promptly and easily and others only with much greater difficulty, in harmony with species differences in the requirements for patterns of action as dictated by the species' structure and mode of life. Ethologists have found repeatedly that while social experience is vital in many animals for normal development of actions and responses, animals reared in restricted environments may still develop many units of action that are normal. The animal has to learn, however, how to put them together in an adaptive sequence.

Modern research on the ethology of learning began when Lorenz discovered imprinting in geese. He found that if he led a flock of newly hatched goslings himself they became imprinted on him. When mature, they would court people as though confused about their own species identity. Learning occurred very rapidly and tended to be restricted to a short sensitive phase early in life. The learning is highly focused by genetically determined preferences both to follow a parent-object with particular appearance and emitting species-specific calls, and also to learn most quickly and accurately at a particular stage of development. The interplay between nature (genetic predisposition) and nurture (environmental influence) in learning is displayed especially clearly in imprinting, hence its special interest to biologists and psychiatrists. Indications are that it is not concerned so much with learning about species as with learning to recognize individual parents and kin, both to ensure mating with one's own kind and to avoid incestuous inbreeding.

There are many forms of imprinting. So-called filial imprinting, ensuring that ducklings and goslings follow only their parent, is distinct from sexual imprinting, affecting mate choice in adulthood; the sensitive phases for learning are different in each case. Imprinting-like processes also shape the development of food preferences and abilities to use the Sun and stars in navigation.

Unlike psychological studies of animal learning in the laboratory, which have tended to favor the "blank-slate" view of the brain's contribution to learning, ethology emphasizes the need to understand all aspects of the biology of a species under study before one can hope to understand how the animal learns to cope with the many complexities of individual existence and social living. Thus ethology may lead not only to an understanding of how natural behavior evolves, but also to new insights into how brains help organisms learn to cope with social and environmental problems confronting them as individuals. *See* ANIMAL COMMUNICATION; BEHAVIOR GENETICS; INSTINCTIVE BEHAVIOR. [P.R.M.]

Ethyl alcohol Probably the best known of the alcohols, ethyl alcohol, formula CH_3CH_2OH, is also called alcohol, ethanol, grain alcohol, industrial alcohol, fermentation alcohol, cologne spirits, ethyl hydroxide, and methylcarbinol. Pure ethyl alcohol is a colorless, limpid, volatile liquid which is flammable and toxic and has a pungent taste. It boils at 78.4°C (173°F) and melts at −112.3°C (−170.1°F), has a specific gravity of 0.7851 at 20°C (68°F), and is soluble in water and most organic liquids. It is one of the most important industrial organic chemicals. Ethyl alcohol is produced by chemical synthesis and by fermentation or biosynthetic processes. *See* BIOSYNTHESIS; ORGANIC SYNTHESIS.

Ethyl alcohol is used as a solvent, extractant, antifreeze, and intermediate in the synthesis of innumerable organic chemicals. It is also an essential ingredient of alcoholic beverages.

Various grades of ethyl alcohol are produced, depending on their intended use. U.S. Pharmaceutical (USP XV) grade is the water azeotrope of ethyl alcohol and is 95% ethyl alcohol by volume. National Formulary (NFX) grade is 99+% ethyl alcohol by weight; it is also called absolute, or anhydrous, alcohol. This grade is generally prepared by azeotropic dehydration with benzene and therefore usually contains about 0.5% benzene. Denatured alcohol contains a small amount of a malodorous or obnoxious material to prevent the use of this grade of ethyl alcohol for beverage purposes. *See* AZEOTROPIC MIXTURE.

The major use of ethyl alcohol is as a starting material for various organic syntheses. Bimolecular dehydration of ethyl alcohol gives diethyl ether, which is employed as a solvent, extractant, and anesthetic. Dehydrogenation of ethyl alcohol yields acetaldehyde, which is the precursor of a vast number of organic chemicals, such as acetic acid, acetic anhydride, chloral, butanol, crotonaldehyde, and ethylhexanol. Reaction with carboxylic acids or anhydrides yields esters which are useful in many applications. The hydroxyl group of ethyl alcohol may be replaced by halogen to give the ethyl halides. Treatment with sulfuric acid gives ethyl hydrogen sulfate and diethyl sulfate, a useful ethylating agent. Reaction of ethyl alcohol with aldehydes gives the respective diethyl acetals, and reaction with acetylene produces the acetals, as well as ethyl vinyl ether. Treatment of ethyl alcohol with ammonia produces acetonitrile, which may be reduced to ethylamine. These and other ethyl alcohol-derived chemicals are used in dyes, drugs, synthetic rubber, solvents, extractants, detergents, plasticizers, lubricants, surface coatings, adhesives, moldings, cosmetics, explosives, pesticides, and synthetic fiber resins. [H.J.P.; E.M.M.]

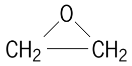
Ethylene A colorless gas, formula $CH_2{=}CH_2$, with a boiling point of −103.8°C (−155°F) and a melting point of −169.4°C (−273°F). Ethylene is the most important synthetic organic chemical in terms of volume, sales value, and number of derivatives. About half of the ethylene produced is used in the manufacture of polyethylene; ethylene dichloride and vinyl chloride production uses about 20%, synthesis of ethylene oxide and derivatives account for about 12%, and styrene production consumes about 8% of the ethylene. Other important derivatives are ethanol, vinyl acetate, and acetaldehyde. Thermal cracking of hydrocarbons in the presence of steam is the most widely used process for producing ethylene.

Polyethylene, the most important derivative of ethylene, is produced by both high- and low-pressure processes to make high- and low-density, high-molecular-weight thermoplastic polymers. Aluminum alkyl catalysts (Ziegler polymerization) are used to polymerize ethylene to relatively low-molecular-weight, straight-chain hydrocarbon derivatives which are convertible to even-numbered-carbon linear olefins, alcohols, and acids. Commercial processes use palladium-catalyzed oxidation of ethylene to produce acetaldehyde, or if acetic acid is used as the solvent, vinyl acetate. Chlorination and oxychlorination processes are used to make vinyl chloride. Ethylene oxide is produced by silver-catalyzed oxidation of ethylene. Acid-catalyzed hydration of ethylene produces ethanol competitively with fermentation processes. *See* Acetylene; Alkene; Ethyl alcohol; Ethylene oxide; Polymer. [R.K.Ba.]

Ethylene glycol A colorless, nearly odorless, sweet-tasting, hygroscopic liquid, formula $HOCH_2CH_2OH$. It is relatively nonvolatile and viscous and is the simplest member of the glycol family. Ethylene glycol freezes at −13°C (8.6°F), boils at 197.6°C (387.7°F), and is completely soluble in water, common alcohols, and phenol. Low molecular weight, low volatility, water solubility, and low solvent action on automobile finishes make ethylene glycol ideal as a radiator antifreeze and coolant. Other uses for this commodity chemical are in polyester resins, explosives, brake and shock-absorber fluids, and alkyl-type resins. *See* Antifreeze mixture; Glycol; Polyester resin.

Dibasic acids or anhydrides react with ethylene glycol to form polyester condensation polymers. Reaction with terephthalic acid or its esters produces polyester resins which can be spun to fibers that find wide use in clothing and general fabrics applications. The polymer also has important film applications. *See* Ethylene oxide; Polyethylene glycol. [R.K.Ba.]

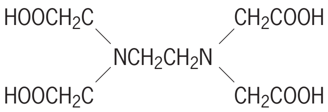
Ethylene oxide The simplest cyclic ether or epoxide, with the formula C_2H_4O, and the structure shown. It is also called epoxyethane and oxirane. Commercial processes use either air or oxygen to oxidize ethylene to ethylene oxide. *See* Ether; Ethylene; Heterocyclic compounds.



Ethylene oxide is a colorless gas boiling at 10.4°C (50.7°F) and melting at −112°C (−169.6°F). Its vapors are flammable and explosive, and it is considered a relatively toxic liquid and gas. It is miscible in all proportions with water, alcohols, ethers, and other organic solvents.

About 50% of the ethylene oxide produced is converted to ethylene glycol; about 30% is used in the manufacture of nonionic surfactants, glycol ethers, and ethanolamines. Gaseous ethylene oxide in CO_2 or difluoromethane is used as a fumigant and a sterilizing agent for medical equipment. *See* Ethylene glycol. [R.K.Ba.]

Ethylenediaminetetraacetic acid A chelating agent for metallic ions, abbreviated EDTA. The structural formula is shown below. Tetrasodium EDTA is the most common form in commerce, but other metallic chelates are marketed, for example, iron, zinc, and calcium. Tetrasodium EDTA is a white solid, very soluble in water and forming a basic solution. Prepared from ethylenediamine, formaldehyde, and sodium cyanide in basic solution, or from ethylenediamine and sodium chloroacetate, EDTA is a strong complexing and chelating agent. It reacts with many metallic ions to form soluble chelates. As such, it is widely used in analysis to retain alkaline earths and heavy metals in solution. The iron chelate is useful in lawn management and gardening as a replacement for ferrous sulfate (copperas). Calcium EDTA is used to control the deterioration of natural seawater in aquariums. Calcium disodium salt of EDTA is used in pharmaceuticals to prevent calcium depletion of the body during therapy. *See* Chelation; Coordination complexes. [F.W.]



Eucalyptus A large and important genus of Australian forest trees; includes about 500 species in the family Myrtaceae. Only two species occur naturally outside Australia in the adjacent islands. Eucalypts occur throughout Australia except in coastal tropical and subtropical rainforests in Queensland and New South Wales and in temperate rainforests in Victoria and Tasmania. They are confined to water courses in the extensive arid zones of central and northwest Australia. Eucalypts grow from sea level to tree line (6600 ft or 2000 m). Because of its large geographic range the genus exhibits many habits, from tall trees to multistemmed, shrubby species called mallees.

Eucalyptus is an evergreen genus with four different leaf types—seedling, juvenile, intermediate, and adult—depending on plant maturity. Juvenile leaves of some species, particularly those that are silvery blue and oval, are extensively used for floral decorations. Most species have white or cream flowers. Some species, particularly those from Western Australia, are planted widely as ornamentals.

Eucalypts have been planted widely for commercial use in Brazil and other South American countries, Africa, the Indian subcontinent, and the Middle East. They are used extensively for fuel and construction and are an important component of third world economies. Foliage of some species yields essential oils for medicines and perfumes. Tannins are extracted from the bark of certain species. *See* Essential oils; Myrtales; Tree. [R.L.E.]

Eucarida The largest and most highly evolved superorder of the crustacean class Malacostraca. It contains the orders Euphausiacea, Amphionidacea, and Decapoda; alternatively, the orders Pygocephalomorpha (fossil), Lophogastrida, Mysida, Euphausiacea, Amphionidacea, and Decapoda are recognized. Despite the great morphological and ecological diversity of eucaridans given either classification, all share (1) a well-developed carapace that is fused to all the thoracic somites; (2) stalked and movable eyes, although in a few these have been secondarily reduced; (3) mandibles that lack a mobile element between the incisor and molar processes (except Mysidacea); (4) a telson without a caudal furca; (5) heart and gills that are thoracic in position; and (6) typically metamorphic larval development. *See* Amphionidacea; Crustacea; Decapoda (Crustacea); Euphausiacea; Malacostraca; Mysidacea. [P.A.McL.]

Euclidean geometry The chief subject matter of the monumental 13-volume work called *The Elements*, written about 300 B.C. by the Greek mathematician Euclid, who taught and founded a school of geometry at Alexandria. One of the milestones in the history of scientific thought, these books of Euclid still occupy an important position in mathematical instruction today.

Geometry, as developed in Euclid, was a systematic body of mathematical knowledge, built by deductive reasoning upon a foundation of three main pillars: (1) definitions of such things as points, lines, planes, angles, circles, and triangles; (2) the assumption of certain geometrical postulates regarded as true but perhaps not self-evident; and (3) the assumption of certain axioms or common notions which were taken to be self-evident truths. The body of Euclid's great work consists of a set of propositions or theorems, each derived systematically and logically from the definitions, axioms, and postulates of his foundation and from theorems already proved.

Five postulates may be paraphrased as:

1. A unique straight line can be drawn from any point to any other point.
2. A finite straight line can be extended continuously in either direction in a straight line.
3. A circle can be described with any given center and radius.
4. All right angles are equal.
5. If a straight line falling on two straight lines makes interior angles on the same side with a sum less than two light angles, the two straight lines, if produced indefinitely, meet on that side on which the angle sum is less than two right angles.

This fifth postulate is known as the parallel postulate and is essentially equivalent to the statement that "a unique line parallel to a given line can be constructed through any point not on the line." For 2000 years many unsuccessful attempts were made to prove that this postulate was a consequence of Euclid's other postulates, definitions, and axioms. Only as recently as the nineteenth century did N. I. Lobachevski (1793–1856), J. Bolyai (1802–1860), and G. F. B. Riemann (1826–1866) show that the parallel postulate was independent of the others, by constructing so-called noneuclidean geometries in which the fifth postulate is not valid.

Certain axioms were stated by Euclid and treated as self-evident truths.

1. Things which are equal to the same thing are equal to each other.
2. If equals be added to equals, the wholes are equal.
3. If equals be subtracted from equals, the remainders are equal.
4. Things which coincide with one another are equal to one another.

A fifth axiom, ascribed by Proclus to Euclid, is believed to have been added by later writers.

5. The whole is greater than the part.

The last has also been replaced by the statement: The whole is equal to the sum of its parts.

The first six books of Euclid include most of the subject matter commonly taught in high school geometry. Book 1, after listing a large number of definitions and the postulates and axioms described above, contains 48 propositions, including many properties relating to perpendicular and parallel lines, angles, and congruent triangles, and the book culminates with the important Pythagorean theorem.

Book 2 contains 14 propositions on geometrical algebra, establishing relationships between the areas of certain related squares and rectangles. Book 3 deals with circles, chords, inscribed angles, and other figures related to the circle; book 4 with inscribed and circumscribed circles and polygons; book 5 with ratios; and book 6 with areas and similar triangles. Books 7, 8, 9, and 10 are concerned with number theory, square and cube roots, and incommensurable magnitudes; books 11 and 12 are concerned with solid geometry and mensuration; and book 13 is concerned with extreme and mean ratio and the five regular solids. *See* DIFFERENTIAL GEOMETRY; POLYHEDRON; PROJECTIVE GEOMETRY; SOLID (GEOMETRY). [J.S.F.]

Eucoccida The most important order of the protozoan subclass Coccidia. In this group there is alternation of asexual and sexual phases of the life cycle, and the parasitic stages occur within the cells of vertebrates or invertebrates. There are three suborders.

In the suborder Adeleina, the macrogamete and microgametocyte are joined during development (syzygy) and the microgametocytes produce only a few microgametes. Members of this suborder are parasites of invertebrates and lower vertebrates; a few even occur in higher vertebrates.

In the suborder Eimeriina, there is no syzygy and the microgametocytes produce a large number of microgametes. This group contains several hundred species of coccidia, most of which occur in the intestinal cells of vertebrates.

In the suborder Haemosporina, there is no syzygy and the microgametocytes produce a moderate number of microgametes. Asexual development takes place in the blood cells of vertebrates, and sexual development in blood-sucking insects or mites. This suborder contains *Plasmodium*, species of which cause malaria in humans, lower primates, birds, and other vertebrates. *See* COCCIDIA; MALARIA; PROTOZOA. [N.D.L.]

Eucommiales An order of flowering plants, division Magnoliophyta (Angiospermae), in the subclass Hamamelidae of the class Magnoliopsida (dicotyledons). The order consists of a single family, genus, and species, *Eucommia ulmoides*, of China. It is a simpleleaved tree with reduced, solitary flowers that lack a perianth, and leaves without stipules, the paired basal appendages found on many leaves. *See* HAMAMELIDAE; MAGNOLIOPSIDA. [A.Cr.]

Eudicotyledons One of the two major types of flowering plants (angiosperms), characterized by possession of three apertures in their pollen; the other major type is magnoliids. Although this difference in pollen development and form has been known for a long time, it has become clear, as a result of several studies of deoxyribonucleic acid (DNA) sequences, that this difference is very significant. The high degree of coincidence of the genetic data with this pollen distinction means that it is more important to recognize this distinction than the number of seed leaves, as previously thought. *See* DICOTYLEDONS; FLOWER; MAGNOLIALES; MONOCOTYLEDONS. [M.W.C.; M.F.F.]

Euechinoidea A subclass of Echinoidea (sea urchins, sand dollars, and heart urchins) in which the test plates are consistently arranged in double rows or columns. Five double rows bear the tube-feet (the ambulacral rows), and these alternate with five which do not (the interambulacral rows). *See* ATELOSTOMATA; DIADEMATACEA; ECHINACEA; ECHINODERMATA; ECHINOIDEA. [A.C.C.]

Eugenics The study of factors that influence the hereditary qualities of future generations. It may be thought of as both a science and a social movement. Eugenics proposes to improve humanity's future by increasing the number of children produced by persons who are, by some definition, superior and by reducing the number produced by persons who are physically or mentally deficient. Attempts to encourage larger families from superior parents are called positive eugenics, attempts to reduce the number of children from defective parents negative eugenics.

There have been a number of proposals regarding negative eugenics in the United States. Several of the states have laws providing for sterilization of persons with severe mental or physical defects. Segregation of persons in public institutions also has the effect of reducing the number of births. Finally there is the advocacy of greater use of contraceptives by persons likely to transmit hereditary weaknesses. Positive eugenics has consisted largely of exhortations for the well endowed to have more children.

Such eugenic proposals have not had complete acceptance. There are objections on religious grounds. There are those who think that eugenic laws, particularly if they involve compulsory sterilization, are an unwarranted infringement on basic human rights. A different reservation comes from those who point out that knowledge of human heredity is not very complete and that prediction of the attributes of children from their parents is not very exact.

The spectacular success of cellular and molecular genetics and the possibility of directly changing, replacing, or otherwise influencing the deoxyribonucleic acid (DNA) in bacteria and viruses have led to considerable speculation about what humans can do to their heredity if and when the techniques known for microbes become available. However, such possibilities are still very much in the future, nobody knows how far away. *See* HUMAN GENETICS. [J.F.Cr.]

Euglenida An order of the class Phytamastigophorea. This order of protozoans, also known as Euglenoidina, includes the largest green noncolonial flagellates, *Euglena ehrenbergii*, which are 400 micrometers long. Many of the colorless members are also large. They have one or two equal or subequal flagella. There are relatively few genera of Euglenida. *See* PHYTAMASTIGOPHOREA.

Euglenids generally show an anteroposterior elongation; however, *Trachelomonas volvocina* is practically spherical, and

Euglena acus is extremely needlelike. Many are enclosed in a thick pellicle which is sculptured into keels. The pellicle is sometimes ornamented with striae or small wartlike protuberances. Colony formation is restricted to *Colacium*, in which a flagellated euglenoid cell usually attaches to a copepod by its anterior end and develops into an arboroid structure of several nonflagellated cells. Tests or shells are common.

Euglenids have two distinguishing features. They synthesize a starchlike polysaccharide, paramylum; and they have a gullet-reservoir system.

In habitat the Euglenida are widespread. Green members occur mostly in fresh water and frequently in such numbers as to form blooms. Unlike the Phytomonadida, the Euglenida appear in warmer waters but do not seem to occur in hot springs. They abound in citrus-waste lagoons and in later stages of sewage-treatment waters, an indication of their partially saprozoic nutrition. *See* MASTIGOPHORA; PROTOZOA. [J.B.L.]

Euglenophyceae A class coextensive with the division Euglenophycota, comprising unicellular colorless or photosynthetic flagellates with very distinctive cytological characters. In protozoological classification, these organisms constitute an order, Euglenida, of the class Phytomastigophora. Although photosynthetic euglenoids are like Chlorophycota in containing chlorophyll *a* and *b*, in most other respects they are so different from those algae as to suggest an independent phylogenetic origin of their pigments. About 1000 species have been described and classified into about 40 genera and 6 orders. *See* EUGLENIDA.

Most euglenoids are free-swimming and have two flagella, one of which may be nonemergent, arising from an anterior invagination known as a reservoir. Photosynthetic euglenoids contain one to many grass-green chloroplasts, which vary from minute disks to expanded plates or ribbons. Colorless euglenoids depend on osmotrophy or phagotrophy for nutrient assimilation.

Euglenoids are found most commonly in fresh water rich in organic matter, but they also occur in marine or brackish habitats, on mud or sand, and in ice or snow. A few species prefer very acidic water. [P.C.Si.; R.L.Moe]

Eugregarinida An order of the subclass Gregarinia. These protozoans are common parasites of invertebrates such as the arthropods and annelids. Only sexual reproduction occurs in the life history of these animals; schizogony is lacking. This order is divided into the suborders Cephalina and Acephalina. In North America grasshoppers of the genus *Melanoplus* are commonly the host for the cephaline *Gregatina rigida*, inhabiting the lumen of the gut. *See* GREGARINIA; INVERTEBRATE PATHOLOGY; PROTOZOA. [E.R.B./N.D.L.]

Eukaryotae The vast array of living and fossil organisms comprising all taxonomic groups above the primitive unicellular prokaryotic level typified by the bacteria. The Eukaryotae thus include all plants and animals, the unicellular protists, and the fungi.

All organisms in this group possess an organized nucleus (or nuclei) in their cells, with a surrounding nuclear envelope and paired deoxyribonucleic acid–containing chromosomes; and elaborate cytoplasmic organelles, such as mitochondria, Golgi bodies, lysosomes, peroxisomes, endoplasmic reticulum, microfilaments and microtubules in various arrays, and, in photosynthetic forms, plastids or chloroplasts. Characteristically, centrioles, cilia, or flagelia are also present, the latter locomotory organelles composed mainly of tubulin with microtubules exhibiting a universal 9 + 2 pattern. *See* CILIA AND FLAGELLA; PROKARYOTAE.

Organization at the organismal level ranges from solitary unicellular to colonial unicellular, mycelial, syncytial (coenocytic), and truly multicellular with extensive tissue differentiation. Modes of nutrition run the gamut: absorptive, ingestive, photoautotrophic, plus combinations of these three major kinds. Life cycles vary tremendously, with haploidy more characteristic of "lower" groups and diploidy of the "higher" taxa. Reproduction, similarly, includes both asexual and sexual methods. In the "higher" multicellular forms, true embryos develop from the diploid zygote stage, which has resulted from fusion of sperm and egg cells.

Aerobic metabolism is commonly exhibited, especially by aquatic and terrestrial forms; anaerobic mechanisms exist, however, for numerous species found in poorly oxygenated habitats, including various sites within bodies of host organisms.

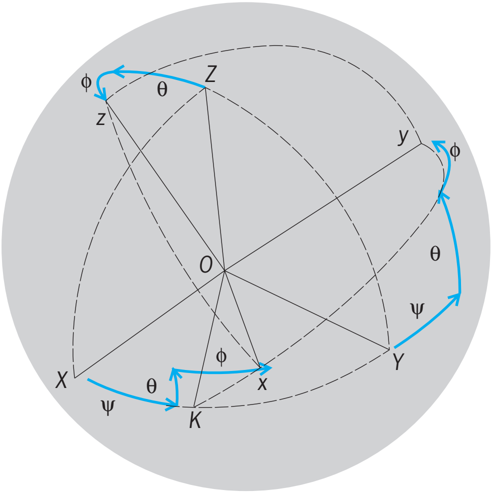
Size of species range from 1 micrometer (certain protozoa and algae) to many meters (whales, trees), Habitats cover all possible ecological niches: aquatic, terrestrial, and aerial, for free-living forms (many of which are motile, with the major exception of the trophic stage of various plants); and in or on all kinds of hosts, for symbiotic or parasitic forms (internal habitats, including cells, tissues, organs, or various body cavities). Dormant stages include cysts, spores, and seeds; these are often involved in dispersion or propagation of the species. *See* ANIMAL KINGDOM; FUNGI; PLANT KINGDOM; PROTOZOA. [J.O.C.]

Euler angles Three angular parameters that specify the orientation of a body with respect to reference axes. They are used for describing rotating systems such as gyroscopes, tops, molecules, and nonspherical nuclei. They are not symmetrical in the three angles but are simpler to use than other rotational parameters.

Unfortunately, different definitions of Euler's angles are used, and therefore it is confusing to compare equations in different references. The definition given here is the majority convention according to H. Margenau and G. Murphy.

Let *OXYZ* be a right-handed cartesian (right-angled) set of fixed coordinate axes and *Oxyz* a set attached to the rotating body (see illustration).

The orientation of *Oxyz* can be produced by three successive rotations about the fixed axes starting with *Oxyz* parallel to *OXYZ*. Rotate through (1) the angle ψ counterclockwise about *OZ*, (2) the angle θ counterclockwise about *OX*, and (3) the angle ϕ counterclockwise about *OZ* again. The line of intersection *OK* of the *xy* and *XY* planes is called the line of nodes.



Euler angles. The successive movements of the axes on a unit sphere described in the text are shown by arrows. The complete rotation may also be obtained by a different sequence of rotations, namely, first through ϕ about *OZ*, then through θ about the displaced x axis (which is *OK*), then through ψ about *OZ*.

Denote a rotation about OZ, for example, by Z (angle). Then the complete rotation is, symbolically, given by the equation below where the rightmost operation is done first.

$$R(\psi, \theta, \phi) = Z(\phi)X(\theta)Z(\psi)$$

[B.G.]

Euler's equations of motion A set of three differential equations expressing relations between the force moments, angular velocities, and angular accelerations of a rotating rigid body. They are equations of motion in the usual dynamical sense, of forms (1)–(3).

$$I_1(d\omega_1/dt) + (I_3 - I_2)\omega_2\omega_3 = M_1 \quad (1)$$

$$I_2(d\omega_2/dt) + (I_1 - I_3)\omega_3\omega_1 = M_2 \quad (2)$$

$$I_3(d\omega_3/dt) + (I_2 - I_1)\omega_1\omega_2 = M_3 \quad (3)$$

The formulation employs as coordinate axes the three principal axes of rotational inertia of the body that can rotate about a body-fixed point, which is the center of mass if constraints are absent. These reference axes, which form a righthand set, are indicated by subscripts 1, 2, and 3 in the equations, where I_1, I_2, and I_3 represent the principal moments of inertia; ω_1, ω_2, and ω_3 the angular velocities about the axes; M_1, M_2, and M_3 the corresponding force moments; and t the time. *See* RIGID-BODY DYNAMICS. [R.A.Fi.]

Eumagnoliids An informal set of flowering plant orders that contains Laurales, Magnoliales, Piperales, and Winterales, plus the monocotyledons, and in total contains roughly one-third of angiosperm species. Formerly, many have equated this group (minus the monocotyledons) to the subclass Magnoliidae, but studies of sequences of deoxyribonucleic acid (DNA) have demonstrated that orders such as Nymphaeales and Ranunculales are distantly related to the others and that the monocotyledons are much closer. A formal taxonomy for this group is not yet feasible because until more data are collected the exact relationships of the eumagnoliids to the eudicots are not clear. The eumagnoliids, including the monocotyledons, exhibit a set of characteristics that reflect their relatively close relationships; these include a tendency to trimerous flowers and a suite of chemical compounds restricted to the group. They also have a set of traits that are "primitive" by most estimations; these include vesselless wood, laminar stamens, and laminar placentation. It now seems quite clear that although the eumagnoliids exhibit some primitive traits they are neither the most archaic nor the earliest of angiosperms, and they contain some of the most advanced taxa, such as many of the monocotyledons (grasses, palms, and orchids). *See* LAURALES; LILIOPSIDA; MAGNOLIALES; PIPERALES; PLANT TAXONOMY. [M.W.C.]

Eumalacostraca The major subdivision (subclass) of the crustacean class Malacostraca. It comprises three, four, or five Recent superorders: Syncarida, Peracarida, and Eucarida are most commonly included and are all that are recognized here. However, some carcinologists still insist on ranking the Hoplocarida among eumalacostracans. Acceptance of a separate superorder, Pancarida for the Thermobaenacea, has not received general support, and thermobaenaceans are commonly now included with peracaridan taxa.

Formerly, the concept of the Eumalacostraca as a homogeneous evolutionary unit generated virtually no controversy. The subclass was defined by a series of characters referred to as the caridoid facies: carapace enclosing the thorax; stalked, movable eyes; biramous antennules; scalelike antennal exopod; thoracopods with natatory exopods; abdomen with well-developed, complex musculature designed for flexing it; telson and uropods forming a tailfan; biramous pleopods 1–5; and internal organs primarily excluded from the abdomen. Opponents of the caridoid theory point to the fact that several of these attributes are not restricted to eumalacostracans, and conversely, not all eumalacostracans possess all of them. The carapace, its origin and evolution, has provided the greatest controversy.

The basic body plan common to all eumalacostracans includes a head of five somites, a thorax of eight somites, and an abdomen of six somites, plus a terminal telson. Zero to three pairs of thoracic somites may be fused to the head and their thoracopods and modified to form feeding appendages (maxillipeds). The thorax usually has five to eight pairs of ambulatory or specialized appendages (pereopods); the abdomen may or may not have paired appendages (pleopods) on the first five somites; and the sixth somite usually has a pair of well-developed appendages (uropods). Female gonopores (coxal or sternal) are present at the level of the sixth thoracic somite, while male gonopores are at the level of the eighth.

Two caridoid attributes shared by the majority of eumalacostracans are the strong abdominal musculature and well-developed tailfan. Together with accompanying neural elements, these appear to be designed as a highly efficient propulsion mechanism, that is, an escape reaction.

Most eumalacostracans are dioecious; however, some isopods, tanaids, and a few decapods are hermaphroditic. Fertilization is by means of spermatophores and may be external or internal. *See* CRUSTACEA; EUCARIDA; MALACOSTRACA; PERACARIDA; SYNCARIDA. [P.A.McL.]

Eumycetozoida An order of Mycetozoia. These are slime molds which form a plasmodium, a multinucleate stage that may in some species measure a foot (30 cm) or more across. The plasmodium, typically found on decaying plant material, is a migratory phagotroph preying on microorganisms. A mature plasmodium is a sheet of protoplasm containing a network of channels through which rapid endoplasmic streaming occurs.

Resistant cysts (spores), possibly haploid, are produced in sporangia. Liberated spores hatch into myxoflagellates or myxamebae (which may change into flagellates). Either type may represent gametes, and mating types have been reported in certain species. [R.P.H.]

Eumycota True fungi, a group of heterotrophic organisms with absorptive nutrition, capable of utilizing insoluble food from outside the cell by secretion of digestive enzymes and absorption. Glycogen is the primary storage product of fungi. Most fungi have a well-defined cell wall that is composed of chitin and glucans. Spindle pole bodies, rather than centrioles, are associated with the nuclear envelope during cell division in most species. Typically, the fungal body (thallus) is haploid and consists of microscopic, branched, threadlike hyphae (collectively called the mycelium), which develop into radiating, macroscopic colonies within a substrate or host. The filamentous hypha may be divided by cross walls (septa) into compartments. Hyphal growth is apical. Some species are coenocytic (without cross walls); others, including yeasts, are unicellular. Reproductive bodies are highly variable in morphology and size, and may be asexual or sexual.

Great changes in understanding the phylogenetic relationships of fungi have been brought about by the use of characters derived from deoxyribonucleic acid (DNA) sequences and the use of computer-assisted phylogenetic analysis; these changes are reflected in current classification schemes. A modern classification follows:

Eumycota
  Phylum: Chytridiomycota
  Phylum: Zygomycota
    Class: Zygomycetes
      Trichomycetes
  Phylum: Ascomycota
    Class: Archiascomycetes
      Hemiascomycetes
      Euascomycetes
  Phylum: Basidiomycota

Class: Hymenomycetes
Urediniomycetes
Ustilaginomycetes

Fungi are found in practically every type of habitat. Most are strictly aerobic, although a few are anaerobes that live in the gut of herbivores. Some species are thermophilic. Many fungi form saprobic (including parasitic) relationships with animals and plants; the majority are saprobes. As now recognized, the Eumycota are a monophyletic group of the crown eukaryotes, presumed to have been present in the fossil record 900–570 million years ago. *See* FUNGI; MYXOMYCOTA; OOMYCETES. [M.Bl.]

Euphausiacea A well-defined marine order of the class crustacea. All are shrimplike in appearance. The order contains two families, one with a single species, the other with 84 species divided among 10 genera. Euphausiids are predominantly pelagic organisms, but a few species are neritic. Euphausiids form a significant proportion of the total planktonic biomass.

Euphausiids, with the exception of *Bentheuphausia amblyops*, possess photophores that emit a brilliant blue-green light. The eyes are compound and contain three pigments: a carotenoid (astaxanthin), a melanoid, and a photolabile substance that is probably a visual pigment. Respiration is by means of foliose, digitiform gills located at the bases of the second to eighth thoracic appendages.

The blood is a pale, leukocyte-bearing fluid with hemocyanin as the respiratory pigment. The heart is compact and has two pairs of ostia.

All species are strictly marine and do not occur in freshwater or brackish environments. Species are found in all oceans and seas, with the exception of the brackish Baltic and Black seas. Known as krill to whalers, they constitute the diet of many whales, particularly the whalebone whales. The euphausiids can be processed to yield large quantities of protein. Krill pastes and meal can be manufactured to feed domestic animals or used in therapeutic diets. Krill sausages, krill-stuffed eggs, and shrimp butter are already marketable products in Japan, Russia, and Germany. *See* CRUSTACEA; DECAPODA (CRUSTACEA); MALACOSTRACA. [J.Mau.]

Euphorbiales An order of flowering plants, division Magnoliophyta (Angiospermae), in the subclass Rosidae of the class Magnoliopsida (dicotyledons). The order consists of the large family Euphorbiaceae (about 7500 species) and 3 small satellite families which have fewer than 100 species among them. The Euphorbiales are a group of few-ovulate, mostly simple-leaved Rosidae in which the flowers have become unisexual and then undergone further reduction accompanied by aggregation.

The Christmas poinsettia (*E. pulcherrima*) and the para rubber tree (*Hevea brasiliensis*) are well-known members of the Euphorbiaceae. Many African euphorbiads are spiny stem-succulents which resemble cacti in habit. Aside from the pronounced floral differences, the euphorbiads have a milky juice, which the cacti do not. *See* MAGNOLIOPSIDA; PLANT KINGDOM; ROSIDAE. [A.Cr.; T.M.Ba.]

Europe Although long called a continent, in many physical ways Europe is but a great western peninsula of the Eurasian landmass. Its eastern limits are arbitrary and are conventionally drawn along the water divide of the Ural Mountains, the Ural River, the Caspian Sea, and the Caucasus watershed to the Black Sea. On all other sides Europe is surrounded by salt water. Of the oceanic islands of Franz Josef Land, Spitsbergen (Svalbard), Iceland, and the Azores, only Iceland is regarded as an integral part of Europe; thus the northwestern boundary is drawn along the Danish Strait.

Europe is not only peninsular but has a large ratio of shoreline to land area reflecting a notable interfingering of land and sea. Excluding Iceland, the maximum north-south distance is (3529 mi) (5680 km); and the greatest east-west extent is 2398 mi (3860 km). Of Europe's area of 3,881,000 mi^2 (10,050,000 km^2) 73% is mainland, 19% peninsulas, and 8% islands. Also, 51% of the land is less than 155 mi (250 km) from shores and another 23% lies closer than 310 mi (500 km). This situation is caused by the inland seas that enter, like arms of the ocean, deep into the northern and southern regions of Europe, which thus becomes a peninsula of peninsulas. The most notable of these branching arms of salt water are the White Sea, the North Sea, the Baltic Sea with the Gulf of Bothnia, the English Channel (La Manche), the Mediterranean Sea with its secondary branches, and finally, the Black Sea. Even the Caspian Sea, presently the largest saltwater lake of the world, formed part of the southern seas before the folding of the Caucasus. The penetration of the landmass by these seas brings marine influences deep into the continent and provides Europe with a balanced climate favorable for human evolution and settlement.

Europe has a unique diversity of land forms and natural resources. The relief, as varied as that of other continents, has an average elevation of 980 ft (300 m) as compared with North America's 1440 ft (440 m). The shape and the overall physiographic aspect of the great peninsula are controlled by geologic structure which delimits the major regional units.

Climate is determined by a number of factors. Probably the most important are a favorable location between 35° and 71°N latitudes on the western or more maritime side of the world's largest continental mass; the west-to-east trend (rather than north-south) of the lofty southern ranges and the Central Lowlands, as well as of the inland seas, which permit the prevailing westerly winds of these latitudes to carry marine influences deep into the continent; the beneficial influence of the North Atlantic Drift, which makes possible ice-free coasts far within the Arctic Circle; and the low elevation of the northwestern mountain ranges and the Urals, which allows the free shifting of air masses over their crests.

The intricate relief and the climates of Europe are well reflected in the drainage system. Extensive drainage basins with large slow-flowing rivers are developed only in the Central Lowlands, especially in the eastern part. Streams with the greatest discharge empty into the Black Sea and the North Sea, although Europe's longest river, the Volga, feeds the Caspian Sea. Second in dimension is the Danube, which crosses the Carpathian Basin and cuts its way twice through mountain ranges at the Gate of Bratislava and at the Iron Gate. The Rhine and Rhone are the two major Alpine rivers with headwater sources close to each other but feeding the North Sea and the Western Mediterranean Basin, respectively. Abundant precipitation throughout the year, as well as the permeable soils and the dense vegetation which temporarily store the water, provides the streams of Europe north of the Southern Highlands with ample water throughout the seasons. The combined effects of poor vegetation, rocky and desolate limestone karstlands, and slight annual precipitation result in intermittent flow of the rivers along the Mediterranean coast, especially on the eastern side of peninsulas. Only the Alpine rivers carry enough water, and if it were not for the Danube and Rhone, both originating in regions north of the Alps, the only major river of the Mediterranean basin would be the Po. *See* ATLANTIC OCEAN; BALTIC SEA; BLACK SEA; CONTINENT; MEDITERRANEAN SEA. [G.T.]

Europium A chemical element, Eu, atomic number 63, atomic weight 151.96, a member of the rare-earth group. The stable isotopes, ^{151}Eu and ^{153}Eu, make up the naturally occurring element. The metal is the second most volatile of the rare earths and has a considerable vapor pressure at its melting point. It is very soft, is rapidly attacked by air, and really belongs more to the calcium-strontium-barium series than to the rare-earth series. *See* PERIODIC TABLE.

The element is attractive to the atomic industry, since the elements can be used in control rods and as nuclear poisons. These poisons are materials added to a nuclear reactor to balance the excess reactivity at start-up, and are so chosen that the poisons burn out at the same rate as the excess activity decreases. The television industry uses considerable quantities of phosphors, such as europium-activated yttrium orthovanadates, and other europium-activated yttrium phosphors have been patented. These phosphors give a brilliant red color and are used in the manufacture of television screens. *See* RARE-EARTH ELEMENTS. [F.H.Sp.]

Eurypterida An extinct Paleozoic group of aquatic arthropods, belonging to the subphylum Chelicerata and class Merostomata and thus related to the living marine xiphosurans (horseshoe crabs) and terrestrial arachnids (spiders, scorpions). Although most eurypterids were less than 10 in. (25 cm) in length, some members of the group were the largest arthropods of all time, reaching sizes up to 6 ft (2 m).

The anterior portion of the eurypterid body is the prosoma. The prosoma is covered dorsally by the carapace, which bears a large pair of lateral compound eyes and a small pair of median simple eyes or ocelli. Visible on the ventral surface of the prosoma are six pairs of appendages. The posterior opisthosoma consists of 12 unfused segments and the terminal telson or tail spine.

Eurypterid fossils are found worldwide. The chitinous body of eurypterids is not mineralized, and so fossil remains are rare and generally restricted to a limited number of ancient aquatic environments. Almost all of the approximately 300 described species, belonging to about 65 genera, are from single localities or regions.

Eurypterids were almost exclusively aquatic, although some forms may have been amphibious. A number of forms were dominantly benthonic, but most were active and agile swimmers. Most eurypterids were probably carnivores, although they lacked the ability to crush heavily armored prey. *See* ARTHROPODA. [R.Pl.]

Eustigmatophyceae A small class of nonmotile, photo-synthetic, unicellular algae, segregated from the class Xanthophyceae (Tribophyceae) on the basis of cytological, ultrastructural, and biochemical features of the vegetative cell and zoospore. Because of their lack of chlorophyll *b*, these organisms may be placed in the division Chromophycota, but their lack of chlorophyll *c*, in contrast to other chromophytes, supports recognition at a higher level (such as the division Eustigmatophyta). Only a dozen species in three genera are known. These live chiefly in fresh water, but also in marine habitats and in soil. *See* ALGAE; XANTHOPHYCEAE. [P.C.Si.; R.L.Moe]

Eutardigrada An order of tardigrades, lacking a cirrus lateralis, a sensory cephalic appendage, and a clava, or club-shaped appendage. Pharyngeal pockets are strengthened by separated rods or macroplacoids or are without thickenings. Claws are of different size, arranged in two pairs in which a larger and smaller claw are united. In *Milnesium* the claws are separated. *Haplomacrobiotus* has two simple claws. *See* HETEROTARDIGRADA; TARDIGRADA. [E.M./Ev.M.]

Eutectics The microstructures that result when a solution of metal of eutectic composition solidifies. The eutectic reaction must be distinguished from eutectic microstructures. The eutectic reaction is a reversible transformation of a liquid solution to two or more solids, under constant pressure conditions, at a constant temperature denoted as the eutectic temperature. Microstructures which are wholly eutectic in nature can occur only for a single, fixed composition in each alloy system demonstrating the reaction.

Although technologically important alloy systems, particularly the Fe-C system (all cast irons used commercially pass through a eutectic reaction during solidification), exhibit at least one eutectic reaction, there has been little exploitation of wholly eutectic microstructures for structural purposes. Some eutectic fusible alloys are used as solders, as heat-transfer media, for punch and die mold and pattern applications, and as safety plugs. A silver-copper eutectic alloy is also used for high-temperature soldering applications. *See* SOLDERING.

Directional solidification of eutectic alloys so as to create a microstructure well aligned parallel to the growth direction produces high-strength, multiphase composite materials with excellent mechanical properties. Among the major advantages of these alloys are extraordinary thermal stability of unstressed microstructures, retention of high strength to very close to the eutectic temperature of the respective alloys, and the ability to optimize strength by appropriate alloying additions to induce either solid-solution strengthening or intraphase precipitation of additional phases.

The most likely future applications for aligned eutectics are as gas turbine engine materials (turbine blades or stator vanes) or in nonstructural applications such as superconducting devices in which directionality of physical properties is important. *See* ALLOY; METAL; SOLID SOLUTION. [N.S.S.]

Eutheria A higher-level taxon that includes all mammals except monotremes and marsupials. Eutheria (Placentalia) is variously ranked as an infraclass or cohort within Mammalia. Eutheria includes over 4000 living species arranged in 18 orders; another 12 orders are known only from fossils. An ecologically diverse group, Eutheria includes primates, insectivores, bats, rodents, carnivores, elephants, ungulates, and whales. Like other mammals, eutherians are generally fur-covered and produce milk to nourish their young. In part because they can make their own body heat and regulate their body temperature, eutherians are widely distributed over most continents and occur in all oceans.

Eutherians, often called placental mammals, have a unique reproductive system in which unborn young are nourished for an extended period via a placenta. This system permits retention of the young in the protective environment of the uterus during most of early development. Fetal survival rates are high under most conditions. Young are born in a relatively advanced state of development and are never sheltered in a pouch after birth. Gestation time ranges from 20 days (for example, shrews and hamsters) to 22 months (elephants). Many eutherians have only one or two young per pregnancy, but as many as 20 offspring may be produced at a single birth in some species.

Eutherians range in size from insectivores and bats that weigh only a few grams to blue whales that can weigh over 190,000 kg (420,000 lb). All have a relatively large brain and exhibit complex behavior, with many living in social groups. Eutherians exhibit more variation in ecology than any other group of vertebrates, and these differences are reflected in their morphological specializations.

The fossil record of Eutheria extends back at least into the Cretaceous Period. Several differences in the skull and dentition distinguish fossil eutherians from early members of other mammal lineages (for example, marsupials). The earliest eutherians were apparently small, nocturnal mammals that may have resembled some modern insectivores. Although Cretaceous eutherians are known from most continents, diversification of the modern orders apparently did not occur until the Paleocene and Eocene. *See* ARTIODACTYLA; CETACEA; CHIROPTERA; DENTITION; MAMMALIA; METATHERIA; RAT; THERIA. [N.B.S.]

Eutrophication The deterioration of the esthetic and life-supporting qualities of lakes and estuaries, caused by excessive fertilization from effluents high in phosphorus, nitrogen, and organic growth substances. Algae and aquatic plants become excessive, and, when they decompose, a sequence of objectionable features arise. Water supplies drawn from such lakes must be filtered and treated. Diversion of sewage, better utilization of manure, erosion control, improved sewage treatment and harvesting of the surplus aquatic crops alleviate the symptoms. Prompt public action is essential. *See* Water conservation; Water pollution. [A.D.H.]

Evaporation The process by which a liquid is converted into a vapor. In the liquid phase, the substance is held together by intermolecular forces. As the temperature is raised, the molecules move more vigorously, and in increasingly high proportion have sufficient energy to escape from their neighbors. Evaporation is therefore slow at low temperatures but faster at higher temperatures. In an open vessel, the molecules escape from the vicinity of the liquid, and there is a net migration from the liquid to the atmosphere. In a closed vessel, net evaporation continues until the number of molecules in the vapor has risen to the stage at which the rate of return from the vapor to the liquid is equal to the rate of evaporation. At this stage there is a dynamic equilibrium between the liquid and its vapor, with evaporation and its reverse, condensation, occurring at the same rate. The pressure of the vapor in the closed vessel is called the vapor pressure of the substance; its value depends on the temperature. Boiling occurs in an open vessel (but not in a closed vessel) when the vapor pressure is equal to the ambient pressure. *See* Boiling point; Kinetic theory of matter; Vapor pressure.

Evaporation is an endothermic (heat-absorbing) process because molecules must be supplied with energy to overcome the intermolecular forces. The enthalpy of vaporization, $\Delta_{\text{vap}}H$ (formerly, the latent heat of vaporization) is the heat required at constant pressure per mole of substance for vaporization. The entropy of vaporization, $\Delta_{\text{vap}}S$, at the boiling point, T_b, is equal to $\Delta_{\text{vap}}H/T_b$. According to Trouton's rule, for many liquids the entropy of vaporization is close to 85 J/K · mol. This value reflects the similar change in disorder that occurs when a liquid is converted into a gas. However, certain liquids (water and mercury among them) are more structured than others, and have a bigger entropy of vaporization than Trouton's rule suggests. *See* Enthalpy; Entropy; Thermodynamic principles.

Volatile liquids evaporate more rapidly than others at the same temperature. Such liquids have relatively weak intermolecular forces. In general, the rate of evaporation depends on the strengths of the intermolecular forces and the rate at which heat is supplied to the liquid. *See* Intermolecular forces; Liquid. [P.W.A.]

Evaporator A device used to vaporize part or all of the solvent from a solution. The valuable product is usually either a solid or a concentrated solution of the solute. If a solid, the heat required for evaporation of the solvent must have been supplied to a suspension of the solid in the solution, otherwise the device would be classed as a drier. The vaporized solvent may be made up of several volatile components, but if any separation of these components is effected, the device is properly classed as a still or distillation column. When the valuable product is the vaporized solvent, an evaporator is sometimes mislabeled a still, such as water still, and sometimes is properly labeled, such as boiler-feedwater evaporator. In the great majority of evaporator installations, water is the solvent that is removed. *See* Distillation.

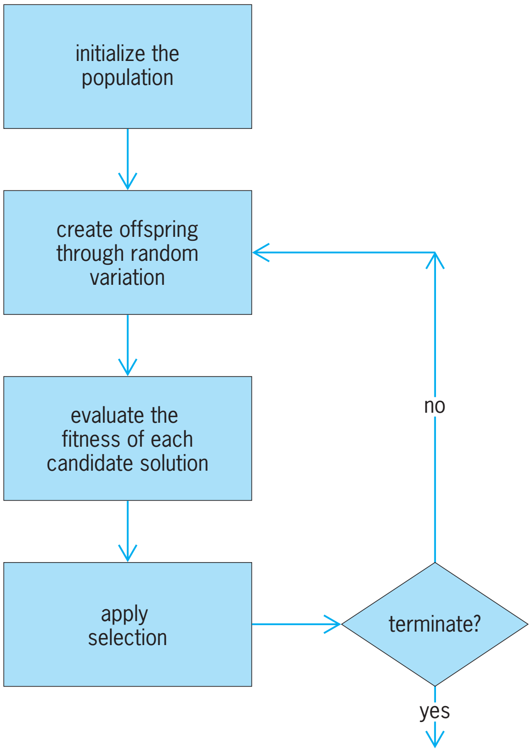
Evaporators are used primarily in the chemical industry. For example, common salt is made by boiling a saturated brine in an evaporator. The salt precipitates as a solid in suspension in the brine. This slurry is pumped continuously to a filter, from which the solids are recovered and the liquid portion returned for further evaporation. Evaporators are widely used in the food industry, usually as a means of reducing volume to permit easier storage and shipment. Evaporators are also the most commonly used means of producing potable water from sea water or other contaminated sources.

The vaporization of solvent requires large amounts of heat. Provisions for transferring this heat to the solution constitute the largest element of evaporator cost and the principal means of distinguishing between types of evaporators. Practically all evaporators fall into one of the following categories:

1. Submerged-combustion evaporators: those heated by a flame that burns below the liquid surface, and in which the hot combustion gases are bubbled through the liquid.
2. Direct-fired evaporators: those in which the flame and combustion gases are separated from the boiling liquid by a metal wall, or heating surface.
3. Stem-heated evaporators: those in which steam or other condensable vapor is the source of heat, and in which the steam condenses on one side of the heating surface and the heat is transmitted through the wall to the boiling liquid. *See* Evaporation. [F.C.S.]

Evergreen plants Plants that retain their green foliage throughout the year. Popularly, needle-leaved trees (pine, fir, juniper, spruce) and certain broad-leaved shrubs (rhododendron, laurel) are called evergreens. In warm regions many broad-leaved trees (magnolia, live oak) are evergreen, and in the tropics most trees are evergreen and nearly all have broad leaves. Many herbaceous biennials and perennials have basal rosettes with leaves close to the ground that remain green throughout the winter. *See* Forest and forestry; Leaf; Plant taxonomy. [N.A.]

Evolutionary computation A rapidly growing interdisciplinary science area that is concerned with modeling aspects of natural evolution in order to solve real-world problems. Living organisms, as well as those long extinct, demonstrate optimized complex behavior at all levels: cells, organs, individuals, and populations. Charles Darwin wrote of "organs of extreme perfection" when describing the ability of evolution to craft ingenious solutions to complex problems such as vision. Evolution is the great unifying principle of biology, but it extends beyond biology and can be used as an engineering principle where individuals in a population of candidate solutions to some particular problem undergo random variation (mutation and recombination) and



Typical flowchart for an evolutionary algorithm.

face competition and selection based on their appropriateness for the task at hand.

The common use of an evolutionary algorithm requires four elements: (1) an evaluation (fitness) function that describes the quality of any candidate solution in quantitative terms, (2) a representation or data structure that the computer uses to store solutions, (3) a random variation operator (or operators) that transform "parents" into "offspring," and (4) a means for selecting which solutions will survive to the next generation and which will be eliminated. In addition, the process must be initialized with a population of candidate solutions to the task at hand. This is often accomplished by seeding the first population with completely random solutions; however, if domain-specific knowledge is available regarding which solutions may be better than others, these hints can be used to bias the initial population and may accelerate the evolutionary optimization procedure.

An evolutionary algorithm (see illustration) is executed over a series of generations of random variation and selection. The variation to the existing solutions can come in the form of single-parent or multiparent operators. Alternative choices offer different sampling distributions from the space of all possible solutions. Each of the individuals in the population is scored with respect to how well the individual accomplishes the task at hand (fitness), and selection is used to eliminate some subset of the population or to amplify the percentage of above-average solutions. The algorithm terminates when some extrinsic criterion has been satisfied, such as prescribed maximum number of generations, or a suitable error tolerance. Over time, by eliminating poor solutions and extending the evolutionary search around those that appear better, the population can discover superior solutions to complex problems.

In comparison to traditional problem-solving techniques, evolutionary algorithms are often much faster and more adaptable to changes in the environment because whatever knowledge has been learned about how to solve a problem is contained in the collection of individual solutions that has survived up to that point. In contrast with, say, dynamic programming, an evolutionary algorithm need not be restarted when facing new data. This feature promises to have a significant potential in future problem solving. As the spread of data and processing speeds continue to increase, it will be necessary to make decisions ever more quickly. The evolutionary approach of bootstrapping off the current basis set of knowledge may eventually become the standard approach to real-world, real-time problem solving. *See* ALGORITHM; CONCURRENT PROCESSING; DISTRIBUTED SYSTEMS (COMPUTERS); GENETIC ALGORITHMS; MULTIPROCESSING; OPTIMIZATION; ORGANIC EVOLUTION; SUPERCOMPUTER. [D.B.F.]

Exchange interaction

Exchange interaction A quantum-mechanical phenomenon that gives the energy of two elementary particles. Exchange effects arise for all kinds of elementary particles, but these effects were first introduced into physics in consideration of atomic structure and the energy of the electrons in an atom. In this context, they arise as a consequence of two facts: electrons are indistinguishable, and they obey the Pauli exclusion principle. *See* ELEMENTARY PARTICLE.

Indistinguishability demands that the wave function describing two electrons either is unchanged or changes sign when the labels of the two electrons are exchanged (that is, it is either symmetric or antisymmetric to this exchange). In the case of electrons, the wave function is antisymmetric; this is a more precise statement of the Pauli exclusion principle. *See* ELECTRON; EXCLUSION PRINCIPLE.

When the spins of the two electrons are parallel the spatial part of the wave function is antisymmetric under exchange, and when they are opposed it is symmetric. The distribution in space of the two electrons is different in these two states, and so their mutual electrostatic energy is different. This difference in the electrostatic energy, called the exchange energy, appears as an interaction between the two electrons which depends on their relative orientation (although this dependence is incidental).

Exchange is the mechanism by which the electron spins in many magnetic materials are lined up parallel or opposed (for example, in α-iron and the ferrites). It is also the mechanism whereby the electron spins are parallel in the first excited state of the helium atom, and the spins of the two electrons are opposed in the carbon-carbon covalent bond. *See* ATOMIC STRUCTURE AND SPECTRA; CHEMICAL BONDING; ELECTRON CONFIGURATION; FERROMAGNETISM; QUANTUM MECHANICS; SPIN (QUANTUM MECHANICS). [J.M.D.]

Excitation

Excitation Any of a number of different phenomena which alter a system in some way or result in some type of response. In electrical network theory, an excitation initiates a response or a response sequence. In other areas of technology, an excitation establishes an altered condition which causes an apparatus or system to exhibit useful response capabilities.

In electrical network theory, the term excitation designates a time-varying independent voltage or current in an n-port system or network. The independent voltage or current—which is also referred to as the excitation or the excitation signal—causes a network response which affects the voltage or current at the dependent port. The nature of the network response, and therefore of the dependent voltage or current, derives from the characteristics of the network. *See* MULTIVIBRATOR; NETWORK THEORY.

In atomic physics, excitation means the addition of energy to an atom at ground state to produce an excited state. *See* ATOMIC STRUCTURE AND SPECTRA; EXCITATION POTENTIAL.

In other contexts, excitation means the application of energy to one portion of a system or apparatus in a manner that enables another portion to perform a specialized function. Excitation energy may differ from the output energy in source, form, level, or location. That is, an excitation produces a primary effect that is linked, through an intermediate physical phenomenon, to a dependent secondary effect. For example, a dynamic loudspeaker uses an excitation current in a field coil to generate a magnetic field; only then can a second magnetic field, generated by an audio signal, actuate the voice cone and produce sound waves. *See* LOUDSPEAKER. [W.W.Sn.]

Excitation potential

Excitation potential The difference in potential between an excited atomic or molecular state and the ground state. The term is most generally used in connection with electron excitation, but it can be applied to excited molecular vibrational and rotational states.

A closely related term is excitation energy. If the unit of potential is taken as the volt and the unit of energy as the electron volt, then the two are numerically equal. According to the Bohr theory, there is a relationship between the wavelength of the photon associated with the transition and the excitation energies of the two states. Thus the basic equation for the emission or absorption of energy is as shown below, where h is Planck's constant,

$$\frac{hc}{\lambda} = E_i - E_f$$

c the velocity of light, λ the wavelength of the photon, and E_f and E_i the energies of the final and initial states, respectively. *See* EXCITED STATE; GROUND STATE; IONIZATION POTENTIAL. [G.H.M.]

Excited state

Excited state In quantum mechanics, a stationary state of higher energy than the lowest stationary state or ground state of a particle or a system of particles. Customarily, only bound stationary states, which generally are at most denumerably infinite in number, are spoken of as excited, although the formal quantum theory often treats the noncountable unbound stationary states on an equal footing with the bound states. *See* GROUND STATE; METASTABLE STATE. [E.G.]

Exciton A fundamental quantum of electronic excitation in condensed matter, consisting of a negatively charged electron and a positively charged hole bound to each other by electrostatic attraction. Excitons exist in all kinds of condensed matter, whenever it is possible for an electron to be excited from a filled energy level to an empty one, leaving behind a hole. Unlike an excitation in a single atom or molecule, an exciton can in general move through the solid like a particle. Excitons transport energy, not charge or mass. Typically, an exciton is created when a photon is absorbed in a solid; the exciton then moves through the crystal; and finally the electron and hole recombine, resulting in the emission of another photon, often at a wavelength different from that of the original photon. Excitons can also be created by injection of free electrons into excited states via an electric current. *See* CRYSTAL ABSORPTION SPECTRA; ELECTRON-HOLE RECOMBINATION; HOLE STATES IN SOLIDS; LUMINESCENCE.

Excitons fall into two broad classes, Wannier (or Wannier-Mott) excitons and Frenkel excitons, based on their size relative to the interatomic or intermolecular distances in the material. In Wannier excitons, typically observed in covalent semiconductors and insulators, the electron and hole are separated by a distance much larger than the atomic spacing, so that the effect of the crystal lattice on the exciton can be taken into account primarily via an average permittivity. In Frenkel excitons, typically seen in molecular or rare-gas crystals, the electron and hole are separated by a distance comparable to the atomic spacing, so that the exciton is localized to a single site at any given time. Wannier excitons move essentially like free particles, while motion of Frenkel excitons is envisioned as hopping from one site to another. *See* ELECTRIC INSULATOR; SEMICONDUCTOR. [D.Sn.]

Exclusion principle No two electrons may simultaneously occupy the same quantum state. This principle, often called the Pauli principle, was first formulated by Wolfgang Pauli in 1925 and, for time-independent quantum states, it means that no two electrons may be described by state functions which are characterized by exactly the same quantum numbers. In addition to electrons, all known particles having half-integer intrinsic angular momentum, or spin, obey the exclusion principle. It plays a central role in the understanding of many diverse phenomena, including the periodic table of the elements and their chemical activities, the electron contribution to the specific heat of metals, the shell structure in the atomic nucleus analogous to that of electrons in atoms, and certain symmetries in the scattering of identical particles. *See* ANGULAR MOMENTUM; QUANTUM NUMBERS; SPIN (QUANTUM MECHANICS).

Using the fact that a system will try to occupy the state of lowest possible energy, the electron configuration of atoms may be understood by simply filling the single-particle energy levels according to the Pauli principle. This is the basis of Niels Bohr's explanation of the periodic table. *See* ATOMIC STRUCTURE AND SPECTRA; ELECTRON CONFIGURATION. [S.A.Wi.]

Exon In split genes, a portion that is included in the ribonucleic acid (RNA) transcript of a gene and survives processing of the RNA in the cell nucleus to become part of a spliced messenger RNA (mRNA) or structural RNA in the cell cytoplasm. Split genes are those in which regions that are represented in mature mRNAs or structural RNAs (exons) are separated by regions that are transcribed along with exons in the primary RNA products of genes, but are removed from within the primary RNA molecule during RNA processing steps (introns). *See* INTRON; RIBONUCLEIC ACID (RNA).

Exons comprise three distinct regions of a protein-coding gene. The first is a portion that is not translated into protein, but contains the signal for the beginning of RNA synthesis, and sequences that direct the mRNA to ribosomes for protein synthesis. The second is a set of exons containing information that is translated into the amino acid sequence of a protein. The third region of a gene that becomes part of an mRNA is an untranslated end portion that contains signals for transcription termination and for the addition of a polyadenylate tract at the end of a transcript.

The mechanism by which the exons are joined in RNA copies of genes is called RNA splicing, and it is part of the maturation of mRNAs and some transfer and ribosomal RNAs (tRNAs and rRNAs) from primary transcripts of genes. Three different RNA splicing processes have been identified. One involves mRNA precursors in nuclei, and specific sequences at exon-intron junctions that are recognized by certain nuclear ribonucleoprotein particles that facilitate the cleavage and ligation of RNA. Another applies to nuclear precursors of tRNA, where splice sites are determined by structural features of the folded RNA molecules. The third form of splicing was discovered in studies of protozoan rRNA synthesis, and has also been shown to be a part of the maturation of both rRNA and mRNA in yeast mitochondria; it is an autocatalytic process that requires neither an enzyme nor added energy such as from adenosine triphosphate. *See* GENE; GENETIC CODE; PROTEIN; RIBOSOMES. [P.M.M.R.]

Exopterygota A division (also known as Hemimetabola) of the subclass Pterygota, including those insects that show relatively slight change in body form with growth. They develop through a series of immature forms (nymphs) from hatchling to adult, so that wings grow as external pads and enlarge with each molt. The nymphs are often scaled-down copies of the adults, but in some cases, a considerable difference in body form exists between adults and their immature forms.

Exopterygota are a very diverse group, encompassing plant feeders, predators, and animal parasites, and living in nearly all habitats and areas where insects are found. Common examples of Exopterygota are mayflies, dragonflies, grasshoppers, termites, cockroaches, aphids, plant bugs, biting and sucking lice, and thrips. *See* ENDOPTERYGOTA; INSECTA; PTERYGOTA. [W.L.Bro.]

Exotic nuclei Nuclei with ratios of neutron number N to proton number Z much larger or much smaller than those of nuclei found in nature. Studies of nuclear matter under extreme conditions, in which the nuclei are quite different in some way from those found in nature, are at the forefront of nuclear research. Such extreme conditions include nuclei at high temperature and at high density (several times normal nuclear density), as well as those with larger or smaller N/Z ratios. The N/Z ratio depends on the nature of the attractive nuclear force that binds the protons and neutrons in the nucleus and its competition and complex interplay with the disruptive Coulomb or electrical force that pushes the positively charged protons apart.

A chart of the nuclides is shown in the illustration. The squares are the stable nuclei ($Z \leq 83$) and the very long-lived nuclei (with half-lives of the order of 10^9 years or more) found in nature. The first jagged lines to either side are the limits of the presently observed nuclei; very little is known about those at the edges. The light, stable nuclei (such as ^{4}He) have $Z = N$, reflecting the preference of the nuclear forces for $N = Z$ symmetry, but as Z increases, the strength of the Coulomb force demands more neutrons than protons to make a particular element stable, and $N \approx 1.6\,Z$ for the heaviest long-lived nuclei (such as ^{238}U). For $Z > 92$, the Coulomb force causes most nuclei to spontaneously fission. *See* NUCLEAR FISSION.

Stable nuclei lie in the so-called valley of beta stability. As the N/Z ratio decreases (proton-rich nuclei) or increases (neutron-rich nuclei) compared to that of the stable isotopes, there is, respectively, energy for a proton or neutron in the nucleus to undergo beta (β^+, β^-) decay to move the nucleus back toward stability. Most knowledge of nuclear structure and decay has been gained from nuclei in or near the valley of beta stability. *See* RADIOACTIVITY.

The spherical shell model was developed to explain the so-called spherical magic numbers for protons and neutrons, which give nuclei with these numbers a very stable structure and spherical shape. Spherical magic Z and N of 2, 8, 20, 28, 50, 82, and

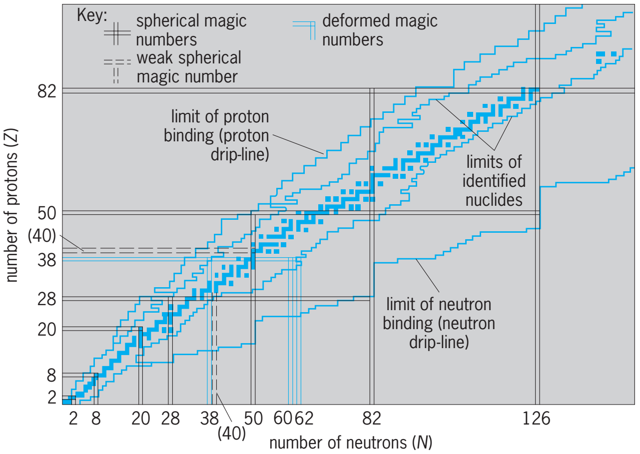


Chart of the nuclides. The squares are the stable and very long-lived nuclei found in nature.

126, and the weaker magic *Z* and *N* at 40, are shown in the illustration as horizontal and vertical lines. The nuclear shell model resembles the atomic shell model, where the noble gases (helium, neon, argon, and so forth) have filled shells and then there is a gap in the binding energy to the next electron shell (or orbit). A major question concerns what happens to these spherical magic proton and neutron gaps (orbits) in exotic nuclei. *See* NUCLEAR STRUCTURE.

Another major question concerns the decay modes whereby a nucleus rids itself of excess energy and returns to the stable forms of nuclear matter. As *N*/*Z* decreases or increases from the stable values, a point is reached for a given *Z* where, if one more neutron is pulled out, one proton becomes unbound (an isotope of that element cannot exist with that number of neutrons), or, if one more neutron is added, that neutron is not bound to that nucleus. These limits define, respectively, the proton and neutron drip-lines (the jagged lines furthest from the valley of stability in the illustration).

Answers to the above questions give significant insights into the structure and decay modes of nuclear matter that make it possible to test and extend theoretical models of the nucleus and the understanding of the nature of both the strong and weak nuclear forces. These insights could not be gained by studies of nuclei in and near the valley of stability.

These insights include the discovery of nuclear shape coexistence. Competing bands of levels occur in one nucleus, which overlap in energy but are quite separate in their decays because they are built on quite different coexisting nuclear shapes. Shape coexistence is now known to be important in many nuclei throughout the periodic table.

A significant advance was made in the nuclear shell model with the discovery of new magic numbers associated with shell gaps in the energies of the proton and neutron orbitals. These new numbers may be called deformed magic numbers because they stabilize a nucleus in a deformed shape, just as the spherical magic numbers give stability to a spherical shape. The deformed magic numbers (shell gaps) identified so far include *N* and *Z* of 38 and *N* of 60 and 62.

Exotic nuclei exhibit decay modes not seen near stability, such as proton radioactivity and beta-delayed particle emission. (After beta decay, the highly excited nucleus can emit one or more particles, such as one or two protons, an alpha particle, or one or two neutrons.) [J.H.H.]

Exotic viral diseases

Viral diseases that occur only rarely in human populations of developed countries. However, many of these diseases cause significant human morbidity and mortality in underdeveloped areas, and have the proven capacity to be transported to population centers in developed countries and to cause explosive outbreaks or epidemics. Most of the exotic viruses are zoonotic, that is, they are transmitted to humans from an ongoing life cycle in animals or arthropods; the exception is smallpox.

Important diseases caused by exotic viruses include yellow fever, Venezuelan equine encephalitis, Rift Valley fever, tick-borne encephalitis, Crimean hemorrhagic fever, rabies, Lassa fever, hemorrhagic fever, and Marburg and Ebola hemorrhagic fevers. Control of these diseases is often very difficult because of the lack of detailed knowledge about the natural history of the viruses in their natural animal hosts, and because of the difficulty of controlling natural populations of alternative hosts such as insects or rodents. [F.A.M.]

Expert control system

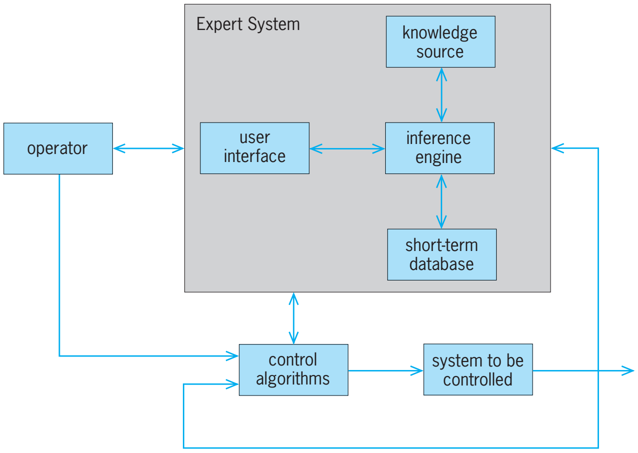
A type of intelligent control system which can emulate the reasoning procedures of a human expert in order to generate the necessary control action. Expert control systems seek to incorporate knowledge about control system design, practical operations, and abnormal system recovery plans to automate tasks normally performed by experienced control engineers (the experts). Techniques relating to the field of artificial intelligence are usually used for the purpose of acquiring and representing knowledge and for generating control decisions through an appropriate reasoning mechanism. As it operates essentially on a knowledge base, an expert control system is often referred to as a knowledge-based control system. One of the most important benefits associated with the use of an expert control system is the inherent capability of the system to deal with uncertainty in information. Information provided to these systems can be general, qualitative, or vague because, like humans, expert control systems possess functionalities to perceive, reason, infer, and deduce new information. They can learn, gain new knowledge, and improve their performance through experience.

The principal components almost certain to be present in all expert control systems are the knowledge source, the database, the inference engine, the control algorithms, and the interface between the expert control system and humans (see illustration).

Central to an expert system is the knowledge source (or knowledge base), which contains knowledge in a specific domain (control in this context). This knowledge consists of domain-specific facts and heuristics, usually in the form of rules or frames, useful for solving problems in the domain.

The database is a short-term memory component which contains the current problem status, inference states, and the history of solutions to date for reference purposes.

The inference engine operates on the information from the knowledge source, from the associated database, or from the



Basic architecture of an expert control system.

user; guides the search process according to the programmed strategy and search algorithms; and uses the inferencing mechanisms, usually in the forms of rules of logic, to solve problems, arrive at conclusions, and activate the final control actions.

The control algorithms are the tools for the expert systems to perform the final control action. A rich library of control algorithms, with advanced features, is usually made available.

The user interface allows the user to interact with the overall system, browse through the knowledge source, edit rules, and perform many other interactive tasks. *See* Artificial intelligence; Control systems; Expert systems; Process control. [T.H.Le.; K.K.T.; C.C.Ha.; K.C.Ta.]

Expert systems Methods and techniques for constructing human-machine systems with specialized problem-solving expertise. The pursuit of this area of artificial intelligence research has emphasized the knowledge that underlies human expertise and has simultaneously decreased the apparent significance of domain-independent problem-solving theory. In fact, new principles, tools, and techniques have emerged that form the basis of knowledge engineering.

Expertise consists of knowledge about a particular domain, understanding of domain problems, and skill at solving some of these problems. Knowledge in any specialty is of two types, public and private. Public knowledge includes the published definitions, facts, and theories which are contained in textbooks and references in the domain of study. But expertise usually requires more than just public knowledge. Human experts generally possess private knowledge which has not found its way into the published literature. This private knowledge consists largely of rules of thumb or heuristics. Heuristics enable the human expert to make educated guesses when necessary, to recognize promising approaches to problems, and to deal effectively with erroneous or incomplete data. The elucidation and reproduction of such knowledge are the central problems of expert systems.

Researchers in this field suggest several reasons for their emphasis on knowledge-based methods rather than formal representations and associated analytic methods. First, most of the difficult and interesting problems do not have tractable algorithmic solutions. This is reflected in the fact that many important tasks, such as planning, legal reasoning, medical diagnosis, geological exploration, and military situation analysis, originate in complex social or physical contexts, and generally resist precise description and rigorous analysis.

The second reason for emphasizing knowledge is pragmatic: human experts achieve outstanding performance because they are knowledgeable. If computer programs embody and use this knowledge, they too attain high levels of performance. This has been proved repeatedly in the short history of expert systems. Systems have attained expert levels in several tasks: mineral prospecting, computer configuration, chemical structure elucidation, symbolic mathematics, chess, medical diagnosis and therapy, and electronics analysis.

The third motivation for focusing on knowledge is the recognition of its intrinsic value. Traditionally, the transmission of knowledge from human expert to trainee has required education and internship periods ranging from 3 to 20 years. By extracting knowledge from humans and transferring it to computable forms, the costs of knowledge reproduction and exploitation can be greatly reduced. At the same time, the process of knowledge refinement can be accelerated by making the previously private knowledge available for public test and evaluation.

Most of the knowledge-engineering applications fall into a few distinct types, summarized in the table.

Generic categories of knowledge engineering applications

Category	Problem addressed
Interpretations	Inferring situation descriptions from sensor data
Prediction	Inferring likely consequences of given situations
Diagnosis	Inferring system malfunctions from observables
Design	Configuring objects under constraints
Planning	Designing actions
Monitoring	Comparing observations to plan vulnerabilities
Debugging	Prescribing remedies for malfunctions
Repair	Executing a plan to administer a prescribed remedy
Instruction Instruction	Diagnosing, debugging, and repairing students' knowledge weaknesses
Control Instruction	Interpreting, predicting, repairing, and monitoring system behaviors

The ideal expert system contains: a language processor for problem-oriented communications between the user and the expert system; a blackboard for recording intermediate results; a knowledge base comprising facts plus heuristic planning and problem-solving rules; an interpreter that applies these rules; a scheduler to control the order of rule processing; a consistency enforcer that adjusts previous conclusions when new data or knowledge alter their bases of support; and a justifier that rationalizes and explains the system's behavior. *See* Artificial intelligence.

Agents are autonomous programs; programs that communicate with an agent communication language (for example, KQML); mobile programs that can travel from one computer to another; or programs that collaborate with humans in solving tasks, offloading tedious tasks, and acting as monitors and liaisons with other agents. Agents can also be viewed as higher-level architectural components, providing distributed open architectures in which the agents can be registered, requests can be brokered, and different organizational structures can be used to solve higher-level tasks. In this architectural view, they are distinguished from objects by their persistence, autonomy, communications capabilities, and behavior. Another key aspect of most agent definitions is the agent's dynamic and uncertain environment. Agents also may or may not have graphical representations, commonly called avatars or personas.

Agents can vary from simple programs, lacking knowledge, to sophisticated autonomous real-time control systems that provide both deliberative reasoning (for example, including sophisticated planning and scheduling) and fast real-time response. The vast majority of simple utilitarian agents, such as off-line browsers that automatically download Web sites, or agents that monitor Web pages for changes, are not knowledge-based. Most knowledge-based agents are still experimental. *See* Internet; World Wide Web. [F.H.Ro.; W.Mu.]

Explosive A substance containing a large amount of stored energy that can be released suddenly, thereby converting the substance into compressed gases or numerous fragments that expand with great force or velocity. An explosion is a sudden expansion of matter into a much larger volume than it formerly occupied, or a sudden increase in the pressure exerted by confined matter.

Uses of industrial explosives include blasting ore, coal, and rock in mining and construction, generating vibrations in seismic prospecting for oil and gas, stimulating and perforating gas and oil wells, bonding sheets of dissimilar metals to each other, and synthesizing industrial diamonds. In contrast to military explosives, industrial explosives tend to have larger critical diameters, lower densities, lower detonation velocities, and lower explosion pressures; and to have more complex compositions and lower cost. Most military explosives are rigid solids, whereas most industrial explosives are formulated to be plastic, pumpable, or free-flowing to permit filling the cross section of deep, rough, and irregular holes in rock.

Industrial explosives usually contain separate fuel and oxidizer ingredients in intimate combination. Usually, they also contain a sensitizer to aid in the initiation and propagation of detonation. Other ingredients may be used to increase or decrease density, to increase explosion energy, to prevent the detonation from igniting methane in coal mines, to provide plasticity, pumpability, or flowability, to prevent setting or stiffening during storage or at low temperature, to prevent separation of ingredients and chemical instability during storage, and to provide resistance to desensitization by water, low temperature, hydrostatic pressure, or transient pressure from explosions in nearby holes. Industrial explosives are usually packaged in bags or cartridges of polymer film or paper, or are carried in bulk form to the blasting site, where they are blown or pumped into the holes through hoses. Sometimes they are mixed at the blasting site.

Most military explosives are simple compositions formulated for high energy density, loading in munitions plant, and long storage life. Most of them are based on explosive chemical compounds that incorporate both oxidizer and fuel components in the same molecule. Many of these compounds are used for special purposes in industrial explosives also. [D.L.C.]

Explosive forming

The shaping or modifying of metals by means of explosions. The explosives may be of either the detonating or deflagrating type. Explosive gas mixtures or stored gas at high pressure may also provide the motive power.

Cold welds can be made between dissimilar metals by driving the two parts together under explosive impact. In other applications of explosive-forming methods, powders are pressed into solid billets. In a different application, high explosives are used to cut large blocks of metal and even to split thin sheets into two layers of exactly one-half the original thickness. Explosives can also be employed to extrude metal shapes and to punch hard metals with the aid of dies. Shapes produced explosively are very exact and free from the fine cracks that sometimes result when pressure is applied slowly. *See* METAL FORMING. [W.E.Go.]

Exponent

In mathematics a symbol or number written to the right of and above another symbol or number to denote how many times the latter is to be multiplied by itself. For example, $7^3 = 7 \cdot 7 \cdot 7$, and $a^3 = a \cdot a \cdot a$. By use of this convenient mathematical device, the number 420,000,000,000,000 can be expressed unmistakably and more compactly as 4.2×10^{14}, which is read as, "four and two-tenths times ten multiplied by itself fourteen times" or, more properly, "four and two-tenths times ten to the fourteenth power." This abbreviated notation is particularly valuable in expressing the extremely large or extremely small numbers encountered in modern scientific work. For example, 0.000000143 may be expressed as

$$\frac{143}{1{,}000{,}000{,}000} \quad \text{or} \quad \frac{143}{10^9} \quad \text{or} \quad 1.43 \times 10^{-7}$$

Operations with exponents are governed by the following rules:

1. $x^a x^b = x^{a+b}$. Example, $x^2 x^3 = xx \cdot xxx = x^5$.
2. $(x^a)^b = x^{ab}$. Example, $(x^2)^3 = (x^2)(x^2)(x^2) = x^6$.
3. $(xy)^a = x^a y^a$. Example, $(xy)^3 xyxyxy = xxxyyy = x^3 y^3$.
4. If $y \neq 0$, $\left(\dfrac{x}{y}\right)^a = \dfrac{x^a}{y^a}$. Example, $\left(\dfrac{x}{y}\right)^3 = \dfrac{x}{y} \cdot \dfrac{x}{y} \cdot \dfrac{x}{y} = \dfrac{x^3}{y^3}$.
5. If $x \neq 0$, $\dfrac{x^a}{x^b} = x^{a-b}$. Example, $\dfrac{x^5}{x^2} = \dfrac{xxxxx}{xx} = xxx = x^3$.

See ALGEBRA. [A.N.L.; S.Bo.]

Exposure meter

An indicating instrument used in photography to determine lens aperture and shutter speed. An exposure meter may be used either in the darkroom to determine approximate printing time for a contact print or an enlargement or, more usually, with a camera to determine exposure of film.

Exposure meters are of two basic types, photovoltaic and photoconductive. In photovoltaic meters, a selenium cell converts photons to electrons, producing a current directly proportional to received light. A sensitive microammeter indicates this current to the user.

In the photoconductive meter, a cadmium sulfide cell changes conductivity in proportion to the received light. A battery (usually a mercury cell) supplies power through the cadmium sulfide cell to the meter movement. Because the received light serves to control the power from the battery, this type of instrument is about three orders of magnitude more power-sensitive than the photovoltaic type.

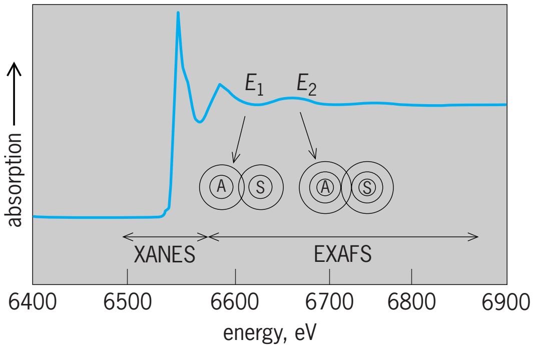
Used at the camera, either type of meter serves as a brightness meter to measure reflected light from the subject. Used at the subject, with a diffuser head over the exposure meter lens, the instrument serves as an illumination meter to indicate incident light. *See* PHOTOGRAPHY; PHOTOMETRY. [F.H.R.]

Extended x-ray absorption fine structure (EXAFS)

The structured absorption on the high-energy side of an x-ray absorption edge. The absorption edges for an element are abrupt increases in x-ray absorption that occur when the energy of the incident x-ray matches the binding energy of a core electron (typically a 1*s* or a 2*p* electron). For x-ray energies above the edge energy, a core electron is ejected from the atom. The ejected core electron can be thought of as a spherical wave propagating outward from the absorbing atom. The photoelectron wavelength is determined by its kinetic energy, which is in turn determined by the difference between the incident x-ray energy and the core-electron binding energy. As the x-ray energy increases, the kinetic energy of the photoelectron increases, and thus its wavelength decreases. *See* ABSORPTION OF ELECTROMAGNETIC RADIATION; LIGHT; PHOTOEMISSION; QUANTUM MECHANICS.

The x-ray-excited photoelectron will be scattered by the neighboring atoms surrounding the absorbing atom. The portion of the photoelectron wave that is scattered back in the direction of the absorbing atom is responsible for the EXAFS oscillations. If the outgoing and backscattered photoelectron waves are out of phase and thus interfere destructively, there is a local minimum in the x-ray absorption cross section. At a higher x-ray energy (shorter photoelectron wavelength), constructive interference leads to a local maximum in x-ray absorption (see illustration). EXAFS thus arises from photoelectron scattering, making it a spectroscopically detected scattering method. *See* INTERFERENCE OF WAVES; SCATTERING OF ELECTROMAGNETIC RADIATION.

EXAFS typically refers to structured absorption from approximately 50 to 1000 eV or more above the absorption edge. X-ray absorption near edge structure (XANES) is often used to refer to the structure in the near (around 50 eV) region of the edge. X-ray absorption fine structure (XAFS) has gained some



X-ray absorption spectrum for manganese, showing XANES and EXAFS regions. As the x-ray energy increases from E_1 to E_2, the interference of the outgoing and backscattered photoelectron wave (shown schematically by concentric circles around the absorbing, *A*, and scattering, *S*, atoms) changes from destructive to constructive.

currency as a reference to the entire structured absorption region (XANES+EXAFS).

EXAFS spectra contain structural information comparable to that obtained from single-crystal x-ray diffraction. The principal advantage of EXAFS in comparison with crystallography is that EXAFS is a local structure probe and does not require the presence of long-range order. This means that EXAFS can be used to determine the local structure in noncrystalline samples. *See* X-RAY CRYSTALLOGRAPHY. [J.P.Ha.]

Extinction (biology) The death and disappearance of a species. The fossil record shows that extinctions have been frequent in the history of life. Mass extinctions refer to the loss of a large number of species in a relatively short period of time. Episodes of mass extinction occur at times of rapid global environmental change; five such events are known from the fossil record of the past 600 million years. Human activity is causing extinctions on a scale comparable to the mass extinctions in the fossil record.

Record. An extinction may be of two types; phyletic or terminal. Phyletic extinction occurs when one species evolves into another with time; in this case, the ancestral species can be called extinct. However, because the evolutionary lineage has continued, such extinctions are really pseudoextinctions. In contrast, terminal extinction marks the end of an evolutionary lineage, termination of a species without any descendants. Most extinctions recorded in the fossil record and those occurring today are terminal. It has been estimated that 99% of all species that have ever lived are now extinct. *See* ORGANIC EVOLUTION.

The fossil record is best known for marine organisms. The mass extinctions of the marine fossil record occurred during the Late Ordovician, Late Devonian, Late Permian, Late Triassic, and Late Cretaceous. These mass extinctions affected a variety of organisms in many different ecological settings. Terrestrial and marine mass extinctions seem to occur at about the same time. The Late Permian, Late Triassic, and Late Cretaceous are also times of extinction for terrestrial vertebrates; the most dramatic extinction of terrestrial vertebrates took place at the end of the Cretaceous, when the last dinosaurs died off. *See* DINOSAUR.

The best record of terrestrial vertebrate extinction is that of the Pleistocene. Late Pleistocene extinctions in North America are especially well known—33 genera of mammals vanished during the last 100,000 years. These extinctions were concentrated among the large mammals—those over 100 lb (44 kg) in weight—and most occurred during a short time interval approximately 11,000 years ago.

Causes. Ever since the work of Georges Cuvier, the French naturalist who demonstrated the reality of extinction, explanations have fascinated both scientists and the general public. Cuvier invoked sudden catastrophic events, whereas his contemporaries favored more gradual processes. These two themes, catastrophism and gradualism, are still debated.

In 1980 high concentrations of iridium were reported precisely at the Cretaceous-Tertiary boundary. Iridium is rare in most rocks but more abundant in meteorites. It was proposed, therefore, that an asteroid struck the Earth 65 million years ago. The impact darkened the atmosphere with dust, caused a catastrophic short-term cooling of the climate, and thus led to the extinction of dinosaurs and many other Cretaceous species. The iridium-rich layer at the boundary marks this terminal Cretaceous event.

Astronomical theories have been put forward to explain the Late Cretacous extinctions as well as the 26-million-year periodicity. In one theory, the Sun has a distant companion star that would pass in orbit near the solar system's cloud of comets every 26 million years. This might perturb many comets, sending a few into the Earth. A comet would produce the same effects as an asteroid.

Other explanations for mass extinctions include lowered sea level, climatic cooling, and changes in oceanic circulation. Biotic processes such as disease, predation, and competition may also cause the extinction of species but are difficult to prove from the fossil record because they leave little evidence. Biotic factors usually affect only one or a few interdependent species. Predation and competition are important causes of more recent extinctions, which continue today. Human activities such as hunting and fishing (predation), habitat alteration (competition for space), and pollution have probably destroyed thousands of species. These activities, together with continued tropical deforestation and resulting changes in climate, are likely to cause extinctions that will be comparable to the mass extinctions seen in the fossil record. *See* FOSSIL. [K.W.F.]

Extraction A method of separating the constituents of a mixture utilizing preferential solubility of one or more components in a second phase. Commonly, this added second phase is a liquid, while the mixture to be separated may be either solid or liquid. If the starting mixture is a liquid, then the added solvent must be immiscible or only partially miscible with the original and of such a nature that the components to be separated have different relative solubilities in the two liquid phases.

Solvent extraction processes can be divided into two broad categories according to the origins of the differential solubility. On the one hand, it arises from purely physical differences between the two solutes, such as polarity, while in other cases it can be traced to definite chemical interaction between solute and solvent. Categories of major importance for the latter cases are ion-association systems and chelate compounds.

Liquid/solid extraction may be considered as the dissolving of one or more components in a solid matrix by simple solution, or by the formation of a soluble form by chemical reaction. The largest use of liquid/solid extraction is in the extractive metallurgical, vegetable oil, and sugar industries. The field may be subdivided into the following categories: leaching, washing extraction, and diffusional extraction. Leaching involves the contacting of a liquid and a solid (usually an ore) and the imposing of a chemical reaction upon one or more substances in the solid matrix so as to render them soluble. In washing extraction the solid is crushed to break the cell walls, permitting the valuable soluble product to be washed from the matrix. In diffusional extraction the soluble product diffuses across the denatured cell walls (no crushing involved) and is washed out of the solid.

Liquid/liquid extraction separates the components of a homogeneous liquid mixture on the basis of differing solubility in another liquid phase. Because it depends on differences in chemical potential, liquid/liquid extraction is more sensitive to chemical type than to molecular size. This makes it complementary to distillation as a separation technique. One of the first large-scale uses was in the petroleum industry for the separation of aromatic from aliphatic compounds. Liquid/liquid extraction also has found application for many years in the coal tar industry. On a smaller scale, extraction is a key process in the pharmaceutical industry for recovery of antibiotics from fermentation broths, in the recovery and separation of vitamins, and for the production of alkaloids from natural products. *See* CHEMICAL SEPARATION TECHNIQUES. [B.M.S.]

Extrapolation A process in mathematics used to find the value of a function outside its tabulated values. This is done as in interpolation by assuming that over a small range of x the function may be closely approximated by a polynomial or some other readily computed function. Any of the interpolation formulas can be used, therefore, and the desired value of x substituted in them. *See* INTERPOLATION. [K.S.K.]

Extraterrestrial intelligence The potential existence beyond the Earth of other advanced civilizations with a technology at least as developed as that on Earth. The idea that life, especially life with intelligence, might exist in other parts of the universe is a very old one. Early ideas were based on an intuitive belief in the enormity of the universe and in what is now called the mediocrity principle, namely that there is nothing special about the Sun, the Earth, and the human race.

Present ideas are also based on the mediocrity principle supported by the universality of the laws of physics and chemistry, and by the enormity of the universe. The Sun is one of 2×10^{11} stars of the Galaxy (the Milky Way), and there are about 10^{11} galaxies in the visible universe. The chemical evolution, that is, the natural formation of complex organic compounds, that led to the origin of life on Earth is quite common in the universe. Life on Earth started at least 3.5×10^9 years ago, that is, soon after the formation of the oceans, indicating a rather straightforward natural process. Through mutations and Darwinian selection, evolution advanced slowly from primitive unicellular microorganisms to advanced multicellular organisms with intelligence. Intelligence, which is favored by evolution because it has a high survival value, evolved into a technological society.

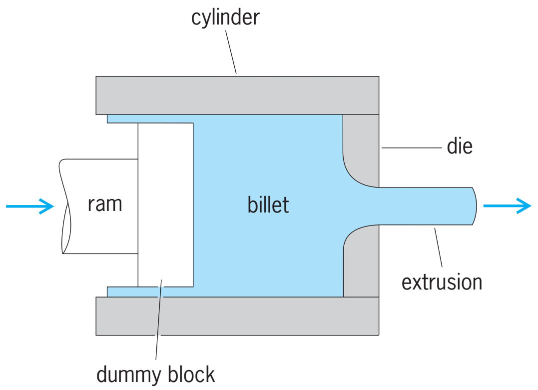
The search for extraterrestrial intelligence was initiated only after the development of radio astronomy and large radio telescopes, because radio waves seem to be the most efficient means of communication over interstellar distances. At least 60 radio searches have been carried out, and three radio observatories search continuously for radio signals. The results continue to be negative, but selecting the proper frequency, bandwidth, polarization, target, and so forth, is an extremely complex problem. *See* RADIO ASTRONOMY; RADIO TELESCOPE.

In the early 1960s, F. Drake developed an equation to estimate the number N of advanced technological civilizations currently active in the Galaxy. The Drake equation, $N = R \times P \times L$, gives N in terms of the rate R at which new stars are born in the Galaxy, the probability P (actually a product of probability factors) that any one of these stars will possess the necessary conditions (luminosity, planets at the appropriate distances, and so forth) for life to originate and to slowly evolve to a technological civilization, and the average longevity L of such civilizations. The values advocated by the proponents of the Drake equation yield a value of N of approximately 200,000 stellar civilizations. However, the uncertainties in P and L are very large and some scientists think that the human race is probably the only advanced civilization in the Galaxy; that is, N equals 1.

In the mid-1970s, the possibility of large human colonies in space began to be seriously considered, and the idea that such self-sustained habitats could undertake multigeneration trips of several centuries to other stars began to gain acceptance. Many scientists think that galactic colonization is not only possible but an almost inevitable consequence of the evolution of intelligence and technology. This concept, however, leads to two extreme alternatives: either the Galaxy has already been colonized, in which case N must be very large; or it has not been colonized, because no one was there to do so, in which case N must be very small. Both alternatives are contrary to the results of the Drake equation, which negates galactic colonization and predicts an intermediate value of N. All three alternatives, however, contain serious contradictions which are not easy to reconcile. [M.D.Pa.]

Extrusion The forcing of solid metal through a suitably shaped orifice under compressive forces. Extrusion is somewhat analogous to squeezing toothpaste through a tube, although some cold extrusion processes more nearly resemble forging, which also deforms metals by application of compressive forces. Most metals can be extruded, although the process may not be economically feasible for high-strength alloys.

The most widely used method for producing extruded shapes is the direct, hot extrusion process. In this process, a heated billet of metal is placed in a cylindrical chamber and then compressed by a hydraulically operated ram (see illustration). The opposite end of the cylinder contains a die having an orifice of the desired shape; as this die opening is the path of least resistance for the billet under pressure, the metal, in effect, squirts out of the opening as a continuous bar having the same cross-sectional shape as the die opening. By using two sets of dies, stepped extrusions can be made.



Schematic of the direct, hot extrusion process.

The extrusion of cold metal is variously termed cold pressing, cold forging, cold extrusion forging, extrusion pressing, and impact extrusion. The term cold extrusion has become popular in the steel fabrication industry, while impact extrusion is more widely used in the nonferrous field.

The original process (identified as impact extrusion) consists of a punch (generally moving at high velocity) striking a blank (or slug) of the metal to be extruded, which has been placed in the cavity of a die. Clearance is left between the punch and die walls; as the punch comes in contact with the blank, the metal has nowhere to go except through the annular opening between punch and die. The punch moves a distance that is controlled by a press setting. This distance determines the base thickness of the finished part. The process is particularly adaptable to the production of thin-walled, tubular-shaped parts having thick bottoms, such as toothpaste tubes.

Advantages of cold extrusion are higher strength because of severe strain-hardening, good finish and dimensional accuracy, and economy due to fewer operations and minimum of machining required. *See* METAL FORMING. [R.L.Fr.]

Eye (invertebrate) An aggregation of photoreceptor cells together with any associated optical structures. Eyes occur almost universally among animals, and are possessed by some species of virtually every major animal phylum. However, the complexity of eyes varies greatly, and this sense organ undoubtedly evolved independently a number of times within the animal kingdom.

The simplest invertebrate organs that might be considered to be eyes are clusters of photoreceptor cells located on the surface of the body. Pigment cells are usually interspersed among the photoreceptors, giving the eye a red or black color. Accessory structures, such as the lens and cornea, are usually absent. Simple eyes of this type, called pigment spot ocelli, are found in such invertebrates as jellyfish, flatworms, and sea stars.

The most basic image-forming type of invertebrate eye probably arose from such patches of photoreceptor cells by an insinking of the sensory epithelium to form a cup, which may have become closed in conjunction with the evolution of a cornea and lens. Such an evolutionary history is clearly suggested by the embryology and comparative anatomy of many invertebrates.

In bilateral cephalic invertebrates, the eyes are typically paired and located at the anterior end of the body. Although one pair is usual, as in mollusks and many arthropods, multiple pairs are not uncommon. Some polychaete annelids have 4 eyes, and scorpions may have as many as 12. The greatest number of eyes is found in marine flatworms, where there may be over 100 ocelli scattered over the dorsal anterior surface and along the sides of the body. The occurrence of eyes on parts of the body other than the head is usually correlated with radial symmetry or unusual modes of existence.

The primitive function of animal eyes was merely to provide information regarding the intensity, direction, and duration of environmental light. The perception of objects is dependent upon several factors, namely, the number of photoreceptors in the retina, the quality of the optics, and central processing of visual information.

Image formation has evolved as an additional capacity of the eyes of some invertebrates. The number of photoreceptor cells composing the retinal surface is of primary importance, since each photoreceptor cell or group of cells acts as the detector for one point of light. An image is formed by the retina through the association of points of light of varying intensity, much as an image is produced by an array of pixels on a computer monitor. The ability of an eye to form an image and the coarseness or fineness of the image are, therefore, dependent upon the number of points of light that are distinguished which, in turn, is dependent upon the number of photoreceptor cells composing the retina. A large number of photoreceptor cells must be present to produce even a coarse image. The great majority of invertebrate eyes cannot form a detailed image because they do not possess a sufficient number of photoreceptor cells. The number of photoreceptor cells might be sufficient to detect movement of an object, but is inadequate to provide much information about the object's form. *See* PHOTORECEPTION.

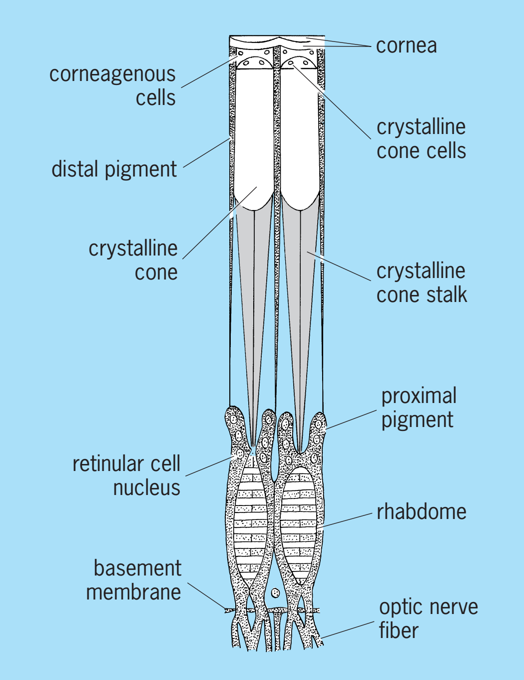
The focusing mechanisms of invertebrate eyes vary considerably. The focus of arthropod eyes tends to be fixed, that is, the distance between the optical apparatus and the retina cannot be changed. Thus objects are in focus only at a certain distance from the eye, determined by the distance between the lens and the retina.

The oceanic family of swimming polychaete worms, Alciopidae, have eyes of that are focused hydrostatically. A bulb to one side of the eye injects fluid into the space between the retina and the lens, forcing the lens outward. Another mechanism is employed in octopods whereby lens movement is brought about by a ciliary muscle attached to the lens (as in aquatic vertebrates, like fish).

The compound eye of crustaceans, insects, centipedes, and horseshoe crabs has a sufficiently different construction from that of other invertebrates to warrant separate discussion. The structural unit of the compound eye is called an ommatidium (see illustration). The outer end of the ommatidium is composed of a cornea, which appears on the surface of the eye as a facet. Beneath the cornea is an elongated, tapered crystalline cone; in many compound eyes the cornea and cone together function as a lens. The receptor element at the inner end of the ommatidium is composed of one or more central translucent cylinders (rhabdome), around which are located several photoreceptor cells (typically 7 or 8).

The rhabdome is the initial photoreceptive element, and it in turn stimulates the adjacent photoreceptor cells to depolarize. The photoreceptor element of each ommatidium functions as a unit and can respond only to one point of light. Thus image formation is dependent upon the number of photoreceptor units present. The number of ommatidia composing a compound eye varies greatly.

Pigment granules surround the ommatidium proximally and distally, forming a light screen that separates one ommatidium from another. The pigment granules migrate, depending upon the amount of light. In bright light the ommatidium is adapted by funneling light directly down to the rhabdome, by extending the pigment screen, so that light received by one ommatidium is prevented from stimulating the rhabdome of another. Under these conditions the image produced is said to be appositional, or mosaic. The term mosaic has been misinterpreted to mean that a given ommatidium forms a separate image, even if only a part of the image. In general, however, the compound eyes function like any other eye—each photoreceptor unit represents one point in visual space. It is not obvious whether or not compound eyes have any special advantages over other eye designs, despite their universal occurrence in crustaceans and insects. However, in many arthropods the total corneal surface is greatly convex, resulting in a wide visual field.



Two ommatidia from compound eye of crayfish *Astacus*. (*After R. D. Barnes*, *Invertebrate Zoology*, *2d ed.*, *W. B. Saunders*, *1968*)

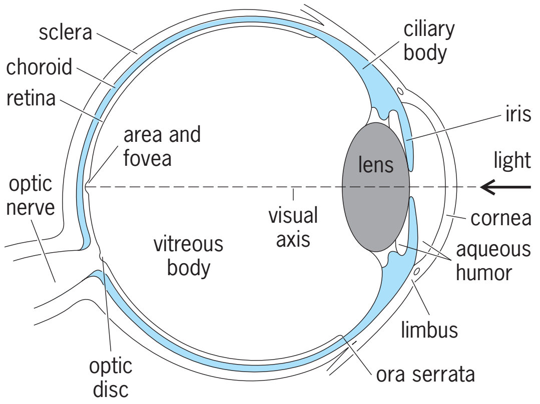
Many invertebrate eyes are capable of seeing and analyzing patterns of polarized light in nature. This capacity reaches its apex in compound eyes, as well as in the simple eyes of cephalopods. Cuttlefish are known to communicate with each other with displays produced on their body surfaces that are visible only to animals that have polarization vision. Most invertebrates with polarization vision, however, use this ability to navigate with the assistance of patterns of polarization in the sky that occur naturally due to scattering of sunlight by the atmosphere. Bees and ants can find their way back to their nests or hives using only these celestial polarization cues. *See* EYE (VERTEBRATE). [T.W.C.; R.D.B.]

Eye (vertebrate) A sense organ that acts as a photoreceptor capable of image formation. The eye of vertebrates is constructed along a basic anatomical pattern which, in the diversification of animals, has undergone a variety of structural and functional modifications associated with different ecologies and modes of living. Often compared with a camera, the vertebrate eye is conveniently described in terms of its wall, cavities, and lens (see illustration).

Wall. The wall of the eye consists of three distinct layers or tunics which, from outward to inward, are termed the fibrous, vascular, and sensory tunics.

Fibrous tunic. This continuous, outermost fibrous tunic comprises a transparent anterior portion, the cornea, and a tough posterior portion, the sclera. In the human, the cornea represents about one-sixth of the fibrous tunic, the sclera five-sixths.

The vertebrate cornea exhibits very few modifications in structure regardless of environmental influences. Its major constituent is connective tissue (both cells and fibers), regularly arranged and bordered on both anterior and posterior surfaces by an epithelium. The anterior epithelium is stratified, ectodermal in origin, and continuous with the (conjunctival) epithelium lining the



Horizontal section through human eye.

eyelids. The transparency of the cornea is attributed to the geometric organization of its connective tissue elements, its constant state of deturgescence, and its chemical composition. It is the first ocular component traversed by the incoming light.

The sclera, a touch connective tissue tunic, provides support for the eye and serves for the attachment (insertions) of the muscles that move it.

The limbus is located at the angle of the anterior chamber. This small, circular transitional zone between the cornea and the sclera houses the major route for the discharge of aqueous humor from the anterior chamber.

Vascular tunic. The vascular tunic or uvea makes up the middle layer of the wall of the eye. It does not form a continuous layer around the eye but is deficient anteriorly, where the opening is termed the pupil. Beginning at the pupil, three continuous components of the uvea can easily be recognized: the iris, ciliary body, and choroid.

The iris is a spongy, circular diaphragm of loose, pigmented connective tissue separating the anterior and posterior chambers and housing a hole, the pupil, in its center. When heavily pigmented, the human iris appears brown; when lightly pigmented, blue.

The ciliary body is continuous with the root of the iris. The posterior epithelium of the iris continues along the internal surface of the ciliary body as a double layer of cells (ciliary part of the retina) which assumes many folds for the attachment of the suspensory ligament of the lens. This ligament holds the lens in position and shape, and marks the posterior boundary of the posterior chamber. The inner layer of the ciliary epithelium contains no pigment. It produces aqueous humor which flows into the posterior chamber and thence into the anterior chamber (via the pupil). The continual production and removal of this fluid maintain the intraocular pressure of the eye (which is increased in glaucoma).

The choroid is the most posterior portion of the uvea. It is directly continuous with the subepithelial portion of the ciliary body and consists primarily of blood vessels embedded within deeply pigmented connective tissue.

Sensory tunic. The retina is the sensory tunic of the eye. It has the form of a cup closely applied to the inner portion of the choroid, and, internally, it is slightly adherent to the semisolid vitreous body. The vertebrate retina contains the light-sensitive receptors (visual cells) and a complex of well-organized impulse-carrying nerve cells (neurons), all arranged into discrete layers.

The pigment epithelium forms an important barrier between the light-sensitive receptors (visual cells) and their blood supply, the choroid. As in the choroid, the pigmentation serves to absorb light and prevent its reflection.

The rods and cones of vertebrates generally occur as single units, but combinations of each type are frequently encountered in several vertebrate classes. Cones appear to be adapted for photopic, or daylight, vision, based on correlations with the visual habits of the animals involved. Rods, which predominate in nocturnal vertebrates, are adapted for scotopic, or night, vision. Except for their external process, the structure of these cells does not reflect these differences. *See* PHOTORECEPTION; VISION.

An important adaptation for improving visual detail in vertebrates is the formation of circumscribed thickenings of the retina resulting from localized increases in the number of visual cells and the other retinal neurons associated synaptically with them. Such thickenings, termed areas of acute vision, appear in some members of all vertebrate classes and reach their greatest development in birds, in which one to three distinct areas may be found in the same retina. Only a single area occurs in humans; it is colored yellow and is called the macula. The macula is situated in the center of the fundus and contains only cones.

Cavities. Three cavities or chambers are present within the vertebrate eye: anterior, posterior, and vitreous. The anterior and posterior chambers are continuous with one another at the pupil and are filled with the aqueous humor. The eye is normally maintained in a distended state by the (intraocular) pressure created by this fluid. The vitreous cavity, on the other hand, is filled with a semisolid material, the vitreous body, which is fixed in amount and relatively permanent. Its consistency is not uniform in all vertebrates, however.

Lens. The lens is a transparent body, supported by thin suspensory fibers and by the vitreous body behind and by the iris in front. It is completely cellular, the anterior cells forming a thin epithelium, and the posterior cells, much elongated, forming the so-called lens fibers. The entire lens is surrounded by an elastic capsule which serves for the attachment of the ciliary zonule. In all vertebrates the lens functions in accommodation, either by moving backward and forward or by changing its shape. An opacity of the lens is termed a cataract.

[D.B.M.; R.O'Ra.]

Electrophysiology of rods and cones. Visual information perceived by the vertebrate eye is fed to the brain in the form of coded electrical impulses that are initiated by the light-sensitive, visual-pigment-containing outer segments of the rods and cones. Light striking the outer segments is absorbed by these pigments, resulting—in the case of rhodopsin, for example—in the isomerization of the 11-*cis*-retinal chromophore to all *trans*-retinal. The outcome of this photolytic process is a change in electrical activity at the plasma membrane enclosing the outer segments, and a sudden and drastic decrease in its permeability (particularly to Na^+). The net result is a hyperpolarization response, or increased negativity of membrane potential. Hyperpolarization generates a membrane current that spreads to the inner segment and finally to the synaptic terminal, where it regulates the release of neurotransmitter and thus controls the flow of information from the visual cells to other retinal cells (bipolars, horizontals, other photoreceptors).

Cyclic GMP is directly responsible for regulating the permeability of the plasma membrane by opening ionic channels (in the light). Its concentration is controlled by a peripheral membrane enzyme, phosphodiesterase, which in turn is activated by transducin, an intracellular messenger protein generated by a photolytic intermediate of rhodopsin. Since one molecule of photoactivated rhodopsin can react with many molecules of transducin, an amplification of the visual cells' response is produced, the final amplitude being enhanced by breakdown of cyclic GMP by phosphodiesterase and subsequent closure of outer segment ionic channels and hyperpolarization.

Since photoreceptors are depolarized in the dark, their axon terminals continually release a transmitter that hyperpolarizes (inhibits) the bipolar cell, and since this cell is hyperpolarized in the dark, it is prevented from releasing its excitatory transmitter at the ganglion cell synapse so that the synapse is not excited. In the light, hyperpolarization of the visual cells causes a decrease in the amount of inhibitory transmitter released at the bipolar synapse, leading to a depolarization of the latter, which in turn increases the amount of excitatory transmitter released at the bipolar-ganglion synapses and affecting the ganglion cells.

A change in the light energy taking place across the retina also initiates a transient complex of electrical waveforms, the electroretinogram, which is recorded as a difference in potential between the cornea and the back of the eye. [D.B.M.]

Eye disorders Disorders of form and function that affect the eye. Disorders of form affect the way the eye looks or feels; disorders of function affect vision. Normal vision requires proper performance from the entire visual system, from the precorneal tear film to the occipital cortex. *See* EYE (VERTEBRATE); VISION.

The eyelids contain many glands that are susceptible to acute or chronic infection. Acute infection produces a hordeolum, or sty, which is a localized nodule up to several millimeters in diameter swelling may develop rapidly. Chronic infection results in a granulomatous nodule, or chalazion. In many cases, surgical removal is indicated.

Conjunctivitis is an inflammation of the conjunctiva, regardless of cause, which may include viral, bacterial, or chlamydial infection; mechanical or chemical trauma; allergy; and so on. The symptoms of conjunctivitis depend on the cause and generally include conjunctival redness (hyperemia), swelling (chemosis), mild to moderate discomfort, and tearing. If the conjunctiva is the only structure involved, vision is usually affected minimally or not at all. Infectious conjunctivitis is often termed pink eye because of the bright red appearance of the conjunctiva. Bacterial infections are usually responsible for pink eye in children. Infectious conjunctivitis in adults is commonly caused by viral agents. Chlamydial infections are responsible for inclusion conjunctivitis and ophthalmia neonatorum in the United States and trachoma in many arid regions of the third world. The initial infection involves the conjunctiva, but ultimately trachoma results in blindness due to a scarred, vascularized, opaque cornea. *See* VISUAL IMPAIRMENT.

If the cornea and conjunctiva are both involved, the condition is referred to as keratoconjunctivitis. Adenovirus infection causes keratoconjunctivitis. If lubrication by the lacrimal glands or accessory lacrimal glands is interrupted by infection, trauma, or autoimmune disease, one of the dry-eye syndromes may ensue. The symptoms include a mild foreign-body sensation, light sensitivity (photophobia), and gritty feeling in the eyes that progresses throughout the day. Paradoxically, increased tearing (epiphora) can be a symptom of dry eyes.

Glaucoma is a serious eye disorder with many subclassifications. It is characterized by intraocular pressure sufficiently high to cause characteristic damage to the optic nerve. *See* GLAUCOMA.

The leading cause of blindness in the world is cataract, an opacity within the crystalline lens. The overwhelming majority of cataracts have no specific cause and are associated with aging. Effective therapy almost always involves surgical removal of the lens. *See* CATARACT.

Degeneration of the retina produces a painless distortion or loss of vision. The function may be disrupted in many ways. The retina itself may be affected by infectious processes. Cytomegalovirus retinitis, for instance, is a frequent cause of visual loss in individuals with acquired immune deficiency syndrome (AIDS). Primary retinal degeneration may occur in many forms. Retinitis pigmentosa tends to manifest itself early in life and progresses from peripheral to central visual loss; prognosis depends in part on the hereditary pattern of the disease. Involutional macular degeneration is fairly common in the elderly. It affects the central vision first and rarely spreads to the peripheral vision. Between these two extremes is a very large number of progressive retinal dystrophies and degenerations, involving central or peripheral vision or both. Although the ultimate visual loss is variable, it is often severe.

Retinal detachment occurs when the sensory layers of the retina are separated from their supporting foundations. It is classified as rhegmatogenous (caused by a retinal hole) or nonrhegmatogenous. Rhegmatogenous retinal detachment occurs spontaneously or following trauma. Nonrhegmatogenous retinal detachment occurs as a final stage of such pathologic conditions as retinopathy of prematurity or diabetic retinopathy. The symptoms of retinal detachment are a painless and sudden segmental or total visual loss in one eye. Treatment is aimed at reestablishing the connection between the sensory-neural retina and its supporting structures.

Diabetic retinopathy is a common cause of severe retinal disease. Research has developed many methods of interrupting the progression of diabetic retinopathy. The most effective include laser therapy for localized retinal edema, hemorrhage, and neovascularization, and vitrectomy for late-stage diabetic retinopathy with vitreous hemorrhage and retinal traction. [M.Dr.]

Eyeglasses and contact lenses Lenses worn to improve vision. The primary function of the eye is to focus light energy on the retina. In the optics of a normal eye, parallel rays of light are refracted into sharply focused points of light on the retina. Refraction is necessary because all natural light rays are divergent. The degree of divergence (or minus power) varies with distance: the closer the observer to the light source, the greater the divergence. The unit of measure of divergence is the diopter; the divergence of light rays in diopters is the reciprocal of the distance of the observer from the light source. The human eye is approximately 1/60 m (1.67 cm or 0.65 in.) and therefore requires about 60 diopters of converging (plus) power to bring light rays parallel at the cornea into focus on the retina.

If the eye is too long or possesses too much converging power, as in nearsightedness (or myopia), the image on the retina is made up of blurred circles rather than focused points of light. This may be remedied in two ways. First, the observer may move closer to the object. A second method of correcting nearsightedness is to introduce a minus lens (or divergence) into the path of light striking the eye. This can be done with concave lenses.

The converse is true for farsightedness. The farsighted (or hyperopic) eye is too short or too weak in refracting power. The convergence applied to incoming light is insufficient to focus it at the retina, and blurred circles form rather than focused points of light. To correct this, plus lenses that add convergence to incoming light are used.

Accommodation, the ability of the eye to change its refractive power for sharp viewing across different distances, decreases with age, and by the mid-forties or early fifties it is often difficult to read print at a normal distance. This condition is known as presbyopia and is corrected with reading glasses, or bifocals in which the distance prescription is in the upper segment and plus power in a lower segment.

In addition to eyeglasses worn in frames, contact lenses can be used to assist the eye in forming a sharp image. The contact lens rests directly on the precorneal tear film; its front surface becomes the initial refracting surface of the eye. Contact lenses can be either divergent or convergent and are classified as hard, soft, or gas-permeable hard according to the materials that they are made of, their rigidity or flexibility, and their permeability to oxygen and other gases. Traditional hard contact lenses are the most rigid and tend to be smaller in diameter than the cornea. Soft lenses are usually larger in diameter than hard contact lenses, very thin and flexible, permeable to oxygen and other gases, and tend to take the shape of the cornea. A gas-permeable contact lens is an improvement of the hard contact lens. It is more rigid than a soft lens but more permeable to gases than the older hard contact lenses. *See* EYE (VERTEBRATE); GEOMETRICAL OPTICS; VISION. [M.Dr.]

Eyepiece A lens or optical system which offers to the eye the image originating from another system (the objective), at a suitable viewing distance. The image can be virtual. *See* OPTICAL IMAGE.

In modern instruments, most eyepieces (also called oculars) are not independently corrected for all errors. They are designed to balance out certain residual aberrations of the objective or (as in the microscope) of a group of objectives, for instance, chromatic difference of magnification. *See* ABERRATION (OPTICS).

The Ramsden eyepiece consists of two planoconvex lenses, the field lens and the eye lens, with their plane sides out. Both of these lenses have the same power and focal length; their separation is equal to their common focal length. *See* GEOMETRICAL OPTICS; LENS (OPTICS).

The Huygens eyepiece also consists of two planoconvex lenses, but the plane sides of both lenses face the eye, The focal length of the field lens is in general three times that of the eye lens, and the separation is twice the focal length of the eye lens. [M.J.H.]

F

Fabales An order of flowering plants, division Magnoliophyta (Angiospermae), in the subclass Rosidae of the class Magnoliopsida (dicotyledons). The order consists of three closely related families (Mimosaceae, Caesalpiniaceae, Fabaceae) collectively called the legumes. Members of the order typically have stipulate, compound leaves, 10–many stamens which are often united by the filaments, and a single capel which gives rise to a dry fruit (legume) that opens at maturity by splitting along two sutures, releasing the nonendospermous seeds. Many, or perhaps most, members of the order harbor symbiotic nitrogen-fixing bacteria in the roots. *See* Alfalfa; Bean; Clover; Cowpea; Lespedeza; Locust (forestry); Magnoliopsida; Pea; Peanut; Soybean; Vetch. [T.M.Ba.]

Facies (geology) Any observable attribute of rocks, such as overall appearance, composition, or conditions of formation, and changes that may occur in these attributes over a geographic area. The term facies is widely used in connection with sedimentary rock bodies, but is not restricted to them. In general, facies are not defined for sedimentary rocks by features produced during weathering, metamorphism, or structural disturbance. In metamorphic rocks specifically, however, facies may be identified by the presence of minerals that denote degrees of metamorphic change.

Sedimentary facies. The term sedimentary facies is applied to bodies of sedimentary rock on the basis of descriptive or interpretive characteristics. Descriptive facies are based on lithologic features such as composition, grain size, bedding characteristics, and sedimentary structures (lithofacies) or on biological (fossil) components (biofacies), or on both. Individual lithofacies or biofacies may be single beds a few millimeters thick or a succession of beds tens to hundreds of meters thick. For example, a river deposit may consist of decimeters-thick beds of a conglomerate lithofacies interbedded with a cross-bedded sandstone lithofacies. The fill of certain major Paleozoic basins may be divided into units hundreds of meters thick comprising a shelly facies, containing such fossils as brachiopods and trilobites, and graptolitic facies.

The term facies can be used also in an interpretive sense for groups of rocks that are thought to have been formed under similar conditions. This usage may emphasize specific depositional processes, such as a turbidite facies, or a particular depositional environment such as a shelf carbonate facies, encompassing a range of depositional processes.

Groups of facies (usually lithofacies) that are commonly found together in the sedimentary record are known as facies assemblages or facies associations. These groupings provide the basis for defining broader, interpretive facies for the purpose of paleogeographic reconstruction. *See* Paleogeography. [A.D.M.]

A metamorphic facies is a collection of rocks containing characteristic mineral assemblages developed in response to burial and heating to similar depths and temperatures. It can represent either the diagnostic mineral assemblages that indicate the physical conditions of metamorphism or the pressure-temperature conditions that produce a particular assemblage in a rock of a specific composition.

The metamorphic facies to which a rock belongs can be identified from the mineral assemblage present in the rock; the pressure and temperature conditions represented by each facies are broadly known from experimental laboratory work on mineral stabilities. These facies names are based on the mineral assemblages that develop during metamorphism of a rock with the composition of a basalt, which is a volcanic rock rich in iron and magnesium and with relatively little silica. For example, the dominant mineral of the blueschist facies (in a rock of basaltic composition) is a sodium- and magnesium-bearing silicate called glaucophane, which is dark blue in outcrop and blue or violet when viewed under the microscope. Characteristic minerals of the greenschist facies include chlorite and actinolite, both of which are green in outcrop and under the microscope. Basaltic rocks metamorphosed in the amphibolite facies are largely composed of an amphibole called hornblende. The granulite facies takes its name from a texture rather than a specific mineral: the pyroxenes and plagioclase that are common minerals in granulite facies rocks typically form rounded crystals of similar size that give the rock a granular fabric. *See* Amphibolite; Basalt; Blueschist; Glaucophane; Granulite; Metamorphic rocks; Metamorphism; Pyroxene. [J.Sel.]

Facsimile The process by which a document is scanned and converted into electrical signals which are transmitted over a communications channel and recorded on a printed page or displayed on a computer screen. The scanner may be compared with a camcorder, and the recorder is similar to an office copier or a computer printer. As an alternative to scanning, a document stored in computer memory can be transmitted. As an alternative to recording, a text facsimile (fax) image can be captured in computer memory and converted into computer-processable text by optical character recognition (OCR) software. Telephone lines or satellites provide the communication channel.

Most facsimile units communicate over the Public Switched Telephone Network, alternatively called the General Switched Telephone Network. A built-in high-speed digital modem automatically selects the highest modem speed (28,800–2400 bits/s) common to both facsimile units. If the telephone-line quality is not good enough for this transmission speed, a lower speed is negotiated during initialization. *See* Modem; Telephone service.

In the scanning process, an image of the original page is formed by a lens in a way similar to that of an ordinary camera. A charge-coupled-device linear array of small photodiodes is substituted in the facsimile scanner for the camera film. The portion of the image falling on the linear diode array is a thin line, 0.005 in. (0.13 mm) high, across the top of the page being transmitted. Typically, 1728 diodes are used to view this line for a page $8\frac{1}{2}$ in. (216 mm) wide. The photodiode corresponding to the left edge of the page is first checked to determine whether the very small portion of the image it detects is white (the paper background) or black (a mark). The spot detected by a single photodiode is called a picture element (a pel for short if it is recorded as either black or white, or a pixel if a gray scale is used). Each of the 1728 diodes is checked in sequence, to read across the page. Then the original page is stepped the height of this thin line, and the next line is read. The step-and-read process repeats until the whole page has been scanned. *See* Camera; Charge-coupled devices; Photodiode; Television camera.

Another class of flatbed scanner uses a contact image sensor linear array of photodiodes whose width is the same as the scanned width. One version has a linear array of fiber-optics rod lenses between the page being scanned and the sensor array. Light from a fluorescent lamp or a linear light-emitting-diode array illuminates the document beneath the rod lenses. The reflected light picked up by the sensor generates a signal that is proportional to the brightness of the spot being scanned. A second version has a hole in the center of each square pixel sensor element. Light from a light-emitting diode passes through this hole to illuminate the area of the document page at this pixel. No lenses or other optical parts are used. *See* Fiber-optics imaging; Light curves.

In drum-type scanning, the original sheet of paper is mounted on a drum that rotates while the scan head with a photosensor moves sideways the width of one scanning line for each turn of the drum. Drum-type scanners are used mainly for remote publishing facsimiles and for color scanning in graphic arts systems.

In the recording process, facsimile signals are converted into a copy of the original. Facsimile receivers commonly print pages as they are received, but in an alternative arrangement pages may be stored and viewed on a computer screen. [K.R.McC.]

Factor analysis A method of quantitative multivariate analysis with the goal of representing the interrelationships among a set of continuously measured variables (usually represented by their intercorrelations) by a number of underlying, linearly independent reference variables called factors. Although the term factor analysis has come to represent a family of analysis methods, the two most commonly used approaches are the full component model, in which the entire variance of the variables (represented by unities inserted in the principal diagonal of the correlation matrix) is analyzed, and the common factor model, in which the proportion of the variance that is accounted for by the common factors (represented by communality estimates inserted in the principal diagonal) is analyzed.

The method was developed in England around the turn of the century and was first applied to the study of the structure of intellectual abilities. Since then it has been used in many disciplines, from agriculture to zoology, in which the underlying structure of multiple variables and their representation in that structure are of interest. Another application of factor analysis is to represent parsimoniously the variables in the set on which the observations are made by a smaller number of underlying reference variables or factors. *See* Statistics. [B.Fr.]

Fagales An order of flowering plants, division Magnoliophyta (Angiospermae), in the superorder Rosidae of Eudicotyledon. The order consists of 8 families (Betulaceae, Casuarinaceae, Fagaceae, Juglandaceae, Myricaceae, Nothofagaceae, Rhoipteleaceae, Ticodendraceae) and approximately 30 genera and nearly 1000 species. The Fagales are either simple or compound-leaved, woody plants. Flowers are mostly unisexual and much reduced for wind pollination. The female flowers produce one- or two-seeded nut fruits (for example, acorn, chestnut, walnut); the male flowers are grouped into pendant catkins (see illustration). Birch (*Betula*), beech (*Fagus*), walnut (*Juglans*), and oak (*Quercus*) are members of the Fagales. *See* Beech; Birch; Magnoliophyta; Oak; Plant kingdom; Rosidae. [K.J.Sy.]

Butternut or white walnut (*Juglans cinerea*), a North American species showing compound leaves and slender drooping male catkins. (*Ken Sytsma, University of Wisconsin*)

Falconiformes A worldwide order of diurnal predacious birds without obvious affinities to other orders of birds. The New World vultures, which had been included in the Falconiformes, are now placed with the Ciconiiformes. *See* Ciconiiformes; Strigiformes.

The Falconiformes are divided into two suborders. The first, Accipitres, has three families: Pandionidae (osprey; one species); Accipitridae (hawks, eagles, kites, harriers, and Old World vultures; 217 species); and Sagittariidae (secretary bird; one species). The second suborder, Falcone, contains a single family, Falconidae (falcons, caracaras; 62 species).

The diurnal raptors have strong feet, usually with three toes pointing forward and one pointing backward, and ending with sharp claws. Their beaks are hooked and powerful. Their well-developed wings vary in shape according to the type of flight: long and pointed in falcons, short and broad in accipitrine hawks, and long and broad in vultures, eagles, and buzzards. Hawks are flying specialists, although most species can walk well. They hunt from the air, and they feed on animal prey from insects to sizable vertebrates, including fish, and on carrion.

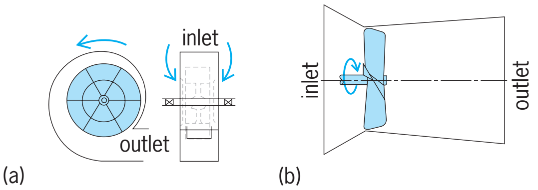
The osprey is specialized for catching fish with a reversible fourth toe, well-developed claws, and spiny scales along its toes. The one species is found almost worldwide. The secretary bird of Africa is long-legged and specialized for a terrestrial way of life. It runs rapidly, flies only infrequently, and catches poisonous snakes as well as many other vertebrates. *See* Aves. [W.J.B.]

Fallopian tube The upper part of the female oviduct present in humans and other higher vertebrates. The Fallopian tube extends from the ovary to the uterus and transports ova from the ovary to the cavity of the uterus. Each tube is about 5 in. (12.5 cm) long; one lies on either side of the uterus and is attached at the upper portion. Each curves outward to end in a hoodlike opening, the infundibulum, with many fingerlike projections; the cavity of the Fallopian tube is continuous with the cavity of the coelom. The ovaries lie below and inside the tubal curve.

The ovum remains viable in the oviduct for about 1–3 days only. If fertilization occurs, the ovum moves into the cavity of the uterus and then implants on its wall. If fertilization fails to occur, the ovum degenerates in the uterus. Occasionally, a fertilized ovum fails to enter the uterus, or may be freed into the abdominal cavity, so that an ectopic pregnancy results if the ovum finds a site for implantation. *See* Pregnancy disorders; Reproductive system. [W.B.]

Fan A fan moves gases by producing a low compression ratio, as in ventilation and pneumatic conveying of materials. The increase in density of the gas in passing through a fan is generally negligible; the pressure increase or head is usually measured in inches of water.

Blowers are fans that operate where the resistance to gas flow is predominantly downstream of the fan. Exhausters are fans that operate where the flow resistance is mainly upstream of the fan.



Fan types. (*a*) Centrifugal. (*b*) Axial.

Fans are further classified as centrifugal or axial (see illustration). The housing provides an inlet and an outlet and confines the flow to the region swept out by the rotating impeller. The impeller imparts velocity to the gas, and this velocity changes to a pressure differential under the influence of the housing and ducts connected to inlet and outlet. [T.Ba.]

Faraday effect Rotation of the plane of polarization of a beam of linearly polarized light when the light passes through matter in the direction of the lines of force of an applied magnetic field. Discovered by M. Faraday in 1846, the effect is often called magnetic rotation. *See* Magnetooptics.

The Faraday effect is particularly simple in substances having sharp absorption lines, that is, in gases and in certain crystals, particularly at low temperatures. Here the effect can be fully explained from the fundamental properties of the atoms and molecules involved. In other substances the situation may be more complex, but the same principles furnish the explanation.

Rotation of the plane of polarization occurs when there is a difference between the indices of refraction n^+ for right-handed polarized light and n^- for left-handed polarized light. Most substances do not show such a difference without a magnetic field, except optically active substances such as crystalline quartz or a sugar solution. It should be noted that the index of refraction in the vicinity of an absorption line changes with the frequency. *See* Absorption; Polarized light. [G.H.Di.; W.W.W.]

Faraday's law of induction A statement relating an induced electromotive force (emf) to the change in magnetic flux that produces it. For any flux change that takes place in a circuit, Faraday's law states that the magnitude of the emf ξ induced in the circuit is proportional to the rate of change of flux as in the expression below.

$$\xi \propto \frac{d\Phi}{dt}$$

The time rate of change of flux in this expression may refer to any kind of flux change that takes place. If the change is motion of a conductor through a field, $d\Phi/dt$ refers to the rate of cutting flux. If the change is an increase or decrease in flux linking a coil, $d\Phi/dt$ refers to the rate of such change. It may refer to a motion or to a change that involves no motion. *See* Electromagnetic induction. [K.V.M.]

Farm crops Farm crops may be roughly classed as follows: (1) food crops—the bread grains (wheat and rye), rice, sugar crops (sugarbeets and sugarcane), potatoes, and dry legume seeds (peanuts, beans, and peas); (2) feed crops—corn, sorghum grain, oats, barley, and all hay and silage; and (3) industrial crops—cotton (lint and seed), soybeans, flax, and tobacco. See separate articles on these topics.

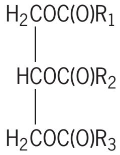
Crop production is regionalized in the United States in response to the combination of soil and climatic conditions and to the land topography, which favors certain kinds of crop management. In general, commercial farm crops are confined to land in humid and subhumid climates that can be managed to minimize soil and water erosion damage, where soil productivity can be kept at a relatively high level, and where lands are smooth enough to permit large-scale mechanized farm operations. In less well-watered regions, cropping is practiced efficiently on fairly level, permeable soils, where irrigation water can be supplied. The tilled crops, such as corn, sorghums, cotton, potatoes, and sugar crops, are more exacting in soil requirements than the close-seeded crops, such as wheat, oats, barley, rye, and flax. The crops planted in soil stands, mostly hay crops (as well as pastures), are efficient crops for lands that are susceptible to soil and water erosion.

The major farming regions of the United States are named from the predominant kinds of crops grown, even though there is tremendous diversity within each region. The Corn Belt includes a great central area extending from Nebraska and South Dakota east across much of Iowa, Missouri, Illinois, and Indiana to central Ohio. To the north and east of this region is the Hay and Dairy Region, which actually grows large quantities of feed grains. To the south of the Corn Belt is the Corn and Winter-Wheat Belt. The southern states, once the Cotton Belt, now concentrate on hay, pasture, and livestock, with considerable acreages of soybeans and peanuts. The cultivated portions of the Great Plains, extending from Canada to Mexcio, are divided into a spring-wheat region in the Dakotas and a winter-wheat region from Texas to Nebraska. The Intermountain Region, between the Rocky Mountains and the Cascade-Sierra Nevada mountain ranges, is cropped only where irrigation is feasible, and a wide range of farm crops is grown. In the three states of the Pacific Region, a great diversity of crops is grown. Cotton is now concentrated in the irrigated regions from Texas to California.

The United States is known most widely for its capacity to produce and export wheat. However, this nation has become a major producer of soybeans for export, and rice exports have become important. Most of the other farm crops are consumed within the United States. Tobacco and sugar crops are high acre-value crops, as are potatoes, peanuts, and dry beans. The production of these high acre-value crops is concentrated in localized areas where soils and climate are particularly favorable, rather than in broad acreages. *See* Agricultural science (plant); Agricultural soil and crop practices. [H.B.S.]

Fat and oil Naturally occurring esters of glycerol and fatty acids that have commercial uses. Since fats and oils are triesters, they are commonly called triglycerides or simply glycerides. A glyceride may be designated a fat or oil, depending on its melting point. A fat is solid and an oil is liquid at room temperature. Some liquid waxes are incorrectly referred to as oils. *See* Ester; Triglyceride; Wax, animal and vegetable.

The structure of triglycerides is shown below, where R_1, R_2, and R_3 represent the alkyl chain of the fatty acid.



$$\begin{array}{c} H_2COC(O)R_1 \\ | \\ HCOC(O)R_2 \\ | \\ H_2COC(O)R_3 \end{array}$$

The physical and chemical properties of fats and oils are determined to a large extent by the types of fatty acids in the glyceride. It is possible for all the acids to be identical, but this is rare. Usually there are two or even three different acids esterified to each glycerol molecule.

In all commercially important glycerides, the fatty acids are straight-chain, and nearly all contain an even number of carbon atoms. Most fats and oils are based on C_{16} and C_{18} acids with zero to three ethylenic bonds. There are exceptions, such as coconut oil, which is rich in shorter-chain acids, and some marine oils, which contain acids with as many as 22 or more carbons and six or more ethylenic linkages.

The majority of fats and oils come from only a few sources. Plant sources are nuts or seeds, and nearly all terrestrial animal fats are from adipose tissue. Marine oils come principally from the whole body, although a small amount comes from trimmings. Plant fats and oils are obtained by crushing and solvent extraction. Animal and marine oils are nearly all recovered by rendering. This is a process of heating fatty tissue with steam or hot water to melt and free the glyceride, followed by separating the oil or fat from the aqueous layer. *See* SOLVENT EXTRACTION.

There are some uses for fats and oils in their native state, but ordinarily they are converted to more valuable products. The most important changes are hydrolysis and hydrogenation. Hydrolysis is commonly called splitting. The purpose is to hydrolyze the ester into its constituent glycerol and fatty acids, which are valuable intermediates for many compounds. Hydrogenation is the catalytic addition of hydrogen to ethylenic bonds, and is applicable to both acids and glycerides. The purpose of hydrogenation is usually to raise the melting point or to increase the resistance to oxidation. *See* HYDROGENATION; HYDROLYTIC PROCESSES. [H.M.H.]

Fat and oil (food) One of the three major classes of basic food substances, the others being protein and carbohydrate. Fats and oils are a source of energy. They also aid in making both natural and prepared foods more palatable by improving the texture and providing a more desirable flavor. *See* FOOD.

Fats are grouped according to source. Animal fats are rendered from the fatty tissues of hogs, cattle, sheep, and poultry. Butter is obtained from milk. Vegetable oils are pressed or extracted from various plant seeds, primarily from soybean, cottonseed, corn (germ), peanut, sunflower, safflower, olive, rapeseed, sesame, coconut, oil palm (pulp and kernel separately), and cocoa beans. Marine oils, which are not consumed in the United States, are obtained mostly from herring, sardine, and pilchard.

Fats and oils are important in the diet. They are the most concentrated form of food energy, contributing about 9 cal/g (38 joules/g), as compared to about 4 cal/g (17 joules/g) for carbohydrates and proteins. Fats make a meal more satisfying by creating a feeling of fullness, and also delay the onset of hunger. Contrary to popular belief, fats are highly digestible, with 94–98% of the ingested fat being absorbed from the intestinal tract.

The polyunsaturated fatty acids, primarily linoleic and arachidonic, are essential nutrients; that is, they are not synthesized by the body but are required for tissue development. Absence of these fatty acids from the diet results in an essential fatty acid syndrome and in a specific form of eczema in infants. Vegetable oils are an excellent source of linoleic acid, while meat fats provide arachidonic acid in small but significant amounts. Fats and oils are carriers of the oil-soluble vitamins A and D, and are the main source of vitamin E. They also have a sparing action on some of the B complex vitamins. *See* NUTRITION.

Several forms of deterioration may occur in fats and oils. Flavor and odor may develop after deodorization of a product to complete blandness. The flavor is generally characteristic of the oil source and is therefore usually acceptable. However, soybean oil can develop disagreeable flavors described as beany, grassy, painty, fishy, or like watermelon rind. Beef fat can become tallowy, which is also objectionable. Reversion is apparently caused by changes in substances which have been oxidized prior to, but not removed by, deodorization.

Oxidative rancidity is a serious flavor defect and highly objectionable. It starts with the formation of hydroperoxides which then decompose to form aldehydes which have a pungent, disagreeable flavor and odor. Retardation of oxidation is brought about by using opaque, airtight containers, or nitrogen blanketing if clear glass bottles are used. Antioxidants are required in meat fats, since lard, tallow, and so on contain no natural antioxidant material. Vegetable oils contain tocopherols. Additional antioxidant, with the exception of tertiary butyl hydroquinone (TBHQ), has little benefit for these oils.

Hydrolytic rancidity results from the liberation of free fatty acids by the reaction of fats and oils with water. While most fats show no detectable off flavors, coconut and other lauric acid oils develop a soapy flavor, and butter develops the strong characteristic odor of butyric acid. Packaged coconut-oil products and lauric-type hard butters sometimes contain added lecithin, which acts as a moisture scavenger, thereby retarding hydrolytic rancidity development.

Fats and oils used in deep fat frying can break down under adverse conditions, especially where frying is intermittent or the fryer capacity is not fully used. Deterioration ultimately results in the oil becoming very dark in color, viscous, foul-odored, and foaming badly during frying. The oil becomes oxidized and then polymerized, requiring that it be discarded, since it imparts strong off flavors to the fried food.

Crystal structure transformation of packaged shortening results in formation of a grainy, soft product, which may also lose incorporated gas and take on the appearance of petroleum jelly. Similar changes in crystal structure can cause bloom in chocolate coatings, a defect which gives a white haze or even open grain on an originally smooth, glossy surface. Chocolate bloom can be inhibited by the addition of lecithin or polysorbates or both. *See* LIPID. [T.J.W.]

Fate maps (embryology) Diagrams of embryos showing the structures that the parts will become in the course of normal development. A series of fate maps for different developmental stages depicts the normal morphogenetic movements that the cells and tissues of an embryo undergo. However, a fate map for a given stage does not in itself include information about the developmental pathway to which different parts of the embryo are committed. States of commitment must be deduced by comparing the structures predicted by the fate map with those formed by tissue regions in isolation, or after grafting to unusual positions. An accurate fate map is thus a necessary tool for further studies in experimental embryology. *See* EMBRYOGENESIS; TRANSPLANTATION BIOLOGY.

For embryos in which there is no increase in size during development, and no random mixing of cells, it is possible in principle to project the fate map back into the fertilized egg. For example, in the nematode *Caenorhabditis elegans* the exact lineage of every cell has been determined. Where there is some local cell mixing, as in amphibian embryos, the fate map cannot be so precise, and represents the average behavior of a population of embryos. *See* CELL LINEAGE.

Clonal analysis, a special form of fate mapping in which a single cell is labeled, can give two pieces of information that a fate map of extended multicellular regions cannot. It allows for the detection of stem cells, which produce an entire structure by a sequence of unequal cell divisions. It also can set a lower bound to the time of developmental commitment. If a single cell can populate two structures, then clearly it cannot have been irreversibly committed to become either structure at the time of labeling.

In clonal analysis of plants, cells are labeled by exposing the seed or developing plant to ionizing irradiation or a chemical mutagen to produce chromosome mutations that result in distinct phenotypic alterations, usually deficiencies in the pigments chlorophyll or anthocyanin. The low frequency of mutations produced indicates that these are single-cell events. Because all of the progeny of a labeled cell will carry the same chromosome mutation, a shoot meristem cell labeled with a chlorophyll deficiency mutation, for example, will produce a sector, or clone, of white tissue in the developing plant. It is possible to deduce the number and fate of meristem cells labeled at one stage of development by examining the size and position of sectors present in the plant at a later stage of development. For example, a sector extending the entire length of the shoot would be generated by a permanent initial cell at the center of the meristem; if the width of that sector occupied one-third of the circumference of the shoot, then the shoot must have been formed by three such initial cells. *See* MUTATION; PLANT GROWTH. [D.E.J.]

Fault analysis The detection and diagnosis of malfunctions in technical systems. Such systems include production equipment, transportation vehicles, and household appliances. While the need to detect and diagnose malfunctions is as old as the construction of such systems, advanced fault detection has been made possible only by the proliferation of the computer. Fault detection and diagnosis actually means a scheme in which a computer monitors the technical equipment to signal any malfunction and determine the components responsible for it. The detection and diagnosis of the fault may be followed by automatic actions enabling the fault to be corrected, such that the system may operate successfully even under the particular faulty condition.

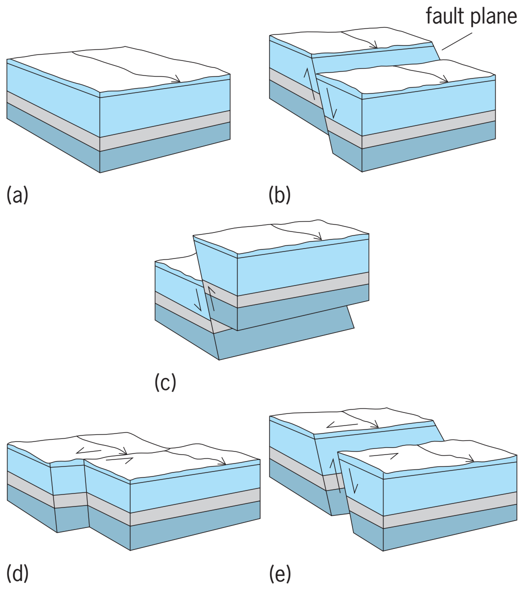
Fault detection and diagnosis applies to both the basic technical equipment and the actuators and sensors attached to it. Actuator and sensor fault detection is very important because these devices are quite prone to faults.

The on-line or real-time detection and diagnosis of faults means that the equipment is constantly monitored during its regular operation by a permanently connected computer, and any discrepancy is signaled almost immediately. On-line monitoring is very important for early detection of any component malfunction, before it can lead to more substantial equipment failure. In contrast, off-line diagnosis involves the monitoring of the system by a special, temporarily attached device, under special conditions (for example, car diagnostics at a service station).

The diagnostic activity may be broken down into several logical stages. Fault detection is the indication of something going wrong in the system. Fault isolation is the determination of the fault location (the component which malfunctions), while fault identification is the estimation of its size.

Fault detection and isolation can never be performed with absolute certainty, because of circumstances such as noise, disturbances, and model errors. There is always a trade-off between false alarms and missed detections, the proper balance depending on the particular application. [J.J.G.]

Fault and fault structures Products of fracturing and differential movements along fractures in continental and oceanic crustal rocks. Faults range in length and magnitude of displacement from small structures visible in hand specimens, displaying offsets of a centimeter or less, to long, continuous crustal breaks, extending hundreds of kilometers in length and accommodating displacements of tens or hundreds of kilometers. Faults exist in deformed rocks at the microscopic scale, but these are generally ignored or go unrecognized in most geological studies. Alternatively, where microfaults systematically pervade rock bodies as sets of very closely spaced subparallel, planar fractures, they are recognized and interpreted as a type of cleavage which permitted flow of the rock body. Fractures along which there is no visible displacement are known as joints. Large fractures which have accommodated major dilational opening (a meter or more) perpendicular to the fracture surfaces are known as fissures. Formation of fissures is restricted to near-surface conditions, for example, in areas of crustal stretching of subsidence.



Slip on faults. (*a*) Block before faulting; (*b*) normal-slip; (*c*) reverse-slip; (*d*) strike-slip; (*e*) oblique-slip. (*After F. Press and R. Siever, Earth, 2d ed., 1978*)

In addition to describing the physical and geometric nature of faults and interpreting time of formation, it has been found to be especially important to determine the orientations of minor fault structures (such as striae and drag folds) which record the sense of relative movement. Evaluating the movement of faulting can be difficult, for the apparent relative movement (separation) of fault blocks as seen in map or outcrop may bear little or no relation to the actual relative movement (slip). The slip of the fault is the actual relative movement between two points or two markers in the rock that were coincident before faulting (see illustration). Strike-slip faults have resulted in horizontal movements between adjacent blocks; dip-slip faults are marked by translations directly up or down the dip of the fault surface; in oblique-slip faults the path of actual relative movement is inclined somewhere between horizontal and dip slip.

Recognizing even the simplest translational fault movements in nature is often enormously difficult because of complicated and deceptive patterns created by the interference of structure and topography, and by the absence of specific fault structures which define the slip path. While mapping, the geologist mainly documents apparent relative movement (separation) along a fault, based on what is observed in plan-view or cross-sectional exposures. *See* TRANSFORM FAULT. [G.H.D.]

Fault-tolerant systems Systems, predominantly computing and computer-based systems, which tolerate undesired changes in their internal structure or external environment. Such changes, generally referred to as faults, may occur at various times during the evolution of a system, beginning with its specification and proceeding through its utilization. Faults that occur during specification, design, implementation, or modification are called design faults; those occurring during utilization are referred to as operational faults, The use of fault tolerance techniques is based on the premise that a complex system, no matter how carefully designed and validated, is likely to contain residual design faults and to encounter unpreventable operational faults.

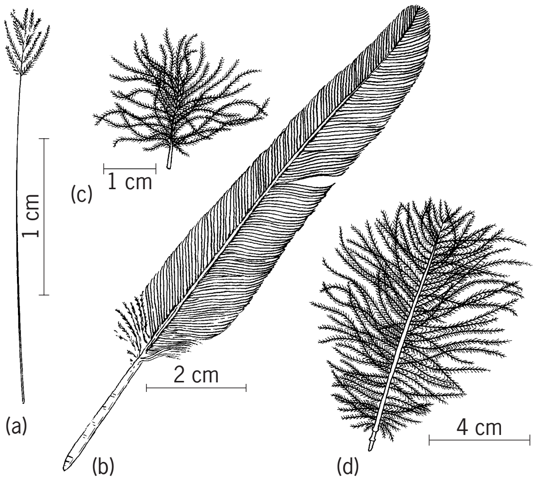
Generally, fault tolerance techniques attempt to prevent lower-level errors (caused by faults) from propagating into system failures. By using various types of structural and informational redundancy, such techniques either mask a fault (no errors are propagated to the faulty subsystem's output) or detect a fault (via an error) and then effect a recovery process which, if successful, prevents a system failure. In the case of a permanent internal fault, the recovery process usually includes some form of structural reconfiguration (for example, replacement of a faulty subsystem with a spare or use of an alternate program) which prevents the fault from causing further errors. Typically, a fault-tolerant system design will incorporate a mix of fault tolerance techniques which complement the techniques used for fault prevention. *See* SOFTWARE ENGINEERING. [J.F.Me.]

Feather

Feather A specialized keratinous outgrowth of the skin, which is a unique characteristic of birds. Feathers are highly complex structures that provide insulation, protection against mechanical damage, and protective coloration, and also function significantly in behavior. One special functional role is in flight, where feathers provide propulsive surfaces and a body surface aerodynamically suitable for flight. Feathers are used in maintenance of balance and occasionally in the capture of prey and various specialized displays.

A representative definitive feather contains a single long central axis which supports a row of small branchlike structures along each side (barbs). Barbs form the vane, or web, of the feather. Individual barbs branch off at variable angles and point toward the outer tip of the feather. The barbules are small branches from the barbs. They lie in the same plane as the barbs and arise in rows from their anterior and posterior surfaces. The anterior barbules have a flattened base and a series of small hooklike projections which attach to the proximal ridge of the posterior barbules of the next barb, forming an interlocking structure characterized by its great strength and light weight. All feather types consist basically of these structural elements.

Most of the superficial feathers are contour feathers (pennae). These include the large flight feathers (remiges) of the wing and the long tail feathers (rectrices). Other common feather types include the down feathers (plumulae), intermediate types (semiplumes), and filoplumes (see illustration).



Types of feathers. (*a*) Filoplume. (*b*) Vane or contour. (*c*) Down. (*d*) Semiplume. (*After J. C. Welty, The Life of Birds, Saunders, 1962*)

Feathers normally undergo attrition because of the physical abuse attendant to the normal activity of birds. In most species, feathers are replaced completely at least annually, and many of the feathers are replaced more frequently. The sequence of feather molt is surprisingly orderly. Penguins, which shed large patches of feathers in an irregular pattern, are an exception. In most species the power of flight is retained during molt. The molt, that is, the normal shedding of feathers and their replacement by a new generation of feathers, is a single growth process which is actively concerned only with the production of the new generation of feathers. The old feathers are pushed out of the follicles passively.

A major physiological role of feathers is to provide insulation. This is accomplished by regulating the configuration of feather and skin in such a way that differing amounts of air are trapped in the dead space so formed. A second mechanism for control of heat dissipation is the balance of the exposure of feathered and unfeathered body parts.

Feathers act as a protective boundary in their role of providing waterproofing. Water repellency is a structural feature of feathers and is the result of precise geometric relationships between the diameter and spacing of barbs and barbules. Preening appears to be more important in the maintenance of this structure than it is for the application of oils or any other natural product, as was once thought.

A third function of the surface configuration and overall pattern of feathers is in the area of behavioral adaptations. These may be of two types. First is concealment, when the bird is cryptically marked to match its background and escape detection. The second type consists of various types of advertisement. *See* PROTECTIVE COLORATION. [A.H.B.]

Federal Telecommunications System

Federal Telecommunications System A private telecommunications network that provides switched voice and data services for government employees in the 50 states of the United States, Guam, Puerto Rico, and the U.S. Virgin Islands.

The Federal Telecommunications System (FTS) intercity services are divided into two nationwide networks, each provided by one of the two vendors. Both vendors provide all-digital, fiber-optic backbone networks that support the integration of voice and nonvoice services on switching and transmission components at lower cost than in the previous system. *See* OPTICAL COMMUNICATIONS; SWITCHING SYSTEMS (COMMUNICATIONS).

The FTS2000 network includes six services and a wide range of capabilities. The enhanced systems have grown significantly in terms of voice usage and provide a full range of data services to meet the growing needs of the federal government. [W.P.Cu.]

Feedback circuit

Feedback circuit A circuit that returns a portion of the output signal of an electronic circuit or control system to the input of the circuit or system. When the signal returned (the feedback signal) is at the same phase as the input signal, the feedback is called positive or regenerative. When the feedback signal is of opposite phase to that of the input signal, the feedback is negative or degenerative.

The use of negative feedback in electronic circuits and automatic control systems produces changes in the characteristics of the system which improve the performance of the system. In electronic circuits, feedback is employed either to alter the shape of the frequency-response characteristics of an amplifier circuit and thereby produce more uniform amplification over a range of frequencies, or to produce conditions for oscillation in an oscillator circuit. It is also used because it stabilizes the gain of the system against changes in temperature, component replacement, and so on. Negative feedback also reduces nonlinear distortion. In automatic control systems, feedback is used to compare the actual output of a system with a desired output, the difference being used as the input signal to a controller. *See* AMPLIFIER; NEGATIVE-RESISTANCE CIRCUITS; SERVOMECHANISM. [H.F.K.]

Feldspar Any of a group of aluminosilicate minerals whose crystal structures are composed of corner-sharing [AlO_4] and [SiO_4] tetrahedra linked in an infinite three-dimensional array, with charge-balancing cations primarily sodium (Na), potassium (K), and calcium (Ca)] occupying large, irregular cavities in the framework of the tetrahedra. Collectively, the feldspars constitute about 60% of the outer 8–10 mi (13–17 km) of the Earth's crust. They are nearly ubiquitous igneous and metamorphic rocks, and are a primary constituent of arkosic sediments derived from them. The importance of the many feldspars that occur so widely in igneous, metamorphic, and some sedimentary rocks cannot be underestimated, especially from the viewpoint of a petrologist attempting to unravel earth history. *See* Arkose; Mineralogy; Petrology; Silicate minerals.

With weathering, feldspars form commercially important clay materials. Economically, feldspars are valued as raw material for the ceramic and glass industries, as fluxes in iron smelting, and as constituents of scouring powders. Occasionally their luster or colors qualify them as semiprecious gemstones. Some decorative building and monument stones are predominantly composed of weather-resistant feldspars. *See* Clay minerals; Igneous rocks; Metamorphic rocks.

The general formula AT_4O_8 characterizes the chemistry of feldspars, where T (for tetrahedrally coordinated atom) represents aluminum (Al) or silicon (Si). The A atom is Ca^{2+} or barium (Ba^{2+}) for the $[Al_2Si_2O_8]^{2-}$ alkaline-earth feldspars and Na^+ or K^+ for the $[AlSi_3O_8]^-$ alkali feldspar series of solid solutions and mixed crystals.

Knowledge of a feldspar's composition and its crystal structure is indispensable to an understanding of its properties. However, it is the distribution of the Al and Si atoms among the available tetrahedral sites in each chemical species that is essential to a complete classification scheme, and is of great importance in unraveling clues to the crystallization and thermal history of many igneous and metamorphic rocks.

Alkali feldspars are assigned to the polymorphs of $KAlSi_3O_8$ and $NaAlSi_3O_8$ in accordance with their symmetry and the Al content of their tetrahedral sites. *See* Albite; Microcline; Orthoclase.

Anorthoclase is a triclinic solid solution of composition $Or_{37}Ab_{63}$-Or_0Ab_{100} containing up to 10 mol % anorthite, or more. *See* Anorthoclase.

Plagioclase feldspars containing significant amounts of exsolved K-rich feldspar are called antiperthites. It is only in once-molten rocks quenched at very high temperatures that the full range of so-called high plagioclases exist as simple solid solutions. With very slow cooling over millions of years, complex textures develop in most feldspar crystals as a coupled NaSi, CaAl ordering. *See* Andesine; Bytownite; Labradorite; Oligoclase; Solid solution.

The variable properties of feldspars are determined by their structure, symmetry, chemical composition, and crystallization and subsequent history of phase transformation, exsolution, and alternation or deformation. Very few feldspars are transparent and colorless; many are white or milky due to internal reflections of light from inclusions, exsolution interfaces, and fracture or cleavage surfaces. Plagioclases are slightly harder (6–6.5) on Mohs scale than K-rich feldspars (6). Feldspars are brittle and, when broken, cleave along the (001) and (010) crystallographic planes. [P.H.R.]

Feldspathoid A member of the feldspathoid group of minerals. Members of this group are characterized by the following related features: (1) All are aluminosilicates with one or more of the large alkali ions (for example, sodium, potassium) or alkaline-earth ions (for example, calcium, barium). (2) The proportion of aluminum relative to silicon, both of which are tetrahedrally coordinated by oxygen, is high. (3) Although the crystal structures of many members are different, they are all classed as tektosilicates. (4) They occur principally in igneous rocks, but only in silica-poor rocks, and do not coexist with quartz (SiO_2). Feldspathoids react with silica to yield feldspars, which also are alkali-alkaline-earth aluminosilicates. Feldspathoids commonly occur with feldspars. *See* Feldspar; Silicate minerals.

The principal species of this group are the following:

Nepheline	$KNa_3[AlSiO_4]_4$
Leucite	$K[AlSi_2O_6]$
Cancrinite	$Na_6Ca[CO_3 \mid (AlSiO_4)_6] \cdot 2H_2O$
Sodalite	$Na_8[Cl_2 \mid (AlSiO_4)_6]$
Nosean	$Na_8[SO_4 \mid (AlSiO_4)_6]$
Haüyne	$(Na,Ca)_{8-4}(SO_4)_{2-1}(AlSiO_4)_6]$
Lazurite	$(Na,Ca)_8[(SO_4,S,Cl)_2 \mid (AlSiO_4)_6]$

The last four species (sodalite group) are isostructural, and extensive solid solution occurs between end members; but members of the sodalite group, cancrinite, leucite, and nepheline have different crystal structures. *See* Cancrinite; Lazurite; Leucite; Leucite rock; Sodalite. [D.R.P.]

Feline infectious peritonitis A fatal disease of both domestic and exotic cats (particularly cheetahs) caused by feline infectious peritonitis virus, a member of the Coronaviridae family. There are multiple strains of the virus which vary in virulence. Feline infectious peritonitis virus is closely related morphologically, genetically, and antigenically to other members of the Coronaviridae and arises as mutants from feline enteric coronaviruses, which infect cats but generally induce very mild or inapparent gastroenteritis. All coronaviruses are single-stranded ribonucleic acid (RNA) viruses with poor or no error correction during replication, resulting in relatively high mutation rates.

Feline coronaviruses are contracted primarily during exposure to infectious cat feces in the environment, but also via ingestion or inhalation during cat-to-cat contact. Feline infectious peritonitis virus is relatively labile once outside the cat's body but may be able to survive for as long as 7 weeks if protected from heat, light, and desiccation. It is readily inactivated by most disinfectants.

Signs of infection with feline infectious peritonitis virus depend upon the severity of infection, the relative ability of the immune system to minimize some of the characteristic inflammatory lesions, and the organ systems affected. There are two clinical forms of the disease. Wet feline infectious peritonitis, which is characterized by protein and fluid leakage into the abdominal cavity (or less frequently thoracic and scrotal spaces), occurs in cats with overwhelming infection, with poor immunity, or during late stages of other forms of the virus. In contrast, if a cat has a moderately competent (but ultimately ineffectual) immune response to the virus infection, granulomas may arise in infected tissues. This form of the disease, known as dry feline infectious peritonitis, commonly affects kidneys, liver, lymph nodes, mesentery, diaphragm, the outer surface of the intestine, and the neurological system. Wet or effusive feline infectious peritonitis is characterized by abdominal swelling, jaundice, and typically difficulty in breathing.

As with most viral infections, there is no specific antiviral drug of proven efficacy in the treatment of feline infectious peritonitis. Clinical management rests upon palliative treatment of the specific signs exhibited by each cat, and upon antibiotics, when indicated, to reduce secondary bacterial infections. The most important therapeutic approach involves the administration of immunosuppressive doses of corticosteroids to reduce the cat's immune response to the virus. *See* Animal virus; Virus. [J.E.F.]

Feline leukemia A type of cancer caused by the feline leukemia virus, a retrovirus which affects only a small percentage of freely roaming or domestic cats. The feline leukemia virus is genetically and morphologically similar to murine leukemia virus, from which it presumably evolved several million years ago.

About 1–5% of healthy-appearing wild or freely roaming domestic cats have lifelong (persistent) infections. These carrier cats shed the virus in urine, feces, and saliva. The principal route of infection is oral. Infections occurring in nature are usually inapparent or mild, and 95% of such cats recover without any signs of illness. Mortality due to a feline leukemia virus infection occurs mainly among persistently infected cats and at a rate of around 50% per year.

There is no treatment that eliminates the virus. Supportive or symptomatic treatment may prolong life for weeks or months, depending on the particular disease manifestation. All cats should be tested for the presence of the virus prior to putting them in contact with feline leukemia virus-free animals. Healthy-appearing or ill infected cats should not be in intimate contact with noninfected cats, even if the latter have been vaccinated. Feline leukemia virus vaccines are available and should be administered annually, although they should not be considered a substitute for testing, elimination, and quarantine procedures. *See* LEUKEMIA; RETROVIRUS. [N.C.P.]

Feline panleukopenia An acute viral infection of cats, also called feline viral enteritis and (erroneously) feline distemper. The virus infects all members of the cat family (Felidae) as well as some mink, ferrets, and skunks (Mustelidae); raccoons and coatimundi (Procyonidae); and the binturong (Viverridae). Panleukopenia is the most important infectious disease of cats. This disease occurs worldwide, and nearly all cats are exposed by their first year because the virus is stable and ubiquitous; the disease is rarely seen in older cats. Without treatment, this disease is often fatal.

Feline panleukopenia virus is classified as a parvovirus, and is one of the smallest known viruses. It is antigenically identical to the mink enteritis virus, and only minor antigenic differences exist between feline panleukopenia virus and canine parvovirus. It is believed that canine parvovirus originated as a mutation from feline panleukopenia virus.

The disease is severe and life threatening in 20–50% of cases. The cat is depressed and may refuse food or water; vomiting and diarrhea are common, resulting in severe dehydration. The cat may have a fever or a subnormal temperature. A low white blood cell count confirms the diagnosis as panleukopenia. Diagnosis can be made by autopsy and evidence of the destruction of the intestinal crypts and villus shortening.

Highly effective and safe vaccines are available for the prevention of panleukopenia. Premises contaminated by feline panleukopenia virus are extremely difficult to disinfect; chlorine bleach, formaldehyde, or a certain quaternary ammonium disinfectant will destroy the virus. A cat should be successfully immunized before being introduced to premises where a pan-leukopenia-infected cat previously lived. *See* ANIMAL VIRUS. [J.H.Car.]

Fennel *Forniculum vulgare*, a culinary herb of the parsley family (Apiaceae). It is grown for the dried, ripe fruits or seeds which are used in bread, pickles, liqueurs, and meat sauces and dishes. Although similar in odor to anise, fennel seed can be distinguished by its warm, sweet character. *See* APIALES.

The three fennel varieties of commercial importance are *vulgare*, *dulce*, and *piperitum*. The variety *vulgare* is grown for its seed and the essential oil, obtained by steam distillation and known as bitter fennel oil. The variety *dulce* (finochio or Florence fennel) is grown for four products; seed and leaf for culinary use, the enlarged leaf base for a vegetable, and for the essential oil from the seeds (sweet fennel oil). The young stems of Italian fennel, variety *piperitum*, are used for flavoring in salads.

Fennel is native to southern Europe and the Mediterranean region and is presently cultivated as an annual or biennial plant in southern and eastern Europe, India, Argentina, China, and Pakistan. *See* SPICE AND FLAVORING. [S.Kir.]

Fermentation Decomposition of foodstuffs generally accompanied by the evolution of gas. The best-known example is alcoholic fermentation, in which sugar is converted into alcohol and carbon dioxide. During fermentation organic matter is decomposed in the absence of air (oxygen); hence, there is always an accumulation of reduction products, or incomplete oxidation products. Some of these products (for example, alcohol and lactic acid) are of importance to humans, and fermentation has therefore been used for their manufacture on an industrial scale. There are also many microbiological processes that go on in the presence of air while yielding incomplete oxidation products. Good examples are the formation of acetic acid (vinegar) from alcohol by vinegar bacteria, and of citric acid from sugar by certain molds (for example, *Aspergillus niger*). These microbial processes, too, have gained industrial importance, and are often referred to as fermentations, even though they do not conform to L. Pasteur's concept of fermentation as a decomposition in the absence of air. *See* INDUSTRIAL MICROBIOLOGY. [C.B.V.N.]

Fermi-Dirac statistics The statistical description of particles or systems of particles that satisfy the Pauli exclusion principle. This description was first given by E. Fermi, who applied the Pauli exclusion principle to the translational energy levels of a system of electrons. It was later shown by P. A. M. Dirac that this form of statistics is also obtained when the total wave function of the system is antisymmetrical. *See* EXCLUSION PRINCIPLE.

Such a system is described by a set of occupation numbers $\{n_i\}$ which specify the number of particles in energy levels ϵ_i. It is important to keep in mind that ϵ_i represents a finite range of energies, which in general contains a number, say g_i, of nondegenerate quantum states. In the Fermi statistics, at most one particle is allowed in a nondegenerate state. (If spin is taken into account, two particles may be contained in such a state.) This is simply a restatement of the Pauli exclusion principle, and means that $n_i \leqq g_i$. The probability of having a set $\{n_i\}$ distributed over the levels ϵ_i, which contain g_i nondegenerate levels, is described by Eq. (1), which gives just the number of ways that n_i can be

$$W = \prod_i \frac{g_i!}{(g_i - n_i)!\, n_i!} \tag{1}$$

picked out of g_i, which is intuitively what one expects for such a probability. The equilibrium state which actually exists is the set of n's that makes W a maximum, under the auxiliary conditions given in Eqs. (2*a*) and (2*b*). These conditions express the fact that

$$\sum_i n_i = N \tag{2a}$$

$$\sum_i n_i \epsilon_i = E \tag{2b}$$

the total energy E and the total number of particles N are given. Equation (3) holds for this most probable distribution. Here A

$$n_i = \frac{g_i}{\frac{1}{A}\epsilon^{\beta\epsilon^i} + 1} \tag{3}$$

and β are parameters, to be determined from Eq. (3); in fact, $\beta = 1/kT$, where k is Boltzmann's constant and T is the absolute temperature. When the 1 in the denominator may be neglected, Eq. (3) goes over into the Boltzmann distribution.

Classical conditions pertain when the volume per particle is much larger than the volume associated with the de Broglie wavelength λ of a particle. For electrons in a metal at 300 K, the ratio of the volume per particle to λ^3 has the value 10^{-4}, showing that classical statistics fail altogether. When the classical distribution fails, a degenerate Fermi distribution results. A somewhat lengthy calculation yields the result that in this case the contribution of the electrons to the specific heat is negligible. This resolves an old paradox, for, according to the classical equipartition law, the electronic specific heat C should be $(3/2)Nk$, whereas in reality it is very small. *See* BOSE-EINSTEIN STATISTICS; KINETIC THEORY OF MATTER; QUANTUM STATISTICS; STATISTICAL MECHANICS. [M.Dr.]

Fermi surface The surface in the electronic wavenumber space of a metal that separates occupied from empty states. Every possible state of an electron in a metal can be specified by the three components of its momentum, or wavenumber. The name derives from the fact that half-integral spin particles, such as electrons, obey Fermi-Dirac statistics and at zero temperature fill all levels up to a maximum energy called the Fermi energy, with the remaining states empty. *See* FERMI-DIRAC STATISTICS.

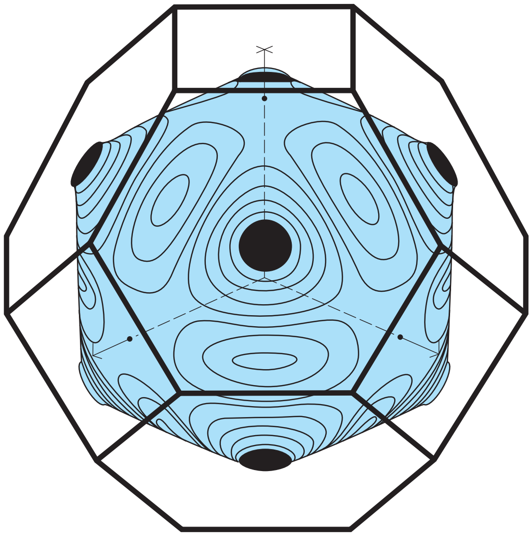
The fact that such a surface exists for any metal, and the first direct experimental determination of a Fermi surface (for copper) in 1957, were central to the development of the theory of metals. A surprise arising from the earliest determined Fermi surfaces was that many of the shapes were close to what would be expected if the electrons interacted only weakly with the crystalline lattice. The long-standing free-electron theory of metals was based upon this assumption, but most physicists regarded it as a serious oversimplification. *See* FREE-ELECTRON THEORY OF METALS.

The momentum p of a free electron is related to the wavelength λ of the electronic wave by the equation below, where $\hbar$

$$p = \frac{2\pi\hbar}{\lambda}$$

is Planck's constant divided by 2π. The ratio $2\pi/\lambda$, taken as a vector in the direction of the momentum, is called the wavenumber k. If the electron did not interact with the metallic lattice, the energy would not depend upon the direction of k, and all constant-energy surfaces, including the Fermi surface, would be spherical.

The Fermi surface of copper was found to be distorted (see illustration) but was still a recognizable deformation of a sphere. The polyhedron surrounding the Fermi surface in the illustration is called the Brillouin zone. It consists of Bragg-reflection planes, the planes made up of the wavenumbers for which an electron can be diffracted by the periodic crystalline lattice. The square faces, for example, correspond to components of the wavenumber along one coordinate axis equal to $2\pi/a$, where a is the cube edge for the copper lattice. For copper the electrons interact with the lattice so strongly that when the electron has a wavenumber near to the diffraction condition, its motion and energy are affected and the Fermi surface is correspondingly distorted. The Fermi surfaces of sodium and potassium, which also have one conducting electron per atom, are very close to a sphere. These alkali metals are therefore more nearly free-electron-like. *See* BRILLOUIN ZONE.



Fermi surface of copper, as determined in 1957; two shapes were found to be consistent with the original data, and the other, slightly more deformed version turned out to be correct.

In transition metals there are electrons arising from atomic d levels, in addition to the free electrons, and the corresponding Fermi surfaces are more complex than those of the nearly free-electron metals. However, the Fermi surfaces exist and have been determined experimentally for essentially all elemental metals.

The motion of the electrons in a magnetic field provides the key to experimentally determining the Fermi surface shapes. The simplest method conceptually derives from ultrasonic attenuation. Sound waves of known wavelength pass through the metal and a magnetic field is adjusted, yielding fluctuations in the attenuation as the orbit sizes match the sound wavelength. This measures the diameter of the orbit and Fermi surface. The most precise method uses the de Haas-van Alphen effect, based upon the quantization of the electronic orbits in a magnetic field. Fluctuations in the magnetic susceptibility give a direct measure of the cross-sectional areas of the Fermi surface. *See* DE HAAS-VAN ALPHEN EFFECT; SKIN EFFECT (ELECTRICITY); ULTRASONICS. [W.A.H.]

Fermium A chemical element, Fm, atomic number 100, the eleventh element in the actinide series. Fermium does not occur in nature; its discovery and production have been accomplished by artificial nuclear transmutation of lighter elements. Radioactive isotopes of mass number 244–259 have been discovered. The total weight of fermium which has been synthesized is much less than one-millionth of a gram. *See* ACTINIDE ELEMENTS; PERIODIC TABLE; RADIOACTIVITY.

Spontaneous fission is the major mode of decay for ^{244}Fm, ^{256}Fm, and ^{258}Fm. The longest-lived isotope is ^{257}Fm, which has a half-life of about 100 days. Fermium-258 decays by spontaneous fission with a half-life of 0.38 millisecond. This suggests the existence of an abnormality at this point in the nuclear periodic table. *See* NUCLEAR CHEMISTRY; NUCLEAR REACTION; TRANSURANIUM ELEMENTS. [G.T.S.]

Ferret The name for the largest member of the weasel family, Mustelidae. This carnivorous animal, also known as the black-footed ferret (*Mustela nigripes*), is an inhabitant of the western states in the Rocky Mountain area, where it is referred to as the prairie dog ferret or prairie dog hunter. Though once abundant, ferrets are now very rare; they suffered from the poisoning campaigns against prairie dogs and larger carnivores.

Two litters are born each year after a gestation period of about 60 days, with 5–10 young in each litter. The maximum life is 13 years. *See* CARNIVORA; WEASEL. [C.B.C.]

Ferricyanide The common name for hexacyanoferrate(III), a compound containing the complex ion $[Fe(CN)_6]^{3-}$.

The $[Fe(CN)_6]^{3-}$ ion is kinetically unstable, and it dissociates to give the free cyanide anion, CN^-. It is therefore quite toxic. In contrast, the ferrocyanide ion, $[Fe(CN)_6]^{4-}$, is stable.

The sodium $[Na_3Fe(CN)_6]$ and potassium $[K_3Fe(CN)_6]$ salts have been isolated as ruby-red crystals and are photosensitive. The potassium salt reacts with metallic silver to produce silver ferrocyanide, and it is used in photographic processes. In addition, the $[Fe(CN)_6]^{3-}$ ion is used in blueprint materials, wood stains, and electroplating process, and as a mild oxidizing agent in organic synthesis. *See* FERROCYANIDE.

The addition of Fe II to ferricyanide produces Prussian blue $(Fe_4\ III)\ [Fe\ II\ (CN)_6]_3 \cdot xH_2O$, where $x = \sim 14–16$), a pigment discovered nearly 300 years ago. The structure of this mixed-valence complex has been determined by x-ray analysis and powder neutron diffraction studies. *See* COORDINATION CHEMISTRY; COORDINATION COMPLEXES; CYANIDE; IRON. [T.J.Me.]

Ferrimagnetic garnets A class of ferrimagnetic oxide materials that have the garnet crystal structure. The typical formula of a ferrimagnetic garnet is $X_3Fe_5O_{12}$, where the trivalent X ion is yttrium, or any of the rare-earth ions with an atomic number greater than 61. (The rare-earth ions below samarium apparently have radii too large to fit into the garnet structure.) However, the larger rare earths and lanthanum can substitute partially for some of the yttrium or smaller rare earths. *See* FERRIMAGNETISM; FERRITE; RARE-EARTH ELEMENTS.

Ferrimagnetic garnets are of great theoretical interest because they have a highly ordered structure and because they accommodate rare-earth ions, some of which have a small contribution to their magnetism due to the orbital motion of electrons, in addition to the magnetism due to electron spin. The first practical engineering interest in the ferrimagnetic garnets was due to the yttrium iron garnet, which is used in certain microwave ferrite devices because of its very narrow ferromagnetic resonance absorption line. Development of magnetic bubbles for use in solid-state nonvolatile memory devices resulted in a large research effort on complex rare-earth iron garnets. In these garnets several different rare-earth ions are simultaneously incorporated in the structure in concentrations designed to optimize a number of physical and magnetic properties which influence the memory parameters. *See* COMPUTER STORAGE TECHNOLOGY; FERRITE DEVICES; GYRATOR. [M.E.Jo.]

Ferrimagnetism A specific type of ordering in a system of magnetic moments or the magnetic behavior resulting from such order. In some magnetic materials the magnetic ions in a crystal unit cell may differ in their magnetic properties. This is clearly so when some of the ions are of different species. It is also true for similar ions occupying crystallographically inequivalent sites. Such ions differ in their interactions with other ions, because the dominant exchange interaction is mediated by the neighboring nonmagnetic ions. They also experience different crystal electric fields, and these affect the magnetic anisotropy of the ion. A collection of all the magnetic sites in a crystal with identical behavior is referred to as a magnetic sublattice. A material is said to exhibit ferrimagnetic order when, first, all moments on a given sublattice point in a single direction and, second, the resultant moments of the sublattices lie parallel or antiparallel to one another. The notion of such an order is due to L. Néel, who showed in 1948 that its existence would explain many of the properties of the magnetic ferrites. *See* FERRITE; FERROMAGNETISM.

In general, there is a net moment, the algebraic sum of the sublattice moments, just as for a normal ferromagnet. However, its variation with temperature rarely exhibits the very simple behavior of the normal ferromagnet. For example, in some materials, as the temperature is raised over a certain range, the magnetization may first decrease to zero and then increase again. Ferrimagnets can be expected, in their bulk properties, measured statically or at low frequencies, to resemble ferromagnets with unusual temperature characteristics. *See* CURIE TEMPERATURE. [L.R.W.]

Ferrite Any of the class of magnetic oxides. Typically the ferrites have a crystal structure which has more than one type of site for the cations. Usually the magnetic moments of the metal ions on sites of one type are parallel to each other, and antiparallel to the moments on at least one site of another type. Thus ferrites exhibit ferrimagnetism. *See* FERRIMAGNETISM; MAGNETIC MATERIALS.

There are three important classes of commercial ferrites. One class has the spinel structure, with the general formula $M^{2+}Fe_2{}^{3+}O_4$, where M^{2+} is a divalent metal ion. So-called linear ferrites used in inductors and transformers are made of Mn and Zn (for frequencies up to 1 MHz) and Ni and Zn (for frequencies greater than 1 MHz). MgMn ferrites are used in microwave devices such as isolators and circulators. Until the late 1970s, ferrites with square loop shapes held a dominant position as computer memory-core elements, but these gave way to semiconductors. *See* COMPUTER STORAGE TECHNOLOGY.

The second class of commercially important ferrites have the garnet structure, with the formula $M_3{}^{3+}Fe_5{}^{3+}O_{12}$, where M^{3+} is a rare-earth or yttrium ion. Yttrium-based garnets are used in microwave devices. Thin monocrystalline films of complex garnets have been developed for bubble domain memory devices.

The third class of ferrites has a hexagonal structure, of the $M^{2+}Fe_{12}{}^{3+}O_{19}$ magnetoplumbite type, where M^{2+} is usually Ba, Sr, or Pb. Because of their large magnetocrystalline anisotropy, the hexagonal ferrites develop high coercivity and are an important member of the permanent magnet family.

Another magnetic oxide, γ-Fe_2O_3, also has the spinel structure, but has no divalent cations. It is the most commonly used material in the preparation of magnetic recording tapes. *See* FERRITE DEVICES. [G.Y.C.]

Ferrite devices Electrical devices whose principle of operation is based upon the use and properties of ferrites, which are magnetic oxides. Ferrite devices are divided into two categories, depending on whether the ferrite is magnetically soft (low coercivity) or hard (high coercivity). Soft ferrites are used primarily as transformers, inductors, and recording heads, and in microwave devices. Since the electrical resistivity of soft ferrites is typically 10^6–10^{11} times that of metals, ferrite components have much lower eddy current losses and hence are used at frequencies generally above about 10 kHz. Hard ferrites are used in permanent-magnet motors, loudspeakers, and holding devices, and as storage media in magnetic recording devices. One type of soft ferrite, referred to as square-loop ferrites, was once deployed in huge quantities as cores for digital computer memories but has now been replaced by semiconductor integrated circuits. *See* FERRIMAGNETISM; FERRITE. [G.Y.C.]

Ferroalloy A member of an important group of metallic raw materials required for the steel industry. Ferroalloys are the principal source of such additions as silicon and manganese which are required for even the simplest plain-carbon steels; and chromium, vanadium, tungsten, titanium, and molybdenum, which are used in both low- and high-alloy steels. Ferroalloys are unique in that they are brittle and otherwise unsuited for any service application, but they are important as the most economical source of these elements for use in the manufacture of the engineering alloys. These same elements can also be obtained, at much greater cost in most cases, as essentially pure metals. The ferroalloys contain significant amounts of iron and usually have a lower melting range than the pure metals and are therefore dissolved by the molten steel more readily than the pure metal. In other cases, the other elements in the ferroalloy serve to protect the critical element against oxidation during solution and thereby give higher recoveries. Ferroalloys are used both as deoxidizers and as a specified addition to give particular properties to the steel. *See* STEEL. [G.D.]

Ferrocyanide The common name for hexacyanoferrate(II), a compound containing the complex ion $[Fe(CN)_6]^{4-}$. The oxidation state of iron is 2+ (Fe^{2+} or Fe^{II}) and is low spin (spin paired), consistent with the strong field nature of the cyanide (CN^-) ligand.

The $[Fe(CN)_6]^{4-}$ ion is very stable, with the CN^- ligands adopting the octahedral geometry typical of Fe^{II} complexes. The free acid hydrogen hexacyanoferrate(II), $H_4[Fe(CN)_6]$, is soluble in water and is isolated as a white powder by ether precipitation of the ion in strongly acidic solutions. The salts of sodium, $Na_4Fe(CN)_6$, and potassium, $K_4Fe(CN)_6$, are prepared by heating an aqueous mixture of sodium cyanide (NaCN), iron(II) sulfate ($FeSO_4$), and other salts. The complexes are substitutionaly inert (in contrast to ferricyanide, $[Fe(CN)_6]^{3-}$, which dissociates rapidly) and are isolated as yellow crystalline decahydrate solids that are insoluble in most organic solvents. Hexacyanoferrate(II) may be converted to hexacyanoferrate(III) (ferricyanide) by strong oxidizing agents such as peroxides and permanganate ion. *See* Ferricyanide.

Ferrocyanide is a commonly used as a reducing agent; and principal applications include the preparation of dyes, preparation of fixatives used in photography, and stabilization of synthetic and natural latex foams, and as an emulsion polymerization catalyst.

Nearly 300 years ago the mixed-valence compound Prussian blue ($Fe_4^{III}[Fe^{II}(CN)_6]_3 \cdot xH_2O$, where $x = 14$–16) was discovered to be a pigment. Prussian blue is prepared by the addition of Fe^{III} to $[Fe(CN)_6]^{4-}$ or of Fe^{II} to $[Fe(CN)_6]^{3-}$, and the structure has been determined by x-ray analysis and powder neutron diffraction studies. Uses of this complex, also known as Turnbull's blue, include artists' colors, carbon paper, typewriter ribbons, and printing inks. The reduction of Prussian blue results in the formation of Everitt's salt, $K_2[Fe^{II}Fe^{II}(CN_6)]$. *See* Coordination chemistry; Coordination complexes; Cyanide; Iron. [T.J.M.]

Ferroelectrics Crystalline substances which have a permanent spontaneous electric polarization (electric dipole moment per cubic centimeter) that can be reversed by an electric field. In a sense, ferroelectrics are the electrical analog of the ferromagnets, hence the name. The spontaneous polarization is the so-called order parameter of the ferroelectric state. The names Seignette-electrics or Rochelle-electrics, which are also widely used, are derived from the name of the first substance found to have this property, Seignette salt or Rochelle salt. *See* Ferromagnetism.

From a practical standpoint ferroelectrics can be divided into two classes. In ferroelectrics of the first class, spontaneous polarization can occur only along one crystal axis; that is, the ferroelectric axis is already a unique axis when the material is in the paraelectric phase. Typical representatives of this class are Rochelle salt, monobasic potassium phosphate, ammonium sulfate, guanidine aluminum sulfate hexahydrate, glycine sulfate, colemanite, and thiourea.

In ferroelectrics of the second class, spontaneous polarization can occur along several axes that are equivalent in the paraelectric phase. The following substances belong to this class: barium(IV) titanate-type (or perovskite-type) ferroelectrics; cadmium niobate; lead niobate; certain alums, such as methyl ammonium alum; and ammonium cadmium sulfate.

From a scientific standpoint, one can distinguish proper ferroelectrics and improper ferroelectrics. In proper ferroelectrics, the structure change at the Curie temperature can be considered a consequence of the spontaneous polarization. In improper ferroelectrics, the spontaneous polarization can be considered a by-product of another structural phase transition. Examples of such systems are gadolinium molybdate and boracites.

The spontaneous polarization can occur in at least two equivalent crystal directions; thus, a ferroelectric crystal consists in general of regions of homogeneous polarization that differ only in the direction of polarization. These regions are called ferroelectric domains. Ferroelectrics of the first class consist of domains with parallel and antiparallel polarization, whereas ferroelectrics of the second class can assume much more complicated domain configurations. The region between two adjacent domains is called a domain wall. Within this wall, the spontaneous polarization changes its direction.

As a rule, the dielectric constant ϵ measured along a ferroelectric axis increases in the paraelectric phase when the Curie temperature is approached. In many ferroelectrics, this increase can be approximated by the Curie-Weiss law. *See* Curie-Weiss law.

Ferroelectrics can be divided into two groups according to their piezoelectric behavior. The ferroelectrics in the first group are already piezoelectric in the unpolarized phase. Those piezoelectric moduli which relate stresses to polarization along the ferroelectric axis have essentially the same temperature dependence as the dielectric constant along this axis, and hence become very large near the Curie point. The spontaneous polarization gives rise to a large spontaneous piezoelectric strain which is proportional to the spontaneous polarization.

The ferroelectrics in the second group are not piezoelectric when they are in the paraelectric phase. However, the spontaneous polarization lowers the symmetry so that they become piezoelectric in the polarized phase. This piezoelectric activity is often hidden because the piezoelectric effects of the various domains can cancel. However, strong piezoelectric activity of a macroscopic crystal or even of a polycrystalline sample occurs when the domains have been aligned by an electric field. The spontaneous strain is proportional to the square of the spontaneous polarization. *See* Piezoelectricity.

Antiferroelectric crystals are characterized by a phase transition from a state of lower symmetry (generally low-temperature phase) to a state of higher symmetry (generally high-temperature phase). The low-symmetry state can be regarded as a slightly distorted high-symmetry state. It has no permanent electric polarization, in contrast to ferroelectric crystals. The crystal lattice can be regarded as consisting of two interpenetrating sublattices with equal but opposite electric polarization. This state is referred to as the antipolarized state. In a certain sense, an antiferroelectric crystal is the electrical analog of an antiferromagnetic crystal.

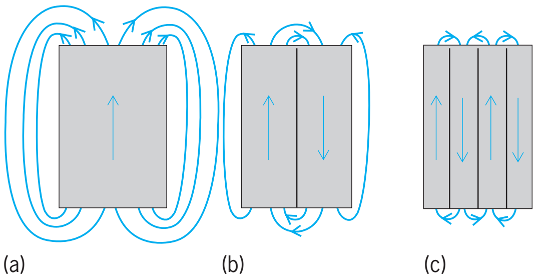
The piezoelectric effect of ferroelectrics (and certain antiferroelectrics) finds numerous applications in electromechanical transducers. The large electrooptical effect (birefringence induced by an electric field) is used in light modulators. In certain ferroelectrics, light can induce changes of the refractive indices. These substances can be used for optical information storage and in real-time optical processors. The temperature dependence of the spontaneous polarization corresponds to a strong pyroelectric effect which can be exploited in thermal and infrared sensors. [W.K.]

Ferromagnetism A property exhibited by certain metals, alloys, and compounds of the transition (iron group), rare-earth, and actinide elements in which, below a certain temperature called the Curie temperature, the atomic magnetic moments tend to line up in a common direction. Ferromagnetism is characterized by the strong attraction of one magnetized body for another.

Atomic magnetic moments arise when the electrons of an atom possess a net magnetic moment as a result of their angular momentum. The combined effect of the atomic magnetic moments can give rise to a relatively large magnetization, or magnetic moment per unit volume, for a given applied field. Above the Curie temperature, a ferromagnetic substance behaves as if it were paramagnetic: Its susceptibility approaches the Curie-Weiss law. The Curie temperature marks a transition between order and disorder of the alignment of the atomic magnetic moments. Some materials having atoms with unequal moments exhibit a special form of ferromagnetism below the Curie temperature called ferrimagnetism. *See* Curie temperature; Curie-Weiss law; Electron spin; Ferrimagnetism; Magnetic susceptibility; Paramagnetism.

The characteristic property of a ferromagnet is that, below the Curie temperature, it can possess a spontaneous magnetization in the absence of an applied magnetic field. Upon application of a weak magnetic field, the magnetization increases rapidly to a high value called the saturation magnetization, which is in general a function of temperature. For typical ferromagnetic materials, their saturation magnetizations, and Curie temperatures, *see* Magnetization.

Small regions of spontaneous magnetization, formed at temperatures below the Curie point, are known as domains. As



Lowering of magnetic field energy by domains. (*a*) Lines of force for a single domain. (*b*) Shortening of lines of force by division into two domains. (*c*) Reduction of field energy by further subdivision.

shown in the illustration, domains originate in order to lower the magnetic energy. In illus. *b* it is shown that two domains will reduce the extent of the external magnetic field, since the magnetic lines of force are shortened. On further subdivision, as in, this field is still further reduced.

Another way to describe the energy reduction is to note that the interior demagnetizing fields, coming from surface poles, are much smaller in the long, thin domains of illus. *c* than in the "fat" domain of illus. *a*.

The question arises as to how long this subdivision process continues. With each subdivision there is a decrease in field energy, but there is also an increase in Heisenberg exchange energy, since more and more magnetic moments are aligning antiparallel. Finally a state is reached in which further subdivision would cause a greater increase in exchange energy than decrease in field energy, and the ferromagnet will assume this state of minimum total energy.

Materials easily magnetized and demagnetized are called soft; these are used in alternating-current machinery. The problem of making cheap soft materials is complicated by the fact that readily fabricated metals usually have many crystalline boundaries and crystal grains oriented in many directions. The ideal cheap soft material would be an iron alloy fabricated by some inexpensive technique which results in all crystal grains being oriented in the same or nearly the same direction. Various complicated rolling and annealing methods have been discovered in the continued search for better grain-oriented or "cube-textured" steels.

Materials which neither magnetize nor demagnetize easily are called hard; these are used in permanent magnets. A number of permanent-magnet materials have enjoyed technological importance. The magnet steels contain carbon, chromium, tungsten, or cobalt additives, serving to impede domain wall motion and thus to generate coercivity. Alnicos are aluminum-nickel-iron alloys containing finely dispersed, oriented, elongated particles precipitated by thermal treatment in a field. Hard ferrite magnets are based on the oxides $BaFe_{12}O_{19}$ and $SrFe_{12}O_{19}$. Hard ferrite magnets are relatively inexpensive and are used in a great variety of commercial applications. Rare earth–transition metal materials whose rare-earth component provides huge magnetocrystalline anisotropy can be translated into large coercivity in a practical magnet, while the magnetization arises chiefly from the transition-metal component. Examples include samarium-cobalt magnets based on the $SmCo_5$ or Sm_2Co_{17} intermetallic compounds. [E.A.; F.Ke.; J.F.He.]

Ferry A ship specifically configured for carrying passengers between two points. It permits persons to make their way from one place to another across a body of water, and it may carry vehicles, including commercial vehicles. A ferry is distinct from a cruise ship or a cargo ship. For a cruise ship the voyage itself is the destination, whereas with a ferry the journey's end point is the destination. While a ferry may carry cargo, in contrast to a cargo ship, this cargo is contained in a commercial vehicle accompanied by a driver.

Ferries may range in speed from slow vessels of 10 knots (18.5 km/h) or less to ultrafast ferries with speeds exceeding 60 knots (110 km/h). They may carry passengers only, or they may carry a mixture of passengers and private automobiles, or passengers, cars, and trucks. Ferries may be characterized by their hull form and their propulsion plant.

The most common hull design for ferries is the displacement monohull ship form, which has one hull. Monohull ferries have been built in all sizes and speeds. Among monohulls a unique form is the double-ended ferry. On short runs, it makes operational sense to build a ship which is identical fore and aft. For example, in use for river crossing, this ship simply shuttles from one dock to the other, putting one "bow" into the slip at one port, the other "bow" at the other port.

The catamaran hull is a very popular form, particularly for high-speed ferries. A catamaran is a twin-hulled ship, having two hulls side by side. The two hulls are generally separated by a distance about equal to the beam of one hull. This results in a broad main deck area, which is more nearly square than the slender deck found on a monohull ship. Because of the broad expanse of the deck area, and because its low-aspect-ratio shape is easier to load with vehicles, the catamaran hull form has been very successfully incorporated into ferry service.

Ferry propulsion systems depend upon the speed and hull form of the ship. The most common propulsion system is the conventional screw propeller. This is a submerged helical screw at the stern of the ship, driven by the ship's engines. Double-ended ferries require some form of reversible or double-ended propulsion system. *See* PROPELLER (MARINE CRAFT).

High speed ferries demand much higher power. The higher weight sensitivity of a fast ferry frequently leads to use of gas turbine engines because of their light weight. *See* MARINE ENGINE.

Virtually all low-speed ferries and many high-speed ferries are propeller-driven. However, at speeds above about 40 knots (75 km/h) the hydrodynamic efficiency of the waterjet propulsor becomes superior to that of a propeller. As a consequence, almost all the fastest high-speed ferries use waterjet propulsion. [C.B.McK.]

Fertilizer Materials added to the soil, or applied directly to crop foliage, to supply elements needed for plant nutrition. These materials may be in the form of solids, semisolids, slurry suspensions, pure liquids, aqueous solutions, or gases.

The chemical elements nitrogren, phosphorus, and potassium are the macronutrients, or primary fertilizer elements, which are required in greatest quantity. Sulfur, calcium, and magnesium, called secondary elements, are also necessary to the health and growth of vegetation, but they are required in lesser amounts compared to the macronutrients. The other elements of agronomic importance, called micronutrients and provided for plant ingestion in small (or trace) amounts, include boron, cobalt, copper, iron, manganese, molybdenum, and zinc. All these fertilizer elements, along with other chemical elements, occur naturally in agricultural soils in varying concentrations and mineral compositions which may or may not be in forms readily accessible to root systems of plants. The addition of fertilizer to soils used for the production of commercial crops is necessary to correct natural deficiencies and to replace the components absorbed by the crops in their growth.

Crop requirements of fertilizer components could be satisfied by the spreading of individual materials for each element deficient in the soil. However, economy favors the single application of a balanced mixture that satisfies all nutritional needs of a crop. Many commercial fertilizers therefore contain more than one of the primary fertilizer elements.

The compositions of fertilizer mixtures, in terms of the primary fertilizer elements, are identified by an N-P-K code: N denotes elemental nitrogen; P denotes the anhydride of phosphoric acid

(P_2O_5); K denotes the oxide of potassium (K_2O). All are expressed numerically in percentage composition, or units of 20 lb each per short ton (10 kg per metric ton) of finished fertilizer as packaged. Formula 8-32-16 thus contains a mixture aggregating 8 wt % N in some form of nitrogen compounds, 32 wt % P_2O_5 in some form of phosphates, and 16 wt % K_2O in some form of potassium compounds, to give a product with a total of 56 fertilizer units. The commercial N-P-K formulas are generally in whole numbers. None of the N-P-K formulas totals 100% plant nutrients because the formulas indicate only the nutrient portions of the primary-element compounds and do not account for any other materials present.

Aqueous solutions of urea, ammonia, and ammonium nitrate (UAN solutions) are used directly by the farmers as well as in the preparation of granular N-P-K products by mixing with other materials. UAN solutions are also spread directly by field application or used to prepare complete N-P-K fertilizer solutions or suspensions. Suspension fertilizers consist of aqueous slurries of fine crystals in saturated solutions that are stabilized by small amounts of gelling materials, such as attapulgite clay. Suspensions can be maintained in uniform composition during spreading on the fields, and give better dispersion than granular material. *See* FERTILIZING. [A.Lo.]

Organic fertilizers are organic materials of vegetable and animal origin which contain certain macro, secondary, or micro nutrients that can be utilized by plants after application to agricultural soils. The primary nutrient sources of vegetable origin are crop residues, green manures, oilseed cakes, seaweeds, and miscellaneous food processing and distillery wastes. Also included in this category is biologically fixed nitrogen from legumes in association with root-nodulating bacteria of the genus *Rhizobium*. Animal sources include animal manures and urine, sewage sludge, septage, latrine wastes, and to a lesser extent materials such as blood meal, bone meal, and fish scraps. Often organic fertilizers are of mixed animal and vegetable origin, such as most farmyard manures, rural and urban composts, and sewage effluents and sludges. *See* NITROGEN FIXATION; SOIL MICROBIOLOGY. [R.I.P.; J.F.P.]

Fertilizing Addition of elements or other materials to the soil to increase or maintain plant yields. Fertilizers may be organic or inorganic. Organic fertilizers are usually manures and waste materials which in addition to providing small amounts of growth elements also serve as conditioners for the soil. Commercial fertilizers are most often inorganic. *See* FERTILIZER.

Methods of applying fertilizers vary widely and depend on such factors as kind of crop and stage of growth, application rates, physical and chemical properties of the fertilizer, and soil type. Two basic application methods are used, bulk spreading and precision placement. Time and labor are saved by the practice of bulk spreading, in which the fertilizer is broadcast over the entire area by using large machines which cover many acres in a short time. Precision placement, in which the fertilizer is applied in one or more bands in a definite relationship to the seed or plants, requires more equipment and time, but usually smaller amounts of fertilizer are needed to produce a given yield increase.

For some deep-rooted plants, subsoil fertilization to depths of 12–20 in. (30–50 cm) is advantageous. This is usually a separate operation from planting, and uses a modified subsoil plow followed by equipment to bed soil over the plow furrow, thereby eliminating rough soil conditions unfavorable for good seed germination. Top-dressings are usually applied by broadcasting over the soil surface for closely spaced crops such as small grains.

Since solid fertilizers range from dense heavy materials to light powders and liquid fertilizers range from high pressure to zero pressure, a variety of equipment is required for accurate metering and placement. In addition, application rates may be as low as 50 lb/acre (56 kg/hectare) or as high as 6 tons/acre (13.3 metric tons/hectare). Large bulk spreaders usually use drag chains or augers to force the material through a gate or opening whose size is varied to regulate the amount passing through and falling on the spreader.

Liquid fertilizer of the high-pressure type (for example, anhydrous ammonia) is usually regulated by valves or positive displacement pumps. The size of the orifice may be controlled manually or automatically by pressure-regulating valves. Low-pressure solutions may be metered by gravity flow through orifices, but greater accuracy is obtained by using compressed air or other gases to maintain a constant pressure in the tank. This method eliminates the effect of temperature and volume changes. Nonpressure solutions may be metered by gravity or by gear, roller, piston, centrifugal, or hose pumps. The accuracy of the gravity type can be improved by the use of a constant head device by which all air is introduced into the tank at the bottom.

Nonvolatile fertilizer solutions are often pumped into the supply lines of irrigation systems to allow simultaneous fertilization and irrigation. With the exception of bulk spreaders and other broadcasters, most fertilizer application devices are built as attachments which can be mounted in conjunction with planters, cultivators, and herbicide applicators. Often the tanks, pumps, and controls used for liquid fertilizers are also used for applying other chemicals such as insecticides. [J.G.F.]

Fescue A group of approximately 100 species of grass; more than 30 are represented in the United States. Tall fescue (*Festuca arundinacea*), a perennial cool-season plant introduced from Europe, occupies about 35×10^6 acres (15×10^6 hectares), primarily in the humid south-central region of the United States. It is popular because of its ease of establishment, vigor, wide range of adaptation, long grazing season, tolerance to abuse, sufferance of drought and poor soils, pest resistance, good seed production, and esthetic value when used for turf, ground cover, and conservation purposes. It is used primarily as pasture and hay for beef cattle, with lesser use for dairy cows or replacement heifers, sheep, and horses. The leafy and vigorous plants can grow to 3–4 ft (0.9–1.2 m) if undisturbed; under grazing or clipping, they can form a dense sod when sufficient water and fertility are available.

Other important fescues include meadow fescue (*F. elatior*), red fescue (*F. rubra*), Chewings fescue (*F. rubra* var. *commutata*), Idaho fescue (*F. idahoensis*), and sheep fescue (*F. ovina*). *See* CYPERALES; GRASS CROPS. [H.A.Fr.]

Fetal alcohol syndrome A spectrum of changes in the offspring of women who consume alcoholic beverages during pregnancy, ranging from severe growth deficiency, mental retardation, and abnormal facial features to mild mental changes. Physical abnormalities include limitation of joint motion, increased congenital heart malformation rate, short palpebral fissures, and maxillary hypoplasia with relative prognathism.

The frequency of adverse outcome of pregnancies of chronic alcoholic women is very high. There is an eightfold increase in perinatal mortality, and the frequency of the fetal alcohol syndrome in the surviving children is high. Almost half of the offspring have IQs below 80, and a smaller percentage have the dysmorphic features noted above.

Medical advice regarding the consumption of alcoholic beverages during pregnancy involves three principles: heavy drinking is clearly deleterious to the fetus; abstinence from alcoholic beverages immediately preceding and during pregnancy is the only assured safe course of action presently known; and therapeutic attention should also be directed to the problems leading to the alcoholism so that the psychological environment of the offspring may be improved. *See* ALCOHOLISM; BEHAVIORAL TOXICOLOGY. [N.K.M.]

Fetal membrane One of the membranous structures which surround the embryo during its developmental period. Since such membranes are external to the embryo proper, they are called extraembryonic membranes. They function in the embryo's protection, nutrition, respiration, and excretion.

There are four fetal membranes—the amnion, chorion, yolk sac, and allantois. In the course of development, the chorion becomes the outermost, and the amnion the innermost, membrane surrounding the developing embryo. As the allantois increases in size, it expands and becomes closely associated, if not fused, with the chorion. The two membranes together are known as the chorioallantoic membrane.

The amniotic cavity within which the embryo is enclosed becomes filled with an aqueous fluid which gives osmotic and physical protection to the embryo during the remainder of its fetal existence. Smooth muscle fibers in the amnion spontaneously contract and gently rock the embryo before it develops the capacity for spontaneous movement.

As the stored nutrients of the yolk are depleted during development, the yolk sac gradually decreases in size and is eventually incorporated into the midgut of the embryo. The yolk sac in the nonyolky eggs of placental mammals is vestigial. It has evolutionary but essentially no functional significance.

At the time of birth or hatching, the embryo becomes completely separated from the amnion and chorion and from the major portion of the allantois. The proximal portion of the latter remains within the embryo, however, as the urinary bladder. *See* Allantois; Amnion; Chorion; Yolk sac. [A.R.B.]

Fever

An elevation in the central body temperature of warm-blooded animals caused by abnormal functioning of the thermoregulatory mechanisms. Fever accompanies a wide variety of disease states, both infectious and noninfectious, and in the great majority of instances is due to an abnormality in the regulation of body temperature by the central nervous system. *See* Thermoregulation.

Experimental studies on the cause of fever suggest that leukocytes, as well as the fixed macrophages can be activated by various stimuli to produce a fever-inducing substance—endogenous pyrogen (EP). Endogenous pyrogen has been characterized as a protein of relatively low molecular weight (13,000) with an essential lipid moiety.

The mechanisms responsible for elevating body temperature include: reduction in heat loss by constriction of peripheral vessels whose tone is under control of the sympathetic nervous system; inhibition of panting and sweating, the latter by way of the cholinergic nerves; and increased heat production by means of shivering in voluntary muscles innervated by somatic motor nerves.

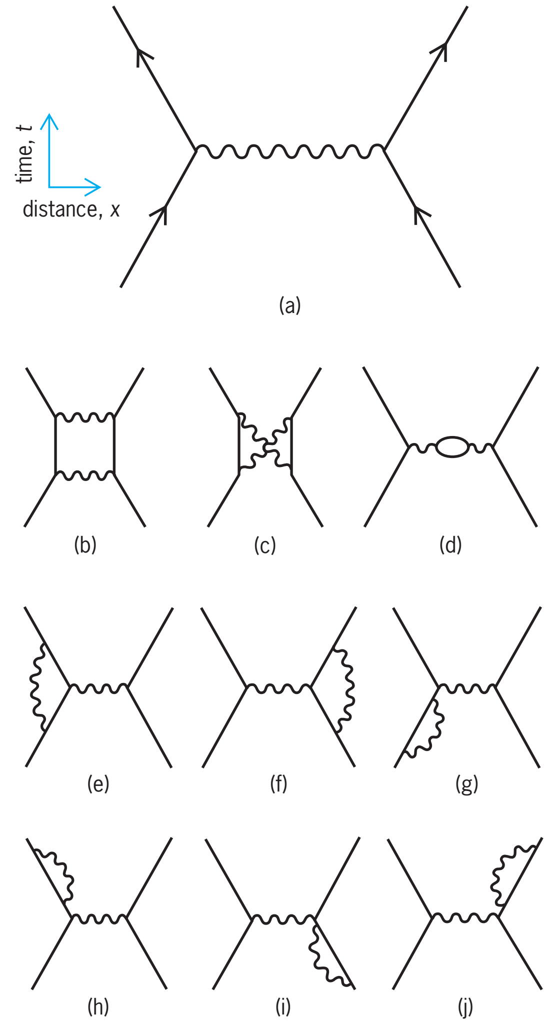
There is no clear evidence that elevated body temperature evoked by most infections is directly injurious to microbial invaders. As fever regularly accompanies inflammation, however, increased body temperature may well accelerate certain biochemical reactions of use to the host in combating infection. *See* Homeostasis; Inflammation. [E.At.]

Feynman diagram

A pictorial representation of elementary particles and their interactions. Feynman diagrams show paths of particles in space and time as lines, and interactions between particles as points where the lines meet.

The illustration shows Feynman diagrams for electron-electron scattering. In each diagram, the straight lines represent space-time trajectories of noninteracting electrons, and the wavy lines represent photons, particles that transmit the electromagnetic interaction. External lines at the bottom of each diagram represent incoming particles (before the interactions), and lines at the top, outgoing particles (after the interactions). Interactions between photons and electrons occur at the vertices where photon lines meet electron lines. *See* Electron; Photon.

Each Feynman diagram corresponds to the probability amplitude for the process depicted in the diagram. The set of all distinct Feynman diagrams with the same incoming and outgoing lines corresponds to the perturbation expansion of a matrix element of the scattering matrix in field theory. This correspondence can be used to formulate the rules for writing the amplitude associated with a particular diagram. The perturbation expansion and the associated Feynman diagrams are useful to the extent that the strength of the interaction is small, so that the lowest-order terms, or diagrams with the fewest vertices, give the main contribution to the matrix element. *See* Perturbation (quantum mechanics); Scattering matrix.



Feynman diagrams for electron-electron (Møller) scattering: (*a*) second-order diagram (two-vertices); (*b–j*) fourth-order diagrams.

Since their introduction in quantum electrodynamics, Feynman diagrams have been widely applied in other field theories. They are employed in studies of electroweak interactions, certain situations in quantum chromodynamics, in acoustooptics, and in many-body theory in atomic, nuclear, plasma, and condensed matter physics. *See* Acoustooptics; Elementary particle; Fundamental interactions; Quantum chromodynamics; Quantum electrodynamics; Quantum field theory; Weak nuclear interactions. [P.M.]

Feynman integral

A technique, also called the sum over histories, which is basic to understanding and analyzing the dynamics of quantum systems. It is named after fundamental work of Richard Feynman. The crucial formula gives the quantum probability density for transition from a point q_0 to a point q_1 in time t as the expression below, where S(path) is the classical

$$\int \exp[i\,S(\text{path})/\hbar]\,d(\text{path})$$

mechanical action of a trial path, and $\hbar$ is the rationalized Planck's constant. The integral is a formal one over the infinite-dimensional space of all paths which go from q_0 to q_1 in time t. Feynman defines it by a limiting procedure using approximation by piecewise linear paths.

Feynman integral ideas are especially important in quantum field theory, where they not only are a useful device in analyzing perturbation series but are also one of the few nonperturbative tools available. *See* Quantum field theory.

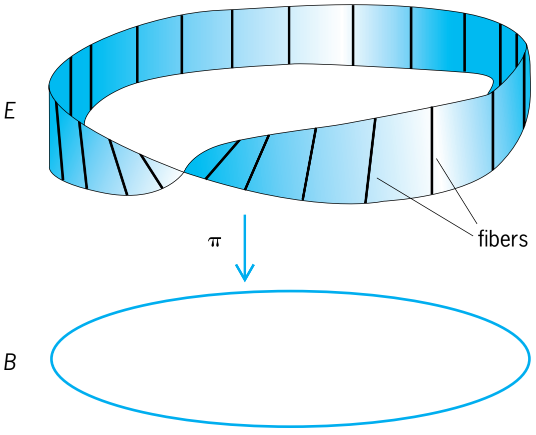
An especially attractive element of the Feynman integral formulation of quantum dynamics is the classical limit, $\hbar \to 0$. Formal application of the method of stationary phase to the above expression says that the significant paths for small $\hbar$ will be the paths of stationary action. One thereby recovers classical mechanics in the hamiltonian stationary action formulation. *See* Least-action principle. [B.Si.]

Fiber bundle A decomposition of a space E into a family of identical subspaces (fibers). The space of subspaces is called the base space. Fiber bundles arise naturally in many physical situations. The theory of fiber bundles has been applied to gauge theory in physics, and there is a lively interaction centered on ideas related to fiber bundles and gauge theories in which significant results have been contributed in both areas. The development of the mathematical theory of fiber bundles was begun in the 1930s and has numerous applications within mathematics.

A fiber bundle consists of three topological spaces, a fiber F, a total space E, and a base B, together with a continuous map $\pi: E \to B$ from the total space to the base. The set of points in E that map to a given point b in B is called the fiber over b. It is required that each fiber be topologically equivalent (that is, homeomorphic) to F. Moreover, the total space E has a local product structure: For a set U of points in B that are sufficiently close together, the points $\pi^{-1}(U)$ in E that map to U can be identified with the set of pairs (b, x) with b an element of U and x an element of F; that is, $\pi^{-1}(U)$ is homeomorphic to $U \times F$. *See* Topology.

The simplest nontrivial example of a fiber bundle is the Möbius strip (see illustration). It is constructed by twisting one end of a piece of paper and then gluing the two ends together. The fibers are line segments, and the space of line segments is a circle. The map π takes all the points in a fiber into the same point on the circle.

Tangent bundles are among the earliest examples of fiber bundles. For spaces M (called manifolds) which are locally like a euclidean space, the space $T(M)$ consisting of pairs (x, v) with x a point in M and v a vector tangent at x to a path in M is called the tangent bundle to M; the fibers form a vector space, and the base space is M. Fiber bundles in which the fibers are vector spaces are called vector bundles. *See* Manifold (mathematics).



Möbius strip, the simplest nontrivial example of a fiber bundle.

Laws of physics are often invariant under the action of an appropriate group. Fiber bundles arise in physics in situations where such a group appears as an internal or local symmetry group; the local symmetry group is the fiber. *See* Group theory; Symmetry laws (physics).

There are numerous, fundamental applications of fiber bundles within mathematics. Many of these applications are obtained through associating numerical invariants to vector bundles. The geometry of manifolds is then studied in terms of invariants of the tangent bundle of the manifold. [R.Po.]

Fiber crops Crops that are grown because of their content or yield of fibrous material which is used for many commercial purposes and for home industry. Fibers may be extracted from various parts of different plants.

Long, multiple-celled fibers can be subdivided into hard, or leaf, fibers that traditionally are used for cordage, such as sisal for binder and baler twine and abaca or manila hemp for ropes; soft, or bast (stem), fibers that are used for textiles, for example, flax for linen, hemp for small twines and canvases, and jute and kenaf for industrial textiles such as burlap; and miscellaneous fibers that may come from the roots, such as "broom" root for brushes, or stems, as Spanish moss for upholstery, or fruits, as coir from coconut husks for cordage and floor coverings. See separate articles on these topics.

Short, one-celled fibers come from the seeds or seed pods of plants such as cotton and kapok. Cotton is the world's most widely grown and used textile fiber. *See* Cotton; Kapok tree; Natural fiber. [E.G.N.]

Fiber-optic circuit The path of information travel, usually from one electrical system to another, in which light acts as the information carrier and is propagated by total internal reflection through a transparent optical waveguide. An electrooptic modulator and an optoelectric demodulator are required to convert the electrical signals into light and back again at the transmit and receive ends of the link, respectively.

A fiber-optic circuit, or link, is used for data transmission when a shielded twisted pair or a coaxial cable fails to meet one or more required performance criteria of the system designer. Depending upon fiber type, the distance-bandwidth product of a fiber is tens to thousands of times larger than that of electrical transmission. An optical communication fiber is a nearly perfect waveguide for light, meaning that little or no energy escapes through radiation. Thus, the data traveling in the fiber are secure from eavesdropping, as well as being harmless in or around equipment sensitive to electromagnetic interference. Telecommunication fiber also has a very small diameter, 5–10 micrometers (0.0002–0.0005 in.), which allows telecommunication cables to be fabricated with a much higher packing density. Also, the most common materials used to make the fibers, silica and plastic, are less dense than copper, making the cable lighter. Lastly, since the fiber is a dielectric it can be used in volatile or sensitive environments that require electrical isolation. *See* Electrical interference; Optical communications; Optical fibers.

The transmitter generally consists of a silicon integrated circuit that converts input voltage levels from a personal computer or a mainframe into current pulses. These, in turn, drive a light-emitting diode (LED). *See* Integrated circuits; Light-emitting diode.

Light from the fiber is focused onto a reverse-biased *pn*-junction photodiode that generates an electron-hole pair for each photon impinging on or near its active area. Another circuit, usually a silicon integrated circuit, amplifies this electron-hole current and converts it into voltage levels suitable for interfacing with the computer at the receiving end. *See* Photodiode; Photovoltaic effect. [K.W.Li.]

Fiber-optic sensor A sensor that uses thin optical fibers to carry light to and from a location to be probed. In performing the sensing, light can be lost from the fibers or modified in velocity by the action of the phenomena on the fiber. Fiber-optic sensors are ideal for probing in remote or hostile locations, where miniature sensors are required such as in the body, or where extreme sensitivity is required. Two classes of fiber sensors have evolved: intensity sensors, in which the amplitude of light in the fiber is changed during sensing, and interferometric sensors, in which the velocity of light or its phase is modified during sensing. The latter class has proved to be extremely sensitive; intensity sensors are used where moderate performance is acceptable and lower cost is important. Depending on their design, intensity sensors can respond to pressure, temperature, liquid level, position, flow, smoke, displacement, electric and magnetic fields, chemical composition, and numerous other conditions.

Optical interferometry is one of the most sensitive means of detecting displacements as small as 10^{-13} m. Interferometric fiber sensors apply this technology to sense many physical phenomena. A fiber gyro based on the Sagnac effect is formed by making a fiber loop which, when rotated, causes the light traveling in both directions in the loop to experience different velocities with or against the rotation. A second type of interferometric sensor is constructed by using the Mach-Zehnder interferometer. Sensitivities equal to or surpassing the best conventional technologies have been achieved in these sensors. *See* GYROSCOPE; INTERFEROMETRY. [T.G.G.]

Fiber-optics imaging The use of fiber optics in image transmission, based on the ability of a precisely aligned bundle of optical fibers to transmit an image from one end of the bundle to the other. Each fiber transmits one element of the image so that the complete image is made up of a matrix of dots (pixels) which blend into a recognizable image like a halftone picture on a printed page.

Light is transmitted through individual fibers by means of total internal reflection from the fiber walls. For efficient transmission, each fiber has a highly transparent core (usually glass) coated with a layer (cladding) of lower refractive index (also usually glass). This cladding prevents light from leaking into neighboring fibers (crosstalk) and protects the core from contamination and wear. Fiber bundles may be either flexible or rigid. *See* CROSSTALK; OPTICAL MATERIALS; REFRACTION OF WAVES.

Flexible image bundles are used in a wide variety of industrial and medical fiberscopes or endoscopes to transmit the image from an objective lens at the distal end to an eyepiece in the control handle. Industrial fiberscopes ranging in length from 3 to 8 ft (1 to 2.5 m) are used in aircraft engine inspection, for example, examination of turbine blades. Longer industrial fiberscopes are used for pipe and weld inspection, including those in nuclear power plants.

Medical endoscopes range in size from less than 0.08 in. (2 mm) for viewing inside the arteries (cardioscope) to 0.6 in. (15 mm) for examining the colon (colonoscope). The latter has an operating channel large enough to perform surgery via remotely controlled forceps or electrosurgical snares. Intermediate-sized endoscopes are used to view the bronchi (bronchoscope), the kidneys (nephroscope), the bladder (cystoscope), the throat (laryngoscope), and the stomach (gastroscope).

Fused-fiber boules are the starting point for various image-transmitting components, including faceplates (windows) for image-intensifier tubes and cathode-ray tubes, image inverters (twisters), magnifiers, and rigid conduits. Image intensifier tubes are used in military night-vision devices, low-light television cameras, and astronomical telescopes. In a cathode-ray tube the fiber-optic faceplate is used to transmit the image on the phosphor screen to the exit face for printing directly onto photographic material. *See* CATHODE-RAY TUBE; LIGHT AMPLIFIER; OPTICAL FIBERS. [W.P.S.]

Fibrinogen The major clot-forming substrate in the blood plasma of vertebrates. Though fibrinogen represents a small fraction of plasma proteins (normal human plasma has a fibrinogen content of 2–4 mg/ml of a total of 70 mg protein/ml), its conversion to fibrin causes a gelation which blocks the flow of blood. Upon injury, sufficient amounts of the clotting enzyme, thrombin, are generated in about 5 min clotting time to produce a gel. Although clotting in the circulation (thrombosis) can be extremely dangerous, clotting is an essential and normal response for preventing the loss of blood. Individuals born with the hereditary absence of fibrinogen (afibrinogenemia) suffer from severe bleeding, which can be counteracted by transfusing normal plasma or purified fibrinogen. *See* HEMORRHAGE; THROMBOSIS.

Fibrinogen is synthesized by the hepatocytes in the liver, and the synthetic rate can be stimulated by hormones. Significant amounts of carbohydrates become attached to the protein before it is secreted into the circulation; alterations in its carbohydrate composition as found in some liver diseases can give rise to abnormal fibrinogens with defective clotting properties.

Clotting is regulated by two enzymes, thrombin and factor XIII_a (fibrinoligase, activated fibrin-stabilizing factor, transglutaminase). Thrombin exerts a dual control by regulating the rate of fibrin formation as well as producing factor XIII_a. In the plasma milieu, the fibrin molecules readily aggregate into a clot. In order to obtain a clot structure of a strength sufficient to stem bleeding, however, it is necessary for the thrombin-modified factor XIII to be activated to XIII_a. Factor XIII_a acts as a transamidating enzyme which strengthens the fibrin clot by creating cross-links between the molecules. Without such cross-links, a clot structure would be like a brick wall without mortar. Individuals with the hereditary absence of factor XIII often suffer from severe bleeding, even though their clotting times are in the normal range. *See* BLOOD; HEMOPHILIA; IMMUNOGLOBULIN. [L.Lo.]

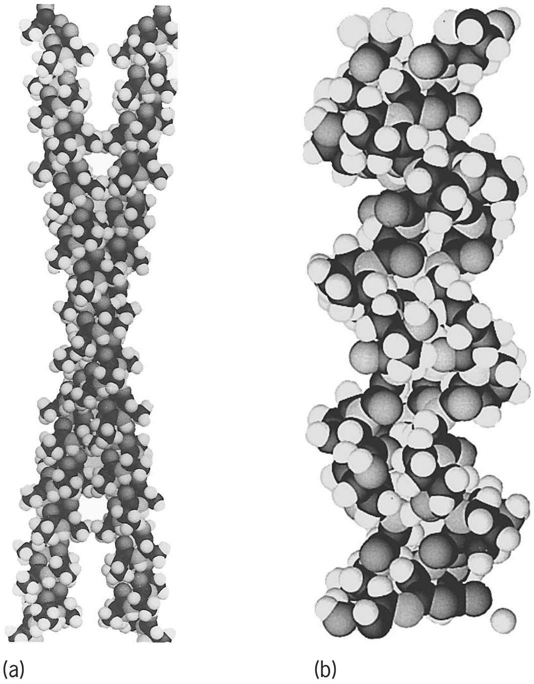
Fibromyalgia syndrome A common disorder characterized by acute and debilitating widespread musculoskeletal pain. It occurs predominantly in adult women and is not limited to any particular geographic region, ethnic group, or climate. The diagnostic feature is the elicitation of acute tenderness or pain by pressure on specific trigger points that can be mapped on the body. Of unknown cause, the disease may be prompted by an injury, physical or emotional stress, or sleep disturbance.

Fibromyalgia syndrome is accompanied by a series of symptoms including massive fatigue, headaches, insomnia, memory loss, diminished capacity to concentrate, low-grade fever, and pains in joints. Since these symptoms are similar to those seen in chronic fatigue immune dysfunction syndrome, it is thought that there may be a direct relationship between the two conditions. If this is so, fibromyalgia syndrome either may be caused by a dysfunction of the immune system or may be related to a previous viral or other infectious episode. *See* CHRONIC FATIGUE IMMUNE DYSFUNCTION SYNDROME.

If not treated, the disease can persist for a long period, frequently several years. Treatment is symptomatic and includes pain relievers and antispasmodics. The immune dysfunction and mental incapacity are also treated. [D.En.]

Fibrous protein One of two major classes of protein molecules, the other being termed globular protein. Fibrous proteins function either in a filamentous aggregate or as long, thin molecules.

One major category of fibrous proteins is the α-fibrous group. It includes intermediate filaments (occurring in skin, wool, and neurons), muscle proteins (myosin, paramyosin, and tropomyosin), and fibrinogen (a plasma protein that forms clots). The protein chain forms a right-handed α-helical structure that is stabilized by hydrogen bonds that lie parallel to the axis of the helix (see illustration). Non-filament-forming α-fibrous proteins include laminin, a triple-stranded molecule found in the basement membrane of certain cells.



Fibrous proteins. (*a*) α-Fibrous protein. (*b*) Collagen.

The second major category is based on the β structure. Feather and scale keratin have a twisted β-sheet structure, that is, an extended array of chains which are held together by hydrogen bonds positioned perpendicular to the chain axis. The sheet aggregates laterally and helically to generate a filamentous structure.

The third major category is exemplified by collagen, a major component of skin, tendon, bone, cornea and cartilage (see illustration). The molecules contain three chains, each of which coils up into a threefold helix. The chains then coil around one another in a right-handed manner to generate the collagen molecule. In turn, molecules generally aggregate to form fibrils.

Fibrous proteins also include the thin filaments of muscle in which globular subunits aggregate helically, and individual molecules that contain long strings of globular domains. *See* Collagen; Fibrinogen; Muscle proteins; Protein. [D.A.D.P.]

Fidelity The degree to which the output of a system accurately reproduces the essential characteristics of its input signal. Thus, high fidelity in a sound system means that the reproduced sound is virtually indistinguishable from that picked up by the microphones in the recording or broadcasting studio. Similarly, a television system has a high fidelity when the picture seen on the screen of a receiver corresponds in essential respects to that picked up by the television camera. Fidelity is achieved by designing each part of a system to have minimum distortion, so that the waveform of the signal is unchanged as it travels through the system. *See* Distortion (electronic circuits); Sound-reproducing systems. [J.Mar.]

Field emission The emission of electrons from a metal or semiconductor into vacuum (or a dielectric) under the influence of a strong electric field. In field emission, electrons tunnel through a potential barrier, rather than escaping over it as in thermionic or photoemission. The effect is purely quantum-mechanical, with no classical analog. It occurs because the wave function of an electron does not vanish at the classical turning point, but decays exponentially into the barrier (where the electron's total energy is less than the potential energy). Thus there is a finite probability that the electron will be found on the outside of the barrier. *See* Photoemission; Quantum mechanics; Thermionic emission.

For a metal at low temperature, the process can be understood in terms of the illustration. The metal can be considered a potential box, filled with electrons to the Fermi level, which lies below the vacuum level by several electronvolts. The distance from Fermi to vacuum level is called the work function, ϕ. The vacuum level represents the potential energy of an electron at rest outside the metal, in the absence of an external field. In the presence of a strong field, the potential outside the metal will be deformed along the line *AB*, so that a triangular barrier is formed, through which electrons can tunnel. Most of the emission will occur from the vicinity of the Fermi level where the barrier is thinnest. *See* Electron emission; Field-emission microscopy. [R.Gom.]

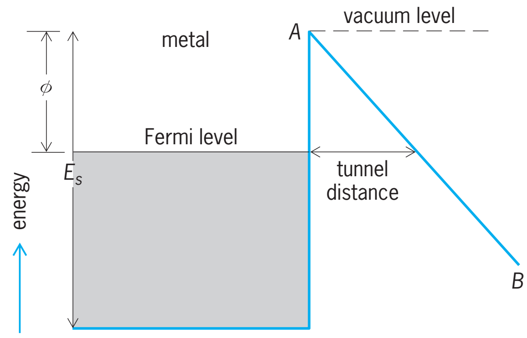


Diagram of the energy-level scheme for field emission from a metal at absolute zero temperature.

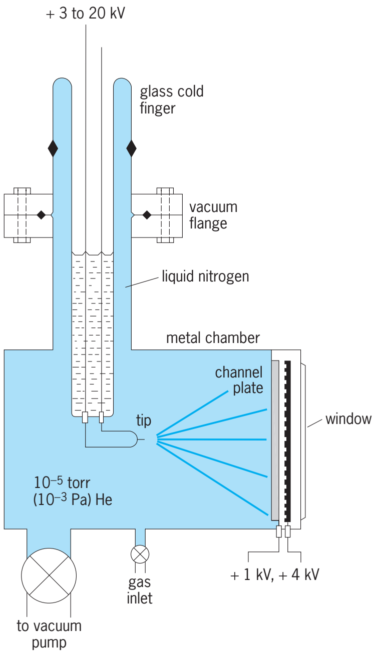
Field-emission microscopy A technique that uses field emission of electrons or positive ions from a needle-shaped emitter to produce a magnified image of the emitter surface on a fluorescent screen.

In the field electron microscope, the image reveals the variation in work function of the emitter surface. Due to the large lateral velocity of the emitted electrons, which arises from a diffraction effect of the de Broglie wave and the large kinetic energy of electrons inside the metal, a resolution of only about 2.5 nanometers can be achieved. The field electron microscope has been used to study adsorption and desorption of gases and vapor-deposited materials, surface migration of adsorption layers and absorbed atoms on single crystal faces, and surface reactions in catalysis. Medium-sized individual molecules such as phythalocyanin have been made visible also. *See* De Broglie wavelength; Electron microscope; Field emission; Work function (electronics).

In the field ion microscope, the emitter is kept at a high positive potential while the microscope chamber is filled with helium, neon, or argon at a pressure of 10^{-5} to 10^{-4} torr (10^{-3} to 10^{-2} pascal) [see illustration]. Under a field of several tens of volts per nanometer, an image gas molecule can be ionized above a protruding surface atom when an atomic electron tunnels into the metal. The ion is then accelerated to the screen by the applied field. Every second about 1000 ions are formed above the same surface atom; thus the atom is continuously imaged. When the tip is cooled down to the temperature of liquid hydrogen or nitrogen, the thermal energy of the image gas molecules is greatly reduced. In combination with their very short de Broglie wavelength, a resolution of about 0.25 nm can be achieved. This is sufficient to resolve the atomic structure of most surfaces. In addition, surface atoms can be evaporated by the applied field if it is gradually increased. Therefore the atomic structure of lattice defects inside the bulk can be revealed also. By using a channel plate for image intensification and image gases of high or low ionization energy, a wide range of metals from beryllium to uranium, semiconductors, and some compounds such



Field ion microscope.

as high-temperature oxide superconductors can be imaged. *See* CHANNEL ELECTRON MULTIPLIER; TUNNELING IN SOLIDS.

The field ion microscope has been used as a research tool for studying lattice defects such as vacancies, interstitials, dislocations, grain boundaries, and radiation damages in metals and alloys. It has also been used to observe directly the behavior of single adsorbed atoms on metal surfaces. *See* CRYSTAL DEFECTS.

The atom-probe field ion microscope combines the field ion microscope with a single ion detection sensitivity mass spectrometer, usually a time-of-flight spectrometer. The tip is mounted on a gimbal system, and a channel plate screen assembly with a small probe hole is used. Behind the probe hole is a flight tube 3–24 ft (1–8 m) long. The probe hole usually covers several atomic image diameters. The chemical identity of atoms chosen by the investigator from the field ion image can be analyzed one by one by adjusting the gimbal until the image of the atoms falls into the probe hole. Nanosecond high-voltage pulses or subnanosecond laser pulses are then applied to field-evaporate surface atoms one by one. Because of the ion optics, only those atoms that have their image covered by the probe hole can go through the probe hole and be detected. From the flight times of these ions, their mass-to-charge ratios are calculated and chemical species identified. *See* TIME-OF-FLIGHT SPECTROMETERS.

The atom-probe field ion microscope represents the ultimate in chemical analysis, that is, an atom selected by an investigator can be analyzed. As field evaporation starts from the edges of a surface layer, composition of a solid surface can also be analyzed atomic layer by atomic layer. The spatial resolution in atom-probe chemical analysis is approximately 5 to 10 angstroms in the lateral direction and much better than 1 angstrom in the vertical direction. [T.T.T.]

Field theory (mathematics)

In algebra, the term field is used to designate an algebraic system or structure containing at least two elements and having two binary rules of composition: addition and multiplication (that is, if a and b are any two elements of the field, then $a + b$ and ab are defined and are elements of the field). The structure rules are as follows: The elements form an abelian (commutative) group under addition with the additive identity denoted by 0; that is, $a + 0 = a$ for all elements a. The set of nonzero elements (and there are some since the field has at least two elements) form an abelian group under multiplication with the multiplicative identity denoted by 1. It follows that all nonzero elements have a multiplicative inverse or reciprocal. The two rules of composition are related by the distributive law: $(a + b)c = ac + bc$ for all elements a, b, c. It follows from the distributive law that $a \cdot 0 = 0$ for all elements a, since $1 \cdot a = (1 + 0)a = 1 \cdot a + 0 \cdot a$, and consequently $0 = 0 \cdot a$. *See* GROUP THEORY.

The most familiar example of a field is the set **Q** of all rational numbers (0, 1, 2, $^1/_2$, −1, −2, −$^1/_2$, 3, $^1/_3$, $^2/_3$, . . .) with the usual rules for equality, addition, and multiplication. Other examples are the set **R** of all real numbers and the set **C** of all complex numbers (both with the usual rules of addition and multiplication). The set of rational functions (formal quotients of two polynomials with rational coefficients) also constitute a field under the usual rules for equality, addition, and multiplication. *See* ALGEBRA; COMPLEX NUMBERS; REAL VARIABLE.

There are fields which contain only finitely many elements. The simplest example is obtained by considering the residue class ring of the integers modulo a prime p. This field, which may be denoted by $\mathbf{F}_p$, has as its elements the p distinct arithmetic progressions or residue classes modulo the prime p, namely I_0, $I_1, \ldots, I_p - 1$ where I_j consists of the integers $j, j \pm p, j \pm 2p, \ldots$. The rules of composition are given by Eqs. (1) and (2).

$$I_j + I_k = I_s \qquad \text{if } j + k \text{ lies in } I_s \tag{1}$$

$$I_j I_k = I_t \qquad \text{if } jk \text{ lies in } I_t \tag{2}$$

If F is a field, and a subset A of F is a field under the rules of composition of F, then A is said to be a subfield of F, and F is said to be an extension of A. Thus the field of rational numbers **Q** is a subfield of the field of real numbers **R**, and **R** is an extension of **Q**. If a field F is an extension of the field A, then F is a vector space over A. If, as a vector space, F is of finite dimension n over A, then F is said to be an extension of A of degree n. *See* LINEAR ALGEBRA.

If a field F is such that every polynomial equation over F of positive degree has a solution in F, then F is said to be algebraically closed. The field of all complex numbers is algebraically closed; but this is a theorem in analysis. The field of rational numbers, the fields of residue classes modulo a prime p, and the field of real numbers are not algebraically closed. Given any field $\bar{F}$, there exists a unique (to within isomorphism) minimal extension $\bar{F}$ of F such that $\bar{F}$ is algebraically closed. [D.J.L.]

Fig

A species of deciduous tree, *Ficus caria*, of the mulberry family (Moracaeae). Leaves are characteristically palmate, with 3 to 7 lobes. A milky latex containing the protein-digesting enyzme ficin is produced. It is of southwest Asian origin and is now cultivated in the subtropical regions of the world for its edible fruit, especially in Asia, Africa, Europe, and the United States.

The fig is a multiple or collective fruit that develops from a fleshy compound inflorescence in the form of a hollow structure (syconium) with an apical canal or pore (ostiole) and numerous tiny unisexual flowers lining the inner wall. The flowers are long-style pistillate (female); short-style pistillate (female); and staminate (male). Two forms of trees characterize *F. carica*: fig and caprifig. The fig bears long-style pistillate flowers exclusively and produces the edible figs of commerce. The caprifig bears short-style pistillate flowers and staminate flowers which are clustered around the inner opening of the ostiole. Caprifigs are the source of pollen for certain cultivars of figs whose flowers must be pollinated to set a crop of fruit. *See* FLOWER; FRUIT.

Figs that are to be eaten or marketed fresh, canned, candied, pickled, or made into jam or preserve usually are picked from the trees by hand. The bulk of the world's fig crop either is eaten dry or is marketed as dried figs or as fig paste, which is used for making fig bars and other bakery products. Figs to be used in these ways usually are allowed to dry on the trees and drop to the ground for harvesting either by hand or by machinery. *See* FRUIT, TREE. [W.B.S.]

Filbert A nut from any plant in the genus *Corylus* (Betulaceae); also called hazelnut. About 15 species are recognized, distributed widely over the north temperate zone and ranging in size from shrubs to tall trees. Filberts in commerce are derived mostly from the European species *C. avellana* and *C. maxima.* Hybrids of these with the American species, *C. americana*, are grown sparingly in the eastern United States.

Filberts are grown widely in Europe and the Mediterranean basin, where much of the crop is consumed locally. Imports to the United States come mostly from Turkey. In the United States filberts are grown in Oregon and Washington. Filberts are sold in shell, or the kernels are roasted and used in confectionery and baked goods. [L.H.MacD.]

Film (chemistry) A material in which one spatial dimension, thickness, is much smaller than the other two. Films can be conveniently classified as those that support themselves and those that exist only as layers on top of a supporting substrate. The latter are known as thin films and have their own specialized science and technology.

Thin films, from one to several hundred molecular layers, are generally defined as those that lie on a substrate, either liquid or solid. Monomolecular films on the surface of water can be made by adding appropriate materials in extremely small quantity to the surface. These materials are inappreciably soluble in water, rendered so by a large hydrocarbon or fluorocarbon functional group on the molecule or by other means; they are, however, able to dissolve in the surface of water by virtue of a hydrogen-bonding group or groups on the molecule.

Thin films can also be deposited directly onto solid substrates by evaporation of material in a vacuum, by sputtering, by chemical reaction (chemical vapor deposition), by ion plating, or by electroplating. *See* DIAMOND; ELECTROPLATING OF METALS; MONOMOLECULAR FILM; SPUTTERING; VACUUM METALLURGY; VAPOR DEPOSITION.

Thin films play an extensive role in both traditional and emerging technologies. Examples are foams and emulsions, the active layers in semiconductors, the luminescent and protective layers in electroluminescent thin-film displays, and imaging and photoelectric devices. *See* ELECTROLUMINESCENCE; ELECTRONIC DISPLAY; EMULSION; FOAM; SOLAR CELL.

Self-supported films have a nominal thickness not larger than 250 micrometers. Films of greater thickness are classified as sheets or foils. Self-supported films are commonly composed of organic polymers, either thermoplastic resins or cellulose-based materials. *See* POLYMER. [S.Ro.]

Filosia A subclass of Rhizopodea characterized by slender filopodia which rarely anastomose. The two orders are Aconchulinida and Gromiida. *See* ACONCHULINIDA; GROMIIDA; PROTOZOA; RHIZOPODEA. [R.P.H.]

Filtration The separation of solid particles from a fluid-solids suspension of which they are a part by passage of most of the fluid through a septum or membrane that retains most of the solids on or within itself. The septum is called a filter medium, and the equipment assembly that holds the medium and provides space for the accumulated solids is called a filter. The fluid may be a gas or a liquid. The solid particles may be coarse or very fine, and their concentration in the suspension may be extremely low (a few parts per million) or quite high (>50%).

The object of filtration may be to purify the fluid by clarification or to recover clean, fluid-free particles, or both. In most filtrations the solids-fluid separation is not perfect. In general, the closer the approach to perfection, the more costly the filtration; thus the operator of the process cannot justify a more thorough separation than is required.

Gas filtration involves removal of solids (called dust) from a gas-solids mixture because: (1) the dust is a contaminant rendering the gas unsafe or unfit for its intended use; (2) the dust particles will ultimately separate themselves from the suspension and create a nuisance; or (3) the solids are themselves a valuable product that in the course of its manufacture has been mixed with the gas.

Three kinds of gas filters are in common use. Granular-bed separators consist of beds of sand, carbon, or other particles which will trap the solids in a gas suspension that is passed through the bed. Bag fitters are bags of woven fabric, felt, or paper through which the gas is forced; the solids are deposited on the wall of the bag. Air filters are light webs of fibers, often coated with a viscous liquid, through which air containing a low concentration of dust can be passed to cause entrapment of the dust particles. *See* AIR FILTER; DUST AND MIST COLLECTION.

Liquid filtration is used for liquid-solids separations in the manufacture of chemicals, polymer products, medicinals, beverages, and foods; in mineral processing; in water purification; in sewage disposal; in the chemistry laboratory; and in the operation of machines such as internal combustion engines.

Liquid filters are of two major classes, cake filters and clarifying filters. The former are so called because they separate slurries carrying relatively large amounts of solids. They build up on the filter medium as a visible, removable cake which normally is discharged "dry" (that is, as a moist mass), frequently after being washed in the filter. It is on the surface of this cake that filtration takes place after the first layer is formed on the medium. The feed to cake filters normally contains at least 1% solids. Clarifying filters, on the other hand, normally receive suspensions containing less than 0.1% solids, which they remove by entrapment on or within the filter medium without any visible formation of cake. The solids are normally discharged by backwash or by being discarded with the medium when it is replaced. *See* CLARIFICATION. [S.A.M.]

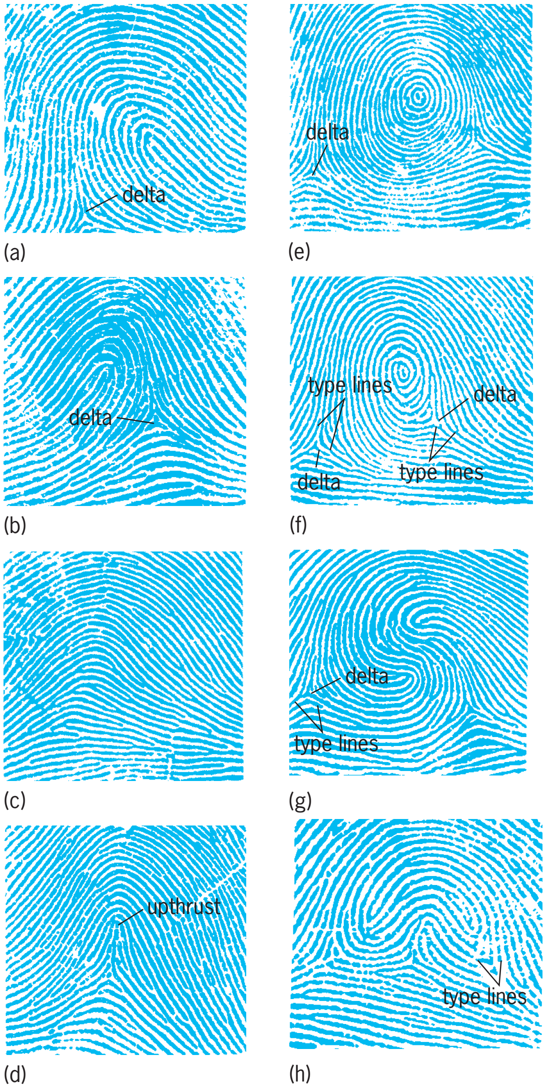
Fine structure (spectral lines) The closely spaced groups of lines observed in the spectra of the lightest elements, notably hydrogen and helium. The components of any one such group are characterized by identical values of the principal quantum number n, but different values of the azimuthal quantum number l and the angular momentum quantum number j.

In atoms having several electrons, this fine structure becomes the multiplet structure resulting from spin-orbit coupling. This gives splittings of the terms and the spectral lines that are "fine" for the lightest elements but that are very large, of the order of an electronvolt, for the heavy elements. [F.A.J./W.W.W.]

Fingerprint Distinctive ridges that appear on the bulbs of the inside of the end joints of the fingers and thumbs. Fingerprints are an infallible means of identification. In addition to their value in criminal matters, fingerprints can ensure personal identification for humanitarian reasons, such as in cases of amnesia, missing persons, or unknown deceased. Fingerprints are invaluable in effecting identifications in tragedies such as fire, flood, and vehicle crashes. The vast majority of fingerprints maintained in the Identification Division of the Federal Bureau of Investigation of the United States, the largest repository of fingerprints in the world, are civil records.

Fingerprints fall into three general types of patterns (see illustration). Each group bears the same general characteristics or family resemblance. The three general pattern types may be further divided into subgroups by means of smaller differences existing between the patterns in the same general group. The arch group includes the plain arch and the tented arch. The loop group includes the radial and ulnar loops. The whorl group includes four types of whorls, the plain whorl, central pocket loop, double loop, and accidental whorl.

The pattern area is that part of a fingerprint in which appear the cores, deltas, and ridges that are used for classification. The pattern areas of loops and whorls are enclosed by type lines, which may be defined as the two innermost ridges which start



(a) (b) (c) (d) (e) (f) (g) (h)

Types of fingerprint patterns. (*a–b*) Loop patterns: (*a*) ulnar loop; (*b*) radial loop. (*c–d*) Arch patterns: (*c*) plain arch; (*d*) tented arch. (*e–h*) Whorl patterns: (*e*) plain whorl; (*f*) central pocket loop; (*g*) double loop; (*h*) accidental whorl. (*Federal Bureau of Investigation*)

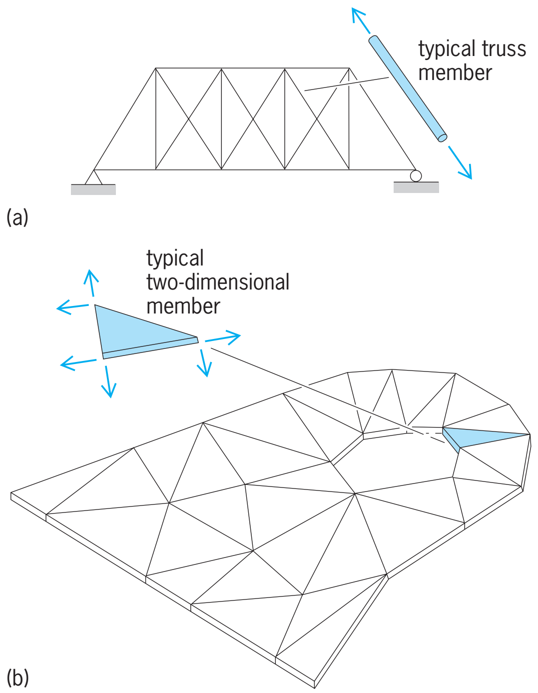
parallel, diverge, and surround or tend to surround the pattern area.

Within the pattern areas of loops and whorls are the focal points which are used in the detailed classification. These points are called the delta and the core. The delta is that point on a ridge at or in front of and nearest the center of the divergence of the type lines. A core may be defined as that point on a ridge which is located in the approximate center of the finger impression.

The distinctive ridges of the palms of the hands and the soles of the feet closely resemble those of the fingerprint and can be identified in the same way. Footprints of persons having no fingers are taken for record purposes. Fingerprint, palm print, and sole print identifications have all been accepted as evidence by the courts. *See* EPIDERMAL RIDGES. [J.E.Ho.]

Finite element method A numerical analysis technique for obtaining approximate solutions to many types of engineering problems. The need for numerical methods arises from the fact that for most practical engineering problems analytical solutions do not exist. While the governing equations and boundary conditions can usually be written for these problems, difficulties introduced by either irregular geometry or other discontinuities render the problems intractable analytically. To obtain a solution, the engineer must make simplifying assumptions, reducing the problem to one that can be solved, or a numerical procedure must be used. In an analytic solution, the unknown quantity is given by a mathematical function valid at an infinite number of locations in the region under study, while numerical methods provide approximate values of the unknown quantity only at discrete points in the region. In the finite element method, the region of interest is divided up into numerous connected subregions or elements within which approximate functions (usually polynomials) are used to represent the unknown quantity.

The physical concept on which the finite element method is based has its origins in the theory of structures. The idea of building up a structure by fitting together a number of structural elements (see illustration) was used in the early truss and framework analysis approaches employed in the design of bridges and buildings in the early 1900s. By knowing the characteristics of individual structural elements and combining them, the governing equations for the entire structure could be obtained. This process produces a set of simultaneous algebraic equations. The limitation on the number of equations that could be solved posed a severe restriction on the analysis. The introduction of the digital computer has made possible the solution of the large-order systems of equations.



(a) (b)

Structures modeled by fitting together structural elements: (*a*) truss structure; (*b*) two-dimensional planar structure.

The finite element method is one of the most powerful approaches for approximate solutions to a wide range of problems in mathematical physics. The method has achieved acceptance in nearly every branch of engineering and is the preferred approach in structural mechanics and heat transfer. Its application has extended to soil mechanics, heat transfer, fluid flow, magnetic field calculations, and other areas. [T.B.]

Finite mathematics Those parts of mathematics which deal with finite sets. More generally, finite mathematics is taken to include those fields which make no use of the concept of limit; thus linear programming, which finds maxima and minima through the four arithmetic operations, is included, whereas classical optimization, which uses differential calculus, is excluded. Other subjects generally considered in the finite mathematics include finite set theory; logic; the study of finite groups, rings, and fields; combinatorial theory; linear algebra; probability; game theory; dynamic programming; and networks. *See* FIELD THEORY (MATHEMATICS); GAME THEORY; GROUP THEORY; LINEAR ALGEBRA; LINEAR PROGRAMMING; LOGIC; OPTIMIZATION; PROBABILITY; RING THEORY; SET THEORY. [G.Ow.]

Fiord A segment of a troughlike glaciated valley partly filled by an arm of the sea. It differs from other glaciated valleys only in the fact of submergence. The floors of many fiords are elongate basins excavated in bedrock, and in consequence are shallower at the fiord mouths than in the inland direction. The seaward rims of such basins represent lessening of glacial erosion at the coastline, where the former glacier ceased to be confined by valley walls and could spread laterally. Some rims are heightened by glacial drift deposited upon them in the form of an end moraine.

Fiords occur conspicuously in British Columbia and southern Alaska, Greenland, Arctic islands, Norway, Chile, New Zealand, and Antarctica—all of which are areas of rock resistant to erosion, with deep valleys, and with strong former glaciation. [R.F.Fl.]

Fir Any tree of the genus *Abies*, of the pine family, characterized by erect cones, by the absence of resin canals in the wood but with many in the bark, and by flattened needlelike leaves which lack definite stalks. The leaves usually have two white lines on the underside and leave a circular scar when they fall.

The native fir of the northeastern United States and adjacent Canada is *A. balsamea*. Its principal uses are for paper pulp, lumber, boxes and crates, and as a source of the liquid resin called Canada balsam. In the eastern United States the fir is commonly used as a Christmas tree.

The Fraser fir (*A. fraseri*) is a similar species found in the southern Appalachians.

Several species of *Abies* grow in the Rocky Mountains region and westward to the Pacific Coast. The most important commercially is the white fir (*A. concolor*), also known as silver fir. Other western species of commercial importance are the subalpine fir (*A. lasiocarpa*), grand fir (*A. grandis*), Pacific silver fir (*A. amabilis*), California red fir (*A. magnifica*), and noble fir (*A. procera*). *See* PINALES. [A.H.G./K.P.D.]

Fire A rapid but persistent chemical reaction accompanied by the emission of light and heat. The reaction is self-sustaining, unless extinguished, to the extent that it continues until the fuel concentration falls below a minimum value. Most commonly, it results from a rapid exothermic combination with oxygen by some combustible material. Flame, the visible manifestation of fire, results from a heating to incandescence of minute particulate matter composed principally of incompletely burned fuel. *See* COMBUSTION; FLAME. [F.J.J.]

Fire detector A device designed to initiate a desired action in response to a change in its surroundings caused by an unwanted fire. Heat detectors respond when the surrounding temperature exceeds a specific minimum value or when the rate of rise exceeds a specified rate. Heat-detector sensing elements are normally mechanical, employing components which melt or expand when heated, but can also be electronic, using elements which produce thermoelectric voltages or change in conductivity.

Smoke detectors are also commonly used fire detectors. They respond when the concentration of solid or liquid particles in the air exceeds a selected value. In ionization-type smoke detectors, a small radioactive source is employed to make the air within the sensing chamber slightly electrically conductive. The presence of particles reduces this conductivity in proportion to the number of particles present. In photoelectric-type smoke detectors, a light source and light-sensitive receiver are arranged so that light from the source does not normally strike the receiver. Smoke particles reflect light from the source onto the receiver in proportion to the number of particles present.

Flame detectors contain receiving elements sensitive to light in certain specific infrared or ultraviolet wavelengths characteristic of flames. Flame detectors can detect a fire within a few milliseconds and are therefore most often used to activate explosion-suppression systems.

The actions initiated by fire detectors include sounding of audible and visual alarms, signal transmission to remote monitoring stations, activation of extinguishing systems, and emergency shutdown of equipment or processes which might increase the severity of the fire hazard. *See* AUTOMATIC SPRINKLER SYSTEM; FIRE EXTINGUISHER. [R.W.Buk.]

Fire extinguisher Fire may be extinguished by the following methods: (1) cooling the burning materials; (2) blanketing the fire with inert gas that chokes it for lack of oxygen; (3) introducing materials that inhibit combustion; and (4) covering the burning matter with a blanket or a layer of solid particles that prevent access of air. Fire extinguishers operate on one or a combination of these principles.

Water is the most effective cooling agent used in fire extinguishing. The generation of steam also drives away the air and forms a blanket, but being less dense than air, it is rapidly displaced. Wetting agents and foaming agents increase the effectiveness of water. In the small, first-aid, water fire extinguishers, a propellant must be provided. Usually this is carbon dioxide, which is either generated when needed or stored in a cartridge. Water should not be used on oil fires or on electrical fires.

Automatic water sprinkler systems are a common form of fire protection in industrial plants and large buildings. The installation of these systems is the greatest single factor to be credited for the sharply reduced incidence of disastrous fires in recent years. *See* AUTOMATIC SPRINKLER SYSTEM.

Carbon dioxide is a safe and effective extinguisher for all confined fires. It acts as an inert blanket, and because it is heavier than air, it will exclude oxygen very efficiently from a fire on the floor of a building or in a vat or similar vessel. It is not effective in an elevated location or outdoors where the wind can blow the gas away.

A dry powder, consisting principally of sodium bicarbonate, may also be used as a fire extinguisher. The powder must have the correct particle size and contain materials that prevent it from caking. The action of the powder is threefold: to generate carbon dioxide; to cool the burning material; and to provide a shielding to prevent access of air. Dry chemical is useful for small fires, and especially electrical fires.

Carbon tetrachloride, CCl_4, has had a long history as a fire-extinguishing agent. As it is customarily used, in small quantities, the principal action is to supply a heavy blanket of vapor over the fire. In addition, carbon tetrachloride, in common with all the halogenated compounds, has a definite chemical inhibiting effect on combustion. Other halogenated hydrocarbons that have been used are chlorobromomethane, and several of the fluorinated hydrocarbons known as freons. The principal difficulty, however, with all the halogenated hydrocarbons, and with CCl_4, in particular, is toxicity.

Other extinguishing methods should be mentioned that require no special equipment. For a household fire, especially involving clothing on a person, a blanket or a rug provides an effective means to smother the fire. Small fires around a kitchen stove may be snuffed out with salt or, better still, with bicarbonate of soda. A bucket of sand, strategically located, is also useful against domestic fire hazards. [W.E.Go.]

Fire technology The application of results of basic research and of engineering principles to the solution of practical fire protection problems, but entailing, in its own right, research into fire phenomena and fire experience.

The contribution of the practices of fire prevention is potentially much greater than that of the actual fire-fighting activities. Fire-prevention and loss-reduction measures take many forms, including fire-safe building codes, periodic inspection of premises, fire-detection and automatic fire-suppression systems in industrial and public buildings, the substitution of flame-retardant materials for their more flammable counterparts, and the investigation of fires of suspicious origin, serving to deter the fraudulent and illegal use of fire. *See* Automatic sprinkler system; Fire detector.

The fundamental techniques used by fire fighters consist primarily of putting water on a fire. Water serves to cool a burning material down to a point where it does not produce gases that burn. While water is the most practical and inexpensive extinguishing agent, modern technology has provided not only additives to water to render desirable properties such as easy flow or enhanced sticking, but also chemical and physical extinguishants such as fluorocarbons, surfactant film-forming proteins, and foams. *See* Fire extinguisher.

A general approach to fire control has been developed involving use of flame inhibitors. Unlike older fire-extinguishing materials such as water and carbon dioxide, these agents operate indirectly in that they interfere with those reactions within a flame that lead to sustained release of heat. As a result, temperature of the system falls below ignition temperature. The most effective liquids are the halogenated hydrocarbons such as chlorobromomethane (CB) and bromotrifluoromethane (better know as Halon 1301) which are colorless, odorless, and electrically nonconductive. *See* Halogenated hydrocarbon.

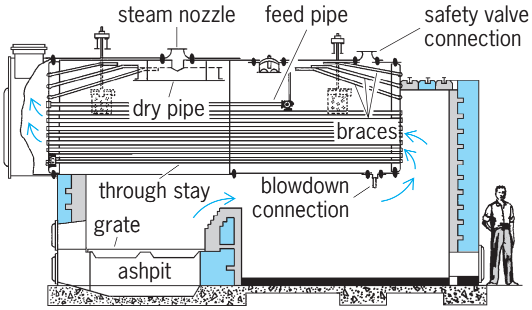
In dry-powder chemical extinguishers, ammonium dihydrogen phosphate is the most useful fire inhibitor. Other dry-powder inhibitors are salts of alkali metals (which include lithium, sodium, potassium, rubidium, and cesium).

Foams are also widely used. Protein-type, low-expansion foams, particularly useful in quenching burning volatile petroleum products, are used in crash-rescue operations. High-expansion foams are available for fire suppression in enclosed areas. Some foams of this type are generated at a rate of 15,000 ft^3/min (424.8 m^3/min). They can contain sufficient air to allow a human to breathe inside them.

A film-forming solution of a specific fluorocarbon surfactant in water, known as light water, was developed by the U.S. Navy for use with dry chemicals to fight aircraft crash fires. It may be used either as a liquid or as a low-expansion foam to interfere with the release of flammable vapors from the burning fuel. Light water is also useful in extinguishing petroleum storage tank fires and may find application to urban fires once the cost is no longer prohibitive. [S.B.M.; A.M.K.]

Fire-tube boiler A steam boiler in which hot gaseous products of combustion pass through tubes surrounded by boiler water. The water and steam in fire-tube boilers are contained within a large-diameter drum or shell, and such units often are referred to as shell-type boilers. Heat from the products of combustion is transferred to the boiler water by tubes or flues of relatively small diameter (approximately 3–4 in. or 7.5–10 cm) through which the hot gases flow. The tubes are connected to tube sheets at each end of the cylindrical shell and serve as structural reinforcements to support the flat tube sheets against the force of the internal water and steam pressure. Braces or tension rods also are used in those areas of the tube sheets not penetrated by the tubes.

Fire-tube boilers may be designed for vertical, inclined, or horizontal positions. One of the most generally used types is the horizontal-return-tube (HRT) boiler (see illustration). In the HRT boiler, part of the heat from the combustion gases is transferred directly to the lower portion of the shell. The gases then make a return pass through the horizontal tubes or flues before being passed into the stack. *See* Steam-generating unit. [G.W.K.]



Horizontal-return-tube boiler.

Fischer-Tropsch process The synthesis of hydrocarbons and, to a lesser extent, of aliphatic oxygenated compounds by the catalytic hydrogenation of carbon monoxide. The synthesis was discovered in 1923 by F. Fischer and H. Tropsch at the Kaiser Wilhelm Institute for Coal Research in Mulheim, Germany. The reaction is highly exothermic, and the reactor must be designed for adequate heat removal to control the temperature and avoid catalyst deterioration and carbon formation. The sulfur content of the synthesis gas must be extremely low to avoid poisoning the catalyst. *See* Coal gasification. [J.H.Fi]

Fisher A carnivorous mammal that is a member of the family Mustelidae, which also includes the minks, ferrets, martens, weasels, badgers, otters, skunks, and wolverine. The American fisher (*Martes pennanti*) occurs in forested areas of North America. The fur, which is valuable, is variable in color, but always dark, and does not change color seasonally. The fisher has a long, lithe powerful body with short legs and a long muzzle. These animals breed once a year, and the two to four young are born in the nest high above the ground. This species is now nearly extinct in the eastern United States. *See* Badger; Carnivora; Marten; Otter; Skunk; Weasel; Wolverine. [C.B.C.]

Fisheries ecology The study of ecological processes that affect exploited aquatic organisms, in both marine and freshwater environments. Because this field is primarily motivated by an attempt to harvest populations, special attention has been given to understanding the regulation of aquatic populations by nature and humans. The foundations of fisheries ecology lie in population and community ecology, with ideas and methods from physiology, genetics, molecular biology, and epidemiology being increasingly relevant. Because of issues associated with harvesting biological resources, fisheries ecology must also go beyond biology and ecology into sociology and economics. *See* Ecology.

The problem of regulating the exploitation of aquatic organisms in order to ensure sustained harvest lies at the core of fisheries ecology. Most experts agree that the harvest of marine resources has peaked and increased yields are likely to come only from fine-tuning of regulations on stocks that are fully exploited.

The typical unit at which management efforts are directed is the exploited population, customarily termed a stock. A central aspect of assessing fisheries resources is to identify these stocks and determine how isolated they are from other stocks of the same species. For example, there are 20 major recognized stocks of cod in the North Atlantic Ocean, each on the whole isolated from every other and distinct with regard to several biological characteristics that determine the potential for harvest. The three main population processes that govern the size and productivity of given stock are somatic growth, mortality, and recruitment (the incorporation of new individuals into the population through birth). A typical assessment of an exploited stock includes the study of these three processes, as well as some protocol to estimate abundance. From this information, and aided by mathematical models and statistical tools, fisheries biologists produce recommendations on how many individuals to harvest, of what size or age, when, and where.

The early history of modern fishing was characterized by attempts to ensure an increasing supply of aquatic organisms at all costs. In the last two decades, that view has yielded to a more realistic perspective, increasingly heedful to the natural limits of aquatic resources and to many environmental aspects of harvested systems. These include habitat degradation, overfishing, incidental mortality of nontarget species, and the indirect effects of species removal at the ecosystem level. *See* MARINE CONSERVATION; MARINE FISHERIES. [M.Pa.; P.D.]

Fissidentales An order of the true mosses (subclass Bryidae) consisting of a single family, the Fissidentaceae, and about 800 species in the genus *Fissidens* plus a few others distributed in four or five segregate genera. *Fissidens* is the largest genus of mosses. The Fissidentales are unique in leaf form and arrangement. The plants, erect and simple or forked, grow (except at the earliest stages) from a two-sided apical cell. The leaves, arranged edgewise to the stem in two rows, have two sheathing blades which clasp the stem and the base of the next leaf above. *See* BRYIDAE; BRYOPHYTA; BRYOPSIDA. [H.Cr.]

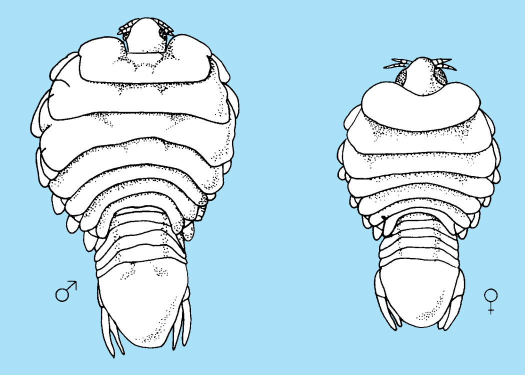
Fission track dating A method of dating geological and archeological specimens by counting the radiation-damage tracks produced by spontaneous fission of uranium impurities in minerals and glasses. During fission two fragments of the uranium nucleus fly apart with high energy, traveling a total distance of about 25 micrometers (0.001 in.) and creating a single, narrow but continuous, submicroscopic trail of altered material, where atoms have been ejected from their normal positions. Such a trail, or track, can be revealed by using a chemical reagent to dissolve the altered material, and the trail can then be seen in an ordinary microscope. The holes produced in this way can be enlarged by continued chemical attack until they are visible to the unaided eye.

Track dating is possible because most natural materials contain some uranium in trace amounts and because the most abundant isotope of uranium, ^{238}U, fissions spontaneously. Over the lifetime of a rock substantial numbers of fissions occur; their tracks are stored and thus leave a record of the time elapsed since track preservation began. The number of tracks produced in a given volume of material depends on the uranium content as well as the age, so that it is necessary to measure the uranium content before an age can be determined.

One feature unique to this dating technique is the time span to which it is applicable. It ranges from less than 100 years for certain synthetic, decorative glasses to approximately 4,500,000,000 years, the age of the solar system. A second useful feature is that measurements can sometimes be made on extremely minute specimens, such as chips of meteoritic minerals or fragments of glass from the ocean bottom. A third useful feature is that each mineral dates the last cooling through the temperature below which tracks are retained permanently. Since this temperature is different for each mineral, it is possible to measure the cooling rate of a rock by dating several minerals—each with a different track-retention temperature. *See* AMINO ACID DATING; ROCK AGE DETERMINATION. [R.L.F.; P.B.P.; R.M.W.]

FitzGerald-Lorentz contraction The contraction of a moving body in the direction of its motion. In 1892 G. F. FitzGerald and H. A. Lorentz proposed independently that the failure of the Michelson-Morley experiment to detect an absolute motion of the Earth in space arose from a physical contraction of the interferometer in the direction of the Earth's motion. According to this hypothesis, as formulated more exactly by Albert Einstein in the special theory of relativity, a body in motion with speed v is contracted by a factor $\sqrt{1 - v^2/c^2}$ in the direction of motion, where c is the speed of light. *See* LIGHT; RELATIVITY. [E.L.Hi.]

Flabellifera The largest and morphologically most generalized suborder of isopod crustaceans. The biramous uropods are attached to the sides of the abdomen and may with the last abdominal segment form a caudal fan (see illustration). More than 1400 species and over 10 families are known.



Ichthyoxenus jellinghausii **Herklots, male and female. (*Proceedings of U.S. National Museum*)**

Members of the family Cirolanidae are actively swimming predators and scavengers with biting mouthparts. They feed on dead and living animals and are notorious for their attacks on the bait of line fishermen and on fishes caught in nets. The legs of bathers are also sometimes bitten.

Members of the families Corallanidae and Excorallanidae are sometimes found parasitizing fishes, but are often free-living. The families Aegidae and Cymothoidae include fish parasites; the Aegidae feed by sucking blood. The Cymothoidae are more highly adapted for a parasitic life than other Flabellifera.

The gribbles, Limnoriidae, are well known for the damage they cause to marine structures of wood. In the family Sphaeromatidae, some species of *Sphaeroma* are economically important in tropical seas because of their habits of boring into wood, clay, and rock. Isopods of the family Serolidae are greatly flattened forms which live partially buried on sandy bottoms. *See* ISOPODA. [T.E.B.]

Flame An exothermic reaction front or wave in a gaseous medium. Consider a uniform body of gas in which an exothermic chemical reaction (that liberates heat) is initiated by raising the temperature to a sufficiently high level; the reaction is started by a localized release of heat, as by a sufficiently energetic spark, and then spreads from the point of initiation. If the reaction is relatively slow, the whole gas will be involved before the initial region has finished reacting. If the reaction is relatively fast, the reaction zone will develop as a thin front or wave propagating into the unreacted gas, leaving fully reacted gas behind. If the front, in addition, shows luminosity (emission of light), the flame may be considered a classical example. However, perceptible emission of visible radiation is not essential to the definition.

Sufficient reaction rates may also be attained under special conditions (when the gas is very slowly heated inside a closed vessel) without very high temperatures if free radicals are generated in good concentration; this gives so-called cool flames.

The most common flame-producing reaction is combustion, which is broadly defined as a reaction between fuel and an oxidizer. The oxidizer is typically oxygen (usually in air), but a variety of other substances (for example, bromine with hydrogen) can play the same role in combination with the right fuel. While the overall theoretical reaction in a combustion flame—namely, fuel and oxidizer making fully oxidized products such as carbon dioxide and water vapor—is invariably simple, the actual reaction mechanism is typically very complex, involving many intermediate steps and compounds. Free radicals are generally present and figure prominently in the mechanism. *See* Free radical.

An overall reaction involving just one reactant is chemical decomposition, for example, ozone decomposing into oxygen. Decomposition flames are usually simpler chemically than combustion flames.

Combustion flames are broadly divided into premixed flames and diffusion flames. Premixed flames occur when fuel and oxidizer are mixed before they burn. Diffusion flames occur when fuel and oxidizer mix and burn simultaneously. The intermediate case, with partial premixing, has been of relatively low theoretical and practical interest. Flames are further categorized on the basis of shape, time behavior (stationary or moving), flow regime (laminar or turbulent), buoyancy regime (forced convection or natural convection), presence or absence of confinement (as by combustion chamber walls), and flow complications (such as swirling flow and crosswind). [H.A.Bec.]

Flameproofing The process of treating materials so that they will not support combustion. Although cellulosic materials such as paper, fiberboard, textiles, and wood products cannot be treated so that they will not be destroyed by long exposure to fire, they can be treated to retard the spreading of fire and to be self-extinguishing after the ligniting condition has been removed.

Numerous methods have been proposed for flameproofing cellulosic products. One of the simplest and most commonly used for paper and wood products is impregnation with various soluble salts, such as ammonium sulfate, ammonium phosphate, ammonium sulfamate, borax, and boric acid. Special formulations are often used to minimize the effects of these treatments on the color, softness, strength, permanence, or other qualities of the paper. For some applications, these treatments are not suitable because the salts remain soluble and leach out easily on exposure to water. A limited degree of resistance to leaching can be achieved by the addition of latex, lacquers, or waterproofing agents. In some cases the flameproofing agent can be given some resistance to leaching by causing it to react with the cellulose fiber (for example, urea and ammonium phosphate).

Leach-resistant flameproofing may also be obtained by incorporating insoluble retardants in the paper during manufacture, by application of insoluble materials in the form of emulsions, dispersions, or organic solutions, or by precipitation on, or reaction with, the fibers in multiple-bath treatments. The materials involved are of the same general types as those used for flameproofing textiles and include metallic oxides or sulfides and halogenated organic compounds. *See* Combustion; Textile chemistry. [T.A.H.]

Flash welding A form of resistance welding that is used for mass production. The welding circuit consists of a low-voltage, high-current energy source (usually a welding transformer) and two clamping electrodes, one stationary and one movable.

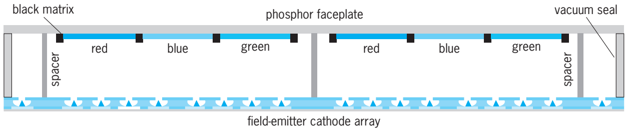
The two pieces of metal to be welded are clamped tightly in the electrodes, and one is moved toward the other until they meet, making light contact. Energizing the transformer causes a high-density current to flow through small areas that are in contact with each other. Flashing starts, and the movable workpiece must accelerate at the proper rate to maintain an increasing flashing action. After a proper heat gradient has been established on the two edges to be welded, an upset force is suddenly applied to complete the weld. This upset force extrudes slag, oxides, molten metal, and some of the softer plastic metal, making a weld in the colder zone of the heated metal. *See* Resistance welding. [E.J.L.]

Flat-panel display device An electronic display in which a large orthogonal array of display elements, such as liquid-crystal or electroluminescent elements, form a flat screen. The term “flat-panel display” is actually a misnomer, since thinness is the distinguishing characteristic. Most television sets and computer monitors currently employ cathode-ray tubes. Cathode-ray tubes cannot be thin because the light is generated by the process of cathodoluminescence whereby a high-energy electron beam is scanned across a screen covered with an inorganic phosphor. The cathode-ray tube must have moderate depth to allow the electron beam to be magnetically or electrostatically scanned across the entire screen. *See* Cathode-ray tube; Cathodoluminescence; Electronic display.

For a flat-panel display technology to be successful, it must at least match the basic performance of a cathode-ray tube by having (1) full color, (2) full gray scale, (3) high efficiency and brightness, (4) the ability to display full-motion video, (5) wide viewing angle, and (6) wide range of operating conditions. Flat-panel displays should also provide the following benefits: (1) thinness and light weight, (2) good linearity, (3) insensitivity to magnetic fields, and (4) no x-ray generation. These four attributes are not possible in a cathode-ray tube.

Flat-panel displays can be divided into three types: transmissive, emissive, and reflective. A transmissive display has a backlight, with the image being formed by a spatial light modulator. A transmissive display is typically low in power efficiency; the user sees only a small fraction of the light from the backlight. An emissive display generates light only at pixels that are turned on. Emissive displays should be more efficient than transmissive displays, but due to low efficiency in the light generation process most emissive and transmissive flat panel displays have comparable efficiency. Reflective displays, which reflect ambient light, are most efficient. They are particularly good where ambient light is very bright, such as direct sunlight. They do not work well in low-light environments.

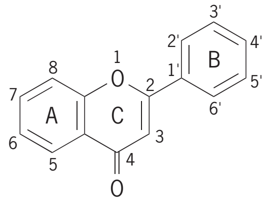
Most flat-panel displays are addressed as an X-Y matrix, the intersection of the row and column defining an individual pixel (see illustration). Matrix addressing provides the potential for an all-digital display. Currently available flat-panel display devices range from 1.25-cm (0.5-in.) diagonal displays used in head-mounted systems to 125-cm (50-in.) diagonal plasma displays.



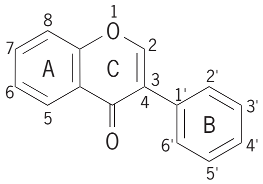
Field-emission display, an example of a matrix-addressed display. Each pixel is addressed in an X-Y matrix. In the case of a color display, each pixel is subdivided into a red, a blue, and a green subpixel.

Currently, most commercially manufactured flat-panel display devices are liquid-crystal displays (LCDs). The benchmark for flat-panel display performance is the active matrix liquid-crystal display (AMLCD). Most portable computers use AMLCDs. Competing flat-panel display technologies include electroluminescent displays, plasma display panels, vacuum fluorescent displays, and field-emission displays. Electroluminescent displays are often used in industrial and medical applications because of their ruggedness and wide range of operating temperatures. Plasma display panels are most often seen as large flat televisions, while vacuum fluorescent displays are used in applications where the information content is fairly low, such as the displays on appliances or in automobiles. Field-emission displays are the most recent of these flat-panel technologies. [B.E.G.]

Flavonoid A large category of natural plant products that derive from γ-pyrone. All flavonoid compounds, which are derived from either 2-phenylbenzopyrone (structure **1**) or 3-phenylbenzopyrone (**2**), can be classified into 10 groups:



(1)



(2)

chalcones, flavanones, flavones, flavonols, anthocyanidins (flavylium cations), flavan 3-ols (catechins), flavan 3,4-diols (proanthocyanidins), biflavonoids and oligomeric flavonoids, isoflavonoids, and the aurones. They differ in the oxidation level or substitution pattern of their heterocyclic ring (ring C).

More than 1300 different flavonoid compounds have been isolated from plants. Individual flavonoids in a group differ from each other by the number and position of the hydroxy, methoxy, and sugar substituents. As a rule, flavonoid compounds occur in plants as glycosides, with hexoses such as glucose, galactose, and rhamnose, and pentoses such as arabinose and xylose as the most commonly found sugars. The sugars can be attached singly or in combination with each other. Glycosylation renders these compounds water-soluble and permits their accumulation in the vacuoles of cells. *See* Glycoside.

The few reports available indicate that flavonoids accumulate in epidermal tissues, with approximately 70% in the upper and 30% in the lower epidermis. Vacuoles are probably the only site of flavonoid accumulation in the cells, but synthesis of flavonoids takes place in the cytoplasm.

Flavonoid compounds were once regarded as stray end products of metabolism, but some are now known to be physiologically active. For example, a number of flavonoid compounds were discovered to be the host-specific signal molecules in the formation of nitrogen-fixing root modules. In addition, flavonoids have been linked to protection from ultraviolet radiation. The enzymatic machinery for flavonoid production is induced by ultraviolet irradiation. Flavonoids accumulate in the vacuoles of epidermal cells and absorb light strongly in the critical range of 280–380 nm, where damage caused by ultraviolet radiation occurs. Finally, many plant species synthesize phytoalexins upon invasion by microorganisms. The majority of phytoalexins produced by legumes are isoflavonoids, and each plant species seems to produce a specific compound.

Because of their strikingly vivid color, ranging from deep red through purple to deep blue, anthocyanins represent the most visible class of flavonoid compounds. Anthocyanins are most obvious in flowers and fruits, but they are also present in roots, stems, leaves, seeds, and other parts of the plant. The accumulated anthocyanins, together with carotenes, provide the varied colors characteristic of autumn. Anthocyanins are also produced when plants are subjected to other stress, such as ultraviolet radiation, injury by insects, malnutrition, or unusual concentrations of metal. *See* Plant metabolism. [G.Hr.]

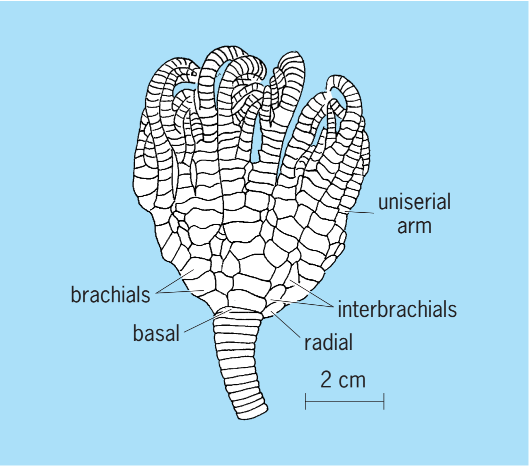
Flavor Any of the six different varieties of quarks. All hadronic matter is composed of quarks, the most elementary constituents of matter. The six different flavors are labeled u, d, s, c, b, and t, corresponding to up, down, strange, charmed, bottom, and top. Quarks are all spin-$^{1}/_{2}$ fermions. The u, c, and t flavors carry a positive electric charge equal in magnitude to two-thirds that of the electron; the d, s, and b flavors have a negative charge one-third that of the electron. Different flavored quarks have vastly different masses ranging from the lightest, the u quark, with a mass around 5 MeV/c^2 (where c is the speed of light), equal to the mass of about 10 electrons, to the top quark, with a mass 35,000 times greater, or 175 GeV/c^2, about the mass of a gold atom. Quarks of any flavor are further characterized by three additional quantum numbers called color: red, green, and blue. Each quark has an antiquark counterpart carrying the corresponding anticolor. *See* Antimatter; Color (quantum mechanics); Elementary particle; Quarks. [V.F.]

Flax The flax plant (*Linum usitatissimum*) is the source of two products: flaxseed for linseed oil and fiber for linen products. Plants with two distinct types of growth are used for seed and fiber production.

Flax for fiber requires fertile, well-drained, and well-prepared soil and a cool, humid climate. The best-known use for flax fiber is in the manufacture of fine linen fabrics; other uses are linen thread, linen twine, toweling, and canvas. Seed from fiber flax is used for replanting and for oil. The major producer of flax fiber is Russia, but the world's best fiber comes from Belgium and adjoining countries. Most Irish linen is manufactured from fiber produced in Belgium. *See* Natural fiber; Textile.

Seedflax is the source of linseed oil. The principal uses of linseed oil are in the manufacture of protective coatings—paint, varnish, and lacquer. It is also used in linoleum, printer's ink, and patent and imitation leathers, and as core oil for making sand forms in metal casting. The linseed cake remaining after the oil is extracted is used as a high-protein livestock feed. Large quantities of clean (weed-free) straw from seedflax are used in the production of a high-grade paper. This product is used to make cigarette and other fine papers. The world's major producers of flaxseed are Argentina, Canada, India, Russia, and the United States. [E.G.N; J.O.Cu.]

Flexibilia An extinct subclass of stalked or creeping Crinoidea which includes some 50 Paleozoic genera, ranging from Ordovician to Permian times. A flexible tegmen was present with open ambulacral grooves. One of the five oral plates served as a madreporite. The anus was at the tip of a short siphon. The uniserial arms branched freely, arching inward to form a globular crown (see illustration). The cylindrical stem lacked cirri and was sometimes discarded to produce a creeping adult. *See* Crinoidea; Echinodermata. [H.B.F.]



***Talanterocrinus* sp.**

Flexible manufacturing system A factory or part *of a factory made* up of programmable machines and devices that can communicate with one another. Materials such as parts, pallets, and tools are transported automatically within the flexible manufacturing system and sometimes to and from it. Some form of computer-based, unified control allows complete or partial automatic operation. Flexible manufacturing systems are part of a larger computer-based technology, termed computer-integrated manufacturing (CIM), which encompasses more than the movement and processing of parts on the factory floor. *See* Automation; Computer-aided design and manufacturing; Computer-integrated manufacturing.

The programmable machines and devices are numerically controlled machine tools, robots, measuring machines, and materials-handling equipment. Each programmable machine or device typically has its own controller which is, in effect, a dedicated digital computer; programs must be written for these controllers, usually in special-purpose languages designed to handle the geometry and machining. Increasingly, numerically controlled machines are being programmed by graphical presentations on computer screens, that is, graphical computer interfaces. This allows the programmer to follow the machining operation and specify desired operations without the need for statements in a programming language. Robots have usually been programmed by so-called teaching, where the robot is physically led through a sequence of movements and operations; the robot remembers them and carries them out when requested. *See* Computer graphics; Digital computer; Intelligent machine; Materials-handling equipment; Programming languages; Robotics.

The programmable machines and devices communicate with one another via an electronic connection between their controllers. Increasingly, this connection is by means of local-area networks, that is, communication networks that facilitate high-speed, reliable communication throughout the entire factory. *See* Local-area network.

The automatic material transport system is usually a guided, computer-controlled vehicle system. The vehicles are usually confined to a fixed network of paths, but typically any vehicle can be made to go from any point in the network to any other point. The network is different from a classical assembly line in that it is more complex and the flow through it is not in one direction.

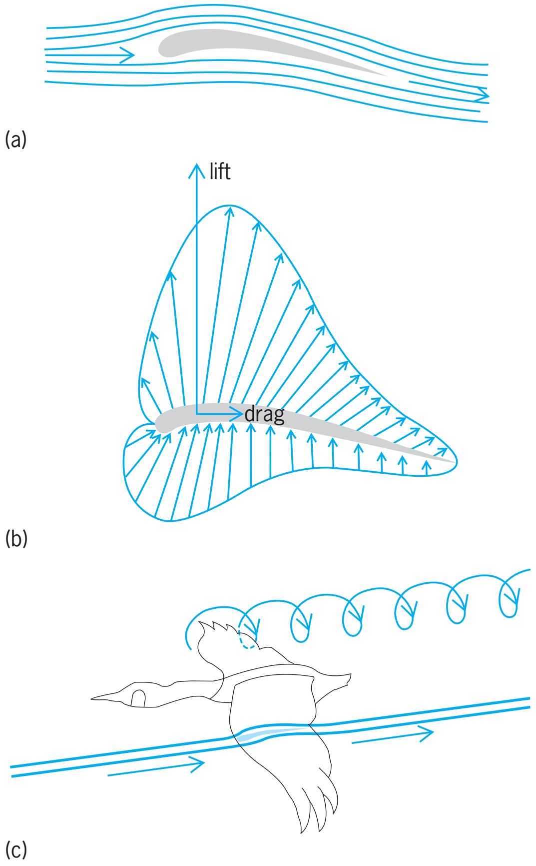
Commands and orders to the flexible manufacturing system are sent to its computer-based, unified control. The control, in turn, issues orders for the transport of various kinds of material, the transfer of needed programs, the starting and stopping of programs, the scheduling of these activities, and other activities.

Flexible manufacturing systems are flexible in the sense that their device controllers and central control computer can be reprogrammed to make new parts or old parts in new ways. They can also often make a number of different types of parts at the same time. However, this flexibility is limited to a certain family of parts, for example, axles. A general goal for designers is to increase flexibility, and advanced flexible manufacturing systems are more flexible than the earlier ones. [A.W.N.]

Flight Movement through the atmosphere or space, sustained by aerodynamic reaction or other forces. Animal flight includes gliding and flapping flight. Flapping flight in vertebrates was probably preceded by gliding; in insects it may have originated by leaping and gliding, by surface skimming on water, or (if small enough) by passive floating in the air. Flying insects show greater variation than flying vertebrates, and their flight spans a wider range of Reynolds numbers, which is the ratio of inertial forces to viscous forces in the flow. Flight of tiny insects is in the lower range of Reynolds numbers, where viscous forces are dominant, whereas large insects and vertebrates operate in the higher range, where inertial forces are important.

Flight is very expensive in terms of energy cost per unit time. However, flying animals can travel several times faster than nonflying ones, and the cost of carrying a unit of weight of an animal through a unit distance (cost of transport) is lower for flight than for running, but higher than for swimming.

The flight characteristics of large insects and vertebrates can be understood by aircraft aerodynamics. In steady level flight, an animal and an aircraft must generate forces that support weight against gravity and provide propulsive thrust against drag forces. The forces acting on an airfoil (the shape of the cross section of the wings) moving through the air depend upon the flow pattern around it. Because of the asymmetric profile on an airfoil, the air flowing over the upper surface travels farther and flows faster than air passing underneath. According to Bernoulli's principle, pressure falls when speed rises in a moving fluid, resulting in a pressure difference between the upper and lower sides of the airfoil (illus. *a*). This pressure difference has to disappear gradually toward the wingtips, and some air will flow upward around the wingtips. The air moves downward behind the wing as trailing vortices (illus. *b*), and the reaction of this momentum flow is experienced by the wing as lift. The stronger the vortex, the greater the lift generated, but with some energy loss to drag. The lift force is responsible for weight support (its vertical component) and thrust or drag (its horizontal component). *See* Aerodynamic force; Airfoil; Bernoulli's theorem.



Aerodynamics of flight. (*a*) Airflow around a typical wing profile. (*b*) Pressure distribution around a typical wing profile. (*c*) The difference in pressure disappears toward the wingtips as trailing vortices in the wake. (*After M. Brooke and T. Birkhead, eds., Cambridge Encyclopedia of Ornithology, Cambridge University Press, 1991*)

Energy must be expended to generate the trailing vortices in the wake and to overcome friction on the wing and body surfaces. These energy losses are experienced as drag forces, which act parallel to the direction of movement of the airfoil. Since drag is a retarding force, the animal must either descend (glide) through the air at such an angle that a component of its weight balances the drag, or do mechanical work with its flight muscles (flap its wings) to overcome it. The rate at which this work is done is the mechanical power required to fly, and it equals speed times drag (measured in watts). The flight muscles also produce heat when they contract, so the total metabolic power expenditure is the sum of this heat loss and the mechanical power.

The metabolic power is estimated to be four to five times the mechanical power, and is dependent on the size of the animal. *See* WORK.

Compared with active flight, gliding flight is very inexpensive, and is found in a wide range of animals, such as squirrels, marsupials, lizards, frogs, fishes, and even one snake. It is the main component in soaring flight used by many birds and some bats, when the animals use thermals or updrafts. Gliding in birds costs only two to three times the basal metabolic rate, because the flight muscles do not perform any mechanical work other than for stability and control of movements, and produce mostly static forces to keep the wings down on the horizontal plane, opposing the aerodynamic force.

When gliding, the wings of the animal leave behind a continuous vortex sheet that rolls up into a pair of vortex tubes (wingtip vortices), as in fixed-wing airplanes (illus. *b*). The lift produced balances the animal's weight, but potential energy must be used to overcome the drag and the animal loses height. An animal gliding at steady speed descends at an angle to the horizontal (glide angle), established by the ratio of lift to drag (glide ratio). The best glide ratios in birds range from 10:1 to 15:1 for vultures and birds of prey and reach 23:1 in the wandering albatross, whereas modern gliders can achieve 45:1. An animal cannot glide more slowly than its stalling speed, which in birds can be reduced by splaying the wingtip primaries, or by spreading the alula (a digit of the wing) at the wrist, or both. An animal can increase its gliding speed by flexing the wings and reducing the wing area.

Hovering flight represents the most expensive form of animal flapping flight. The essence of hovering is to produce a vertical force to balance body weight. The wake consists of a chain of vortex rings continuously shed during the wing strokes. In hummingbirds and insects, lift is produced during both the downstroke and upstroke of the wings (symmetrical hovering), and two vortex rings are produced during each wing stroke. In other hovering animals the wings are flexed during the upstroke (asymmetrical hovering), and the rings are produced during the downstrokes only. *See* AERODYNAMICS; AVES. [U.M.N.]

Flight controls The devices and systems which govern the attitude of an aircraft and, as a result, the flight path followed by the aircraft. Flight controls are classified as primary flight controls, auxiliary flight controls, and automatic controls. In the case of many conventional airplanes, the primary flight controls utilize hinged, trailing-edge surfaces called elevators for pitch, ailerons for roll, and the rudder for yaw. These surfaces are operated by the human pilot in the cockpit or by an automatic pilot. In the case of vertically rising aircraft, a lift control is provided. *See* AILERON; AIRCRAFT RUDDER; ELEVATOR (AIRCRAFT); ELEVON.

Controls to govern the engine power and speed, while not usually classified as flight controls, are equally important in the overall control of the aircraft. This is especially true if the engine exhaust can be directed to produce pitch or yaw motions.

Auxiliary flight controls may include trimming devices for the primary flight controls, as well as landing flaps, leading-edge flaps or slats, an adjustable stabilizer, a wing with adjustable sweep, dive brakes or speed brakes, and a steerable nose wheel.

Automatic controls include systems which supplement or replace the human pilot as a means of controlling the attitude or path of the aircraft. Such systems include automatic pilots, stability augmentation systems, automatic landing systems, and active controls. Active controls encompass automatic systems which result in performance improvement of the aircraft by allowing reductions in structural weight or aerodynamic drag, while maintaining the desired integrity of the structure and stability of flight.

The control system incorporates a set of cockpit controls which enable the pilot to operate the control surfaces. Because of the approximately fixed size and strength of the human pilot and the need to standardize the control procedures for airplanes, the primary controls are similar in most types of airplanes. The cockpit controls incorporate a control stick which operates the elevators and ailerons, and pedals which operate the rudder. Sometimes a column/wheel arrangement is used to operate the elevators and ailerons, respectively. The cockpit controls for auxiliary control devices are not as completely standardized as those for the primary controls.

Control systems with varying degrees of complexity are required, depending on the size, speed, and mission of an airplane. In relatively small or low-speed airplanes, the cockpit controls may be connected directly to the control surfaces by cables or pushrods, so that the forces exerted by the pilot are transmitted directly to the control surfaces. In large or high-speed airplanes, the forces exerted by the pilot may be inadequate to move the controls. In these cases, either an aerodynamic activator called a servotab or spring tab may be employed, or a hydraulic activator may be used . In some airplanes, particularly those with swept wings and those which fly at high altitudes, the provision of adequate static stability and damping of oscillations by means of the inherent aerodynamic design of the airplane becomes difficult. In these cases, stability augmentation systems are used. These systems utilize sensors such as accelerometers and gyroscopes to sense the motion of the airplane. These sensors generate electrical signals which are amplified and used to operate the hydraulic actuators of the primary control surfaces to provide the desired stability or damping. *See* STABILITY AUGMENTATION.

The weight and complication of mechanical control linkages and the extensive reliance on electrical signals in automatic controls led to the development of control systems in which the control inputs from the pilot, as well as those from the stability augmentation sensors, are transmitted to the primary control actuators by electrical signals. Systems of this type are called fly-by-wire systems. The electrical signals are readily compatible with computers, typically digital, which can perform the functions of combining the signals from the pilot and the sensors. *See* DIGITAL COMPUTER.

Fly-by-wire systems can malfunction when exposed to high-intensity electromagnetic fields. The solution to this problem has been to shield the transmission media and extensively test the system before certifying it, adding cost and weight to the system. These difficulties, the intrinsic immunity of optical technology to electromagnetic interference, and the availability of optical-fiber-based transmission media from the communications industry led to the development of fly-by-light systems. These systems use optical fibers to transmit signals instead of wires; the interface units are replaced with optical-electrical converters. *See* OPTICAL COMMUNICATIONS; OPTICAL FIBERS.

There are three major reasons why digital flight control computers are used in modern airplanes. First, digital flight control computers can enhance the pilot's control of the airplane by optimizing the movement of the control surfaces in response to pilot commands, over the operating flight conditions of the airplane. Second, as a result of their ability to rapidly monitor and interpret multiple sensor inputs, digital flight control computers can often exceed the performance of an unassisted pilot in compensating for critical situations which might otherwise result in loss of airplane control. Third, digital flight control computers permit input directly from remote control and navigation devices such as digital automatic landing systems, assisting the pilot in zero-visibility conditions or freeing the pilot for other airplane management tasks.

A digital flight control computer evaluates its inputs based on precomputed models of the airplane's expected behavior under various conditions of flight in order to produce command signals for the control surface actuators. Typically, wind-tunnel data are used to derive and verify the precomputed models used in the computer. Test flights and computer simulations are also used extensively to verify computer operation. *See* AIRCRAFT TESTING; WIND TUNNEL.

The flight of an aircraft may be controlled automatically by providing the necessary signals for navigation as inputs to the control system. In practice, automatic pilots are used to relieve the human pilot of routine flying for long periods, and automatic control systems are used to make precision landings and takeoffs under conditions of reduced visibility. *See* AUTOPILOT. [W.H.P.; P.D.A.]

Flight dynamics The study of the motion of an aircraft or missile. Flight dynamics is generally concerned with transient or short-term effects, which have to do with the stability and control of the vehicle, rather than with calculating such performance as ultimate range, attitude, or velocity of the vehicle. Sometimes, however, the two are treated together, particularly in the case of aircraft. *See* AEROELASTICITY; FLIGHT CONTROLS. [J.R.Se.]

Flight science The sum total of all knowledge that enables humans to accomplish flight. Flight science is compounded of both science and engineering. It is concerned with airplanes, missiles, and crewed and uncrewed space vehicles.

The scope of flight science is illustrated by some of the diverse fields which are included within it, such as electronics, aerodynamics, propulsion engineering, structural engineering, nuclear engineering, metallurgy, chemistry, space medicine, certain parts of astronomy, mathematics, classical and modern physics, and other branches of engineering, such as civil engineering for the planning and construction of airports. These constitute the major branches of science and technology needed to solve modern flight problems. [J.R.Se.]

Floodplain The relatively broad and smooth valley floor that is constructed by an active river and periodically covered with floodwater from that river during intervals of overbank flow. Engineers consider the floodplain to be any part of the valley floor subject to occasional floods that threaten life and property. Various channel improvements or impoundments may be used to restrict the natural process of overbank flow. Geomorphologist consider the floodplain to be a surface that develops by the active erosional and depositional processes of a river. Floodplains are underlain by a variety of sediments, reflecting the fluvial history of the valley.

Most floodplains consist of the following types of deposits: colluvium—slope wash and mass-wasting products from the valley sides, as is common in small, narrow floodplains; channel lag—coarse debris marking the bottoms of former channels; lateral accretion deposits—sand and gravel deposited as the meandering river migrates laterally; vertical accretion deposits—clay and silt deposited by overbank flooding of the river; crevassesplay deposits—relatively coarse sediment carried through breaks in the natural river levees and deposited in areas that usually receive overbank deposition; and channel-fill deposits—fills of former river channels. Channel fills may be coarse for sandy rivers. The noncohesive character of coarse sediments allows these rivers to easily erode laterally. *See* STREAM TRANSPORT AND DEPOSITION. [V.R.B.]

Floor construction A floor of a building generally provides a wearing surface on top of a flat support structure. Its form and materials are chosen for architectural, structural, and cost reasons. A ground-supported floor may be of almost any firm material, ranging from compacted soil to reinforced concrete. It is supported directly by the subsoil below.

An elevated floor spans between, and is supported by, beams, columns, or bearing walls. It is designed to be strong and stiff enough to support its design loading without excessive deflection; to provide for an appropriate degree of fire resistance; and to supply diaphragm strength to maintain the shape of the building as a whole, if necessary. A ceiling may be hung from the underside of the floor assembly as a finish surface for the room below. The optimum floor design meets these criteria while being as thin as possible and economical to construct. *See* BEAM; COLUMN; LOADS, TRANSVERSE.

Wooden floors are generally used in light residential construction. Such flooring generally consists of a finish floor installed on a subfloor of tongue-and-groove planking or plywood, spanning between wooden beams that are commonly called joists. Slabs fabricated of reinforced concrete are a common type of floor for heavier loading. The concrete is cast on forms, and reinforced with properly placed and shaped steel bars (rebars), so as to span between steel or reinforced concrete beams or between bearing walls. Composite floors are commonly used in modern office building construction. Concrete is cast on, and made structurally integral with, corrugated metal deck, which spans between steel joists of either solid-beam or open-web types, generally spaced between about 16–48 in. (40–120 cm) on center. Prestressed concrete is used for long span slabs. Highly prestressed high-tension steel wires within the high-strength concrete slab produce a thin, stiff, and strong floor deck. A lift slab is used for economy and efficiency. A concrete slab is first formed at ground level, reinforced and cured to adequate strength, and then carefully jacked up into its final position on supporting columns. *See* COMPOSITE BEAM; CONCRETE SLAB; PRESTRESSED CONCRETE; STRUCTURAL DESIGN. [M.A.]

Floriculture The segment of horticulture concerned with commercial production, marketing, and sale of bedding plants, cut flowers, potted flowering plants, foliage plants, flower arrangements, and noncommercial home gardening.

Commercial crops are grown either in the field or under protected cultivation, such as in glass or plastic structures. Field production is confined to warm climates or to summer months in colder areas. Typical field crops are gladiolus, peonies, stock, gypsophila, asters, and chrysanthemums. Greenhouse production is not as confined by climate or season, but most greenhouses are located in areas that have advantages such as high light intensity, cool night temperatures, or ready access to market. Jet air transportation resulted in major changes in international crop production.

Pronounced improvements in cultivars have been realized because of excellent breeding programs conducted by commercial propagators and by some horticulture departments. Modern cultivars have traits such as more attractive flower colors and forms, longer-lasting flowers, better growth habit, increased resistance to insects and disease organisms, or ability to grow and flower at cooler night temperatures. *See* BREEDING (PLANT). [R.A.L.]

Flotation A process used to separate particulate solids, which have been suspended in a fluid, by selectively attaching the particles to be removed to a light fluid and allowing this mineralized fluid aggregation to rise to where it can be removed. The principal use of the process is to separate valuable minerals from waste rock, or gangue, in which case the ground ore is suspended in water and, after chemical treatment, subjected to bubbles of air. The minerals which are to be floated attach to the air bubbles, rise through the suspension, and are removed with the froth which forms on top of the pulp. Although most materials subjected to flotation are minerals, applications to chemical and biological materials have been reported. [R.L.At.]

Flow-induced vibration The dynamic response of structures immersed in or conveying fluid flow. Fluid flow is a source of energy that can induce structural and mechanical oscillations. Flow-induced vibrations best describe the interaction that occurs between the fluid's dynamic forces and a structure's inertial, damping, and elastic forces. *See* FLUID MECHANICS; MECHANICAL VIBRATION; STRUCTURAL ANALYSIS; VIBRATION.

The study of flow-induced vibrations has rapidly developed in aeronautical and nonaeronautical engineering. In aeronautics, flow-induced vibration is often referred to as flutter, a topic of aeroelasticity concerning the mutual interactions of aerodynamic, elastic, and inertial forces in a flying object, its components, or its propulsion systems. Flow-induced vibration also covers classical flutter of an airfoil in a low-speed flow, stall flutter associated with a separated flow, and buffeting flutter related to turbulent wakes. Nonaeronautical flow-induced vibrations are often found in blood vessels, smokestacks, suspension bridges, oil pipe lines, power transmission lines, telephone wires, television antennas, heat exchanger tubes, nuclear fuel assemblies, and submarine periscopes and hulls. All nonaeronautical structures are unstreamlined and susceptible to both stall flutter and buffeting flutter caused by flow separation. The interaction of these structures with a fluid stream usually is more complicated than that of aeronautical structures and offers more possibilities for the flow to trigger unstable oscillations in the structures. *See* Aeroelasticity; Flutter (aeronautics).

Aircraft wing flutter. The fluid-elastic instability of an airplane wing or its control surfaces in a smooth flow without shock waves is called classical flutter. Flight tests show that the lift on an airfoil increases with increasing Mach number for a fixed angle of attack. This lifting force reaches a maximum at a critical Mach number, then drops sharply, and never increases no matter how high the flight speed is. This drop is due to flow separation or shock wave formation. Either of these two flow mechanisms can cause the airfoil to stall or can damage it. In these cases, the airfoil is said to be stall-fluttered or shock-stalled, depending on the flow process. *See* Shock wave.

When a flow separates from an airplane wing, the flow behind the wing is turbulent and random in nature. The airplane's tail is therefore subject to random excitations from the wing's turbulent wake. The wings and tails that oscillate randomly can lose stability. This type of dynamic aeroelastic instability is called buffeting flutter because the oscillations are random. *See* Boundary-layer flow; Turbulent flow; Wake flow.

Vibrations of cylinder arrays. Among the topics of flow-induced vibration, cylindrical structures play very important and vital roles. For instance, the slender bodies of aircraft fuselages, missiles, and rockets, and the main bodies of industrial smokestacks, power transmission cables, telephone wires, oil pipelines, reactor fuel rods, heat-exchanger tubes, and offshore structures, as well as the blood vessels are primarily made up of cylindrical structures. These structures, when in operation, are subject to unsteady fluid-dynamic forces and prone to vibrations. Such vibrations can be classified as axial-flow-induced or cross-flow-induced vibrations, depending on the incident angle of the incoming flow with respect to the cylinders' axes. Stall and buffeting flutter, also called fluid-elastic instabilities, including fluid-damping- and fluid-stiffness-controlled instabilities, as well as vortex shedding are all possible during flow-induced vibration. [S.S.C.; W.W.Li.]

Flow measurement The determination of the quantity of a fluid, either a liquid, vapor, or gas, that passes through a pipe, duct, or open channel. Flow may be expressed as a rate of volumetric flow (such as liters per second, gallons per minute, cubic meters per second, cubic feet per minute), mass rate of flow (such as kilograms per second, pounds per hour), or in terms of a total volume or mass flow (integrated rate of flow for a given period of time).

Flow measurement, though centuries old, has become a science in the industrial age. This is because of the need for controlled process flows, stricter accounting methods, and more efficient operations, and because of the realization that most heating, cooling, and materials transport in the process industries is in the form of fluids, the flow rates of which are simple and convenient to control with valve or variable speed pumps. *See* Process control.

Measurement is accomplished by a variety of means, depending upon the quantities, flow rates, and types of fluids involved. Many industrial process flow measurements consist of a combination of two devices: a primary device that is placed in intimate contact with the fluid and generates a signal, and a secondary device that translates this signal into a motion or a secondary signal for indicating, recording, controlling, or totalizing the flow. Other devices indicate or totalize the flow directly through the interaction of the flowing fluid and the measuring device that is placed directly or indirectly in contact with the fluid stream. *See* Metering orifice; Pitot tube; Venturi tube. [M.Br.; L.P.E.]

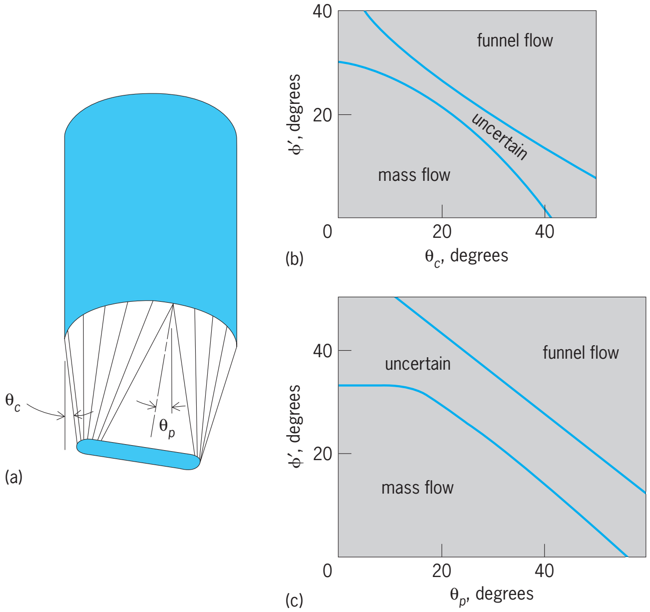
Flow of solids The gravity flow of particulate solids such as ceramic powders, plastic pellets, and ores in the form of separate particles, with the particles in contact and the voids between them filled with gas, usually air.

Particulate solids are a two-phase, solid-gas system. They are compressible; their bulk density changes during flow. Since the volume of the particles changes little during this process, it is the size of the voids that is mostly affected. Changes in the size of the voids can cause changes in gas pressure and result in gas-pressure gradients across a flowing solid which tend to reduce the rate of gravity discharge. When the solid is made up of large particles, that is, its permeability is high, when the required flow rates are low, the gas-pressure gradients are not significant; the gaseous phase can be ignored and the solid treated as a one-phase, solid-only system.

A bin (silo, bunker) generally consists of a vertical cylinder and a converging hopper. From the standpoint of flow, there are three types of bins: mass-flow, funnel-flow, and expanded-flow.

Mass flow occurs when the hopper walls are sufficiently steep and smooth to cause flow of all the solid, without stagnant regions, whenever any solid is withdrawn. The range of hopper slope and friction angles leading to mass flow is shown in the illustration. Funnel flow will occur unless both the conditions for mass flow shown there are satisfied.

Mass-flow bins have advantages. Flow is uniform, and feed density is practically independent of the head of solid in the bin. Segregation is minimized because, while a solid may segregate at the point of charge into the bin, continuity of flow enforces remixing of the fractions within the hopper. Mass-flow bins have



Bounds on mass flow and funnel flow. (*a*) Geometry of a transition hopper, showing slope angles θ_c and θ_p. (*b*) Range of kinematic angle of friction (ϕ') and θ_c leading to mass flow and funnel flow. (*c*) Range of ϕ' and θ_p leading to mass flow and funnel flow.

a first-in-first-out flow sequence, thus ensuring uniform residence time and deaeration of the stored solid.

Funnel flow occurs when the hopper walls are not sufficiently steep and smooth to force material to slide along the walls or when the outlet of a mass-flow bin is not fully effective.

In a funnel-flow bin, solid flows toward the outlet through a channel that forms within stagnant material. The diameter of that channel approximates the largest dimension of the effective outlet. As the level of solid within the channel drops, layers slough off the top of the stagnant mass and fall into the channel. This erratic behavior is detrimental with cohesive solids since the falling material packs on impact, thereby increasing the chance of material developing a stable arch across the hopper so that a complete stoppage of flow results. A channel, especially a narrow, high-velocity channel, may empty out completely, forming what is known as a rathole, and powder charged into the bin then flushes through. Powders flowing at a high rate in a funnel-flow bin may remain fluidized because of the short residence time in the bin, and flush on exiting the bin. A rotary valve is often used under these conditions to contain the material, but a uniform flow rate cannot be ensured because of the erratic flow to the valve.

Funnel-flow bins are more prone to cause arching of cohesive solids than mass-flow bins, and they therefore require larger outlets for dependable flow. These bins also cause segregation of solids and are unsuitable for solids which degrade with time in the stagnant regions. Cleanout of a funnel-flow bin is often uncertain because solids in the stagnant regions may pack and cake.

Expanded-flow bins are formed by attaching a mass-flow hopper to the bottom of a funnel-flow bin. The outlet usually requires a smaller feeder than would be the case for a funnel-flow bin. The mass-flow hopper should expand the flow channel to a dimension sufficient to prevent ratholing. [A.W.Je.; J.W.Ca.]

Flower A higher plant's sexual apparatus in the aggregate, including the parts that produce sex cells and closely associated attractive and protective parts (Fig. 1). "Flower" as used in this article will be limited, as is usual, to the angiosperms, plants with enclosed seeds and the unique reproductive process called double fertilization. In its most familiar form a flower is made up of four kinds of units arranged concentrically. The green sepals (collectively termed the calyx) are outermost, showy petals (the corolla) next, then the pollen-bearing units (stamens, androecium), and finally the centrally placed seed-bearing units (carpels, gynoecium). This is the "complete" flower of early botanists, but it is only one of an almost overwhelming array of floral forms. One or more kinds of units may be lacking or hard to recognize depending on the species, and evolutionary modification has been so great in some groups of angiosperms that a flower cluster (inflorescence) can took like a single flower.

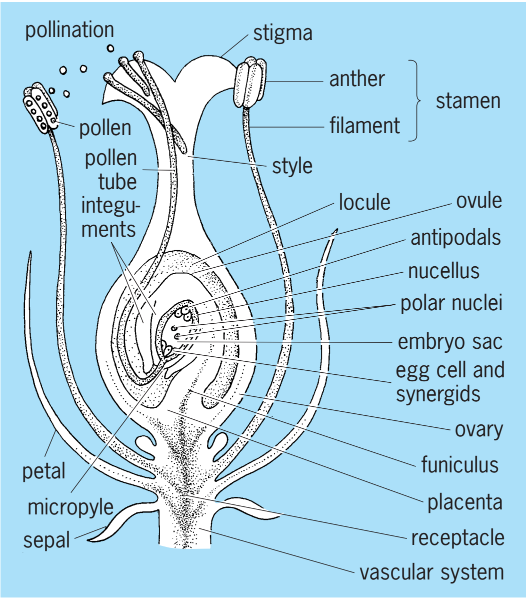


Fig. 1. Flower structure, median longitudinal section.

Flora diversity. Most botanical terms are descriptive, and a botanist must have a large store of them to impart the multiformity of flowers. The examples that follow are only a smattering. An extra series of appendages alternating with the sepals, as in purple loosestrife, is an epicalyx. A petal with a broad distal region and a narrow proximal region is said to have a blade and claw: the crape myrtle has such petals. The term perianth, which embraces calyx and corolla and avoids the need to distinguish between them, is especially useful for a flower like the tulip, where the perianth parts are in two series but are alike in size, shape, and color. The members of such an undifferentiated perianth are tepals. When the perianth has only one series of parts, however, they are customarily called sepals even if they are petallike, as in the windflower.

A stamen commonly consists of a slender filament topped by a four-lobed anther, each lobe housing a pollen sac. In some plants one or more of the androecial parts are sterile rudiments called staminodes: a foxglove flower has four fertile stamens and a staminode. Carpellode is the corresponding term for an imperfectly formed gynoecial unit.

A gynoecium is apocarpous if the carpels are separate (magnolia, blackberry) and syncarpous if they are connate (tulip, poppy). Or the gynoecium may regularly consist of only one carpel (bean, cherry). A solitary carpel or a syncarpous gynoecium can often be divided into three regions: a terminal, pollen-receptive stigma; a swollen basal ovary enclosing the undeveloped seeds (ovules); and a constricted, elongate style between the two. The gynoecium can be apocarpous above and syncarpous below; that is, there can be separate styles and stigmas on one ovary (wood sorrel).

Every flower cited so far has a superior ovary: perianth and androecium diverge beneath it (hypogyny). If perianth and androecium diverge from the ovary's summit, the ovary is inferior and the flower is epigynous (apple, banana, pumpkin). A flower is perigynous if the ovary is superior within a cup and the other floral parts diverge from the cup's rim (cherry). A syncarpous ovary is unilocular if it has only one seed chamber, plurilocular if septa divide it into more than one. The ovules of a plurilocular ovary are usually attached to the angles where the septa meet; this is axile placentation, a placenta being a region of ovular attachment. There are other ways in which the ovules can be attached—apically, basally, parietally, or on a free-standing central placenta—each characteristic of certain plant groups (Fig. 2).

The term bract can be applied to any leaflike part associated with one or more flowers but not part of a flower. Floral bracts are frequently small, even scalelike, but the flowering dogwood has four big petallike bracts below each flower cluster. The broad end of a flower stalk where the floral parts are attached is the receptacle. The same term is used, rather inconsistently, for the broad base bearing the many individual flowers (florets) that make up a composite flower like a dandelion or a sunflower.

Sexuality. A plant species is diclinous if its stamens and carpels are in separate flowers. A diclinous species is monoecious if each plant bears staminate and carpellate (pistillate) flowers, dioecious if the staminate and carpellate flowers are on different plants. The corn plant, with staminate inflorescences (tassels) on top and carpellate inflorescences (ears) along the stalk, is monoecious. Hemp is a well-known dioecious plant.

Nectaries. Flowers pollinated by insects or other animals commonly have one or more nectaries, regions that secrete a sugar solution. A nectary can be nothing more than a layer of tissue lining part of a floral tube or cup (cherry), or it can be as conspicuous as the secretory spur of a nasturtium or a

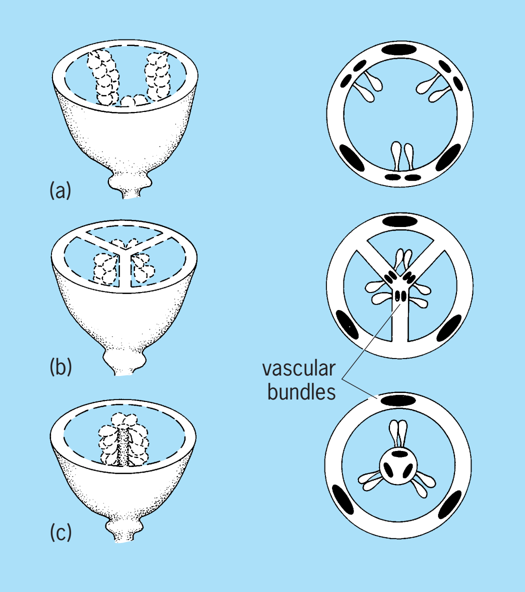

Fig. 2. Placentation: (*a*) parietal, (*b*) axile, and (*c*) free central. (*After P. H. Raven, R. F. Evert, and H. Curtis, Biology of Plants, Worth Publishers, 1976*)

larkspur. It can be a cushionlike outgrowth at the base of a superior ovary (orange blossom) or atop an inferior ovary (parsley family). Gladiolus and a number of other monocotyledons have septal nectaries, deep secretory crevices where the carpels come together. Substances that give off floral odors—essential oils for the most part—ordinarily originate close to the nectar-producing region but are not coincident with it. Production by the epidermis of perianth parts is most common, but in some species the odor emanates from a more restricted region and may even come from a special flap or brush. Most insect-pollinated plants have visual cues, some of them outside the human spectral range, as well as odor to bring the pollinators to the flowers and guide them to the nectar. *See* SECRETORY STRUCTURES (PLANT).

Inflorescence. Inflorescence structure, the way the flowers are clustered or arranged on a flowering branch, is almost as diverse as floral structure. To appreciate this, one need only contrast the drooping inflorescences (catkins) of a birch tree with the coiled flowers of a forget-me-not or with the solitary flower of a tulip. In some cases one kind of inflorescence characterizes a whole plant family. Queen Anne's lace and other members of the parsley family (Umbelliferae) have umbrellalike inflorescences with the flower stalks radiating from almost the same point in a cluster. The stalkless flowers (florets) of the grass family are grouped into clusters called spikelets, and these in turn are variously arranged in different grasses.

Flowers of the arum family (calla lily, jack-in-the-pulpit), also stalkless, are crowded on a thick, fleshy, elongate axis. In the composite family, florets are joined in a tight head at the end of the axis; the heads of some composites contain two kinds, centrally placed florets with small tubular corollas and peripheral ray florets with showy, strap-shaped corollas (the "petals" one plucks from a daisy). *See* INFLORESCENCE.

Anatomy. Some of the general anatomical features of leaves can be found in the floral appendages. A cuticle-covered epidermis overlies a core of parenchyma cells in which there are branching vascular bundles (solitary bundles in most stamens). Sepal parenchyma and petal parenchyma are often spongy, but palisade parenchyma occurs only rarely in flowers and then only in sepals. As in other parts of the plant, color comes mostly from plastids in the cytoplasm and from flavonoids in the cell sap. Cells of the petal epidermis may have folded side walls that interlock so as to strengthen the tissue. In some species the outer walls of the epidermis are raised as papillae; apparently, this is part of the means of attracting pollinators, for the papillae are light reflectors.

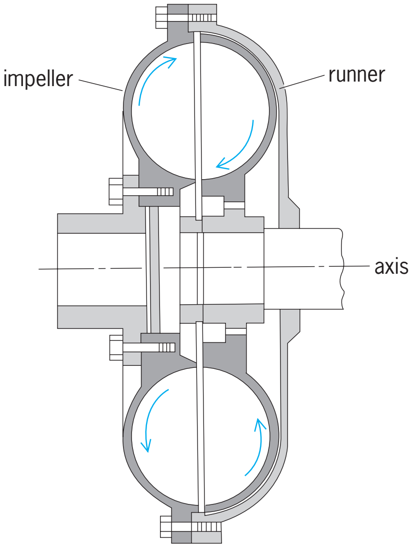
Stamen. As a stamen develops, periclinal divisions in the second cell layer of each of its four lobes start a sequence that will end with the shedding of pollen. The first division makes two cell layers. The outer daughter cells give rise to the wall of the pollen sac, and the inner ones are destined to become pollen after further divisions. When mature, a pollen sac typically has a prominent cell layer just below a less distinctive epidermis. The inner wall and the side walls of an endothecium cell carry marked thickenings, but the outer wall does not. Splitting of the ripe anther is due partly to the way in which these differentially thickened walls react to drying and shrinking and partly to the smaller size of the cells along the line of splitting. *See* POLLEN.

Carpel. Like other floral parts, a carpel is made up of epidermis, parenchyma, and vascular tissue. In addition, a carpel commonly has a special tissue system on which pollen germinates and through which, or along which, pollen tubes are transmitted to the ovules. Most angiosperms have solid styles, and the transmitting tissue is a column of elongate cells whose softened walls are the medium for tubal growth. The epidermis at the stigmatic end of a carpel usually changes to a dense covering of papillae or hairs; the hairs can be unicellular or pluricellular, branched or unbranched. In taxa with hollow styles, the transmitting tissue is a modified epidermis running down the stylar canal. There are two kinds of receptive surfaces, and they are distributed among the monocotyledons and the dicotyledons with taxonomic regularity. One kind has a fluid medium for germinating the pollen, and the other has a dry proteinaceous layer over the cuticle. The proteins of the dry stigmas have a role in the incompatibility reactions that encourage outbreeding.

Ovule. Ovule development usually takes place as the gynoecium forms, but it may be retarded when there is a long interval between pollination and fertilization (oaks, orchids). A typical ovule has a stalk (funiculus), a central bulbous body (nucellus), and one or two integuments (precursors of seed coats), which cover the nucellus except for a terminal pore (micropyle). Orientation of the ovule varies from group to group. It can be erect on its stalk or bent one way or another to differing degrees. There are also taxonomic differences in the extent to which the ovule is vascularized by branches from the gynoecial vascular system. *See* FRUIT; REPRODUCTION (PLANT). [R.H.E.]

Fluid coupling

A device for transmitting rotation between shafts by means of the acceleration and deceleration of a



Basic fluid coupling.

hydraulic fluid. Structurally, a fluid coupling consists of an impeller on the input or driving shaft and a runner on the output or driven shaft. The two contain the fluid (see illustration). Impeller and runner are bladed rotors, the impeller acting as a pump and the runner reacting as a turbine. Basically, the impeller accelerates the fluid from near its axis, at which the tangential component of absolute velocity is low, to near its periphery, at which the tangential component of absolute velocity is high. This increase in velocity represents an increase in kinetic energy. The fluid mass emerges at high velocity from the impeller, impinges on the runner blades, gives up its energy, and leaves the runner at low velocity. *See* HYDRAULICS. [H.J.Wir.]

Fluid flow Motion of a fluid subjected to unbalanced forces or stresses. The motion continues as long as unbalanced forces are applied. For example, in the pouring of water from a pitcher the water velocity is very high over the lip, moderately high approaching the lip, and very low near the bottom of the pitcher. The unbalanced force is gravity, that is, the weight of the tilted water particles near the surface. The flow continues as long as water is available and the pitcher remains tilted. *See* FLUIDS.

A fluid may be a liquid, vapor, or gas. The term vapor denotes a gaseous substance interacting with its own liquid phase, for example, steam above water. If this phase interaction is not important, the vapor is simply termed a gas.

Gases have weak intermolecular forces and expand to fill any container. Left free, gases expand and form the atmosphere of the Earth. Gases are highly compressible; doubling the pressure at constant temperature doubles the density. *See* GAS.

Liquids, in contrast, have strong intermolecular forces and tend to retain constant volume. Placed in a container, a liquid occupies only its own volume and forms a free surface which is at the same pressure as any gas touching it. Liquids are nearly incompressible; doubling the pressure of water at room temperature, for example, increases its density by only 0.005%.

Liquids and vapors can flow together as a mixture, such as steam condensing in a pipe flow with cold walls. This constitutes a special branch of fluid mechanics, covering two-phase-flow.

The physical properties of a fluid are essential to formulating theories and developing designs for fluid flow. Especially important are pressure, density, and temperature.

Since shear stresses cause motion in a fluid and result in differences in normal stresses at a point, it follows that a fluid at rest must have zero shear and uniform pressure at a point. This is the hydrostatic condition. The fluid pressure increases deeper in the fluid to balance the increased weight of fluid above. For liquids, and for gases over short vertical distances, the fluid density can be assumed to be constant. *See* HYDROSTATICS.

When a fluid is subjected to shear stress, it flows and resists the shear through molecular momentum transfer. The macroscopic effect of this molecular action, for most common fluids, is the physical property called viscosity. Shear stress results in a gradient in fluid velocity; the converse is also true.

The common fluids for which the linear relationship of flow velocity and sheer stress holds are called newtonian viscous fluids. More complex fluids, such as paints, pastes, greases, and slurries, exhibit nonlinear or non-newtonian behavior and require more complex theories to account for their behavior. *See* NEWTONIAN FLUID; NON-NEWTONIAN FLUID; VISCOSITY.

A common characteristic of all fluids, whether newtonian or not, is that they do not slip at a solid boundary. No matter how fast they flow away from the boundary, fluid particles at a solid surface become entrapped by the surface structure. The macroscopic effect is that the fluid velocity equals the solid velocity at a boundary. This is called the no-slip condition where the solid is fixed, so that the fluid velocity drops to zero there. No-slip sets up a slow-moving shear layer or boundary layer when fluid flows near a solid surface. The theory of boundary-layer flow is well developed and explains many effects involving viscous flow past immersed bodies or within passages. *See* BOUNDARY-LAYER FLOW.

All fluids are at least slightly compressible, that is, their density increases as pressure is applied. In many flows, however, compressibility effects may be neglected. A very important parameter in determining compressibility effects is the Mach number Ma, or ratio of flow velocity V to fluid speed of sound. For subsonic flow, Ma < 1, whereas for supersonic flow, Ma > 1. The flow is essentially incompressible if Ma < 0.3; hence for air the flow velocity is less than about 100 m/s (330 ft/s). Almost all liquid flows and many gas flows are thus treated as incompressible. Even a supersonic airplane lands and takes off in the incompressible regime. *See* COMPRESSIBLE FLOW; MACH NUMBER.

For various types of fluid flow *see* FLUID MECHANICS; HYDRODYNAMICS; ISENTROPIC FLOW; LAMINAR FLOW; PIPE FLOW; RAREFIED GAS FLOW; TURBULENT FLOW; WAKE FLOW. [F.M.Wh.]

Fluid mechanics The engineering science concerned with the relation between the forces acting on fluids (liquids and gases) and their motions, and with the forces caused by fluids on their surroundings. It is distinct from solid mechanics by virtue of the different responses of fluids and solids to applied forces. In an ideal elastic solid, the deflection or deformation is proportional to the applied stress, whereas a fluid cannot support an applied shear stress unless it is in motion. In most fluids, called simple or newtonian fluids, it is the rate of deformation of the fluid, as opposed to the amount of deformation in a solid, that is proportional to the applied stress. *See* FLUID FLOW; NEWTONIAN FLUID.

Many substances of everyday experience and of engineering importance are found naturally in the fluid state. These include water (liquid and vapor), air (gaseous and liquid), as well as other liquids and gases of natural and industrial importance. The most common fluids are newtonian under most flow conditions.

Fluid mechanics treats the fluid as a continuum, ignoring the fact that it actually consists of individual molecules that may be, in the case of gases, widely spaced compared to molecular dimensions. Nevertheless, the continuum assumption is valid for almost all applications down to the size of bacteria. An exception occurs with gases at very low densities, such as exist in the uppermost regions of the atmosphere. At extremely high altitudes the mean free paths of air molecules—that is, the distances they travel between collisions in random thermal motion—can become as large, or even larger than, the dimensions of a space vehicle, making the assumption of a continuum invalid. *See* RAREFIED GAS FLOW.

Fluid mechanics is of fundamental importance to a number of disciplines, including aerospace, chemical, civil, environmental, mechanical, and ocean engineering, as well as to climatology, geology, meteorology, and oceanography. Applications in these fields include, but are not limited to, the study of fluid forces acting on vehicles; flows in natural rivers and artificial channels and the flow of ground water; the dispersion of pollutants in the atmosphere, lakes, rivers, and oceans; the flows in the circulatory and pulmonary systems of humans and animals; the flows in pipelines that carry crude oil and natural gas over many hundreds, or even thousands, of miles from the petroleum fields of their origin to deep-water ports or refineries; the flow of molten plastics or metals filling molds in the manufacture of numerous solid parts; the flow in pumps for water distribution systems; and both hydraulic and gas turbines for power generation and propulsion. Fluid mechanics forms the basis for much of chemistry and physics, and is sometimes applied to such apparently remote fields as cosmology. The fluid mechanical behavior of gases and liquids plays an important role in the dispersion of dissolved or entrained substances. *See* AERODYNAMIC FORCE; AERODYNAMICS; BIOMEDICAL ENGINEERING; HYDRAULICS; HYDRODYNAMICS. [D.A.Ca.; J.A.Li.]

Fluidization The processing technique employing a suspension or fluidization of small solid particles in a vertically rising stream of fluid—usually gas—so that fluid and solid come into intimate contact. This is a tool with many applications in the petroleum and chemical process industries. Suspensions of solid particles by vertically rising liquid streams are of lesser interest in modern processing, but have been shown to be of use, particularly in liquid contacting of ion-exchange resins. However, they come in this same classification and their use involves techniques of liquid settling, both free and hindered (sedimentation), classification, and density flotation. *See* ION EXCHANGE; MECHANICAL CLASSIFICATION.

The interrelations of hydromechanics, heat transfer, and mass transfer in the gas-fluidized bed involve a very large number of factors. Because of the excellent contacting under these conditions, numerous chemical reactions are also possible—either between solid and gas, two fluidized solids with each other or with the gas, or most important, one or more gases in a mixture with the solid as a catalyst. In the usual case, the practical applications in plants have far outrun the exact understanding of the physical, and often chemical, interplay of variables within the minute ranges of each of the small particles and the surrounding gas phase.

With such excellent opportunities for heat and mass transfer to or from solids and fluids, fluidization has become a major tool in such fields as drying, roasting, and other processes involving chemical decomposition of solid particles by heat. An important application has been in the catalysis of gas reactions, wherein the excellent opportunity of heat transfer and mass transfer between the catalytic surface and the gas stream gives performance unequaled by any other system. *See* CATALYSIS; CRACKING; FLUIDIZED-BED COMBUSTION; GAS ABSORPTION OPERATIONS; HEAT TRANSFER; UNIT OPERATIONS. [D.F.O.]

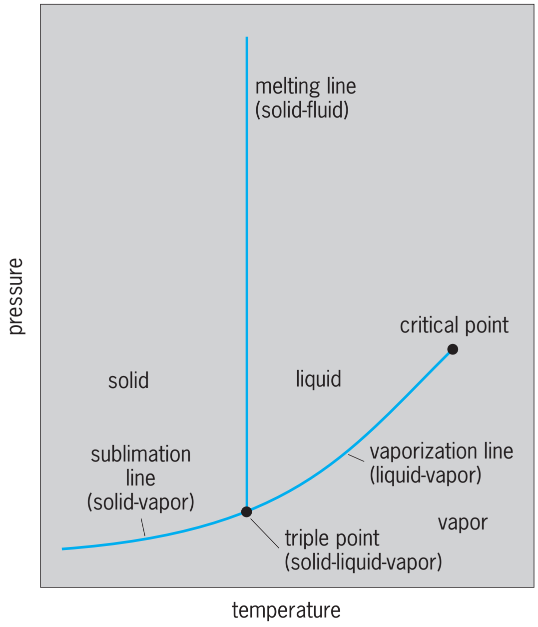
Fluidized-bed combustion A method of burning fuel in which the fuel is continually fed into a bed of reactive or inert material while a flow of air passes up through the bed, causing it to act like a turbulent fluid. Fluidized beds have long been used for the combustion of low-quality, difficult fuels and have become a rapidly developing technology for the clean burning of coal. *See* FLUIDIZATION.

A fluidized-bed combustor is a furnace chamber whose floor is slotted, perforated, or fitted with nozzles. Air is forced through the floor and upward through the chamber. The chamber is partially filled with particles of either reactive or inert material, which will fluidize at an appropriate air flow rate. When fluidization takes place, the bed of material expands (bulk density decreases) and exhibits the properties of a liquid. As air velocity increases, the particles mix more violently, and the surface of the bed takes on the appearance of a boiling liquid. If air velocity were increased further, the bed material would be blown away.

Once the bed is fluidized, its temperature can be increased with ignitors until a combustible material can be injected to burn within the bed. Proper selection of air velocity, operating temperature, and bed material will cause the bed to act as a chemical reactor. The three broad areas of application of fluidized-bed combustion are incineration, gasification, and steam generation. *See* COAL GASIFICATION; COMBUSTION; GAS TURBINE; STEAM-GENERATING UNIT. [M.Po.]

Fluids Substances that flow under shear stress and have a density range from essentially zero (gases) to solidlike values (liquids). Fluids are one of the two major forms of matter. Solids, the other form, generally deform very little when shear forces are applied, and their densities do not change significantly with pressure or temperature.

The distinction between solids and fluids is easily seen in substances and mixtures which show a well-defined melting process. For substances with large molecules, such as polymers, ceramics, and biologicals, this distinction is less clear. Instead, there is a slow evolution of structure and of resistance to flow as temperature or some other variable is changed. *See* GLASS TRANSITION; MELTING POINT; POLYMER.



Conditions of pure-component phase behavior.

Molecular density varies greatly in fluids and is their most important characteristic. The distinction between vapors (or gases) and liquids is most clear for substances and mixtures that show well-defined vaporizing (boiling) and condensing processes. The high-density liquid boils to make a low-density gaseous vapor. The illustration shows the pressures and temperatures for which pure substances are single phases. At the conditions of the lines between the single-phase regions, two phases can be observed to coexist. At the state of intersection of the lines (the triple point), three phases can coexist. For most substances, the triple-point pressure is well below atmospheric. However, for carbon dioxide, it is very high, so that dry ice sublimes rather than melts, as water ice does. Beyond the end of the liquid-vapor (saturation or vapor-pressure) line, vaporization and condensation cannot be observed. The state at the end of this line is called the critical point, where all the properties of the vapor and liquid become the same. There is no such end to the solid-liquid (or melting) line, because the solid and fluid structures cannot become the same. *See* CRITICAL PHENOMENA; PHASE TRANSITIONS; TRIPLE POINT.

Mixtures of fluids show the same general density and multiphase behavior as pure fluids, but the composition is an extra variable to be considered. For example, the density differences between the vapor and the liquid phases cause them to have different relative amounts of the components. This difference in composition is the basis of the separation process of distillation, where the vapor will be richer in some components while the liquid will be richer in others. It is also possible for mixtures of liquids to be partially or nearly wholly immiscible, as are water and oil. The separation process of liquid extraction, used in some metal-purification systems and chemical-pollution-abatement processes, depends on different preferences of chemical solutes for one liquid phase or the other. *See* DISTILLATION; EXTRACTION; PHASE RULE.

The usual observation of the presence of more than one fluid phase is the appearance of the boundary or interface between them. This is seen because the density or composition (or both) changes over a distance of a few molecular diameters, and this variation bends or scatters light in a detectable way. At the interface, the molecules feel different forces than in the bulk phases and thus have special properties. Energy is always required to create interface from bulk, the amount per unit area being called the interfacial tension. Water is a fluid with an extremely high vapor-liquid (or surface) tension; this surface tension allows insects to crawl on ponds and causes sprinkler streams to break up into sprays of droplets. *See* INTERFACE OF PHASES; SURFACE TENSION.

In mixtures, the molecules respond differently to the interfacial forces, so the interfacial composition is generally different from that of the bulk. This has also been the basis of a separation process. If the difference of composition is great enough and it varies with time and position because of evaporation of one or more of the components, the interfacial forces can push the fluid into motion, as can be observed on the walls of a glass of brandy (the Marangoni effect). Some substances strongly adsorb at the interface because their chemical structure has one part that prefers to be in one phase, such as water, and another part that prefers the other phase, such as oil or air. Such surfactants or detergents help solubilize dirt into wash water, keep cosmetics and other immiscible mixtures together, and form foams when air and soapy water are whipped together. *See* ADSORPTION; DETERGENT; FOAM; SURFACTANT.

Besides the relations among pressure, density, temperature, and composition of static or equilibrium fluids, there are also characteristics associated with fluid flow, heat transfer, and material transport. For example, when a liquid or gas flows through a tube, energy must be supplied by a pump, and there is a drop in pressure from the beginning to the end of the tube that matches the rise in pressure in the pump. The pump work and pressure drop depend on the flow rate, the tube size and shape, the density, and a property of the molecules called the viscosity. The effect arises because the fluid molecules at the solid tube wall do not move and there are velocity gradients and shear in the flow. The molecules that collide with one another transfer momentum to the wall and work against one another, in a sort of friction which dissipates mechanical energy into internal energy or heat. The greater the viscosity, the greater the amount of energy dissipated by the collisions and the greater the pressure drop. If only chemical constitution and physical state are needed to characterize the viscosity, and if shear stress is directly proportional to velocity gradient, the fluid is called newtonian and the relation for pressure drop is relatively simple. If the molecules are large or the attractive forces are very strong over long ranges, as in polymers, gels, and foods such as bread dough and cornstarch, the resistance to flow can also depend on the rate of flow and even the recent deformations of the substance. These fluids are called non-newtonian, and the relationship of flow resistance to the applied forces can be very complex. *See* FLUID FLOW; NEWTONIAN FLUID; NON-NEWTONIAN FLUID; VISCOSITY.

Another fluid-transport property, thermal conductivity, indicates the ability of a static fluid to pass heat from higher to lower temperature. This characteristic is a function of chemical constitution and physical state, as is the viscosity. In mixtures, these properties may involve simple or complex dependence on composition, the variation becoming extreme if the unlike species strongly attract each other. The values of both properties increase rapidly near a critical point. *See* CONDUCTION (HEAT); HEAT TRANSFER.

Finally, the ability of molecules to change their relative position in a static fluid is called the diffusivity. This is a particularly important characteristic for separation processes whose efficiency depends on molecular motion from one phase to another through a relatively static interface, or on the ability of some molecules to move faster than others in a static fluid under an applied force. *See* DIFFUSION; GAS; LIQUID. [J.P.O'C.]

Fluorescence Fluorescence is generally defined as a luminescence emission that is caused by the flow of some form of energy into the emitting body, this emission ceasing abruptly when the exciting energy is shut off. In attempts to make this definition more meaningful it is often stated, somewhat arbitrarily, that the decay time, or afterglow, of the emission must be of the order of the natural lifetime for allowed radiative transitions in an atom or a molecule, which is about 10^{-8} s for transitions involving visible light. Perhaps a better distinction between fluorescence and its counterpart, phosphorescence, rests not on the magnitude of the decay time per se, but on the criterion that the fluorescence decay is temperature-independent.

In the literature of organic luminescence, the term fluorescence is used exclusively to denote a luminescence which occurs when a molecule makes an allowed optical transition. Luminescence with a longer exponential decay time, corresponding to an optically forbidden transition, is called phosphorescence, and it has a different special distribution from the fluorescence. *See* PHOSPHORESCENCE.

The decay time of fluorescent materials varies widely, from the order of 5×10^{-9} s for many organic crystalline materials up to 2 s for the europium-activated strontium silicate phosphor. Fluorescent materials with decay times between 10^{-9} and 10^{-7} s are used to detect and measure high-energy radiations, such as x-rays and gamma rays, and high-energy particles such as alpha particles, beta particles, and neutrons. These agents produce light flashes (scintillations) in certain crystalline solids, in solutions of many polynuclear aromatic hydrocarbons, or in plastics impregnated with these hydrocarbons. The so-called fluorescent lamps employ the luminescence of gases and solids in combination to produce visible light. *See* ABSORPTION; FLUORESCENT LAMP; LUMINESCENCE. [J.H.S.; C.C.K.]

Fluorescence microscope An instrument for the observation and study of microscopic specimens that absorb light and emit fluorescence. In most cases, in order to obtain specific and meaningful fluorescence, staining with fluorescing dyes called fluorophores or fluorochromes is necessary. Fluorescence microscopy is a highly sensitive method, since often minute quantities of a fluorophore can be visualized with good microscopic contrast. In appropriate applications, brightly fluorescing images can be observed against a dark background. Individual fluorophores have different absorption and emission spectra and a different quantum efficiency (the ratio between the energy absorbed and the energy emitted), factors that must be considered for optimum fluorescence. *See* BIOLUMINESCENCE; FLUORESCENCE.

The basics for fluorescence microscopy are the light source necessary to illuminate the specimen and the optics needed to observe the fluorescence. In addition, filters must be used to single out appropriate excitation and emission wavelengths. Excitation filters select out a limited range of excitation wavelengths from the light source that corresponds to the absorption spectrum of the fluorochrome. Barrier filters separate emitted light from unabsorbed exciting light. Fluorescence can then be observed by eye, photographed, measured by a photomultiplier, or recorded by a television camera. Two types of illumination are used in fluorescence microscopy: transmitted and incident. The earliest fluorescence microscopes relied on transmitted illumination, which generally used a dark-ground condenser to facilitate the separation of fluorescent and exciting light. With the development of epi-illumination, the exciting light reaches the preparation from above by way of a dichroic mirror and the objective, which at the same time acts as a condenser. Epi-illumination by means of a vertical illuminator, which permits the excitation with more wavelengths, is known as a fluorescence illuminator, and has become the routine instrument for fluorescence microscopy.

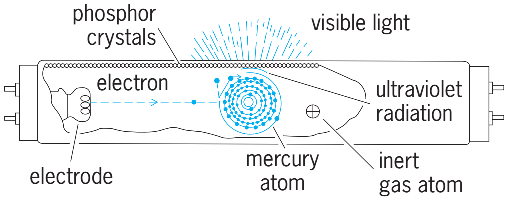
In laser-scanning fluorescence microscopy, the object is not illuminated as a whole but is scanned step by step with a laser-illuminated spot. From each point the fluorescence is measured and, after analog-to-digital conversion, stored as a matrix in computer memory. The main advantage of laser-scanning microscopy over conventional methods in flourescence microscopy is the point-by-point illumination. Most stray light is avoided. In the confocal mode, the fluorescence from above and below the selected focal plane is almost completely eliminated from the image, removing most of the glare experienced in conventional fluorescence microscopy of thicker specimens. Confocal fluorescence microscopy allows optical image sectioning of the specimen and, after combining the multiple images at different focal levels of a specimen, a computerized reconstruction of three-dimensional images of a section. *See* Confocal microscopy; Laser.

The primary application of fluorescence microscopy is in the field of medicine, where diagnostic tests have been developed that use monoclonal antibodies to which a red, green, or blue fluorescent dye has been attached. The dyes thus reveal various components in the specimen, such as bacteria, viruses, or macromolecules like deoxyribonucleic acid (DNA) and ribonucleic acid (RNA). *See* Immunofluorescence. [J.S.P.]

Fluorescent lamp

A lamp that produces light largely by conversion of ultraviolet energy from a low-pressure mercury arc to visible light. Phosphors, chemicals that absorb radiant energy of a given wavelength and reradiate at longer wavelengths, produce most of the light provided by fluorescent lamps. *See* Phosphorescence.

The lamp consists of a glass tube containing two electrodes, a coating of activated powdered phosphor, and small amounts of mercury. The glass tube seals the inner parts from the atmosphere. The electrodes provide a source of free electrons to initiate the arc, and are connected to the external circuit through the ends of the lamp. The phosphor converts short-wave ultraviolet energy into visible light. The mercury, when vaporized in the arc, produces the ultraviolet radiation that causes fluorescence. An inert gas, such as argon, krypton, or neon, introduced in small quantities provides the ions that facilitate starting of the lamp (see illustration). *See* Fluorescence.



Parts of a typical fluorescent lamp.

Fluorescent lamps are usually operated on ac circuits with a frequency of 60 Hz. However, higher frequencies permit higher-efficacy lamp operation along with ballasts of lower power dissipation per watt. Consequently, systems have been developed for the operation of fluorescent lamps at frequencies from 360 to 50,000 Hz. The most important high-frequency ballasts operate the lamps in the 25-kHz range, are lighter in weight, can have flicker-free light output, and will continue to be more cost-effective as the cost of electricity increases. Electronic technology permits these ballasts to be made with more features, such as dimming and low-cost remote controls, enhancing their overall performance value.

Fluorescent lamps provide light at several times the efficacy of incandescent lamps, the exact ratio depending on the fluorescent lamp color. Lamp color is determined by the selection of chemicals used in the phosphors; various chemicals respond to the ultraviolet energy in the arc by producing different colors of light. Several types of essentially white fluorescent lamps are available commercially, as well as a range of tinted and saturated colors. [E.E.H.]

Fluorine

A chemical element, F, atomic number 9, the member of the halogen family that has the lowest atomic number and atomic weight. Although only the isotope with atomic weight 19 is stable, the other, radioactive isotopes between atomic weight 17 and 22 have been artificially prepared. Fluorine is the most electronegative element, and by a substantial margin the most chemically energetic of the nonmetallic elements. *See* Periodic table.

Properties. The element fluorine is a pale yellow gas at ordinary temperatures. The odor of the element is somewhat in doubt. Some physical properties are listed in the table. The reactivity of the element is so great that it will react readily at ordinary temperatures with many other elementary substances, such as sulfur, iodine, phosphorus, bromine, and most metals. Since the products of the reactions with the nonmetals are in the liquid or gaseous state, the reactions continue to the complete consumption of the fluorine, frequently with the evolution of considerable heat and light. Reactions with the metals usually form a protective metallic fluoride which blocks further reaction, unless the temperature is raised. Aluminum, nickel, magnesium, and copper form such protective fluoride coatings.

Fluorine reacts with considerable violence with most hydrogen-containing compounds, such as water, ammonia, and all organic chemical substances whether liquids, solids, or gases. The reaction of fluorine with water is very complex, yielding mainly hydrogen fluoride and oxygen with less amounts of hydrogen peroxide, oxygen difluoride, and ozone. Fluorine displaces other nonmetallic elements from their compounds, even those nearest fluorine in chemical activity. It displaces chlorine from sodium chloride, and oxygen from silica, glass, and some ceramic materials. In the absence of hydrofluoric acid, however, fluorine does not significantly etch quartz or glass even after several hours at temperatures as high as 390°F (200°C).

Fluorine is a very toxic and reactive element. Many of its compounds, especially inorganic, are also toxic and can cause severe and deep burns. Care must be taken to prevent liquids or vapors from coming in contact with the skin or eyes.

Natural occurrence. At an estimated 0.065% of the Earth's crust, fluorine is roughly as plentiful as carbon, nitrogen, or chlorine, and much more plentiful than copper or lead, though much less abundant than iron, aluminum, or magnesium. Compounds whose molecules contain atoms of fluorine are widely distributed in nature. Many minerals contain small amounts of the element, and it is found in both sedimentary and igneous rocks.

Uses. Fluorine-containing compounds are used to increase the fluidity of melts and slags in the glass and ceramic industries. Fluorspar (calcium fluoride) is introduced into the blast furnace to reduce the viscosity of the slag in the metallurgy of iron. Cryolite, Na_2AlF_6, is used to form the electrolyte in the metallurgy of aluminum. Aluminum oxide is dissolved in this electrolyte, and the metal is reduced electrically from the melt. The use of halocarbons containing fluorine as refrigerants was patented in 1930, and these volatile and stable compounds found a market in aerosol propellants as well as in refrigeration and air-conditioning systems. However, use of fluorocarbons as propellants has declined sharply because of concern over their possible damage to the ozone layer of the atmosphere. A use for fluorine that became prominent during World War II is in the enrichment of the fissionable isotope ^{235}U; the most important process employed

Physical properties of fluorine

Property	Value
Atomic weight	18.998403
Boiling point, °C	−188.13
Freezing point, °C	−219.61
Critical temperature, °C	−129.2
Critical pressure, atm*	55
Density of liquid at b.p., g/ml	1.505
Density of gas at 0°C + 1 atm*, g/liter	1.696
Dissociation energy, kcal/mol	36.8
Heat of vaporization, cal/mol	1510
Heat of fusion, cal/mol	121.98
Transition temperature (solid), °C	−227.61

*1 atm = 101.325 kilopascals.

uranium hexafluoride. This stable, volatile compound was by far the most suitable material for isotope separation by gaseous diffusion.

While consumers are mostly unaware of the fluorine compounds used in industry, some compounds have become familiar to the general public through minor but important uses, such as additives to toothpaste and nonsticking fluoropolymer surfaces on frying pans and razor blades (for example Teflon).

Compounds. In all fluorine compounds the high electronegativity of this element suggests that the fluorine atom has an excess of negative charge. It is convenient, however, to divide the inorganic binary fluorides into saltlike (ionic lattice) nonvolatile metallic fluorides and volatile fluorides, mostly of the nonmetals. Some metal hexafluorides and the noble-gas fluorides show volatility that is frequently associated with a molecular compound. Volatility is often associated with a high oxidation number for the positive element.

The metals characteristically form nonvolatile ionic fluorides where electron transfer is substantial and the crystal lattice is determined by ionic size and the predictable electrostatic interactions. When the coordination number and valence are the same, for example, BF_3, SiF_4, and WF_6, the binding between metal and fluoride is not unusual, but the resulting compounds are very volatile, and the solids show molecular lattices rather than ionic lattice structures. For higher oxidation numbers, simple ionic lattices are less common and, while the bond between the central atom and fluorine usually still involves transfer of some charge to the fluorine, molecular structures are identifiable in the condensed phases.

In addition to the binary fluorides, a very large number of complex fluorides have been isolated, often with a fluoroanion containing a central atom of high oxidation number. The binary saltlike fluorides show a great tendency to combine with other binary fluorides to form a large number of complex or double salts.

The fluorine-containing compounds of carbon can be divided into fluorine-containing hydrocarbons and hydrocarbon derivatives (organic fluorine compounds) and the fluorocarbons and their derivatives. The fluorine atom attached to the aromatic ring, as in fluorobenzene, is quite unreactive. In addition, it reduces the reactivity of the molecule as a whole. Dyes, for example, that contain fluorine attached to the aromatic ring are more resistant to oxidation and are more light-fast than dyes that do not contain fluorine. Most aliphatic compounds, such as the alkyl fluorides, are unstable and lose hydrogen fluoride readily. These compounds are difficult to make and to keep and are not likely to become very important. *See* FLUOROCARBON; HALOGEN ELEMENTS. [I.S.]

Organic compounds. The carbon compounds containing fluorine belong to several classes, depending on what other substituents besides fluorine are present. The physical properties and chemical reactivity of organic molecules containing fluorine are quite different when compared to the same molecules containing other halogen atoms, such as chlorine. This is due, in part, to a unique combination of the properties of fluorine, which include its small atomic size and high electronegativity. Stepwise replacement of several or all of the hydrogen atoms or other substituents attached to carbon is possible.

Many methods are available for creating a carbon-to-fluorine bond. A widely used method is to exchange a chlorine attached to carbon by reacting the compound with hydrofluoric acid. Elemental fluorine, which is very highly reactive, has also been used to prepare fluorine-containing compounds from a wide variety of organic compounds. The unusual property imparted to an organic molecule by fluorine substitution has led to the development of compounds that fulfill specific needs in refrigeration, medicine, agriculture, plastics, textiles, and other areas.

Fluoroolefins. These are a class of unsaturated carbon compounds containing fluorine; that is, they have a $C{=}C$ in addition to other substituents. A typical fluoroolefin is tetrafluoroethylene ($F_2C{=}CF_2$). It is prepared from chlorodifluoromethane ($CHClF_2$), which loses HCl upon heating to produce $F_2C{=}CF_2$.

Many fluoroolefins combine with themselves or other olefins by the process of polymerization. Thus, polymerization of $F_2C{=}CF_2$ yields the polymer polytetrafluoroethylene (PTFE). This remarkable solid substance has outstanding physical and chemical properties. Nonstick polytetrafluoroethylene surfaces are used in kitchen utensils, bearings, skis, and many other applications. Since polytetrafluoroethylene is very viscous above its melting point, special methods have to be used for fabrication. For this reason, copolymers of tetrafluoroethylene with such olefins as ethylene have been developed. The chemical resistance of these copolymers is less than that of perfluorinated polymers. To obtain polymers with desired properties, the chemical processes to make them are carried out under rigorously controlled conditions. *See* COPOLYMER; POLYFLUOROOLEFIN RESINS; POLYMER; POLYMERIZATION.

There are many oxygen-containing fluorocarbons such as ethers, acids, ketones, and alcohols. Simple, fluorinated ethers are compounds of the type R-O-R, where R is a fluorinated alkyl group. The simple compound perfluoro ether (F_3COCF_3) is an analog of dimethyl ether. *See* ETHER.

Organofluorine chemicals offer some unique properties and solutions. In addition to the applications mentioned above, they are used in dyes, surfactants, pesticides, blood substitutes, textile chemicals, and biologically active compounds. *See* FLUOROCARBON; HALOGENATED HYDROCARBON. [V.N.M.R.]

Fluorite A mineral of composition CaF_2. It is the most abundant fluorine-bearing mineral, and occurs as cubes or compact masses and more rarely as octahedra with complex modifications. Fluorite has a perfect octahedral cleavage, hardness 4 (Mohs scale), and specific gravity 3.18. The color is extremely variable, the most common being green and purple; but fluorite may also be colorless, white, yellow, blue, or brown. Colors may result from the presence of impurity ions. Fluorite frequently emits a blue-to-green fluorescence under ultraviolet radiation, especially if rare-earth or hydrocarbon material is present. Some fluorites are thermoluminescent; that is, they emit light when heated.

Fluorite occurs as a typical hydrothermal vein mineral with quartz, barite, calcite, sphalerite, and galena. Crystals of great beauty from Cumberland, England, and Rosiclare, Illinois, are highly prized by mineral fanciers. It also occurs as a metasomatic replacement mineral in limestones and marbles. [P.B.M.]

Fluorocarbon Any of the organic compounds in which all of the hydrogen atoms attached to a carbon atom have been replaced by fluorine; also referred to as a perfluorocarbon. Fluorocarbons are usually gases or liquids at room temperature, depending on the number of carbon atoms in the molecule. A major use of gaseous fluorocarbons is in radiation-induced etching processes for the microelectronics industry; the most common one is tetrafluoromethane. Liquid fluorocarbons possess a unique combination of properties that has led to their use as inert fluids for cooling of electronic devices and soldering. Solubility of gases in fluorocarbons has also been used to advantage. For example, they have been used in biological cultures requiring oxygen, and as liquid barrier filters for purifying air. *See* FLUORINE; HALOGENATED HYDROCARBON. [V.N.M.R.]

Flutter (aeronautics) An aeroelastic self-excited vibration with a sustained or divergent amplitude, which occurs when a structure is placed in a flow of sufficiently high velocity. Flutter is an instability that can be extremely violent. At low speeds, in the presence of an airstream, the vibration modes of an aircraft are stable; that is, if the aircraft is disturbed, the ensuing motion will be damped. At higher speeds, the effect of the airstream is to couple two or more vibration modes such that the vibrating structure will extract energy from the airstream.

The coupled vibration modes will remain stable as long as the extracted energy is dissipated by the internal damping or friction of the structure. However, a critical speed is reached when the extracted energy equals the amount of energy that the structure is capable of dissipating, and a neutrally stable vibration will persist. This is called the flutter speed. At a higher speed, the vibration amplitude will diverge, and a structural failure will result. *See* AEROELASTICITY.

Aircraft manufacturers now have engineering departments whose primary responsibility is fluffer safety. Modern flutter analyses involve extensive computations, requiring the use of large-capacity, high-speed digital computers. Flutter engineers contribute to the design by recommending stiffness levels for the structural components and control surface actuation systems and weight distributions on the lifting surfaces, so that the aircraft vibration characteristics will not lead to flutter within the design speeds and altitudes. *See* AIRFRAME; WING. [W.P.R.]

Fluvial erosion landforms Landforms that result from erosion by water flowing on land surfaces. This water may concentrate in channels as streams and rivers or flow in thin sheets and rills down slopes. Essentially all land surfaces are subjected to modification by running water, and it is among the most important surface processes. Valleys are cut, areas become dissected, and sediment is moved from land areas to ocean basins. With increasing dissection and lowering of the landscape, the land area may pass through a series of stages known as the fluvial erosion cycle.

The most distinctive fluvial landform is the stream valley. Valleys range greatly in size and shape, as do the streams that flow in them. They enlarge both through down and lateral cutting by the stream and mass wasting processes acting on the valley sides.

Waterfalls occur where there is a sudden drop in the stream bed. This is often the case where a resistant rock unit crosses the channel and the stream is not able to erode through it at the same rate as the adjacent less resistant rock. Waterfalls also occur where a main valley has eroded down at a faster rate than its tributary valleys which are left hanging above the main stream. With time, waterfalls migrate upstream and are reduced to rapids.

Many streams flow in a sinuous or meandering channel, and stream velocity is greatest around the outside of meander bends. Erosion is concentrated in this area, and a steep, cut bank forms. If the river meander impinges against a valley wall, the valley will be widened actively.

A stream terrace represents a former floodplain which has been abandoned as a result of rejuvenation or downcutting by the stream. It is a relatively flat surface with a scarp slope that separates it from the current floodplain or from a lower terrace. Terraces are common features in valleys and are the result of significant changes in the stream system through time. *See* FLOODPLAIN.

Fluvial erosion also has regional effects. Streams and their valleys form a drainage network which reflects the original topography and geologic conditions in the drainage basin. A dendritic drainage pattern, like that of a branching tree, is the most common and reflects little or no control by underlying earth materials. Where the underlying earth materials are not uniform in resistance, streams develop in the least resistant areas, and the drainage pattern reflects the geology. If the rocks contain a rectangular joint pattern, a rectangular drainage pattern develops; if the rock units are tilted or folded, a trellis pattern of drainage is common. Topography also controls drainage development; parallel and subparallel patterns are common on steep slopes, and a radial pattern develops when streams radiate from a central high area. *See* EROSION; RIVER; STREAM TRANSPORT AND DEPOSITION. [W.H.J.]

Fluvial sediments Deposits formed by rivers. A river accumulates deposits because its capacity to carry sediment has been exceeded, and some of the sediment load is deposited. Such accumulations range from temporary bars deposited on the insides of meander bends as a result of a loss of transport energy within a local eddy, to deposits tens to hundreds of meters thick formed within major valleys or on coastal plains as a result of the response of rivers to a long-term rise in base level or to the uplift of sediment source areas relative to the alluvial plain. The same processes control the style of rivers and the range of deposits that are formed, so that a study of the deposits may enable the geologist to reconstruct the changes in controlling factors during the accumulation of the deposits. *See* DEPOSITIONAL SYSTEMS AND ENVIRONMENTS; RIVER; STREAM TRANSPORT AND DEPOSITION.

Coarse debris generated by mechanical weathering, including boulders, pebbles, and sand, is rolled or bounced along the river bed and is called bedload. The larger particles may be moved only infrequently during major floods. Finer material, of silt and clay grade, is transported as a suspended load, and there may also be a dissolved load generated by chemical weathering. Whereas the volume of sediment tends to increase downstream within a drainage system, as tributaries run together, the grain size generally decreases as a result of abrasion and selective transport. This downstream grain-size decrease may assist in the reconstruction of transport directions in ancient deposits where other evidence of paleogeography has been obscured by erosion or tectonic change. *See* MASS WASTING.

River deposits of sediment occur as four main types. (1) Channel-floor sediments consist of the coarsest bedload, such as gravel, waterlogged vegetation, or fragments of caved bank material. (2) Bar sediments are accumulations of gravel, sand, or silt which occur along river banks and are deposited within channels, forming bars that may be of temporary duration, or may last for many years, eventually becoming vegetated and semipermanent. (3) Channel-top and bar-top sediments are typically composed of fine-grained sand and silt, and are formed in the shallow-water regions on top of bars, in the shallows at the edges of channels, and in abandoned channels. (4) Floodplain deposits are formed when the water level rises above the confines of the channel and overflows the banks. Much of the coarser floodplain sediment is deposited close to the channel, in the form of levees; silt and mud may be carried considerable distances from the channel, forming blanketlike deposits. *See* FLOODPLAIN.

The thickest (up to 6 mi or 10 km) and most extensive fluvial deposits occur in convergent plate-tectonic settings, including regions of plate collision, because this is where the highest surface relief and consequently the most energetic rivers and most abundant debris are present. Some of the most important accumulations occur in foreland basins, which are formed where the continental margin is depressed by the mass of thickened crust formed by convergent tectonism. *See* BASIN.

Thick fluvial deposits also occur in rift basins, where continents are undergoing stretching and separation. The famous hominid-bearing sediments of Olduvai Gorge and Lake Rudolf are fluvial and lacustrine deposits formed in the East Africa Rift System. Fluvial deposits are also common in wrench-fault basins, such as those in California.

Significant volumes of oil and gas are trapped in fluvial sandstones. Placer gold, uranium, and diamond deposits of considerable economic importance occur in the ancient rock record in South Africa and Ontario, Canada, and in Quaternary deposits in California and Yukon Territory. Fluvial deposits are also essential aquifers, especially the postglacial valley-fill complexes of urban Europe and North America. [A.D.M.]

Fluxional compounds Molecules that undergo rapid intramolecular rearrangements among equivalent structures in which the component atoms are interchanged. The rearrangement process is usually detected by nuclear magnetic resonance (NMR) spectroscopy. With sufficiently rapid rates, a single resonance is observed in the NMR spectrum for a molecule that might be expected to have several nonequivalent nuclei on the basis of its instantaneous structure.

Within organic chemistry, degenerate Cope rearrangements represented some of the first examples of interconversions between equivalent structures, but these were relatively slow. The rate of this rearrangement is rapid in more complex molecules. The epitome of degeneracy is reached in bullvalene, which has more than 1,200,000 equivalent structures and rapidly interconverts among them.

Fluxional molecules are frequently encountered in organometallic chemistry, and rapid rearrangements which involve migrations about unsaturated organic rings are commonly observed. The best known (called ring-whizzers) are cyclopentadienyl and cyclooctatetraene complexes of iron.

Inorganic structures also exhibit fluxional phenomena, and five-coordinate complexes provide the greatest number of well-known examples, one being phosphorus pentafluoride (PF_5).

The rearrangement of PF_5 involves interconversion of the trigonal bipyramidal molecule to a square pyramidal configuration and back. If two such nonequivalent structures are present in observable concentrations but interconvert rapidly to cause averaging in the NMR experiments, they are said to be stereochemically nonrigid. This term is generally taken to embrace all compounds that undergo rapid reversible intramolecular rearrangements. Thus, fluxional compounds are a subset of nonrigid compounds with equivalent structures. Nonequivalent structures, that is, tautomers, might be stereochemically nonrigid if they rearranged rapidly, but would not be considered fluxional.

Some workers prefer to reserve the term fluxional for molecules in which bonds are broken and reformed in the rearrangement process. Hence, of the examples above, only bullvalene and the iron complexes would be termed fluxional, whereas all would be considered stereochemically nonrigid. *See* Nuclear magnetic resonance (NMR); Resonance (molecular structure); Tautomerism. [J.W.F.]

Fly A member of the insect order Diptera. Insects of other orders are popularly called flies; mayflies, stoneflies, dragonflies, dobsonflies, and caddis flies all have four wings and therefore are not true flies. Mosquitoes, gnats, and midges all have two wings and are therefore also true flies, order Diptera. Hindwings of all Diptera are greatly reduced balancing organs called halteres.

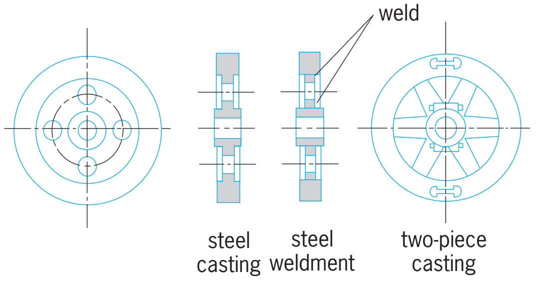
Flies are a numerous and diverse lot, with over 85,000 described species worldwide. North America has 16,000 species belonging to 107 families. Flies are old, their fossils dating from the Triassic, over 200,000,000 years ago.

The flies of greatest importance to humanity are those that suck blood from people or domestic animals. Females of many mosquitoes, deerflies, horseflies, blackflies, and gnats require a meal of blood before producing eggs. When biting, they may introduce pathogenic microorganisms. Mosquitoes may transmit malaria, yellow fever, viral encephalitis, or parasitic roundworms. Tropical blackflies transmit onchocerciasis (river blindness), and sandflies transmit leishmaniasis, a debilitating protozoan infection. Tsetse flies, in which both sexes bite, transmit African sleeping sickness.

Some flies that do not bite may become a nuisance because of their sheer numbers and association with human habitations. The ubiquitous housefly is bothersome and, in unsanitary situations, may contaminate food with the pathogens of hepatitis, polio, cholera, typhoid, or tuberculosis.

Many thousands of flies are predatory, and they doubtless help to suppress populations of insect pests. Especially important are larvae of the family Syrphidae that eat up to 50 aphids per day. Scavenging Diptera are quite important in aiding the quick breakdown of dead animals and plants. *See* Diptera; Entomology, economic. [D.J.Hor.]

Flywheel A rotating mass used to maintain the speed of a machine between given limits while the machine releases or receives energy at a varying rate. A flywheel is an energy storage device. It stores energy as its speed increases, and gives up energy as the speed decreases. The specifications of the machine usually determine the allowable range of speed and the required energy interchange.



Typical flywheel structures.

The difficulty of casting stress-free spoked flywheels leads the modern designer to use solid web castings or welded structural steel assemblies. For large, slow-turning flywheels on heavyduty diesel engines or large mechanical presses, cast-spoked flywheels of two-piece design are standard (see illustration). *See* Energy storage. [L.S.L.]

Foam A material made up of gas bubbles separated from one another by films of liquid. The bubbles are spherical when the liquid films separating them are thick (approximately 0.01 mm). Pure liquids do not foam; that is to say, they cannot produce liquid films of any permanence. Relatively permanent films are created only when a substance is present that is adsorbed at the surface of the liquid. Substances capable of being so adsorbed may be in true solution in the liquid or may be particles of a finely divided solid, which, because of poor wetting by the liquid, remain at the surface. In both cases, surface layers of the added substance are produced. The reluctance of the adsorbed substance to enter the bulk of the liquid preserves the surface and, hence, the thermodynamic stability of the foam. *See* Surfactant.

Although thermodynamically stable, a foam is mechanically fragile. Offsetting this fragility to some extent are mechanisms that provide the liquid films with resiliency and plasticity.

Although foams of exceptional stability are desired in some commercial applications, foam is a nuisance in many situations. A common recourse is the addition of chemical antifoams, which are usually insoluble liquids of very low surface tension. When a droplet of such a liquid is sprayed onto the foam or is carried into it by mechanical agitation, it spreads spontaneously and rapidly at the surface of the film, virtually sweeping the film away as it does so. *See* Adsorption; Interface of phases; Surface tension. [S.Ro.]

Focal length A measure of the collecting or diverging power of a lens or an optical system. Focal length, usually designated f' in formulas, is measured by the distance of the focal point (the point where the image of a parallel entering bundle of light rays is formed) from the lens, or more exactly by the distance from the principal point to the focal point. *See* Geometrical optics.

The power of a lens system is equal to n'/f', where n' is the refractive index in the image space (n' is usually equal to unity). A lens of zero power is said to be afocal. Telescopes are afocal lens systems. *See* Diopter; Lens (optics); Telescope. [M.J.H.]

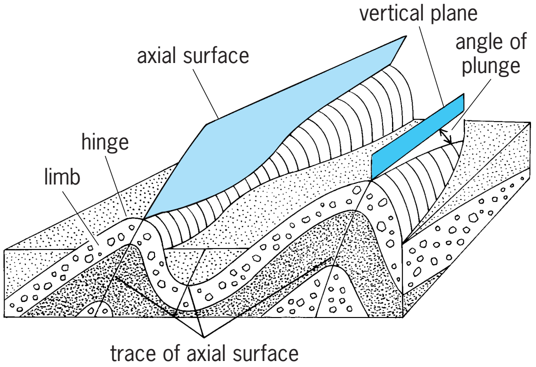
Fog A cloud comprising waterdroplets or (less commonly) ice crystals formed near the ground and resulting in a reduction in visibility to below 0.6 mi (1 km). This is lower than that occurring in mist, comprising lower concentration of waterdroplets, and haze, comprising smaller-diameter aerosol particles.

Fog results from the cooling of moist air below its saturation (dew) point. Droplets form on hygroscopic nuclei originating from ocean spray, combustion, or reactions involving trace chemicals in the atmosphere. Visibility is reduced even more when such nuclei are present in high concentrations and faster cooling rates activate a larger fraction of such nuclei. Thus, polluted fog, with more numerous smaller droplets, results in lower visibility for a given water content. *See* Dew point.

Haze, the precursor to fog and mist, forms at relative humidity below 100% to about 80%. It is composed of hygroscopic aerosol particles grown by absorption of water vapor to a diameter of about 0.5 micrometer, concentration 1000 to 10,000 per cubic centimeter. Fog and mist form as the relative humidity increases just beyond saturation (100%), so that larger haze particles grow into cloud droplets with a diameter of 10 μm and a concentration of several hundred per cubic centimeter. Fog and mist are a mix of lower-concentration cloud droplets and higher-concentration haze particles. By contrast, smog is formed of particles of 0.5–1-μm diameter, produced by photochemical reactions with organic vapors from automobile exhaust. *See* Atmospheric chemistry; Humidity; Smog. [J.Hal.]

Fold and fold systems Layered rocks that have been distorted into wavelike forms. Some folds are fractions of an inch across and have lengths measured in inches, whereas others are a few miles wide and tens of miles long.

Some terms used to describe folds are shown in the illustration. The axial surface divides a fold into two symmetrical parts, and the intersection of the axial surface with any bed is an axis. In general, an axis is undulatory, its height changing along the trend of the fold. Relatively high points on an axis are culminations; low points are depressions. The plunge of a fold is the angle between an axis and its horizontal projection. The limbs or flanks are the sides. A limb extends from the axial surface of one fold to the axial surface of the adjacent fold. Generally, the radius of curvature of a fold is small compared to its wavelength and amplitude, so that much of the limb is planar. The region of curvature is the hinge. *See* Anticline; Syncline.



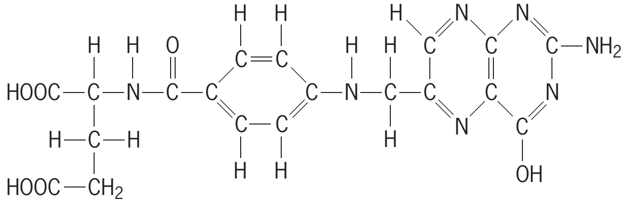
Elements of folds.

The geometry of folds is described by the inclination of their axial surfaces and their plunges. Upright folds have axial surfaces that dip from 81° to 90°; inclined folds have axial surfaces that dip from 10° to 80°; and recumbent folds have axial surfaces that dip less than 10°. Vertical folds plunge from 81° to 90°; plunging folds plunge from 10° to 80°; and horizontal folds plunge less than 10°. Auxiliary descriptive terms depend on the attitude or the relative lengths of the limbs. Overturned folds are inclined folds in which both limbs dip in the same direction; isoclinal folds are those in which both limbs are parallel; symmetrical folds have limbs of equal length; and asymmetrical folds have limbs of unequal length. The descriptions of folds consist of combinations of the above terms, for example, isoclinal upright horizontal fold, overturned plunging fold, asymmetrical inclined horizontal fold.

In a section of folded rocks the layers possess different rheological properties; some have apparent stiffness (competency), whereas others behave less stiffly (incompetency). The most competent layers or group of layers control the folding, and the less competent units tend to conform to the fold-form of the most competent units.

Folds generally do not occur singly but are arranged in festoons in mobile belts with lengths of thousands of miles and widths of hundreds of miles. The folds of these belts, or fold systems, commonly consist of great complex structures composed of many smaller folds. The development of fold systems is closely tied to concepts of global tectonics. The favored hypothesis is that of plate tectonics, in which fold systems are formed at converging margins where continents are underriden by oceanic crust, or where collision occurs between a continent and an island arc or between two continents. [P.H.O.]

Folic acid A yellow vitamin, slightly soluble in water, which is usually found in conjugates containing varying numbers of glutamic acid residues. It is also known as pteroylglutamic acid (PGA), and has the structural formula shown.



Folic acid is so widespread in nature and intestinal synthesis is so great that a folic acid deficiency in humans because of low dietary intake is probably not very common. Deficiencies of other nutrients (particularly iron, ascorbic acid, or vitamin B_{12}) may lead to a number of clinical conditions in which folic acid deficiency is involved. These include various nutritional macrocytic anemias, sprue, idiopathic steatorrhea, and pernicious anemia. *See* Vitamin. [S.N.G.]

Food Any substance taken into the body for the purpose of providing nourishment. However, factors such as satisfying social needs, achieving psychological ends, and satisfying hunger, more than nutritional needs, govern the selection and consumption of foods. When foods are selected carefully, they can provide all of the essential nutrients needed for normal functioning of the human body. In this context, food is necessary to provide energy, to provide structural components for building and repairing body tissues, and to regulate body processes. *See* Metabolism; Nutrition.

There are essential nutrients (carbohydrates, fats, proteins, minerals, vitamins, and water) that have specific functions in the human body. When the energy-yielding nutrients, that is, carbohydrates, fats, and proteins, are oxidized in the body, energy is captured in a chemical compound known as adenosine triphosphate (ATP), which will then release the energy slowly so that it can be used for physical activity (work), heat production, and metabolic processes. Enzymes, vitamins, and minerals, as well as water, are needed in order for these oxidation reactions to take place. Energy requirements are expressed in terms of kilocalories (kcal), calories (cal), or kilojoules (kJ). Fats and carbohydrates contain only the elements carbon, oxygen, and hydrogen. Since fats contain less oxygen than carbohydrates, they have greater potential for oxidation and thus provide more energy per gram than carbohydrates. Proteins also contain nitrogen, but this does not contribute substantially to the energy value. The physiological fuel value, or the amount of energy generated in the body, of 1 gram of protein is 4 kcal (17 kJ); carbohydrate, 4 kcal (17 kJ); fat, 9 kcal (38 kJ). *See* Enzyme; Vitamin.

Although it is unlikely that any individual food or combination of foods can provide complete disease protection, risk of chronic disease can be reduced by increased consumption of plant-based foods and decreased consumption of fats. *See* FOOD ENGINEERING; FOOD MANUFACTURING; FOOD MICROBIOLOGY; FOOD SCIENCE. [B.P.Kl.]

Food engineering The application of engineering concepts and principles to the conversion of raw foods into safe consumer products of the highest possible quality. The entire spectrum of food engineering is associated with operation and maintenance of food processing plants as well as sophisticated research involving process design.

The applications of engineering in food handling, processing, packaging, and distribution can be described in terms of unit operations. There are many different unit operations associated with the conversion of raw food materials to consumer products. The movement of foods and other materials within the processing plant requires the use of unique equipment and processes. For example, special sanitary pumps are used to transport liquid foods, and the material-handling equipment for solid foods requires careful design for product-contact surfaces.

The importance of thermal treatments for food preservation requires that a broad range of heat-exchange equipment be used. Heat exchangers for liquids are unique in terms of sanitary design and cleanability of surfaces following thermal processing. A special component of thermal preservation is the design of thermal processes.

Several unit operations involve heat transfer in order to achieve the desired preservation even though storage stability is not the direct result of thermal treatment. An excellent example is the freezing process, where removal of thermal energy reduces product temperatures to levels where deterioration reactions are significantly inhibited. Concentration processes achieve a degree of preservation by reducing the availability of water for deterioration reactions, although the primary aim is reduction of liquid-product mass and volume. Although traditional concentration processes have used thermal energy to evaporate water, membranes of various types are now used to achieve the same results. The preservation of food products is achieved by reduction of the water content to low levels by means of dehydration processes which use thermal energy. These processes are applied to liquid foods and to products that are naturally solid.

Another series of unit operations is used to alter the product composition or structure in some manner. These include separation, mixing, and extrusion. Separation processes are designed to divide food products into two or more components. While a variety of physical or chemical properties of the product components are used in the various separation processes, two of the most important processes are filtration and extraction. Filtration, a physical process, has several applications in addition to its use for separating product components. Extraction is most often designed to remove a specific or unique product component for use in a separate operation or product formulation. After separation, the final product is obtained through the use of a mixing process which includes a variety of equipment types. Finally, the extrusion process involves the use of both thermal and flow properties to achieve product preservation as well as some specified set of structural and textural characteristics.

The importance of cleaning and sanitation must be emphasized due to direct relationships to final product quality. The required operations vary considerably depending on the type of product handled and the type of equipment used. The processes required to manage the wastes generated during food handling, processing, packaging, and distribution are all similar, and many of the waste-handling and treatment operations are the same as those used directly with the food products.

The final operation to which the product is subjected before distribution is packaging. The package barrier is important for maintaining food products at desirable quality levels. Food packaging involves the selection of equipment needed for placing the product in the package as well as the selection of packaging material needed to protect the product in an optimum manner.

An engineering input to food handling, processing, packaging, and distribution that is applied to almost all unit operations is process control. The use of instrumentation and associated electronic controls has a significant impact on the efficiency of all components of the food delivery system. *See* FOOD; FOOD MANUFACTURING; FOOD MICROBIOLOGY; FOOD PRESERVATION; FOOD SCIENCE; UNIT OPERATIONS. [D.R.H.]

Food fermentation Production of food with the aid of microorganisms, which may be yeasts, molds, or bacteria. Fermented commodities include cereals such as wheat, rice, sorghum, corn; legumes, peanuts, soybeans, pulses; red meat, sausages, pork; milk; fish, shellfish; and plant juices. There are countless varieties of food fermentations in the world, sometimes known under different names in different countries and varying greatly in complexity. *See* FERMENTATION.

Among the molds used in food fermentations are *Aspergillus*, *Rhizopus*, *Penicillium*, *Neurospora*, *Actinomucor*, *Mucor*, *Amylomyces*, and *Monascus*. The yeasts include species of *Saccharomycopsis*, *Zygosaccharomyces*, and *Candida*. The bacteria are *Bacillus* and lactic acid bacteria, including *Lactobacillus*, *Streptococcus*, *Pediococcus*, and *Leuconostoc*.

The inoculum or fermentation starter may be of four types. The substrate may be moistened, heat-sterilized, and inoculated with a single organism. In a second type, more than one strain of a single species is used. A third type of inoculum contains more than one species of microorganism. Finally, some substrates contain a complex inoculum in which many different microorganisms of unknown identity are present. [C.W.H.]

Food manufacturing A total sequence of food operations, including the growth and selection of raw materials, harvesting, processing, preservation, and distribution. In general, the aim of all food manufacturing operations is to extend the availability of seasonal crops to year-round use.

The products of food manufacturing differ from traditional foods of plant or animal origin which have undergone minimal treatment. For example, the quality of apples sold in the winter can be maintained, through the use of controlled-atmosphere storage, which retards the ripening process by controlling the levels of oxygen, nitrogen, and carbon dioxide in the atmosphere of the storage facility. Atmosphere control is also used to hasten ripening so that fruits may be harvested in the unripe stage for ease of handling and then ripened rapidly in storage. In other cases the package itself allows the diffusion of only certain atmospheric gases and thus maintains quality. There are certain foods that cannot be maintained in a state close to the raw product. Tomatoes, for example, are not amenable to freezing or long periods of storage. Therefore, such products as heat-processed sauces, pastes, and stewed tomatoes have been developed. Other food products are even further removed from the raw product: oil is produced from seed; and plant proteins are used as extenders or substitutes for meat, as additives for nutritious beverages, and as bases for many formulated foods.

There are many other forms of food preservation representing both ancient and modern technologies. The ancient operation of sun-drying was first employed when it was realized that dried fruits remained wholesome and edible for long periods of time. Today, with the additional knowledge that drying, evaporation, and concentration all reduce the water activity or increase the osmotic pressure of a food to the point where bacteria will not grow, this technology is used for sophisticated products such as powdered milk and freeze-dried mushrooms. Food additives, such as salt, sugar, and other solutes, which reduce the water activity or increase the osmotic pressure, and acids, which inhibit bacterial growth, also achieve the preservation effect. Many food additives are natural in origin, and their preservative effect was noted in nature prior to their use as food additives. Freezing, heat sterilization (canning), pasteurization, fermentation, baking, and meat curing are other well-known forms of preservation. Irradiation processes for food have also been developed, and low-level irradiation has been approved in the United States by the Food and Drug Administration (FDA).

Food manufacturing is not solely involved with the preservation of food but is also concerned with the production of high-quality, appealing, wholesome food. To fulfill these goals, five broad categories of food additives are often used: flavors, coloring agents, preservatives, texturizing agents, and miscellaneous. The last category includes a variety of substances that may retain moisture, control acidity, act as leavening agents, or provide nutrients such as vitamins and minerals.

The final operation in the manufacturing process is that of packaging, which is governed by the physicochemical attributes of the food, the preservation process involved, the gaseous permeability desired, the conditions under which the product is to be stored, the desirability of viewing the product through a clear film or glass, and the expense.

Historically, metal and glass have been used to package heat-processed foods; more flexible films are used for foods which undergo less vigorous treatment. Adoption of the regulation allowing the use of hydrogen peroxide as a package sterilant has permitted the use of nonrigid flexible packages for heat-sterilized foods (aseptic packaging). This type of packaging is very cost-effective. *See* FOOD ENGINEERING; FOOD PRESERVATION. [F.M.Cl.]

Food microbiology A subdiscipline in the field of microbiology concerned with the study of bacteria, fungi, and viruses that grow in or are transmitted by foods. While bacteria are frequently associated with food spoilage and food poisoning, some species preserve foods through fermentation or produce food ingredients. Food microbiology is a broad field that can include not only microbiology but also sanitation, epidemiology, biochemistry, engineering, statistics, and mathematical modeling.

Most food-related illnesses have historically been attributed to one of five major groups of pathogenic bacteria. These five groups are *Salmonella* and *Shigella*; *Clostridium botulinum*; *Clostridium perfringens* and *Bacillus cereus*; and *Staphylococcus aureus*. These have been joined by the emerging pathogens *Yersinia enterocolitica*, *Escherichia coli*, *Listeria monocytogens*, and *Campylobacter jejuni*. *See* BACTERIA; FOOD POISONING.

When certain bacteria grow in foods, they produce desirable flavors and textures, and may also inhibit pathogenic organisms. Most of these bacteria belong to the genera *Streptococcus*, *Lactobacillus*, *Leuconostoc*, *Pediococcus*, or *Micrococcus*. They are used to make fermented dairy products, meats, and vegetables, and to preserve food by converting the sugars needed by competing microbes to lactic acid, which inhibits their growth. *Acetobacter* and *Gluconobacter* are used in the production of vinegar. Yeasts, usually *Saccharomyces*, which produce ethanol and carbon dioxide, are used in the processes of brewing and baking.

Modern food microbiology views foods as habitats where different organisms compete for survival. The fact that there are 250 genera of bacteria and that only 25 of these (8 pathogenic) are found in foods suggests that foods provide unique ecological niches. Viruses do not reproduce in foods and are not competitors in this sense (the food acts only as a carrier). Yeasts and molds usually grow more slowly than bacteria and are rarely a problem in foods that support bacterial growth. *See* FUNGI; YEAST.

Bacteria reproduce by binary fission; it takes only 20 doublings for one cell to yield more than 1 million cells. In environments where the doubling time is short, this occurs quite rapidly. Many preservation methods alter foods' environmental conditions, such as temperature, acidity, and water and oxygen availability, in order to slow microbial growth. *See* BACTERIAL GROWTH.

Microbial analysis of foods frequently requires "zero defects" in the absence of 100% testing. Legally, ready-to-eat foods must be free of *Salmonella*. This demands that the food microbiologist be able to detect one *Salmonella* among millions of innocuous bacteria in a pound of food. Moreover, all of the food cannot be tested because microbial analysis is destructive. Therefore, statistical sampling plans determine how many samples must be tested to have confidence that the whole lot is free of *Salmonella*.

In the classical methods for counting microorganisms, a food or its hemogenate is highly diluted so that only 30–300 cells are transferred to growth media. After 2–10 days, each cell grows into a colony, and these are counted and multiplied by the dilution factor to estimate the number of cells in the food. Automated methods have been developed that measure growth products, bacterial deoxyribonucleic acid (DNA), or specific toxins; these methods dramatically reduce the analysis time and are rapidly replacing the petri-dish method.

A procedure known as hazard analysis critical control points (HACCP) can replace much postproduction testing. This technique examines a food, its ingredients, and its processing to identify points critical to safety. These points are then heavily monitored during production; if they are maintained, a safe product results.

Advances in molecular biology have generated interest in applications to food processing. The most important contribution of biotechnology to food microbiology is the production of probes that detect pathogenic organisms much faster than conventional methods. For example, conventional methods require 5 days to confirm the presence of *Salmonella* in foods; probes that detect *Salmonella*-specific DNA or antigens can give similar results in 2 days.

The dairy industry has benefitted from advances in biotechnology by acquiring the ability to determine the genetic basis for the bacterial metabolism of lactose in milk and to stabilize it. In addition, enzymes that accelerate the aging of cheese have become commercially available, making it possible to produce a cheese with the taste of 9-month-old cheddar in just 3 months. *See* BACTERIA; BIOTECHNOLOGY; ENZYME; FOOD ENGINEERING; FOOD MANUFACTURING; FOOD PRESERVATION; GENETIC ENGINEERING; VIRUS. [T.J.Mo.]

Food poisoning An acute gastrointestinal or neurologic disorder caused by bacteria or their toxic products, by viruses, or by harmful chemicals in foods.

Bacteria may produce food poisoning by three means: (1) they infect the individual following consumption of the contaminated food; (2) they produce a toxin in food before it is consumed; or (3) they produce toxin in the gastrointestinal tract after the individual consumes the contaminated food.

Infectious bacteria associated with food poisoning include *Brucella*, *Campylobacter jejuni*, enteroinvasive *Escherichia coli*, enterohemorrhagic *E. coli*, *Listeria monocytogenes*, *Salmonella*, *Shigella*, *Vibrio parahaemolyticus*, *V. vulnificus*, and *Yersinia enterocolitica*. These organisms must be ingested for poisoning to occur, and in many instances only a few cells need be consumed to initiate a gastrointestinal infection. *Salmonella* and *C. jejuni* are the most prevalent causes of food-borne bacterial infections. *See* YERSINIA.

Staphylococcus aureus and *Clostridium botulinum* are bacteria responsible for food poisonings resulting from ingestion of preformed toxin. *Staphylococcus aureus* produces heat-stable toxins that remain active in foods after cooking. *Clostridium botulinum* produces one of the most potent toxins known. Botulinal toxin causes neuromuscular paralysis, often resulting in respiratory failure and death. *See* BOTULISM; STAPHYLOCOCCUS; TOXIN.

Food-poisoning bacteria that produce toxin in the gastrointestinal tract following their ingestion include *Bacillus cereus*, *Clostridium perfringens*, enterotoxigenic *E. coli*, and *V. cholerae*. *Bacillus cereus* and *C. perfringens* are spore-forming bacteria that often survive cooking and grow to large numbers in improperly refrigerated foods. Following ingestion, their cells release enterotoxins in the intestinal tract. Enterotoxigenic *E. coli* is a leading cause of travelers' diarrhea. *See* DIARRHEA; ESCHERICHIA.

Viruses that cause food-borne disease generally emanate from the human intestine and contaminate food through mishandling by an infected individual, or by way of water or sewage contaminated with human feces. Hepatitis A virus and Norwalk-like virus are the preeminent viruses associated with food-borne illness. *See* HEPATITIS.

Chemical-induced food poisoning is generally characterized by a rapid onset of symptoms which include nausea and vomiting. Foods contaminated with high levels of heavy metals, insecticides, or pesticides have caused illness following ingestion. *See* FOOD MICROBIOLOGY; MEDICAL BACTERIOLOGY; TOXICOLOGY.

[M.Do.]

Food preservation The branch of food science and technology that deals with the practical control of factors capable of adversely affecting the safety, nutritive value, appearance, texture, flavor, and keeping qualities of raw and processed foods. Since thousands of food products differing in physical, chemical, and biological properties can undergo deterioration from such diverse causes as microorganisms, natural food enzymes, insects and rodents, industrial contaminants, heat, cold, light, oxygen, moisture, dryness, and storage time, food preservation methods differ widely and are optimized for specific products. *See* FOOD SCIENCE.

Food preservation methods involve the use of heat, refrigeration, freezing, concentration, dehydration, irradiation, pH control, chemical preservatives, and packaging applied to produce various degrees of preservation in accordance with the differing use patterns and shelf-life needs of unique products.

Thermal processes to preserve foods vary in intensity. True sterility to ensure total destruction of the most heat-resistant bacterial spores in nonacidic foods may require a treatment of at least 250°F (121°C) of wet heat for at least 15 min to be delivered throughout the entire food mass. The term commercial sterility refers to a less severe condition that still assures destruction of all pathogenic organisms, as well as organisms that, if present, could grow in the product and produce spoilage under normal conditions of handling and storage. *See* STERILIZATION.

Many foods are subjected to still less severe heating by methods that produce pasteurization to assure destruction of pathogens and extend product shelf life. *See* PASTEURIZATION.

The slowing of biological and chemical activity with decreasing temperature is the principle behind cooling (refrigeration) and freezing preservation. In addition, when water is converted to ice, free water required for its solvent properties by all living systems is removed. Commercial freezing methods utilize refrigerated still air; high-velocity air, which is faster and more efficient; and high-velocity air made to suspend particulate foods, such as peas, as in a fluidized-bed fast freezer. Indirectcontact freezing utilizes hollow flat plates chilled with an internally circulated refrigerant to freeze solid foods, or with refrigerated tubular heat exchangers that rapidly slush-freeze liquids. Immersion freezing involves direct contact of the food or its container with refrigerants approved for food or a fast-freezing cryogenic liquid. *See* COLD STORAGE.

When sufficient water is removed from foods, microorganisms will not grow, and many enzymatic and nonenzymatic reactions will cease or be markedly slowed. Concentration preservation can be achieved by physically removing water, as by boiling or with lower-temperature vacuum evaporation, or by binding water through the addition of sugar, salt, or other solutes.

Foods preserved by dehydration contain considerably lower water activity and less total water than concentrated foods. Most dehydration methods utilize heat to vaporize and remove water. The heat and oxygen sensitivity of many foods necessitates vacuum dehydration for high quality. Under vacuum, water can be removed at reduced temperature, and oxidative changes are minimized. In freeze-drying, foods are frozen quickly and placed in a chamber under high vacuum. A food's structure remains rigid as it goes directly from the frozen state to dryness. *See* SUBLIMATION.

Food irradiation remains highly controversial, partly because of fears that the safety of products and processes cannot be adequately regulated. The natural acids of certain fruits and vegetables, acid added as a chemical, and acid produced by fermentation can inhibit or partially inhibit several pathogenic and spoilage organisms. The pH of acidic foods, however, is rarely sufficiently low to assure long-term preservation from acid alone. Many acidic and fermented foods further depend upon prior pasteurization of their ingredients, the addition of salt and other chemicals, and refrigeration. *See* PH.

The U.S. Food and Drug Administration and comparable agencies in various countries vigorously regulate the chemicals that may be added to foods as well as the conditions of their use. Chemical preservatives and similar substances include antimicrobials, enzyme inhibitors, and antioxidants. There is much pressure to remove chemicals from the food supply, especially where their effects can be achieved by other means.

Packaging protects foods from contamination, moisture gain or loss, flavor loss and odor pickup, the adverse effects of light, physical damage, and intentional tampering. Ultimately, a food product's quality and storage life are determined largely by its package. *See* FOOD ENGINEERING; FOOD MANUFACTURING; FOOD MICROBIOLOGY. [N.N.P.]

Food science The study of the physical, chemical, and biological properties of foods, in addition to the factors affecting them and their ultimate effects upon the sensory, nutritional, and storage properties and the safety of foods. Food properties are influenced by growing, harvesting, and slaughtering practices, preservation and preparation methods, processing and storage conditions, and packaging. Food science and its applications must be further concerned with economics and marketing; food preferences of various populations; quality assurance and control; regulatory aspects dealing with safety, wholesomeness, and honest representation; and the production of affordable, quality food on a worldwide basis. Therefore, food science interfaces with and draws upon many disciplines, including chemistry, physics, mathematics, the plant and animal sciences, biochemistry, enzymology, microbiology, genetics, engineering, statistics, computer science, nutrition, toxicology, psychology, and law.

Food science deals with many food commodities and thousands of derived products. These commodities are processed for many reasons, including preservation, creation of new product forms, improvement of sensory and nutritional qualities, convenience, and removal of natural toxicants. Common processes are heating, cooling, freezing, concentration, dehydration, fermentation, sometimes irradiation, and packaging. Each process can be further classified by method. Each process utilizes unique equipment that requires optimization of variables to maximize product quality and minimize costs, and is capable of yielding product with distinct characteristics. Further, commodities are increasingly utilized for their constituents which are separated, extracted, chemically and physically modified, and then recombined into an endless variety of formulated and engineered foods that are indistinguishable from their source materials. This often requires the use of highly specific food additives to improve processing properties and acceptance factors, including nutritional quality. Nutrient levels and nutrient availability from foods may be decreased or increased by handling and processing practices.

Food science is also concerned with all aspects of food safety, including natural food toxicants, industrial contaminants, misuse of food additives, and microbiological contamination, as well as methods for the detection, exclusion, inactivation, removal, and regulation of harmful substances. *See* FOOD ENGINEERING; FOOD MANUFACTURING. [N.N.P.]

Food web A diagram depicting those organisms that eat other organisms in the same ecosystem. In some cases, the organisms may already be dead. Thus, a food web is a network of energy flows in and out of the ecosystem of interest. Such flows can be very large, and some ecosystems depend almost entirely on energy that is imported. A food chain is one particular route through a food web.

A food web helps depict how an ecosystem is structured and functions. Most published food webs omit predation on minor species, the quantities of food consumed, the temporal variation of the flows, and many other details.

Along a simple food chain, A eats B, B eats C, and so on. For example, the energy that plants capture from the sun during photosynthesis may end up in the tissues of a hawk. It gets there via a bird that the hawk has eaten, the insects that were eaten by the bird, and the plants on which the insects fed. Each stage of the food chain is called a trophic level. More generally, the trophic levels are separated into producers (the plants), herbivores or primary consumers (the insects), carnivores or secondary consumers (the bird), and top carnivores or tertiary consumers (the hawk).

Food chains may involve parasites as well as predators. The lice feeding in the feathers of the hawk are yet another trophic level. When decaying vegetation, dead animals, or both are the energy sources, the food chains are described as detrital. Food chains are usually short; the shortest have two levels. One way to describe and simplify various food chains is to count the most common number of levels from the top to the bottom of the web. Most food chains are three or four trophic levels long (if parasites are excluded), though there are longer ones.

There are several possible explanations for why food chains are generally short. Between each trophic level, much of the energy is lost as heat. As the energy passes up the food chain, there is less and less to go around. There may not be enough energy to support a viable population of a species at trophic level five or higher.

This energy flow hypothesis is widely supported, but it is also criticized because it predicts that food chains should be shorter in energetically poor ecosystems such as a bleak arctic tundra or extreme deserts. These systems often have food chains similar in length to energetically more productive systems. *See* ECOLOGICAL ENERGETICS.

Another hypothesis about the shortness of food chains has to do with how quickly particular species recover from environmental disasters. For example, in a lake with phytoplankton, zooplankton, and fish, when the phytoplankton decline the zooplankton will also decline, followed by the fish. The phytoplankton may recover but will remain at low levels, kept there by the zooplankton. At least transiently, the zooplankton may reach higher than normal levels because the fish, their predators, are still scarce. The phytoplankton will not completely recover until all the species in the food chain have recovered. Mathematical models can show that the longer the food chain, the longer it will take its constituent species to recover from perturbations. Species atop very long food chains may not recover before the next disaster. Such arguments predict that food chains will be longer when environmental disasters are rare, short when they are common, and will not necessarily be related to the amount of energy entering the system.

The number of trophic levels a food web contains will determine what happens when an ecosystem is subjected to a short, sharp shock—for example, when a large number of individuals of one species are killed by a natural disaster or an incident of human-made pollution and how quickly the system will recover. The food web will also influence what happens if the abundance of a species is permanently reduced (perhaps because of harvesting) or increased (perhaps by increasing an essential nutrient for a plant).

Some species have redundant roles in an ecosystem so that their loss will not seriously impair the system's dynamics. Therefore, the loss of such species from an ecosystem will not have a substantial effect on ecosystem function. The alternative hypothesis is that more diverse ecosystems could have a greater chance of containing species that survive or that can even thrive during a disturbance that kills off other species. Highly connected and simple food webs differ in their responses to disturbances, so once again the structure of food webs makes a difference. *See* ECOLOGICAL COMMUNITIES; ECOSYSTEM; POPULATION ECOLOGY. [S.Pi.]

Foot-and-mouth disease A highly contagious viral disease of domesticated and wild cloven-hoofed animals with the potential to cause enormous economic losses. It is characterized by the formation of vesicles on the feet, in and around the mouth, and on the mammary gland. At the acute stage there is high fever, depression, lameness, and reduced appetite. Milking animals show a sudden reduction in production. The mortality in adult animals is usually less than 3%, but in young animals it can exceed 90%.

The causative virus is a member of the *Aphthovirus* genus of the family Picornaviridae. The virus can infect by different routes and mechanisms. During the acute phase of disease, large amounts of virus occur throughout the tissues and organs of the infected animal and in its excretions and secretions. The movement of infected animals and the transmission of virus by contact to susceptible animals in a new herd or flock is by far the most common mechanism of spread. Next in frequency is the movement of contaminated animal products, such as meat and milk—most likely to infect pigs through ingestion.

Immunity to the disease is primarily mediated through neutralizing antibodies directed against the structural proteins of the virus. Specific antibodies are detectable by bioassay 4–5 days after infection, at which time viremia ceases and there is a progressive reduction in virus excretion as the lesions heal. The detection of the viral antigen is sufficient for a positive diagnosis. Normally, viral antigen is detected and serotyped by enzyme-linked immunosorbent assay (ELISA).

Control in countries where the disease is endemic or sporadic is mainly by vaccination. The vaccines contain inactivated viral antigens of one or more serotypes, depending on the prevailing disease situation. Immunity following primary and booster doses of vaccine lasts for around 6 months. *See* ANIMAL VIRUS; EPIDEMIOLOGY; SEROLOGY. [A.I.D.]

Foot disorders Musculoskeletal, neurological, or dermatologic abnormalities of the foot. They may be of developmental or acquired origin.

Clubfoot, also known as talipes, is a congenital deformity of the foot characterized by a club-shaped appearance, and occurs in approximately 1 in 1000 live births. Clubfoot takes a number of forms, the most common being talipes equinovarus, an extreme turning down and under of the foot.

During normal intrauterine development, and normally continuing after birth, the position of the foot changes gradually from one of inversion such that the soles of both feet face each other to one of alignment with the leg. In the flatfoot that positional change is not always complete, so that the foot undergoes a series of complex compensations to reach the ground that is called pronation. Twisting of the ankle and obliteration of the normal arch of the foot result. In addition, the joints of the foot tend to lose their functional articular contacts, and the resulting hypermobility at the joint interfaces predisposes the foot to arthritis. Bunions and hammertoe deformities, with painful stretching of the soft tissues of the sole, are additional complications that result from hypermobility.

Heel spurs, or calcaneal exostoses, are bony growths produced by excessive musculoskeletal tension at the heel. When the pull by ligaments and connective tissue becomes excessive, as is seen with flatfoot deformities and tight or shortened heel cords, the outer covering of the heel bone known as the periosteum enlarges. The bone growth is known as an exostosis or spur.

The nerves of the foot are subject to irritation from pressure originating from the structures of the foot and from external forces. In cases of Morton's neuroma, the third intermetatarsal nerve thickens over a period of years, and a small benign fusiform tumor eventually forms in the space between the third and fourth toes. The posterior tibial nerve is located at the inside of the ankle behind the ankle bone, and it travels to the bottom of the foot through a channel known as the tarsal canal. In tarsal tunnel syndrome, the nerve becomes compressed and damaged within the tarsal canal.

The skin of the foot undergoes stress from pressure and friction. As a response, it protects itself with defensive modifications such as corns and calluses that themselves cause pain.

Warts are tumors of the skin induced by the human papilloma virus. Second only to corns and calluses in prevalence, warts are benign skin lesions. Transmission of warts from person to person may occur, but individual immunity plays an important role in susceptibility to these infectious lesions.

Ingrown toenail, also called onychocryptosis, is caused by the penetration of the free portion, or edge, of the nail into the surrounding soft tissue. The cause may be related to congenital variations in the shape of the nail itself or the nail fold (the skin adjacent to the edges of the nail), biomechanical abnormalities in foot structure or function, nail disease, or ill-fitting shoegear. [H.Lem.]

Forage crops Grasses and legumes that make up grasslands and are used as forages for livestock. The grasslands represent an ancient renewable natural resource. They form 25% of the world's vegetation and occupy the largest area of any single plant type. They benefit humanity indirectly by providing food for both wild animals and domesticated livestock, some of which are ruminants that, because their digestive systems contain microorganisms, are able to digest fibrous forage material. Thus, the prime value of grassland areas lies in the meat, milk, or work produced by the livestock that graze on them. *See* GRASSLAND ECOSYSTEM; LEGUME.

Grasslands have other attributes as well. In order to withstand the tug and pull of the grazing animal, a forage plant must have an extensive root system, and this makes a contribution to soil fertility. When the plant is grazed or cut, the photosynthetic area that remains is not large enough to provide sugars to maintain root respiration, and so part of the root system dies and adds to the organic material in the soil and to soil structure. Such is the basis of many highly productive crop rotations that maintain soil fertility without expensive fertilizer applications. Most forage plants are long-lived perennials that can be defoliated repeatedly during a growing season.

Forages also protect the soil from erosion by both wind and water. In fact, where row crop farming has led to soil deterioration, as it did when dust bowl conditions prevailed in North America, forages are used to restore and stabilize the land. *See* EROSION. [P.D.W.]

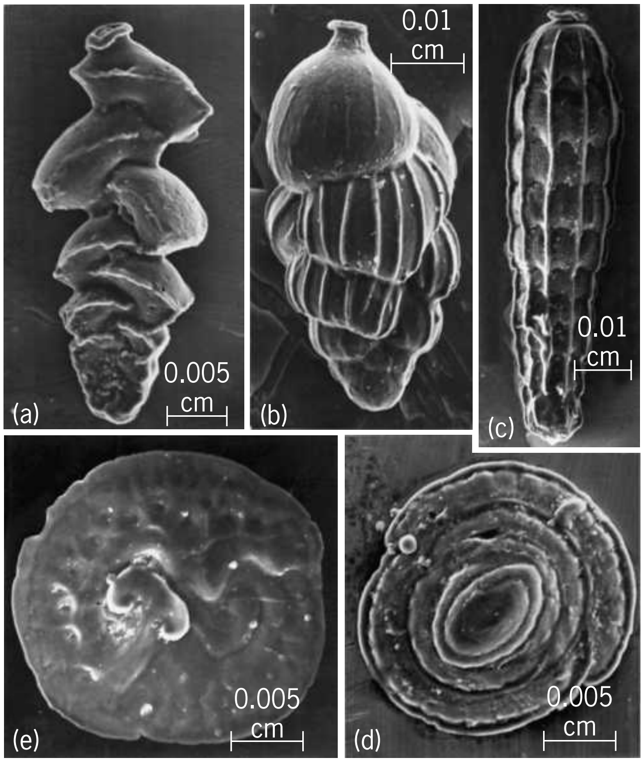
Foraminiferida An order of Granuloreticulosia in the class Rhizopodea. Foraminiferans are dominantly marine protozoans, with a secreted or agglutinated shell, or test, enclosing the continually changing ameboid body (see illustration) that characterizes this and other orders of the superclass Sarcodina. Their unique combination of long geologic history, ubiquitous geographic distribution, and exceptional diversity of test composition, form, and structure make the foraminiferans the most useful of all marine fossils for stratigraphic correlation, geologic age dating of sediments, and paleoecologic interpretation. Their tests accumulated in great numbers and are recoverable from small quantities of sediment, rock outcroppings, well cores or cuttings, or ocean dredging and submarine coring.

Pseudopodia from the ameboid body form a delicate anastomosing network of 2–10 times the test diameter. The pseudopodial net may arise from the apertural region of the test alone in those with tectinous, porcelaneous, and agglutinated walls, or may radiate in all directions through many tiny perforations of the hyaline test wall. The pseudopodia variously serve in capture, ingestion, and digestion of food, in test and temporary cyst construction, for anchorage, and for locomotion. The characteristic granular streaming of the continuously moving cytoplasm differentiates the Foraminiferida from the other Sarcodina orders.

The foraminiferan constructs its own test. Growth of the individual may cease after test construction, or the test may enlarge by continued growth in one or more directions (tubular or branching tests) or by periodic formation of separate but always interconnected chambers. Growth may be either continuous or periodic and may be in a straight line, a planispiral or trochospiral coil, a cycle, or a zigzag. The latter (zigzag) is expressed by chambered forms in biseriality. Variations and combinations of these growth patterns occur repeatedly in different lineages (isomorphism).

As is true of most protists with skeletons or tests, systematic differentiation and classification of foraminiferans is based on test composition, microstructure, and gross morphology. Information currently available concerning cytoplasmic characters, life cycles, and so on has shown good agreement with this classification, although the function and origin of many shell characters believed to be of systematic importance (canal systems, pores, septal doubling, and apertural tooth plates) are yet undetermined. There are 11 suborders.

Foraminiferans have shown a remarkable diversification and rapid evolutionary development over their 500,000,000-year known history. Some with uncomplicated tests have been reported to have a long geologic range, but most with diagnostic



Scanning electron micrographs of foraminiferans of suborder Rotaliina. Superfamily Buliminacea: (*a*) *Eouvigerina*, elongate test. (*b*) *Uvigerina*, elongate triserial test. (*c*) *Siphogenerinoides*, reduced early biserial stage. Superfamily Spirillinacea; *Patellina*: (*d*) spiral view of low conical test; (*e*) umbilical view. (*R. B. MacAdam*, *Chevron Oil Field Research Co.*)

shell structure and morphology had relatively short histories, each successively replaced by others. The oldest-known and presumably primitive tests are the morphologically simple tectinous and agglutinated one of the Cambrian and Ordovician, globular, tubular, branching, or irregular form.

Most foraminiferans are benthic, living upon the sea floor, within the upper few centimeters of ooze, or upon benthic algae or other organisms. They occur from the intertidal zone to oceanic depths, in brackish, normal marine, or hypersaline waters, and from the tropics to the poles. Some modern Lagynacea live in fresh water, but none are known as fossils. Assemblages vary widely in response to local conditions, with the greatest diversity occurring in warm, shallow water. A smaller number, the Globigerinina, are planktonic, living at various depths in the water column from the surface to the bottom, being most numerous between 18 and 90 ft (6 and 30 m). Vertical migration may be diurnal and may occur during ontogenetic development. The preferred depth range of a species may vary geographically in response to temperature differences or to changes in water density. *See* GRANULORETICULOSIA; RHIZOPODEA; SARCODINA. [H.T.L.]

Force

Force may be briefly described as that influence on a body which causes it to accelerate. In this way, force is defined through Newton's second law of motion.

This law states in part that the acceleration of a body is proportional to the resultant force exerted on the body and is inversely proportional to the mass of the body. An alternative procedure is to try to formulate a definition in terms of a standard force, for example, that necessary to stretch a particular spring a certain amount, or the gravitational attraction which the Earth exerts on a standard object. Even so, Newton's second law inextricably links mass and force. *See* ACCELERATION; MASS.

One may choose either the absolute or the gravitational approach in selecting a standard particle or object. In the so-called absolute systems of units, it is said that the standard object has a mass of one unit. Then the second law of Newton defines unit force as that force which gives unit acceleration to the unit mass. Any other mass may in principle be compared with the standard mass (m) by subjecting it to unit force and measuring the acceleration ($\mathbf{a}$), with which it varies inversely. By suitable appeal to experiment, it is possible to conclude that masses are scalar quantities and that forces are vector quantities which may be superimposed or resolved by the rules of vector addition and resolution.

In the absolute scheme, then, the equation $\mathbf{F} = m\mathbf{a}$ is written for nonrelativistic mechanics; boldface type denotes vector quantities. This statement of the second law of Newton is in fact the definition of force. In the absolute system, mass is taken as a fundamental quantity and force is a derived unit of dimensions MLT^{-2} (M = mass, L = length, T = time).

The gravitational system of units uses the attraction of the Earth for the standard object as the standard force. Newton's second law still couples force and mass, but since force is here taken as the fundamental quantity, mass becomes the derived factor of proportionality between force and the acceleration it produces. In particular, the standard force (the Earth's attraction for the standard object) produces in free fall what one measures as the gravitational acceleration, a vector quantity proportional to the standard force (weight) for any object. It follows from the use of Newton's second law as a defining relation that the mass of that object is $m = w/g$, with g the magnitude of the gravitational acceleration and w the magnitude of the weight. The derived quantity mass has dimensions $FT^2 L^{-1}$. *See* FREE FALL. [G.E.P.]

Force fit

A means for holding mating mechanical parts in fixed position relative to each other. In a force fit of cylindrical parts, the inner member has a greater diameter than the hole of the outer member; that is, the metals of the two parts interfere. In a true force fit, the parts are highly stressed, the interference amounting to 0.002 or 0.003 in. (0.05 or 0.07 mm) for parts with a basic diameter of 1 in. *See* ALLOWANCE; SHRINK FIT. [P.H.B.]

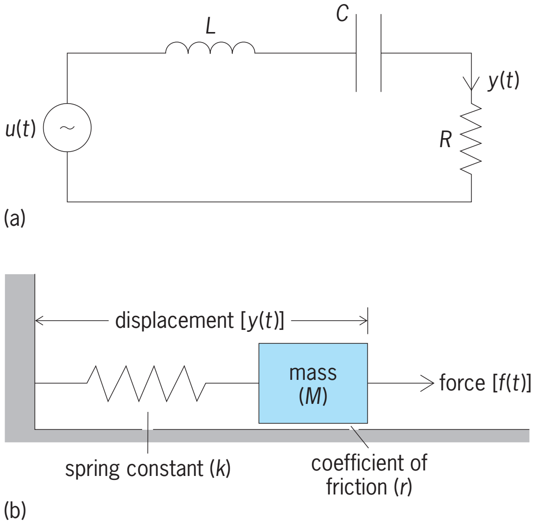
Forced oscillation

A response of a mechanical or electrical system in reaction to an external signal.

A simple electrical *RLC* circuit (illus. *a*) consists of a resistor with resistance R (measured in ohms), an inductor with inductance L (measured in henrys), and a capacitor with capacitance C (measured in farads). The dynamics relating the input voltage, $u(t)$, to the current, $y(t)$, passing through the resistor are described by Eq. (1). Equation (1) states that the input voltage is equal to

$$L\frac{dy}{dt} + Ry + \frac{1}{C}\int y\,dt = u(t) \qquad (1)$$

the sum of the voltage across the inductor, the voltage across the resistor, and the voltage across the capacitor, where the voltage across the inductor is the product of its inductance (L) and the rate of change of the current through the inductor; the voltage across the resistor is the product of its resistance (R) and the current passing through it; and the voltage across the capacitor is the integral over time of the current through the capacitor (that is, the charge on the capacitor plates) divided by the capacitance (C).



Examples of forced oscillation. (*a*) Electrical system, an *RLC* circuit. (*b*) Analogous mechanical system, a spring-mass-damper system.

A fundamental property of differential equations states that the response of a differential equation to a periodic input can be decomposed as a sum of two responses. The first one, called the zero-input response or free oscillation, is due to initial energy stored in the circuit and decays eventually to zero. The second one, due to the voltage input $u(t)$, converges to a periodic signal with the same frequency as $u(t)$. The latter is referred to as the forced oscillation or the steady-state response. The decaying rate of the free oscillation depends on the time constant of the circuit which is determined by the values of R, L, and C and the structure of the circuit. *See* TIME CONSTANT.

Similarly, an analogous mechanical system, a simple spring-mass-damper system (illus. *b*), consists of a body with mass M, which is attached to a wall by a spring with spring constant k, and rests on a horizontal surface over which it moves with friction coefficient r. The dynamic equation that relates the force applied to the body, $f(t)$, to the body's displacement, $y(t)$, is given by Eq. (2). Equation (2) states that the force applied to the body

$$M\frac{d^2y(t)}{dt^2} + r\frac{dy(t)}{dt} + ky(t) = f(t) \qquad (2)$$

equals the sum of the three quantities: the product of the body's mass and its acceleration, the negative of the frictional force, and the negative of the force exerted by the spring. Here, the negative of the frictional force is the product of the coefficient of friction and the body's velocity, and the negative of the force exerted by the spring is the product of the spring constant and the body's displacement. Moreover, the body's velocity is the first derivative of its displacement with respect to time, and its acceleration is the second derivative of its displacement with respect to time.

Analogous to the *RLC* circuit case, application of a sinusoidal force $f(t)$ results eventually in a forced oscillation of the displacement $y(t)$ that is also a sinusoidal function. The magnitude and the phase of the displacement $y(t)$ depends on the complex mechanical impedance that is a function of the mass (M), the spring constant (k), and the friction coefficient (r). The exact evaluation is similar to the *RLC* circuit case. *See* MECHANICAL IMPEDANCE; MECHANICAL VIBRATION; OSCILLATION; VIBRATION. [E.W.Ba.]

Forcipulatida An order of Asteroidea characterized by straight or crossed pedicellariae or both. These may be carried on stalks, and in some cases are arranged in rosettes around the bases of the spines. The spines usually occur singly, and are ungrouped. The body is stellate in outline, but is not necessarily restricted to five arms or radial axes.

The order contains four families, whose genera are numerous and widely distributed. The Brisingidae and Zoroasteridae are characteristically deep-water families, and the former includes species with as many as 44 arms. The Asteridae is the largest family, and includes many well-known predatory starfishes, some of which are economically significant because of the damage they inflict upon oyster and clam beds. The fourth family is the Heliasteridae. *See* ASTEROIDEA; ECHINODERMATA. [A.C.C.]

Forensic anthropology The application of physical anthropology theory and techniques to answering questions for the law. Medical evidence and biological techniques used on the living can be applied to intact remains, as can extensive internal examinations and histological preparations. However, burned, decomposed, mutilated, or fragmented bodies contain less soft tissue evidence and are therefore more difficult for the medical examiner or forensic pathologist to analyze. In these cases, the information provided by the skeleton becomes more important, and may yield the only information available about the identity of the individual and the circumstances surrounding death. Age, sex, ancestry, stature, muscularity, handedness, habits, occupational activities, disease, and injuries can be ascertained from elements of the skeleton, and in such cases the services of a forensic anthropologist may be a valuable adjunct to the work of the forensic pathologist or coroner.

Training is required in such areas as skeletal variation in current populations or injuries from modern weapons. Many physical anthropologists, however, are increasingly involved in the forensic applications of their expertise, a few on a full-time basis. Recently, archeologists have been asked to aid in the excavation of human remains from clandestine graves, and so the field of forensic archeology has arisen, but the term "forensic anthropology" usually refers to the biological aspects. *See* ANTHROPOLOGY; ARCHEOLOGY; PHYSICAL ANTHROPOLOGY. [D.L.F.]

Forensic biology The study of biological evidence such as DNA (deoxyribonucleic acid) which may link a suspect or victim to a crime, disprove an alibi, or develop leads in a criminal investigation. Biological evidence may also exonerate the innocent. *See* DEOXYRIBONUCLEIC ACID (DNA).

Biological evidence has been associated with many types of crime but is typically seen with violent crimes such as homicide, assault, sexual assault, child abuse, and hit-and-run accidents. Common sources submitted to forensic laboratories are blood and bloodstains; semen and seminal stains; tissues and organs; bones and teeth; hairs and nails; and saliva, urine, and other biological fluids.

Evidence transfer and collection. Biological specimens can be used to make linkages (for example, person-person, person-other physical evidence, and person-crime scene). In general, biological evidence can be transferred by direct deposit or by secondary transfer.

Blood, semen, body tissue, bone, hair, urine, and saliva can be transferred to an individual's body or clothing, to an object, or to a crime scene by direct deposit. Once liquid biological materials are deposited, they adhere to the surface or the substratum and become stains. Nonfluid biological evidence, such as tissue or hair, can also be transferred by direct contact.

Blood, semen, tissue, hair, saliva, or urine also can be transferred to a person, object, or location through an intermediary (a person or an object). With secondary transfer, there is no direct contact between the original source (donor of the biological evidence) and the target surface. Secondary transfer may, but does not necessarily, establish a direct link between an individual and a crime.

The ability to analyze biological evidence is impacted by many factors regarding its collection. Unless the evidence is properly recognized, documented, collected, packaged, and preserved, it will not meet the legal or scientific requirements for admissibility into a court of law.

Laboratory analysis. The identification of individuals by analyzing their biological material such as blood, semen, hair, and bone has been used since 1904. Historically, testing has been based on serological markers, including red blood cell antigen systems, isoenzymes, red cell and serum protein variants, and human leukocyte antigens (HLAs). Since the mid-1980s, DNA analysis has been increasingly important in forensic science, forensic medicine, and paternity testing. Genetic variation can be detected by many DNA tests, including restriction fragment length polymorphism (RFLP) analysis, polymerase chain reaction (PCR), and DNA sequencing. Developments in the 1990s, such as more sensitive and discriminating PCR typing methods, the felon DNA databank, and increased governmental funding, have greatly enhanced the use of DNA in criminal investigations. *See* FORENSIC CHEMISTRY; FORENSIC MEDICINE.

Serological methods. Prior to the advent of DNA typing, serological tests were employed to identify the source of the biological evidence, to determine if the sample was of human origin, and to individualize the specimen. Today, serological analysis is generally limited to identifying the type of biological evidence collected. Subsequently, the evidence is individualized by DNA analysis. The process of examining items for the presence of biological material begins with recognizing and identifying likely candidates for further testing. First, various screening tests determine if a stain could be blood, saliva, or semen. Second, confirmatory tests identify the source of the body fluid (for example, human blood). Third, the body fluid is individualized.

DNA testing. The ability to differentiate between individuals using genetic markers can be pivotal to the successful investigation of many crimes. Evidence that is suitable for DNA typing (with the exception of mitochondrial DNA) is limited to samples containing nucleated cells. Conventional DNA typing is possible only on hairs with roots. The hair shaft does not contain nuclei and can be typed only by mitochondrial DNA analysis. Other types of biological material such as tears, perspiration, serum, and other body fluids without nucleated cells are not amenable to standard DNA analysis.

Several factors affect the ability to obtain DNA typing results. The first issue is sample quantity. The second factor is sample degradation. The third consideration is sample purity.

Two general types of genetic variation are exploited by forensic DNA typing methods: length differences produced by variable number of tandem repeats (VNTRs) and sequence variation (single base changes). Most forensic DNA tests detect length variation. Numerous loci have been identified which contain multiple copies of a core element arranged head to tail. The number of these repeated units can differ from person to person. Following restriction endonuclease digestion which cuts the double helix at specific sites flanking the variable region, DNA fragments ranging in size from 500 to 22,000 base pairs are resolved by agarose gel electrophoresis. This process is RFLP analysis, and it is the oldest DNA typing method for both criminal and paternity cases. *See* ELECTROPHORESIS.

Polymerase chain reaction (PCR) amplifies (duplicates) small segments of DNA. At the end of the process, the target DNA molecule has been amplified 1 million to 10 million times. As a forensic tool, PCR-based strategies have several advantages over RFLP analysis. First, PCR requires only trace quantities of DNA, approximately 10 to 100 times less than RFLP typing. Second, PCR generates a large quantity of product in a very short period of time, considerably less time than that required for typing by RFLP analysis. Third, degradation of the DNA sample is less of a concern when using PCR because it amplifies small segments of DNA. *See* GENE AMPLIFICATION.

Mitochondrial DNA (mtDNA) analysis is an important forensic tool. The mitochondrial genome contains 16,569 base pairs of circular DNA. Mitochondrial DNA exists outside the nucleus and is present in multiple copies per cell. In addition, mtDNA is maternally inherited. Typically, mtDNA typing involves PCR amplification followed by direct sequencing of the DNA. Mitochondrial DNA testing is extremely sensitive and is particularly useful with minute samples (for example, old or degraded skeletal remains) and tissues (for example, hair shafts) lacking nuclear DNA. Given its inheritance, an mtDNA profile can be compared to anyone with the same maternal lineage. *See* MITOCHONDRIA.

Felon DNA databanks. A significant development in forensic science is felon DNA databanks. Given the high rate of recidivism associated with sexual assault, felon DNA databanks are particularly useful for solving these crimes; they will also assist in the investigation of many other violent crimes. The national DNA databank system, CODIS (Combined DNA Index System), became operational in fall 1998. This allows states to compare their no-suspect profiles to a national DNA repository and solve additional crimes. [H.C.L.; C.La.; H.M.C.]

Forensic chemistry The application of chemistry to the study of physical materials or theoretical problems, the results of which may be entered into court as technical evidence. Boundaries are not sharply defined for forensic chemistry, and it includes topics that are not entirely chemical in nature.

Some of the items most often encountered in crime laboratories, and the information sought in regard to them, are: (1) body fluids and viscera to be analyzed for poisons, drugs, or alcohol, quantitation of which may assist in determining the dosage taken or the person's behavior prior to death; (2) licit and illicit pills, vegetable matter, and pipe residues for the presence of controlled substances; (3) blood, saliva, and seminal stains, usually in dried form, to be checked for species, type, and genetic data; (4) hairs, to determine if animal or human; if human, the race, body area of origin, and general characteristics; (5) fibers, to determine type (animal, vegetable, mineral, or synthetic), composition, dyes used, and processing marks; (6) liquor, for alcoholic proof, trace alcohols, sugars, colorants, and other signs of adulteration; (7) paint, glass, plastics, and metals, usually in millimeter-sized chips, to classify and compare to known materials; (8) inks on documents, to determine type, dye content, or possible age; also chemical obliterations and restoration of chaffed papers; (9) swabs from the hands of suspects, to be checked for the presence of gunshot residue; (10) debris from a fire or explosion scene, for the remains of the accelerant or explosive used. *See* ANALYTICAL CHEMISTRY; FORENSIC MEDICINE; FORENSIC TOXICOLOGY. [M.J.C.]

Forensic medicine The branch of medicine concerned with the resolution of legal issues by the application of scientific medical knowledge. The issues may be of criminal or civil nature. The specialty of forensic medicine is often referred to as legal medicine in Europe and in Spanish-speaking countries. The development of forensic medicine began in Europe in the early nineteenth century. Although forensic medicine has its basis in the specialty of pathology, physicians in other specialties, such as psychiatry, orthopedics, cardiology, and neurology as well as specialists in other disciplines, may be called on to resolve legal questions posed by judges, attorneys, investigators, and hearing boards.

In death investigations, a number of forensic specialists may work together. A forensic odontologist may be called in to identify the deceased person through dental examination, or the perpetrator of bite marks left on the deceased's body. A forensic anthropologist may be needed to identify skeletal remains; a forensic toxicologist for the identification of poisons or drugs; and a criminalist for investigation at the scene and collection of evidence, or for study of trace evidence such as blood stains, hair, paints, and seminal fluid. In cases of equivocal suicides, forensic psychiatrists and psychologists may be called in. Recently the biomechanical engineer has been added to the roster of forensic specialists, to test and study injury patterns to determine how the injury came about. The forensic medical specialist may express an opinion in writing or may be required to testify in person in the courtroom. As with all legal proceedings, the physician witness must be cognizant of issues such as the degree of proof, the chain of custody of specimens or evidence, competency of the witness, and court procedures.

An important development in forensic medicine is genetic analysis. Every individual has a unique genetic content determined by deoxyribonucleic acid (DNA) sequences. The DNA present in forensic samples such as hair, bloodstains, and seminal fluid can identify a suspect. One analysis technique is called DNA fingerprinting; it can be used to compare the DNA sequence of a suspect or a defendant with material evidence at the crime scene. The DNA is broken into unique fragments by restriction endonucleases and then separated by electrophoresis. The pattern seen after hybridization with specific probes is called the DNA fingerprint, and like an ordinary fingerprint is characteristic of the individual. DNA analysis is also used in identification of an unknown person or of parts of a human body. Paternity exclusion by ABO blood typing has been replaced by DNA fingerprinting. *See* DEOXYRIBONUCLEIC ACID (DNA); FORENSIC ANTHROPOLOGY; FORENSIC TOXICOLOGY. [T.T.N.]

Forensic toxicology An interdisciplinary science dealing with the adverse effects of drugs and chemicals on various biological systems in a medical-legal context. The forensic toxicologist may work with a medical examiner or coroner in order to determine the role that a particular chemical compound may have played in a death. The forensic toxicologist's activities may also involve assessing emergency room patients, helping to determine suitability of an individual for employment or promotion, screening for performance-altering drugs in athletes, and working with law enforcement agencies, for example, performing tests to determine if a driver operated a motor vehicle under the influence of drugs. The forensic toxicologist is involved not only in the analysis of body fluids and tissue for drugs and poisons but also in the interpretation of the resulting information in a judicial context.

Toxicological data can be obtained from pharmaceutical manufacturers, published literature, or various registries. The greatest challenge facing the forensic toxicologist is the interpretation of cases involving combinations of drugs and chemicals and their complex interactions. *See* FORENSIC CHEMISTRY; FORENSIC MEDICINE; TOXICOLOGY. [J.H.Bi.]

Forest and forestry A plant community consisting predominantly of trees and other woody vegetation, growing closely together, is a forest. Forests cover about one-fourth of the land area on Earth. The trees can be large and densely packed, as they are in the coastal forests of the Pacific Northwest, or they can be relatively small and sparsely scattered, as they are in the dry tropical forests of sub-Saharan Africa.

Forests are complex ecosystems that also include soils and decaying organic matter, fungi and bacteria, herbs and shrubs, vines and lichens, ferns and mosses, insects and spiders, reptiles and amphibians, birds and mammals, and many other organisms. All of these components constitute an intricate web with many interconnections. *See* FOREST ECOSYSTEM.

Forests have important functions, such as cleansing the air, moderating the climate, filtering water, cycling nutrients, providing habitat, and performing a number of other vital environmental services. They also supply a variety of valuable products ranging from pharmaceuticals and greenery to lumber and paper products. *See* FOREST TIMBER RESOURCES; LUMBER.

Forest types. There are many ways to classify forests, as by (1) location (for example, temperate zone forests, tropical zone forests); (2) ownership (for example, public forests, private forests); (3) age or origin (for example, old-growth forests, second-growth forests, plantation forests); (4) important species (such as Douglas-fir forests, redwood forests); (5) economic and social importance (for example, commercial forests, noncommercial forests, urban forests, wilderness); (6) wood properties (for example, hardwood forests, softwood forests); (7) botanical makeup (for example, broadleaf forests, evergreen forests); or (8) a combination of features (such as moist temperate coniferous forests, dry tropical deciduous forests). The last approach tends to be the most descriptive because it often integrates several dominant characteristics related to climate, geography, and botanical features.

Some examples of the major forest types are: Northern coniferous forests which span the cold, northern latitudes of Canada and Europe; Temperate mixed forests which occupy the eastern United States, southeastern Canada, central Europe, Japan, and East Asia, and parts of the Southern Hemisphere in Chile, Argentina, Australia, and New Zealand; Temperate rainforests which are situated along moist, coastal regions of the Pacific Northwest, southern Chile, southeastern Australia, and Tasmania; Tropical rainforests which are found in the equatorial regions of Central and South America (for example, Costa Rica, Brazil, and Ecuador); on the west coast of Africa (for example, Congo, Ivory Coast, and Nigeria); and Southeast Asia (for example, Thailand, Malaysia, and Indonesia); Dry forests which occur in the southwestern United States, the Mediterranean region, sub-Saharan Africa, and semiarid regions of Mexico, India, and Central and South America; and mountain forests which are characteristic of mountainous regions throughout the world.

Characteristics. Although forests take a variety of forms, they have several features in common that allow them to develop in their respective environments. Forests generally contain a broad array of species, each of which is well adapted to the environmental conditions of the region. This biodiversity and adaptability help the forests cope with natural (and in some cases human-caused) forces of destruction, including wildfire, windstorms, floods, and pests. This built-in resiliency also allows the periodic extraction of wood and other products without jeopardizing the long-term health and productivity of the ecosystems—provided such harvesting operations are performed with care. Forests are dynamic—they are constantly changing at both landscape and smaller scales of resolution. This natural propensity to change and develop over time is called forest succession. Forests have a mitigating influence on the environment. This characteristic not only facilitates their own survival and development but also moderates the surrounding climate.

Ecological processes and hydrologic cycle. Forests play a vital role in ecological processes. From a global perspective, they help convert carbon dioxide in the atmosphere to oxygen, thereby facilitating life for aerobic organisms. Forests can also capture, store, convert, and recycle a variety of nutrients such as nitrogen, phosphorus, and sulfur. Forests also play a critical role in the hydrologic cycle. Finally, forests play a crucial ecological role in the habitat that they provide for countless organisms. *See* AIR POLLUTION; ECOLOGICAL SUCCESSION; FOREST SOIL; FORESTRY, URBAN.

Forestry and forest management. The Society of American Foresters defines forestry as the science, the art, and the practice of managing and using for human benefit the natural resources that occur on and in association with forest lands. Natural resources have traditionally entailed major commodities such as wood, forage, water, wildlife, and recreation. However, the concept of forestry has expanded to encompass consideration of the entire forest ecosystem, ranging from mushrooms to landscapes. The practice of forestry requires in-depth knowledge of the complex biological nature of the forest. It also requires an understanding of geology and soils, climate and weather, fish and wildlife, forest growth and development, and social and economic factors. Foresters, wildlife managers, park rangers, and other natural resource specialists are trained in biology, physics, chemistry, mathematics, statistics, computer science, communications, economics, and sociology. *See* FOREST MANAGEMENT.

Silviculture is the art, science, and practice of controlling the establishment, composition, and growth of a forest. It entails the use of both natural and induced processes to foster forest development. For example, reforestation of a harvested or burned-over area can be accomplished by natural seeding from nearby trees or by planting seedlings. *See* REFORESTATION; SILVICULTURE.

Laws and policies. The management of forest land in the United States is regulated by numerous laws and policies. Federal agencies must comply with laws such as the National Forest Management Act (1976), the Forest and Rangeland Renewable Resources Planning Act (1974), and the National Environmental Policy Act (1969). Other public and private forest landowners generally must comply with state regulations or guidelines designed to promote sound forest stewardship in their respective regions. Policy makers in government, industry, environmental organizations, and the private sector strive to balance the multitude of interests surrounding forest resources. Input from the public as well as resource managers and specialists is a crucial ingredient in the process.

Utilization of forest resources. Forests are often focused on particular uses. For example, plantation forests are generally designed to produce wood and fiber products. Conversely, public forests are increasingly devoted to nonconsumptive purposes such as the preservation of biodiversity, natural conditions, and scenic vistas. However, all forests can provide multiple benefits, including harvestable products, watershed protection, recreation opportunities, wildlife habitat, and ecological services. *See* FOREST GENETICS; FOREST HARVEST AND ENGINEERING; FOREST MANAGEMENT; WOOD PRODUCTS. [M.J.Cou.]

Forest ecosystem

The entire assemblage of organisms (trees, shrubs, herbs, bacteria, fungi, and animals, including people) together with their environmental substrate (the surrounding air, soil, water, organic debris, and rocks), interacting inside a defined boundary. Forests and woodlands occupy about 38% of the Earth's surface, and they are more productive and have greater biodiversity than other types of terrestrial vegetation. Forests grow in a wide variety of climates, from steamy tropical rainforests to frigid arctic mountain slopes, and from arid interior mountains to windy rain-drenched coastlines. The type of forest in a given place results from a complex of factors, including frequency and type of disturbances, seed sources, soils, slope and aspect, climate, seasonal patterns of rainfall, insects and pathogens, and history of human influence.

Ecosystem concept. Often forest ecosystems are studied in watersheds draining to a monitored stream: the structure is then defined in vertical and horizontal dimensions. Usually the canopy of the tallest trees forms the upper ecosystem boundary, and plants with the deepest roots form the lower boundary. The horizontal structure is usually described by how individual trees, shrubs, herbs, and openings or gaps are distributed.

Wildlife ecologists study the relation of stand and landscape patterns to habitat conditions for animals.

Woody trees and shrubs are unique in their ability to extend their branches and foliage skyward and to capture carbon dioxide and most of the incoming photosynthetically active solar radiation. Some light is reflected back to the atmosphere and some passes through leaves to the ground (infrared light). High rates of photosynthesis require lots of water, and many woody plants have deep and extensive root systems that tap stored ground water between rain storms. Root systems of most plants are greatly extended through a relation between plants and fungi, called mycorrhizal symbiosis. *See* PHOTOSYNTHESIS; ROOT (BOTANY).

The biomass of a forest is defined here as the mass of living plants, normally expressed as dry weight per unit area. Biomass production is the rate at which biomass is accrued per unit area over a fixed interval, usually one year. If the forest is used to grow timber crops, production measures focus on the biomass or volume of commercial trees. Likewise, if wildlife populations are the focus of management, managers may choose to measure biomass or numbers of individual animals. Ecologists interested in the general responses of forest ecosystems, however, try to measure net primary production (Npp), usually expressed as gross primary production (Gpp) minus the respiration of autotrophs (Ra).

Another response commonly of interest is net ecosystem production (NEP),

$$\mathrm{NEP} = \mathrm{Gpp} - (\mathrm{Ra} + \mathrm{Rh}) = \mathrm{Npp} - \mathrm{Rh}$$

usually expressed as where Rh is respiration of heterotrophs. *See* BIOMASS.

Productivity is the change in production over multiple years. Monitoring productivity is especially important in managed forests. Changes in forest productivity can be detected only over very long periods. *See* BIOLOGICAL PRODUCTIVITY.

Forested ecosystems have great effect on the cycling of carbon, water, and nutrients, and these effects are important in understanding long-term productivity. Cycling of carbon, oxygen, and hydrogen are dominated by photosynthesis, respiration, and decomposition, but they are also affected by other processes. Forests control the hydrologic cycle in important ways. Photosynthesis requires much more water than is required in its products. Water is lost back to the atmosphere (transpiration), and water on leaf and branch surfaces also evaporates under warm and windy conditions. Water not taken up or evaporated flows into the soil and eventually appears in streams, rivers, and oceans where it can be reevaporated and moved back over land, completing the cycle.

Forest plants and animals alter soil characteristics, for example, by adding organic matter, which generally increases the rate at which water infiltrates and is retained. Nutrient elements cycle differently from water and from each other.

Elements such as phosphorus, calcium, and magnesium are released from primary minerals in rocks through chemical weathering. Elements incorporated into biomass are returned to the soil with litterfall and root death; these elements become part of soil organic matter and are mineralized by decomposers or become a component of secondary minerals. All elements can leave ecosystems through erosion of particles and then be transported to the oceans and deposited as sediment. Deeply buried sediments undergo intense pressure and heat that reforms primary minerals. Volcanoes and plate tectonic movements eventually distribute these new minerals back to land.

Nitrogen is the most common gas in the atmosphere. Only certain bacteria can form a special enzyme (nitrogenase) which breaks apart N_2 and combines with photosynthates to form amino acids and proteins. In nature, free-living N_2-fixing microbes and a few plants that can harbor N_2-fixing bacteria in root nodules play important roles controlling the long-term productivity of forests limited by nitrogen supply. Bacteria that convert ammonium ion ($NH^{+}{}_4$) to $NO^{-}{}_3$ (nitrifiers) and bacteria that convert $NO^{-}{}_3$ back to N_2 (denitrifiers) are important in nitrogen cycling as well. *See* FOREST SOIL; HYDROLOGY; NITROGEN CYCLE.

Changes in the plant species of a forest over 10 to 100 years or more are referred to as succession. Changes in forest structure are called stand development; changes in composition, structure, and function are called ecosystem development. Simplified models of succession and development have been created and largely abandoned because the inherent complexity of the interacting forces makes model predictions inaccurate. *See* ECOLOGICAL SUCCESSION; FOREST FIRE. [B.T.B.]

Streams. One of the products of an undisturbed forest is water of high quality flowing in streams. The ecological integrity of the stream is a reflection of the forested watershed that it drains. When the forest is disturbed (for example, by cutting or fire), the stream ecosystem will also be altered. Forest streams are altered by any practices or chemical input that alter forest vegetation, by the introduction of exotic species, and by the construction of roads that increase sediment delivery to streams. *See* ACID RAIN; STREAM POLLUTION; STREAM TRANSPORT AND DEPOSITION. [J.L.Mey.]

Vertebrates. Forest animals are the consumers in forest ecosystems. They influence the flow of energy and cycling of nutrients through systems, as well as the structure and composition of forests, through their feeding behavior and the disturbances that they create. In turn, their abundance and diversity is influenced by the structure and composition of the forest and the intensity, frequency, size, and pattern of disturbances that occur in forests. Forest vertebrates make up less than 1% of the biomass in most forests, yet they can play important functional roles in forest systems.

Invertebrates. Invertebrates are major components of forest ecosystems, affecting virtually all forest processes and uses. Many species are recognized as important pollinators and seed dispersers that ensure plant reproduction. Even so-called pests may be instrumental in maintaining ecosystem processes critical to soil fertility, plant productivity, and forest health.

Invertebrates affect forests primarily through the processes of herbivory and decomposition. They are also involved in the regulation of plant growth, survival, and reproduction; forest diversity; and nutrient cycling. Typically, invertebrate effects on ecosystem structure and function are modest compared to the more conspicuous effects of plants and fungi. However, invertebrates can have effects disproportionate to their numbers or biomass.

Changes in population size also affect the ecological roles of invertebrates. For example, small populations of invertebrates that feed on plants may maintain low rates of foliage turnover and nutrient cycling, with little effect on plant growth or survival, whereas large populations can defoliate entire trees, alter forest structure, and contribute a large amount of plant material and nutrients to the forest floor. Different life stages also may represent different roles. Immature butterflies and moths are defoliators, whereas the adults often are important pollinators. [T.Sc.]

Microorganisms. Microorganisms, including bacteria, fungi, and protists, are the most numerous and the most diverse of the life forms that make up any forest ecosystem. The structure and functioning of forests are dependent on microbial interactions. Four processes are particularly important: nitrogen fixation, decomposition and nutrient cycling, pathogenesis, and mutualistic symbiosis.

Nitrogen fixation is crucial to forest function. While atmospheric nitrogen is abundant, it is unavailable to trees or other plants unless fixed, that is, converted to ammonia (NH_4), by either symbiotic or free-living soil bacteria. *See* AIR POLLUTION; NITROGEN FIXATION.

Most microorganisms are saprophytic decomposers, gaining carbon from the dead remains of other plants or animals. In the process of their growth and death, they release nutrients from the forest litter, making them available once again for the growth of plants. Their roles in carbon, nitrogen, and phosphorus cycling are particularly important. Fungi are generally most important in acid soils beneath conifer forests, while bacteria are more important in soils with a higher pH. Bacteria often are the last scavengers in the food web and in turn serve as food to a host of microarthropods.

Microorganisms reduce the mass of forest litter and, in the process, contribute significantly to the structure and fertility of soils as the organic residue is incorporated.

Some bacteria and many fungi are plant pathogens, obtaining their nutrients from living plants. Some are opportunists, successful as saprophytes, but capable of killing weakened or wounded plant tissues. Others require a living host, often preferring the most vigorous trees in the forest. Pathogenic fungi usually specialize on roots or stems or leaves, on one species or genus of trees.

Pathogenic fungi are important parts of all natural forest ecosystems. The forest trees evolved with the fungi, and have effective means of defense and escape, reducing the frequency of infection and slowing the rates of tissue death and tree mortality. However, trees are killed, and the composition and structure of the forest is shaped in large part by pathogens.

Pathogens remove weak or poorly adapted organisms from the forest, thus maintaining the fitness of the population. Decay fungi that kill parts of trees or rot the heartwood of living trees create an essential habitat for cavity-nesting birds and the other animals dependent on hollow trees.

By killing trees, pathogens create light gaps in the forest canopy. The size and rate of light gap formation and the relative susceptibility of the tree species present on the site determine the ecological consequences of mortality. Forest succession is often advanced as shade-tolerant trees are released in small gaps. Gaps allow the growth of herbaceous plants in the island of light, creating habitat and food diversity for animals within the forest. In many forests, pathogens are the most important gap formers and the principal determinants of structure and succession in the long intervals between stand-replacing disturbances such as wildfires or hurricanes. *See* ECOLOGICAL SUCCESSION; PLANT PATHOLOGY.

The fungus roots of trees, and indeed most plants, represent an intimate physical and physiological association of particular fungi and their hosts. Mycorrhizae are the products of long coevolution between fungus and plant, resulting in mutual dependency. Mycorrhizae are particularly important to trees because they enhance the uptake of phosphorus from soils. Mycorrhizal fungi greatly extend the absorptive surface of roots through the network of external hyphae. *See* ECOSYSTEM; FOREST AND FORESTRY; MYCORRHIZAE. [E.Ha.]

Forest fire

The term wildfire refers to all uncontrolled fires that burn surface vegetation (grass, weeds, grainfields, brush, chaparral, tundra, and forest and woodland); often these fires also involve structures. In addition to the wildfires, several million acres of forest land are intentionally burned each year under controlled conditions to accomplish some silvicultural or other land-use objective or for hazard reduction.

Most wildfires are caused by human beings, directly or indirectly. In the United States less than 10% of all such fires are caused by lightning, the only truly natural cause. In the West (the 17 Pacific and Rocky Mountain states) lightning is the primary cause, with smoking (cigarettes, matches, and such) the second most frequent. Combined they account for 50 to 75% of all wildfires. In the 13 southern states (Virginia to Texas) the primary cause is incendiary. This combined with smoking and debris burning make up 75% of the causes. The 20 eastern states have smoking and debris burning as causing close to 50% of all wildfires. Miscellaneous causes of wildfires are next in importance in most regions. The other causes of wildfires are machine use and campfires. Machine use includes railroads, logging, sawmills, and other operations using equipment.

The manner in which fuel ignites, flame develops, and fire spreads and exhibits other phenomena constitutes the field of fire behavior. Factors determining forest fire behavior may be considered under four headings: attributes of the fuel, the atmosphere, topography, and ignition. A forest fire may burn primarily in the crowns of trees and shrubs (a crown fire); primarily in the surface litter and loose debris of the forest floor and small vegetation (a surface fire); or in the organic material beneath the surface litter (a ground fire). The most common type is a surface fire.

The U.S. Forest Service has developed a National Fire Danger Rating System (NFDRS) to provide fire-control personnel with numerical ratings to help them with the tasks of fire-control planning and the suppression of specific fires. The system includes three basic indexes: an occurrence index, a burning index, and a fire load index. Each of these is related to a specific part of the fire-control job. These indexes are used by dispatchers in making decisions on setting up firefighting forces, lookout systems, and so forth. [W.S.Br.]

Forest genetics

The subdiscipline of genetics concerned with genetic variation and inheritance in forest trees. The study of forest genetics is important because of the unique biological nature of forest trees (large, long-lived plants covering 30% of the Earth's surface) and because of the trees' social and economic importance. Forest genetics is the basis for conservation, maintenance, and management of healthy forest ecosystems; and development of programs which breed high-yielding varieties of commercially important tree species.

Variation in natural forests. The outward appearance of a tree is called its phenotype. The phenotype is any characteristic of the tree that can be measured or observed such as its height or leaf color. The phenotype is influenced by (1) the tree's genetic potential (its genotype); and (2) the environment in which the tree grows as determined by climate, soil, diseases, pests, and competition with other plants.

No two trees of the same species have exactly the same phenotype, and in most forests there is tremendous phenotypic variation among trees of the same species. Forest geneticists often question whether the observed phenotypic variation among trees in forests is caused mostly by genetic differences or by differences in environmental effects. Common garden tests are often used to hold the environment constant and therefore isolate the genetic and environmental effects on phenotypic variability.

Geographic variation. The term "provenance" refers to a specific geographical location within the natural range of a tree species. Natural selection during the course of evolution has adapted each provenance to its particular local environment. This means that there are large genetic differences among provenances growing in different environments. Provenances originating from colder regions, for example, tend to have narrower crowns with flatter branches better adapted to the dry snow and types of frosts in colder climates. To demonstrate that these differences are genetic in origin, common garden tests called provenance tests have been planted. That is, seed has been collected from several provenances and planted for comparison in randomized, replicated studies in various forest locations. The study of geographic variation through provenance tests should be a first step in the genetic research of any tree species.

Genetic variation. In addition to genetic differences among provenances, there is usually substantial genetic variation among trees within the same provenance and even within the same forest stand. There are two reasons for this genetic diversity: (1) Different trees have different genotypes in most natural stands. (2) Each tree is heterozygous for many genes, meaning that a given tree has multiple forms (different alleles) of many genes. Population genetics studies patterns of genetic diversity in populations (such as forest stands). Results of many studies have shown that most forest tree species maintain very high levels of genetic diversity within populations. *See* POPULATION GENETICS.

Forest tree breeding. Beginning with the natural genetic variation that exists in an undomesticated tree species, tree breeding programs use selection, breeding, and other techniques to change gene frequencies for a few key traits of the chosen species. As with agricultural crops, tree breeders produce genetically improved, commercial varieties that are healthier, grow faster, and yield better wood products. After an existing forest stand is harvested, a new stand of trees is planted to replace the previous stand in the process called reforestation. Use of a genetically improved variety for this reforestation means that the new plantation will grow faster and produce wood products sooner than did the previous stand.

Several laboratory techniques promise to make major contributions to forest genetics and tree breeding: (1) Somatic embryogenesis is a technique to duplicate (or propagate) selected trees asexually from their vegetative (somatic) cells, and this allows the best trees to be immediately propagated commercially as clones without sexual reproduction (that is, no seed is involved). (2) Genetic mapping of some important tree species is well under way, and these maps will be useful in many ways to understand the genetic control of important traits, such as disease resistance. (3) Marker-assisted selection is the use of some kinds of genetic maps to help select excellent trees at very early ages based on their deoxyribonucleic acid (DNA) genotype as assessed in a laboratory (instead of growing trees in the field and selecting based on performance in the forest). (4) Functional genomic analysis is an exciting new field of genetics that aims to understand the function, controlled expression, and interaction of genes in complex traits such as tree growth. (5) Genetic engineering or genetic modification is the insertion of new genes into trees from other species.

Conservation of genetic resources. For commercially important species of forest trees, gene conservation is practiced by tree breeding programs to sustain the genetic diversity needed by the program. However, conservation of genetic diversity is a major global concern and is important for all forest species to maintain the health and function of forest ecosystems, and to sustain the genetic diversity of noncommercial species that may eventually have economic value. There are two broad categories of gene conservation programs. In-situ programs conserve entire forest ecosystems in forest reserves, national parks, wilderness areas, or other areas set aside for conservation purposes. Ex-situ programs obtain a sample of the genotypes from different provenances of a single tree species and collect seed or vegetative plant material from each genotype to store in a separate location (such as a seed bank in a refrigerated room). Both types of programs are important for conserving the world's forest resources. *See* BREEDING (PLANT); FOREST AND FORESTRY; FOREST ECOSYSTEM; GENETIC ENGINEERING; PLANT PROPAGATION. [T.L.W.]

Forest harvest and engineering

Application of engineering principles to the solution of forestry problems, such as those dealing with harvesting, forest transportation, materials handling, and mechanical silviculture, with regard to long-range environmental and economic effects.

The work that forest engineers perform varies widely throughout the United States. In the Northeast and Southeast, tasks include mechanization of harvesting, site preparation, planting, and product handling. Development and modification of machinery is an important part of this job, as is the improvement of the ability of workers to use machines in the woods, an activity known as work science. In the West, the terrain changes the job, as does the size of the trees usually harvested. Planning, design, and construction of road systems are major operational and environmental challenges in the West. Harvesting with mechanical fellers or yarding with ground skidders is often limited by tree size and terrain. Cable systems are commonly used to overcome these constraints, and the design and layout of these cable logging units require a great deal of engineering skill if logging is to be done in an economic and environmentally acceptable manner. In short, the skills possessed by forest engineers in the eastern United States parallel most closely those of the mechanical or agricultural engineer. In the West, the skills are more closely aligned with civil engineering. *See* AGRICULTURAL ENGINEERING; CIVIL ENGINEERING; FOREST AND FORESTRY; MECHANICAL ENGINEERING; SILVICULTURE. [J.E.O'L.]

Forest management

The planning and implementation of sustainable production of forest crops and other forest resources and uses. Key decisions include land allocation to different uses or combination of uses, silvicultural method and practices, intensity of management, timber harvest scheduling, and environmental protection.

Nearly three-fourths (360 million acres or 140 million hectares) of all commercial forest land in the United States is privately owned by farmers, forest investment groups, other types of nonindustrial owners, or industrial firms engaged in the business of growing and harvesting timber for conversion to wood products. The objectives and practices of private owners are extremely diverse. Many states and local governments have enacted laws that regulate the practice of private forestry. Therefore, management planning for a specific property requires a detailed review of the owner's objectives, resources, and any legal constraints regarding land uses or choice of management practices in the local area.

One-fourth (about 120 million acres or 49 million hectares) of the commercial forest in the United States is administered by federal and state agencies. The National Forest System, managed by the U.S. Forest Service, is particularly important in the western United States, where it includes nearly one-half of the commercial forest. Each national forest is required by federal law to develop a long-term land management plan, involve the public in evaluating alternatives, project future practices and outputs, and identify methods to mitigate adverse environmental impacts. These plans provide for timber harvesting, wilderness management, watershed protection, wildlife habitat, and other services in combinations that vary from forest to forest. The recovery plans of many endangered species occur primarily on public forest lands.

Forest land-use planning and project implementation requires information about the physical, vegetative, and developmental characteristics of forest resources within the management unit. Aerial photography, satellite imagery, and statistically designed ground surveys are commonly used to obtain the necessary information. The resource assessment should normally include estimates of timber volume classified according to species, age or size class, quality, location, and other attributes that affect value in the local market or have relevance to decision-making. Typically, statistically designed sampling procedures using plots or strips are employed by specially trained technicians to estimate volume. Information about nontimber resources such as wildlife, streams and lakes, fisheries, and historical and archeological sites may also be required, depending upon the owner's objectives and local forest practice regulations. Assessment methods normally utilize both ground and aerial surveys, and professional specialists employed by the owner or by outside consultants. *See* FOREST MEASUREMENT; GEOGRAPHIC INFORMATION SYSTEMS; LAND-USE PLANNING; REMOTE SENSING.

A forest typically will have complex structure. There may be a range of soil types, slopes, and aspects that differ in potential productivity. To facilitate planning for such complex situations, optimization methods may be used to schedule management activities over time, determine the timber harvest level, allocate the land base among alternative uses, and calculate benefits and costs. A common method, linear programming, requires that the manager specify both a linear objective function to be maximized and a set of linear equations that describe management constraints. *See* LINEAR PROGRAMMING; FOREST TIMBER RESOURCES; SILVICULTURE.

Modern forest management usually involves the production of multiple services of value to the owner or to society. Determining the best mix of services requires technical information on trade-offs between the different outputs, costs and values, and pertinent legal constraints. Subjective evaluations may be required in the case of unpriced services such as wildlife, water, and scenery. Forest structure has a major impact on the mix of outputs. Forest outputs or services can generally be classified as complementary or competitive. Services are complementary if an increase in the output of one is accompanied by an increase in the output of the other. They are competitive if effort to increase the output of one results in a reduction in the output of the other. In response to concerns about landscapes, such as maximum opening sizes, spatial diversity, and wildlife habitat, new scheduling methods are being developed and used (for example, tabu search, simulated annealing, and heuristics). Unlike linear programming, these methods do not guarantee optimal solutions. However, they do provide quality solutions that consider the complexity of modern forest management and can be implemented on the ground. *See* FOREST AND FORESTRY. [D.E.Te.]

Forest measurement The science and practice of measuring the volume, growth, and development of trees individually and collectively and estimating the products obtainable from them. Foresters use quantitative sciences such as mathematics and statistics for these measurements.

Regardless of the land management objectives—timber, wildlife, recreation, watershed, or a combination of these resources—the tree overstory (the forest canopy) must be quantified for informed decision making. Forest cover is an important part of wildlife habitat, and the understory component is related to the overstory characteristics. The recreation potential of wildland is a function of many variables, including the size and number of trees present. Water yields are related to the composition and density of the tree canopy. The measurement principles discussed here are applicable to all forest resource management situations that require quantitative information about the tree component of the land base.

Standing trees are commonly measured for diameter, height, and age. The diameter and height measurements are used to estimate the volume (or weight) and value of individual trees; ages are used in assessing site quality and predicting growth. *See* DENDROLOGY; TREE GROWTH; WOOD ANATOMY.

In addition to inventories aimed at determining current conditions, land managers need trend data. Monitoring consists of collecting information over time, generally on a sample basis by measuring change in key indicator variables, in order to determine the effects of management treatments in the long term. These data, along with research results, can be used to modify management on a continuing basis to ensure that objectives are being met. The sampling design for monitoring generally involves repeated measurements on the same sample plots or individuals.

Forest inventory information is commonly stored, updated, and retrieved through geographic information systems (GISs). A GIS is a computerized database for storing, manipulating, and displaying map (spatial) data and tabular (attribute) information. In a GIS, forest inventory information can be stored in a computer and directly linked to associated forest maps, making it easier and faster to analyze and graphically display the results of forest inventories. GISs can make forest inventory information more powerful by allowing forest resource managers to integrate it with other data commonly needed to make management decisions.

Foresters estimate site quality to assess present and future forest productivity and to provide a frame of reference for land management. Many parameters that affect productivity are difficult or impossible to measure directly, and as a consequence site quality is determined indirectly. Most commonly, site quality is evaluated from tree height in relation to age. Theoretically, height growth is sensitive to differences in site quality, is little affected by varying stand-density levels, is relatively stable under varying thinning intensities, and is strongly correlated with volume. Thus height has been found to be a practical, consistent, and useful indication of site quality.

Quantitative measures of stand density are used when deriving silvicultural prescriptions and predicting growth and yield. The two most commonly used measures of stand density are tree basal area per unit area and number of trees per unit area. Stand basal area is the cross-sectional area at diameter at breast height of all stems, or some specified portion of the stand, expressed on a per-acre (or per-hectare) basis. Similarly, trees per acre may be determined for all stems or for some specified portion of the stand. *See* SILVICULTURE.

Growth is the increase (increment) over a given period of time. Yield is the total amount available for harvest at a given time, that is, the summation of the annual increments. The factors most closely related to growth and yield of forest stands of a given species composition are the point in time in stand development, the site quality, and the degree to which the site is occupied. *See* FOREST AND FORESTRY; FOREST MANAGEMENT. [H.E.B.]

Forest pest control Forest pest control or forest protection refers to the approaches and tactics for protecting forests from insects and pathogens. The traditional view is that plant-feeding insects and pathogens are destructive agents that must be controlled to protect forest resources. Pest activity generally is triggered by specific changes in host-tree condition and density that often result from forest management practices. Integrated forest pest management represents the current approach to optimize accomplishment of forest management goals by evaluating the costs and benefits of various forest species for production of multiple resources. A number of pest management tools are available, including computerized models that facilitate evaluation and decision-making, and a variety of chemical, biological, and silvicultural techniques for manipulating pest abundances. *See* PLANT PATHOLOGY.

A variety of organisms can interfere with forest management objectives. Most of these are insects, fungal pathogens, and nematodes. Insects are responsible for vectoring some microbial pathogens, and pathogens frequently increase the vulnerability of infected trees to insects.

A critical first step in integrated forest pest management is identification of the forest management goals. If not justified by contribution to forest management goals, that is, optimized production of forest resources, suppression represents unnecessary costs in terms of time, money, and environmental quality.

Forest managers must be aware of potential impediments, including effects of insect and pathogens, in the accomplishment of their goals. Effective management requires information on which species can affect forest resources and at what densities. The relative threats of potential pests to particular management goals must be weighed carefully to determine tolerable or optimal abundances. Substantial data are needed to evaluate pest status. Examples of information needed for assessment include current and projected abundances of potential pests, action thresholds (abundance at which loss of resources exceeds costs of control efforts), environmental conditions favorable to various pests, and factors that influence the effectiveness of control tactics. This information can be used to project losses or gains for various forest resources as a result of specific insect or pathogen species. Such projections can be improved greatly by use of computerized models that synthesize available data and permit simulation and prediction of resource production under various environmental conditions or pest management scenarios.

The objective of pest suppression should be maintenance of pest populations below their action thresholds. Elimination of native species is impractical and would interfere with their natural ecological functions. Reducing abundances to levels that no longer interfere with management goals is sufficient. However, preventing the establishment of exotic species may be critical to sustainability of forest resources.

A variety of control options are available, but many have limited utility against particular pest species. Pesticides can be applied as aerial or ground aerosols or as fumigants. Fungicides are relatively ineffective against fungal pathogens that generally are protected from exposure. Microbial pathogens and antibiotics can be delivered as aerosols or applied to surfaces exposed to infectious agents. Other biological control options include augmentation of natural enemy populations. Biological control is most effective when the predator, parasite, or pathogen selectively and efficiently preys on the pest species. Pheromones are chemicals produced by animals, most commonly to attract potential mates. In some species, especially of bark beetles, a combination of attractive and repellent pheromones limits population density and reduces competition for resources. Silvicultural options include thinning, prescribed understory burning, and fertilization to reduce competition among trees for light, water, and nutrient resources. Thinning also slows spread of insects and pathogens between trees.

A goal of integrated forest pest management is variation in control tactics over time and across landscapes to minimize development of resistance to particular control options. *See* FUNGISTAT AND FUNGICIDE; INSECT CONTROL, BIOLOGICAL; PESTICIDE; PHEROMONE; SILVICULTURE. [T.Sc.]

Forest recreation Recreation involving direct contact with forests in various activities ranging from walking in the woods to wilderness backpacking. The primary suppliers of forest recreation opportunities in the United States are federal land management agencies such as the U.S. Department of Agriculture (USDA) Forest Service, the National Park Service, and the Bureau of Land Management; state recreation, park, wildlife, and forest departments; and private landowners and corporations (ski areas, industrial forests, resorts).

In the early decades of the twentieth century, recreation management was mostly custodial management, keeping areas free from litter and pollutants and providing fire protection. As recreation use increased dramatically in the 1950s, a concept of activity-based management emerged with a focus on the numbers of users, the activities in which they participated, and the sites necessary for participation. In 1958 the U.S. Congress empaneled the Outdoor Recreation Resources Review Commission to assess the situation and make recommendations for the future of outdoor recreation. *See* FOREST MANAGEMENT.

As outdoor recreation use of forests grew and as research began to focus on behavior of participants, the activity-based management concept evolved into a more sophisticated concept of experience-based management that focused on the achievement of satisfying experiences from recreation engagement. Three important concepts that have come from experience-based management are a definition of recreation that is behaviorally based, the Recreation Opportunity Spectrum (ROS) approach to recreation classification and management, and the Limits of Acceptable Change (LAC) planning system.

Using specific criteria to define different types of outdoor recreation, the Recreation Opportunity Spectrum allows managers to characterize the kind of recreation to be offered and to guide management decisions. It also is used to assess the impacts of recreation and proposed recreation on other uses such as timber management.

The Limits of Acceptable Change incorporates the Recreation Opportunity Spectrum and explicitly makes monitoring and evaluation of use and impacts a part of planning and management. The Limits of Acceptable Change is important in integrating forest recreation issues and concerns into multiple-use land management.

Recreation management has evolved to focus on the potential benefits that recreationists, society, and communities might realize from recreation opportunities and participation. This has become known as benefits-based management, and expected benefits are used to guide design of recreation sites and their access systems, to develop recreation information programs, and to integrate recreation with other forest uses.

The educational, physical, and mental health effects on individuals engaged in recreation on forest lands can have positive effects on sustainability of environmental and natural resources. Likewise, recreation can be detrimental. For example, wildlife can be adversely affected by off-road vehicle users or traffic on recreational roads. A major challenge for forestland managers is to help people achieve their recreational goals, but in ways that minimize negative impacts on ecosystems. *See* FOREST AND FORESTRY; FOREST ECOSYSTEM. [P.J.Bro.]

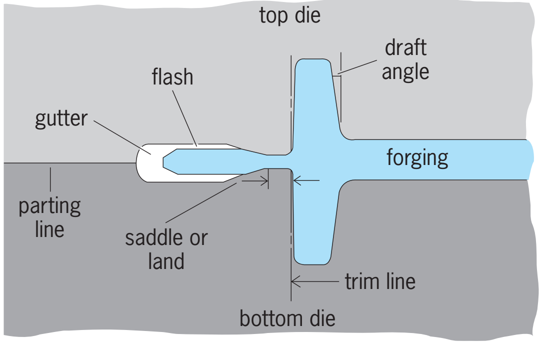
Forestry, urban The planning and implementation of actions to establish, protect, restore, and maintain trees and forests in cities and smaller communities. When it began in the 1960s, the field of urban forestry focused on individual trees along streets and adjacent to homes and buildings, and on groups of trees in specific spatial areas such as parks. Since then, it has evolved toward more holistic consideration of the structure, processes, and functions of urban ecosystems at a larger scale. Scientists have come to realize that trees and forests play a critical role in maintaining healthy urban ecosystems, providing ecological services such as filtering water and air pollution, reducing stormwater flows, sequestering carbon emissions, conserving energy, and reducing soil erosion, as well as providing human health benefits, recreation, esthetics, and fish and wildlife habitat. These ecological services can be translated into economic values worth billions of dollars by comparing them to the costs of achieving the same benefits with technology and human-made infrastructure. Urban trees, forests, and related vegetation are often referred to as green infrastructure in order to compare and contrast them with human-made or hard infrastructure, such as buildings and roads. *See* ECOLOGICAL COMMUNITIES; ECOLOGICAL SUCCESSION.

New satellite remote sensing and geographic information system tools are enabling communities to assess changes in their green infrastructure and to develop plans for restoring and maintaining urban trees and forests. City planners and policymakers use the same tools to address other urban infrastructure needs, such as transportation and housing, which allows them to integrate green infrastructure information into plans for other infrastructure development.

As urban forestry has expanded to include larger ecosystems, spatial boundaries between urban and rural areas have begun to blur. Their ecological, social, and economic links have come into view. Watershed connections have become a key consideration, while other social and economic links related to movements of people, businesses, goods, and services have also become clearer. Rural lands, both public and private, provide an array of ecological services to nearby cities, including drinking water, recreational opportunities, fish and wildlife habitat, and agricultural and forest products.

Urban forests are owned by a diverse array of public and private entities, including individual homeowners, private businesses, and federal, state, and local governments. Their management and use are closely tied to the homes, buildings, transportation systems, utilities, and other infrastructure in an urban area. A key challenge is coordinating the efforts of the large number of individuals, groups, and organizations involved in urban forestry, each with its own information, resources, and objectives. *See* LAND-USE PLANNING. [G.J.Ga.; G.A.Mo.]

Forging The plastic deformation of metals, usually at elevated temperatures, into desired shapes by compressive forces exerted through a die. Forging processes are usually classified either by the type of equipment used or by the geometry of the



Closed-die forging terminology.

end product. The simplest forging operation is upsetting, which is carried out by compressing the metal between two flat parallel platens. From this simple operation, the process can be developed into more complicated geometries with the use of dies. A number of variables are involved in forging; among major ones are properties of the workpiece and die materials, temperature, friction, speed of deformation, die geometry, and dimensions of the workpiece.

In practice, forgeability is related to the material's strength, ductility, and friction. In terms of factors such as ductility, strength, temperature, friction, and quality of forging, various engineering materials can be listed as follows in order of decreasing forgeability: aluminum alloys, magnesium alloys, copper alloys, carbon and low-alloy steels, stainless steels, titanium alloys, iron-base superalloys, cobalt-base superalloys, columbium alloys, tantalum alloys, molybdenum alloys, nickel-base superalloys, tungsten alloys, and beryllium. *See* METAL.

Some of the terminology in forging is shown in the illustration. Draft angles facilitate the removal of the forging from the die cavity. The purpose of the saddle or land in the flash gap is to offer resistance to the lateral flow of the material so that die filling is encouraged. Die filling increases as the ratio of land width to thickness increases up to about 5; larger ratios do not increase filling substantially and are undesirable due to increased forging loads and excessive die wear. The purpose of the gutter is to store excess metal. The flash is removed either by cold or hot trimming or by machining.

A number of methods produce the necessary force and die movement for forging. Two basic categories are open-die and closed-die forging. Drop hammers supply the energy through the impact of a failing weight to which the upper die is attached. Another type of forging equipment is the mechanical press. For large forgings the hydraulic press is the only equipment with sufficient force. However, the speed for such presses is about one-hundredth that of hammers. *See* METAL FORMING. [S.Ka.]

Formaldehyde The simplest aldehyde, formula HCH═O. Because of its extreme reactivity, even with itself, it cannot be readily isolated or handled in the pure state. Therefore, it is produced and marketed as an aqueous solution (usually 37–50% formaldehyde by weight), sometimes known as Formalin. It is also sold as the solid hydrated polymer known as paraformaldehyde or paraform.

Formaldehyde is used principally to produce synthetic resins and adhesives by reaction with phenols, urea, and melamine. Other uses are in the manufacture of textiles, dyes, drugs, paper, leather, photographic materials, embalming agents, disinfectants, and insecticides. *See* ALDEHYDE; PHENOLIC RESIN. [L.M.]

Formation A fundamental geological unit used in the description and interpretation of layered sediments, sedimentary rocks, and extrusive igneous rocks. A formation is defined on the basis of lithic characteristics and position within a stratigraphic succession. It is usually tabular or sheetlike, and is mappable at the Earth's surface or traceable in the subsurface (for example, between boreholes or in mines). Examples are readily recognized in the walls of the Grand Canyon of northern Arizona. Each formation is referred to a section or locality where it is well developed (a type section), and assigned an appropriate geographic name combined with the word formation or a descriptive lithic term such as limestone, sandstone, or shale (for example, Temple Butte Formation, Hermit Shale). This usage of "formation" by geologists differs from its informal lay usage for stalactites, stalagmites, and other mineral buildups in caves. *See* STRATIGRAPHY.

Distinctive lithic characteristics used to designate formations include chemical and mineralogical composition, particle size and other textural features, primary sedimentary or volcanic structures related to processes of accumulation, fossils or other organic content, and color. Contacts or boundaries between formations are chosen at surfaces of abrupt lithic change or within zones of gradational lithic character. Commonly, these contacts correspond with recognizable changes in topographic expression, related to variations in resistance to weathering. *See* SEDIMENTARY ROCKS; SEDIMENTOLOGY.

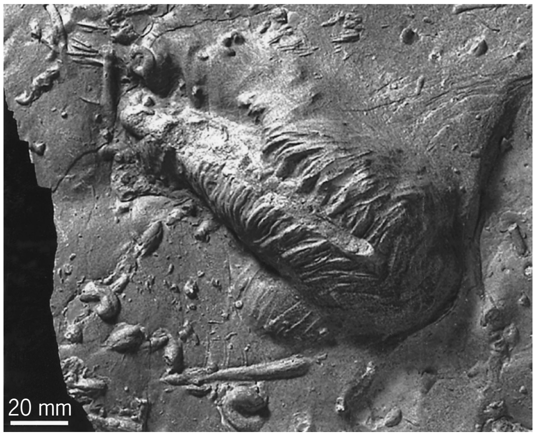
Mappability is an essential characteristic of a formation because such units are used to delineate geological structure (faults and folds), and it is useful to be able to recognize individual formations in isolated outcrops or areas of poor exposure. Well-established formations are commonly divisible into two or more smaller-scale units termed members and beds (for example, subdivisions of the Redwall Limestone). In other cases, formations of similar lithic character or related genesis are combined into composite units termed groups and supergroups (for example, Supai Group). The rank of a named unit may vary from one area to another (for example, from group to formation) according to whether or not subunits are readily mappable. Changes in rank are also justified in the light of new geological knowledge.

Although commonly used as a framework for interpreting geological history, formations and related units are conceptually independent of geological time. They may represent either comparatively short or comparatively long intervals of time. Accumulation of a particular unit may have begun earlier in some places than in others, and the time span represented by a unit may be influenced by later erosion. In some cases, a formation cropping out at one locality may be entirely older or younger than the same lithic unit at another locality. Although the concept of time plays no role in the definition of a formation, evidence of age is useful in the recognition of lithologically similar units far from their type localities. [N.C.B.]

Fossil A record of earlier life buried in rock. Originally meaning any distinctive object that has been dug up (from Latin *fodio*, dig), the term "fossil" soon came to refer particularly to things resembling animals and plants.

Fossilization. A widespread conception is that a fossil is a shell or skeleton turned into stone. This picture represents only a few of the ways in which life can leave its trace in Earth's accreting skin of sedimentary rocks. Any part of an organism can get preserved, not only hard parts but also soft tissues, cells, and organelles. Even when nothing of the original organisms is preserved, impressions and traces in the sediment give important information about their former presence, activities, and ecological roles. Also, fossilization can imply everything from preservation of the almost unaltered original tissues to their complete replacement with sediment or minerals growing in place. Organic molecules can be preserved, though in a more or less degraded state.

The biosphere normally recycles all organic and inorganic matter produced by organisms; fossils represent dead individuals that to some degree escaped that process. Most decomposition is by aerobic scavengers, fungi, and bacteria, and so a prerequisite for fossilization is that the dead body is quickly and permanently



Trace fossil, *Cruziana*, formed by an arthropod (probably a trilobite) digging for a wormlike animal in soft mud during the Cambrian Period. The picture shows the lower side of a sandstone bed casting of the original markings in the mud (now vanished). (*Swedish Geological Survey; from S. Jensen, Trace fossils from the Lower Cambrian Mickwitzia sandstone, south-central Sweden, Fossils and Strata, 42, 1997*)

subjected to an environment in which decomposers cannot be active. A combination of anoxic water and rapid sedimentation is a typical condition favorable to fossilization, though other conditions, such as extreme temperatures, salinity, poisonous environment, desiccation, or rapid mineralization, are also known to promote fossilization. Some kind of microbial activity, however, seems to be a prerequisite for many types of fossilization, particularly of soft tissue. *See* EDIACARAN BIOTA.

Shells and skeletons. Mineralized hard parts, such as shells, spicules, and bones, are by far the most common type of fossil. Although they typically contain a substantial proportion of organic material, their mineral phase usually ensures that they are more resistant than soft tissues to biological decomposers. The most common skeletal minerals are opal (hydrated silica), apatite (calcium phosphates), and calcite and aragonite (calcium carbonates). Even when none of the original hard tissue is preserved, its former presence may promote fossilization through its initial resistance to degradation. Shells are frequently preserved as molds or casts; for example, lithified infillings (internal molds) of mollusk shells are common fossils. Some hard or protective tissues may not contain any appreciable mineral phase but are nevertheless resistant to degradation and may commonly be fossilized. Arthropod cuticle, cnidarian perisarc, hemichordate periderm, leaf cuticle, and spore exine are examples of such outer protective tissues. What gives them their resistance is usually tanned proteins, polysaccharides, or waxes.

Exceptional preservation. Paleontology is increasingly dependent on sites with unusual conditions of preservation, allowing for the fossilization of soft as well as hard parts and of more complete samples of the total biota. Early silicification of sediments may trap and preserve biota; this is the main process responsible for knowledge of the microbially dominated biosphere of the Archean and Proterozoic eons, up to about 550 million years ago. Another process known to promote exquisite preservation is impregnation with calcium phosphate during early diagenesis (physical and chemical changes occurring in sediments between deposition and solidification); this has been known to preserve soft tissues, even to cellular detail. Seemingly destructive forest fires may result in excellently preserved plant tissues through coalification. Amber, fossilized tree resin, is well known for its capacity to trap and fossilize insects and other small animals and plant parts. Freezing has yielded spectacular finds of soft-tissue preservation of, for example, mammoths. The dependence on permanent low temperatures for maintaining the fossils, however, limits this kind of preservation to the most recent fossil biotas.

Various types of fine-grained shales and mudstones are more or less compressed by the weight of overlying sediment, and so the fossils are not preserved in as full relief as in the other types of extraordinary preservation mentioned earlier. However, the shaley deposits are capable of preserving much larger fossils than most of the other processes. *See* BURGESS SHALE.

Other types of exceptional fossil preservation are known, though they are more incidental and may be restricted to a short stratigraphic interval.

Trace fossils (marks of animal activities in sediment) and coprolites (fossilized feces) generally give less information than body fossils about the anatomy of the ancient organisms, but they are important sources of ecological and behavioral information (see illustration). *See* TRACE FOSSILS. [J.J.Se.]

Fossil apes

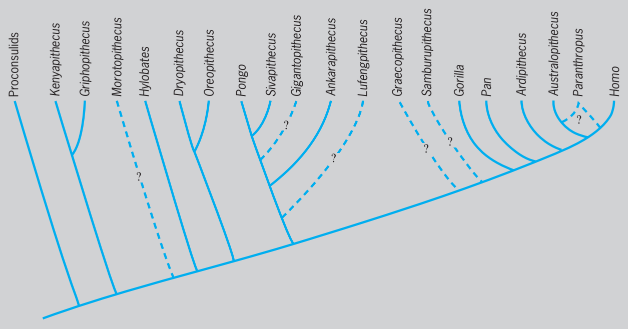
Apes and humans are closely related primates in the superfamily Hominoidea. The living hominoids are subdivided into the families Hylobatidae and Hominidae. The hylobatids or lesser apes (genus *Hylobates*) are represented by approximately nine species found throughout Southeast Asia. Humans and the great apes—the orangutan (*Pongo pygmaeus*), the gorilla (*Gorilla gorilla*), the common chimpanzee (*Pan troglodytes*), and the pygmy chimpanzee or bonobo (*Pan paniscus*)—are grouped in the Hominidae. In the past, the great apes were included in a separate family, the Pongidae, but subsequent anatomical and molecular studies showed that the African apes (*Gorilla* and *Pan*) are more closely related to humans than they are to the Asian orangutan.

The evolutionary history of the extant hominoids is poorly known, with the notable exception of humans, which have a relatively complete fossil record extending back more than 4 million years. The earliest fossil apes that can be definitively linked to the modern hylobatids are known from sites in China dated to less than 1.5 million years ago (Ma), while the fossil record for the African apes is entirely unknown. The evolution of the orangutan is, by comparison, much better documented. In contrast to the paucity of fossils available to trace the evolutionary history of hominoids over the past 5 million years, there is a wealth of evidence from the Miocene Period (23–5 Ma). This evidence shows that apes were once much more common and more diverse than they are today.

Proconsulids. The remains of apelike fossil primates, commonly known as proconsulids, have been recovered from sites in Kenya, Uganda, and Saudi Arabia dating to the early Miocene (23–16 Ma). Studies have shown that proconsulids represent either the earliest known hominoids or primitive stem catarrhines (the group which gave rise to both Old World monkeys and apes). They are certainly more primitive than any of the living apes, retaining generalized skulls and teeth, and monkeylike postcranial skeletons. However, during the early Miocene there was at least one species of hominoid living in East Africa, *Morotopithecus bishopi*, which had already acquired some of the unique features of modern apes.

During the middle Miocene (16–10 Ma), conditions in East Africa became somewhat drier, cooler, and more seasonal, and open woodland habitats replaced the humid tropical forests that were typical of the early Miocene. These ecological changes coincided with the appearance in East Africa of a more advanced type of hominoid, *Kenyapithecus*. The limb bones indicate that *Kenyapithecus* was more terrestrially adapted than proconsulids and exhibited a number of specialized features that link it more closely to extant hominoids.

Eurasian hominoids. Until the middle Miocene, hominoids were restricted to Africa, but during this period they migrated into Eurasia. Once in Eurasia, hominoids became established over a wide geographical region, extending from Spain in western Europe to eastern China, and they became increasingly diversified during the middle and late Miocene (16–5 Ma). The



Cladogram of the evolutionary relationships of fossil and living apes. Broken lines indicate uncertain relationships.

best-known fossil Eurasian hominoids are *Dryopithecus* (western and central Europe), *Oreopithecus* (Italy), *Graecopithecus* or *Ouranopithecus* (Greece), *Ankarapithecus* (Turkey), *Sivapithecus* (Indo-Pakistan), and *Lufengpithecus* (China). Of these forms, *Sivapithecus* is evidently closely related to the living orangutan, but the relationships of the other Eurasian Miocene hominoids remain contentious (see illustration).

An ecological shift from moist temperate woodlands to drier, more seasonal habitats during the later Miocene coincided with a sharp decline in the diversity of hominoids in Eurasia. The only survivor in Europe toward the end of the Miocene was *Oreopithecus*, a highly specialized relative of *Dryopithecus. Lufengpithecus* and *Sivapithecus*, along with *Gigantopithecus*, are found in the late Miocene of Asia. All of these Eurasian hominoids became extinct by the close of the Miocene, except for *Gigantopithecus*, whose remains have been recovered from Pleistocene cave sites in China dated to less than 1 Ma.

Hominoids also became extremely rare in Africa during the late Miocene. A large hominoid, *Samburupithecus*, known only by a single maxilla from Kenya (dated to 10–8 Ma), may represent a close relative of the African apes and humans. The earliest definitive record of fossil hominoids that are more closely related to humans than they are to the African great apes is known from the Pliocene (5.2–1.6 Ma) with the appearance of *Ardipithecus ramidus* from Ethiopia (4.4 Ma), *Australopithecus anamensis* from Kenya (4.2–3.9 Ma), and *Australopithecus afarensis* from Ethiopia and Tanzania (4–3 Ma). *See* Apes; Fossil humans; Mammalia; Monkey. [T.Har.]

Fossil fuel Any naturally occurring carbon-containing material which when burned with air (or oxygen) produces (directly) heat or (indirectly) energy. Fossil fuels can be classified according to their respective forms at ambient conditions. Thus, there are solid fuels (coals); liquid fuels (petroleum, heavy oils, bitumens); and gaseous fuels (natural gas, which is usually a mixture of methane, CH_4, with lesser amounts of ethane, C_2H_6, hydrogen sulfide, H_2S, and numerous other constituents in small proportions).

Heating values of representative fuels

Fossil fuel	Btu/lb	Btu/ft^3	MJ/k	MJ/m^3
Natural gas		900		33.5
Petroleum	19,000		44.1	
Heavy oil	18,000		41.8	
Tar-sand bitumen	17,800		41.3	
Coal				
Lignite	8,000*		18.6	
Subbituminous	10,500*		24.4	
Bituminous	15,500*		36.0	
Anthracite	15,000*		34.8	

*Representative values are given because of the spread of subgroups with various heating values.

One important aspect of the fossil fuels is the heating value of the fuel, which is measured as the amount of heat energy produced by the complete combustion of a unit quantity of the fuel. For solid fuels and usually for liquid fuels the heating value is quoted for mass, whereas for gaseous fuels the heating value is quoted for volume. The heating values are commonly expressed as British thermal units per pound (Btu/lb). In SI units the heating values are quoted in megajoules per kilogram (MJ/kg). For gases, the heating values are expressed as Btu per cubic foot (Btu/ft^3) or as megajoules per cubic meter (MJ/m^3). The table gives heating values of representative fuels. *See* Asphalt and asphaltite; Coal; Energy sources; Heat; Natural gas; Petroleum. [J.G.S.]

Fossil humans All prehistoric skeletal remains of humans which are archeologically earlier than Neolithic (necessarily an imprecise limit), regardless of degree of mineralization or fossilization of bone, and regardless of whether the remains may be classed as *Homo sapiens sapiens*, anatomically modern humans. In this sense, the term "humans" is used broadly to mean all primates related to living people since the last common ancestor of people and African apes, thus all species currently included in the genera *Homo, Australopithecus, Ardipithecus*, and *Paranthropus*.

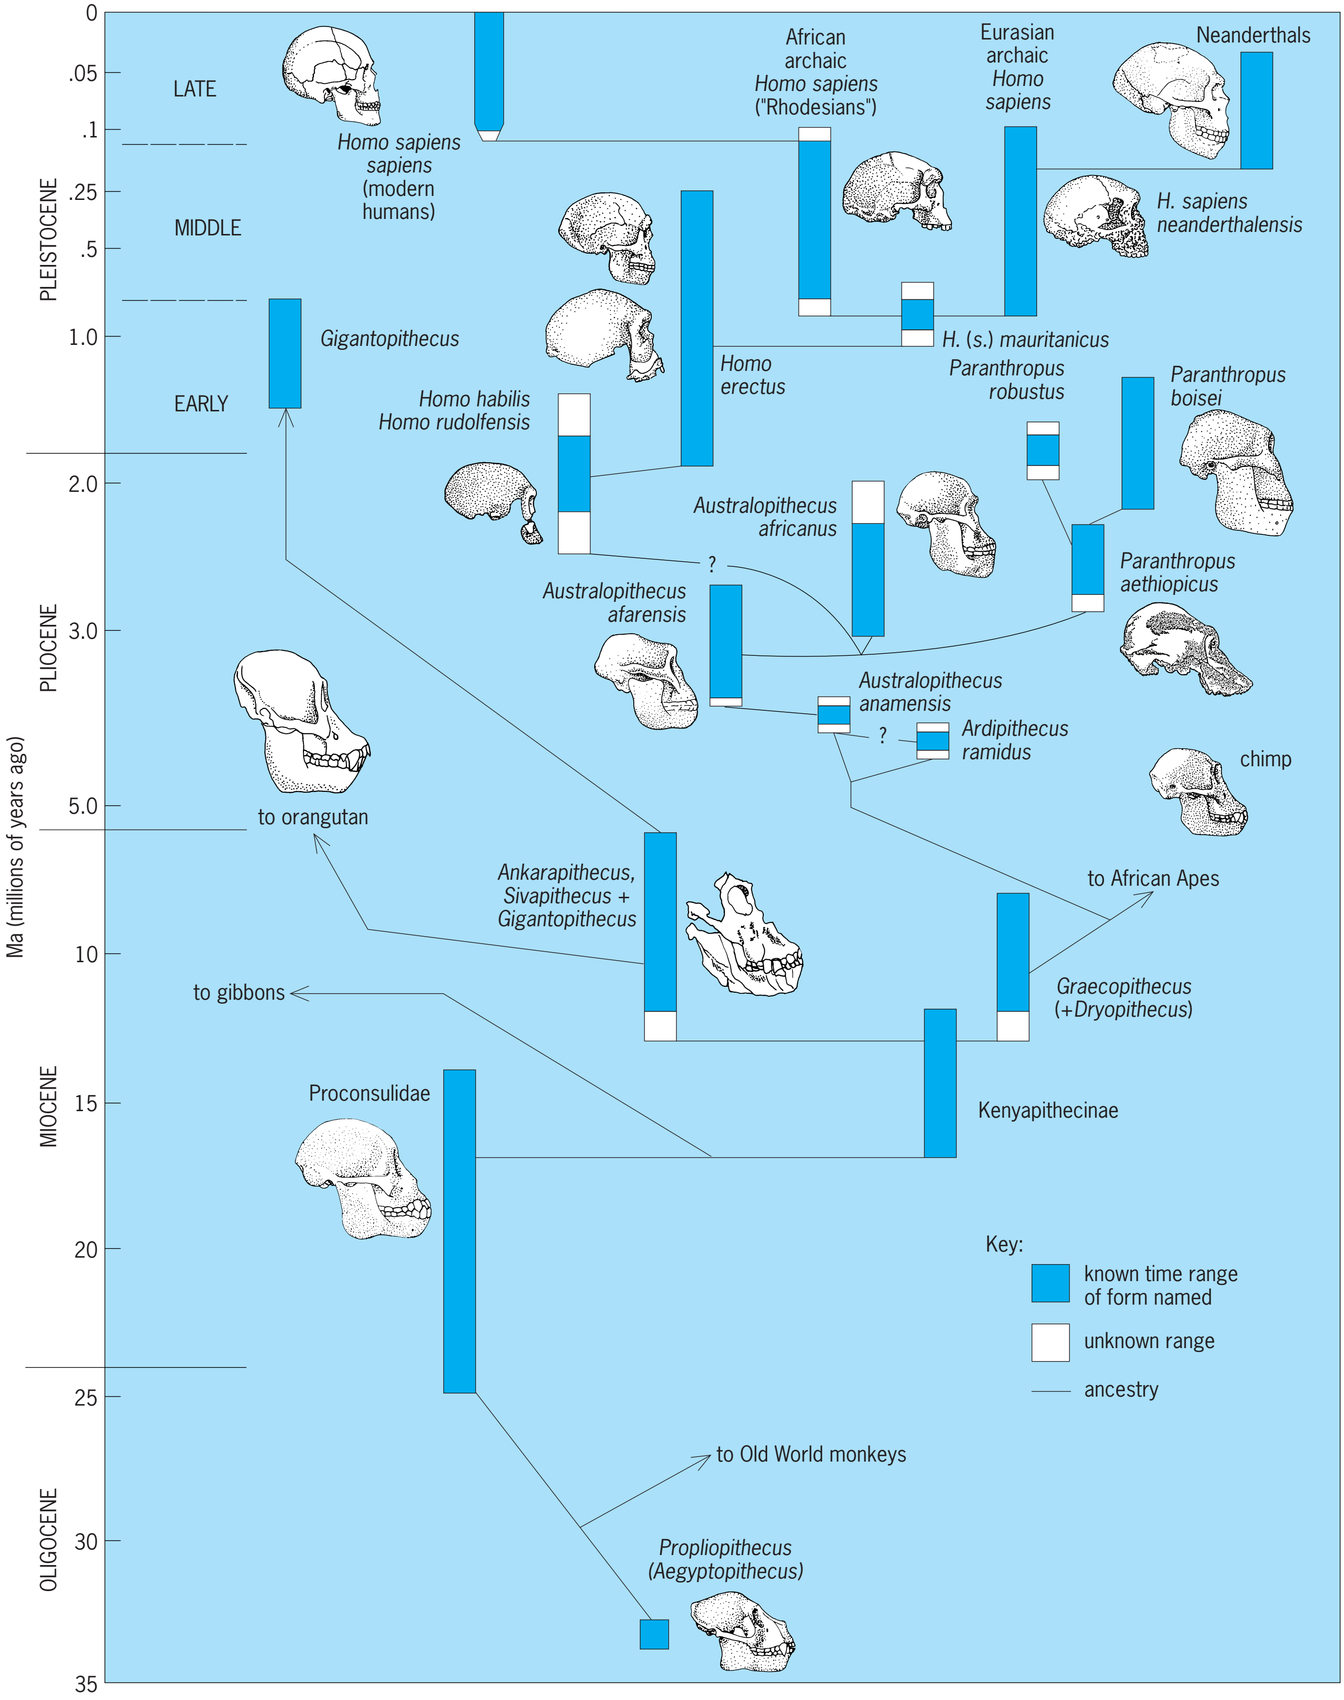
Prehuman ancestry. Humans are catarrhine primates, part of a group including Old World monkeys, apes, and various extinct forms. Most evidence from both comparative morphology and molecular studies of proteins shows that humans' closest living relatives are the African apes: the chimpanzee and the gorilla. Less close is the Asian orangutan, and most distinctive of all apes are the gibbons.

The oldest certain representatives of the Catarrhini are fossils from the Fayum beds of northern Egypt dated around 34 million years ago (Ma). The best known is *Propliopithecus* (=*Aegyptopithecus*) *zeuxis*, a species near the common ancestor of apes, humans, and Old World monkeys (see illustration). Hominoid evolution took place only in Africa in the late Oligocene and early Miocene (26–17 Ma). *See* Fossil apes; Fossil primates; Molecular anthropology; Monkey; Primates.

Pliocene Homininae. *Australopithecus*, the first truly humanlike beings, appear in the fossil record in quantity some 4.5 Ma, during the early Pliocene. Pliocene humans have been grouped in various ways, but it now seems that four main types can be distinguished. Three of these, dating from 4.5–1 Ma, have often been assigned to the genus *Australopithecus* and can informally be termed australopiths; the fourth group includes early species of *Homo*, beginning about 2.5 Ma. All australopith species appear to share a number of basic characteristics distinguishing them from living and fossil apes and also from later humans, although clearly linking them to the latter. Many researchers are coming to accept a division into at least the two genera *Australopithecus* and *Paranthropus*, and one species has been placed in its own genus, *Ardipithecus*, but others continue to recognize only a single genus, *Australopithecus*. *See* Australopithecine.

The oldest known probable human species, *Ardipithecus ramidus*, is based upon a small group of fossils found at the Aramis locality in the Middle Awash Valley, Ethiopia. The remains of *Ard. ramidus* described so far document a mosaic pattern combining features similar to those of younger humans with others reflecting retention of apelike conditions. The remaining components of the *Ard. ramidus* mosaic are all reasonably interpreted as ancestral conditions, to be expected in an ancient human ancestor. Slightly younger hominin fossils named *Aus. anamensis* have been found since 1994 at sites in the southern Lake Turkana region of Kenya.

Fossils from sites in Ethiopia and Tanzania reveal far more details about a still younger species, *Aus. afarensis*. In 1974 a partial skeleton was found and identified as a female by its pelvic bones (and small size compared to other fossils) and nicknamed Lucy. Lucy's pelvis and leg bones, as well as remarkably preserved



Human phylogeny from the Oligocene to the present time, showing the skulls of the major known fossil relatives and possible ancestors of modern humans.

footprints from Laetoli, clearly demonstrate that upright bipedal walking was well developed by 3.6 Ma, along with a brain somewhat larger than in modern apes of similar body size. Arguments as to the priority of brain expansion or walking ability in human evolution thus have yet to be resolved. *Australopithecus afarensis* combines both of these advanced, human characteristics with numerous other features reminiscent of later Miocene hominids and modern apes.

Early Homo. The only other genus of the Hominini is *Homo*, true humans, into which all later forms are placed. The identification of the earliest specimens of *Homo* is a subject of debate among paleoanthropologists. In the late 1970s the scientific pendulum had swung back to an idea proposed on less secure grounds by L. S. B. Leakey and colleagues in 1964. They named the species *H. habilis*, based on several finds from Olduvai. It was made clear from additional finds at Olduvai, Lake Turkana, and probably an upper level at Sterkfontein that a relatively small-brained (510–700 ml) and small-toothed *Homo* was present in the 2.0–1.5 Ma time period.

Several fossils, especially from the Lake Turkana region, appeared to represent a different "morph" or structural pattern. These were typified by skull KNM-ER-1470 (its catalog number in the Kenya National Museum) which has a brain size of about 750 ml, a high rounded vault and probably large teeth but a relatively protruding face. It has been suggested that the known variation in brain size and other aspects of craniofacial morphology is too great to represent merely the sexes of even a strongly dimorphic species. All of the Olduvai fossils, the smaller Turkana region specimens and some from South Africa, are recognized as *H. habilis*, while the 1470 specimen and other larger (non-*Paranthropus*) individuals from Turkana are considered as *H. rudolfensis*. This two-species view is gaining adherents and is accepted here.

Homo erectus. While *H. habilis* and *H. rudolfensis* apparently were short-lived and relatively rare African species, their likely successor, *H. erectus*, was common, widespread, and long-surviving. The first fossils were found in Java in 1893 and termed *Pithecanthropus erectus*. Each of the later finds in China and across Africa were given distinctive generic and specific names, but all are now usually considered local variants or subspecies of the single species *H. erectus*.

The earliest specimens are probably from East Africa, dating to as much as 1.9 Ma. *Homo erectus* (presumably as a result of increasing population size) spread into Eurasia through the Middle East, perhaps earlier than has previously been thought. Nonetheless, *H. erectus* must have been the first human species to leave Africa in large numbers. Fossils of this species may extend in Asia to nearly 200,000 years ago, mostly associated with fauna from the warmer intervals in this time of alternating glacial climate. The first Chinese *H. erectus*, called Beijing (Peking) man, was found at Zhoukoudian, near Beijing, where they occupied a large cave during most of the period between 500 and 250 Ka. Although there have been claims, no definite *H. erectus* fossils are yet known from Europe, nor are archeological remains or more modern humans unambiguously documented there as older than about 800,000 years.

Premodern Homo sapiens. It has been suggested that the increased rigor of the glacial climate in Europe at this time was the impetus leading to the evolution of humans who seem to be physically more "modern" in several ways than Afro-Asian *H. erectus*. These people are often termed early or archaic *H. sapiens*, or sometimes placed in their own species, *H. heidelbergensis*. There are competing interpretations of the number of species of *Homo* known in the past million years. Some workers continue to place all post-*erectus* fossils in archaic *Homo sapiens*, sometimes recognizing a variety of temporal and geographic subspecies (such as the Neanderthals and anatomically modern humans). However, some researchers accept between three and six species in the same time period: *H. antecessor, H. heidelbergensis* (either restricted to Europe or extended to Africa and even East Asia), *H. rhodesiensis* (for early African "archaics"), *H. neanderthalensis, H. sapiens* (restricted to anatomically modern humans), and perhaps others.

Early representatives of *H. s. neanderthalensis* and *H. s. rhodesiensis* occur in Europe and Africa between 500 (or even 600) and 250 Ka, thus contemporaneous with *H. erectus* populations in eastern Asia. It is likely that these archaic *H. sapiens* spread gradually eastward across the Old World, replacing late-surviving populations of the broadly ancestral *H. erectus* everywhere by 200 Ka, when a poorly known (and here unnamed) variant occurs in northern China. These three geographic variants were not only distinct from *H. erectus* but also from each other to a greater degree than is true among living varieties or "races" of anatomically modern humans.

The best known of the archaic varieties are the Neanderthals, from Europe and western Asia. It now seems likely that this group evolved locally in Europe from earliest *H. sapiens* via intermediate forms ("pre-Neanderthals" or "ante-Neanderthals"). They were essentially stocky humans, but had long, low skulls with a projecting occipital region, large faces, teeth, and brow ridges; and brains averaging 1500 ml in volume. There is intense argument among paleoanthropologists as to how "modern" the Neanderthals were behaviorally, in terms of their stoneworking and hunting techniques and modes of foraging. Such controversies feed back into the question of whether the Neanderthals are a distinct species or, as accepted here, a distinctive subspecies of *H. sapiens*. A related question is whether the Neanderthals were in any way ancestral to anatomically modern humans, especially of Europe.

Spread of modern humans. One of the major foci of recent paleoanthropological research is the clarification of the area of origin and early history of anatomically modern humans, *H. s. sapiens*. The skull of this form is characterized by a small, upright face; small teeth and brow ridges; chin; and high, rounded braincase. There are no specimens of this type known (or even hinted at) anywhere in the world earlier than about 150 thousand years ago (Ka). But from about 150–100 Ka, in eastern and southern Africa, some fossils suggest the persistence of a "Rhodesian-like" morphology, while others are often considered to be nearly modern. Two somewhat younger sites in South Africa have produced the most important evidence. In combination, these remains and other, less complete fossils indicate that early moderns were living in sub-Saharan African by about 100 Ka. From such a possible sub-Saharan origin, anatomically modern *H. s. sapiens* may have spread across the Old World, differentiating into local races by 80–50 Ka. This view of human dispersal has received support from studies of the distribution pattern of human mitochondrial deoxyribonucleic acid (DNA) haplotypes (variants) and other genetic evidence. The majority of these studies suggest that the major dichotomy in modern human population genetics is between Eurasians and Africans. Such results fit well with the fossil evidence for African versus Eurasian divergence about 100 Ka.

In contrast to the "Out of Africa" view of human dispersal (based on the idea that modern humans evolved in sub-Saharan Africa more than 100,000 years ago from Neanderthal populations), a minority view (the "Multiregional" hypothesis) interprets the fossil record to document the nearly parallel origin of modern humans in different regions of the Old World from a *H. erectus* ancestry. Each regional variety is said to present morphological characteristics linking archaic to modern populations, while gene flow between regions kept the geographical varieties united in a single species at any one time. Most scholars reject the implication that Neanderthals, for example, were ancestral to modern Europeans, or Chinese *H. erectus* to modern north Asians. *See* EARLY MODERN HUMANS. [E.D.]

Fossil primates Extinct members of the order of mammals to which humans belong. All current classifications divide the living primates into two major groups (suborders), but zoologists differ as to whether the tarsier (*Tarsius*) should be classified with the lower primates (lemurs, lorises, and bushbabies) or the higher primates (New and Old World monkeys, greater and lesser apes, and humans).

All primates have a common origin which, however, is not reflected in the universal possession of a suite of diagnostic features. The order as a whole has been characterized in terms of showing a group of progressive evolutionary trends, notably toward the predominance of the visual sense, the reduction of the sense of smell and associated structures, improved grasping and manipulative capacities, and enlargement of the higher centers of the brain. Among the extant primates, the lower primates more closely resemble forms that evolved relatively early in the history of the order, while the higher primates represent a group more recently evolved (see illustration).

Early primates. The earliest primates are placed in their own suborder, Plesiadapiformes, because they have no direct evolutionary links with, and bear no adaptive resemblances to, any group of living primates. However, the chewing teeth and the locomotor anatomy of these fossil forms sufficiently resemble those of later primates to demonstrate the common origin of the two groups. Best known from the Paleocene Epoch, around 66–54 million years ago (Ma), and found in both the Old World and the New World, the plesiadapiforms retained clawed hands and feet, had rather small brains compared to their body size, possessed large specialized front teeth, and were probably arboreal in habit.

Eocene primates. Often termed euprimates, they are divided broadly into lemurlike forms, usually grouped into the superfamily Adapoidea, and tarsierlike forms (Omomyoidea). Eocene primates of both the Old and New Worlds already display the trends that mark modern primates as a whole: These arboreal animals possessed grasping hands and feet in which sharp claws were replaced by flat nails backing sensitive pads; the snout was reduced, suggesting a deemphasis of smell, while the bone-ringed eyes faced more forward, producing stereoscopic vision and suggesting primary reliance on the sense of sight; and the brain was somewhat enlarged relative to body size when compared to those of other mammals of the period.

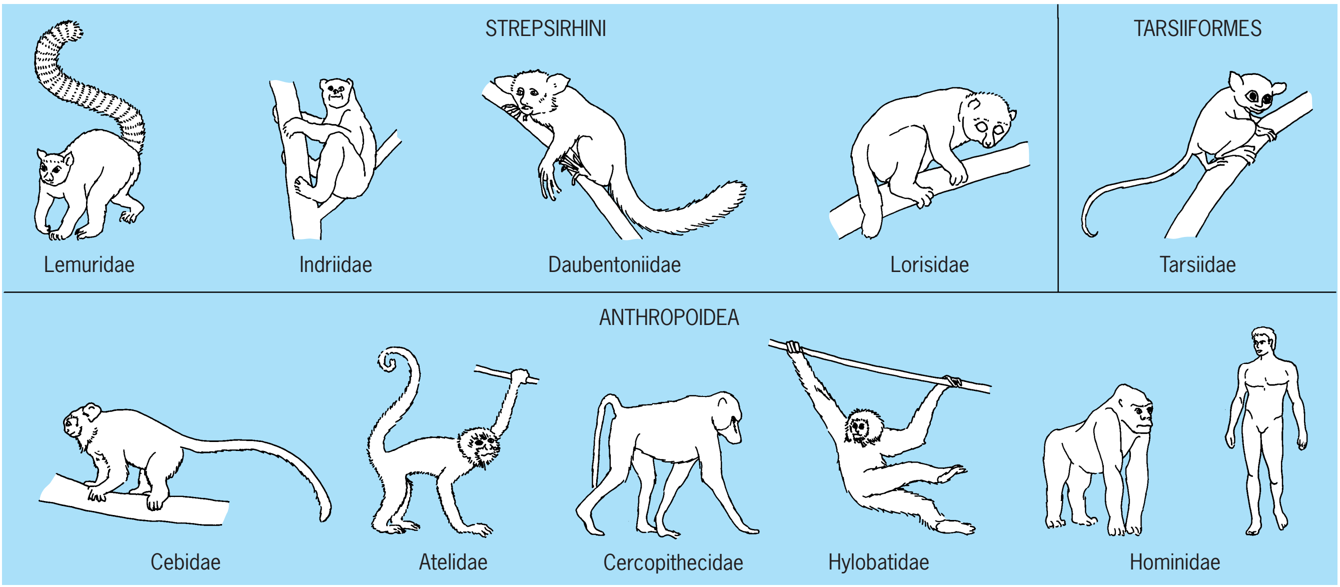
Modern lower primates. The extant lower primates are allocated to the suborder Prosimii if *Tarsius* is included, and to the suborder Strepsirhini if this strange primate is excluded, as is provisionally done here (see illustration). There is no ancient primate fossil record in Madagascar, home of the most diverse group of modern lower primates, but extinct species little more than a thousand years old document a much wider adaptive radiation before the arrival of humans on the island.

Tarsiers. The tiny *Tarsius*, which lives today in Southeast Asia, represents a link between the strepsirhines and the anthropoids (monkeys, apes, and humans). In many respects it is related to the anthropoids, but dentally it is usually thought primitive, although some authors have found similarities to some strepsirhines. The extinct Eocene omomyoids are close to tarsiers skeletally; they are often considered broadly ancestral to the anthropoids for that reason and also because some have monkeylike front teeth.

Higher primates. The anthropoids include three main groups (infraorders) of living animals and their extinct relatives paracatarrhini (archaic anthropoids), platyrrhini (New World anthropoids), and catarrhini (old world anthrapoids). Their divergence from a possibly omomyoid stock probably took place some 50 Ma. The monkeys of the New World and those of the Old are of similar evolutionary grade, but the latter share a much more recent common ancestry with apes and humans, with which they are grouped in the infraorder Catarrhini.

Three main groups of early higher primates are the oligopithecids, the parapithecids, and the propliopithecids. The former two appear to be only distantly related to any of the living monkeys or apes. The propliopithecids may be close to the common ancestry of later catarrhines (Old World anthropoids). These arboreal animals were the size of small cats, with apelike teeth, small brain, and limbs similar to those of the acrobatic South American atelines. Representatives of modern lineages begin to occur in the fossil record by about 28–20 Ma in both hemispheres.

New World primates. The platyrrhine or ateloid monkeys of South and Central America are divided into two families. All living (and well-known extinct) forms are arboreal and occupy forested areas between Argentina and southern Mexico. A distinctive evolutionary pattern observed in this group is the antiquity of the extant lineages as reflected by the close relationships of most of the few known fossils to modern genera. The small marmosets and the common squirrel and capuchin monkeys are grouped into the family Cebidae, while the generally large-bodied spider-howler and saki-uakari groups are linked to the smaller titis and (probably) owl monkeys in the Atelidae. These two families differ in the relative robustness of their jaws and reduction of last molars. *See* MONKEY.



Representatives of living primate families.

The earliest fossil platyrrhine, 26-million-year-old *Branisella* from Bolivia, is as yet known only by teeth and jaw fragments. The largest number of fossil platyrrhines comes from the La Venta beds of Colombia, dated about 13 Ma. The last 100,000 years saw another flowering of extinct platyrrhine lineages. A cave site in eastern Brazil has yielded partial skeletons of "giant" relatives of the howler and spider monkeys, while several localities in the Caribbean produced controversial fossils perhaps related to howlers, saki-uakaris, and squirrel monkeys (or possibly representing a distinct lineage whose members came to resemble those other groups).

Old World monkeys. The living Cercopithecidae (see illustration) are divided into two subfamilies, Colobinae and Cercopithecinae. The oldest cercopithecids are found in Africa, with a few fossil forms such as *Victoriapithecus* of 20–15 Ma probably predating the divergence of the modern subfamilies. The cercopithecines include a wide variety of forms, all of which share cheek pouches for temporary food storage and usually large incisors reflecting a fruit diet; colobines, by contrast, are more restricted in morphology, range, and behavior pattern, and all are leaf eaters with a complicated digestive tract to facilitate the low-nutrition diet.

The earliest members of the two living subfamilies also are mainly African. One colobine jaw is known by 9 Ma, and from 7 to 5 Ma species of both cercopithecines and colobines become more abundant. Large collections of Old World monkey fossils have been recovered from East and South African sites (often in association with early human remains) in the 4–1.5 Ma interval.

Cercopithecids entered Eurasia from Africa. *Mesopithecus pentelicus*, an 11 to 8-million-year-old colobine known in a geographical range from Germany through Afghanistan, is the best-represented Eurasian fossil monkey, with dozens of individuals recovered from sites in Greece. The living macaques (*Macaca*) are widespread across eastern Asia and in North Africa, and their fossil record adds to that large range. Scattered specimens are known from North Africa after 7 Ma, and populations have been recovered across Europe from 5.5 Ma to about 100,000 years ago.

Hominoids. The most humanlike of all primates are the apes, which form a group distinguished by generally large body size, relatively large brain, lack of an external tail, and advanced placentation pattern. Living forms include the lesser apes, or gibbons (*Hylobates*), placed in their own family Hylobatidae, and the several great apes: orangutan (*Pongo*), chimpanzee (*Pan*), and gorilla (*Gorilla*). The great apes and humans, along with some extinct relatives, are grouped as the Hominidae by some authors, while others place only humans in the Hominidae and class all great apes in the Pongidae.

One of the earliest probable members of Hominoidea is *Proconsul*, of the East African Miocene, 23–14 million years old; a few teeth of a similar form date to 26 Ma. *Proconsul* is well known by most of its skeleton. Several species ranged in size from small chimpanzee to small gorilla, with a somewhat chimplike skull, large projecting canine teeth, and limb bones seemingly adapted to quadrupedal running. However, *Proconsul* has few of the defining features of the ape group. For the present, *Proconsul* is retained as a hominoid belonging to a distinct archaic family of its own. Two other groups of roughly contemporaneous species (the Eurasian Pliopithecidae and the African "*Dendropithecus-group*") are clearly more "primitive" than *Proconsul*, although they have at times wrongly been included in Hominoidea, usually as purported relatives of the gibbons. The oldest fossil gibbons date only to about 1 Ma.

Although interpretations vary, there appear to be three groups of Eurasian hominids between 13 and 7 Ma. *Dryopithecus* is characteristic of the Dryopithecinae, which may include the common ancestors of all later great apes (and humans).

Spread of modern ape ancestors. Most scientists today agree that, of the great apes, the orangutan is evolutionarily farthest from humans. As a result, orangutans and their extinct relatives are here placed in the subfamily Ponginae, while African apes, humans, and their relatives are included in Homininae. The orangutan lineage is, however, the oldest well-documented one among all catarrhines. *See* APES.

Two species which probably belong to the Ponginae are placed in the genus *Gigantopithecus*: One dates to about 9–6 Ma from India and Pakistan; the other lived about 1.5–0.5 Ma in China and perhaps Vietnam. Hundreds of specimens, mostly isolated teeth, are known from China, and these document a species which was probably the largest primate that ever lived (perhaps weighing 200–400 kg or 440–880 lb).

The pongines probably evolved in Asia from an arboreal dryopithecine (or even kenyapithecine) ancestry which expanded into less forested environments. Such a habitat would have provided an abundance of gritty and tough food objects, to which this group's dentition appears adapted. They share with orangutans and some early humans a complex of dental-related features.

The origin of the Homininae is more problematic. The fossil ape *Graecopithecus* (also termed *Ouranopithecus*) is known from several Greek localities estimated to date between 10 and 8 Ma. Well-preserved facial material of this animal and of *Dryopithecus* recovered or reanalyzed in the 1990s has led different workers to suggest that one or both forms may lie near the split between Ponginae and Homininae or already on the hominine lineage, effectively close to the common ancestor of African apes and humans. At present *Graecopithecus* appears more derived in the direction of later hominines. At about the same time in Africa, the only known ape fossil is a single upper jaw which was named *Samburupithecus* in 1997 and which may also represent an early, gorillalike member of Homininae. These fossils imply that the hominines may have evolved in Eurasia and then returned to Africa after about 10 Ma. Previous workers often thought that the hominine lineage could be traced purely within Africa, but that hypothesis now appears less likely.

The ancestry of the African apes is still a mystery, as no fossils have yet been found which clearly represent their lineage before or after separation from humans. *See* FOSSIL HUMANS; MAMMALIA.

[E.D.; I.Ta.]

Fossil seeds and fruits

Seeds, ovules containing a fertilized egg and ready to be shed from the plant, are reproductive organs characteristic of both gymnospermous and angiospermous plants. In angiosperms (Magnoliophyta) an additional structure, the matured ovary, encloses one or more seeds to form a fruit. Seeds and fruits are less commonly found as fossils than are vegetative remains. They may be preserved structurally as casts, or as compressions which are sometimes found with leaf compressions. Seeds and fruits often occur in lignites. *See* LIGNITE; MAGNOLIOPHYTA.

The oldest known seed plants are of Mississippian age. Carboniferous seed plants include the extinct Cordaitales, probable conifer ancestors, and Pteriodospermae, seed plants with fernlike foliage. During the Mesozoic Era, all major modern groups of seed plants were represented, along with members of the declining cordaitalean and pteridospermous stocks. Among the most completely known Mesozoic seeds are those of the cycadeoids, extinct cycad relatives. *See* CORDAITALES; CYCADEOIDALES; PTERIDOSPERMS.

Upper Cretaceous fruits are known from northern Africa, Long Island, New York, and elsewhere. Tertiary fruits and seeds have been found in numbers in the United States in the Brandon lignite of Vermont and in the Clarno Formation of central Oregon. The best-known European Tertiary fruits and seeds are from the brown coals of Germany and the Eocene London Clay Formation of England.

Important paleobotanical findings resulting from the study of fossil seeds and fruits include the knowledge obtained of the independent evolution of the seed habit in unrelated groups; the discovery that much Carboniferous fernlike foliage was borne on seed plants rather than on ferns; and the discovery that *Glossopteris*, an important plant in widespread Permian floras of the Southern Hemisphere, was a seed plant. Pyritized fruits from the London Clay Formation reveal the presence of many extinct genera along with modern genera in early Tertiary time. Morphological changes in herbaceous angiosperm seeds from sequences of Tertiary beds furnish data on rates of evolution in plants. Because plant classification is based primarily upon reproductive structures, fossil seeds and fruits provide highly reliable evidence for identification and interpretation of fossil plants. *See* PALEOBOTANY. [R.A.Sc.]

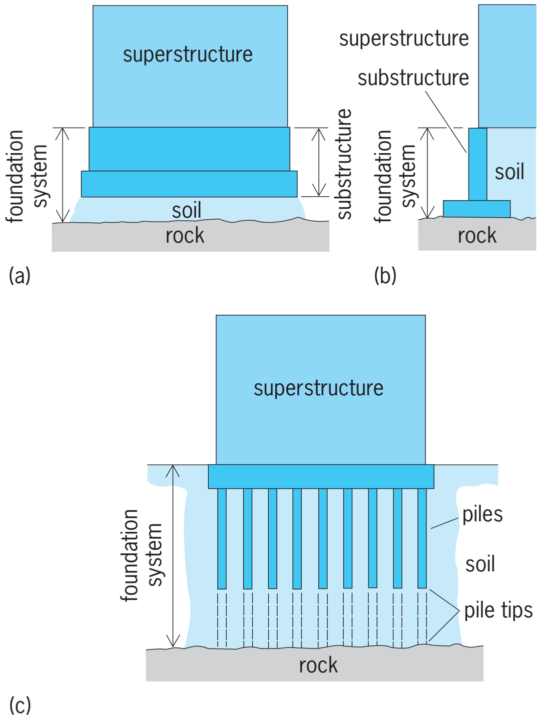
Foucault pendulum A pendulum or swinging weight, supported by a long wire, by which J. B. L. Foucault demonstrated in 1851 the rotation of Earth on its axis. Foucault used a 62-lb (28-kg) iron ball suspended on about a 200-ft (60-m) wire in the Pantheon in Paris. The upper support of the wire restrains the wire only in the vertical direction. The bob is set swinging along a meridian in pure translation (no lateral or circular motion). In the Northern Hemisphere the plane of swing appears to turn clockwise; in the Southern Hemisphere it appears to turn counterclockwise, the rate being 15 degrees times the sine of the local latitude per sidereal hour. Thus, at the Equator the plane of swing is carried around by Earth and the pendulum shows no apparent rotation; at either pole the plane of swing remains fixed in space while Earth completes one rotation each sidereal day. *See* DAY; INERTIAL GUIDANCE SYSTEM; PENDULUM; SCHULER PENDULUM. [F.H.R.]

Foundations Structures or other constructed works are supported on the earth by foundations. The word "foundation" may mean the earth itself, something placed in or on the earth to provide support, or a combination of the earth and the elements placed on it. The foundation for a multistory office building could be a combination of concrete footings and the soil or rock on which the footings are supported. The foundation for an earth-fill dam would be the natural soil or rock on which the dam is placed. Concrete footings or piles and pile caps are often referred to as foundations without including the soil or rock on which or in which they are placed. The installed elements and the natural soil or rock of the earth form a foundation system; the soil and rock provide the ultimate support of the system. Foundations that are installed may be either soil-bearing or rock-bearing. The reactions of the soil or rock to the imposed loads generally determine how well the foundation system functions. In designing the installed portions, the designer must determine the safe pressure which can be used on the soil or rock and the amount of total settlement and differential settlement which the structure can withstand.

The installed parts of the foundation system may be footings, mat foundations, slab foundations, and caissons or piles, all of which are used to transfer load from a superstructure into the earth. These parts, which transmit load from the superstructure to the earth, are called the substructure (see illustration).

Footings or spread foundations are used to spread the loads from columns or walls to the underlying soil or rock. Normally, footings are constructed of reinforced concrete; however, under some circumstances they may be constructed of plain concrete or masonry. When each footing supports only one column, it is square. Footings supporting two columns are called combined footings and may be either rectangular or trapezoidal. Cantilever footings are used to carry loads from two columns, with one column and one end of the footing placed against a building line or exterior wall. Footings supporting walls are continuous footings.

Mat or raft foundations are large, thick, and usually heavily reinforced concrete mats which transfer loads from a number of columns or columns and walls to the underlying soil or rock. Mats are also combined footings, but are much larger than a footing supporting two columns. They are continuous footings and are designed to transfer a relatively uniform pressure to the underlying soil or rock.



Examples of foundation systems. (*a*) Structure supported on a foundation bearing on soil. (*b*) Structure supported on a foundation bearing on rock. (*c*) Structure supported by a pile foundation.

Slab foundations are used for light structures wherein the columns and walls are supported directly on the floor slab. The floor slab is thickened and more heavily reinforced at the places where the column and wall loads are imposed. *See* CAISSON FOUNDATION; PILE FOUNDATION; RETAINING WALL. [G.M.R.]

Four-bar linkage A basic linkage mechanism used in machinery and mechanical equipment. The term has been applied to three types of linkages: plane, spherical, and skew.

The plane four-bar linkage (Fig. 1) consists of four pin-connected links forming a closed loop, in which all pin axes are parallel. The spherical four-bar linkage consists of four pin-connected links forming a closed loop, in which all pin axes intersect at one point. The skew four-bar linkage (Fig. 2) consists of four jointed links forming a closed loop, in which crank 2 and link 4 are pin-connected to ground 1 and the axes of the pins are generally nonparallel and nonintersecting; coupler 3 is connected to crank 2 and link 4 by ball joints.

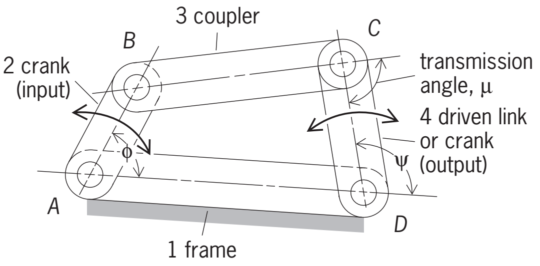


Fig. 1. Plane four-bar linkage with joints at *A*, *B*, *C*, and *D*. ϕ, ψ, and μ are angles defining orientations of joints.

Four-bar linkages are most frequently used to convert a uniform continuous rotation (the motion of crank 2) into a nonuniform rotation or oscillation (the motion of link 4). In instrument

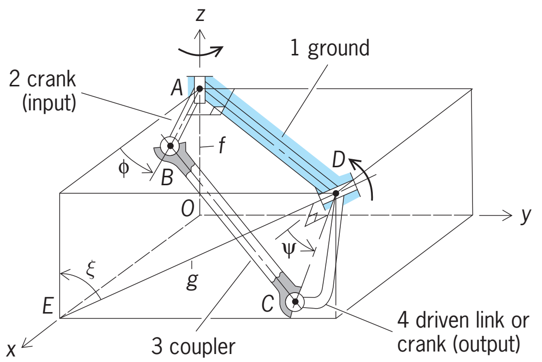

Fig. 2. Skew four-bar linkage with joints at *A*, *B*, *C*, and *D*. *OA* = *f*; *ED* = *g*; *OE* = common perpendicular between axes of pin joints at *A* and *D*; ϕ, ψ, and ξ are angles defining orientations of joints.

applications the primary function of the linkage is the conversion of motion, while in power applications both motion conversion and power transmission are fundamental.

Each of the above linkages can be proportioned for three types of motion, or linkage types: crank-and-rocker, drag, and double-rocker.

Crank-and-rocker linkages have a motion in which the crank (link 2) is capable of unlimited rotation, while the output link (link 4) oscillates or rocks through a fraction of one turn (usually less than 90°). This is the most common form of the plane and the skew four-bar linkage, and is used in machinery and appliances of all types.

In drag linkages the motions of cranks 2 and 4 are both capable of unlimited rotations. The plane drag linkage has been used for quick-return motions. The most common drag linkage is the spherical drag linkage. One such linkage is the Hooke-type universal joint, or hooke joint. *See* Universal joint.

In double-rocker linkages, neither crank 2 nor 4 is capable of complete rotations. Such motions occur in hand tools and mechanical equipment in which only limited rotations are required. *See* Linkage (mechanism); Straight-line mechanism. [F.F.]

Fourier series and transforms Mathematical tools for the analysis of functions through decomposition into sinusoids. In 1822, J. Fourier proposed that ordinary mathematical functions could be represented by a sum of sinusoids, even though at first sight it might seem that the blandness and repetitive nature of the sinusoid ill suited it to accommodate the variety of functions in general. The advantage of such a representation is this: A differential equation that is difficult to solve under the untidy given external conditions that often arise in technology may very well be soluble under an external condition that is simply sinusoidal. If solutions can be obtained for each of the constituent sinusoids that make up the given external function, then perhaps the required solution will be the sum of the separate simple solutions. This was indeed so in the case studied by Fourier, who was interested in the differential equation governing the diffusion of heat in homogeneous solids; in fact, it is often the case that solving for sinusoids permits synthesis of the required solution. When this does happen, the solution is itself composed of sinusoids and there is said to be a sinusoidal response to sinusoidal input; the differential equation will also exhibit linearity combined with shift invariance. *See* Differential equation; Harmonic analyzer; Linearity; Trigonometry.

A Fourier series is a sum of a constant and any number of sinusoidal functions, say of t, with the property that the frequencies of the component functions belong to an arithmetic sequence. An example is expression (1), where ω_0 is the fundamental frequency. The phase of each term is arbitrary, as is the amplitude, and in particular the amplitude associated with the fundamental term may be zero. Allowing an amplitude c_n for the nth term, and a phase α_n, the most general time-dependent Fourier series is given by expression (2). An equivalent expression, which uses two amplitudes a_n and b_n instead of one amplitude and a phase, is (3), where the coefficients in the two expressions are related by Eqs. (4). If the fundamental frequency is unity, the Fourier series in its simplest form results in expression (5). Fourier series have wide application in physics because systems that vibrate in response to a stimulus often do so periodically; a violin string offers an example. The reason that the vibrations of a clamped uniform string are closely periodic is that the velocity of low-amplitude transverse waves on a stretched uniform string is dependent, to a good approximation, on only the string tension and the string mass per unit length. *See* Vibration.

$$2 + \cos(\omega_0 t + 0.4) + {}^1/_2 \cos(2\omega_0 t + 0.5) + {}^1/_4 \cos(3\omega_0 t - 0.2) \tag{1}$$

$$\sum_{n=0}^{\infty} c_n \cos(n\omega_0 t + \alpha_n) \tag{2}$$

$$\sum_{n=0}^{\infty} (a_n \cos n\omega_0 t + b_n \sin n\omega_0 t) \tag{3}$$

$$\begin{aligned} a_n &= c_n \cos \alpha_n \\ b_n &= -c_n \sin \alpha_n \end{aligned} \tag{4}$$

$$a_0 + (a_1 \cos t + b_1 \sin t) + (a_2 \cos 2t + b_2 \sin 2t) + \cdots \tag{5}$$

Not all natural vibrations are periodic; examples are furnished by drums, bells, bars, and horns, where the more general trigonometric series applies, namely expression (6). The frequencies ω_n in such cases are not necessarily in arithmetic sequence.

$$\sum_{n=0}^{\infty} c_n \cos(\omega_n t + \alpha_n) \tag{6}$$

No term in the series (5) is altered in value if t is replaced by $t + 2\pi$; consequently if the series has a finite sum, that sum will be a function of t that is periodic in t with period 2π. In the discussion of Fourier series, attention may therefore be restricted to periodic functions. A real function $f(t)$ defined on the closed interval $[-\pi, \pi]$ and periodic with period 2π is said to have a Fourier series (5), where the coefficients are given by Eq. (7), and for $n > 0$, by Eqs. (8) and (9).

$$a_0 = \frac{1}{2\pi} \int_{-\pi}^{\pi} f(t)\, dt \tag{7}$$

$$a_n = \frac{1}{\pi} \int_{-\pi}^{\pi} f(t) \cos nt\, dt \tag{8}$$

$$b_n = \frac{1}{\pi} \int_{-\pi}^{\pi} f(t) \sin nt\, dt \tag{9}$$

The integrals in Eqs. (8) and (9), which are Fourier integrals, have been of great historical importance. In modern times they have gained additional importance for Fourier analysis of aperiodic functions and the corresponding spectral analysis or diffraction of electromagnetic radiation (especially for chemical analysis by ultraviolet, visible, and infrared light, and by x-rays), microwaves, seismic waves, sound waves, ocean waves and tides, and vibrations. The advent of fast computing has also given importance to algorithms such as the fast Fourier and fast Hartley transforms, which have facilitated progress in plasma physics and fluid dynamics, where numerical multidimensional analysis was previously infeasible. *See* Diffraction; Holography; Infrared spectroscopy; Interferometry; Ocean waves; Seismology; X-ray crystallography.

A function $f(x)$ that is not periodic does not analyze into a discrete set of terms, each of which has finite energy carried by a single frequency, but rather into a spectral continuum. This continuum is analogous to the spectrum of sunlight, whose energy spectrum is describable in terms of the energy per hertz or other unit of frequency. A function $f(x)$ and its amplitude spectrum or Fourier transform $F(s)$ are related by Eqs. (10). If x represents

$$\begin{aligned} F(s) &= \int_{-\infty}^{\infty} f(x) e^{-i2\pi sx} dx \\ f(x) &= \int_{-\infty}^{\infty} F(s) e^{i2\pi sx} ds \end{aligned} \qquad (10)$$

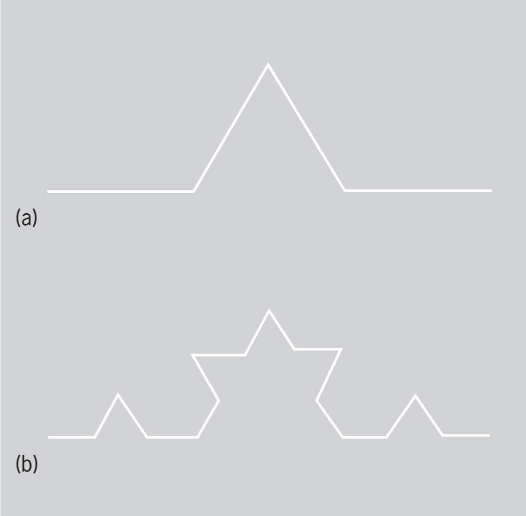
time in seconds, then s is frequency in cycles per second, or hertz; while if x represents distance, then s is spatial frequency in cycles per unit of x. [R.N.Br.]

Fractals Geometrical objects that are self-similar under a change of scale, for example, magnification. The concept is helpful in many disciplines to allow order to be perceived in apparent disorder. For instance, in the case of a river and its tributaries, every tributary has its own tributaries so that it has the same structure organization as the entire river except that it covers a smaller area. The branching of trees and their roots as well as that of blood vessels, nerves, and bronchioles in the human body follows the same pattern. Other examples include a landscape with peaks and valleys of all sizes, a coastline with its multitude of inlets and peninsulas, the mass distribution within a galaxy, the distribution of galaxies in the universe, and the structure of vortices in a turbulent flow. The rise and fall of economic indices has a self-similar structure when plotted as a function of time. *See* GALAXY, EXTERNAL; TURBULENT FLOW; UNIVERSE.

The triadic Koch curve, shown in the illustration, is a good example of how a fractal may be constructed. The procedure begins with a straight segment. This segment is divided into three equal parts, and the (single) central piece is replaced by two similar pieces (illus. *a*). The same procedure is now applied to each of the four new segments (illus. *b*), and this is repeated an infinite number of times. The curve is self-similar, because a magnification by 3 of any portion will look the same as the original curve.

Fractals came into natural sciences when it was recognized that natural objects are random versions of mathematical fractals. They are self-similar in a statistical sense; that is, given a sufficiently large number of samples, a suitable magnification of a part of one sample can be matched closely with some member of the ensemble. Unlike the Koch curve which must be magnified by an integral power of 3 to achieve self-similarity, natural fractal objects are usually self-similar under arbitrary magnification.

Physicists have used the concept of fractals to study the properties of amorphous solids and rough interfaces and the dynamics of turbulence. It has also been found useful in physiology to analyze the heart rhythm and to model blood circulation, and in ecology to understand population dynamics. In computer graphics it has been shown that the vast amount of information contained in a natural scene can be compressed very effectively by identifying the basic set of fractals therein together with their rules of construction. When the fractals are reconstructed, a close approximation of the original scene is reproduced. *See* AMORPHOUS SOLID; CARDIOVASCULAR SYSTEM; COMPUTER GRAPHICS. [S.H.L.]



Koch curve, (*a*) first and (*b*) second stages.

Frame of reference A base to which to refer physical events. A physical event occurs at a point in space and at an instant of time. Each reference frame must have an observer to record events, as well as a coordinate system for the purpose of assigning locations to each event. The latter is usually a three-dimensional space coordinate system and a set of standardized clocks to give the local time of each event. For a discussion of the geometrical properties of space-time coordinate systems *see* SPACE-TIME. *See also* RELATIVITY.

In the ordinary range of experience, where light signals, for all practical purposes, propagate instantaneously, the time of an event is quite distinct from its space coordinates, since a single clock suffices for all observers, regardless of their state of relative motion. The set of reference frames which have a common clock or time is called newtonian, since Isaac Newton regarded time as having invariable significance for all observers.

For discussion of other types of reference frames *see* ACCELERATED REFERENCE FRAME; ASTRONOMICAL REFERENCE FRAME. [B.G.]

Francisella A genus of very small, coccoid to ellipsoidal, pleomorphic, nonmotile and nonsporulating, gram-negative, rod-shaped bacteria. Fastidious and strictly aerobic, it grows at 98.6°F (37°C) within several days, but only in enriched media such as coagulated egg yolk or glucose-cysteine-blood-agar. The organisms occur in natural waters of the Northern Hemisphere, and can be parasitic and pathogenic in birds, anthropods, and mammals, including humans. *Francisella tularensis* has been found in many wild animals throughout North America, continental Europe, and Asia. Tularemia in humans is acquired via transmission by blood-sucking arthropods or by contact with infected animals, most frequently by hunters and butchers. *See* ANTIBIOTIC; MEDICAL BACTERIOLOGY; TULAREMIA. [W.Ma.]

Francium A chemical element, Fr, atomic number 87, an alkali metal element falling below cesium in group I of the periodic table. Distinguished by nuclear instability, francium exists only in short-lived radioactive forms, the most durable of which has a half-life of 21 min. The chief isotope of francium is actinium-K, an isotope of mass 223, which arises from the radioactive decay of the element actinium. From the properties of the known isotopes, it is reasonably certain that no long-lived form of element 87 will ever be found in nature or synthesized artificially. *See* PERIODIC TABLE.

The chemical properties of francium can be studied only on the tracer scale. The element has all the properties expected of the heaviest alkali element. With few exceptions, all the salts of francium are water-soluble. *See* ACTINIUM; ALKALI METALS. [E.K.H.]

Franck-Condon principle The generalization that the transition from one energy state of a molecular system to another occurs so nearly instantaneously that the nuclei of the atoms involved can be considered as stationary during the process. The Franck-Condon principle is closely related to the Born-Oppenheimer approximation, in which the various motions (electronic, nuclear vibrations and rotations) are considered to be separable, and in which the electrons respond to the instantaneous vibrations of the system whereas the system responds only to the average position of the electrons. The principle, proposed by J. Franck in 1925 and developed quantum-mechanically by E. U. Condon in 1928, is important in discussing systems of more than one atom. It is therefore valuable in molecular spectroscopy and in the interpretation of the optical properties of liquids and solids. *See* MOLECULAR STRUCTURE AND SPECTRA. [J.H.S.; C.C.K.]

Franklinite A natural member of the spinel structure type, with composition $Zn^{2+}Fe_2^{3+}O_4$. The habit is octahedral, often modified by the cube and dodecahedron, but the mineral usually occurs as bands of isolated rounded grains, blebs, or compact masses. It is black with a metallic luster and red internal reflections; its hardness is 6 (Mohs scale); specific gravity is 5.3; and it is weakly magnetic.

Franklinite is confined in its occurrence to the unique ore bodies at Franklin and Sterling Hill (Ogdensburg), Sussex County, New Jersey. Franklinite is a major ore mineral and is still mined at Sterling Hill for spiegeleisen and zinc. *See* WILLEMITE; ZINC; ZINCITE. [P.B.M.]

Fraunhofer lines Dark absorption features in the solar spectrum. J. von Fraunhofer first studied them in 1814. They occur from the ultraviolet at about 180 nanometers to the infrared at 20 micrometers. Each line represents the net absorption of light by a particular atom or molecule. Most lines form in the Sun's atmosphere, although the Earth's telluric spectrum contributes lines of molecular oxygen (O_2), carbon monoxide (CO), and other molecules. Some lines, such as Fraunhofer's C line in the red (hydrogen-alpha), can be seen with a pocket spectroscope. Powerful research instruments reveal millions of lines, most of which are weak and blended together in an almost inextricable tangle.

A spectrum line is caused by the absorption of photons of light that excite the atom from a lower to a higher energy level. Spontaneous decay back to the atom's lower level then follows, accompanied by the isotropic emission of light at the wavelength of the line. The result is a loss of light in the Sun-Earth direction.

The study of the Fraunhofer spectrum is the principal means of learning about physical conditions in the solar atmosphere. On the resolved solar disk, variations in line strength from point to point convey information about temperature, Doppler shifts of the lines reveal gas motions, and line splitting from the Zeeman effect maps magnetic fields. Because each line represents a chemical element, the composition of the solar atmosphere can be deduced. *See* ASTRONOMICAL SPECTROSCOPY; DOPPLER EFFECT; SOLAR MAGNETIC FIELD; SUN; SUPERGRANULATION; ZEEMAN EFFECT. [W.C.Li.]

Free-electron theory of metals The treatment of a metal as containing a gas of electrons completely free to move within it. The theory was originally proposed in 1900 to describe and correlate the electrical and thermal properties of metals. Later, quantum mechanics became the basis for the theory of most of the general properties of simple metals such as sodium, with one free electron per atom, magnesium with two, and aluminum with three. Transition metals, such as iron, have partially filled electronic *d* states and are not treated by the free-electron model.

Three years after J. J. Thomson's 1897 discovery of the electron, P. Drude suggested that the transport properties of metals might be understood by assuming that their electrons are free and in thermal equilibrium with their atoms. This theory was made more quantitative by H. A. Lorentz. Assuming that the mean free path of electrons was limited by collisions, he was able to derive Ohm's law for the electrical conductivity and obtain the ratio of thermal to electrical conductivity in excellent agreement with experiment. This ratio, divided by the absolute temperature, is called the Wiedemann-Franz ratio and had been observed to be universal 50 years earlier. *See* CONDUCTION (ELECTRICITY); CONDUCTION (HEAT); ELECTRICAL CONDUCTIVITY OF METALS; KINETIC THEORY OF MATTER; MEAN FREE PATH; OHM'S LAW; THERMAL CONDUCTION IN SOLIDS; WIEDEMANN-FRANZ LAW.

The theory, however, had two major shortcomings. First, it predicted a large component of the specific heat of a metal, not present in insulators, which was not observed. Second, comparison of the theory with experiment indicated that the mean free path of the electrons became extremely large at low temperatures; the model offered no justification.

In 1928 A. Sommerfeld revised Lorentz's treatment by using quantum statistics, which removed the difficulty of the specific heat without losing the successful description of transport properties. The resulting theory remains the basis for the understanding of most transport properties of metals and semiconductors. At about the same time, W. V. Houston and F. Bloch solved the quantum-mechanical wave equation for electrons in a regular periodic structure, finding that they could indeed have arbitrarily large mean free paths if there were no defects in the periodicity, thereby putting the free-electron theory on a firm basis. *See* BAND THEORY OF SOLIDS; BLOCH THEOREM; FERMI-DIRAC STATISTICS; SPECIFIC HEAT OF SOLIDS; STATISTICAL MECHANICS.

Even in the context of a free-electron gas, there are strong Coulomb interactions between electrons which are frequently neglected in the free-electron theory of metals. This neglect was justified in the late 1950s by L. D. Landau, who asserted that, even with strong electron–electron interactions, there is a one-to-one correspondence between the excited states, called quasiparticle states, of the real system and the one-electron excitations from the ground state of the noninteracting electron gas. Thus, the formulations for free-electron theory still follow, but perhaps with modifications of parameters such as mass. Subsequent theory indicates that indeed these modification due to the electron-electron interaction are extremely small for the low-energy excitations present in thermal equilibrium, and so again the simplest theory succeeds for many properties, although substantial modifications are required for the higher-energy excitations caused by light. There are additional corrections, which are much larger than those from the electron-electron interaction, arising from the interaction between electrons and phonons, the quantum-mechanical term for lattice vibrations. In many metals these vibrations reduce the electron velocities by factors of as much as 2, increasing the electronic specific heat although they turn out not to modify the conductivity itself. *See* PHONON.

Another feature of the electron–phonon interaction is a resulting interaction among electrons, which is attractive and tends to cancel or exceed the repulsive electron-electron interaction. At low temperatures the net attraction binds electrons in pairs in a superconducting state. The theory of J. Bardeen, J. R. Schrieffer, and L. N. Cooper (the BCS theory of superconductivity), which first explained this phenomenon, is also a free-electron theory, but assumes that the free electrons have such a net attractive interaction. In contrast, it is generally believed that the high-temperature superconductors discovered in 1986 are very far from free-electron in character, and most workers do not believe that phonons are primarily responsible for the attractive interaction. *See* SOLID-STATE PHYSICS; SUPERCONDUCTIVITY. [W.A.H.]

Free energy A term in thermodynamics which in different treatments may designate either of two functions defined in terms of the internal energy E or enthalpy H, and the temperature-entropy product TS.

The function $(E - TS)$ is the Helmholtz free energy and is the function ordinarily meant by free energy in European references. The Gibbs free energy is the function $(H - TS)$. For the Lewis and Randall school of American chemical thermodynamics, this is the function meant by the free energy F. To avoid confusion with the symbol F as applied elsewhere to the Helmholtz free energy, the symbol G has also been used. Another development was the introduction of the name free enthalpy, with symbol G, for the Gibbs function. *See* WORK FUNCTION (THERMODYNAMICS).

For a closed system (no transfer of matter across its boundaries), the work which can be done in a reversible isothermal process is given by the series shown in Eq. (1). For these conditions,

$$W_{rev} = -\Delta A = -\Delta(E - TS) = -(\Delta E - T\Delta S) \qquad (1)$$

$T\Delta S$ represents the heat given up to the surroundings. Should the process be exothermal, $T\Delta S < 0$, then actual work done on the surroundings is less than the decrease in the internal energy of the system. The quantity $(\Delta E - T\Delta S)$ can then be thought of as a change in free energy, that is, as that part of the internal energy change which can be converted into work under the specified conditions. This then is the origin of the name free energy. Such an interpretation of thermodynamic quantities can be misleading, however; for the case in which $T\Delta S$ is positive, Eq. (1) shows that the decrease in "free" energy is greater than the decrease in internal energy. *See* CHEMICAL THERMODYNAMICS.

For constant temperature and pressure in a reversible process the decrease in the Gibbs function G for the system again corresponds to a free-energy change in the above sense, since it is equal to the work which can be done by the closed system other than that associated with its change in volume ΔV under the given constant pressure P. The relations shown in Eq. (2) can be formed since $\Delta H = \Delta E + P\Delta V$.

$$\Delta G = -(\Delta H - T\Delta S) = W_{net} = W_{rev} - P\Delta V \qquad (2)$$

Each of these free-energy functions is an extensive property of the state of the thermodynamic system. For a specified change in state, both ΔA and ΔG are independent of the path by which the change is accomplished. Only changes in these functions can be measured, not values for a single state.

The thermodynamic criteria for reversibility, irreversibility, and equilibrium for processes in closed systems at constant temperature and pressure are expressed naturally in terms of the function G. For any infinitesimal process at constant temperature and pressure, $-dG \geqq \delta w_{\text{net}}$. If δw_{net} is never negative, that is, if the surroundings do no net work on the system, then the change dG must be negative or zero. For a reversible differential process, $-dG > \delta w_{\text{net}}$; for an irreversible process, $-dG > \delta w_{\text{net}}$. The free energy G thus decreases to a minimum value characteristic of the equilibrium state at the given temperature and pressure. At equilibrium, $dG = 0$ for any differential process taking place, for example, an infinitesimal change in the degree of completion of a chemical reaction. A parallel role is played by the work function A for conditions of constant temperature and volume. Because temperature and pressure constitute more convenient working variables than temperature and volume, it is the Gibbs free energy which is the more commonly used in thermodynamics. *See* ENTROPY; THERMODYNAMIC PRINCIPLES. [P.J.B.]

Free fall The accelerated motion toward the center of the Earth of a body acted on by the Earth's gravitational attraction and by no other force. If a body falls freely from rest near the surface of the Earth, it gains a velocity of approximately 9.8 m/s every second. Thus, the acceleration of gravity g equals 9.8 m/s^2 or 32.16 ft/s^2. This acceleration is independent of the mass or nature of the falling body. For short distances of free fall, the value of g may be considered constant. After t seconds the velocity v_t of a body failing from rest near the Earth is given by Eq. (1).

$$v_t = gt \qquad (1)$$

If a falling body has an initial constant velocity in any direction, it retains that velocity if no other forces are present. If other forces are present, they may change the observed direction and rate of fall of the body, but they do not change the Earth's gravitational pull; therefore a body may still be thought of as freely "failing" even though the resultant observed motion is upward.

For a body failing a very large distance from the Earth, the acceleration of gravity can no longer be considered constant. According to Newton's law of gravitation, the force between any two bodies varies inversely with the square of the distance between them; therefore with increasing distance between any body and the Earth, the acceleration of the body toward the Earth decreases rapidly. The final velocity v_f, attained when a body falls freely from an infinite distance to the surface of the Earth, is given by Eq. (2), where R is the radius of the Earth,

$$v_f = \sqrt{2gR} \qquad (2)$$

which gives a numerical value of 11.3 km/s or 7 mi/s. This is consequently the "escape velocity," the initial upward velocity for a rising body to completely overcome the Earth's attraction.

Because of the independent action of the forces involved, a ball thrown horizontally or a projectile fired horizontally with velocity v will be accelerated downward at the same rate as a body falling from rest, regardless of the horizontal motion.

At a sufficiently large horizontal velocity, a projectile would fall from the horizontal only at the same rate that the surface of the Earth curves away beneath it. The projectile would thus remain at the same elevation above the Earth and in effect become an earth satellite. *See* BALLISTICS; GRAVITATION. [R.D.Ru.]

Free radical Any molecule or atom which possesses one unpaired electron. There are some molecules which contain more than one unpaired electron (for example, oxygen); they normally are not considered as free radicals. Free radicals can be chemically very reactive (for example, the methyl radical) or they can be very stable entities (for example, nitric oxide).

Free radicals can be grouped into three major classes: atoms (for example, H, F, and Cl), inorganic radicals (for example, OH, CN, NO_2, and ClO_3), and organic radicals (for example, CH_3, CH_3CH_2, and $C_6H_6^-$). Such radicals are of great importance since they often appear as intermediates in thermal and photochemical reactions. Radicals are also known to initiate and propagate polymerization and combustion reactions.

In general, free radicals are formed by the rupture of a bond in a stable molecule with the production of two fragments, each with an unpaired electron. The resulting free radicals may participate in further reactions or may combine to reform the original compound.

There are many ways in which radicals can be generated-among these are thermal decomposition, electric discharge photochemical reactions, electrolysis at an electrode such as mercury or platinum, rapid mixing of two reactants, and gamma- or x-ray irradiation. [J.R.Bo.]

Frequency (wave motion) The number of times which sound pressure, electrical intensity, or other quantities specifying a wave vary from their equilibrium value through a complete cycle in unit time. The most common unit of frequency is the hertz (Hz), which is equal to 1 cycle per second. In one cycle there is a positive variation from equilibrium, a return to equilibrium, then a negative variation, and return to equilibrium. This relationship is often described in terms of the sine wave, and the frequency referred to is that of an equivalent sine-wave variation in the parameter under discussion. *See* FREQUENCY MEASUREMENT; SINE WAVE; WAVE MOTION. [W.J.G.]

Frequency counter An electronic instrument used to precisely measure the frequency of an input signal. Frequency counters are commonly used in laboratories, factories, and field environments to provide direct frequency measurements of various devices. The most common applications for frequency counters are measurement and characterization of oscillator and transmitter frequencies. *See* OSCILLATOR; RADIO TRANSMITTER.

There are several classes of frequency counters. Basic frequency counters provide measurement of frequency only. Universal counter-timers are two-channel instruments that provide measurement of frequency, period, phase, totalize (the total number of pulses generated by some type of event over the duration of an experiment), ratio (of frequencies on two channels), and time intervals such as pulse width or rise time. Microwave counters are an extension of basic frequency counters offering coverage of microwave frequency ranges to 40 GHz and beyond. *See* MICROWAVE.

The three main architectures are conventional counting, reciprocal counting, and continuous counting. Conventional counting is the oldest and simplest but has the lowest performance and the least measurement flexibility. A conventional counter uses a simple register to count each cycle of the input signal during a 1-s measurement gate time.

Reciprocal counting is the most common architecture. It provides improved performance and flexibility over conventional counting. The main gate is set by the user and determines the nominal time over which the measurement is to be made (measurement gate time).

Continuous counting is based on the reciprocal technique, but employs high-speed digital circuits to continuously sample the contents of the count registers. These continuous samples can be digitally processed to provide improved resolution to as many as 12 digits in 1 s of measurement time. [B.Dr.]

Frequency divider An electronic circuit that produces an output signal at a frequency that is an integral submultiple of the frequency of the input signal.

Several information-processing and transmitting techniques require frequency division. In television, for example, it is essential to maintain a precise relationship between the horizontal-scanning frequency and the vertical-scanning frequency. Frequency division can be conveniently accomplished in two ways, digital division and division by triggering a subharmonic.

Many circuits are available to count pulses. A bistable or flip-flop circuit produces one output pulse for every two input pulses. By cascading successive flip-flops, any desired degree of division can be obtained. This is the method of digital division.

Any circuit which has a characteristic resonance responds to certain types of input energy by ringing, that is, by going through one or more cycles of electrical activity caused by the nature of the circuit rather than by the nature of the input. This characteristic can be used to accomplish frequency division, provided the input frequency does not vary over any extensive frequency range. This is the method for triggering a subharmonic. [W.W.Sn.]

Frequency measurement The determination of the number of cycles of a periodically varying quantity occurring in unit time. Many physical systems demonstrate cyclic behavior; that is, one or more of their properties vary in a characteristic fashion before returning to the initial value and then repeating the cycle. Examples are the angular positions of the planets and satellites in the solar system, the pressure in a cylinder in a reciprocating engine, and the heights and fields associated with surface, acoustic, and electromagnetic waves. The duration of a single cycle, the period, may vary widely, from 10^{-27} s for the electromagnetic field associated with a cosmic gamma ray to 10^8 years for the rotation of a galaxy in space. The frequency, which is the inverse of the period, is the number of cycles, including fractions, occurring in unit time. The unit of frequency is the hertz (Hz), named after Heinrich Hertz, who investigated the nature of electromagnetic radiation. Measurement of the characteristic frequencies of a system, and their variation with time or under changing conditions, yields valuable information on its properties and behavior. Together with temperature and voltage, frequency ranks as one of the quantities most often measured in modern science and technology. *See* CELESTIAL MECHANICS; CERENKOV RADIATION; ELECTROMAGNETIC RADIATION; GAMMA-RAY ASTRONOMY; MILKY WAY GALAXY; WAVE MOTION.

The measurement of an unknown frequency requires a standard producing a fixed, stable, and known frequency, and a system or technique for the comparison of the unknown frequency with the standard. In the past, a wide variety of analog techniques and material standards have been employed. An example is the use of a tuning fork to adjust a musical instrument, usually a piano. Analog frequency measurement techniques possessed two major disadvantages: The frequency of the standards depended upon the material properties and dimensions of critical components, which meant that they were prone to drift and affected by variations in the ambient temperature. In addition, optimum accuracy was achieved only when the unknown and standard frequencies were close or harmonically related.

Developments in electron-tube and, later, solid-state electronics improved matters. These included the quartz crystal oscillator, in which a thin slice of crystalline quartz acts as the resonant element in an electronic feedback circuit. As a result of the sharpness of the resonance and the stability of the properties of the quartz, this device provides a stable frequency in the range from 10 kHz to 100 MHz and remains the most common secondary frequency standard in use. In addition, a range of circuits were developed to generate more complex harmonic and subharmonic frequencies from a standard source. This led ultimately to the frequency synthesizer which, with an array of phase-locked loops, could be set to produce one of a very wide range of output frequencies. In use, however, it was still necessary to measure the beat or heterodyne frequency from the unknown frequency. *See* FEEDBACK CIRCUIT; FREQUENCY DIVIDER; FREQUENCY MULTIPLIER; OSCILLATOR; PHASE-LOCKED LOOPS; PIEZOELECTRICITY; QUARTZ CLOCK.

Fast, inexpensive solid-state digital circuits have replaced analog frequency measurement techniques and many of their associated standards. The underlying principle of the digital technique is simple: the electrical signal from the sensor or transducer observing the physical system under test generally contains, from Fourier analysis, the fundamental frequency and components at integral harmonics of this frequency. It is filtered to select the fundamental and converted into a rectangular waveform, representing transitions between the binary logic levels 0 and 1. A frequency measurement then consists of counting the number of positive- or negative-going transitions between the two levels in a known time. *See* FOURIER SERIES AND TRANSFORMS.

In parallel with the production of counters capable of operating at frequencies up to around 1 GHz, frequency standards based upon selected atomic transitions rather than the properties of bulk materials have been developed. These have the advantage that the frequency produced from a particular transition is in principle universal; that is, it is largely independent of the design of the standard and the materials used in its construction, and of changes in the ambient conditions. The combination of high-speed digital counters and of very stable atomic reference sources allows a wide range of frequencies to be determined simply, inexpensively, and very accurately.

As a result, much work has been carried out on the definition and measurement of other physical quantities in terms of frequency. Clearly, time and frequency are closely related; not only are the measurement, calibration, and dissemination techniques largely interchangeable, but any frequency standard may be converted into a standard of time, that is, a clock, by adding an appropriately designed counter. The unit of time, the second, is itself defined as the duration of 9 192 631 770 cycles of the electromagnetic radiation corresponding to the transition between the two hyperfine levels of the ground state of the cesium-133 atom. The primary standards of voltage and resistance are now also realized in terms of frequency using, respectively, the superconducting Josephson effect and the von Klitzing (quantum Hall) effect. *See* ATOMIC TIME; ELECTRICAL UNITS AND STANDARDS; RESISTANCE MEASUREMENT; TIME; VOLTAGE MEASUREMENT.

To calibrate the internal quartz oscillators in frequency counters, and to enable frequency measurements to be made at the highest accuracies, up to and occasionally beyond 10^{-12}, standards laboratories require a selection of very stable frequency standards. The four types in common use are the temperature-stabilized or ovened quartz crystal oscillator, the rubidium gas cell, the cesium atomic beam standard, and the hydrogen maser. Their performance depends essentially upon the quality factor Q—the ratio of the resonant or transition frequency f_T to its half-bandwidth—and the sensitivity of f_T to changes in the properties of materials or in the ambient and operating conditions.

Quartz oscillators are employed in most of the atomic standards to reduce the short-term noise and to provide a convenient output frequency (usually 10 MHz). In these, f_T is set by atomic transitions whose properties are in principle fixed and universal. In practice, small interactions with the containment system and the operating conditions mean that this ideal is not completely realized. In the rubidium gas cell, the transition is perturbed by collisions with other buffer gas atoms whose temperature and composition may change in time; in the hydrogen maser, collisions of the hydrogen atoms with the inert coating inside the containing bulb produce the so-called wall shift, which depends upon the condition of the coating. Atoms in the cesium beam standard are very well isolated from each other and the container, and this is reflected in the low drift rates and temperature coefficients observed. *See* ATOMIC CLOCK. [P.B.Co.]

Frequency modulation A special kind of angle modulation in which the instantaneous frequency of a sine-wave carrier is varied by an amount proportional to the magnitude of the modulating wave. *See* ANGLE MODULATION; PHASE MODULATION.

Either amplitude modulation (AM) or frequency modulation (FM) offers a solution to the important problem of how to impress the message wave to be communicated upon a high-frequency oscillation. However, FM offers important advantages in exchange for extra bandwidth occupancy. Also, FM with negative feedback minimizes noise problems and receiver distortion. *See* MODULATION.

Frequency modulation is defined in terms of a generalized concept known as instantaneous frequency which is directly proportional to the time rate of change of the angle of a sine function, the argument of which is a function of time. When the argument is expressed in radians and the time in seconds, the instantaneous frequency in hertz is the time rate of change of the angle divided by 2π.

In frequency modulation the instantaneous frequency is linearly proportional to the magnitude of the modulating wave. Louder tones with AM mean greater changes in amplitude. Louder tones with FM mean greater changes in frequency.

In radio broadcasting, provided the frequency deviation (peak difference between instantaneous and carrier frequencies) is large and provided multipath transmission effects are small, FM is capable of high-fidelity reception combined with the advantages of reduced noise, less interference between stations, and less transmitter power to cover a given area. Constant average power and constant peak power that is only twice the average power are two factors that permit a ready realization of a simple high-efficiency transmitter, simplify problems of automatic volume control, and allow amplifiers and other devices to operate closer to their maximum power capability without the penalties normally associated with nonlinearities.

Practically, when estimating approximate bandwidth occupancy, a rule of thumb states that angle modulation requires the band traversed by the instantaneous frequency plus the bandwidth of the modulating wave added at both top and bottom. For some purposes an even wider band may be required.

Moreover, unambiguous representation and recovery of the wanted message by angle-modulation techniques also require that the unmodulated carrier frequency comfortably exceed the sum of the frequency deviation in the down direction plus the bandwidth of the modulating wave. In other words, in FM the carrier frequency must be high compared to the maximum frequency deviation.

For certain types of noise disturbance characterized by a noise spectrum that is uncorrelated and independent of frequency, the ratio of average signal power to average noise power in the output of the FM receiver will be proportional to the square of the peak-frequency deviation. Therefore under certain important conditions, the signal-to-noise ratio of an angle-modulation system improves 6 decibels for each 2:1 increase in bandwidth occupancy.

However, the noise advantage of FM cannot be increased indefinitely. As the bandwidth occupancy is continually increased to accommodate an increased frequency deviation, more noise reaches the FM detector. Presently, the assumption that the noise is less than the so-called improvement threshold is violated, whereupon the noise advantage of FM is quickly lost. FM with negative feedback acts differently in that the improvement threshold is minimized and held constant, independent of the bandwidth occupied by the incoming FM signal. FM with negative feedback is accompanied by a decrease in distortion originating within the FM receiver and by an increased tolerance to noise failing within the frequency band occupied by the incoming FM signal. These two important advantages are not possessed by nonfeedback receivers. Substantial benefits are realized only when the amount of negative feedback is large. In common with nonfeedback FM systems, any large reduction in noise must be paid for by a corresponding increase in the bandwidth occupied by the transmitted FM signal.

Many schemes for production and detection are possible and nearly all use spectrum translation. For the production of FM most schemes resort to spectrum multiplication. Spectrum translation of an angle-modulated wave is accomplished by single-sideband modulation. The translated spectrum, with or without inversion, is centered about a new carrier. Otherwise its significant properties are unchanged. Spectrum multiplication implies angle multiplication. By generating the xth harmonic of an angle-modulated wave, the angle is multiplied by x. If the required multiplication is too great, then after a convenient number of multiplications the resulting spectrum may be translated downward and multiplication resumed. *See* FREQUENCY-MODULATION DETECTOR; FREQUENCY-MODULATION RADIO. [H.S.B.]

Frequency-modulation detector A device for the detection or demodulation of a frequency-modulated (FM) wave. FM detectors operate in several ways. In one class of detector, known as a discriminator, the frequency modulation is first converted to amplitude modulation, which is then detected by an amplitude-modulation detector. Another type of FM detector employs a phased-locked oscillator to recover the modulation. A still different type converts the frequency modulation to plus-rate modulation, which can be converted to the desired signal by use of an integrating circuit. *See* AMPLITUDE-MODULATION DETECTOR. [C.L.A.]

Frequency-modulation radio Radio transmission accomplished by symmetrical variation of the carrier frequency by an analog input signal. The amount of swing from center frequency is dependent upon the peak value of the modulating voltage, as well as upon its frequency. The frequency of the modulation signal governs the rate at which the changes in carrier frequency occur. Frequency-modulation (FM) sidebands are formed during the modulation process and are separated from one another by an amount equal to the audio frequency. The amplitude of the sidebands diminishes progressively as the sidebands occur farther and farther from the center frequency, and the number of significant sidebands depends on the amplitude of the modulating signal. The deviation ratio of the carrier-frequency variation to the highest signal frequency transmitted may be any selected value, from fractional to large values.

Because there is no amplitude change in the output of an FM transmitter, whatever the deviation ratio, this mode is an almost perfect cure for amplitude-related interference problems that plague radio-frequency reception. Another property of FM receivers is the relative freedom from interference between distant and local stations using the same channel; only the strongest signal is received, even if the wanted signal is only 3–6 dB stronger than the interfering one. This characteristic is known as the capture effect. In contrast, AM radio signals differing in strength by 35 dB result in noticeable interference.

Since most FM receivers are equipped with a muting circuit (squelch) that silences the audio channel when no signal is present, an irritating hiss noise is not emitted from the loudspeaker when the frequency (or channel) being monitored is not in use.

Frequency modulation is used mainly for transmissions above 25 megahertz (MHz). Typical uses are in broadcasting, television sound, mobile radio telephony, radio paging systems, space telemetry, intercity microwave relaying of all classes of public traffic including voice channels, teleprinting, facsimile, broadcast network programs, and television and computer data, and intercontinental telecommunications via satellite. Frequency modulation is used for both analog and digital communications, and phase modulation as well as frequency modulation is employed.

FM broadcasting. The frequency band 88–108 MHz is allocated to FM broadcasting in a large part of the world by international agreement. For a channel spacing of 200 kHz, there are 100 allocatable channels for transmission of an audio range of 50–15,000 Hz, with a frequency-deviation ratio of 5. This means that there are five significant sidebands above and below the carrier, the carrier is deviated a maximum of ±75 kHz, and the emitted spectrum is twice this value. Because of the relatively small signal power in the modulating frequencies above 4 kHz, the received signal-to-noise ratio is improved substantially by preemphasis of the audio signal in transmission, necessitating complementary deemphasis in the receiver to restore natural program balance. In fact, preemphasis produces a sort of hybrid form of modulation, being pure frequency modulation at the lowest audio frequencies, and gradually changing to phase modulation at the highest. *See* FREQUENCY MODULATION.

FM mobile transmission. Millions of land, maritime, and aeronautical mobile FM transceivers are employed by police, firemen, public safety agencies, industrial and commercial enterprises, private citizens, and radio amateurs who desire the benefits of enroute telephony. The intensity of such usage has grown exponentially, mainly because of the availability of reliable, small, low-power-consumption solid-state equipments that are economical, and also because of the public realization of the benefits of having such communications.

Radio relaying. Frequency modulation is used for microwave radio relaying over land, over water, and to great distances using satellites, sometimes carrying thousands of simultaneous telephone conversations or several television channels.

The advent of requirements for short-haul services, local distribution networks within cities, television relay, and a wide variety of optical communication services including high-speed computer communications, electronic mail, data transmission, and other services, where it may be cost-effective to avoid the local telephone loop, presents another application for FM radio relaying.

Telegraphy. Telegraphy, including teleprinting and binary digital data transmission, is based on shifting the carrier frequency or its phase between two limiting values, one of which represents a mark signal and the other a space signal. This frequency shift (or phase shift) is a form of FM signaling used over a wire, cable, or radio. *See* TELEGRAPHY.

Facsimile. Black-and-white images (line drawings and typed copy) can be transmitted by employing the principles used in FM telegraphy; one limit frequency corresponds to black, and the other to white, on the image to be transmitted. A continuous gray scale can be transmitted and recorded if, instead of just two frequencies, a continuous frequency shift is employed between some low frequency (say, 1500 Hz) and some higher frequency (say, 2700 Hz), the exact frequency at any instant being proportional to the gray level of the image. *See* FACSIMILE.

Telemetry. Frequency modulation is the preferred method for transmission of information or data from a remote or inaccessible location such as a rocket vehicle in flight. Each condition to be remotely observed actuates one subchannel, which, when multiplexed with other channels reporting other status conditions, modulates the radio carrier by frequency modulation. *See* TELEMETERING. [J.S.B]

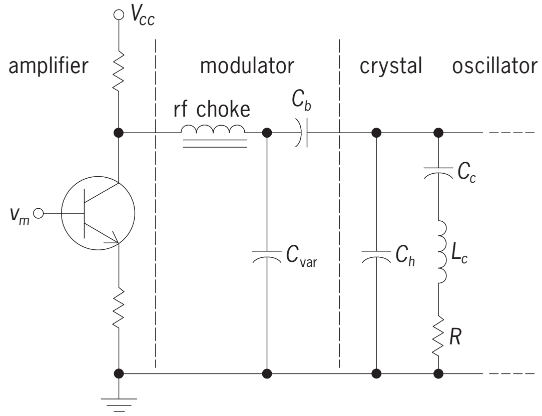
Frequency modulator

Frequency modulator An electronic circuit or device producing frequency modulation. This device changes the frequency of an oscillator in accordance with the amplitude of a modulating signal. If the modulation is linear, the frequency change is proportional to the amplitude of the modulating voltage.

High-frequency oscillators usually employ either *LC* (inductance-capacitance) tuned circuits or piezoelectric crystals to establish the frequency of oscillation. This frequency can be controlled by changing the effective capacitance or inductance of the tuned circuit in accordance with the modulating signal. Practical circuits usually employ a varactor diode to change the oscillator in accordance with a modulating voltage.

The oscillators in high-frequency electronic systems, such as frequency-modulating (FM) transmitters, usually employ piezoelectric crystals for precise control of the carrier frequency. These crystals are equivalent to a series *LC* tuned circuit with an extremely high *Q*. The crystal holder has a small capacitance which is in parallel with the crystal and therefore causes parallel resonance at a slightly higher frequency than the series resonant frequency of the crystal. The actual oscillator frequency is between these two resonant frequencies and is controllable by the parallel capacitance. *See* PIEZOELECTRICITY; Q (ELECTRICITY).

The junction capacitance of a semiconductor diode varies with the diode voltage, and a reverse-biased diode may be used to control the oscillator frequency to produce frequency modulation. Low-loss diodes designed for this service are known as varactor diodes and have trade names such as Varicaps or Epicaps. A basic varactor modulating scheme is shown in the illustration. In this circuit, the transistor that drives the varactor modulator provides reverse bias as well as the modulating voltage v_m. The radio-frequency (rf) choke provides very high impedance at the oscillator frequency to isolate the transistor amplifier output impedance from the oscillator circuit but to allow the modulating signal to pass through with negligible attenuation. Only the frequency-determining part of the oscillator is shown. The symbols C_c, L_c, and R represent the electrical equivalents of the compliance, mass, and loss, respectively, of the crystal; C_h is the crystal-holder capacitance and C_b is a dc blocking capacitor. *See* SEMICONDUCTOR DIODE; VARACTOR.



Basic varactor modulator circuit. V_{CC} = collector supply voltage.

The varactor-diode modulator is also commonly used to control the frequency of local oscillators in radio receiving equipment where programmed, push-button, or remote tuning is desirable. In these applications, conventional *LC* tuned circuits may be used. [C.L.A.]

Frequency multiplier An electronic circuit that produces an output frequency which is an integral multiple of the input frequency. There are two basic types of frequency multipliers. The first type is a nonlinear amplifier which generates harmonics in its output current and a tuned load that resonates at one of these harmonics. The second type uses the nonlinear capacitance of a junction (semiconductor) diode to couple energy from the input circuit, which is tuned to the fundamental, to the output circuit, which is tuned to the desired harmonic.

A highly efficient doubler can be devised by using two amplifiers, such as transistors, with their inputs driven with opposite polarity, obtained from opposite ends of a center-tapped coil, and their outputs connected in parallel. *See* AMPLIFIER; SEMICONDUCTOR. [C.L.A.]

Fresh-water ecosystem Fresh water is best defined, in contrast to the oceans, as water that contains a relatively small amount of dissolved chemical compounds. Some studies of fresh-water ecosystems focus on water bodies themselves, while others include the surrounding land that interacts with a lake or stream. *See* ECOLOGY; ECOSYSTEM.

Fresh-water ecosystems are often categorized by two basic criteria: water movement and size. In lotic or flowing-water ecosystems the water moves steadily in a uniform direction, while in lentic or standing-water systems the water tends to remain in the same general area for a longer period of time. Size varies dramatically in each category. Lotic systems range from a tiny rivulet dripping off a rock to large rivers. Lentic systems range from the water borne within a cup formed by small plants or tree holes to very large water bodies such as the Laurentian Great Lakes. Fresh-water studies also consider the interactions of the geological, physical, and chemical features along with the biota, the organisms that occur in an area.

Physical environment. The quantity and spectral quality of light have major influences on the distribution of the biota and also play a central role in the thermal structure of lakes. The light that reaches the surface of a lake or stream is controlled by latitude, season, time of day, weather, and the conditions that surround a water body. Light penetration is controlled by the nature of water itself and by dissolved and particulate material in a water column.

Water exhibits a number of unusual thermal properties, including its existence in liquid state at normal earth surface temperatures, a remarkable ability to absorb heat, and a maximum density at 39.09°F (3.94°C), which leads to a complex annual cycle in the temperature structure of fresh-water ecosystems.

As water is warmed at the surface of a lake, a stable condition is reached in which a physically distinct upper layer of water, the epilimnion, is maintained over a deeper, cooler stratum, the hypolimnion. The region of sharp temperature changes between these two layers is called the metalimnion. The characteristic establishment of two layers is of major importance in the chemical cycling within lakes and consequently for the biota.

As the surface waters of a lake cool, the density of epilimnetic waters increases, which decreases their resistance to mixing with the hypolimnion. If cooling continues, the entire water column will mix, an event known as turnover. At temperatures below 39.09°F (3.94°C), water again becomes less dense; ice and very cold water float above slightly warmer water, maintaining liquid water below ice cover even in lakes in the Antarctic. Many lakes in the temperate zones undergo two distinct periods of mixing annually, one in the spring and the other in the fall, that separate periods of stratification in the summer and winter.

Water movement is more extensive in lotic than in standing-water ecosystems, but water motion has important effects in both types. Turbulence occurs ubiquitously and affects the distribution of organisms, particles, dissolved substances, and heat. Turbulence increases with the velocity of flowing water, and the amount of material transported by water increases with turbulence. Flowing-water ecosystems are characterized by large fluctuations in the velocity and amount of water. Aside from surface waves on large lakes, most water movement in lentic systems is not conspicuous. *See* LAKE; LIMNOLOGY; RIVER.

Chemical environment. For an element, three basic parameters are of importance: the forms in which it occurs, its source, and its concentration in water relative to its biological demand or effect. Most elements are derived from dissolved gases in the atmosphere or from minerals in geological materials surrounding a lake. In some cases the presence of elements is strongly mediated by biological activities. *See* BIOGEOCHEMISTRY.

Oxygen occurs as dissolved O_2 and in combination with other elements resulting from chemical or biological reactions. It enters water primarily from the atmosphere through a combination of diffusion and turbulent mixing. When biological demands for oxygen exceed supply rates, it can be depleted from fresh-water ecosystems. Anoxic conditions occur in hypolimnia during summer and under ice cover in winter when lake strata are isolated from the atmosphere. Oxygen depletion may also occur in rivers that receive heavy organic loading. Aside from specialized bacteria, few organisms can occur under anoxic conditions.

Carbon dioxide is derived primarily from the atmosphere, with additional sources from plant and animal respiration and carbonate minerals. Its chemical species exert a major control on the hydrogen ion concentration of water (the acidity or pH). *See* PH.

Phosphorus occurs primarily as a phosphate ion or in a number of complex organic forms. It is the element which is most commonly in the shortest supply relative to biological demand. Phosphorus is thus a limiting nutrient, and its addition to fresh-water ecosystems through human activities can lead to major problems due to increased growth of aquatic plants.

Nitrogen occurs in water as N_2, NO_2, NO_3, NH_4, and in diverse organic forms. It may be derived from precipitation and soils, but its availability is usually regulated by bacterial processes. Nitrogen occurs in relatively short supply relative to biological demand. It may also limit growth in some fresh-water systems, particularly when phosphorus levels have been increased because of human activity. *See* NITROGEN FIXATION.

A variety of other elements also help determine the occurrence of fresh-water organisms either directly or by the elements' effects on water chemistry.

Biota. In addition to taxonomy, fresh-water organisms are classified by the areas in which they occur, the manner in which they move, and the roles that they occupy in trophic webs. Major distinctions are made between organisms that occur in bottom areas and those within the water column, the limnetic zone. Production is the most difficult variable to measure, but it provides the greatest information on the role of organisms in an ecosystem. *See* BIOLOGICAL PRODUCTIVITY; BIOMASS.

Plankton organisms occur in open water and move primarily with general water motion. Planktonic communities occur in all lentic ecosystems. In lotic systems they are important only in slow-moving areas.

Phytoplankton (plant plankton) comprise at least eight major taxonomic groups of algae, most of which are microscopic. They exhibit a diversity of forms ranging from one-celled organisms to complex colonies. *See* ALGAE; BACILLARIOPHYCEAE; PHYTOPLANKTON.

Zooplankton (animal plankton) comprise protozoans and three major groups of eukaryotic organisms: rotifers, cladocerans, and copepods. Most are microscopic but some are clearly visible to the naked eye. *See* COPEPODA; POPULATION ECOLOGY; ROTIFERA; ZOOPLANKTON.

Animals, such as fishes and swimming insects, that occur in the water column and can control their position independently of water movement are termed nekton. In addition to their importance as a human food source, fishes may affect zooplankton, benthic invertebrates, vegetation, and lake sediments.

Benthic organisms are a diverse group associated with the bottoms of lakes and streams. The phytobenthos ranges from microscopic algae to higher plants. Benthic animals range from microscopic protozoans and crustaceans to large aquatic insects and fishes. *See* FOOD WEB.

Bacteria occur throughout fresh-water ecosystems in planktonic and benthic areas and play a major role in biogeochemical cycling. Most bacteria are heterotrophic, using reduced carbon as an energy source; others are photosynthetic or derive energy from reduced compounds other than carbon. *See* BACTERIAL PHYSIOLOGY AND METABOLISM.

Interactions. Ultimately the conditions in a fresh-water ecosystem are controlled by numerous interactions among biotic and abiotic components. Primary production in a fresh-water ecosystem is controlled by light and nutrient availability. As light diminishes with depth in a column or water, a point is reached where energy for photosynthesis balances respiratory energy demands. In benthic areas, the region where light is sufficient for plant growth is termed the littoral zone; deeper areas are labeled profundal.

Nutrient availability generally controls the total amount of primary production that occurs in fresh-water ecosystems. One classification scheme for lakes ranks them according to total production, ranging from oligotrophic lakes, where water is clear and production is low, to eutrophic systems, characterized by high nutrient concentrations, high standing algal biomass, high production, low water clarity, and low concentrations of oxygen in the hypolimnion. Eutrophic conditions are more likely to occur as a lake ages. This aging process, termed eutrophication, occurs naturally but can be greatly accelerated by anthropogenic additions of nutrients. A third major lake category, termed dystrophy, occurs when large amounts of organic materials that are resistant to decomposition wash into a lake basin. These organic materials stain the lake water and have a major influence on water chemistry which results in low production. *See* BOG; EUTROPHICATION.

[T.M.F.]

Friction

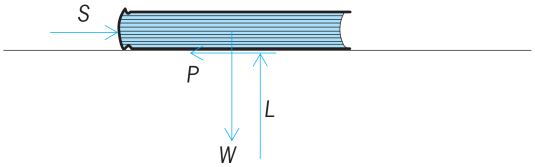
Friction Resistance to sliding, a property of the interface between two solid bodies in contact. Many everyday activities like walking or gripping objects are carried out through friction, and most people have experienced the problems that arise when there is too little friction and conditions are slippery. However, friction is a serious nuisance in devices that move continuously, like electric motors or railroad trains, since it constitutes a dissipation of energy, and a considerable proportion of all the energy generated by humans is wasted in this way. Most of this energy loss appears as heat, while a small proportion induces loss of material from the sliding surfaces, and this eventually leads to further waste, namely, to the wearing out of the whole mechanism. *See* WEAR; WORK.

In stationary systems, friction manifests itself as a force equal and opposite to the shear force applied to the interface. Thus, as in the illustration, if a small force S is applied, a friction force P will be generated, equal and opposite to S, so that the surfaces remain at rest. P can take on any magnitude up to a limiting value F, and can therefore prevent sliding whenever S is less than F. If the shear force S exceeds F, slipping occurs. During sliding, the friction force remains approximately equal to F and always acts in a direction opposing the relative motion. The friction force is proportional to the normal force L, and the constant of proportionality is defined as the friction coefficient f. This is expressed by the equation $F = fL$.

In prehistoric and early historic times, humans' main interest in friction was to reduce the friction coefficient, to reduce the labor involved in dragging heavy objects. This led to the invention of lubricants, the first of which were animal fats and vegetable oils. A great breakthrough was the use of rolling action, first in the form of rolling logs and then in the form of wheels, to take advantage of the lower friction coefficients of rolling systems. *See* LUBRICANT.

In modern engineering practice available materials and lubricants reduce friction to acceptable values. In special circumstances when energy is critical, determined efforts to minimize friction are undertaken. Friction problems of practical importance are those of getting constant friction in brakes and clutches, so that jerky motion is avoided, and avoiding low friction in special circumstances, such as when driving a car on ice or on a very wet road. Also, there is considerable interest in developing new bearing materials and new lubricants that will produce low friction even at high interfacial temperatures and maintain these properties for long periods of times, thus reducing maintenance expenses. Perhaps the most persistent problem is that of avoiding frictional oscillations, a constant cause of noise pollution of the environment.

[E.R.]



The forces acting on a book resting on a flat surface when a sheer force *S* is applied. The friction from *P* is equal to *S* (up to a limiting value *F*), while *L*, the normal force, is equal to the weight *W* of the book.

Friedel-Crafts reaction

Friedel-Crafts reaction A substitution reaction, catalyzed by aluminum chloride, in which an alkyl (R—) group or an acyl (RCO—) group replaces a hydrogen atom of an aromatic nucleus. This general reaction is the most important member of a larger group of aromatic substitution reactions known to be catalyzed by conventional or Lewis acids.

In the classical alkylation reaction, an alkyl halide (RX) serves as the alkylating agent. Alkenes may be substituted for alkyl halides. For acylation of aromatic hydrocarbons, acyl halides have proved most valuable although acid anhydrides have also been used. *See* AROMATIC HYDROCARBON; SUBSTITUTION REACTION.

[C.K.B.]

Fringe (optics)

Fringe (optics) One of the light or dark bands produced by interference or diffraction of light. Distances between fringes are usually very small, because of the short wavelength of light. Fringes are clearer and more numerous when produced with light of a single color.

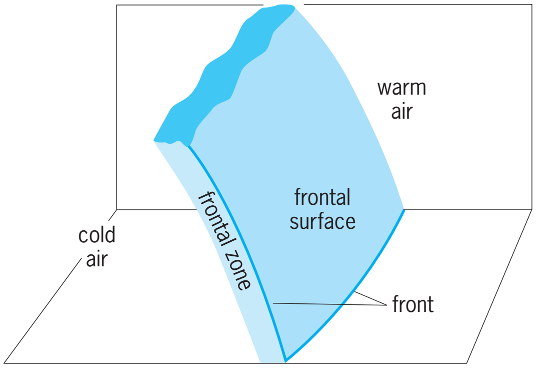
Diffraction fringes are formed when light from a point source, or from a narrow slit, passes by an opaque object of any shape. Interference fringes are obtained by bringing together two or more beams of light that have originated from a common source. This is usually accomplished by means of an apparatus especially designed for the purpose called an interferometer, although interference fringes may also be seen in nature. Examples are the colors in a soap film and in an oil film on water. *See* DIFFRACTION; INTERFERENCE OF WAVES; INTERFEROMETRY; RESOLVING POWER (OPTICS).

[F.A.J./W.W.W.]

Front

Front An elongated, sloping zone in the troposphere, within which changes of temperature and wind velocity are large compared to changes outside the zone. Thus the passage of a front at a fixed location is marked by rather sudden changes in temperature and wind and also by rapid variations in other weather elements such as moisture and sky condition.

In its idealized sense, a front can be regarded as a sloping surface of discontinuity separating air masses of different density or temperature. In practice, the temperature change from warm to cold air occurs mainly within a zone of finite width, called a transition or frontal zone. The three-dimensional structure of the frontal zone is shown in the illustration. In typical cases, the zone is about 1 km (0.6 mi) in depth and 100–200 km (60–120 mi) in width, with a slope of approximately 1/100. The cold air lies beneath the warm in the form of a shallow wedge. Temperature



Schematic diagram of the frontal zone, angle with Earth's surface much exaggerated

contrasts generally are strongest at or near the earth's surface, the frontal zone usually being narrowest near the ground and becoming wider and more diffuse with height.

The surface separating the frontal zone from the adjacent warm air mass is referred to as the frontal surface, and it is the line of intersection of this surface with a second surface, usually horizontal or vertical, that strictly speaking constitutes the front. According to this more precise definition, the front represents a discontinuity in temperature gradient rather than in temperature itself. The boundary on the cold air side is often ill-defined, especially near the earth's surface, and for this reason is not represented in routine analysis of weather maps. *See* WEATHER MAP.

The wind gradient, or shear, like the temperature gradient, is larger within the frontal zone than on either size of it. In well-developed fronts the shift in wind direction often is concentrated along the frontal surface, while a more gradual change in wind speed may occur throughout the frontal zone. An upper-level jet stream normally is situated above the frontal zone. *See* JET STREAM. [S.E.M.]

Frost A covering of ice in one of several forms produced by the freezing of supercooled water droplets on objects colder than 32°F (0°C). The partial or complete killing of vegetation, by freezing or by temperatures somewhat above freezing for certain sensitive plants, also is called frost. Air temperatures below 32°F (0°C) sometimes are reported as "degrees of frost"; thus, 10°F (−12°C) is 22 degrees of frost (this usage is confined to the Fahrenheit scale and is not applied to Celsius temperatures).

Frost forms in exactly the same manner as dew except that the individual droplets that condense in the air a fraction of an inch from a subfreezing object are themselves supercooled, that is, colder than 32°F (0°C). When the droplets touch the cold object, they freeze immediately into individual crystals. When additional droplets freeze as soon as the previous ones are frozen, and hence are still close to the melting point because all the heat of fusion has not been dissipated, amorphous frost or rime results.

At more rapid rates of condensation, the drops form a thin layer of liquid before freezing, and glaze or glazed frost ("window ice" on house windows, "clear ice" on aircraft) generally follows. Glaze formation on plants, buildings and other structures, and especially on wires sometimes is called an ice storm, a silver frost storm, or thaw.

At slower deposition rates, such that each crystal cools well below the melting point before the next joins it, true crystalline or hoar frosts form. These include fernlike assemblages on snow surfaces, called surface hoar; similar feathery plumes in cold buildings, caves, and crevasses, called depth hoar; and the common window frost or ice flowers on house windows.

Killing frosts or freezes damage or kill vegetation depending on their duration and their intensity, that is, how far the plant temperatures go below 32°F (0°C). Such conditions result from advection of much colder air, which then cools the plants, as in the infamous cold waves of the north-central United States; or from radiational cooling of the plants themselves, by long-wave radiation to clear skies at night. In either case, the extent to which plant fluids freeze determines the severity of the frost. *See* AIR TEMPERATURE; DEW; DEW POINT. [A.Cou.]

Froude number The dimensionless quantity $U(gL)^{-1/2}$, where U is a characteristic velocity of flow, g is the acceleration of gravity, and L is a characteristic length. The Froude number can be interpreted as the ratio of the inertial to gravity forces in the flow. This ratio may also be interpreted physically as the ratio between the mean flow velocity and the speed of an elementary gravity (surface or disturbance) wave traveling over the water surface. *See* WAVE MOTION IN LIQUIDS.

When the Froude number is equal to one, the speed of the surface wave and that of the flow is the same. The flow is in the critical state. When the Froude number is less than one, the flow velocity is smaller than the speed of a disturbance wave traveling on the surface. Flow is considered to be subcritical (tranquil flow). Gravitational forces are dominant. The surface wave will propagate upstream and, therefore, flow profiles are calculated in the upstream direction. When the Froude number is greater than one, the flow is supercritical (rapid flow) and inertial forces are dominant. The surface wave will not propagate upstream, and flow profiles are calculated in the downstream direction.

The Froude number is useful in calculations of hydraulic jump, design of hydraulic structures, and ship design, where forces due to gravity and inertial forces are governing. In these cases, geometric similitude and the same value of the Froude number in model and prototype produce a good approximation to dynamic similitude. *See* DIMENSIONAL ANALYSIS; DIMENSIONLESS GROUPS; HYDRAULICS; SHIP DESIGN. [R.M.Wr.]

Fructose A sugar that is the commonest of ketoses and the sweetest of the sugars. It is also known as D-fructose, D-fructopyranose, and levulose fruit sugar. It is found in free state, usually accompanied by D-glucose and sucrose in fruit juices, honey, and nectar of plant glands. D-Fructose is the principal sugar in seminal fluid. *See* CARBOHYDRATE.

Fructose is readily utilized by diabetic animals. In persons with diabetes mellitus or parenchymal hepatic disease, the impairment of fructose tolerance is relatively small and not at all comparable to the diminution in their tolerance to glucose. *See* MONOSACCHARIDE. [W.Z.H.]

Fruit A matured carpel or group of carpels (the basic units of the gynoecium or female part of the flower) with or without seeds, and with or without other floral or shoot parts (accessory structures) united to the carpel or carpels. Carpology is the study of the morphology and anatomy of fruits. The ovary develops into a fruit after fertilization and usually contains one or more seeds, which have developed from the fertilized ovules. Parthenocarpic fruits usually lack seeds. Fruitlets are the small fruits or subunits of aggregate or multiple fruits. Flowers, carpels, ovaries, and fruits are, by definition, restricted to the flowering plants (angiosperms), although fruitlike structures may enclose seeds in certain other groups of seed plants. The fruit is of ecological significance because of seed dispersal. *See* SEED.

Morphology. A fruit develops from one or more carpels. Usually only part of the gynoecium, the ovary, develops into a fruit; the style and stigma wither. Accessory (extracarpellary or noncarpellary) structures may be closely associated with the carpel or carpels and display various degrees of adnation (fusion) to them, thus becoming part of the fruit. Such accessory parts include sepals (as in the mulberry), the bases of sepals, petals, and stamens united into a floral tube (apple, banana, pear, and other species with inferior ovaries), the receptacle (strawberry), the pedicel and receptacle (cashew), the peduncle (fleshy part of the fig), the involucre composed of bracts and bracteoles (walnut and pineapple), and the inflorescence axis (pineapple). *See* FLOWER.

A fruit derived from only carpellary structures is called a true fruit, or, because it develops from a superior ovary (one inserted above the other floral parts), a superior fruit (corn, date, grape, plum, and tomato). Fruits with accessory structures are called accessory (or inaptly, false or spurious) fruits (pseudocarps), or, because of their frequent derivation from inferior ovaries (inserted below the other floral parts), inferior fruits (banana, pear, squash, and walnut).

Fruits can be characterized by the number of ovaries and flowers forming the fruit. A simple fruit is derived form one ovary, an aggregate fruit from several ovaries of one flower (magnolia, rose, and strawberry). A multiple (collective) fruit is derived from the ovaries and accessory structures of several flowers consolidated into one mass (fig, pandan, pineapple, and sweet gum).

The fruit wall at maturity may be fleshy or, more commonly, dry. Fleshy fruits range from soft and juicy to hard and tough. Dry fruits may be dehiscent, opening to release seeds, or indehiscent, remaining closed and containing usually one seed per fruit. Fleshy fruits are rarely dehiscent.

The pericarp is the fruit wall developed from the ovary. In true fruits, the fruit wall and pericarp are synonymous, but in accessory fruits the fruit wall includes the pericarp plus one or more accessory tissues of various derivation. Besides the fruit wall, a fruit contains one or more seed-bearing regions (placentae) and often partitions (septa).

Anatomy. Anatomically or histologically, a fruit consists of dermal, ground (fundamental), and vascular systems and, if present, one or more seeds. After fertilization the ovary and sometimes accessory parts develop into the fruit; parthenocarpy is fruit production without fertilization. The fruit generally increases in size and undergoes various anatomical changes that usually relate to its manner of dehiscence, its mode of dispersal, or protection of its seeds. The economically important, mainly fleshy fruits have received the most histological and developmental study.

Size increase of fruits is hormonally controlled and results from cell division and especially from cell enlargement. Cell number, volume, and weight thus control fruit weight. Cell division generally is more pronounced before anthesis (full bloom); cell enlargement is more pronounced after.

Functional aspects. Large fruits generally require additional anatomical modifications for nutrition or support or both. The extra phloem in fruit vascular bundles and the often increased amount of vascular tissue in the fruit wall and septa supply nutrients to the developing seeds and, especially in fleshy fruits, to the developing walls. Large, especially fleshy fruits (apple, gourd, and kiwi) usually contain proportionally more vascular tissue than small fruits. Vascular tissue also serves for support and in lightweight fruits may be the chief means of support.

Crystals, tannins, and oils commonly occur in fruits and may protect against pathogens and predators. The astringency of tannins, for example, may be repellent to organisms. With fruit maturation, tannin content ordinarily decreases, so the tannin repellency operative in early stages is superseded in fleshy fruits by features (tenderness, succulence, sweetness through odor and increased sugar content, and so on) attractive to animal dispersal agents. Many fruits are dispersed by hairs, hooks, barbs, spines, and sticky mucilage adhering the fruit to the surface of the dispersal agent. Lightweight fruits with many air spaces or with wings or plumes may be dispersed by wind or water. Gravity is always a factor in dispersal of fruits and seeds. [R.S.]

Fruit, tree Tree fruits include temperate, subtropical and tropical zone species. Most temperate zone fruits are grown principally in regions protected from prolonged summer heat and severe winter cold (above −10 to −15°F or −23 to −26°C). The principal deciduous tree fruits grown in the United States are apple, peach, pear, plum, apricot, sweet cherry, tart cherry, and nectarine. Tree nuts, such as almond, pecan, walnut, and filbert, are sometimes classified as deciduous tree fruit crops.

Most subtropical fruit trees are evergreen. They will withstand temperatures somewhat below freezing during their dormant or semidormant season, but not the extreme temperatures tolerated by the temperate zone crops. Major subtropical fruits in the United States are the citrus group (for example, orange, grapefruit, lemon), olive, avocado, fig, and others of lesser importance. The Japanese persimmon might be considered as a borderline case between the temperate and subtropical zone groups, and avocado is often classed as a tropical fruit.

The tree fruit crops are grown commercially in orchards or groves, usually in single rows which permit necessary cultural operations for each tree. Nearly all tree fruit crops have similar requirements of training, pruning, spraying to control diseases and insects, and cultivation or chemical control of weeds. [R.P.L.]

Fucales A large and diverse order of conspicuous brown algae (Phaeophyceae) including such well-known seaweeds as *Fucus* and *Sargassum*. Definitive features include apical growth, production of sex organs in cavities, and a life history with only one somatic phase, which is diploid. The mature thallus consists typically of a holdfast from which arise several axes with dichotomous or radial primary branching. Sexual reproduction is oogamous, with oogonia and antheridia produced in flask-shaped cavities called conceptacles.

In the family Fucaceae (rockweeds), the thallus typically is composed of a discoid or conical holdfast with a cluster of erect fronds that are branched dichotomously in one plane. *Fucus* is common throughout the North Atlantic and North Pacific. *Pelvetia* is also common in the Northern Hemisphere, but is not found on the American side of the Atlantic. *Ascophyllum* occurs abundantly in the North Atlantic, both in exposed sites and in estuaries far from the open sea. In subtropical and tropical regions of all oceans, the family Sargassaceae is common, dominating the biomass of benthic seaweeds. The holdfast is discoid, conical, hapteroid (with root-like outgrowths), or rhizomatous. *Sargassum* is by far the largest and most important genus in the Sargassaceae. Hundreds of species and varieties have been described.

Rockweeds are well known to coastal peoples of the temperate regions of the Northern Hemisphere. Traditionally, the seaweed was either plowed into the soil as a green manure or burned to an ash that was spread on the fields. In modern chemical industry, *Ascophyllum* is an important source of alginate, especially in Norway. *See* ALGAE; ALGINATE; PHAEOPHYCEAE. [P.C.Si.; R.L.Moe]

L-Fucose A methyl pentose (also known as 6-deoxy-L-galactose, L-galactomethylose, L-rhodeose, and L-fucopyranose) present in some algae (seaweed), especially in *Laminaria digitata*, and in a number of gums; it has been identified in the polysaccharides of blood group–specific substances from animal and human sources. L-Fucose has also been found to be a constituent of certain bacterial polysaccharides. *See* BLOOD GROUPS; MONOSACCHARIDE. [W.Z.H.]

Fuel cell An electrical cell that converts the intrinsic chemical free energy of a fuel directly into direct-current electrical energy in a continuous catalytic process. As in the classical definition of catalysis, the fuel cell should not itself undergo change; that is, unlike the electrodes of a battery, its electrodes ideally remain invariant. For most fuel-oxidant combinations, the available free energy of combustion is somewhat less than the heat of combustion. In a typical thermal power conversion process, the heat of combustion of the fuel is turned into electrical work via a Carnot heat-engine cycle coupled with a rotating electrical generator. Since the Carnot conversion rarely proceeds at an efficiency exceeding 40% because of heat source and sink temperature limitations, the efficiency of conversion in a fuel cell

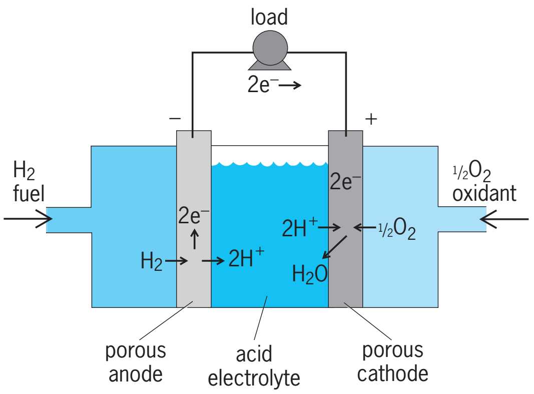


Diagram showing the principle of operation of a fuel cell. (*After A. J. Appleby and F. R. Foulkes, Fuel Cell Handbook, Van Nostrand Reinhold, 1989*)

can be greater than in a heat engine, especially in small devices. *See* CARNOT CYCLE; CATALYSIS.

The fuel cell reaction usually involves the combination of hydrogen (H) with oxygen (O)

$$H_2(g) + {}^1/_2O_2(g) \rightarrow H_2O(l)$$

as shown in the illustration. Under standard conditions of temperature and pressure, 25°C (77°F) and 1 atm (100 kilopascals), the reaction takes place with a free-energy change $\Delta G = -56.69$ kcal (237 kilojoules) per mole of water. Since the formation of water involves two electrons, this value corresponds to −1.23 electronvolts (1 eV = 23.06 kcal/equivalent). Thus, at thermodynamic equilibrium (zero current), the cell voltage should be 1.23 V, yielding a theoretical efficiency based on the heat of combustion [ΔH for $H_2O(l) = -1.48$ eV] of 83.1%. *See* FREE ENERGY.

At a net (nonzero) current, all cells show losses in cell voltage (V). In low-temperature fuel cells, these are due largely to the kinetic slowness (irreversibility) of the oxygen reduction reaction, which requires the breaking of a double bond with transfer of four electrons per molecule in a complex sequence of reactions. In high-temperature systems, oxygen reduction losses are less significant, since the reaction rate increases with temperature. However, the available free energy then decreases, falling to a value corresponding to about 1.0 V at 1000°C (1832°F). A further thermodynamic loss results from high cell fuel (or oxidant) conversion to avoid waste, so that the effective reversible potential is displaced from the standard state. Thus, at high temperature, the major loss is thermodynamic, which tends to compensate for the irreversible oxygen electrode losses at low temperature. As a result, cell voltages under typical loads vary from about 0.6 V for simple terrestrial cells to 1.0 V for aerospace cells. Cell voltage falls with increasing current per unit area. Since thermal efficiency is given by $V/1.48$, cell performance is a compromise between relative cost (that is, kilowatts available per unit area) and fuel efficiency, to give the lowest cost of electricity for a given application. *See* OXIDATION-REDUCTION.

While any chemically suitable fuel, including metals such as lithium (Li), sodium (Na), aluminum (Al), and zinc (Zn), may be used in a fuel cell, hydrocarbons (for example, natural gas) will not react at a significant rate in low-temperature fuel cells. They will crack thermally before reacting electrochemically if injected directly into high-temperature fuel cells. Simple low-power units operating directly on methanol at ambient temperature do find some use, and liquid-fueled hydrazine cells have also found specialized applications. However, the high manufacturing energy requirement for hydrazine, together with its high cost and hazardous nature, leaves hydrogen the only suitable general high-performance fuel candidate. *See* HYDRAZINE; HYDROGEN; METHANOL.

For practical fuel cells, hydrogen can be produced from readily available fuels such as clean light distillate (for example, naphtha), usually by steam reforming, or from coal via gasification at high temperature (the direct use of coal or carbon has been abandoned). In the high-temperature cells under certain conditions, internal steam reforming of simple hydrocarbons and alcohols (for example methane and methanol) can take place by the injection of the fuel with steam, which avoids cracking. Since methanol fuel reacts only slowly at low temperature, it is also steam-reformed to hydrogen. Methanol reforming takes place at only about 250°C (480°F), giving mixtures of hydrogen and carbon dioxide (CO_2) with a small amount of carbon monoxide (CO). In contrast, steam reforming of higher-molecular-weight alcohols or clean light distillates requires temperatures in excess of 700°C (1290°F). This favors mixtures of hydrogen and carbon monoxide, as in coal synthesis gas. [A.J.A.]

Fuel gas A fuel in the gaseous state whose potential heat energy can be readily transmitted and distributed through pipes from the point of origin directly to the place of consumption. The types of fuel gases are natural gas, LP gas, refinery gas, coke oven gas, and blast-furnace gas. The last two are used in steel mill complexes.

Most fuel gases are composed in whole or in part of the combustibles hydrogen, carbon monoxide, methane, ethane, propane, butane, and oil vapors and, in some instances, of mixtures containing the inerts nitrogen, carbon dioxide, and water vapor. *See* COAL GASIFICATION; LIQUEFIED NATURAL GAS (LNG); LIQUEFIED PETROLEUM GAS (LPG); NATURAL GAS. [J.Hu.]

Fuel injection The pressurized delivery of a metered amount of fuel into the intake airflow or combustion chambers of an internal combustion engine. Metering of the fuel charge may be performed mechanically or electronically. In a diesel engine, the fuel is injected directly into the combustion chamber (direct injection) or into a smaller connected auxiliary chamber (indirect injection). In the spark-ignition engine, the fuel is injected into the air before it enters the combustion chamber by spraying the fuel into the airstream passing through the throttle body (throttle-body injection) or into the air flowing through the port to the intake valve (port injection). *See* COMBUSTION CHAMBER.

The diesel engine must be supplied with fuel from the injection nozzle at a pressure of 1500–5000 lb/in.^{2} (10–35 megapascals) for indirect-injection engines, and up to 15,000 lb/in.^{2} (100 MPa) or higher for direct-injection engines. The high pressure is necessary to deliver fuel against the highly compressed air in the engine cylinders at the end of the compression stroke, and to break up the fuel oil which has low volatility and is often viscous. Extremely accurate fuel metering is necessary, with the start of injection occurring within a precision of up to 1° of engine crankshaft angle. A timing device in the injection pump automatically advances the start of fuel delivery as engine speed increases to optimize the start of combustion.

The intake air is not throttled in a diesel engine, with load and speed control accomplished solely by controlling the quantity of fuel injected. The mean effective pressure developed by combustion is controlled by the volumetric capacity of the injection pump. To prevent an unloaded diesel engine from increasing in speed until it destroys itself, a governor is required to limit maximum engine speed. *See* DIESEL CYCLE; DIESEL ENGINE; GOVERNOR; INTERNAL COMBUSTION ENGINE; MEAN EFFECTIVE PRESSURE.

On automotive spark-ignition engines, the carburetor has largely been replaced by a gasoline fuel-injection system with either mechanical or electronic control of fuel metering. Many of the systems are of the speed-density type, in which the mass airflow rate is calculated based on cylinder displacement and the measured intake-manifold absolute pressure (engine load), engine speed, intake-manifold air temperature, and theoretical volumetric efficiency. When the feedback signal from an exhaust-gas oxygen sensor is included, these systems allow the engine air-fuel ratio to be maintained near the stoichiometric ratio (14.7:1) during normal operating conditions. This minimizes exhaust emissions. *See* Carburetor.

In the typical gasoline fuel-injection system, an electric fuel pump provides a specified fuel flow at the required system pressure to one or more fuel-injection valves, or fuel injectors. The gasoline fuel injector is an electromagnetic (solenoid-operated) or mechanical device used to direct delivery of or to meter pressurized fuel, or both. A fuel-pressure regulator maintains a controlled fuel pressure at each injector, or a controlled differential pressure across the injector. *See* Fuel pump; Fuel system. [D.L.An.]

Fuel oil Any of the petroleum products which are less volatile than gasoline and are burned in furnaces, boilers, or other types of heaters. The two primary classes of fuel oils are distillate and residual. Distillate fuel oils are composed entirely of material which has been vaporized in a refinery distillation tower. Consequently, they are clean, free of sediment, relatively low in viscosity, and free of inorganic ash. Residual fuel oils contain fractions which cannot be vaporized by heating. These fractions are black and viscous and include any inorganic ash components which are in the crude. In some cases, whole crude is used as a residual fuel.

Distillate fuel oils are used primarily in applications where ease of handling and cleanliness of combustion are more important than fuel price. The most important use is for home heating. They are also used in certain industrial applications where low sulfur or freedom from ash is important. Increasing amounts of distillate fuel oils have been burned in gas turbines used for electricity generation. *See* Gas turbine.

Residual fuel oils are used where fuel cost is an important enough economic factor to justify additional investment to overcome the handling problems they pose. They are particularly attractive where large volumes of fuel are used, as in electric power generation, industrial steam generation, process heating, and steamship operation. *See* Electric power generation; Oil furnace. [C.W.S.]

Fuel pump A mechanical or electrical pump for drawing fuel from a storage tank and forcing it to an engine or furnace. The type of pump chosen for a given fuel depends to a great extent on the volatility of the liquid to be pumped. In a gasoline engine the fuel is highly volatile at ambient temperature. Therefore, the fuel line is completely sealed from the tank to the carburetor or fuel-injection system to prevent escape of fuel and to enable the pump to purge the line of vapor in the event of vapor lock—a condition in which the fuel vaporizes owing to abnormally high ambient temperature. *See* Carburetor; Fuel injection; Fuel system.

Most carbureted gasoline engines use a spring-loaded diaphragm-type mechanical pump which is normally actuated by a rocker arm or pushrod that rides on an eccentric on the engine camshaft. Electric motor-driven and solenoid-operated diaphragm pumps and plunger pumps are also available that can be mounted near the main fuel tank to minimize vapor lock in the fuel lines. Many gasoline-engine vehicles have a submersible electric fuel pump, which serves as the main supply pump, located in the fuel tank. In some fuel-injection systems, the in-tank pump is used as the supply pump for a high-pressure fuel-injection pump. The in-tank pump may be of the gear, plunger, sliding-vane, or impeller type.

Diesel engines normally use a gear, plunger, or vane-type pump to supply fuel to the injection pump. In the diesel engine, where fuel is injected at high pressure through an injection nozzle into the highly compressed air in the combustion chamber, a plunger or piston serves as its own inlet valve and as the compression member of the injection pump. When the required high pressure is reached in the injection nozzle, a spring-biased needle valve opens and fuel sprays into the combustion chamber. In an oil-fired furnace, although nozzle pressures need not be so high as in diesel engines, a piston pump is also used to provide positive shutoff of the fuel line when the pump stops. *See* Diesel engine. [D.L.An.]

Fuel system The system that stores fuel for present use and delivers it as needed to an engine; includes the fuel tank, fuel lines, pump, filter, vapor return lines, carburetor or injection components, and all fuel system vents and evaporative emission control systems or devices that provide fuel supply and fuel metering functions. Some early vehicles and other engines had a gravity-feed fuel system, in which fuel flowed to the engine from a tank located above it. Automotive and most other engines have a pressurized fuel system with a pump that draws or pushes fuel from the tank to the engine. *See* Carburetor; Fuel injection; Fuel pump.

Automobile. The commonly used components for automobile and stationary gasoline engines are fuel tank, fuel gage, filter, electric or mechanical fuel pump, and carburetor or fuel-injection system. In the past, fuel metering on automotive engines was usually performed by a carburetor. However, this device has been largely replaced by fuel injection into the intake manifold or ports, which increases fuel economy and efficiency while lowering exhaust gas emissions. Various types of fuel management systems are used on automotive engines, including electronically controlled feedback carburetors, mechanical continuous fuel injection, and sequential electronic fuel injection. *See* Automobile. [D.L.An.]

Aircraft. The presence of multiple engines and multiple tanks complicates the aircraft fuel system. Also, the reduction of pressure at altitude necessitates the regular use of boost pumps, submerged in the fuel tanks, which are usually of the centrifugal type and electrically driven. These supplement the engine-driven fuel supply pumps, which are usually of the gear or eccentric vane type. Components of a typical aircraft fuel system include one main and two auxiliary tanks with their gages; booster, transfer, and engine-driven pumps; various selector valves; and a fuel jettisoning or defuel valve and connection, which is typical also of what would be needed for either single-point ground or flight refueling (see illustration). The arrangement is usually such that all the fuel supply will pass to the engines by way of the main tank, which is refilled as necessary from the auxiliary tanks. In case of emergency, the system selector valve may connect the auxilary tanks to the engines directly. Tank vents, not shown, are

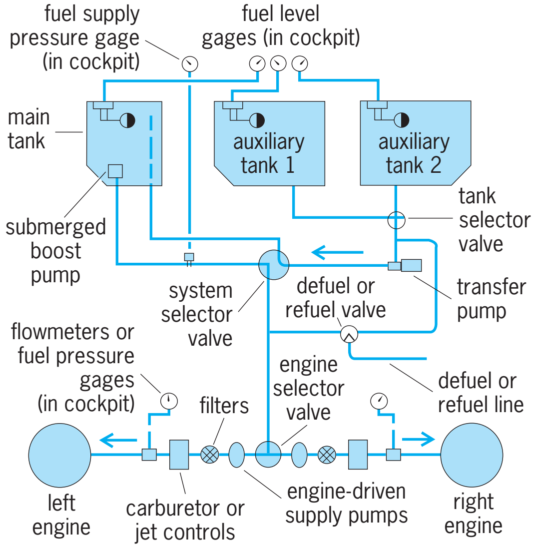

Diagram of a typical aircraft fuel system.

arranged so that overflow will go safely overboard. *See* Aircraft engine. [J.A.B.]

Fugacity A function introduced by G. N. Lewis to facilitate the application of thermodynamics to real systems. Thus, when fugacities are substituted for partial pressures in the mass action equilibrium constant expression, which applies strictly only to the ideal case, a true equilibrium constant results for real systems as well.

The fugacity f_i of a constituent i of a thermodynamic system is defined by the following equation (where μ_i is the chemical potential and μ_i^* is a function of temperature only), in combination with the requirement that the fugacity approach the partial pressure as the total pressure of the gas phase approaches zero. At a given temperature, this is possible only for a particular value for μ_i^*, which may be shown to correspond to the chemical potential the constituent would have as the pure gas in the ideal gas state at 1 atm pressure. This definition makes the fugacity identical to the partial pressure in the ideal gas case. For real gases, the ratio of fugacity to partial pressure, called the fugacity coefficient, will be close to unity for moderate temperatures and pressures. At low temperatures and appropriate pressures, it may be as small as 0.2 or less, whereas at high pressures at any temperature it can become very large. *See* Activity (thermodynamics); Chemical equilibrium; Chemical thermodynamics; Gas. [P.J.B.]

$$\mu_i = \mu_i^* + RT \ln f_i$$

Fullerene A hollow, pure carbon molecule in which the atoms lie at the vertices of a polyhedron with 12 pentagonal faces and any number (other than one) of hexagonal faces. The molecule was named after R. Buckminster Fuller, the inventor of geodesic domes, which conform to the same underlying structural formula.

Buckminsterfullerene (C_{60} or fullerene-60; Fig. 1) is the archetypal member of the fullerenes. Other stable members of the fullerene family have similar structures (Fig. 2). The fullerenes can be considered, after graphite and diamond, to be the third well-defined allotrope of carbon. Macroscopic amounts of various fullerenes were first isolated in 1990, and since that time it has been discovered that members of this class of spheroidal organic molecules have numerous novel physical and chemical properties. The fullerenes promise to have synthetic, pharmaceutical, and industrial applications. Derivatives have been found to exhibit fascinating electrical and magnetic behavior, in particular superconductivity and ferro-magnetism. *See* Carbon; Diamond; Graphite.

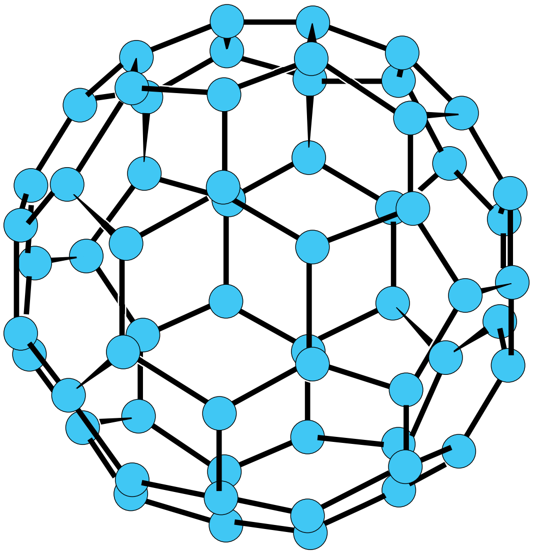

Fig. 1. Structure of fullerene-60 (C_{60}).

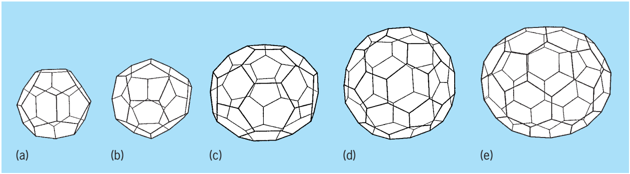

Fig. 2. Some of the more stable members of the fullerene family. (*a*) C_{28}. (*b*) C_{32}. (*c*) C_{50}. (*d*) C_{60}. (*e*) C_{70}.

Structures and properties. In the fullerene molecule an even number of carbon atoms are arrayed over the surface of a closed hollow cage. Each atom is trigonally linked to its three near neighbors by bonds that delineate a polyhedral network, consisting of 12 pentagons and *n* hexagons. (Such structures conform to Euler's theorem for polyhedrons in that *n* may be any number other than one including zero.) All 60 atoms in fullerene-60 are equivalent and lie on the surface of a sphere distributed with the symmetry of a truncated icosahedron. The 12 pentagons are isolated and interspersed symmetrically among 20 linked hexagons.

In benzene solution, fullerene-60 is magenta and fullerene-70 red. Fullerene-60 forms translucent magenta face-centered cubic (fcc) crystals that sublime. The ionization energy is 7.61 eV and the electron affinity is 2.6–2.8 eV. The strongest absorption bands lie at 213, 257, and 329 nanometers. Studies with nuclear magnetic resonance spectroscopy yield a chemical shift of 142.7 parts per million; this result is commensurate with an aromatic system.

Solid C_{60} exhibits interesting dynamic behavior in that at room temperature the individual round molecules in the face-centered cubic crystals are rotating isotropically (that is, freely) at around 10^8 Hz. At around 260 K (8.3°F) there is a phase transition to a simple cubic (sc) lattice accompanied by an abrupt lattice contraction. Rotation is no longer free, and the individual molecules make rotational jumps between two favored (relative) orientational configurations—in the lower-energy one a double bond lies over a pentagon, and in the other it lies over a hexagon. At 90 K (−300°F) the individual molecules stop rotating altogether, freezing into an orientationally disordered crystal involving a mix of the two configurations. *See* Crystal.

Chemistry and formation. Fullerene-60 behaves as a soft electrophile, a molecule that readily accepts electrons during a primary reaction step. It can readily accept three electrons and perhaps even more. The molecule can be multiply hydrogenated, methylated, ammonated, and fluorinated. It forms exohedral complexes in which an atom (or group) is attached to the outside of the cage, as well as endohedral complexes in which an atom is trapped inside the cage.

The C_{60} molecule behaves as though it has only a single resonance form—one in which the 30 double bonds are localized in the bonds that interconnect the pentagons. This is a key factor, as addition to these double bonds is the most important reaction as far as the application of C_{60} in synthesis is concerned.

On exposure of C_{60} to certain alkali and alkaline earth metals, exohedrally doped crystalline materials are produced that exhibit superconductivity at relatively high temperatures (10 to 33 K or −440 to −400°F). The C_{60} molecule has a triply degenerate lowest unoccupied molecular orbital (LUMO), which in the superconducting materials is half filled, containing three electrons. Other ionic phases, such as M_nC_{60} ($n = 1, 2, 4, 6$, where M is the intercalated metal atom), exist but are not superconducting—they appear to be metallic or semiconductor/insulators. *See* Molecular orbital theory; Superconductivity.

Perhaps the most important aspect of the fullerene discovery is that the molecule forms spontaneously. This fact has important implications for understanding the way in which extended carbon materials form, and in particular the mechanism of graphite growth and the synthesis of large polycyclic aromatic molecules. It has become clear that as far as pure carbon aggregates of around 60–1000 atoms are concerned, the most stable species are closed-cage fullerenes. [J.Hare; H.W.Kr.]

Fuller's earth Any natural earthy material that decolorizes mineral and vegetable oils and has high sorbent capacity for water and oil. The term fuller's earth has no genetic or mineralogic significance. However, the most common earthy materials classed as fuller's earth are calcium montmorillonites and palygorskites (attapulgites) and sepiolites. The term originated in England, where in ancient times raw wool was cleaned by kneading it in water with clay materials that adsorbed dirt and lanolin. The process was known as fulling, and the clay or earth became known as fuller's earth. *See* ADSORPTION; MONTMORILLONITE; SEPIOLITE.

Several clay deposits in the world are mined and processed for their absorbent, adsorbent, and decolorizing or bleaching properties. Some clays have a high natural decolorizing ability; however, in most instances a clay, normally a calcium montmorillonite, is acid-activated to enhance its bleaching or decolorizing properties. Sulfuric acid is commonly used, and in the treatment process sodium, calcium, magnesium, and iron that occupy the cation exchange sites on the clay surface are removed by the acid and replaced by hydrogen. Also, some aluminum, iron, or magnesium is removed from the mineral structure, increasing the negative charge on the clay surface. These highly charged surfaces covered with hydrogen ions selectively absorb the color bodies and other impurities in the oil. *See* CLAY; CLAY MINERALS.

The largest applications for fuller's earth are as sorbents, and by far the biggest market is pet-litter production. Other large sorbent applications are as carriers for insecticides, pesticides, and fertilizers used in agriculture and as absorbers of oil and water spills on the floors of machine shops, factories, service stations, and other manufacturing plants for safety purposes. [H.H.Mu.]

Fulminate A compound containing the —ONC group and derived from fulminic acid, HONC. Fulminates are isomeric with cyanates; that is, cyanates have the same atoms but in different arrangement, —OCN.

The fulminates have been commercially important because of the use of mercury fulminate, $Hg(ONC)_2$, in priming compositions and as an initial detonating agent; lead azide is replacing mercury fulminate as a detonating agent. *See* CYANATE. [E.E.W.]

Fumigant A pesticidal chemical or chemical formulation that functions in a gaseous state. Chemical formulations are designed to increase toxicity, reduce flammability, give off warning odors, and provide for sorption at different rates.

Physical types of fumigants include gases, liquids, and solids. There are several chemical types of fumigants. These include: halogenated hydrocarbons, such as carbon tetrachloride and ethylene dibromide; sulfur-containing compounds, such as carbon disulfide and sulfur dioxide; cyanides, such as hydrogen cyanide and calcium cyanide; and others, such as phosphine and ethylene dioxide.

Fumigants are used in space fumigations to disinfest food-processing plants, warehouses, grain elevators, boxcars, shipholds, stores, and households, and in spot fumigations within those structures. They are used in atmospheric vaults and vacuum chambers and are applied extensively to stacked bags of grain or stored foods under polyethylene sheets, to trees under tents to control scale insects, and to areas of land to destroy weeds, soil-infesting insects, and nematodes. [D.A.W.]

Funariales An order of the true mosses (subclass Bryidae). The Funariales, often annuals or biennials and sometimes ephemeral, are for the most part characterized by a uniformity of gametophytic structure in contrast to a variability of sporophytic characters. Reduction in sporophytic characters is often associated with disturbed habitats and a shortened life cycle.

The plants are generally small or minute, growing scattered or tufted mostly on soil. The stems are erect, and the leaves, inserted in numerous rows, are usually broadly oblong-lingulate and rounded-to-acuminate at the apex, with a single costa. The leaf cells are lax, thin-walled, and smooth, or less commonly papillose because of projecting upper ends. The sporophytes are terminal with variable seta length. The capsules are generally exserted, erect, and symmetric but sometimes inclined and strongly asymmetric, ovoid to pyriform, and often with a noticeably differentiated sterile neck. The spores may be spherical or tetrahedral, while the calyptra may be cucullate or mitrate.

The Funariales include five families (Funariaceae, Gigaspermaceae, Disceliaceae, Pseudoditrichaceae, and Splachnobryaceae), and are heterogeneous in composition. *See* BRYIDAE; BRYOPHYTA; BRYOPSIDA. [H.Cr.]

Function generator An electronic instrument which generates periodic voltage or current waveforms that duplicate various types of well-defined mathematical functions. The simplest function generator usually generates a combination of square waves, triangular waves, and sine waves.

One electronic circuit approach to the design of a simple function generator is to begin with a bistable multivibrator or "flip-flop" controlled in time by a succession of clock pulses which generates the square wave. The triangular waveform is obtained by integrating the square wave through the use of the operational amplifier integrator. The sine wave is obtained by applying the triangular wave to a shaping circuit consisting of a combination of resistors and diodes. *See* AMPLIFIER; MULTIVIBRATOR; WAVE-SHAPING CIRCUITS.

Alternatively the sine wave may be generated by a sinusoidal oscillator. From this output, the square wave may be obtained by amplication, limiting, and clipping of the sine wave. Then the triangular wave may be obtained using an integrator as before. *See* LIMITER CIRCUIT.

A combination of counters, programmed read-only memories (PROMS), and a digital-to-analog converter can be used as a function generator, generating almost any function desired to almost any degree of accuracy. *See* COMPUTER STORAGE TECHNOLOGY; DIGITAL-TO-ANALOG CONVERTER. [G.M.G.]

Functional analysis and modeling (engineering) The discipline that addresses the activities that a system, a software, or an organization must perform to achieve its desired outputs; that is, what transformations are necessary to turn the available inputs into the desired outputs. Additional considerations include the flow of data or items between functions, the processing instructions that are available to guide the transformations, and the control logic that dictates the activation and termination of functions. Functional analysis diagrams have been developed to capture some or all of these concepts.

Functional analysis is performed in systems engineering, software systems engineering, and business process reengineering as a portion of the design process. These design processes typically involve the steps of requirements definition and analysis, functional analysis, physical or resource definition, and operational analysis. This last step of operational analysis involves the marriage of functions with resources to determine if the requirements are met. The concept of examining the logical architecture via functional analysis concurrent with the development of the physical architecture has become a well-accepted principle in the related fields of systems engineering, software engineering, and business process reengineering. *See* REENGINEERING; SOFTWARE ENGINEERING; SYSTEMS ENGINEERING.

Elements. There are four elements to be addressed by any specific functional analysis approach. First, the functions are represented as a hierarchical decomposition, in which there is a top-level function for the system or organization. The top-level function is partitioned into a set of subfunctions that use the same inputs and produce the same outputs as the top-level function. Each of these subfunctions can then be partitioned further, with the decomposition process continuing as often as it is useful.

Second, functional analysis diagrams can represent the flow of data or items among the functions within any portion of the functional decomposition. As the first and subsequent functional decompositions are examined, it is common for one function to produce outputs that are not useful outside the boundaries of the system or organizations. These outputs are needed by other functions in order to produce the needed and expected external outputs.

Processing instructions are a third element that appear in some functional analysis diagrams. These instructions contain the needed information for the functions to transform the inputs to the outputs.

The fourth element is the control flow that sequences the termination and activation of the functions so that the process is both efficient and effective.

Feedback and control. Feedback plays an important role in functional analysis and modeling. Feedback and control is the comparison of the actual characteristics of an output with desired characteristics of that output for the purpose of adjusting the process of transforming inputs into that output. Open-loop control processes may or may not make this measurement, but in either case make no adjustments to the process once started. Closed-loop control processes use measurements of the output as feedback for the purpose of adjusting or controlling the transformation process. [D.M.B.]

Fundamental constants That group of physical constants which play a fundamental role in the basic theories of physics. These constants include the speed of light in vacuum, c; the magnitude of the charge on the electron, e, which is the fundamental unit of electric charge; the mass of the electron, m_e; Planck's constant, $\hbar$; and the fine-structure constant, α.

These five quantities typify the different origins of the fundamental constants: c and $\hbar$ are examples of quantities which appear naturally in the mathematical formulation of certain physical theories—Einstein's theories of relativity, and quantum theory, respectively; e and m_e are examples of quantities which characterize the elementary particles of which all matter is constituted; and α, the fundamental constant of quantum electrodynamics (QED), is an example of quantities which are combinations of other fundamental constants, but are actually constants in their own right since the same combination always appears together in the basic equations of physics.

Reliable numerical values for the fundamental physical constants are required for two main reasons. First, they are necessary if quantitative predictions from physical theory are to be obtained. Second, and even more important, the self-consistency of the basic theories of physics can be critically tested by a careful intercomparison of the numerical values of fundamental constants obtained from experiments in the different fields of physics. In general, the accuracy of fundamental constants determinations has continually improved over the years. Whereas in the past, 100 ppm (0.01%) and even 1000 ppm (0.1%) measurements were commonplace, today 0.01 ppm and better determinations are not unusual (ppm = parts per million).

Complex relationships can exist among groups of constants and conversion factors, and a particular constant may be determined either directly by measurement or indirectly by an appropriate combination of other directly measured constants. If the direct and indirect values have comparable accuracy, then both must be taken into account in order to arrive at a best value for that quantity. (By best value is meant that value believed to be closest to the true but unknown value.) Generally, each of the several routes which can be followed to a particular constant, both direct and indirect, will give a slightly different numerical value. Such a situation may be satisfactorily handled by the mathematical method known as least-squares. This technique provides a self-consistent procedure for calculating best "compromise" values of the constants from all of the available data. It automatically takes into account all possible routes and determines a single final value for each constant being calculated. It does this by weighting the different routes according to their relative uncertainties. The appropriate weights follow from

Recommended values (1986) of selected fundamental physical constants

Quality	Symbol	Numerical value*	Units†	Relative uncertainty, ppm
Speed of light in vacuum	c	299792458	m/s	(defined)
Constant of gravitation	G	6.67259(85)	10^{-11} m^3/(kg · s^2)	128
Planck constant	h	6.6260755(40)	10^{-34} J · s	0.60
Elementary charge	e	1.60217733(49)	10^{-19}C	0.30
Magnetic flux quantum, $h/(2e)$	Φ_0	2.06783461(61)	10^{-15} Wb	0.30
Fine-structure constant,	α	7.29735308(33)	10^{-3}	0.045
$\mu_0 ce^2/(2h)$	α^{-1}	137.0359895(61)		0.045
Electron mass	m_e	9.1093897(54)	10^{-31} kg	0.59
Proton mass	m_p	1.6726231(10)	10^{-27} kg	0.59
Neutron mass	m_n	1.6749286(10)	10^{-27} kg	0.59
Proton-electron mass ratio	m_p/m_e	1836.152701(37)		0.020
Rydberg constant, $m_e c\alpha^2/(2h)$	R_∞	1.0973731534(13)	m^{-1}	0.0012
Bohr radius, $\alpha/(4\pi R_\infty)$	a_0	5.29177249(24)	10^{-11} m	0.045
Compton wavelength of the electron, $h/(m_e c) = \alpha^2/(2R_\infty)$	λ_c	2.42631058(22)	10^{-12} m	0.089
Classical electron radius, $\mu_0 e^2/(4\pi m_e) = \alpha^3/(4\pi R_\infty)$	r_e	2.81794092(38)	10^{-15} m	0.13
Bohr magneton, $eh/(4\pi m_e)$	μ_B	9.2740154(31)	10^{-24} J/T	0.34
Electron magnetic moment in Bohr magnetons	μ_e/μ_B	1.001159652193(10)		10^{-5}
Nuclear magneton, $eh/(4\pi m_p)$	μ_N	5.0507866(17)	10^{-27} J/T	0.34
Proton magnetic moment in nuclear magnetons	μ_p/μ_N	2.792847386(63)		0.023
Boltzmann constant	k	1.380658(12)	10^{-23} J/K	8.5

the uncertainties assigned the individual measurements constituting the original set of data.

The 1986 least-squares adjustment, carried out under the auspices of the CODATA Task Group on Fundamental Constants, succeeded a CODATA adjustment in 1973 by E. R. Cohen and B. N. Taylor; CODATA, the Committee on Data for Science and Technology, is an interdisciplinary committee of the International Council of Scientific Unions. Recommended values are shown in the table. [E.R.Co.]

Fundamental interactions Fundamental forces that act between elementary particles, of which all matter is assumed to be composed.

At present, four fundamental interactions are distinguished. Their properties are summarized in the table.

Properties of the four fundamental interactions

Interaction	Range	Exchanged quanta
Gravitational	Long-range	Gravitons (*g*)
Electromagnetic	Long-range	Photons (γ)
Weak nuclear	Short-range $\approx 10^{-18}$ m	W^+, Z^0, W^-
Strong nuclear	Short-range $\approx 10^{-15}$ m	Gluons (*G*)

The gravitational interaction manifests itself as a long-range force of attraction between all elementary particles.

The electromagnetic interaction is responsible for the long-range force of repulsion of like, and attraction of unlike, electric charges. At comparable distances, the ratio of gravitational to electromagnetic interactions (as determined by the strength of respective forces between an electron and a proton) is approximately 4×10^{-37}. *See* Coulomb's law; Electrostatics; Gravitation.

In modern quantum field theory, the electromagnetic interaction and the forces of attraction or repulsion between charged particles are pictured as arising secondarily as a consequence of the primary process of emission of one or more photons (particles or quanta of light) emitted by an accelerating electric charge (in accordance with Maxwell's equations) and the subsequent reabsorption of these quanta by a second charged particle. A similar picture may also be valid for the gravitational interaction.

The third fundamental interaction is the weak nuclear interaction, which is responsible for the decay of a neutron into a proton, an electron, and an antineutrino. Unlike electromagnetism and gravitation, weak interactions are short-range, the range of the force being of the order of 10^{-18} m.

An important question was finally answered in 1983: Is the weak interaction similar to electromagnetism in being mediated primarily by intermediate objects, the W^+ and W^- particles. The experimental answer, discovered at the CERN laboratory at Geneva, is that W^+ and W^- do exist, with a mass of 80.4 GeV/c^2. Each carries a spin of magnitude $\hbar$, where $\hbar$ is Planck's constant divided by 2π, just as does the photon (γ). The mass of these particles gives the range of the weak interaction. *See* Intermediate vector boson.

Another crucial discovery in weak interaction physics was the neutral current phenomenon in 1973, that is, the discovery of new types of weak interactions where (as in the case of electromagnetism or gravity) the nature of the interacting particles is not changed during the interaction. The 1983 experiments at CERN also gave evidence for the existence of an intermediate particle Z^0, with a mass of 91.2 GeV/c^2, which is believed to mediate such reactions. *See* Neutral currents; Weak nuclear interactions.

The fourth fundamental interaction is the strong nuclear interaction between protons and neutrons, which resembles the weak nuclear interaction in being short-range, although the range is of the order of 10^{-15} m rather than 10^{-18} m. Within this range of distances the strong force overshadows all other forces between protons and neutrons.

Protons and neutrons are themselves believed to be made up of yet more fundamental entities, the up (*u*) and down (*d*) quarks ($P = uud$, $N = udd$). Each quark is assumed to be endowed with one of three color quantum numbers [conventionally labeled red (*r*), yellow (*y*), and blue (*b*)]. The strong nuclear force can be pictured as ultimately arising through an exchange of zero rest-mass color-carrying quanta of spin $\hbar$ called gluons (*G*) [analogous to photons in electromagnetism], which are exchanged between quarks (contained inside protons and neutrons). Since neutrinos, electrons, and muons (the so-called leptons) do not contain quarks, their interactions among themselves or with protons and neutrinos do not exhibit the strong nuclear force. *See* Color (quantum mechanics); Gluons; Lepton; Quantum chromodynamics; Quarks; Strong nuclear interactions.

Three of the four fundamental interactions (electromagnetic, weak nuclear, and strong nuclear) appear to be mediated by intermediate quanta (photons γ; W^+, Z^0, and W^-; and gluons *G*, respectively), each carrying spin of magnitude $\hbar$. This is characteristic of the gauge interactions, whose general theory was given by H. Weyl, C. N. Yang, R. Mills, and R. Shaw. This class of interactions is further characterized by the fact that the force between any two particles (produced by the mediation of an intermediate gauge particle) is universal in the sense that its strength is (essentially) proportional to the product of the intrinsic charges (electric, or weak-nuclear, or strong-color) carried by the two interacting particles concerned.

The fourth interaction (the gravitational) can also be considered as a gauge interaction, with the intrinsic charge in this case being the mass; the gravitational force between any two particles is proportional to the product of their masses. The only difference between gravitation and the other three interactions is that the gravitational gauge quantum (the graviton) carries spin $2\hbar$ rather than $\hbar$. It is an open question whether all fundamental interactions are gauge interactions. *See* Gauge theory.

Ever since the discovery and clear classification of these four interactions, particle physicists have attempted to unify these interactions as aspects of one basic interaction between all matter. A unification of weak and electromagnetic interactions, employing the gauge ideas was suggested by S. Glashow and by A. Salam and J. C. Ward in 1959. Following this initial attempt, Glashow (and independently Salam and Ward) noted that such a unification could be effected only if neutral current weak interactions were postulated to exist.

There were two major problems with this unified electroweak gauge theory considered as a fundamental theory. Yang and Mills had shown that masslessness of gauge quanta is the hallmark of unbroken gauge theories. The origin of the masses of the weak interaction quanta W^+, W^-, and Z^0 (or equivalently the short-range of weak interactions), as contrasted with the masslessness of the photon (or equivalently the long-range character of electromagnetism), therefore required explanation. The second problem concerned the possibility of reliably calculating higher-order quantum effects with the new unified electroweak theory, on the lines of similar calculations for the "renormalized" theory of electromagnetism elaborated by S. Tomonaga, Schwinger, Feynman, and F. J. Dyson around 1949. The first problem was solved by S. Weinberg and Salam and the second by G. t'Hooft and by B. W. Lee and J. Zinn-Justin. *See* Renormalization.

Weinberg and Salam considered the possibility of the electroweak interaction being a "spontaneously broken" gauge theory. By introducing an additional self-interacting Higgs-Englert-Brout-Kibble particle into the theory, they were able to show that the W^+, W^-, and Z^0 would acquire well-defined masses through the so-called Higgs mechanism. The predicted theoretical mass values of the *W* and *Z* particles are in good accord with the experimental values found by the CERN 1983 experiments.

The Weinberg-Salam electroweak theory contains an additional neutral particle (the Higgs) but does not predict its mass.

A search for this particle will be undertaken when the large hadron collider (LHC) at CERN comes into commission. *See* ELECTROWEAK INTERACTION; HIGGS BOSON; PARTICLE ACCELERATOR; SYMMETRY BREAKING.

The gauge unification of weak and electromagnetic interactions, which started with the observation that the relevant mediating quanta (W^+, W^-, Z^0, and γ) possess intrinsic spin $\hbar$, can be carried further to include strong nuclear interactions as well, if these strong interactions are also mediated through quanta (gluons) carrying spin $\hbar$. The resulting theory, which appears to explain all known low-energy phenomena, is called the standard model. (It is a model based on three similarly constituted generations of quarks and leptons plus the mediating quanta W^+, W^-, Z^0, photons, and gluons plus the Higgs particle.) A complete gauge unification of all three forces (electromagnetic, weak nuclear, and strong nuclear) into a single electronuclear interaction seems plausible. Such a (so-called grand) unification necessarily means that the distinction between quarks on the one hand and neutrinos, electrons, and muons (leptons) on the other, must disappear at sufficiently high energies, with all interactions (weak, electromagnetic, and strong) clearly manifesting themselves then as facets of one universal gauge force. The fact that at low energies presently available, these interactions exhibit vastly different effective strengths is ascribed to differing renormalizations due to successive spontaneous symmetry breakings. A startling consequence of the eventual universality and the disappearance of distinction between quarks and leptons is the possibility of protons transforming into leptons and pions. Contrary to the older view, protons would therefore decay into leptons and pions and not live forever. *See* GRAND UNIFICATION THEORIES; PROTON; STANDARD MODEL.

Research in unification theories of fundamental interactions is now concerned with uniting the gauge theories of gravity and of the electronuclear interactions. The most promising approach appears to be that of superstring theories. Such theories appear to describe the only possible theory of gravity which is finite and suffers from no ultraviolet infinities. A closed string is a (one-dimensional) loop which may exist in a d-dimensional space-time (where d must equal 10 to completely eliminate all ultraviolet infinities). The quantum oscillations of the string correspond to particles of higher spins and higher masses. The theory has a unique built-in gauge symmetry. *See* SUPERSTRING THEORY. [A.S.]

Fungal biotechnology All aspects of cultivating fungi together with products and processes derived from such cultures. Fungi exhibit a wide range of biosynthetic and biodegradative activities. Since fungi can bring about chemical change in almost any natural or synthetic organic molecule, many species have been selected and propagated in pure culture specifically for applications in biotechnology and industry, for example in food and beverage production.

While the fermentation industry remains the largest and economically most important user of fungal cultures, fungi are also utilized by the pharmaceutical, cosmetic, chemical, agricultural, food, enzyme, wood product, and waste treatment industries. In the United States, two prominent examples of fungal products are citric acid, with an annual production of 350,000 tons (160,000 kg), and beta-lactam antibiotics. Yeasts are the most commercially exploited microorganisms. They have been used extensively in baking, brewing, winemaking, and distilling, and in making various metabolic products. Several million tons of fresh yeast are produced each year, mostly for the baking industry. *See* FERMENTATION; FOOD FERMENTATION.

Because they are capable of secreting large quantities of certain proteins in liquid culture, fungi have proven to be useful as cloning hosts for the production of recombinant proteins of fungal and human origin. Technologies have been developed to scale up the production of new or novel products. *Aspergillus nidulans* has been designed to produce many human therapeutic proteins, including growth factors and protein hormones. The yeasts *Sac. cerevisiae* and *P. pastoris* have been utilized for the expression of human interferon and serum albumin. Yeast chromosomes are also being employed in the mapping of the human genome. *See* GENETIC ENGINEERING. [S.C.J.]

Manufactured products which contain living fungi and are used to control pests are called mycopesticides. They are utilized to control weeds, harmful insects, nematodes (roundworms), or even other fungi. Although formerly confined to experimental settings, mycopesticides are increasingly available as commercial products, especially for the agricultural market. They may impact pest populations through direct parasitism, secretion of antibiotics, competition for nutrients, or a combination of these effects, and may be used alone or in combination with chemical pesticides. [F.M.D.]

Fungal ecology The subdiscipline in mycology and ecology that examines community composition and structure; responses, activities, and interactions of single species; and the functions of fungi in ecosystems. These organisms display an extraordinary diversity of ecological interactions and life history strategies, but are alike in being efficient heterotrophs. Fungi, along with bacteria, are the primary decomposers, facilitating the flow of energy and the cycling of materials through ecosystems. *See* ECOLOGICAL ENERGETICS; FUNGI.

Fungi occur in many different habitat types—on plant surfaces; inside plant tissues; in decaying plant foliage, bark and wood; and in soil—generally changing in abundance and species composition through successional stages of decomposition. Fungi are also found in marine and aquatic habitats; in association with other fungi, lichens, bacteria, and algae; and in the digestive tracts and waste of animals. Some fungi grow in extreme environments: rock can harbor free-living endolithic fungi or the fungal mutualists of lichens; thermotolerant and thermophilic fungi can grow at temperatures above 45°C (113°F); psychrophilic fungi can grow at temperatures to below −3°C (27°F). Xerotolerant fungi are able to grow in extremely dry habitats, and osmotolerant fungi grow on subtrates with high solute concentrations. Most fungi are strict aerobes, but species of the chytrid *Neocallimastix*, which inhabit the rumen of herbivorous mammals, are obligate anaerobes. Several aquatic fungi are facultative anaerobes. Many fungi occur as free-living saprobes, but fungi are particularly successful as mutualistic, commensal, or antagonistic symbionts with other organisms. *See* POPULATION ECOLOGY.

Fungi possess unique features that affect their capacity to adapt and to function in ecosystems:

1. Fungi are composed of a vegetative body (hyphae or single cells) capable of rapid growth. Hyphae are linear strands composed of tubular cells that are in direct contact with the substrate. The cells secrete extracellular enzymes that degrade complex polymers, such as cellulose, into low-molecular-weight units that are then absorbed and catabolized. Many fungi also produce secondary metabolites such as mycotoxins and plant growth regulators that affect the outcomes of their interactions with other organisms.
2. Filamentous fungi are able to mechanically penetrate and permeate the substrate.
3. Fungi have an enormous capacity for metabolic variety. Fungal enzymes are able to decompose highly complex organic substances such as lignin, and to synthesize structurally diverse, biologically active secondary metabolites. Saprotrophic fungi are very versatile; some are able to grow on tree resins and even in jet fuel.
4. Structural and physiological features of fungi facilitate absorption and accumulation of mineral nutrients as well as toxic elements. The capacity of fungi to absorb, accumulate, and translocate is especially significant ecologically where hyphal networks permeate soil and function as a link between microhabitats.

5. Fungi have the capacity for indeterminate growth, longevity, resilience, and asexual reproduction. The vegetative cells of Eumycota are often multinucleate, containing dissimilar haploid nuclei. This combination of features gives the fungi an unparalleled capacity for adaptation to varying physiological and ecological circumstances and ensures a high level of genetic diversity.

6. Many species of fungi have a capacity to shift their mode of nutrition. The principal modes are saprotrophy (the utilization of dead organic matter) and biotrophy, which is characteristic of parasitic, predacious, and mutualistic fungi (including mycorrhizae and lichen fungi). *See* BIODEGRADATION; FUNGAL GENETICS; MYCORRHIZAE.

Fungi interact with all organisms in ecosystems, directly or indirectly, and are key components in ecosystem processes. As decomposers, fungi are crucial in the process of nutrient cycling, including carbon cycling as well as the mineralization or immobilization of other elemental constituents. As parasites, pathogens, predators, mutualists, or food sources, fungi can directly influence the species composition and population dynamics of other organisms with which they coexist. Fungi may act both as agents of successional change or as factors contributing to resilience and stability. Mycorrhizal fungi function as an interface between plant and soil, and are essential to the survival of most plants in natural habitats.

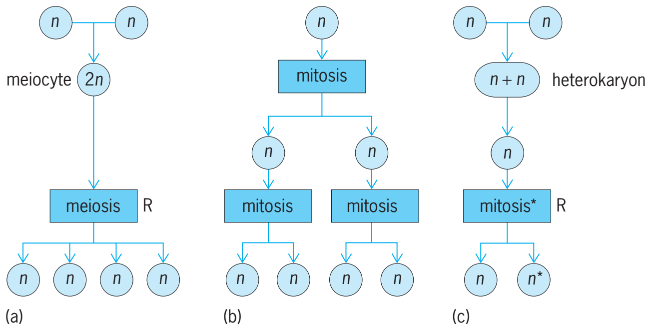
There are several economically important areas that benefit from application of the principles of fungal ecology: biotechnology, biological control, bioremediation, agriculture, forestry, and land reclamation. With only a small fraction of the total species known, the fungi offer a rich potential for bioprospecting, the search for novel genetic resources with unique, useful biochemical properties. *See* ECOLOGY; ECOSYSTEM; FUNGI; FUNGAL BIOTECHNOLOGY. [M.Ch.; J.K.St.]

Fungal genetics The study of gene structure and function in fungi. Genetic research has provided important knowledge about genes, heredity, genetic mechanisms, metabolism, physiology, and development in fungi, and in higher organisms in general, because in certain respects the fungal life cycle and cellular attributes are ideally suited to both mendelian and molecular genetic analysis.

Fungal nuclei are predominantly haploid; that is, they contain only one set of chromosomes. This characteristic is useful in the study of mutations, which are usually recessive and therefore masked in diploid organisms. Mutational dissection is an important technique for the study of biological processes, and the use of haploid organisms conveniently allows for the immediate expression of mutant genes. *See* MUTATION.

Reproduction in fungi can be asexual, sexual, or parasexual (see illustration). Asexual reproduction involves mitotic nuclear division during the growth of hyphae, cell division, or the production of asexual spores. Sexual reproduction is based on meiotic nuclear divisions fairly typical of eukaryotes in general. In ascomycetes and basidiomycetes, the spores, containing nuclei that are the four products of a single meiosis, remain together in a group called a tetrad. The isolation and testing of the phenotypes of cultures arising from the members of a tetrad (tetrad analysis) permit the study of the genetic events occurring in individual meioses; this possibility is offered by virtually no other eukaryotic group. In other groups, genetic analysis is limited to products recovered randomly from different meioses. Since a great deal of genetic analysis is based on meiosis, fungal tetrads have proved to be pivotal in shaping current ideas on this key process of eukaryotic biology. *See* EUKARYOTAE; MEIOSIS.

Because their preparation in large numbers is simple, fungal cells are useful in the study of rare events (such as mutations and recombinations) with frequencies as little as one in a million or less. In such cases, selective procedures must be used to identify cells derived from the rare events. The concepts and techniques of fungal asexual and parasexual genetics have been applied to the genetic manipulation of cultured cells of higher eukaryotes such as humans and green plants. However, the techniques remain much easier to perform with fungi.



Three different kinds of reproduction occurring in fungi, each of which provides opportunities for genetic analysis. (*a*) Sexual reproduction leads to recombination (R) of genes at meiosis. (*b*) Asexual reproduction (shown here in a typical haploid fungal cell) usually reproduces the gene set faithfully. (*c*) Parasexual reproduction derives from an atypical mitotic division of an unstable cell that produces haploid cells and other aneuploid (deviating from normal chromosome complement) unstable intermediates.

The fact that each enzyme is coded by its own specific gene was first recognized in fungi and was of paramount importance because it showed how the many chemical reactions that take place in a living cell could be controlled by the genetic apparatus. The discovery arose from a biochemical study of nutritional mutants in *Neurospora*. *See* ENZYME.

In genetically transformed organisms, the genome has been modified by the addition of DNA, a key technique in genetic engineering. The cell wall is temporarily removed; exogenous DNA is then taken up by cells and the cell wall is restored. The incorporation of DNA must be detected by a suitable novel genetic marker included on the assimilated molecule in order to distinguish transformed from nontransformed cells. The fate of the DNA inside the cell depends largely on the nature of the vector or carrier. Some vectors can insert randomly throughout the genome. Others can be directed to specific sites, either inactivating a gene for some purpose or replacing a resident gene with an engineered version present on the vector. A third kind of vector remains uninserted as an autonomously replicating plasmid. The ability to transform fungal cells has permitted the engineering of fungi with modified metabolic properties for making products of utility in industry. *See* GENETIC ENGINEERING.

A surprising development in the molecular biology of eukaryotes was the discovery of transposons, pieces of DNA that can move to new locations in the chromosomes. Although transposons were once known only in bacteria, they are now recognized in many eukaryotes. The transposons found in fungi mobilize by either of two processes: one type via a ribonucleic acid (RNA) intermediate that is subsequently reverse-transcribed to DNA, and the other type via DNA directly. In either case, a DNA copy of the transposed segment is inserted into the new site and may contain, in addition to the transposon itself, segments of contagious DNA mobilized from the original chromosomal site. Because of the rearrangements which transposons may produce, they have been important in the evolution of the eukaryotic genome. *See* FUNGI; GENETICS; TRANSPOSONS. [A.J.F.G.; R.U.]

Fungal infections Several thousand species of fungi have been described, but fewer than 100 are routinely associated with invasive diseases of humans. In general, healthy humans have a very high level of natural immunity to fungi, and most fungal infections are mild and self-limiting. Intact skin and mucosal surfaces and a functional immune system serve as the primary barriers to colonization by these ubiquitous organisms, but these barriers are sometimes breached.

Unlike viruses, protozoan parasites, and some bacterial species, fungi do not require human or animal tissues to perpetuate or preserve the species. Virtually all fungi that have been implicated in human disease are free-living in nature. However, there are exceptions, including various *Candida* spp., which are frequently found on mucosal surfaces of the body such as the mouth and vagina, and *Malassezia furfur*, which is usually found on skin surfaces that are rich in sebaceous glands. These organisms are often cultured from healthy tissues, but under certain conditions they cause disease. Only a handful of fungi cause significant disease in healthy individuals. Once established, these diseases can be classified according to the tissues that are initially colonized.

Superficial mycoses. Four infections are classified in the superficial mycoses. Black piedra, caused by *Piedraia hortai*, and white piedra, caused by *Trichosporn beigleii*, are infections of the hair. The skin infections include tinea nigra, caused by *Exophiala werneckii*, and tinea versicolor, caused by *M. furfur*. Where the skin is involved, the infections are limited to the outermost layers of the stratum corneum; in the case of hairs, the infection is limited to the cuticle. In general, these infections cause no physical discomfort to the patient, and the disease is brought to the attention of the physician for cosmetic reasons.

Cutaneous mycoses. The cutaneous mycoses are caused by a homogeneous group of keratinophilic fungi termed the dermatophytes. Species within this group are capable of colonizing the integument and its appendages (the hair and the nails). In general, the infections are limited to the nonliving keratinized layers of skin, hair, and nails, but a variety of pathologic changes can occur depending on the etiologic agent, site of infection, and immune status of the host. The diseases are collectively called the dermatophytoses, ringworms, or tineas. They account for most of the fungal infections of humans.

Subcutaneous mycoses. The subcutaneous mycoses include a wide spectrum of infections caused by a heterogeneous group of fungi. The infections are characterized by the development of lesions at sites of inoculation, commonly as a result of traumatic implantation of the etiologic agent. The infections initially involve the deeper layers of the dermis and subcutaneous tissues, but they eventually extend into the epidermis. The lesions usually remain localized or spread slowly by direct extension via the lymphatics, for example, subcutaneous sporotrichosis.

Systemic mycoses. The initial focus of the systemic mycoses is the lung. The vast majority of cases in healthy, immunologically competent individuals are asymptomatic or of short duration and resolve rapidly, accompanied in the host by a high degree of specific resistance. However, in immunosuppressed patients the infection can lead to life-threatening disease. *See* FUNGI; MEDICAL MYCOLOGY. [G.S.K.]

Fungal virus Any of the viruses that infect fungi (mycoviruses). In general these viruses are spheres of 30–45-nanometer diameter composed of multiple units of a single protein arranged in an icosahedral structure enclosing a genome of segmented double-stranded ribonucleic acid (dsRNA). Viruses are found in most species of fungi, where they usually multiply without apparent harm to the host. Most fungal viruses are confined to closely related species in which they are transmitted only through sexual or asexual spores to progeny or by fusion of fungal hyphae (filamentous cells). Some fungal strains are infected with multiple virus species. Although hundreds of virus-containing fungi have been reported, very few have been studied in significant detail. Three families of mycoviruses are recognized by the International Committee on Taxonomy of Viruses. The most thoroughly studied mycoviruses are in the family Totiviridae. *See* FUNGI; MYCOLOGY; PLANT PATHOLOGY; VIRUS; VIRUS CLASSIFICATION. [R.F.Bo.]

Fungi Nucleated, usually filamentous, sporebearing organisms devoid of chlorophyll; typically reproducing both sexually and asexually; living as parasites in plants, animals, or other fungi, or as saprobes on plant or animal remains, in aquatic, marine, terrestrial, or subaerial habitats. Yeasts, mildews, rusts, mushrooms, and truffles are examples of fungi.

Some fungal classifications were constructed to facilitate identification, whereas others emphasize phylogeny. The more widely used classifications reflect a series of compromises between identification and phylogeny, and tend to conserve the vocabulary and nomenclature familiar to broad groups of users. The following is a conventional classification, in which all organisms are treated as members of the kingdom Fungi:

Division: Eumycota
  Subdivision: Mastigomycotina
    Class: Chytridiomycetes
      Hyphochytriomycetes
      Oomycetes
  Subdivision: Zygomycotina
    Class: Zygomycetes
      Trichomycetes
  Subdivision: Ascomycotina
    Class: Hemiascomycetes
      Plectomycetes
      Pyrenomycetes
      Discomycetes
      Loculoascomycetes
  Subdivision: Basidiomycotina
    Class: Hymenomycetes
      Gasteromycetes
      Urediniomycetes
      Ustilaginomycetes
  Subdivision: Deuteromycotina
    Class: Blastomycetes
      Hyphomycetes
      Coelomycetes
      Agonomycetes
Division: Myxomycota
[F.M.D.]

Organisms in the kingdom Fungi are mostly haploid, use chitin as a structural cell-wall polysaccharide, and synthesize lysine by the alpha amino adipic acid pathway; and their body is made of branching filaments (hyphae). The fungi arose about 1 billion years ago along with plants (including green algae), animals plus choanoflagellates, red algae, and stramenopiles. Ribosomal comparison indicates that the closest relatives to the fungi are the animals plus choanoflagellates. *See* CHOANOFLAGELLIDA.

Ascomycetes are the most numerous fungi (75% of all described species), and include lichen-forming symbionts. The group has traditionally been divided into unicellular yeasts and allies with naked asci, and hyphal forms with protected asci. However, ribosomal gene sequences indicate that some traditional yeasts and allied forms diverged early (early ascomycetes), at about the time ascomycetes were diverging from basidiomycetes. Hyphal ascomycetes protect their asci with a variety of fruiting bodies; the earliest fruiting bodies may have been open cups (Discomycetes), while in more recent groups they are flask shaped (Pyrenomycetes and Loculoascomycetes) or are completely closed (Plectomycetes). Ascomycetes lacking sexual structures have been classified in the Fungi Imperfecti, but molecular comparisons now allow their integration with the ascomycetes. *See* ASCOMYCOTA; DEUTEROMYCOTINA; DISCOMYCETES; LOCULOASCOMYCETES; PLECTOMYCETES; PLECTOMYCETES. [J.W.T.]

The mycelium, generally the vegetative body of fungi, is extremely variable. Unicellular forms, thought to be primitive or derived, grade into restricted mycelial forms; in most species, however, the mycelium is extensive and capable of indefinite growth. Some are typically perennial though most are ephemeral. The mycelium may be nonseptate, that is, coenocytic, with myriad scattered nuclei lying in a common cytoplasm, or septate, with each cell containing one to a very few nuclei or an indefinite number of nuclei. Septa may be either perforate or solid. Cell walls are composed largely of chitinlike materials except in one group of aquatic forms that have cellulose walls. Most mycelia are white, but a wide variety of pigments can be synthesized by specific forms and may be secreted into the medium or deposited in cell walls and protoplasm. Mycelial consistency varies from loose, soft wefts of hyphae to compact, hardened masses that resemble leather. Each cell is usually able to regenerate the entire mycelium, and vegetative propagation commonly results from mechanical fragmentation of the mycelium.

Asexual reproduction, propagation by specialized elements that originate without sexual fusion, occurs in most species and is extremely diverse. The most common and important means of asexual reproduction are unicellular or multicellular spores of various types that swim, fall, blow, or are forcibly discharged from the parent mycelium.

Sexual reproduction occurs in a majority of species of all classes. Juxtaposition and fusion of compatible sexual cells are achieved by four distinct sexual mechanisms, involving various combinations of differentiated sexual cells (gametes), undifferentiated sexual cells (gametangia), and undifferentiated vegetative cells. [J.R.Ra.]

Fungi obtain organic substances (food) from their environment which have been produced through the (photosynthetic) activities of green plants, since fungi do not contain chlorophyll and are unable to manufacture their own food. Fungi are able to digest food externally by releasing enzymes into their environment. These smaller molecules can be absorbed into the fungal body and transported to various locations where they can be used for energy or converted into different chemicals to make new cells or to serve other purposes. Some of the by-products of fungal metabolism may be useful to humans. Most fungi use nonliving plant material for food, but a few use nonliving animal material and therefore are called saprophytic organisms. In nature the decomposition of dead plant material is an important function of fungi, as the process releases nutrients back into the surrounding ecosystem where they can be reused by other organisms, including humans. *See* Biodegradation; Fungal ecology.

A few fungi have the physiological capability to grow on living plants and may cause diseases such as wheat rust or corn smut on these economically important plants. Some fungi can grow on grains and may produce substances known as aflatoxins which can be detrimental to animals or humans. A few species of fungi have the ability to grow and acquire their food from skin or hair on living animals such as cats, horses, and humans. The disease known as ringworm may result. It is not caused by a worm but by an expanding circular growth of a fungus which has the physiological capability to use the components of skin or hair as the food source. The most frequently encountered fungal disease in humans is candidiasis, which is caused by one of the few fungi that is normally found associated with humans (*Candida albicans*). *See* Aflatoxin; Medical mycology; Plant pathology; Yeast infection.

A number of fungal species are able to enter plant roots and develop an association that may be beneficial to the plant under natural field conditions. This association of a higher plant root and a fungus that does not produce a disease is called a mycorrhiza. This fungal association with the plant root may permit the plant to live under soil conditions where it may not otherwise survive because of an excess of acid in the soil or a lack or excess of certain nutrients. *See* Mycorrhizae.

Certain species of fungi have been used by humans since early times in the preparation of foods such as leavened bread, cheeses, and beverages. Additional by-products of fungal physiology are used in industrial applications such as antibiotics, solvents, and pharmaceuticals. *See* Fungal biotechnology; Industrial microbiology; Yeast. [M.C.W.]

Fungistat and fungicide Synthetic or biosynthetic compounds used to control fungal diseases in animals and plants. A fungistat prevents the spread of a fungus, whereas a fungicide kills the fungus.

Seeds and seedlings are protected against fungi in the soil by treating the seeds and the soil with fungicides. Seed-treating materials must be safe for seeds and must resist degradation by soil and soil microorganisms. Some soil fungicides are safe to use on living plants. Others are injurious to seeds and living plants. These compounds are useful because they are volatile. Used before planting, they have a chance to kill soil fungi and then escape from the soil.

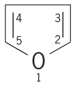
Formic acid, acetic acid, and propionic acid up through pelargonic acid and capric acid (the C_1-C_{10} volatile fatty acids) possess significant fungicidal activity. Many of them are present in natural foodstuffs that are resistant to fungal attack. Use of the volatile fatty acids and their salts in bread to prevent ropy mold is widespread. A. I. Virtanen was awarded the Nobel prize in 1945 for his discovery and development of these lower volatile fatty acids to prevent fungal growth and so preserve the nutritious quality of cattle fodders. Since these volatile fatty acids stop fungal growth, they prevent mycotoxin generation and lessen the risk of cancer from exposure to mycotoxins. *See* Animal feeds. [J.G.H.; S.Ri.]

Two types of fungicides are used to control plant diseases: (1) Surface protectants remain on the plant surface and exert their toxic action on fungi before they have penetrated into plant tissue. (2) Systemic fungicides move into plant tissue and exert their toxic action on fungi which have already penetrated internally. These fungicides can also provide surface protection by acting on fungi before they have penetrated the plant.

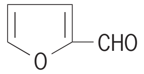
Most agricultural fungicides are systemic compounds that act at a single target site in fungal cells, such as cell membranes, microtubules, or ribosomes.

There have been very few instances of fungal resistance to surface protectant fungicides which is attributed to their action at multiple sites within fungal cells. However, most systemic fungicides that act at a single site have generated serious problems with fungal resistance. A single gene mutation in a fungus can lead to loss of effectiveness of all fungicides in a particular mode-of-action group. Experience has shown that frequent, uninterrupted use of a fungicide increases the risk for development of a resistant strain of the target organism. That risk can be reduced by alternating use of fungicides with different modes of action or by using them in mixtures. *See* Fungi. [H.D.S.]

Furan One of a group of organic heterocyclic compounds containing a diunsaturated ring of four carbon atoms and one oxygen atom. Furan (I) is a typical member of the group. Furfural (II) and some of its close relatives, such as furfuryl alcohol, tetrahydrofurfuryl alcohol, and tetrahydrofuran, are important chemicals of commerce. *See* Heterocyclic compounds.



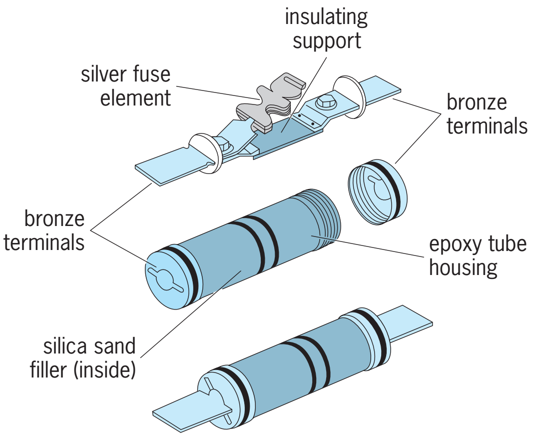
(1)



(2)

Furan (I) is a colorless, volatile liquid, bp 31.4°C (88.5°F), which is stable to alkali but not to mineral acid. Its water solubility is approximately 1% at room temperature. On exposure to air, furan decomposes very slowly by autoxidation. Substituted furans, particularly negatively substituted furans, are much less sensitive. The furan system is aromatic. Nitration, halogenation, acylation, mercuration, and sulfonation reactions occur with relative ease. [W.J.Ge.]

Fuse (electricity) An expendable protective device that eliminates overload on an electric circuit. The fuse is connected



Power fuse assembly. (***After A. J. Pansini, Electric Power Equipment, Prentice-Hall, 1988***)

in series with the circuit being protected. The components of a typical low-voltage high-power fuse are a fuse element or wire, an insulating material support and housing, two metal end fittings, and a filler (see illustration).

The fuse element is a silver strip or wire that melts when the current is higher than the rated value. The melting of the wire generates an electric arc. The extinction of this arc interrupts the current and protects the circuit. The fuse element is connected to the metal end fittings which serve as terminals. *See* Arc discharge.

The filler facilitates the arc extinction. The most commonly used filler is sand, which surrounds the fuse element. When the fuse element melts, the heat of the arc melts the sand near the element. This removes energy from the arc, creating a channel filled with the mixture of melted sand and metal. The metal particles from the melting fuse wire are absorbed by the melted sand. This increases the channel resistance, which leads to the gradual reduction of the current and the extinction of the arc. The insulating support and the tubular housing holds the fuse elements and the filler, which also serves as insulator after the fuse has interrupted the current.

The interruption time is the sum of the melting and the arcing time. It is inversely proportional to the current, that is, a higher current melts the wire faster. The fuse operates in a time-current band between maximum interruption time and minimum meeting time. It protects the electric circuit if the fault current is interrupted before the circuit elements are overheated. The arc extinction often generates overvoltages, which produce flashovers and damage. A properly designed fuse operates without overvoltage, which is controlled by the shape of the fuse element and by the filler. [G.G.K.]

Fused-salt phase equilibria Conditions in which two or more phases of fused-salt mixtures can coexist in thermodynamic equilibrium. Phase diagrams of these equilibrium conditions summarize basic knowledge about fused salts. Numerous advances in the technologies which are based on high-temperature chemistry have become possible through the increase in knowledge about fused salts. The increasingly significant role of fused salts in industrial processes is evident in the widening application of these materials as heat-transfer media, in extractive metallurgy, in nonaqueous reprocessing of nuclear reactor fuels, and in the development of nuclear reactors which create more fuel than they consume (breeder reactors). *See* Nuclear reactor; Phase equilibrium.

Fused-salt mixtures find application in technology when the need arises for liquids which are stable at high temperatures. For most applications, suitably low melting temperatures and low vapor pressures are primary considerations. To some extent these requirements are conflicting, because salts which are useful in obtaining low freezing temperatures often tend to have appreciable covalent character and therefore to exhibit unfavorably high vapor pressures.

As a special class of liquids, one which is composed entirely of positively and negatively charged ions undiluted by weak-electrolyte supporting media, fused salts are used in many different types of research. For example, advances in solution theory, thermodynamics, and crystal chemistry have come about through studies of fused-salt systems. *See* Fused-salt solution.

A close connection between fused-salt phase diagrams and geochemistry stems from the model principle developed by V. M. Goldschmidt, who noted that isomorphic structures are assumed by ions of the same proportionate size and stoichiometric relations but of different charge. Thus the fluorides of beryllium, calcium, and magnesium, for example, are structural models for silicon dioxide (SiO_2), titanium dioxide (TiO_2), and zirconium dioxide (ZrO_2). The fluoride structures are referred to as weakened models because of the smaller electrostatic forces resulting from smaller ionic charges; they have been useful for comparisons with oxide and silicate systems. According to Goldschmidt's interpretation, saltlike materials were derived from components such as water (H_2O), carbon dioxide (CO_2), sulfur trioxide (SO_3), chlorine (Cl_2), and fluorine (F_2), which were volatilized from molten magmas as they crystallized. Crystallization equilibria in fused-salt systems therefore provide a convenient way to study the mechanisms occurring in the formation of igneous rocks. *See* Igneous rocks. [R.E.Th.]

Fused-salt solution A nonaqueous solvent system particularly useful in coordination chemistry. Fused salts are a large class of liquids which are composed largely of ions. Many simple inorganic salts melt at rather high temperatures (greater than 600°C or 1000°F), forming liquids which have high specific conductivities, 1–6 ohm^{-1} · cm^{-1}. There are, however, a number of exceptions to this generalization; for example, the electrical conductivity of $AlCl_3$ decreases sharply upon melting due to the formation of molecular liquid (Al_2Cl_6). *See* High-temperature chemistry; Solvent.

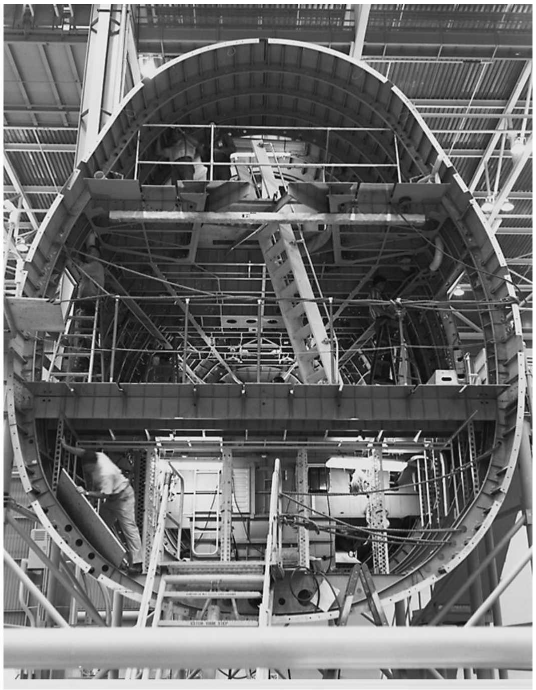
The use of binary or ternary melt compositions results in liquids which typically have much lower melting temperatures and somewhat lower specific conductivities than do pure salts. The choice of melts for use as solvents is frequently based on such considerations as the availability and cost, the lowest melting temperature attainable, and the ease of purification of the solvent, as well as the width of the electrochemical span and the spectroscopic transparency of the melt. Several molten-salt solvents, such as the LiCl–KCl eutectic and the equimolar $NaNO_3$–KNO_3 melt, have been extensively studied, and many of their physical and chemical properties are well known. Many melt systems, particularly ternary and more complex compositions, have been only partially characterized; their physical properties are estimated by using the data available for less complex systems, such as the binary component melts.

One use of fused salts is as media for organic reactions. Not only does the fused-salt environment provide for a better thermal control of the reaction (heat dissipation is readily possible), but the fused salt may serve as a catalyst. For example, molten $SbCl_3$ and $ZnCl_2$ have been found to be effective hydrocracking catalysts for coal. It has been found that polycyclic hydrocarbons, such as anthracene, undergo several types of reactions in $SbCl_3$ melts, including formation of radical cations and protonated species which react further to form condensed systems, such as anthra[2.1-*a*]aceanthrylene. *See* Catalysis.

Another technological area of great interest in which molten salts play a key role is that of advanced batteries and fuel cells. Thus, LiCl–KCl eutectic is the solvent in the rechargeable Li(Al)–FeS (or FeS_2) battery, and sodium polysulfide melts are employed in the sodium/sulfur battery which operates at about 350°C (660°F). The rechargeable cell Na/Na$^+$ conductor/S(IV) in $AlCl_3$–NaCl has an open circuit voltage of 4.2 V at 200–250°C (390–480°F) as well as high energy densities.

Molten carbonates, such as the ternary Li_2CO_3–Na_2CO_3–K_2CO_3 melt, are used in fuel cells which employ H_2/CO mixtures and oxygen as electrochemical fuels. *See* BATTERY; FUEL CELL. [G.Ma.]

Fuselage The component of an aircraft that provides the payload containment and the structural connection for the wing and the empennage (tail assembly). The fuselage and the wing are major structural components of an aircraft. The fuselage is the mounting structure for the horizontal and tail surfaces that provides stability as well as the means of introducing pitch and yaw control to the aircraft. For some aircraft like fighter and private aircraft, the fuselage houses the engine or engines. The nose or tail gear and the main landing gear are often attached to the fuselage structure.



Boeing 747 fuselage with stringer-stiffened skin supported by frames. (*Boeing Co.*)

The history of the construction of aircraft fuselages has evolved through the early wood truss structural arrangements to the current metal semi-monocoque shell structures. A majority of aircraft fuselages are fabricated from aluminum alloys and are produced by a process of automatic machining of the skins and stringers (see illustration), with much of the assembly being done by automatic drilling, countersinking, and fastener installation. In some areas, adhesive bonding is used as a means of attaching doublers to reinforce skin panels. In many of the high-performance aircraft, such as fighters and bombers, extensive use is made of titanium and high-strength steel. *See* AIRFRAME. [J.E.McC.]

Fusulinacea An extinct superfamily of marine organisms in the phylum Protozoa, order Foraminiferida. Fusulinaceans first appeared late in the Mississippian Period, and in the succeeding 100,000,000 years evolved into more than 125 genera and 6000 species before becoming extinct near the close of the Permian Period. Among protozoans fusulinaceans became giants, many reaching 0.4 in. (1 cm) in length and some even attaining 4 in. (10 cm) in length. The group is characterized by rapid evolution of distinctive morphological features, which have enabled paleontologists to establish a detailed fusulinacean phylogeny and biostratigraphic zonation.

In general, the calcareous shell of fusulinaceans is constructed on a simple plan. The initial chamber, the proloculus, is a small calcareous sphere with an opening on one side. As the individual grew and the volume of protoplasm increased, chambers were added successively in a planispiral coil around the proloculus. In most genera these chambers overlap the ends of the previous chambers and become elongate, parallel to the axis of coiling. The spiral wall (spirotheca) is composed of several layers. The initial wall is formed of a thin, dark organic-rich layer (tectum), beneath which is a thicker translucent layer (diaphanotheca) formed of calcium carbonate. *See* FORAMINIFERIDA. [C.A.R.]

Fuzzy sets and systems A fuzzy set is a generalized set to which objects can belong with various degrees (grades) of memberships over the interval [0,1]. Fuzzy systems are processes that are too complex to be modeled by using conventional mathematical methods. In general, fuzziness describes objects or processes that are not amenable to precise definition or precise measurement. Thus, fuzzy processes can be defined as processes that are vaguely defined and have some uncertainty in their description. The data arising from fuzzy systems are, in general, soft, with no precise boundaries. Examples of such systems are large-scale engineering complex systems, social systems, economic systems, management systems, medical diagnostic processes, and human perception. *See* SET THEORY.

The mathematics of fuzzy set theory was originated by L. A. Zadeh in 1965. It deals with the uncertainty and fuzziness arising from interrelated humanistic types of phenomena such as subjectivity, thinking, reasoning, cognition, and perception. This type of uncertainty is characterized by structures that lack sharp (well-defined) boundaries. This approach provides a way to translate a linguistic model of the human thinking process into a mathematical framework for developing the computer algorithms for computerized decision-making processes. The theory has grown very rapidly. Many fuzzy algorithms have been developed for application to process control, medical diagnosis, management sciences, engineering design, and many other decision-making processes where soft data are generated. Thus, fuzzy mathematics provides a modeling link between the human reasoning process, which is vague, and computers, which accept only precise data.

For example, in the design of many engineering systems, process information is not available both because it is difficult to understand precisely the complexity of the phenomena and because human reasoning is inexact and is based upon subjective perception. However, by virtue of knowledge and experience, which is inexact, it is possible to build increasingly good systems. In fact, fuzziness in thinking and reasoning processes is an asset since it makes it possible to convey a large amount of information with a very few words. However, in order to emulate this experience and these reasoning processes on a computer, for example, for intelligent robotics applications and medical diagnosis, a mathematical precision must be given to the vagueness of the information so that a computer can accept it. This is done by using the theory of fuzzy sets. Probability theory deals with the uncertainty or randomness that arises in mechanistic systems, whereas fuzzy set theory has been created to deal with the uncertainty that arises in human cognitive processes. *See* PROBABILITY.

The premise of fuzzy set theory is that the key elements in human reasoning processes are not numbers but labels of fuzzy sets. The degree of membership is specified by a number between 1 (full membership) and 0 (full nonmembership). An ordinary set is a special case of a fuzzy set, where the degree of membership is either 0 or 1. By virtue of fuzzy sets, human concepts like small, big, rich, old, very old, and beautiful can be translated into a form usable by computers. [M.M.G.]

Fuzzy-structure acoustics Large structures such as ships and airplanes can undergo a variety of complicated vibrations. Such structures typically consist of an outer body made of metal plating (for example, the hull of a ship) or perhaps a massive metallic frame (for example, the chassis of a truck), and a large variety of internal objects that are connected to either the plating or the frame. In designing such structures, it is highly desirable to have some method for predicting how they will vibrate under various conditions. The radiation of sound caused by these vibrations, either into the environment or into the empty portions of the structure, is also of interest because this sound is often either unwanted noise or a means of inferring information about the details of the structure or the excitation. Fuzzy-structure acoustics refers to a class of conceptual viewpoints in which precise, computationally intensive models of the overall structure are replaced by nonprecise analytical models, for which the initial information is said to be fuzzy. *See* FUZZY SETS AND SYSTEMS.

Fuzzy-structure theories divide the overall structure into a master structure and one or more attached structures, the latter being referred to as the fuzzy substructures, the internal structures, or the internals. (An example of a master structure is the hull and major framework of a ship.) The master structure is presumed to be sufficiently well known at the outset that its vibrations or dynamical response could be predicted if the forces that were exerted on it were known. Some of the forces are exerted on it by the substructures at the points at which they are attached. Such forces can be very complicated; nevertheless, there is some hope that a satisfactory approximate prediction of the vibrations of the master structure itself can be achieved with a highly simplified model.

The fuzzy substructures can be regarded as structures that are not known precisely. Recently developed theories of fuzzy structures lead, after various plausible idealizations, to a formulation that requires only a single function, this being the modal mass per unit frequency bandwidth. The influence of fuzzy substructures attached to the master structure tends to resemble that of an added frequency-dependent mass attached to the master structure in parallel with a frequency-dependent dashpot connecting the master structure to a hypothetical rigid wall. The added mass is a frequency-weighted integral over the modal mass per unit natural frequency, the weighting being such that the natural modes whose natural frequencies are less than the driving frequency have a positive contribution, while those for which the natural frequencies are greater than the driving frequency have a negative contribution. The master structure can seem to be less massive than it actually is when the bulk of the substructure mass is associated with resonant frequencies less than the excitation frequency.

One implication of the newly emerging fuzzy-structure theories is that, insofar as there is concern with the vibrations of only the master structure, it is possible to drastically curtail the estimation or measurement of any parameters within the substructures that are associated with internal damping. *See* MECHANICAL VIBRATION; VIBRATION. [A.D.P.]

G

Gabbro The plutonic equivalent of its more abundant extrusive equivalent, basalt. Because it crystallized from a magma intruded deep within the crust, gabbro has a grain size visible to the naked eye with approximately equal amounts of calcic plagioclase (with 50% or more anorthite, the calcium aluminium feldspar) and pyroxene. Olivine is common as an early crystallized mineral, but either nepheline or quartz could be a late-stage crystallization product found in the matrix. Hornblende or biotite is commonly formed as an alteration product of pyroxene during the late stages of the magmatic crystallization, when water becomes enriched in the residual magma. *See* Biotite; Hornblende.

Gabbro is found in diverse tectonic environments, ranging through oceanic ridges, convergent plate boundaries, stable continents, and rifts. The forms of the intrusive gabbro bodies include dikes, sills, pipes, laccoliths, stocks, batholiths, and large layered intrusive complexes.

The grain size of gabbroic rocks ranges from a millimeter to centimeters. The finer-gained gabbro is commonly referred to as a diabase (or dolerite in the United Kingdom) that usually has small granular pyroxene interstitially enclosed by randomly oriented laths of calcic plagioclase. This diabasic texture results from the faster cooling of the magma due to its injection as small dikes and sills in shallow crust. In coarser-grained gabbro found in large plutons injected in deeper crust, the pyroxenes are larger and enclose partially (a texture called subophitic) or fully (a texture called ophitic) randomly oriented labradorite. Gabbros with mineral gains larger than 2 cm (0.8 in.) are rare, but such rocks are referred to as gabbro pegmatites. At contacts with country rock, the gabbro is commonly very fine grained or glassy because of the fast chilling of the magma. In some plutons, especially near their margins, gabbroic minerals are aligned perpendicular to the walls, yielding comb layering. *See* Dolerite; Magma; Pluton.

Unlike basalts, which are found in surface or near-surface environments, gabbros are found as shallow-to-deep intrusive bodies. Large blocks measuring more than 10 km (6 mi) thick, with a suite of rocks including serpentinite, pillow lavas, and chert, contain gabbro. This suite, called ophiolites, is commonly found on continents along convergent plate boundaries; it is thought to have been tectonically emplaced by thrusting onto the continental margins. It consists of a suite of rocks that are believed to represent the oceanic crust and upper mantle. *See* Chert; Ophiolite; Serpentinite; Stratigraphy. [A.M.K.]

Gadiformes A well-defined order of actinopterygian fishes, also known as the Anacanthini, which includes the codfishes and grenadiers, or rattails. Structurally the group is more or less intermediate between typical soft-rayed and spiny-rayed fishes. As in the former, there are no fin spines, the scales are cycloid, and the pelvic fin often has many rays. As in typical perciforms, however, the swim bladder has no duct, the orbitosphenoid and mesocoracoid are absent, and the upper jaw is bordered only by the protractile premaxillae. The pelvic fins, if present, are jugular in position but are attached to the cleithra only by ligaments. *See* Codfish; Perciformes.

Gadiform fishes are known from the Paleocene. Recent forms are classified into 8 families, about 185 genera, and nearly 730 species. The best-known family, the Gadidae, comprises 60 species that live in northern seas, where cod, haddock, pollock, and hake form the basis for extensive commercial fisheries. *See* Actinopterygii. [R.M.B.]

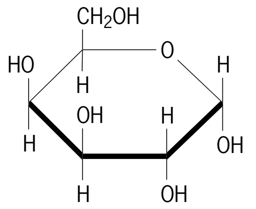
Gadolinium A metallic chemical element, Gd, atomic number 64 and atomic weight 157.25, belonging to the rare-earth group. The naturally occurring element is composed of eight isotopes. It is named in honor of the Swedish scientist J. Gadolin. The oxide, Gd_2O_3, in powdered form is white, and solutions of the salt are colorless. Gadolinium metal is paramagnetic and becomes strongly ferromagnetic below room temperatures. The Curie point, where this transition occurs, is about 16 K. *See* Periodic table; Rare-earth elements. [F.H.S.]

Gages Devices for determining the relative size or shape of objects. The function of gages is to determine whether parts are within or outside of the specified tolerances, which are expressed in a linear unit of measurement. Gages are the most widely used production tools for controlling linear dimensions during manufacture and for assuring interchangeability of finished parts. A gage may be an indicating type that measures the amount of deviation from a mean or basic dimension, or it may be a fixed type that simply accepts parts within tolerance and rejects parts outside tolerance. *See* Tolerance. [R.A.Bo.]

Gain An increase in signal power or voltage produced by an amplifier in transmitting a signal from one point to another. The amount of gain is usually expressed in decibels above a reference level. *See* Amplifier.

Antenna gain is a measure of the effectiveness of a directional antenna as compared to a nondirectional antenna. *See* Antenna (electromagnetism). [J.Mar.]

Galactose A monosaccharide and a constituent of oligosaccharides, notably lactose, melibiose, raffinose, and stachyose. It is also known as D-galactose and cerebrose (see illustration). Agar, gum arabic, mesquite gum, larch arabo galactan, and a variety of other gums and mucilages contain D-galactose. *See* Agar; Gum; Monosaccharide.



Structural formula for α-D-galactose.

L-Galactose (enantiomorph of D-galactose) occurs in several polysaccharides, including agar, flaxseed mucilage, snail galactogen, and chagual gum. Since D-galactose is usually also present, hydrolysis of these polysaccharides produces DL-galactose. *See* Carbohydrate; Polysaccharide. [W.Z.H.]

Galaxy, external One of the large self-gravitating aggregates of stars, gas, and dust that contain nearly all of the observed matter in the universe. Typical large galaxies have symmetric and regular forms, are about 50,000 light-years (3×10^{17} mi or 5×10^{17} km) in diameter, and are roughly 3×10^{10} times more luminous than the Sun. The stars and other material within a galaxy move through it, often in regular rotation, with periods of a few hundred million years. The nearest galaxies to the Milky Way Galaxy, the Magellanic Clouds, are about 150,000 light-years (9×10^{17} mi or 1.5×10^{18} km) away; the farthest, almost 1×10^{10} light-years (6×10^{22} mi or 1×10^{23} km). *See* MAGELLANIC CLOUDS.

The hundreds of billions of stars making up a galaxy are not generally individually observable with current telescope technology because they are too faint and distant. Only the brightest stars in the nearest galaxies can be observed directly with large telescopes. Two general types of stellar populations are distinguished: One type (population I) is characterized by the presence of young stars and by ongoing star formation. It is usually associated with the presence of gas. The second type (population II) shows an absence of gas and young stars as well as other indications that star formation ceased long ago. The Sun is a population I star. *See* STAR; STELLAR POPULATION.

Galaxies contain gas (mostly un-ionized hydrogen) in amounts varying from essentially zero up to a considerable fraction of their total mass. Dust in galaxies, although small in mass (typically 1% of the gas mass), is often dramatic in appearance because it obscures the starlight. *See* INTERSTELLAR MATTER.

Galaxies generally display strikingly regular forms. The most common form is a disk with a central bulge. The disk is typically 100,000 light-years (6×10^{17} mi or 1×10^{18} km) in diameter and only about 1000 light-years (6×10^{15} mi or 1×10^{16} km) thick. Its appearance is characterized by radially decreasing brightness with a superposed spiral or bar pattern, or both (see illustration). The central bulge may vary in size from hundreds to many thousands of light-years. Such galaxies are classified as spirals (S) and subclassified a, b, or c (for example, Sa) to distinguish increasingly open spiral structure and small bulge size. The letter B is added after the S in the classification of spiral galaxies that contain conspicuous barlike features. The Milky Way Galaxy is an Sb type. *See* MILKY WAY GALAXY.

"Whirlpool" galaxy (NGC 5194), type Sc, and a companion irregular satellite (NGC 5195)

Another common type of galaxy is a featureless ellipsoid with radially decreasing brightness. These galaxies are classified as ellipticals (E) and subclassified according to their axial ratios by a number from 0 (E0 = round) to 7 (E7 = 3-to-1 axial ratio). They may vary in size from thousands to several hundred thousand light-years. They are most commonly found in clusters of galaxies and rarely contain much gas or dust. The brightest galaxies are usually ellipticals. [E.L.T.; J.B.T.]

Some galaxies lie outside the normal range of morphologies. One of the more spectacular examples of such exotic galaxies is the starbursters, galaxies that are presently manufacturing stars at an unusually vigorous rate. It is now known that some gravitational impulse has triggered the unusual star formation activity in at least most cases. Another type of exotic galaxy is the low-surface-brightness galaxies, star systems that have such a low spatial density of stars that they are almost invisible. A significant fraction of the mass of the universe may be in the form of these nearly invisible galaxies. [P.Hod.]

Although galaxies are scattered through space in all directions for as far as they can be observed, their distribution is not uniform or random. Most galaxies are found in associations containing from two to hundreds of individual bright galaxies and at least 10 times as many fainter dwarf galaxies. The Milky Way Galaxy and the Andromeda Nebula are members of a cluster called the Local Group. *See* ANDROMEDA GALAXY; LOCAL GROUP.

On scales larger than individual small groups and rich clusters, the distribution of galaxies through space is still not random. This very large scale structure in the galaxy distribution is usually referred to as superclustering to indicate that it involves the higher-order clustering of the individual first-order associations of galaxies. Neither empirical nor theoretical understanding of this very large scale structure is well established or generally agreed upon. *See* UNIVERSE.

In the very central regions (sizes at least as small as a light-year, 6×10^{12} mi or 1×10^{13} km) of galaxies, violent and apparently explosive behavior is often observed. This activity is manifested in many ways, including the high-velocity outflow of gas, strong nonthermal radio emission (implying relativistic particles and magnetic fields), intense and often polarized and highly variable radiation at infrared, optical, ultraviolet, and x-ray wavelengths, and ejection of jets of relativistic material. In the most extreme cases the energy in the nuclear activity surpasses that in the rest of the galaxy combined. These phenomena are generically referred to as nuclear activity, and the objects that exhibit them are called active galactic nuclei.

There are a variety of classes of active galactic nuclei. The Seyfert galaxies display the broad emission lines produced by the rapid outflow of hot gas but frequently do not exhibit much radio-wavelength emission. Another complementary class shows strong radio emission but weak or absent emission lines. Yet another class (BL Lac objects, often referred to as blazars) also shows only weak emission lines but is often extremely variable. When active galactic nuclei achieve such great luminosities that they dominate that of the rest of the galaxy, they are sometimes referred to as AGNs. Quasars are widely believed to be the most extreme sort of active galactic nuclei, having emission so intense that the ordinary galaxy in which they exist is entirely lost in the glare of the nuclear emission. *See* QUASAR.

Perhaps the most intriguing question concerning active galactic nuclei is that of the nature of the energy source that drives all of their diverse phenomena. According to a widely accepted best guess or consensus model, active galactic nuclei are powered by the energy released when matter falls into a massive black hole occupying the center of a galaxy. These black holes are imagined to have masses in the rough range of 10^6–10^9 solar masses and to have formed because of the high density of material expected to accumulate at the center of a galaxy due to its gravitational field. Such a black hole will continue to accrete any gas that finds its way into the vicinity. As such gas falls toward the black hole, its angular momentum will cause it to take up a nearly circular orbit in a disk of material surrounding the black hole. This disk (called an accretion disk) will slowly inject gas into the black hole. As the gas approaches the black hole, the latter's enormous gravitational field will compress and heat the gas to very high temperatures, causing it to radiate. A given mass of gas can release 10 or more times as much energy in this way as it could if it were used as nuclear fuel in a star or a reactor. *See* Astrophysics, high-energy; Black hole. [E.L.T.; J.B.T.]

Galena A mineral with composition PbS (lead sulfide) and belonging to the rock salt (NaCl) structure type. Galena usually occurs as cubes, sometimes modified by the octahedral form, with perfect cubic cleavage, brilliant metallic luster, color lead gray, specific gravity 7.5, and hardness $2^{1}/_{2}$ on Mohs scale.

Galena is widely distributed and constitutes by far the most important ore for lead. Silver, antimony, arsenic, copper, and zinc minerals often occur in intimate association with galena; consequently, galena ores mined for lead also include many valuable by-products. Important localities include Broken Hill, Australia; the tristate district of Missouri, Kansas, and Oklahoma; and numerous occurrences in Colorado, Montana, and Idaho. [P.B.M.]

Galilean transformations The family of mathematical transformations used in newtonian mechanics to relate the space and time variables of uniformly moving (inertial) reference systems. In the simple case of two similarly oriented cartesian reference frames, moving along their common (x, x') axis, the transformation equations can be put in the form

$$x' = x - vt \qquad y' = y \qquad z' = z \qquad t' = t$$

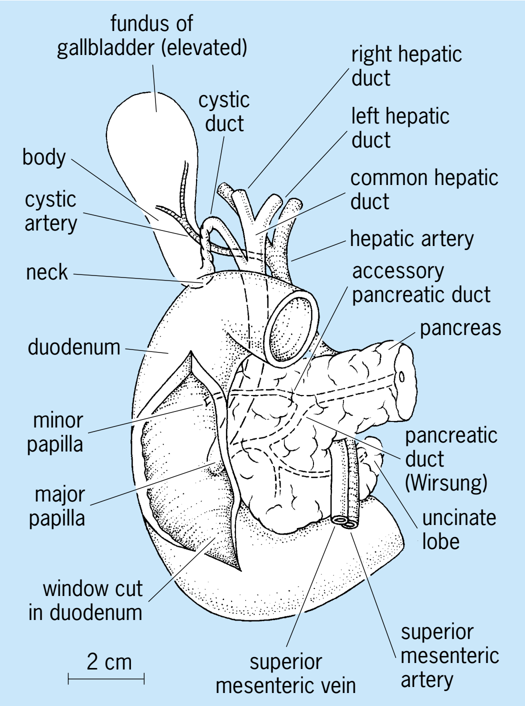
where x, y, z and x', y', z' are the space coordinates of a given particle, and v is the speed of one system relative to the other. *See* Frame of reference. [E.L.Hi.]

Gallbladder A hollow muscular organ, present in humans and most vertebrates, which receives dilute bile from the liver, concentrates it, and discharges it into the duodenum. It also participates in the entero-hepatic (re)circulation of bile, and in secretion and removal of conjugated xenobiotics, including radiopaque substances taken orally or intravenously for diagnostic purposes. Although not a vital organ, it stores bile, regulates biliary tract pressures, and, when diseased, enhances precipitation of various constituents of the bile as gallstones.

The system of bile ducts lying outside the liver is known as the extrahepatic biliary tract. In humans (Illus.) right and left hepatic ducts empty into the common hepatic duct, which continues to the duodenum as the common bile duct, or ductus choledochus. The gallbladder and cystic duct thus appear to be accessory organs and therefore are removable. However, they are converted into main-line structures by the presence of a sphincter (sphincter of Oddi) at the choledochoduodenal junction. Tonic contraction of this sphincter between meals forces the bile to back up into the gallbladder.

In most other vertebrates essentially similar relations exist except when the gallbladder is absent, but there is considerable variation in proportion and arrangement of ducts, including the pancreatic ducts. *See* Liver; Pancreas.

In humans, evacuation of the gallbladder is accomplished by a trigger mechanism which is set off by the presence of fatty foods, meat, and hydragogue cathartics in the duodenum and upper jejunum. Absorption of these substances by the mucous membrane results in the release of cholecystokinin (CCK), a hormone which rapidly circulates in the bloodstream and simultaneously produces contraction of the gallbladder and relaxation of the sphincter of Oddi. The most effective food is egg yolk, which contains certain *l*-amino acids. Resorption of bile salts by the intestine stimulates secretion of bile for hours after a meal. *See* Digestive system. [E.A.B.; J.Gi.]



Extrahepatic biliary tract in humans.

Gallbladder disorders Although not essential to life or health, the gallbladder is the site and source of appreciable suffering and disease in humans. With its cystic duct, the gallbladder constitutes a blind-ended, lateral extension of the common bile duct. Besides acting as a reservoir for bile, the gallbladder concentrates and otherwise alters the composition of bile. *See* Gallbladder.

Gallstones are round, oval, or faceted concretions formed within the gallbladder from the salts and pigment of bile. Although the mechanism and reason for their formation are not clearly understood, the major predisposing factors are stasis (prolonged retention of bile in the gallbladder), abnormal composition of the bile (excessive amounts of cholesterol, bilirubin, or calcium), and infection. Passage of a gallstone through the ducts into the duodenum usually produces severe pain, called biliary colic. If a stone causes obstruction of the ducts, the result may be damage to the liver, pancreas, biliary system, and related structures either directly or through concomitant inflammation. Gallstones are rare in animals, although they have been found in nearly all species, especially in cattle. *See* Bilirubin; Cholesterol; Cirrhosis.

Cholecystitis, or inflammation of the gallbladder, is a common disease in humans. It is nearly always associated with gallstones and is particularly common in obese middle-aged women. It is rare in animals. Most cases are thought to be the result of chemical irritation caused by excessively concentrated bile, which is in turn the result of partial or complete obstruction to the outflow of bile. Prolonged or recurrent episodes of inflammation result in chronic cholecystitis, characterized by thickening and scarring of the wall, contraction, and impairment of normal function.

Malignant tumors in the gallbladder are almost invariably associated with the presence of gallstones. Because they produce little in the way of symptoms, and because they very soon invade the liver, these tumors are rarely curable by surgical therapy at the time they are discovered. Benign tumors of the gallbladder and ducts are rare in humans, and in animals both benign and malignant tumors of these sites are extremely uncommon. *See* Liver disorders. [M.R.H.]

Galliformes A large order of birds containing the gallinaceous or chickenlike birds. They are found worldwide, although the several subgroups have a more limited distribution. Part of the superorder Neognathae, the galliforms are closely related to the anseriforms and include the most important domesticated birds, the chicken (*Gallus gallus*) and the turkey (*Meleagris gallopavo*). *See* Anseriformes.

The order Galliformes is divided into two suborders with two families, as follows.

Order Galliformes
  Suborder Cracoidea
    Family: Megapodiidae (megapodes or brush turkeys; 7 species)
      Cracidae (curassows, guans, chachalacas; 49 species)
  Suborder Phasianoidea
    Family: Phasianidae (grouse, pheasant, quail, guinea fowl, turkey; 212 species)
      Subfamily: Tetraonidae (grouse)
        Phasianiaen (pheasant, peafowl, chicken)
        Odontophorinae (New World quail)
        Numidinae (guinea fowl)
        Meleagrinae (turkey)

The galliforms have been one of the most economically important group of birds to humans. Almost all species have been or are still being hunted for food. Many species of galliforms have become reduced in numbers because of overhunting and habitat destruction. Some species, especially the forest pheasants of Asia, are seriously endangered. *See* Aves. [W.J.B.]

Gallium A chemical element, Ga, atomic number 31, atomic weight 69.72. Gallium is a member of group 13 and the fourth period of the periodic table (IUPAC). *See* Periodic table.

The major commercial sources of gallium are bauxite, containing gallite ($CuGaS_2$), and zinc and germanium sulfides. Normal ore-grade deposits usually contain substantially less than 0.1% gallium. In the United States the bauxite deposits in Arkansas and the zinc deposits in Oklahoma are the main sources of domestic production. Much of the gallium used in the United States is imported from Switzerland and Germany, with lesser amounts from Canada and France. *See* Bauxite.

Gallium is a unique element in that it possesses the largest liquid range of any element. Its normal freezing point of 29.78°C (85.60°F) is lower than any metal except mercury and cesium. Its boiling point is in the vicinity of 2420°C (4388°F), although there is some uncertainty owing to the reactivity of gallium with the container material at this temperature.

The valence-electron notation of gallium corresponding to its ground-state term is [Ar, $3d^{10}4s^24p^1$], which accounts for the maximum oxidation state of III in its chemistry. Compounds of formal oxidation state II and I are also known.

Approximately 95% of the gallium consumed in the United States and presumably in the world is used in the electronics industry. Minor quantities have been used or studied for use in thermometers, low-melting solders, as a heat-transfer fluid, in arc lamps, batteries, vanadium-gallium superconductors, and in catalyst mixtures.

The most important gallium semiconductors are gallium arsenide (GaAs) and gallium phosphide (GaP). The magnitude of the energy gap in GaAs favors its use in transistors. The electron mobility in GaAs is very much higher than the hole mobility; in contrast, the electron and hole mobility in GaP are of similar magnitude and very much lower than in GaAs. By doping with the appropriate elements, these properties can be altered. Electron transport (*n*-type) GaP semiconductors are used in rectifiers, hole transport (*p*-type) in light sources and photocells. *n*-Type GaAs semiconductors are used in injection lasers and *p*-type GaAs in electroluminescent transistors. *See* Hole states in solids; Semiconductor.

GaN is prepared by the reaction of metallic gallium or Ga_2O_3 at elevated temperature with ammonia, and the other semiconductors by direct reaction with the elements or Ga_2O at high temperature. *See* Aluminum; Indium; Thallium. [E.M.L.]

Galvanizing The generic term for any of several techniques for applying thin coatings of zinc to iron or steel stock or finished products to protect the ferrous base metal from corrosion; more specifically, the hot dipping that is widely practiced with mild steel sheet and corrugated sheets. During dipping, molten zinc reacts with the steel to form a brittle zinc-iron alloy. For marine use, magnesium is added.

An electrolytic process (also called cold galvanizing or electrogalvanizing) is also used for wire, as well as for applications requiring deep drawing. An alloy layer does not form, hence the smooth electroplated coating does not flake in the drawing die. *See* Metal coatings. [F.H.R.]

Galvanomagnetic effects Electrical and thermal phenomena occurring when a current-carrying conductor or semiconductor is placed in a magnetic field. The galvanomagnetic effects are closely related to the thermomagnetic effects. *See* Thermomagnetic effects.

Let the electric current density j be transverse to the magnetic field H_z, for example, along x. Then the following transverse-transverse effects are observed: (1) Hall effect, an electric field along y. (2) Ettingshausen effect, a temperature gradient along y. Also the following transverse-longitudinal effects are observed: (3) Transverse magnetoresistance, an electrical potential change along x. (4) Nernst effect, a temperature gradient along x. *See* Hall effect; Magnetoresistance.

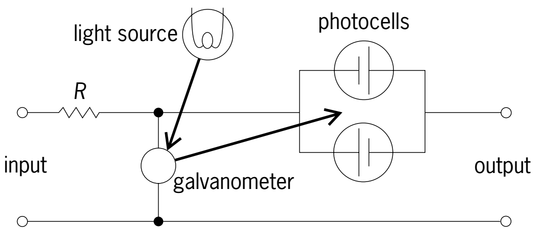
Let the electric current density j be along H. Then, the most important effect is longitudinal magnetoresistance, or an electrical potential change along H. [E.A.; F.Ke.]

Galvanometer A device for indicating very small electric currents. Although the deflection of a galvanometer results from current in the moving coil, the voltage in a closed circuit producing this current is frequently the quantity of interest to the user. In this mode, galvanometers are used to detect a null or an unbalanced condition in a bridge or potentiometer circuit. Electronic instruments that employ amplifying circuits to achieve sensitivities approaching the nanovolt level are also used as balance detectors in bridge circuits. However, in applications where extreme sensitivity and high rejection of ac signals are required, a galvanometer in combination with a photocell amplifier is to be preferred.

Galvanometers may also be used ballistically to integrate a transient current, as from the discharge of a capacitor, or a transient voltage, as produced when a coil moves relative to a magnetic field. *See* Current measurement; Voltage measurement.

The d'Arsonval galvanometer is the most common type and is widely used. Its indicating system consists of a light coil of wire suspended from a copper or gold ribbon a few thousandths of an inch wide and less than 0.001 in. (0.025 mm) thick. This coil, free to rotate in the radial field between the shaped pole pieces of a permanent magnet, carries a small mirror which serves as an optical pointer and indicates the coil position by reflecting a light beam onto a fixed scale. Current is conducted to and from the coil by the suspension ribbons. The torque which deflects the indicating element is produced by the reaction of the coil current with the magnetic field in which it is suspended.

Voltage sensitivity is of importance in applications where the galvanometer serves as the detector of unbalance in a bridge



Simplified schematic of photocell galvanometer amplifier.

or potentiometer network. The energy of motion in the indicating system must be dissipated and the system brought to rest in order for the deflection to be evaluated. This process, common to all indicating systems in which equilibrium must be achieved between a driving torque and a restoring torque, is called damping. *See* DAMPING.

The sensitivity of modern galvanometers ranges up to 0.04 in. (1 mm) of deflection, on a scale 40 in. (1 m) distant from the mirror, for a current of 0.00001 microampere. Such a galvanometer may have a coil resistance of 800 ohms and a critical damping resistance of 100,000 Ω. The voltage response of this instrument amounts to 0.04 in./microvolt (1 mm/μV) at critical damping. A galvanometer designed for voltage sensitivity, has a coil resistance of 20 Ω, a critical damping resistance of 30 Ω, and a response of 0.04 in. (1 mm) for 0.05 μV in the critically damped circuit. It will be seen from these examples that a large response to current is associated with large coil resistance and high critical damping resistance, whereas voltage response is associated with low coil resistance and low critical damping resistance.

The limitations reached in improving a galvanometer's resolution by increasing its scale length or using multiple reflections can be overcome by operating the galvanometer in its equilibrium position by using a negative-feedback network. In this system the beam of light reflected from the galvanometer mirror is directed onto a pair of photocells connected in series opposition (see illustration). As the galvanometer coil rotates, the light received on one photocell increases while the other decreases, and an amplified output current is produced whose sign and magnitude depend on the direction and amount of the coil deflection, respectively. The photocell output current is monitored by an external indicator and is approximately 1800 times the galvanometer input current. This photocell output also provides a negative-feedback current to servo the galvanometer at its equilibrium position, so that the linearity and input resistance of the system are increased. In such an arrangement it is frequently possible to approach rather closely the theoretical limit of resolution of angular motion imposed by the brownian motion of the coil, or by the Johnson noise of the circuit connected to the galvanometer. In a low-resistance galvanometer this theoretical resolution may be about 0.001 μV. *See* BROWNIAN MOVEMENT; ELECTRICAL NOISE; KINETIC THEORY OF MATTER.

A galvanometer is an extremely efficient low-pass filter, and it is still the most sensitive low-level detector at input impedances of 1 kΩ or less. At higher input impedances, chopper-stabilized amplifiers, called nanovoltmeters, exhibit better resolution, noise, and drift characteristics than galvanometers. These instruments modulate the input dc signal by using a chopper (mechanical contact, transistor, or photocell switching), then amplify the signal by traditional ac techniques to achieve sensitivities of 10 nV or less. State-of-the-art digital voltmeters are now available with nanovolt resolution and are useful as low-level detectors. *See* AMMETER; ELECTRIC FILTER; ELECTRICAL INTERFERENCE; ELECTRICAL MEASUREMENTS; ELECTROMETER; VOLTMETER. [F.K.H.; R.F.Dz.]

Game theory

The theory of games of strategy can briefly be characterized as the applicaiton of mathematical analysis to abstract models of conflict situations. The first such models analyzed by the theory were parlor games such as chess, poker, and bridge. Since then, models arising from the behavioral sciences such as economics, sociology, and political science have been analyzed. Game theory is used in or closely connected to other areas such as linear programming, statistical decisions, management science, operations research, and military planning. In certain areas, the language and concepts of the theory are sometimes used even though the corresponding mathematics is not. *See* LINEAR PROGRAMMING; OPERATIONS RESEARCH.

Games in extensive form. The players of a game are called persons, and such a person may actually consist of one or more people (for instance, in bridge the pairs of partners, east-west and north-south, each make up a player in the game). Chance moves occur when hands are dealt from a shuffled pack, dice are rolled, or pointers are spun. One says that all chance moves are allotted to the chance player—a fiction that is useful in abstracting properties of games.

When specified by a list of rules, a game is said to be in extensive form. For mathematical purposes, it is convenient to have games in normalized form, and for that, the idea of a pure strategy is needed.

A pure strategy for a player (not the chance player) is a complete list of choices of legal moves that he or she will make for every possible situation that can occur during the game. This is a much more complete list of decisions than that commonly called a strategy. The number of pure strategies in a game can be astronomical even for childish games such as tic-tac-toe. Because of the enormous number of pure strategies, the actual applications of game theory even to parlor games have been severely limited by computational difficulties. Simplified versions of the games have been developed for which computations have been completely carried out.

Games in normalized form. After players have chosen pure strategies in a game, they need not physically play the game. Instead they could hand their strategies to a neutral person, or umpire, who could then carry out their instructions and make the moves they would have made. This intuitively obvious idea leads naturally to the normalized form of the game.

Assume for the moment there are no chance moves in the game, that is, that there are n real players but no chance player. Denote by $s_1, s_2, \ldots, s_n$ specific pure strategies for players 1, 2, ..., n, respectively. Given these, the game must be played in exactly one way and a unique outcome will result. Let $P_i(s_1, s_2, \ldots, s_n)$ be the monetary outcome to player i for this play of the game.

Before the effect of the chance player can be introduced, the important concept of mathematical expectation must be explained. Suppose that $O_1, O_2, \ldots, O_k$ are mutually exclusive monetary outcomes of a chance event, and suppose further that they happen with probabilities, $p_1, p_2, \ldots, p_k$ where $p_i > 0$ and $p_1 + p_2 + \cdots + p_k = 1$. Then the mathematical expectation E of the chance event is defined to be the sum $E = p_1O_1 + p_2O_2 + \cdots + p_kO_k$. *See* PROBABILITY.

If there are chance moves in the game, a set of pure strategies, one for each player, will not determine a unique outcome of the game but merely a set of possible outcomes. These outcomes will be mutually exclusive and have probabilities depending on the chance moves associated with their occurrence. Hence in this case one can let $P_i(s_1, s_2, \ldots, s_n)$ be the expected payoff to player i for each $i = 1, 2, \ldots, n$.

Now the normalized form of a game is defined as the list of all expected payoffs to each player for every possible combination of pure strategies. In the case of two-person games it is most convenient to list these in tables called matrices. *See* MATRIX THEORY.

Classification of games. A game is called zero-sum if, for every possible n-tuple of pure strategies $s_1, \ldots, s_n$, the sum of the payoffs to all players is zero, that is, Eq. (1) holds. If this sum

$$P_1(s_1, \ldots, s_n) + P_2(s_1, \ldots, s_n) + \cdots + P_n(s_1, \ldots, s_n) = 0 \quad (1)$$

is not zero for some n-tuple of pure strategies, the game is called nonzero-sum.

A game in extensive form is said to have perfect information if every player knows and remembers each move of each of her or his opponents as they are made. A game is said to have perfect recall if each player knows and remembers everything he or she did (but not necessarily what the opponent did). Bridge does not have perfect recall, because the personality of a player (=team) is divided between two actual persons and, for instance, north does not see what is in south's hand (except when south is dummy) even though they are members of the same team.

Games can then be classified according to the number of players they have, whether or not they are zero-sum, and whether or not they have perfect information or perfect recall.

Nonzero-sum games. By far the most satisfactory part of the theory of games consists of the zero-sum two-person cases, that is, in matrix games. Applications of the theory to such areas as economics, sociology, and political science almost invariably lead to many-person nonzero-sum games. Although no universally accepted theory has been developed to cover these games, many interesting and useful attempts have been made to deal with them.

When more than two persons are involved in a conflict situation, the important feature of the game becomes the coalition structure of the game. A coalition is a group of players who band together and, in effect, act as a new player in the game. There are two extremes to be considered. One is the noncooperative game in which such coalitions are banned by some means. Equilibrium-point solutions, discussed below, provide reasonably satisfactory solutions to such games. The other extreme is that in which all the players join together in a coalition to maximize jointly their total payoff. A game in which coalitions are permitted is called a cooperative game.

In the noncooperative game, each player is solely interested in his or her own payoff. By an equilibrium point in such a game is meant a set of mixed strategies $s_1, \ldots, s_n$ such that Eq. (2) holds

$$P_i(s_1, \ldots, s_i, \ldots, s_n) = P_i(s_i, \ldots, s_n', \ldots, s_n) \qquad (2)$$

for each $i = 1, \ldots, n$ for all strategies s_i, of player i. What this means is that no player can, by changing strategy and assuming that the other strategies stay fixed, improve the payoff. By a theorem of J. Nash, every game has at least one equilibrium-point solution (commonly there are several).

Simple games. An important class of n-person games for application to political behavior are the so-called simple games. Each coalition in such a game can be either winning, losing, or blocking. For instance, a winning coalition may be a set of voters who can elect their candidate, or a group of lawmakers who can pass their bill. The players not in a given winning coalition form a losing coalition. Finally, a coalition is blocking if neither it nor the players not in it can enforce their wishes.

Continuous games. If, in the normalized form of the game, each player is permitted to have a continuous range of pure strategies and the payoff function is permitted to be a function of the two real variables that range over each player's strategies, the result is a continuous game.

Game-playing machines. One of the first applications of large electronic computers to numerical problems was in solving large matrix games. Several methods have been devised for finding such solutions. One such method is the simplex method. So-called decomposition methods can extend these methods to certain problems having thousands or even millions of variables and constraints. The principal application of the method is to solve linear programming problems, which can be shown to be equivalent to matrix games.

Computers have also been programmed to play board games such as checkers and chess. Strictly speaking they do not use the theory of games at all at present, but instead use some of the game sense of the people who devised the codes. *See* DECISION THEORY; INFORMATION THEORY; STOCHASTIC PROCESS. [G.L.T.]

Gametogenesis

Gametogenesis The production of gametes, either eggs by the female or sperm by the male, through a process involving meiosis. In animals, the cells which will ultimately differentiate into eggs and sperm arise from primordial germ cells set aside from the potential somatic cells very early in the formation of the embryo.

The final products of gametogenesis are the large, sedentary egg cells, and the smaller, motile sperm cells. Each type of gamete is haploid; that is, it contains half the chromosomal complement and thus half as much deoxyribonucleic acid (DNA) as the somatic cells, which are diploid. Reduction of the DNA content is accomplished by meiosis, which is characterized by one cycle of DNA replication followed by two cycles of cell division. *See* CHROMOSOME; MEIOSIS.

The production of sperm differs from that of oocytes in that each primary spermatocyte divides twice to produce four equivalent spermatozoa which differ only in the content of sex chromosomes (in XY sex determination, characteristic of mammals, two of the sperm contain an X chromosome and two contain a Y). The morphology of sperm is highly specialized, with distinctive organelles forming both the posterior motile apparatus and the anterior acrosome, which assists in penetration of the oocyte at fertilization. *See* SPERMATOGENESIS.

The cytoplasm of the primary oocyte increases greatly during the meiotic prophase and often contains large quantities of yolk accumulated from the blood. Meiotic divisions in the oocyte are often set in motion by sperm entry, and result in the production of one large egg and three polar bodies. The polar bodies play no role, or a very subordinate one, in the formation of the embryo. *See* OOGENESIS.

After fertilization and the formation of the polar bodies, the haploid sperm and egg nuclei (pronuclei) fuse, thus restoring the normal diploid complement of chromosomes. *See* FERTILIZATION; REPRODUCTION (ANIMAL). [S.J.B.]

Meiosis in flowering plants, or angiosperms, is essentially similar to that in animals. However, the cells produced after meiosis are spores, and these do not develop directly into gametes. Female spores (megaspores) and male spores (microspores) develop into gametophytes, that is, female and male haploid plants that bear within them the egg and sperm, respectively. There is a wide range in the details of development and structure of gametes among the different groups of plants other than angiosperms. *See* REPRODUCTION (PLANT). [J.P.M.]

Gamma function

Gamma function A particular mathematical function that can be used to express many definite integrals. There are, however, no significant applications where the gamma function by itself constitutes the essence of the solution. Instead it occurs usually in connection with other functions, such as Bessel functions and hypergeometric functions.

A special case of the gamma function is the factorial $n! = 1 \cdot 2 \cdot 3 \cdot \cdots \cdot n$ (for example, $1! = 1, 2! = 2, 3! = 6, 4! = 24$). It is defined only for integral positive values of n. The factorial occurs, for instance, in the expansion

$$exp\, z = 1 + z/1! + z^2/2! + z^3/3! + \cdots$$

The binomial coefficient (N/n) can be expressed in terms of factorials as $N!/[n!(N - n)!]$. Many occurrences of the factorial are found in combinatorial theory (for instance, $n!$ is the number of permutations of n different elements), in probability theory, and in the applications of this theory to statistical mechanics. For large values of n, the factorial can be easily, although only approximately, computed with Stirling's formula,

$$n! \approx (n/e)^n (2\pi n)^{1/2}$$

See BESSEL FUNCTIONS. [J.Meix.]

Gamma-ray astronomy

Gamma-ray astronomy The study of gamma rays of cosmic origin. This vast spectral domain extends from an energy of 0.05 MeV (wavelength of 2.5×10^{-11} m), the adopted boundary between x-ray and gamma-ray photons, to 10^{11} MeV (10^{-23} m), an experimental barrier imposed by the extreme scarcity of ultrahigh-energy photons. *See* GAMMA RAYS.

Low-energy (or soft) gamma-ray astronomy (up to a few megaelectronvolts) deals mainly with processes in dense media, such as plasmas confined close to neutron stars and black holes. It also concerns cosmic sites where monoenergetic photons are released either by deexcitation of atomic nuclei (nuclear lines) or by positron annihilation (the 0.511-MeV line). Gamma-ray astronomy at higher energies relates to emissions induced by relativistic particles throughout the whole interstellar medium, as well as in the vicinity of some neutron stars and in the powerful jets beamed by active galactic nuclei. The penetration power of gamma-ray photons enables exploration of regions that are hidden at other wavelengths, such as the galactic center region, as well as of the first stages of the universe, since the cosmos is particularly transparent to gamma rays (with the exception of photons whose energy exceeds 10^6 MeV).

Because photons in the gamma-ray regime are completely absorbed by the Earth's atmosphere, gamma-ray detectors are placed on board high-altitude balloons or, better still, artificial satellites. Ground-based telescopes, making use of the upper atmospheric layers as a detector, operate successfully in the very high energy gamma-ray band. *See* SATELLITE (ASTRONOMY).

Instrumentation. In other regions of the electromagnetic spectrum, sensitivity is increased by the straightforward method of gathering large numbers of photons and concentrating them to form an image, by means of arrangements of reflectors or lenses. Such a method does not apply to gamma-ray telescopes, since gamma-ray photons can be neither reflected nor refracted. However, gamma-ray concentrators based on Laue diffraction have become feasible, and signal-to-noise ratio could be dramatically improved.

Soft gamma-ray telescopes use the coded-aperture technique to image celestial sources. A coded mask is a pattern of tungsten blocks that absorb gamma-ray photons and are arranged so that a given point source at infinity projects on a position-sensitive detector a pattern that is characteristic of the direction of arrival of the photons. The position of the source in the sky is determined by comparing the observed pattern with all possible projection patterns.

High-energy gamma-ray observations are performed with devices derived from particle-physics detectors. High-energy gamma-ray photons interact almost exclusively via electron-positron pair production. After passing undetected through an anticoincidence shield sensitive to charged particles, a photon is converted to an electron-positron pair in one of the conversion foils. Trajectories of the resulting electron and positron are measured by particle tracking detectors. The energy deposited in an underlying calorimeter is used with the trajectory data to determine the arrival direction and total energy of the gamma rays.

As the gamma-ray energy approaches 10^5 MeV, the intensities of celestial gamma rays become too low for them to be seen with space telescopes. However, at energies above a few thousand megaelectronvolts (wavelengths of less than 10^{-15} m), a gamma-ray photon induces in the upper atmosphere a shower of secondary relativistic particles whose propagation through the air produces a narrow beam of Cerenkov visible light which can be detected on the ground by a large parabolic mirror. Detailed studies of the Cerenkov light beam enable the determination of the arrival direction of the generating gamma ray to within 0.1° while discriminating gamma-ray-induced events from much more numerous events induced by interactions of very high energy cosmic-ray protons and nuclei. *See* CERENKOV RADIATION; COSMIC RAYS.

Stellar sources. Other than the Sun, all stellar sources of gamma rays relate to massive stars in their final stages of evolution. Major contributions to the theoretical understanding of explosive nucleosynthesis have come from the data obtained on supernova SN 1987A, which appeared on February 24, 1987, in the Large Magellanic Cloud, a nearby galaxy. *See* NUCLEOSYNTHESIS; SUPERNOVA.

Attested by the discovery of radio pulsars in 1967, the capability of neutron stars to accelerate relativistic electrons was confirmed a few years later by the discovery of the gamma-ray emission of the Crab and Vela pulsars. Six or more pulsars were detected by the *Compton Gamma-Ray Observatory*. The energy spectrum of the Crab pulsar suggests that the gamma radiation results from the synchrotron emission of relativistic electrons in the intense magnetic fields which prevail in the close vicinity of newly formed neutron stars. It is generally agreed that the ultimate source of the radiated energy is the rotational energy of the neutron star. Electrons are accelerated to very high energies by the huge electric fields induced by the pulsar rotation. *See* CRAB NEBULA; NEUTRON STAR; PULSAR.

Almost all the known accreting black-hole systems produce strong and variable gamma-ray emission. In systems with low-mass (less than one solar mass) companion stars, huge outbursts called x-ray novae are observed, such as Nova Muscae 1991, which for one week was the brightest source in the soft gamma-ray sky. Several accreting black holes have been observed in the central region of the Milky Way Galaxy. *See* ASTROPHYSICS, HIGH-ENERGY; BLACK HOLE.

Other galactic sources. A large fraction of the cosmic gamma-ray photons originates in interstellar sites. Cosmic-ray-induced interstellar emission results mostly from the interaction of cosmic rays (electrons and protons) with the interstellar gas. The high-energy gamma-ray sky is dominated by radiation from the galactic plane whose spatial distribution and intensity can be reliably modeled from knowledge of the interstellar gas distribution. A large fraction of the pointlike sources observed at medium galactic latitude may be related to the local interstellar medium, and more specifically to the giant cloud complexes of Gould's Belt.

Spectroscopic observations of the whole galactic center region have demonstrated the presence of a large-scale component of 0.511-MeV radiation due to the annihilation of positrons in the interstellar medium. The source of such interstellar positrons is thought to be the β^+-decay products from radioactive nuclides produced by novae, red giants, Wolf-Rayet stars, and supernovae. *See* GIANT STAR; NOVA; POSITRON; WOLF-RAYET STAR.

Extragalactic sources. With the exception of the Large Magellanic Cloud, all localized extragalactic sources of gamma rays are active galactic nuclei, the most energetic and distant objects in the universe. These include radio sources such as Seyfert galaxies and quasars, all with different properties depending on the observing wavelength. The ultimate source of active galactic nuclei activity is believed to be massive (10^6–10^9-solar-mass) black holes, accreting 10–100 solar masses per year to account for their overall luminosity. An accretion disk with a collimated perpendicular jet is the favored model for explaining the luminous, broadband radiation emitted from the central engines of active galactic nuclei. *See* GALAXY, EXTERNAL; QUASAR. [J.Pa.]

Gamma-ray bursts. Gamma-ray bursts were first detected by means of the *Vela* spacecraft in 1967, and their discovery was announced in 1973. More than 2700 bursts were detected by the *Compton Gamma-Ray Observatory*. Its observations give strong evidence for an isotropic distribution of bursts; that is, the burst directions appear to be random and show no preference for the galactic plane, in particular. The nearest reasonable source location is probably in an extended halo surrounding the Milky Way Galaxy; a great many astrophysicists now favor greater (cosmological) distances.

Knowledge about gamma-ray bursts has increased rapidly in recent years due to the launch of spacecraft such as *BeppoSAX*, and to the development of a very rapid alert network (the Gamma-Ray Burst Coordinate Network) to allow follow-up observations by ground observers. Optical, x-ray, and radio afterglows have been detected for a number of gamma-ray bursts, and in a few cases redshifts have been reported for optical sources in the gamma-ray burst error boxes.

The arguments for cosmological distances of most gamma-ray bursts include the highly isotropic distribution of sources and the redshifts reported for a small number of gamma-ray bursts, at least for optical sources within the error boxes for the bursts. To account for the enormous amounts of energy required for such cosmological distances (greater than 10^{54} ergs or 10^{47} J) models have been developed based on "hypernovae" (much brighter than supernovae), collisions between two neutron stars, narrow searchlight beams of emission aimed at the Earths, and even gravitational lensing to increase the intensity. [J.Te.]

Gamma-ray detectors Instruments that register the presence of gamma (γ) radiation. Such detectors convert some or all of the energy of gamma radiation into an electrical signal. Most instruments are capable of detecting individual gamma-ray photons (or quanta), each of which produces a short (0.1–5-microsecond) current pulse at the detector output. The output pulses may be made visible on an oscilloscope, made audible through a speaker (such as the familiar Geiger counter), or be electronically processed further, depending on the application. *See* GAMMA RAYS; OSCILLOSCOPE.

In common with most radiation detectors, gamma-ray detectors respond not to the radiation but to its secondary effects, in this case energetic electrons. Photons have neither mass nor charge and pass through matter rather easily. In so doing, they lose energy by (1) elastic scattering of electrons (Compton effect), (2) electron-positron ($\beta^+\beta^-$) pair production, and (3) at lower energies by photoabsorption. In these processes the energy of the photon is converted to the kinetic energy of the few electrons with which it interacts. Since electrons are much less penetrating than gamma-ray photons, their energy is largely trapped within the detector, where their ionizing effect creates a response convertible to an electrical output. In a gas-ionization device, such as Geiger counter, this occurs by the production of ion-electron pairs and in a solid-state device, such as a germanium detector, by production of electron-hole pairs. In a scintillation device, for example, a sodium iodide (NaI) detector, the response is caused by the emission of optical photons from atoms excited by the passage of energetic electrons. *See* COMPTON EFFECT; ELECTRON-POSITRON PAIR PRODUCTION; GEIGER-MÜLLER COUNTER; IONIZATION CHAMBER; SCINTILLATION COUNTER.

In accurate instruments the magnitude of the current pulse created by a single gamma-ray photon is closely proportional to the energy within the detector volume. However, gamma radiation is so penetrating that any particular event may involve only partial absorption of the photon. For example, a single Compton scattering may be followed by the escape of the scattered photon (now reduced in energy) from the detector, leaving behind only the energy of the scattered electron.

Gamma-ray detectors range from hand-held devices capable of giving some indication of the intensity of a radiation field, to devices that accurately measure the energy and event time of individual photons reaching detectors assembled into a single complex instrument. These diverse detectors are widely used in industry, medicine, and research. [D.Wa.]

Gamma rays Electromagnetic radiation emitted from excited atomic nuclei as an integral part of the process whereby the nucleus rearranges itself into a state of lower excitation (that is, energy content). *See* NUCLEAR STRUCTURE; RADIOACTIVITY.

The gamma ray is an electromagnetic radiation pulse—a photon—of very short wavelength. The electric (E) and magnetic (H) fields associated with the individual radiations oscillate in planes mutually perpendicular to each other and also the direction of propagation with a frequency ν which characterizes the energy of the radiation. The E and H fields exhibit various specified phase-and-amplitude relations, which define the character of the radiation as either electric (EL) or magnetic (ML). The second term in the designation indicates the order of the radiation as 2^L-pole, where the orders are monopole (2^0), dipole (2^1), quadrupole (2^2), and so on. The most common radiations are dipole and quadrupole. Gamma rays range in energy from a few kiloelectronvolts to 100 MeV, although most radiations are in the range 50–6000 keV. As such, they lie at the very upper high-frequency end of the family of electromagnetic radiations, which include also radio waves, light rays, and x-rays. *See* ELECTROMAGNETIC RADIATION; MULTIPOLE RADIATION; PHOTON.

The dual nature of gamma rays is well understood in terms of the wavelike and particlelike behavior of the radiations. For a gamma ray of intrinsic frequency ν, the wavelength is $\lambda = c/\nu$, where c is the velocity of light; energy is $E = h\nu$, where h is Planck's constant. The photon has no rest mass or electric charge but, following the concept of mass-energy equivalence set forth by Einstein, has associated with it a momentum given by $p = h\nu/c = E/c$. *See* LIGHT; QUANTUM MECHANICS; RELATIVITY.

Various nuclear species exhibit distinctly different nuclear configurations; the excited states, and thus the γ-rays which they produce, are also different. Precise measurements of the γ-ray energies resulting from nuclear decays may therefore be used to identify the γ-emitting nucleus. This has ramifications for nuclear research and also for a wide variety of more practical applications. One of the most useful studies of the nucleus involves the bombardment of target nuclei by energetic nuclear projectiles to form final nuclei in various excited states. Measurements of the decay γ-rays are routinely used to identify the various final nuclei according to their characteristic γ-rays.

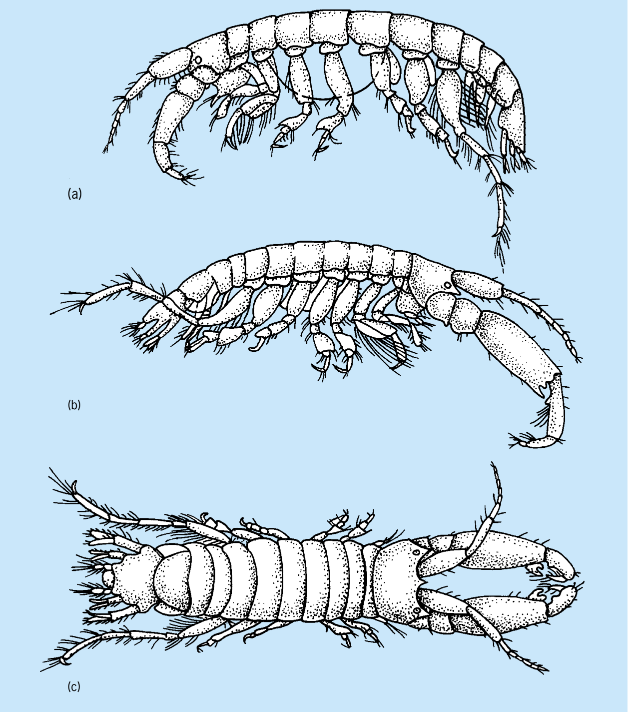
In practical applications, the presence of γ-rays is used to detect the location or presence of radioactive atoms which have been deliberately introduced into the sample. In irradiation studies, for example, the sample is activated by placing it in the neutron flux from a reactor. The resultant γ-rays are identified according to isotope, and thus the composition of the original sample can be inferred. Such studies have been used to identify trace elements found as impurities in industrial production, or in ecological studies of the environment, such as minute quantities of tin or arsenic in plant and animal tissue. *See* ACTIVATION ANALYSIS.

In tracer studies, a small quantity of radioactive atoms is introduced into fluid systems (such as the human blood stream), and the flow rate and diffusion can be mapped out by following the radioactivity. Local concentrations, as in tumors, can also be determined. *See* RADIOACTIVE TRACER.

For the three types of interaction with matter which together are responsible for the observable absorption of γ-rays, namely, Compton scattering, the photoelectric effect, and pair production, *see* COMPTON EFFECT; ELECTRON-POSITRON PAIR PRODUCTION; PHOTOEMISSION. [J.W.Ol.]

Gammaridea A suborder of Amphipoda. These crustaceans are commonly known as scuds in aquatic environments, and as sandhoppers on beaches. In 1956 the suborder comprised 3200 species in 672 genera and 57 families. The majority of the species is marine but more than 500 species are limnetic, to an altitude of 13,000 ft (4000 m), or are subterranean; 80 species are terrestrial (family Talitridae). The terrestrial species are confined mainly to beaches in high latitudes, but in the Indo-Pacific insular region they penetrate far inland and to an altitude of 10,000 ft (3000 m) in moist environments.

Gammaridea are usually compressed laterally and are poor walkers, unlike the Isopoda, except for the families Corophiidae and Cheluridae, which have depressed bodies (see illustration). The head and segments are free, lacking a carapace. The head bears two pairs of antennae and six kinds of mouthparts, some of them paired. The mandibles usually bear cutting and trituration surfaces for chewing, but a few species lack these devices or have the mouthparts modified for sucking the tissues of animals such as compound ascidians.



Corophium crassicorne **(Corophiidae). (*a*) Female. (*b*) Male. (*c*) Male, dorsal view. (*After G. O. Sars, An Account of the Crustacea of Norway, vol. 1, 1895*)**

Gammaridea are largely scavengers, feeding on organic debris or detritus which falls to the ocean bottom. Species in the families Ampeliscidae, Photidae, and Corophiidae build nesting tubes attached to solid intertidal objects or lying on the sea bottom. The tubes are spun either from secreting glands on the first two pairs of pereiopods or from cuticular glands on the body. These animals use their well-developed antennae to strain food particles. Species in the Phoxocephalidae and Haustoriidae have strongly spinose appendages for burrowing into bottom sediments. Some of these ingest mud, while others are selective deposit feeders. Semiparasitic and commensal species with sucking or lapping mouthparts are known in the families Stenothoidae, Leucothoidae, and Dexaminidae. They inhabit coelenterates, ascidians, and sponges, or grasp lobsters and fish. *See* AMPHIPODA. [J.L.B.]

Ganglion

A group of nerve cell bodies, usually located outside the brain and spinal cord. A ganglion located inside the central nervous system is called a nucleus.

The dorsal root ganglia are rounded clusters of cell bodies and fibers, surrounded by a connective tissue covering, located on the dorsal, or sensory, root of each spinal nerve. Other ganglia are given specific names which indicate their function or location, such as acoustic, cardiac, carotid, jugular, celiac, and sympathetic ganglia. Sympathetic ganglia, lying on either side of the vertebral column, unite by fiber strands to form a sympathetic chain. *See* SYMPATHETIC NERVOUS SYSTEM.

The term ganglion may be applied to a tumorlike, often cystic growth found on tendons, joints, and other connective tissues, but this usage is rare. *See* BRAIN; SPINAL CORD. [W.B.]

Gangrene

A form of tissue death, or necrosis, usually occurring in an extremity and due to insufficient blood supply.

If no bacterial contamination is present, the part becomes dry, greenish-yellow, and finally turns brown or black. This is known as mummification. A sharp inflammatory border marks the edge of the adjacent viable tissue. This dry gangrene is seen most often in small portions of the extremities, such as the fingers and toes. Senile gangrene is the form caused by deterioration of blood supply in the elderly, usually as the result of progressive arteriosclerosis. Similar types are often present in diabetes, Reynaud's disease, and Buerger's disease (thromboangiitis obliterans). *See* ARTERIOSCLEROSIS; DIABETES.

When bacterial infection intervenes, putrefaction ensues, thus producing the moist or wet type of gangrene. Moist gangrene may occur anywhere in the body that the blood supply is blocked and bacterial contamination occurs.

Gas gangrene is a localized, but rapidly spreading, necrotizing wound infection, characterized by extensive edema with gas production and discoloration of the tissue, and often accompanied by a putrefactive odor. The disease commonly arises following septic abortion or dirt contamination of deep wounds. The microbial flora of the gangrenous wound usually comprises one or more species of toxigenic anaerobic bacteria mixed with nontoxigenic anaerobic species, aerobic species, or both. [E.G.St.; N.K.M.]

Gangrene does not necessarily follow the presence of bacteria in a wound, as initiation of the disease depends on the virulence of the organisms and other factors relating to the resistance of the host. The virulence of the gangrene-producing organisms depends on the toxins produced and the same species may produce several immunologically different toxins. *See* TOXIN; VIRULENCE.

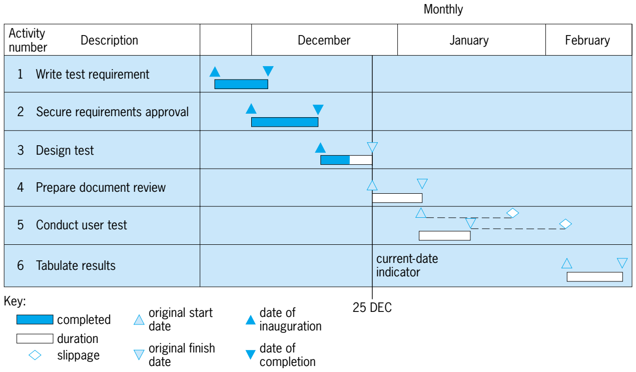
The rapidly spreading nature of the disease precludes extensive laboratory diagnostic aids because therapeutic measures, possibly including amputation, usually must be instituted before laboratory results are available. The effectiveness of antibiotic therapy seems to depend on the species involved in the infection and the elapsed time between injury and treatment. Hyperbaric oxygen therapy is beneficial for individuals who are diagnosed early. [L.S.McC.]

Gantt chart

A graphic device that depicts tasks, machines, personnel, or whatever resources are required to accomplish a job on a calendar-oriented grid. Charts may be provided for various managerial levels and responsibilities, but detailed planning occurs at the lowest organizational level. Performance may be monitored and controlled throughout the organization.

The Gantt chart is an effective tool for planning and scheduling operations involving a minimum of dependencies and interrelationships among the activities. The technique is best applied to activities for which time durations are not difficult to estimate, since there is no provision for treatment of uncertainty. On the other hand, the charts are easy to construct and understand, even though they may contain a great amount of information. In general, the charts are easily maintained provided the task requirements are somewhat static.

An initial step in development of a Gantt chart may be to specify the tasks or activities making up a project, as shown in the illustration. The amount of time required for each activity is represented as a horizontal bar on the chart, with open triangles designating original start and finish dates in this example. The



Example of a Gantt bar chart.

open start triangle is changed to a filled triangle upon inauguration of the activity, and the bar is filled in with vertical lines to indicate progress and completion. The open finish triangle is also filled upon completion. Slippage times are documented on the chart by broken lines, and the diamond symbols are employed to indicate rescheduled work. The vertical line on the chart is the current-date indicator and indicates present and future status of the project as of that date.

Updating of a Gantt chart will reveal difficulties encountered in the conduct of a project. Possible solutions include rescheduling, overtime, multishift operations, use of additional equipment and facilities, and changes in method.

An outgrowth of the bar chart technique is the milestone chart. A milestone is an important activity in the sequence of project completion. The most significant activities may be designated major milestones. The primary difference in this concept is the graphic display, since the method and collection of data are the same. The milestone approach offers no intrinsic improvement over the basic Gantt chart but provides a means for focusing resources on critical items. *See* PERT. [L.S.H.]

Garlic A hardy perennial, *Allium sativum*, of Asiatic origin and belonging to the plant order Liliales. Garlic is grown for its pungent bulbs, segments of which are used primarily for seasoning. Europeans have grown it for more than 200 years. Propagation is commonly by bulb segments, sometimes called cloves; seeds are seldom produced. Cultural practices are similar to those used for onions. Popular varieties are Italian, Tahiti, and Creole or Mexican. Harvest of the mature dry bulbs is 7–8 months after planting. Garlic salt is made from dehydrated cloves. California is the most important producing state; smaller acreages are planted to garlic in Louisiana and Texas. *See* LILIALES; ONION. [H.J.C.]

Garnet A hard, dense silicate mineral which occurs as crystals of cubic symmetry in a wide range of geologic environments. The general chemical formula of the silicate garnet group is $A_3B_2(SiO_4)_3$ where, in natural occurrences, the A cations are dominantly Fe^2, Mn^2, Mg, and Ca, and the B cations are Al, Fe^3, and Cr^3.

The garnet mineral group is generally divided into a number of individual species on the basis of chemical composition. The more common of these species are pyrope, almandine, spessartine, grossular, andradite, and uvarovite.

Garnets are substantially denser than most chemically analogous silicates, with specific gravities ranging between 3.58 (pyrope) and 4.32 (almandine). They also have high refractive indices (1.71–1.89) and hardness, on Mohs scale, of $6^1/_2$ to $7^1/_2$. The relative hardness, coupled with the absence of cleavage, has led to the use of garnet as an abrasive. The color of garnet is primarily controlled by its chemical composition. Uvarovite is emerald green; gem varieties of garnet are generally clear, deep red pyrope. *See* GEM; SILICATE MINERALS.

Garnets are widespread in their occurrence, particularly in rocks which formed at high temperatures and pressures. Because of the large, readily identifiable crystals which form, the first appearance of garnet is commonly used by geologists as an index of the intensity, or grade, of metamorphism. Garnets are strongly resistant to weathering and alteration and are hence widespread constituents of sands and sediments in areas of garnetiferous primary rocks. *See* METAMORPHIC ROCKS. [B.J.Wo.]

Gas A phase of matter characterized by relatively low density, high fluidity, and lack of rigidity. A gas expands readily to fill any containing vessel. Usually a small change of pressure or temperature produces a large change in the volume of the gas. The equation of state describes the relation between the pressure, volume, and temperature of the gas. In contrast to a crystal, the molecules in a gas have no long-range order.

At sufficiently high temperatures and sufficiently low pressures, all substances obey the ideal-gas, or perfect-gas, equation of state below, where p is the pressure, T is the absolute temperature,

$$p\overline{V} = RT$$

$\overline{V}$ is the molar volume, and R is the gas constant. Absolute temperature T is expressed on the Kelvin scale. The gas constant is 8.314 joules/(mole K). The molar volume is the molecular weight divided by the gas density.

At lower temperatures and higher pressures, the equation of state of a real gas deviates from that of a perfect gas. Various empirical relations have been proposed to explain the behavior of real gases. *See* GAS DYNAMICS. [C.F.C.; J.O.H.]

Gas absorption operations The separation of solute gases from gaseous mixtures of noncondensables by transfer into a liquid solvent. This recovery is achieved by contacting the gas stream with a liquid that offers specific or selective solubility for the solute gas or gases to be recovered. The operation of absorption is applied in industry to purify process streams or recover valuable components of the stream. It is used extensively to remove toxic or noxious components (pollutants) from effluent gas streams. *See* ABSORPTION.

The absorption process requires the following steps: (1) diffusion of the solute gas molecules through the host gas to the liquid boundary layer based on a concentration gradient, (2) solvation of the solute gas in the host liquid based on gas-liquid solubility, and (3) diffusion of the solute gas based on concentration gradient, thus depleting the liquid boundary layer and permitting further solvation. The removal of the solute gas from the boundary layer is often accomplished by adding neutralizing agents to the host liquid to change the molecular form of the solute gas. This process is called absorption accompanied by chemical reaction. *See* DISTILLATION. [A.J.T.]

Gas and atmosphere analysis Qualitative identifications and quantitative determinations of substances essential for the evaluation of the air quality in the ambient air and in the industrial workplace. *See* AIR POLLUTION; INDUSTRIAL HEALTH AND SAFETY.

Qualitative identification. The qualitative identification of air pollutants may require the use of several instruments which provide complementary information about composition and structure. Since the entire sample is often limited to milligram or microgram quantities, the classical identification methods, such as boiling point and refractive index determinations, functional group tests, combustion analyses, and derivative preparations, have been largely replaced by instrumental methods. Information for identification purposes is now generally obtained from instruments such as mass, nuclear magnetic resonance, infrared, and ultraviolet spectrometers that rely upon the response of a molecule to an energy probe.

Mass spectroscopy is probably the single most powerful technique for the qualitative identification of volatile organic compounds, and has been particularly useful in the identification of many environmental contaminants. When a sample is introduced into the mass spectrometer, electron bombardment causes the parent molecule to lose an electron and form a positive ion. Some of the parent ions are also fragmented into characteristic daughter ions, while other ions remain intact. All of the ions are accelerated, separated, and focused on an ion detector by means of either a magnetic field or a quadrupole mass analyzer. Using microgram quantities of pure materials, the mass spectrometer yields information about the molecular weight and the presence of other atoms, such as nitrogen, oxygen, and halogens, within the molecule. In addition, the fragmentation pattern often provides a unique so-called fingerprint of a molecule, allowing positive identification. If the gas is a mixture, interpretation of the mass spectral data is difficult since the fragmentation patterns are superimposed. However, interfacing the mass spectrometer to a gas chromatograph provides an elegant solution to this problem. *See* MASS SPECTROMETRY.

A gas chromatograph is essentially a highly efficient apparatus for separating a complex mixture into individual components. When a mixture of components is injected into a gas chromatograph equipped with an appropriate column, the components travel down the column at different rates and therefore reach the end of the column at different times. The mass spectrometer located at the end of the column can then analyze each component separately as it leaves the column. In essence, the gas chromatograph allows the mass spectrometer to analyze a complex mixture as a series of pure components. More than 100 compounds have been identified and quantified in automobile exhaust by using a gas chromatograph–mass spectrometer combination. *See* GAS CHROMATOGRAPHY.

Quantitative analysis. The methods employed chiefly for quantification can be classified for convenience into direct and indirect procedures. Direct-reading instruments are generally portable and may analyze and display their results in a few seconds or minutes, and can operate in a continuous or semicontinuous mode. Indirect methods are those involving collection and storage of a sample for subsequent analysis.

Direct methods utilize colorimetric indicating devices and instrumental methods. Three types of direct-reading colorimetric indicators have been utilized: liquid reagents, chemically treated papers, and glass tubes containing solid chemicals (detector tubes). The simplest of these methods is the detector tube. Detector tubes are constructed by filling a glass tube with silica gel coated with color-forming chemicals. For use, the ends of the sealed tube are broken and a specific volume of air, typically 6 in.^{3} (100 cm^3), is drawn through the tube at a controlled rate. Detector tubes for analyzing approximately 400 different gases are commercially available. Accuracy is sometimes low, and detector tubes for only 25 gases meet the National Institute for Occupational Safety and Health (NIOSH) accuracy requirement of ±25%. For some gases, semicontinuous analyzers have been developed that operate by pulling a fixed volume of air through a paper tape impregnated with a color-forming reagent. The intensity of the color is then measured for quantification. Phosgene, arsine, hydrogen sulfide, nitric oxide, chlorine, and toluene diisocyanate have been analyzed by indicating tapes. *See* COLORIMETRY.

With the availability of stable and sensitive electronics, direct-reading instruments capable of measuring gases directly at the parts-per-billion range were developed. Most direct-reading instruments contain a sampling system, electronics for processing signals, a portable power supply, a display system, and a detector. The detector or sensor is a component that is capable of converting some characteristic property of the gas into an electrical signal. While there are dozens of properties for the bases of operation of these detectors, the most sensitive and popular detectors are based on electrical or thermal conductivity, ultraviolet or infrared absorption, mass spectrometry, electron capture, flame ionization, flame photometry, heat of combustion, and chemiluminescence. Many of these detectors respond to the presence of 10^{-9} g quantities, and even to 10^{-12} g levels. In addition to improved accuracy, precision, and analysis time, another advantage is that most instruments produce an electrical signal which can be fed into a computer for process control, averaging, and record keeping. Rapid fluctuations and hourly, daily, and yearly averages are readily obtained.

For indirect methods of quantification, the main collection devices are freeze traps, bubblers, evacuated bulbs, plastic bags, and solid sorbents. Because of their convenience, solid sorbents dominate collection procedures. NIOSH developed a versatile method for industrially important vapors, based on the sorption of the vapors on activated charcoal or, to a lesser extent, on other solid sorbents such as silica gel and porous polymers. Typically, in this technique a few liters of air are pulled through a glass tube containing about 0.004 oz (100 mg) of charcoal. The charcoal tube is only 7 cm × 6 mm (3 in. × 0.2 in.), and has the advantage that it can be placed on the worker's lapel. A battery-operated pump small enough to fit into a shirt pocket is connected by a plastic tube to the collecting device, so that the contaminants are continuously collected from the breathing zone of the worker. Many solvent vapors and gases are efficiently trapped and held on the charcoal. The ends of the sample tube are then capped, and the tube is returned to a laboratory for analysis. In the laboratory the tube is broken open, and the charcoal is poured into carbon disulfide to desorb the trapped vapors. Following desorption, a sample of the solution is injected into a gas chromatograph for quantification.

This technique has been highly successful for several classes of compounds, such as aromatics, aliphatics, alcohols, esters, aldehydes, and chlorinated compounds. Sulfur- and nitrogen-containing compounds can also be analyzed by using a gas chromatograph which is equipped with a sulfur- or nitrogen-sensitive detector. [W.R.Bu.; M.Gl.; L.S.Be.]

Gas chromatography

A method for the separation and analysis of complex mixtures of volatile organic and inorganic compounds. Most compounds with boiling points less than about 250°C (480°F) can be readily analyzed by this technique. A complex mixture is separated into its components by eluting the components from a heated column packed with sorbent by means of a moving-gas phase. *See* CHROMATOGRAPHY.

Gas chromatography may be classified into two major divisions: gas-liquid chromatography, where the sorbent is a nonvolatile liquid called the stationary-liquid phase, coated as a thin layer on an inert, granular solid support, and gas-solid chromatography, where the sorbent is a granular solid of large surface area. The moving-gas phase, called the carrier gas, is an inert gas such as nitrogen or helium which flows through the chromatographic column packed with the sorbent. The solute partitions, or divides, itself between the moving-gas phase and the sorbent and moves through the column at a rate dependent upon its partition coefficient, or solubility, in the liquid phase (gas-liquid chromatography) or upon its adsorption coefficient on the packing (gas-solid chromatography) and the carrier-gas flow rate.

The apparatus used in gas chromatography consists of four basic components: a carrier-gas supply and flow controller, a sample inlet system providing a means for introduction of the sample, the chromatographic column and associated column oven, and the detector system.

Qualitative and quantitative information is obtained from analyzing the peaks appearing on a chromatogram. Combination of gas chromatography with mass spectrometry provides the ultimate in qualitative information and has been used extensively in research. *See* MASS SPECTROMETRY; QUALITATIVE CHEMICAL ANALYSIS. [R.S.J.]

Gas constant

The universal constant R that appears in the ideal gas law, Eq. (1), where P is the pressure, V the volume,

$$PV = nRT \tag{1}$$

n the amount of substance, and T the thermodynamic (absolute) temperature. The gas constant is universal in that it applies to all gases, providing they are behaving ideally (in the limit of zero pressure). The gas constant is related to the more fundamental Boltzmann constant, k, by Eq. (2), where N_A is the Avogadro

$$R = N_A k \tag{2}$$

constant (the number of entities per mole). The best modern value in SI units is $R = 8.314\ 472\ (15)$ J/K · mol, where the number in parentheses represents the uncertainty in the last two digits. *See* BOLTZMANN CONSTANT; GAS.

According to the equipartition principle, at a temperature T, the average molar energy of each quadratic term in the expression for the energy is $(1/2)RT$; as a consequence, the translational contribution to the molar heat capacity of a gas at constant volume is (3/2)R; the rotational contribution of a linear molecule is R. *See* KINETIC THEORY OF MATTER.

Largely because R is related to the Boltzmann constant, it appears in a wide variety of contexts, including properties unrelated to gases. Thus, it occurs in Boltzmann's formula for the molar entropy of any substance, Eq. (3), where W is the number of

$$S = R \ln W \tag{3}$$

arrangements of the system that are consistent with the same energy; and in the Nernst equation for the potential of an electrochemical cell, Eq. (4), where E° is a standard potential, F is

$$E = E^\circ - (RT/nF) \ln Q \tag{4}$$

the Faraday constant, and Q is a function of the composition of the cell. The gas constant also appears in the Boltzmann distribution for the population of energy levels when the energy of a level is expressed as a molar quantity. *See* BOLTZMANN STATISTICS; ELECTRODE POTENTIAL; ENTROPY. [P.W.A.]

Gas discharge A system made up of a gas, electrodes, and an enclosing wall in which an electric current is carried by charged particles in response to an electric field, the gradient of the electric potential, or the voltage between two surfaces. The gas discharge is manifested in a variety of modes (including Townsend, glow, arc, and corona discharges) depending on parameters such as the gas composition and density, the external circuit or source of the voltage, electrode geometry, and electrode material. *See* ARC DISCHARGE; CORONA DISCHARGE; ELECTRICAL BREAKDOWN; GLOW DISCHARGE; TOWNSEND DISCHARGE.

Gas discharges are useful both as tools to study the physics existing under various conditions and in technological applications such as in the lighting industry and in electrically excited gas lasers. New applications in gas insulation, in high-power electrical switching, and in materials reclamation and processing will assure a continuing effort to better understand all aspects of gas discharges. *See* GAS TUBE; LASER; VAPOR LAMP.

Electrons, rather than ions, are the main current carriers in gas discharges because their mass is smaller and their mobility is correspondingly much higher than that of ions. Electrons are produced by ionization of the gas itself, or they originate at the electrodes present in the system. Gas ionization can be accomplished in several ways, including electron impact ionization, photoionization, and associative ionization. Bombardment by photons, energetic ions or electrons, and excited neutral particles can cause secondary emission from the electrodes. A high-energy-per-unit electrode surface area can induce thermionic or field emission of electrons. Each of these means of producing electrons leads to a different response of the gas discharge as a circuit element. *See* ELECTRICAL CONDUCTION IN GASES; ELECTRON EMISSION; FIELD EMISSION; IONIZATION; PHOTOEMISSION; SECONDARY EMISSION; THERMIONIC EMISSION. [L.C.P.]

Gas dynamics The study of gases in motion. In general, matter exists in any of three states: solid, liquid, or gas. Liquids are incompressible under normal conditions; water is a typical example. In contrast, gases are compressible fluids; that is, their density varies depending on the pressure and temperature. The air surrounding a high-speed aircraft is an example. *See* GAS; LIQUID.

Gas dynamics can be treated in a variety of ways. One such way deals with gases as a continuum. The structure of gases on the particle level is called rarefied gas dynamics. *See* AEROTHERMODYNAMICS; COMPRESSIBLE FLOW; FLUID FLOW.

Gases in motion are subject to certain fundamental laws. These are the laws of the conservation of mass, momentum, and energy. In the case of the dynamics of incompressible fluids, it is usually sufficient to satisfy only the laws of conservation of mass and momentum. This distinction constitutes the fundamental difference between high-speed gas dynamics and hydrodynamics. If irreversibilities are involved, a fourth equation called the entropy balance equation may be considered. Whereas mass, momentum, and energy are conserved, the entropy is not. Real problems are irreversible; that is, losses such as friction are involved. However, as a first approximation such effects are generally not considered. *See* CONSERVATION LAWS (PHYSICS); CONSERVATION OF ENERGY; CONSERVATION OF MASS; CONSERVATION OF MOMENTUM.

The mass, momentum, and energy equations are higher-order, nonlinear equations that have no general solution, and only a limited number of special cases can be solved. Another approach is to resort to numerical solutions using high-speed digital computers. While this approach has proven to be very useful, it limits the degree to which flow phenomena can be conceptualized. Accordingly, it is frequently permissible to write the equations in one-dimensional form. By one-dimensional flow is meant that the properties of gas such as its velocity and density are assumed to be constant in the direction perpendicular to the direction of the gas flow. Generally, the one-dimensional approach gives excellent insights into understanding the physical behavior of the flow. It is also very useful in setting up the computer algorithm for numerical solutions. *See* COMPUTATIONAL FLUID DYNAMICS; DIFFERENTIAL EQUATION.

One other matter must be considered, namely whether the flow is steady or unsteady. In steady flow, the flow characteristics do not vary with time, whereas unsteady flow implies that the flow assumes different configurations over time. Thus, unsteady flow is broader in scope. In this case the continuity equations for conservation of mass may be written as Eq. (1). In this equation,

$$\frac{\partial(\rho V)}{\partial x} + \frac{\partial \rho}{\partial t} = 0 \tag{1}$$

the first term defines the mass-flow changes with respect to the space coordinates, whereas the second term indicates the changes with time. Here, ∂ is the partial differential operator; x denotes the space coordinate, in this case the direction of flow; ρ is the gas density; V is the gas velocity; and t is the time.

If the flow is steady, there is no time-dependent term, and hence the continuity equation can be written in integrated form as Eq. (2), where A denotes the area in the direction perpendicular to the flow direction.

$$\rho V A = \text{constant} \tag{2}$$

The momentum equation is the mathematical representation of the law of conservation of momentum. It is a statement of the forces acting on the gas. Different types of forces must be recognized. Body forces, such as gravitation and electromagnetic forces, act at a distance. The so-called surface forces may assume different forms, such as normal stresses and viscosity. The simple form of the momentum equation is Eq. (3), which, in spite

$$\frac{p}{\rho} + \frac{V^2}{2} = \text{constant} \tag{3}$$

of its simplicity, is very powerful. Called Bernoulli's theorem, this equation makes a crucial statement that when the velocity increases, the pressure p decreases. *See* BERNOULLI'S THEOREM.

The energy equation expresses the first law of thermodynamics and accounts for the changes in energy as the gas moves about its path. It can also take into consideration energy exchanges between the gas and its environment, such as radiation. Its simplest form is Eq. (4), where c_p denotes the specific heat at constant pressure.

$$c_p \frac{p}{\rho} + \frac{V^2}{2} = \text{constant} \tag{4}$$

The speed of sound or the acoustic velocity is a very important term in gas dynamics because it serves as a criterion to identify flow regimes. Being able to do so is crucial because the designer must know the conditions that the gas will generate or, conversely, experience. In prescribing flow regimes, the flow velocity of the gas is compared with the acoustic velocity. This ratio, called the Mach number (M), is defined by Eq. (5).

$$M = \frac{V}{a} \tag{5}$$

Using the Mach number the following flow regimes are described:

$M < 1$	subsonic flow
$M = 1$	sonic flow
$0.9 < M < 1.1$	transonic flow
$M > 1$	supersonic flow
$M > 5$	hypersonic flow

High-speed aircraft are categorized by the Mach number. *See* Mach number; Sound.

Flows can be classified as internal flow and external flow. Internal flow refers to the cases where the gas is constrained by a duct of some sort. Characteristically external flow is flow over an airplane or missile. Internal flows are conveniently characterized by (1) the shape of the duct and its variation, (2) the heat transfer through the walls of the duct and internal heat sources, and (3) frictional effects. By varying one of these characteristics at a time, the essential features of internal flow can be discussed most simply.

Boundary layers and wakes are the centers of interest in external flows. Here the effects of compressibility are substantially more difficult to analyze than in internal flows, if for no other reason than the inapplicability of a one-dimensional approach. *See* Boundary-layer flow; Wake flow. [J.Men.; A.B.C.]

Rarefied gas dynamics is that branch of gas dynamics dealing with the flow of gases under conditions where the molecular mean free path is not negligibly small compared to some characteristic dimension of the flow field. Rarefied flows occur when the gas density is extremely low, as in the cases of vacuum systems and high-altitude flight, but also when gases are at normal densities if the characteristic dimension is sufficiently small, as in the case of very small particles suspended in the atmosphere.

The dimensionless parameter which describes the degree of rarefaction existing in a flow is the Knudsen number, $\mathrm{Kn} = \lambda/L$, defined as the ratio of the mean free path λ to some characteristic dimension L of the flow field. Depending on the situation, L might be chosen, for example, as the diameter of a duct in a vacuum system, the wavelength of a high-frequency sound wave, the diameter of a suspended submicrometer-size particle, the length of a high-altitude rocket, or the thickness of a boundary layer or a shock wave. The mean free path λ, which is the average distance traveled by a gas molecule between successive collisions with other molecules, is equal to the molecular mean speed, given by Eq. (6) [where R is the gas constant and T is

$$\bar{C} = \sqrt{\frac{8}{\pi}RT} \tag{6}$$

the gas temperature], divided by the collision frequency ν_c: thus, Eq. (7) is satisfied. However, it is often more convenient in evaluating the Knudsen number to use the viscosity-based mean free path given by Eq. (8), where ν is the kinematic viscosity.

$$\lambda = \frac{\bar{C}}{\nu_c} \tag{7}$$

$$\lambda \simeq \frac{2\nu}{\bar{C}} \tag{8}$$

See Viscosity.

It is convenient to divide rarefied flows into three flow regimes, according to the range of values of the appropriate Knudsen numbers. The regime of highly rarefied flow, which obtains for Kn much greater than 1 (typically greater than 10), is called collisionless or free-molecule flow, while the regime of slight rarefaction, where Kn is much less than 1 (typically less than 0.1), is called slip flow. Flows at Knudsen numbers intermediate to these limiting values are termed transition flows. The phenomena and methods of analysis associated with the three regimes are in general quite dissimilar. [L.T.]

Gas field and gas well The term gas field refers to a geographical area which is underlain by one or more commercial reservoirs of petroleum. This commercially valuable gas, primarily methane but with smaller amounts of ethane, propane, and butanes and in some cases containing significant concentrations of carbon dioxide, hydrogen sulfide, and nitrogen, is produced through wells which penetrate subterranean reservoirs, composed of porous rock. The gas in the reservoir may be free or dissolved in crude oil.

About one-third of the gross production of natural gas in the United States is produced from reservoirs in which there is no substantial amount of crude oil (mixture of higher-molecular-weight pentanes plus hydrocarbons) in contact with the gas. The gas in such reservoirs is called nonassociated gas. Associated gas is that produced from reservoirs in which there is a substantial contact of free gas (in the gas cap) with crude oil or gas dissolved in crude oil. *See* Natural gas; Oil and gas field exploitation; Oil and gas well drilling; Petroleum; Petroleum geology; Petroleum reservoir engineering. [T.M.D.]

Gas furnace An enclosure in which a gaseous fuel is burned. Domestic heating systems may have gas furnaces. Some industrial power plants are fired with gases that remain as a by-product of other plant processes. Utility power stations may use gas as an alternate fuel to oil or coal, depending on relative cost and availability. Some heating processes are carried out in gas-fired furnaces. Among the gaseous fuels are natural gas, producer gas from coal, blast furnace gas, and liquefied petroleum gases such as propane and butane. *See* Fuel gas; Furnace; Steam-generating furnace. [R.M.H.]

Gas thermometry A method of measuring temperatures with gas as the thermometric fluid. Gas thermometry is the primary source of information about a fundamental physical parameter, temperature, over the range from about 3 to 900 K (−454 to 1160°F).

In principle, gas thermometry consists of using the ideal gas law, Eq. (1), where P is the pressure, V the volume, n the number

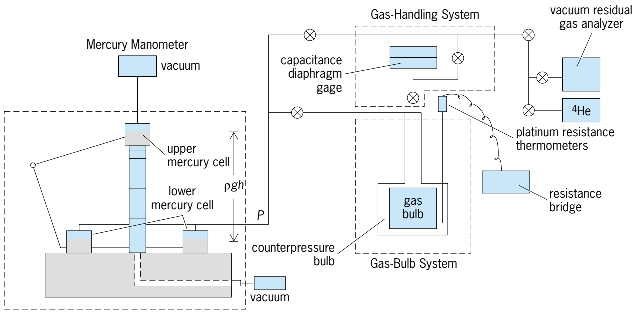
$$PV = nRT \tag{1}$$

of moles of gas, R the molar gas constant, and T the thermodynamic temperature, to evaluate an unknown temperature by reference to the single defining temperature of the Kelvin thermodynamic temperature scale, namely the triple-point temperature of water. This reference temperature, achievable within about one part in 10^7 by standard laboratory practice, has the value 273.16 K (0.01°C or 32.018°F). Determination of the unknown temperature requires two sets of measurements of the pressure P and the volume V of n moles of an ideal gas. One set of measurements usually is performed while the gas is maintained at the water triple-point temperature; the second set is obtained with the gas at the unknown temperature. The unknown temperature can readily be evaluated by rewriting Eq. (1) as $n = (PV)/(RT)$, which has the same value for both sets of measurements. The desired result is given by Eq. (2), where the primed quantities

$$T' = \frac{273.16(P'V')}{(PV)} \tag{2}$$

refer to the unknown temperature. In Eq. (2) the precise values of the gas constant R and of n need not be considered. *See* Gas; Triple point.

Constant-volume gas thermometry is by far the most commonly used of the gas-thermometry methods. The name is somewhat misleading because no gas bulb truly exhibits constant



Typical constant-volume gas thermometer. (*After J. F. Schooley, Thermometry, CRC Press, 1986*)

volume over any substantial temperature range. Several steps are involved: inserting a fixed mass of a working gas into a rigid container or bulb; determining the pressure of the gas at the triple-point temperature of water; heating or cooling the container to a new temperature whose value is to be determined; and measuring the gas pressure at the new temperature.

A typical constant-volume gas thermometer (see illustration) includes a mercury manometer, used for the measurement of pressure; a gas-bulb system; and a gas-handling system. The part-per-million accuracy achievable in manometric pressure measurements is central to the thermometric accuracy of this instrument. The entire manometer is operated in a temperature-controlled environment. The distance between the surface of the mercury in an upper cell and mercury surfaces in two lower cells is measured by the use of wrung stacks of calibrated end gage blocks. Axial holes through the gage blocks permit detection of the quality of the wringing process by measurement of the internal vacuum of the stack. The pressure exerted by the column of mercury is given by the product ρgh, where ρ is the density of the mercury, g is the acceleration due to gravity at the manometer, and h is the height of the gage-block stack.

The gas bulb is completely enclosed by a second bulb in which a so-called counterpressure of helium gas equal to the gas-bulb pressure is maintained at all times. The counterpressure gas minimizes pressure-induced changes in the gas-bulb volume and helps to reduce contamination of the working gas from impurities in the gas-bulb thermostat.

It is possible to determine the thermodynamic temperature of a gas bulb by repeatedly adding measured quantities of a working gas to it and measuring the resulting pressures. The repeated measurements at a single temperature are known as an isotherm. The virial equation (3) can be used to obtain both

$$PV = nRT(1 + BP + CP^2 + \cdots) \tag{3}$$

the unknown gas-bulb temperature and the value of the second virial coefficient. *See* VIRIAL EQUATION.

Two variations on the technique can be used, the absolute isotherm and the relative isotherm. In absolute isothermal gas thermometry, measured quantities of working gas are introduced into a gas bulb at the unknown temperature from a known volume that is maintained at 273.16 K. In the relative isotherm method, the working gas is added stepwise to a gas bulb while it is maintained at another, more convenient reference temperature. *See* LOW-TEMPERATURE THERMOMETRY; PHYSICAL MEASUREMENT; TEMPERATURE MEASUREMENT. [J.F.Sc.]

Gas tube An electron tube that contains gas or vapor at low pressure in which an electrical discharge takes place. Gas tubes are of two general types: cold-cathode tubes, in which the phenomenon known as glow discharge serves to maintain a conducting path between the electrodes, and hot-cathode tubes, in which an arc discharge conducts the current. The cold-cathode glow tubes are characterized by a relatively high voltage drop and a low current, while the hot-cathode arc tubes are characterized by a low voltage drop and relatively high current. *See* ELECTRON TUBE.

Cold-cathode gas tubes, or glow tubes, require no cathode heater power and are therefore always ready for instant service. Glow tubes are commonly constructed as two-element (diode) or three-element (triode) tubes.

Three representative types of hot-cathode gas tubes may be distinguished: the Tungar (sometimes called a Rectigon), the phanotron, and the thyratron. The first two are simple rectifier tubes while the third is a control tube having one or two grids between cathode and anode. Both phanotrons and thyratrons may be built with glass, ceramic, or metal envelopes. [J.D.Co.]

Gas turbine One of a class of heat engines which use fuel energy to produce mechanical output power, either as torque through a rotating shaft (industrial gas turbines) or as jet power in the form of velocity through an exhaust nozzle (aircraft jet engines). The fuel energy is added to the working substance, which is gaseous in form and most often air, either by direct internal combustion or indirectly through a heat exchanger. The heated working substance, air co-mixed with combustion products in the usual case of internal combustion, acts on a continuously rotating turbine to produce power. The gas turbine is thus distinguished from heat engine types where the working substance produces mechanical power by acting intermittently on an enclosed piston, and from steam turbine engines where the working substance is water in liquid and vapor form. *See* INTERNAL COMBUSTION ENGINE; STEAM TURBINE.

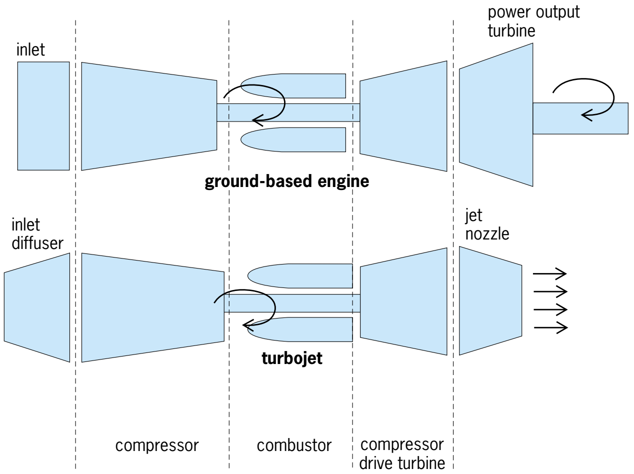
Gas turbine engines depend on the principle of the air cycle, where, ambient air is first compressed to a maximum pressure level, at which point fuel heat energy is added to raise its temperature, also to a maximum level. The air is then expanded from high to low pressure through a turbine. The expansion process through the turbine extracts energy from the air, while the compression process requires energy input.

As the air moves through the engine, the turbine continuously provides energy sufficient to drive the compressor. In addition, because the turbine expansion process starts from a high temperature that comes from the fuel energy released by combustion, surplus energy beyond that required for compression can be extracted from the air by further expansion. At the point where the turbine has provided sufficient energy to power the compressor, the air pressure remains higher than the outside ambient level. This higher pressure represents available energy in the air that can be turned into useful output power by a final expansion process that returns the air pressure to ambient. The exhaust air leaves the engine with pressure equal to the outside, but at a higher temperature. As with any heat engine, the high exhaust temperature represents wasted energy that will dissipate into the outside atmosphere. *See* COMPRESSOR.

From an energy accounting standpoint, the sequence of processes acting on the air from front to rear constitutes a full cycle. It starts with the outside air entering at its initial state, and is completed when the air returns again to both ambient pressure and temperature levels. The series of cycle processes includes the final outside dissipation of the wasted exhaust energy, inevitable for every heat engine according to Carnot's principle. The ideal version of the gas turbine cycle is known as the Brayton cycle. *See* BRAYTON CYCLE; CARNOT CYCLE.

For any completed cycle, the total energy added from the fuel sources will always be equal to the sum of the useful output energy and the wasted exhaust energy. The thermal efficiency, which is the ratio of net output energy to fuel input energy for the cycle, measures the engine's ability to minimize wasted energy. A thermal efficiency of 60% means that for every 100 units of added energy 60 units will be available as useful output while 40 units will leave the engine as high-temperature exhaust.

Another performance measure is the specific power, which is the ratio of output power to quantity of working substance mass flow rate. Gas turbine engines, in comparison with other



Simple gas turbine component arrangements.

types of heat engines, are characterized not only by high levels of efficiency but also by very high levels of specific power. They are especially useful for applications that need compact power.

By far the most common mechanical arrangement for the gas turbine is an in-line axial flow positioning of all components (see illustration). In the ground-based engine, the inlet at the front guides the incoming air into the compressor, which in turn delivers high-pressure air into the combustor section. The combustor burns the injected fuel at a high reaction temperature, using some of the air itself as an oxygen source. The combustion products in the combustor mix with the remaining unused air to reach a uniform equilibrium temperature, still high but diluted down from the reaction temperature. The hot, high-pressure combustor exit air enters the compressor drive turbine, where it expands down in pressure toward, but stays higher than, ambient level. This expansion process results in output shaft power that can be delivered directly to the compressor through a connecting rotating shaft. Starting from the exit of the compressor drive turbine, net output power remains available. This power can be realized through the process of further pressure expansion completely down to the ambient level. For ground-based applications, the final expansion takes place through a power turbine whose output shaft is connected to the external load. In the single-spool arrangement the power turbine and compressor drive turbine are indistinguishably combined into one unit which, together with the compressor and the output load, is connected to a common shaft. For aircraft applications, either a power turbine extracts useful power to drive a propeller through a separate shaft (turboprop), or the expansion process takes place through a nozzle which acts to convert some of the thermal energy into velocity energy to be used for jet propulsion. *See* Aircraft engine; Jet propulsion.

Gas turbines characteristically produce smooth and linear throttle response over their entire operating range. Rotor speeds normally vary continuously over this range without the need for the gear shifting and clutch mechanisms found in piston engines. The governing fuel control senses rotor speeds, pressures, and temperatures to maintain stable, steady power or thrust output and, when needed, ensure rapid accelerations and decelerations. The control is programmed, normally by electronic input, to guard against harming the engine during throttle changes by governing the appropriate fuel input rate. Most important, during throttle transients the control functions to prevent turbine overheating, burner blowout, and compressor surge. [J.H.Le.; W.H.D.]

Gasket Deformable material used to make a pressure-tight joint between stationary parts, such as cylinder head and cylinder, that may require occasional separation. Gaskets are known as static seals, as compared with packing or dynamic seals. In packings the parts are frequently in motion, as in piston rods and valve stems.

Gaskets are made of sheet materials such as natural or synthetic rubber, cork, vegetable fiber such as paper, asbestos and plastic pastes, or of soft metallic materials such as lead and copper. Rubber in the form of O-rings is used for light pressure. *See* Pressure seal. [P.H.B.]

Gasoline A mixture of hydrocarbons whose boiling point is below 200°C (390°F), obtained in the fractional distillation of petroleum. Gasoline is a liquid at ambient temperature, but it volatilizes readily in air to form a flammable mixture. The hydrocarbon fuel is used to power the internal combustion engine. Gasoline is composed primarily of the alkanes (paraffins) hexane, heptane, and octane, plus smaller amounts of higher-boiling alkanes. *See* Alkane; Internal combustion engine.

Gasoline is usually produced by catalytic cracking or by reforming processes. In catalytic cracking, the petroleum (or petroleum-derived feedstock) is fed into a reaction vessel containing a catalyst. In reforming, naphtha (refined or unrefined) is heated with hydrogen in the presence of a catalyst. Reforming causes a rearrangement of the structures of the molecular constituents and creates a gasoline product. *See* Cracking; Petroleum processing and refining; Reforming processes.

The hydrocarbon constituents in the boiling range of gasoline are those that have 4–12 carbon atoms in their molecular structure. Thus, gasoline can vary widely in composition; even gasolines with the same octane number may be quite different. For example, low-boiling distillates with high (above 20%) aromatics contents can be obtained from some crude oils. The variation in aromatics content as well as the variation in the content of normal paraffins, branched paraffins, cyclopentanes, and cyclohexanes is dependent upon the characteristics of the petroleum feedstock, and influence the octane number of the gasoline. *See* Aromatic hydrocarbon; Distillation.

The differences in composition of gasoline dictate that, in order to produce a uniform product, blending of the products from several component streams is necessary. The properties of each stream may vary considerably, significantly affecting the product gasoline. The blending process is relatively straightforward, but the determination of the amount of each component to include in a blend is much more difficult. The operation is carried out by simultaneously pumping all the components of a gasoline blend into a pipeline that leads to the gasoline storage. The pumps adjust for the correct proportion of each component, while baffles in the pipeline are often used to mix components as they flow to the storage tank.

Volatility is an important property of gasoline and is a necessity to ensure engine starting in cold weather. In winter, volatility is raised and the flash point is lowered by adding the more volatile butanes and pentanes. To prevent vapor lock in warm weather, the amounts of the more volatile constituents are reduced to produce mixtures that will not vaporize in the fuel lines.

Additives are incorporated into commercial gasoline blends, for example to inhibit oxidation and gum formation during storage. Dyes may be added for identification purposes. Alcohol and surfactants are used to reduce carburetor icing and corrosion. Detergent additives remove from the engine and fuel injector some of the deposits produced by gasoline combustion.

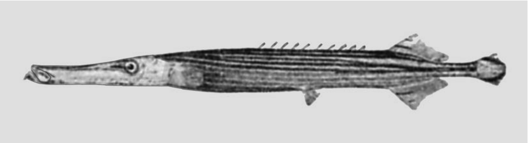
Before they are ignited by a spark plug, the hydrocarbons in a gasoline blend may ignite spontaneously under the high temperature and pressure conditions inside an engine cylinder. This preignition causes a characteristic engine knock. The octane number is a measure of the ability of a hydrocarbon fuel to resist preignition. It is obtained by comparing the antiknock performance of the gasoline with that of a mixture of isooctane and heptane: a gasoline blend with an octane number of 90 equals in performance a mixture of 90% octane and 10% heptane. The octane number of a gasoline can be increased by the use of reforming techniques and by alkylation, where gasoline components are recombined to build a larger molecule with a high octane number. *See* OCTANE NUMBER. [J.G.S.]

Gasteromycetes An artificial class of fungi in the phylum Basidiomycota in which basidiospores are produced in a mass (gleba) and enclosed within a membrane called the peridium. Such enclosed fruit bodies evolved many times; hence the class is heterogeneous. Most Gasteromycetes have lost the ability to discharge spores ballistically off basidia directly into air. Since internal sporulation prevents normal spore drop into air currents, these fungi have developed other dispersal mechanisms.

Gasteromycetes are either saprophytic or mycorrhizal. Historically, mature dry spores of puffballs were used to clot wounds. Young puffballs are edible, but false puffballs are poisonous. Because of their phallic shape, stinkhorns have been associated with witchcraft. *See* ASCOMYCOTA; BASIDIOMYCOTA; EUMYCOTA; FUNGI. [S.A.R.]

Gasterosteiformes An order of actinopterygian fishes which includes the groups Solenichthyes, Thoracostei, Hemibranchii, Lophobranchii, and Syngnathiformes of other classifications, Members of this order, commonly known as sticklebacks, tube-snouts, snipefishes, pipefishes, and seahorses, may be classified in 3 suborders, 7–9 families, 50–55 genera, and 200 or more species. The group dates from the Eocene.

Common characters include a swim bladder without a duct; pelvic fin, if present, with or without a spine and abdominal to subthoracic in position; pelvic girdle not in contact with the cleithrum; and articulation of the quadrate with the lower jaw in advance of the orbit. Fin spines are present or absent. The snout is commonly produced, the mouth opening at the end of a long tube (see illustration).



Trumpetfish (*Aulostomus maculatus*). (*After D. S. Jordan and B. W. Evermann, The Fishes of North and Middle America, U.S. Nat. Mus. Bull. no. 47, 1900*)

Most species are inhabitants of warm seas, but some sticklebacks live in fresh waters of northern continents, and a few tropical pipefishes enter or reside permanently in rivers. *See* ACTINOPTERYGII; TELEOSTEI. [R.M.B.]

Gastornithiformes An order of extinct flightless birds known from Paleocene and Eocene deposits in North America and Europe. These were giant, 2-m-tall (7-ft) birds with large heads, huge laterally compressed bills, broad cervical vertebrae, wide pelves, massive legs with relatively short tarsi and heavy toes suggestive of a slow-moving gait, and reduced wings that were evidently too short to permit flight. Gastornithiforms have been depicted as fast-running predators that evolved to fill the bipedal carnivore niche vacated by theropod dinosaurs at the end of the Cretaceous Period. However, their jaw and hindlimb anatomy indicates that they were primarily herbivorous and incapable of sustained rapid running. Various skull and postcranial characters suggest that gastornithiforms are related to the waterfowl (Anseriformes) and, more distantly, to the true fowl (Galliformes).

Three genera have been reported. The type-genus, *Gastornis*; an apparently confamilial form, *Diatryma*; and third genus, *Zhongyuanus*, of uncertain phylogenetic affinity.

***Diatryma steini* (reconstruction). (*American Museum of Natural History*)**

Gastornithiforms are most abundant in alluvial sediments of the Bighorn Basin of Wyoming, where the most complete known skeleton, the holotype of *Diatryma steini* Matthew and Granger (=*D. gigantea* Cope; see illustration), was discovered, and in lake and swamp deposits of the Geiseltal of Germany. *See* AVES. [A.V.A.]

Gastrointestinal tract disorders Malfunctions of the organs of digestion from the esophagus to the rectum. The gastrointestinal tract usually functions unnoticed, intruding into consciousness only in the form of specific sensations of hunger, intestinal motion, or the need to defecate. However, it is subject to a wide array of pathologic states.

Esophagus. The esophagus is the site of two principal disorders: disturbance of the muscular contractions, and mechanical interference with the passage of food caused by a narrowed lumen. Carcinoma of the esophagus produces mechanical obstructions to swallowing; the long-term prognosis is poor. Excessive acid reflux or regurgitation from the stomach may result in inflammation of the lower esophagus with heartburn and indigestion. Changes in diet and eating habits may bring relief.

The prime example of muscular or neuromuscular disorder is achalasia, a condition of unknown etiology characterized by degeneration of the nervous mechanisms that coordinate contractions of the esophagus and relaxation of the lower esophageal sphincter. Swallowing solids and liquids is difficult, and nutritional consequences usually result.

Other disorders that affect the esophagus include connective tissue diseases such as scleroderma or dermatomyositis. Scleroderma is characterized by weakening of the smooth musculature, which is present in the lower two-thirds of the esophagus, and the lower esophageal sphincter. Dermatomyositis affects the striated musculature present in the upper third of the esophagus. *See* CONNECTIVE TISSUE DISEASE.

Mechanical problems include stricture or scarring of the lower esophagus, which usually develops from acid reflux. Swallowing is also impeded mechanically by a lower esophageal, or Schatzki, ring, which is a mucosal constriction at the junction of the esophagus and stomach in the presence of a hiatus hernia. *See* HERNIA.

Carcinoma of the esophagus causes mechanical obstructions to swallowing.

Reflux esophagitis is an inflammation of the lower esophagus that results from excessive acid reflux or regurgitation from the stomach.

Stomach. The stomach is the site of secretion of the highly concentrated hydrochloric acid. The lining of the stomach and duodenal both need to be protected against the effects of the acid.

Peptic ulcer disease is characterized by breaks in the mucosa of the proximal duodenum (duodenal ulcer) or stomach (gastric ulcer). Duodenal ulcer is one of the most common maladies, but for unknown reasons its incidence seems to be declining. It is associated with high concentrations of hydrochloric acid caused by excessive gastrin secretion. In persons with a gastric ulcer, acid concentrations are usually normal or low. The cause of gastric ulcer is not known but may involve increased reflux of bile and other constituents of the small intestine.

Inflammation of the stomach lining, known as gastritis, ranges in severity from acute to chronic and can ultimately lead to atrophy of the tissues and loss of function.

The typical symptoms of gastric cancer include early satiety after eating small amounts of food, abdominal pain, anemia from blood loss, and difficulty in swallowing. Benign stomach tumors are usually asymptomatic but may cause bleeding.

Small intestine. The small intestine is normally resistant to disease. When nutrition is adequate, structure and function remain intact into old age with only slight changes if no specific diseases occur. A prototypical disease of malabsorption is gluten enteropathy, or nontropical sprue. Probably due in part to genetic abnormalities, gluten enteropathy is characterized by inflammation and loss of the normal architecture of the small intestine following ingestion of some proteins. The causative substance is contained in gluten, the protein of cereal grains; a gluten fraction, gliadin, contains the toxin that is responsible. A gluten-free diet, once it has been adopted, is usually maintained for life. Other conditions may also interfere with the absorptive function of the small intestine. Tropical sprue, found in tropical and subtropical climates, resembles gluten enteropathy in its manifestations. It may, however, be an infectious diarrhea; it can be treated with antibiotics and high doses of folic acid. A gluten-free diet does not cure the condition. Infections within the small intestine, particularly those of the parasite *Giardia lamblia*, may also cause malabsorption. Bacterial infection by *Escherichia coli* causes most cases of traveler's diarrhea. Among the many other diseases that may lead to malabsorption is regional enteritis, or Crohn's disease. *See* INFLAMMATORY BOWEL DISEASE.

Of all the body's organs, the small intestine is one of the most resistant to neoplastic disease. Benign tumors are rare, as are cancer and lymphoma. (In some familial conditions, however, benign polyps may develop.)

Colon. The colon, or large intestine, is subject to malfunction of widely varying degrees, ranging from mild irritation to life-threatening diseases.

Disturbance of bowel function is among the most common complaints. Constipation probably predominates, particularly with advancing age, but loose stool and diarrhea are also frequent and troublesome. A familiar condition associated with altered function is irritable bowel syndrome, a nonspecific label for an intestinal disturbance without known anatomic cause. *See* DIARRHEA.

In diverticulosis, small pouches appear along the wall of the colon. Diverticulosis is associated with high pressures within the colon and particularly its narrowest segment, the sigmoid colon. The pressure pushes the mucosa through the weakest points in the wall, leading to formation of the diverticuli.

The second most common internal cancer is that of the colon and rectum. Cancers frequently arise in benign polyps of the colon, which are stalklike or leafed structures (villous adenomas). A high intake of red meat and low fiber and low vitamin A consumption may be contributing factors; a genetic predisposition has been suggested.

Hemorrhoids are veins near the anus that have become distended or occluded. The cause is not fully understood but may be related to straining at stool.

Appendix. Appendicitis, that is, inflammation of the vermiform appendix, was once common among young people but is now relatively rare; the reason for the sharp drop in frequency is unclear. Appendicitis seems to result when a hardened piece of fecal matter known as a fecalith becomes trapped within the appendix and causes infection that can lead to gangrene. If the condition persists, the appendix may perforate, resulting in widespread infection in the abdomen. *See* APPENDICITIS; CANCER (MEDICINE); DIGESTIVE SYSTEM; GASTROINTESTINAL TRACT; TUMOR.

[L.A.Ka.]

Gastrolith

Gastrolith Any of the pebbles swallowed by animals and retained for a time in the gizzard or stomach, where they serve to grind up the food and in so doing become rounded and highly polished. Birds generally use such pebbles, as do some living reptiles, notably the crocodile and certain lizards. Some of the Mesozoic reptiles also used gastroliths. [C.O.D.]

Gastropoda

Gastropoda The largest and most varied class in the phylum Mollusca, possibly numbering over 74,000 species and commonly known as snails.

General characteristics. The shell is in one piece which, in the majority of forms, grows along a turbinate (equiangular) spiral (see illustration), but which is modified into an open cone in various limpets or is secondarily lost in various slugs.

All gastropods, at some time in their phylogeny and at some stage in their development, have undergone torsion. The process does not occur in any other mollusks. It implies that the visceral mass and the mantle shell covering it have become twisted through 180° in relation to the head and foot. As a result of torsion, all internal organs are twisted into a loop. Similarly in gastropods, the mantle cavity (the semi-internal space enclosed by the pallium or mantle) containing the characteristic molluscan gills (ctenidia) has become anterior and placed immediately above and behind the head. The most primitive gastropods retain a pair of aspidobranch (bipectinate or featherlike) gills, each with alternating ctenidial leaflets on either side of a ctenidial axis in which run afferent and efferent blood vessels. Lateral cilia on the faces of the leaflets create a respiratory water current (toward the midline and anteriorly) in the direction opposite to the flow of blood through the gills, to create the physiological efficiency of a countercurrent exchange system.

Longitudinal section ground through the shell of a specimen of *Conus spurius* to reveal the central columella and spiral of whorls expanding to the aperture. (*From W. D. Russell-Hunter, A Life of Invertebrates, Macmillan, 1979*)

Classification and diversity. The usual systematic arrangement of the class Gastropoda involves three somewhat unequal subclasses. The first, the largest and most diverse, is the subclass Prosobranchia, which is made up largely of marine snails all retaining internal evidence of torsion. Prosobranchs are divided into at least four orders: Archaegastropoda, Caenogastropoda, Neritida, and Patellogastropoda; three superfamilies remain to be assigned to one of the four orders, and may each comprise a distinct order. The other two subclasses (Opisthobranchia and Pulmonata) are each considerably more uniform than the subclass Prosobranchia and, in both, the effects of torsion are reduced or obscured by secondary processes of development and growth. *See* OPISTHOBRANCHIA; PROSOBRANCHIA; PULMONATA.

More than half of all molluscan species are gastropods, and they encompass a range from marine zygobranchs, which can be numbered among the most primitive of all living mollusks, to the highly evolved terrestrial air-breathing slugs and snails. Pulmonates and certain mesogastropod families are the only successful molluscan colonizers of land and fresh waters. [W.D.R.H.]

Fossils. Fossil gastropods have a long geologic history, being common throughout the Paleozoic and increasingly abundant in the Mesozoic and Cenozoic. All three subclasses are known in the fossil record; many superfamilies, particularly prosobranchs, are extinct. Average duration of a genus has been estimated to range from 30,000,000 to 90,000,000 years.

Marine gastropods are important stratigraphic indicators in Cenozoic strata and locally are abundant in Cretaceous rocks. They are less common and less useful in the Jurassic and Triassic. Although individual genera have stratigraphic utility within the Paleozoic, it is only in the Ordovician that they are significant for correlation. *See* MOLLUSCA. [E.L.Y.]

Gastrotricha

A phylum of minute metazoan animals (formerly placed in the aschelminth group) numbering 500 described species worldwide. Some 300 species have been reported from the marine habitat, with new ones being described every year.

Gatrotrichs comprise two orders, the Macrodasyida and the Chaetonotida. The term Gastrotricha refers to the ventral locomotor cilia by which the animals glide gracefully over the substratum or through its interstices; unlike many other ciliated animals, they cannot move in reverse. Gastrotrichs have a complete digestive tract, with a sucking pharynx, a simple intestine with a wall only a single cell thick, and an anus. They appear to be selective feeders on bacteria, very small protozoa, and yeasts. Most have protonephridia, accounting in part for their broad salinity tolerances.

Gastrotrichs appear to be regionally cosmopolitan, with 20–30% having broad distributions within continents, and 10–15% between continents; endemism probably does not exceed 20%.

The phylum Gastrotricha is the most primitive in the aschelminth group of phyla. Gastrotrichs and nematodes probably share a common ancestor, which in turn was descended from a stock that included gnathostomulids and turbellarianoid animals. *See* CHAETONOTIDA; GNATHOSTOMULIDA; MACRODASYIDA; NEMATA; TURBELLARIA. [W.D.Hu.]

Gastrulation

The formation of the primordial gut, the archenteron, or digestive cavity of an early animal embryo. More generally, and originally, the term gastrulation referred to the process by which the gastrula stage of the embryo is formed. Thus to nineteenth-century embryologists, gastrulation was the process by which the single-layered blastula, a hollow ball of cells, is converted into the double-layered gastrula. The term has now come to have a still more general meaning, namely, the process by which the three germ layers, or primordial tissues of the embryo, are brought into the positions and relations characteristic of the late gastrula stage, with ectoderm (outer skin), mesoderm (middle skin), and endoderm (inner skin) from the outside to the inside. The terms epiblast, mesoblast, and hypoblast are also used to denote ectoderm, mesoderm, and endoderm, respectively. *See* BLASTULATION.

Two general but not mutually exclusive methods of gastrulation have been recognized: epiboly and emboly. Epiboly is the growing or extending of one part, such as the upper hemisphere of a spherical blastula, over and around another part, such as the lower hemisphere. Emboly is the pushing or growing of one part into another. In many embryos, both types of cell movement may occur; in certain invertebrate embryos, one type may predominate almost to the exclusion of the other. Generally speaking, epiboly tends to be the major, but not the only, method of gastrulation in forms with large, yolky eggs. *See* GERM LAYERS. [N.T.S.]

Gate circuit

An electronic circuit that consists of elements, which may be transistors, diodes, or resistors, combined in such a manner that they perform a logic operation. Gate circuits are the most basic building blocks of a digital system. These circuits have one or more inputs and one output which is a boolean function of the inputs. The input and output signals can have only two discrete values, low (for example, 0 V) and high (for example, 3.3 V). These values are usually represented as 0 and 1, or "false" and "true," respectively.

Whereas the early gate circuits consisted of diodes, resistors, and transistors, the majority of gate circuits nowadays are built exclusively with transistors. The dominant technology for fabricating gate circuits is the metal oxide semiconductor (MOS) silicon method, followed by the silicon bipolar and gallium arsenide (GaAs) techniques. The manufacturing process has become so sophisticated that transistors smaller than 1 square micrometer can be fabricated, allowing the placement of millions of gate circuits on a silicon chip the size of a fingernail. The main advantage of MOS technology is that it gives rise to very low power circuits that can still operate at relatively high clock speed. It is these characteristics that have allowed the fabrication of very complex digital systems such as microprocessors and memories. *See* INTEGRATED CIRCUITS; MICROPROCESSOR; SEMICONDUCTOR MEMORIES.

The transistors in a gate circuit are used as ON-OFF switches. By combining these transistors in a certain way, it is possible to realize logical, arithmetical, and memory functions. There are two type of MOS transistors: NMOS and PMOS field-effect transistors (FETs), corresponding to a normally-OFF or normally-ON switch, respectively. Circuits in which both types of transistors are used are called CMOS (complementary MOS) circuits. CMOS circuits now constitute the majority of gate and logic circuits.

In switch circuits an MOS transistor is used to pass or block the flow of information in a similar fashion to a mechanical switch. By placing these switches in a network, it is possible to realize different logic functions. A transistor used in this fashion is often called a pass-transistor. In order to improve the switching characteristics, an NMOS switch and a PMOS switch are placed in parallel, each clocked at opposite clock signals. Such a combination is called a CMOS transmission gate. Several transmission gates can be combined to form a logic AND circuit. *See* SWITCHING CIRCUIT.

An alternative way to realize logic functions is to make use of logic gates. The simplest gate circuit, the inverter, takes an input signal and presents the inverted signal at the output. *See* LOGIC CIRCUITS; TRANSISTOR. [J.V.S.]

Gauge theory

The theoretical foundation of the four fundamental forces of nature, the electromagnetic, weak, strong, and gravitational interactions. Gauge symmetry lies at the heart of gauge theory. A gauge symmetry differs from an ordinary symmetry in two important respects:

1. Gauge symmetry is a local symmetry rather than a global symmetry. For a local symmetry, the element of the symmetry

group (G) that acts on the fields of a theory at a space-time point ($\mathbf{x}$, t) depends on the position $\mathbf{x}$ and time t, whereas for a global symmetry a fixed group element acts on fields at different space-time points.

2. A gauge transformation leaves a physical state invariant. Gauge symmetry reflects a redundancy in the variables used to describe a physical state. By contrast, a global symmetry acting on a physical state in general produces a new, distinct physical state. *See* FUNDAMENTAL INTERACTIONS; SPACE-TIME.

The simplest example of a gauge theory is electromagnetism. In classical electrodynamics, gauge invariance reflects the arbitrariness that exists in choosing the potentials $\mathbf{A}(\mathbf{x}, t)$ and $\phi(\mathbf{x}, t)$ to represent the electric and magnetic fields, $\mathbf{E}$ and $\mathbf{B}$, according to Eqs. (1), where c is the speed of light. If $\Lambda(\mathbf{x}, t)$ is an arbitrary scalar field, Eqs. (2) define a gauge transformation.

$$\begin{aligned} \mathbf{E}(\mathbf{x}, t) &= -\nabla\phi - \frac{1}{c}\frac{\partial \mathbf{A}}{\partial t} \\ \mathbf{B}(\mathbf{x}, \mathrm{t}) &= \nabla \times \mathbf{A} \end{aligned} \tag{1}$$

$$\begin{aligned} \phi \rightarrow \phi' &= \phi - \frac{1}{c}\frac{\partial \Lambda}{\partial t} \\ \mathbf{A} \rightarrow \mathbf{A}' &= \mathbf{A} + \nabla\Lambda \end{aligned} \tag{2}$$

The potentials $\mathbf{A}'$ and ϕ' may equally well be used to represent the electromagnetic fields $\mathbf{E}$ and $\mathbf{B}$. *See* MAXWELL'S EQUATIONS; POTENTIALS; RELATIVISTIC ELECTRODYNAMICS.

In nonrelativistic quantum mechanics, gauge invariance is realized as follows. The Schrödinger equation for a particle with an electromagnetic charge q and mass m is Eq. (3), where $\hat{H}$ is

$$\begin{aligned} \hat{H}\Psi &= \frac{1}{2m}\left(\hat{\mathbf{p}} - \frac{q}{c}\mathbf{A}\right)^2 \Psi + q\phi\Psi \\ &= \frac{1}{2m}\left(-i\hbar\nabla - \frac{q}{c}\mathbf{A}\right)^2 \Psi + q\phi\Psi \\ &= i\hbar\frac{\partial}{\partial t}\Psi \end{aligned} \tag{3}$$

the hamiltonian operator, $\hat{\mathbf{p}}$ is the momentum operator, Ψ is the wave function of the particle, and $\hbar$ is Planck's constant divided by 2π. Equation (3) is invariant under the gauge transformation given by Eqs. (4). Electromagnetism is a $U(1)$ gauge symmetry

$$\begin{aligned} \Psi \rightarrow \Psi' &= \exp\left(\frac{iq\Lambda}{\hbar c}\right) \cdot \Psi \\ \phi \rightarrow \phi' &= \phi - \frac{1}{c}\frac{\partial \Lambda}{\partial t} \\ \mathbf{A} \rightarrow \mathbf{A}' &= \mathbf{A} + \nabla\Lambda \end{aligned} \tag{4}$$

[where $U(1)$ is the one-dimensional unitary group, which is represented by the complex numbers $e^{i\varphi}$ with $0 \leq \varphi < 2\pi$] because a gauge transformation rotates the phase of the wave function in a space-time–dependent manner and adjusts the potentials A and ϕ accordingly. *See* NONRELATIVISTIC QUANTUM THEORY; QUANTUM MECHANICS; SCHRÖDINGER'S WAVE EQUATION; UNITARY SYMMETRY.

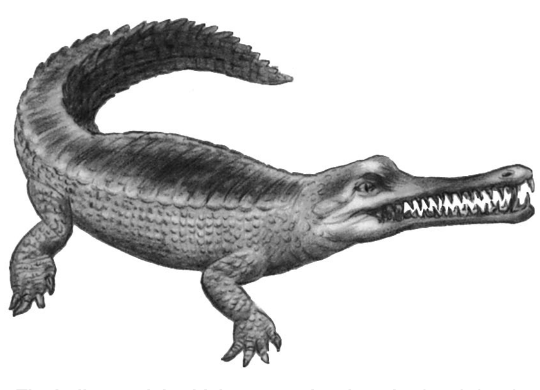
The concept of a gauge theory may be generalized to larger, nonabelian Lie groups, such as $G = SU(2)$, $SU(3)$, $SU(5)$, or $SO(10)$. In 1954 C. N. Yang and R. L. Mills suggested gauging the $SU(2)$ isospin symmetry, thus developing the first nonabelian gauge theory, also known as Yang-Mills theory. In 1971 G. 't Hooft demonstrated the renormalizability of nonabelian gauge theory. Nonabelian gauge theory is the foundation of the electroweak and strong interactions. In the electroweak theory, formulated by S. Weinberg and A. Salam in 1967, the gauge group $G = SU(2)_{\mathrm{L}} \times U(1)_{\mathrm{Y}}$ is spontaneously broken to $U(1)_{\mathrm{Q}}$, the gauge group of ordinary electromagnetism, by the condensation of a Higgs field. There are four kinds of particles that mediate the gauge interactions, called gauge bosons: two massive charged weak gauge bosons, the W^+ and W^-, with a mass of 80.4 GeV; a neutral gauge boson, the Z, with a mass of 91.2 GeV; and finally a massless photon (γ). The $W^{\pm}$ and the Z are responsible for the charged and neutral weak interactions, respectively, and the photon is the gauge particle responsible for the electromagnetic interaction. In quantum chromodynamics (QCD) the symmetry group is $SU(3)_{\mathrm{color}}$, which remains unbroken. There are eight gauge bosons called gluons. Quarks, which come in three colors, carry a color charge, and the quark field forms an $SU(3)$ triplet. *See* ELECTROWEAK INTERACTION; SYMMETRY BREAKING.

One remarkable property of quantum chromodynamics is that color charge is antiscreened rather than screened, a feature arising from the nonabelian character of the gauge symmetry. This situation is opposite to that in QED. Consequently, as shorter distance scales are probed, the coupling constant α_{QCD} decreases, so that at very short distances QCD approaches a free (noninteracting) field theory. This feature, pointed out in 1973 by D. Gross and F. Wilczek and by H. D. Politzer, is known as asymptotic freedom. Although on large scales QCD is a strongly coupled theory, at very small scales, which may be probed by scattering at very high energies, the constituents of hadrons (quarks and gluons) behave almost as if they were free particles, originally called partons. Similarly, at larger distances scales α_{QCD} becomes larger, and perturbation theory breaks down. This increase in the coupling constant at large distances leads to a phenomenon known as confinement, which prevents colored objects (such as quarks or gluons) from being isolated. *See* GLUONS; QUANTUM CHROMODYNAMICS; QUARKS. [M.Bu.]

Gauss' theorem The assertion, under certain light restrictions, that the volume integral through a volume V of the divergence of vector function $\mathfrak{F}(x,y,z)$ is equal to the surface integral of the exterior normal component of $\mathfrak{F}$ over the boundary surface S of V, or in symbols $\iiint \nabla \cdot \mathfrak{F}\, dV = \iint \mathfrak{F} \cdot \mathbf{v}\, dS$, with $\mathbf{v}$ the unit exterior normal to S. This theorem is also known as the divergence theorem and as Green's theorem.

The divergence theorem plays an important role in a variety of subjects such as electricity and magnetism, mechanics of continuous media (including fluid dynamics), heat flow, partial differential equations, and potential theory. *See* CALCULUS OF VECTORS; GREEN'S THEOREM. [H.V.C.]

Gavial The name of two species of reptiles which form the family Gavialidae in the order Crocodilia. The Indian gavial (*Gavialis gangeticus*) is confined to the Ganges River and its tributaries, while the Malayan gavial (*Tomistoma schlegeli*) is found in Borneo and Sumatra.



The Indian gavial, which may attain a length of 30 ft (9 m).

The gavial is distinguished from other members of the order by its extremely long, slender snout (see illustration). The tip of the snout is enlarged, and fleshy elevations surround the openings of the nostrils. The females lay about 30–40 eggs in nests which they have prepared on the riverbanks. The newly hatched young are about 1 ft (30 cm) long and quite active. *See* ALLIGATOR; CROCODILE; REPTILIA. [C.B.C.]

Gaviiformes A small order of aquatic birds that contains a single living family, the Gaviidae (loons), whose five species are restricted to the Northern Hemisphere, and a fossil family, the Colymboididae. Loons are large swimming and diving birds that catch fish with their strong bills in underwater pursuits. They are foot-propelled swimmers, with short legs placed far back on the body and webbed feet; land locomotion is awkward. Loons take wing with difficulty but are strong fliers. Sexes are similar in plumage, which is white below and checked black and white above. Loons are monogamous, have a strong pair bond, and engage in elaborate courtship rituals that include loud, quavering calls often given in flight. Breeding is solitary and takes place on freshwater lakes. The young are downy, leave the nest after hatching, and are cared for by both parents. Because all flight features are molted simultaneously, the birds are rendered temporarily flightless. Loons migrate south to wintering areas, which are mostly along ocean coasts. *See* Aves; Charadriiformes; Hesperornithiformes; Podicipediformes. [W.J.B.]

Gear A machine element used to transmit motion between rotating shafts when the center distance of the shafts is not too large. Toothed gears provide a positive drive, maintaining exact velocity ratios between driving and driven shafts, a factor that may be lacking in the case of friction gearing which is subject to slippage. *See* Belt drive; Chain drive; Rolling contact.

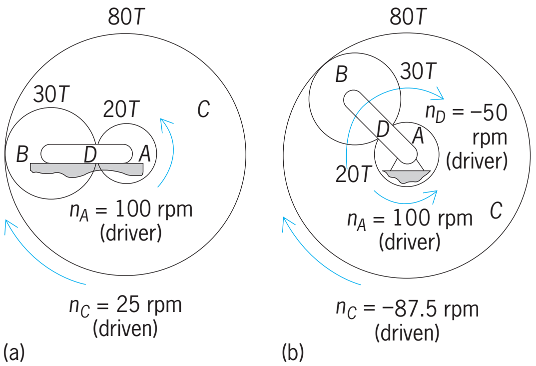
The application of gears for power transmission between shafts falls into three general categories: those with parallel shafts, those for shafts with intersecting axes, and those whose shafts are neither parallel nor intersecting but skew. *See* Gear train. [J.R.Z.]

Gear train A combination of two or more gears used to transmit motion between two rotating shafts or between a shaft and a slide. In theory two gears can provide any speed ratio in connecting shafts at any center distance, but it is often not practical to use only two gears. If the ratio is large or if the center distance is relatively great, the larger of the two gears may be excessively large. Moreover, an additional gear may be necessary simply to give the proper direction to the output gear. Belt, rope, and chain drives are frequently used in conjunction with gear trains. *See* Belt drive; Chain drive; Gear; Planetary gear train.

The most important distinction in classifying gear trains is that between ordinary and epicyclic gear trains. In ordinary trains (illustration *a*), all axes remain stationary relative to the frame. But in epicyclic trains (illustration *b*), at least one axis moves relative to the frame. In illustration *b*, gear *B*, whose axis is in motion, is called a planet. The gears *A* and *C* are sun gears.

A simple gear train is one in which each gear is fastened to a separate shaft, as in illustration *a*. If at least one shaft has two or more gears fastened to it, the train is said to be compound. The train is a reverted gear train when the input and output shafts are in line. If the input shaft does not line up with the output shaft, the train is said to be nonreverted.

If a machine must be operated at any one of several output speeds, a multiple-speed gearbox, or transmission, may be used as a component part. Machine tools and motor vehicles are familiar instances of the need for transmissions. The speed of the output shaft of a transmission can be varied by sliding gears in and out of contact or by connecting gears in continual mesh to shafts by means of clutches. *See* Automotive transmission. [J.R.Z.]

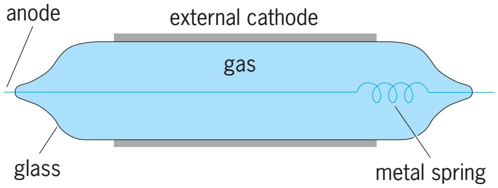


Gear trains. (*a*) Ordinary. (*b*) Epicyclic.

Gecko The name for about 300 species of reptiles that form the family Gekkonidae in the order Squamata. They are small lizards, primarily arboreal and nocturnal, which occur in the warm regions of the world. The body is flattened; most species have five digits, while some have only four; the toes often have adhesive pads to assist the animal when climbing on smooth surfaces. Geckos feed on small animals, especially insects, and all species have a long sensitive tongue to aid in capturing their prey. Most species of gecko are oviparous.

The largest, most aggressive species is the orange-spotted Tokay (*Gekko gecko*), which is indigenous to Southeast Asia. Another species is the flying gecko (*Ptychozoon homalocephalum*), which is essentially arboreal and is well adapted to leaping and gliding because it has folds of skin on either side of the body that can be opened out to form a planing surface. The banded gecko (*Coelonyx variegatus*) of the southwestern United States is one of the few species with movable eyelids, and with claws instead of pads on the toes. *See* Squamata. [C.B.C.]

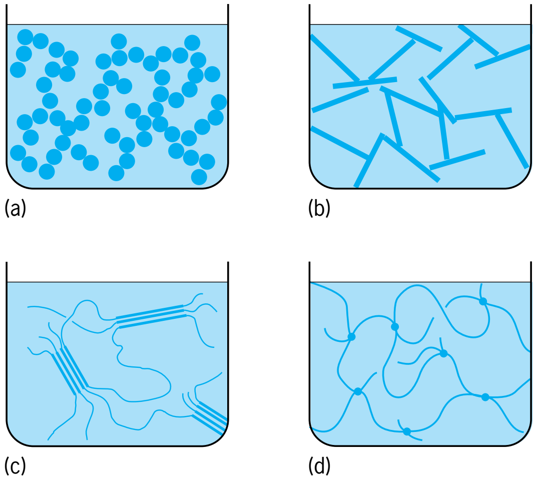
Geiger-Müller counter A detector of ionizing radiation. When a fast-moving charged particle traverses a Geiger-Müller counter, an electrical impulse is produced. These impulses can readily be counted by electronic circuits. Geiger-Müller (GM) counters, usually referred to simply as Geiger counters, are widely used to indicate the presence and intensity of nuclear radiations.



Cylindrical external-cathode Geiger-Müller counter, with thin soda glass and central wire of 0.003-in.-diameter (0.008-cm) tungsten. Metal spring keeps central wire taut.

A GM counter consists of a gas between two electrodes (see illustration). One electrode, usually cylindrical and hollow, is the cathode. The other electrode, a fine “wire stretched along the axis of the cylinder, is the anode. A potential of about 1000 volts is placed on the wire. When an atom of the gas between the two electrodes is ionized by collision with a charged particle passing through the gas, the electron produced in the collision is drawn toward the central wire. The electron then collides with the atoms of the gas. Near the central wire the electric field is very intense, and the electron may acquire enough energy between two collisions to allow it to ionize another atom. A second electron is then set free, and by successive collisions, an avalanche of electrons is produced which is then collected as charge on the central wire. This charge produces an electrical impulse which in typical cases may be 50 volts. *See* Ionization chamber; Particle detector. [W.B.Fr.]

Gel A continuous solid network enveloped in a continuous liquid phase; the solid phase typically occupies less than 10 vol % of the gel. Gels can be classified in terms of the network structure.



Gel structures. (*a*) Agglomerated particles. (*b*) Framework of fibers or plates. (*c*) Polymers linked by crystalline junctions. (*d*) Polymers linked by covalent bonds. (*After M. Djabourov, Architecture of gelatin gels, Contemp. Phys., 29(3):273–297, 1988*)

The network may consist of agglomerated particles (formed, for example, by destabilization of a colloidal suspension; illus. *a*); a "house of cards" consisting of plates (as in a clay) or fibers (illus. *b*); polymers joined by small crystalline regions (illus. *c*); or polymers linked by covalent bonds (illus. *d*).

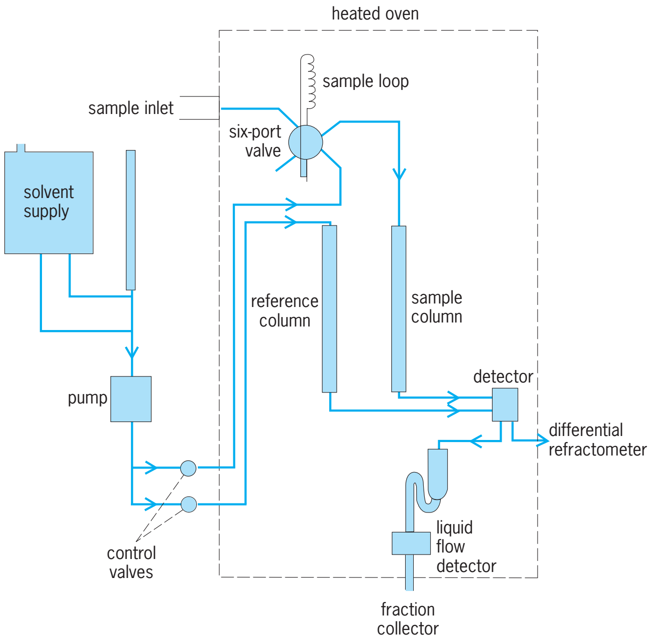
In a gel the liquid phase does not consist of isolated pockets, but is continuous. Consequently, salts can diffuse into the gel almost as fast as they disperse in a dish of free liquid. Thus, the gel seems to resemble a saturated household sponge, but it is distinguished by its colloidal size scale: the dimensions of the open spaces and of the solid objects constituting the network are smaller (usually much smaller) than a micrometer. This means that the interface joining the solid and liquid phases has an area on the order of 1000 m^2 per gram of solid. As a result, the properties of a gel are controlled by interfacial and short-range forces, such as van der Waals, electrostatic, and hydrogen-bonding. Factors that influence these forces, such as introduction of salts or another solvent, application of an electric field, or changes in pH or temperature, affect the interaction between the solid and liquid phases. Variations in these parameters can induce huge changes in volume as the gel imbibes or expels liquid, and this phenomenon is exploited to make mechanical actuators or hosts for controlled release of drugs from gels. For example, a polyacrylamide gel (a polymer linked by covalent bonds) shrinks dramatically when it is transferred from a dish of water (a good solvent) to a dish of acetone (a poor solvent), because the polymer chains tend to favor contact with one another rather than with acetone, so the network collapses onto itself. Conversely, the reason that water cannot be gently squeezed out of such a gel is that the network has a strong affinity for the liquid, and virtually all of the molecules of the liquid are close enough to the solid-liquid interface to be influenced by those attractive forces. *See* Hydrogen bond; Intermolecular forces.

The most striking feature of a gel is its elasticity: if the surface of a gel is displaced slightly, it springs back to its original position. If the displacement is too large, gels, except those with polymers linked by covalent bonds, may suffer some permanent plastic deformation, because the network is weak. The process of gelation, which transforms a liquid into an elastic gel, may begin with a change in pH that removes repulsive forces between the particles in a colloidal suspension, or a decrease in temperature that favors crystallization of a solution of polymers or the initiation of a chemical reaction that creates or links polymers. *See* pH.

Many inorganic gels can be made from solutions of salts or metallorganic compounds, and this offers several advantages in ceramics processing: the reactants are readily purified; the components can be intimately mixed in the solution or sol stage; the sols can be applied as coatings, drawn into fibers, emulsified or spray-dried to make particles, or molded and gelled into shapes. Hybrid materials can be made by combining organic and inorganic components in the gel. Many hybrids have such compliant networks that they collapse completely during drying, leaving a dense solid; therefore, they can be used as protective coatings (on plastic eyeglass lenses, for example) without heat treatment. Hybrid gels show great promise for active and integrated optics, because optically active organic molecules retain their activity while encapsulated in the gel matrix. [G.W.Sc.]

Gel permeation chromatography A separation technique involving the transport of a liquid mobile phase through a column containing the separation medium, a porous material. Gel permeation chromatography (GPC), also called size exclusion chromatography and gel filtration, affords a rapid method for the separation of oligomeric and polymeric species. The separation is based on differences in molecular size in solution. It is of particular importance for research in biological systems and is the method of choice for determining molecular weight distribution of synthetic polymers.

The separation medium is a porous solid, such as glass or silica, or a cross-linked gel which contains pores of appropriate dimensions to effect the separation desired. The liquid mobile phase is usually water or a buffer for biological separations, and an organic solvent that is appropriate for the sample and is compatible with the column packing for synthetic polymer characterization. Solvent flow may be driven by gravity, or by a high-pressure pump to achieve the desired flow rate through the column. The sample to be separated is introduced at the head of the column (see illustration). As it progresses through the column, small molecules can enter all pores larger than the molecule, while larger molecules can fit into a smaller number of pores, again only those larger than the molecule. Thus, the larger the molecule, the smaller is the amount of pore volume available into which it can enter. The sample emerges from the column in the inverse order of molecular size; that is, the largest molecules emerge first followed by progressively smaller molecules. In order to determine the amount of sample emerging, a concentration detector is located at the end of the column. Additionally, detectors may be used to continuously determine the molecular



Gel permeation chromatography.

weight of species eluting from the column. The volume of solvent flow is also monitored to provide a means of characterizing the molecular size of the eluting species.

As the sample emerges from the column, a concentration detector signal increases above the baseline, passes through a maximum, and returns to the baseline. This signal provides a relative concentration of emerging species and is recorded as a function of elution volume. Molecular-weight detectors based on light scattering or viscometry produce a signal, independent of molecular weight, that increases with increasing molecular weight for a given sample concentration. The molecular-weight chromatograms therefore are skewed with respect to the concentration detector signal. Typically, constant-volume pumps are used, and the time axis is transformed into a volume axis. Devices such as siphons that empty after a known volume of solvent has collected, or electronic circuitry that measures the transit time of a thermal pulse between two points in the flowing solvent, have been used to provide a measurement of the volumetric flow rate.

Gel permeation chromatography has had widespread applications. For determining the molecular weight of synthetic polymers, at least 50 types of polymers have been characterized. These include alkyd resins, natural and synthetic rubbers, cellulose esters, polyolefins, polyamides, polyesters, polystyrenes, polyacrylates, uncured epoxy, urethane and phenolic resins, and a wide variety of oligomeric materials. Additionally, the ability to determine the molecular-weight distribution and changes in distribution has led to many applications in areas such as blending distributions, chain-length studies in semicrystalline polymers, interactions in solution, radiation studies, mechanical degradation studies, mechanisms of polymerization research, polymerization reactor control, and evaluation of the processing of polymers. In the field of natural and biological polymers, numerous systems have been separated and analyzed. Among these are acid phosphatases, adrenalin, albumin, amino acids and their derivatives, enzymes, blood group antibodies, collagen and related compounds, peptides, and proteins.

Additionally, gel permeation chromatography is capable of making separations of low-molecular-weight compounds. This is particularly important when both low- and high-molecular-weight species are present in the same sample. *See* CHROMATOGRAPHY; POLYMER. [A.R.C.]

Gelatin A protein extracted after partial hydrolysis of collagenous raw material from the skin, white connective tissue, and bone of animals. It is a linear polymer of amino acids, most often with repeating glycine-proline-proline and glycine-pro-line-hydroxyproline sequences in the polypeptide linkages. *See* COLLAGEN; PROTEIN.

The unique characteristics of gelatin are: reversible sol-to-gel formation, amphoteric properties, swelling in cold water, film-forming properties, viscosity-modifying properties, and protective colloid properties. Gelatin contains 26.4–30.5% glycine, 14.8–18% proline, 13.3–14.5% hydroxyproline, 11.1–11.7% glutamic acid, 8.6–11.3% alanine, and in decreasing order arginine, aspartic acid, lysine, serine, leucine, valine, phenylala-nine, threonine, isoleucine, hydroxylysine, histidine, methionine, and tyrosine. Absence of only two essential amino acids—tryptophan and methionine—makes gelatin a good dietary food supplement.

The principal uses of gelatin are in foods, pharmaceuticals, and photographic industries. Other uses of industrial gelatin are in the field of microencapsulation, health and cosmetics, and plastics. [F.V.]

Gem A mineral or other material that has sufficient beauty for use as personal adornment and has the durability to make this feasible. With the exception of a few materials of organic origin, such as pearl, amber, coral, and jet, and inorganic substances of variable composition, such as natural glass, gems are lovely varieties of minerals.

Natural gems. Each distinct mineral is called a species by the gemologist. Two stones that have the same essential composition and crystal structure but that differ in color are considered varieties of the same species. Thus ruby and sapphire are distinct varieties of the mineral species corundum, and emerald and aquamarine are varieties of beryl. *See* MINERAL; MINERALOGY.

Most gemstones are crystalline (that is, they have a definite atomic structure) and have characteristic properties, most of which are related directly to either beauty or durability. Each mineral has a characteristic hardness (resistance to being scratched) and toughness (resistance to cleavage and fracture). With few exceptions, the most important gemstones are those at the top of the Mohs hardness scale; for example, diamond is 10, ruby and sapphire are 9, chrysoberyl is $8\frac{1}{2}$, and topaz, beryl (emerald and aquamarine), and spinel are 8.

Optical properties are particularly important to the beauty of the various gem materials. The important optical properties include color; dispersion (or "fire"); refractive index (relating the breaking up of white light into colors—a rough measure of brilliancy); and pleochroism (the property of some doubly refractive materials of absorbing light unequally in the different directions of transmission, resulting in color,differences). Gemstones usually are cherished for their color, brilliancy, fire, or one of the several optical phenomena, such as asterism (the star effect caused by certain reflections of light); chatoyancy, or a cat's-eye effect; play of color, such as displayed by an opal; and adularescence (the billowy light effect seen in adularia or moonstone varieties of orthoclase feldspar).

Gemstones are commonly designated as precious or semiprecious. This is a somewhat meaningless practice, however, and often misleading, since many of the so-called precious gem varieties are inexpensive and many of the more attractive varieties of the semiprecious stones are exceedingly expensive and valuable. For example, a piece of fine-quality jadeite may be valued at approximately 100 times the price per carat of a low-quality star ruby. Fine black opals, chrysoberyl cat's-eyes, and alexandrites are often much more expensive than many sapphires of certain colors. *See* PRECIOUS STONES.

More than 100 natural materials have been fashioned at one time or another for ornamental purposes. Of these, however, only a relatively small number are likely to be encountered in jewelry articles.

The table lists the important gem minerals and the properties most useful in identification. For further information on the individual species or groups *see* AMBER; AMETHYST; AZURITE; BERYL; CAMEO; CHRYSOBERYL; CORUNDUM; DIAMOND; EMERALD; FELDSPAR; GARNET; INTAGLIO (GEMOLOGY); JADE; JET (GEMOLOGY); LABRADORITE; LAZURITE; MALACHITE; OLIVINE; ONYX; OPAL; ORTHOCLASE; PEARL; QUARTZ; RUBY; SAPPHIRE; SPINEL; SPODUMENE; TOPAZ; TOURMALINE; TURQUOISE; ZIRCON.

Manufactured gems. A mineral or other material that has sufficient beauty and durability for use as a personal adornment can be manufactured. The term "manufactured," as used here, does not include such processes as shaping, faceting, and polishing, but only the processes that affect the material from which the finished gem is produced. These processes are (1) those that change the mineral in some fundamental characteristic, such as color, called a treated gem; (2) those by which a material is made that is identical with the naturally occurring mineral, called a synthetic gem; and (3) those that produce a simulated material with the appearance but not both the composition and structure of the natural gem, called an imitation gem.

Treated gems. There are four basic methods of treatment: (1) dyeing and staining, (2) plastic or other impregnation, (3) heat treatment, and (4) radiation. When the process to which a gem material is subjected changes its structure or adds something, such as a dye or a plastic binder, an effect on value takes

Hardness, specific gravity, and refractive indices of gem materials

Gem material	Hardness	Specific gravity	Refractive index
Amber	2–2½	1.05	1.54
Beryl	7½–8	2.67–2.85	1.57–1.58
Chrysoberyl	8½	3.73	1.746–1.755
Corundum	9	4.0	1.76–1.77
Diamond	10	3.52	2.42
Feldspar	6–6½	2.55–2.75	1.5–1.57
Garnet			
Almandite	7½	4.05	1.79
Pyrope	7–7½	3.78	1.745
Rhodolite	7–7½	3.84	1.76
Andradite	6½–7	3.84	1.875
Grossularite	7	3.61	1.735
Spessartite	7–7½	4.15	1.80
Hematite	5½–6½	5.20	
Jade			
Jadeite	6½–7	3.34	1.66–1.68
Nephrite	6–6½	2.95	1.61–1.63
Lapis lazuli	5–6	2.4–3.05	1.50
Malachite	3½–4	3.34–3.95	1.66–1.91
Opal	5–6½	2.15	1.45
Pearl	4	2.7	
Peridot	6½–7	3.34	1.654–1.690
Quartz			
Crystalline	7	2.65	1.54–1.55
Chalcedonic	6½–7	2.60	1.535–1.539
Spinel	8	3.60	1.72
Spodumene	6–7	3.18	1.66–1.676
Topaz	8	3.53	1.61–1.62
Tourmaline	7–7½	3.06	1.624–1.644
Turquois	5–6	2.76	1.61–1.65
Zircon			
Blue and colorless	7½	4.7	1.92–1.98
Green	6	4.0	1.81

place. When such changes are made, the nature of the alteration must be disclosed. An example of the second category of treatment, wherein there is no obvious effect on value, is gentle heating of amethyst to even its color, or stronger heating to change it to yellow or brown citrine. The change is permanent and nothing but temporary heat has been added. Many colored stones, including most green tourmaline, aquamarine, and colorless and flame-colored zircon and all pink topaz and blue zircon have been heated to improve their color.

Synthetic gems. The U.S. Federal Trade Commission has restricted the term synthetic gems to manufactured materials that have the same chemical, physical, and optical properties as their naturally occurring counterparts. Many gem materials, including diamond, have been synthesized, but in such small crystals or poor quality that they are unsatisfactory as gemstones. Some attempts to make gemstones have resulted in producing substances hitherto not known, many of which are of great importance industrially. Others have resulted in significant improvements in existing processes.

Imitation gems. Since prehistoric times glass has been the most widely used gem imitation. Since World War II colored plastics have replaced glass to a great extent in the least expensive costume jewelry.

Identification. Materials made by a flame-fusion process almost always contain gas bubbles, which are usually spherical or nearly so. Those with medium to dark tones of color often show color banding, or striae, with a curvature corresponding to that of the top of the boule. Natural gem materials are characterized by angular inclusions and straight color bands, if any are present.

Flux-fusion synthetic emeralds have distinctly lower refractive indices and specific gravities than natural emeralds and are characterized by wisplike or veillike flux inclusions. They show a red fluorescence under ultraviolet light, whereas most natural emeralds are inert.

Hydrothermally made synthetic emeralds have properties similar to many natural emeralds, but their inclusions differ and they are characterized by a very strong red fluorescence under ultraviolet.

The cheaper forms of glass are cast in molds and, under a hand lens, show rounded edges at the intersections of facets; the facets are often concave. The better grades, known as cut glass, have been cut and polished after first being molded approximately into the desired form. Cut glass has facets that intersect in sharp edges. Both types may contain gas bubbles or have a roiled appearance in the heart or have both, in contrast to most of the colored stones they imitate. [R.T.L.]

Geminga A nearby neutron star that emits pulsed x-rays and gamma rays, steady optical radiation, and possibly radio and optical pulsations. Since the 1970s, it has been studied at a level of detail very unusual for a neutron star. As a result, not only are its nature and distance well known, but also a good understanding has been reached of the physical processes responsible for its multiwavelength emission.

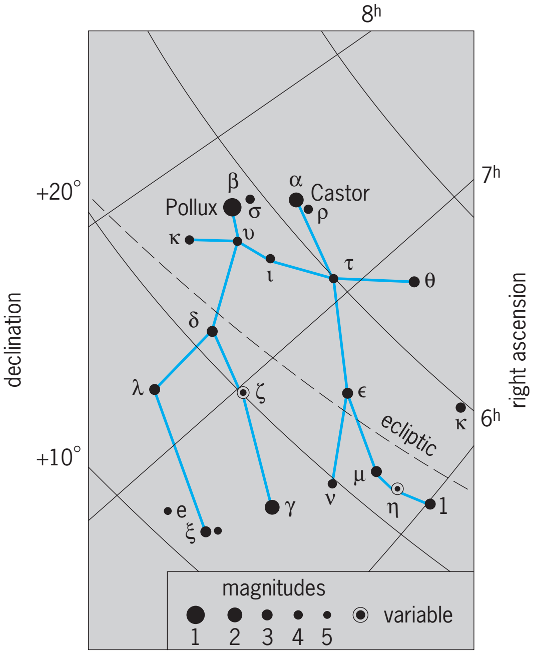
Owing to their large, rapidly spinning magnetic fields, neutron stars emit significant nonthermal luminosity, that is, radiation produced by the interaction of accelerated particles and electromagnetic fields, or by the spinning fields themselves. This radiation was first detected at radio frequencies with the discovery of pulsars in 1968. Subsequently, notably with the launch of *COS-B* in 1975 and of the *Compton Gamma-Ray Observatory* in 1991, came the observation of gamma-ray pulsars. These are radio pulsars that emit a large flux of high-energy (100-MeV) gamma-ray photons. At the same time, a gamma-ray source was discovered that had all the markings of being connected with a radio pulsar but had no such object in its positional error box in the sky. *See* Gamma-ray astronomy; Radio astronomy; Satellite (astronomy).

The object, named Geminga, is indeed a rotating neutron star. It was the first unidentified gamma-ray source in the sky, and subsequently became the first isolated neutron star to be discovered through its x-ray and gamma-ray emission, without the help of radio astronomy. High-precision positional measurements using the *Hipparcos* satellite and the Hubble Space Telescope allowed, for the first time, the absolute astrometry of an object this faint. Through a delicate space-time correlation, this work has made it possible to count every single rotation of the neutron star (at the rate of about 4 per second) throughout a period of over 25 years. *See* Astrometry; X-ray astronomy.

Optical and ultraviolet observations, carried out from the ground and from space, have allowed the measurement of Geminga's annual parallax, defining its distance to be about 150 parsecs (450 light-years), and thus determining with accuracy the star's absolute energy output at each wavelength. Detailed spectral data have also shown evidence for a thin atmosphere (a few centimeters thick), the first such detection on a neutron star. In the optical domain, a proton cyclotron feature has been detected, which enabled the first direct measurement of the magnetic field of an isolated neutron star. *See* Parallax (astronomy); Particle accelerator.

Wide-band data have shown that both thermal and nonthermal processes are at work in this neutron star, which is approximately 350,000 years old. Such processes originate on its surface as well as in the extremely intense stellar magnetic field. *See* Neutron star; Pulsar. [G.F.Bi.]

Gemini The Twins, in astronomy, is a winter zodiacal constellation. Gemini is the third sign of the zodiac. It is conspicuous, containing first-, second-, and third-magnitude stars. These stars, α, β, γ, and μ, form a rough quadrilateral figure (see illustration). The constellation is pictured as the figures of the twin heroes Castor and Pollux, with the two brightest stars of the same names representing the heroes' heads. Pollux, slightly brighter than



Line pattern of the constellation Gemini. Grid lines represent coordinates of the sky. Apparent brightness, or magnitudes, of stars is shown by sizes of dots graded by appropriate numbers as indicated.

Castor, is a navigational star. The Sun is in this constellation at the time of the summer solstice. *See* Constellation. [C.-S.Y.]

Gemology The science of those minerals and other materials which possess sufficient beauty and durability to make them desirable as gemstones. It is concerned with the identification, grading, evaluation, fashioning, and other aspects of gemstones. *See* Gem. [R.T.L.]

Gene The basic unit in inheritance. There is no general agreement as to the exact usage of the term, since several criteria that have been used for its definition have been shown not to be equivalent.

The facts of mendelian inheritance indicate the presence of discrete hereditary units that replicate at each cell division, producing remarkably exact copies of themselves, and that in some highly specific way determine the characteristics of the individuals that bear them. The evidence also shows that each of these units may at times mutate to give a new equally stable unit (called an allele), which has more or less similar but not identical effects on the characters of its bearers. These hereditary units are the genes, and the criteria for the recognition that certain genes are alleles have been that they (1) arise from one another by a single mutation, (2) have similar effects on the characters of the organism, and (3) occupy the same locus in the chromosome. It has long been known that there were a few cases where these criteria did not give consistent results, but these were explained by special hypotheses in the individual cases. However, such cases have been found to be so numerous that they appear to be the rule rather than the exception. *See* Allele; Gene action; Mendelism; Mutation; Recombination (genetics).

The term gene, or cistron, may be used to indicate a unit of function. The term is used to designate an area in a chromosome made up of subunits present in an unbroken unit to give their characteristic effect. *See* Chromosome.

Every gene consists of a linear sequence of bases in a nucleic acid molecule. Genes are specified by the sequence of bases in DNA in prokaryotic, archaeal, and eukaryotic cells, and in DNA or ribonucleic acid (RNA) in prokaryotic or eukaryotic viruses. The ultimate expressions of gene function are the formation of structural and regulatory RNA molecules and proteins. These macromolecules carry out the biochemical reactions and provide the structural elements that make up cells. *See* Deoxyribonucleic acid (DNA); Nucleic acid; Ribonucleic acid (RNA); Virus.

One goal of molecular biology is to understand the function, expression, and regulation of a gene in terms of its DNA or RNA sequence. The genetic information in genes that encode proteins is first transcribed from one strand of DNA into a complementary messenger RNA (mRNA) molecule by the action of the RNA polymerase enzyme. Many kinds of eukaryotic and a limited number of prokaryotic mRNA molecules are further processed by splicing, which removes intervening sequences called introns. In some eukaryotic mRNA molecules, certain bases are also changed posttranscriptionally by a process called RNA editing. The genetic code in the resulting mRNA molecules is translated into proteins with specific amino acid sequences by the action of the translation apparatus, consisting of transfer RNA (tRNA) molecules, ribosomes, and many other proteins. The genetic code in an mRNA molecule is the correspondence of three contiguous (triplet) bases, called a codon, to the common amino acids and translation stop signals; the bases are adenine (A), uracil (U), guanine (G), and cytosine (C). There are 61 codons that specify the 20 common amino acids, and 3 codons that lead to translation stopping. *See* Genetic code; Intron. [A.H.St.]

In many cases, the genes that mediate a specific cellular or viral function can be isolated. The recombinant DNA methods used to isolate a gene vary widely depending on the experimental system, and genes from RNA genomes must be converted into a corresponding DNA molecule by biochemical manipulation using the enzyme reverse transcriptase. The isolation of the gene is referred to as cloning, and allows large quantities of DNA corresponding to a gene of interest to be isolated and manipulated.

After the gene is isolated, the sequence of the nucleotide bases can be determined. The goal of the large-scale Human Genome Project is to sequence all the genes of several model organisms and humans. The sequence of the region containing the gene can reveal numerous features. If a gene is thought to encode a protein molecule, the genetic code can be applied to the sequence of bases determined from the cloned DNA. The application of the genetic code is done automatically by computer programs, which can identify the sequence of contiguous amino acids of the protein molecule encoded by the gene. If the function of a gene is unknown, comparisons of its nucleic acid or predicted amino acid sequence with the contents of huge international databases can often identify genes or proteins with analogous or related functions. These databases contain all the known sequences from many prokaryotic, archaeal, and eukaryotic organisms. Putative regulatory and transcript-processing sites can also be identified by computer. These putative sites, called consensus sequences, have been shown to play roles in the regulation and expression of groups of prokaryotic, archaeal, or eukaryotic genes. However, computer predictions are just a guide and not a substitute for analyzing expression and regulation by direct experimentation. *See* Genetic engineering; Human Genome Project; Molecular biology. [M.E.Wi.]

Gene action The functioning of genes (hereditary units) in determining the structural and functional characteristics of an individual, that is, its phenotype. Gene action is studied by two somewhat different, but complementary, approaches: (1) the analysis of changes which occur in the phenotype when a gene mutates, or is changed in dosage, or in position relative to other genes; this is frequently called the study of phenogenetics; and (2) the more direct approach, which attempts to determine the actual means by which genes exert their control over metabolism and the processes of development in multicellular, differentiated organisms. The more direct approach is best described as study of primary gene action, but includes study of the interaction of primary or secondary products of gene action. *See* GENE.

All genes, with the exception of those in ribonucleic acid (RNA) viruses, are constituted of deoxyribonucleic acid (DNA), and the primary action of the great majority of them is to initiate a series of events leading directly or indirectly to the determination of the amino acid sequences of specific polypeptides. *See* DEOXYRIBONUCLEIC ACID (DNA); PROTEIN; VIRUS.

The base sequence of one of the chains of the DNA double helix constituting the gene is transcribed into an RNA molecule with a chain of complementary bases in the presence of RNA polymerases. This RNA molecule may then frequently become a messenger RNA (mRNA) by some alteration of the original transcript, or it may become a transfer RNA (tRNA) or a ribosomal RNA (rRNA). *See* RIBONUCLEIC ACID (RNA).

The primary action of a gene is transcription, but the expression of this action lies in the next step—translation—for many genes. The mRNAs are translated into polypeptides in what may be considered the culmination of the primary process of gene action. The proteins so formed may act as enzymes, structural units, regulators of various metabolic processes by interacting with other proteins and genes, and essential agents in guiding and directing the processes of development.

The actual effects of gene action are recognized for the most part by noting the effects of gene mutation on the phenotype, but in complex multicellular organisms the final phenotypic effect observed superficially may be far removed from the initial action of the gene itself, for example, a change in shape of the ear or a change in eye color. Studies of a wide variety of different genetic strains of organisms ranging over phages and bacteria, plants and animals, including humans, have shown that the mutations of some genes are reflected in the qualitative alteration of the proteins they code for. These kinds of genes are called structural genes. Frequently the protein changes resulting from their mutation are simple substitutions of a single amino acid in the chain by another. The cause for this substitution can be traced back to a change in the genetic code. If a codon in the DNA of a gene coding for a specific polypeptide is altered by a base, for example, AAA → CAA, this mutation will result in the substitution of valine for the phenylalanine originally present at the specific site in the polypeptide chain coded for by this codon. A protein so changed, even though it may involve only one amino acid residue out of more than 100, may have no noticeable effects on the phenotype, or it may have drastic effects. *See* GENETIC CODE.

If there is no noticeable effect of mutation on a protein's action in forming the phenotype, the mutant allele may be called a neutral allele. However, even a single amino acid substitution may cause a protein to be completely inactive and, if the protein is an enzyme, create a genetic metabolic block. Over 100 different inherited blocks are known in humans, including phenylketonuria. The mutant protein may also be active, but its activity is altered so that it is less active than the wild type, or more active, or only active at certain temperatures or pH, or may be inhibited by substances not inhibitory to the wild-type enzyme. The range of possible effects is considerable, and by no means are all recognized and cataloged. *See* PHENYLKETONURIA.

Some genes code for RNA that is not translated. The obvious ones are those that code for tRNA and rRNA, but other RNAs are also transcribed that do not appear to be transcribed and may have a role in the regulation of the activity of other genes. Finally, some genes code for proteins that act as regulators of the processes of metabolism and development. As yet, little is known about this class of genes in the eukaryotes, but they have been studied intensively in bacteria and phages. Mutations of genes coding for regulators may have profound effects on the course of development and, if they do not cause early lethality, they may result in the birth of a malformed individual. *See* BACTERIAL GENETICS; OPERON.

Under certain conditions, an increase in the number of times a particular gene is present has a direct quantitative effect on one or more aspects of the phenotype. This effect is considered to be a manifestation of quantitative gene activity or gene dosage. It means that the gene does something, and that the higher the dose with which it is present, the greater the physiological or chemical end result. The best examples of this are found in the genetics of polyploid plants. In these plants, it is possible to increase the dosage of a particular allele from zero to four or more, when this is done, for example, with certain genes which control the production of the flower pigments of *Dahlia*, there is a demonstrable increase in the amount of pigment in the petals. *See* POLYPLOIDY.

An increase in the dose of an active allele of a gene does not always cause an increase in the manifestation of a particular aspect of the phenotype. It may have quite the opposite effect, and cause a decrease. Plants and animals are also subject to aneuploidy, in which not all of the chromosomes of the genome are increased in number proportionately. Instead, only one of the chromosomes of the diploid set may be increased or decreased in number. In humans these conditions usually lead to the early death of the embryo. If the fetus reaches term and is born, it is always abnormal. A relatively common occurrence in humans is trisomy-21, which leads to Down syndrome. *See* DOWN SYNDROME.

Some heterozygous combinations of mutant alleles do not produce the phenotype expected from the phenotypes of the homozygotes. This is defined as a manifestation of allelic interaction. It is in contrast to those situations in which one allele is dominant over the other, so that the phenotype of the heterozygote is very similar or identical to that of the homozygous dominant. Also, it is different from those situations in which the two alleles show an additive effect, and the phenotype of the heterozygote is intermediate between those expected from the homozygotes. Diploid organisms heterozygous for two mutant alleles will produce two polypeptide species, one for each allele. The two proteins may interact and form hybrid multimers, which may be more or less active than the homomultimers formed by the polypeptides of each of the two genes alone. *See* DOMINANCE.

The final phenotype of an organism is the resultant of the action of all the active genes in its cell or cells. These genes may act independently in producing their respective primary products, but the primary products, and the products of their activity, that is, enzymes and other macromolecules, interact at the level of extragenic metabolism to give the final phenotype. Thus, there is really no one gene determining the shape of an organ, or even the production of a certain pigment. These end products are determined by many genes acting together through their respective immediate and then succeeding interrelated products. The manifestation of these interactions, as determined initially by the results from breeding experiments and in a few cases from biochemical analysis, is called gene interaction. This term does not necessarily imply that the genes themselves interact. In general, the term is applied to apparent interactions between genes. Examples include: complementary genes, in which nonallelic genes are so directly involved in the formation of the same end product, or phenotype, that the mutation of any one of them to an inactive state will result in no end product or type effect; epistasis, in which one gene masks the effects of other genes that may be present; and suppressor genes, which cause a wild-type or normal phenotype despite the presence of nonallelic mutant genes.

The environment must be considered in any analysis of gene action, if it is desired to arrive at an understanding of how genes act toward the production of the phenotype. Practically, this is best done by keeping the environment as constant as possible while making studies of gene action. However, much also can be learned by varying the environmental conditions and keeping the genotype as constant as possible. *See* GENETICS.

The environment of genes is a complex one. For convenience, two areas can be defined: (1) that immediately around the genes, the intracellular environment of the rest of the cell; and (2) the extracellular and extraorganismal environment. The intracellular environment can be changed by the mutation of other genes, which may then modify the action of a gene under study. Gene interaction is thus seen to be in part an aspect of the study of the internal environment of the cell. Extracellular environmental factors, such as light and heat, may also influence the action of genes greatly.

Changes in phenotype which occur against a constant genetic background are in reality responses to the environment by the extragenic part of the living system. The genes themselves are not changed, as can be readily demonstrated by changing the environment back to the original condition, or by breeding the individual and showing that the offspring inherit the original parental genotype. *See* DEVELOPMENTAL GENETICS; GENE. [R.P.W.]

Gene amplification The process by which a cell specifically increases the copy number of a particular gene to a greater extent than it increases the copy number of genes composing the remainder of the genome (all the genes which make up the genetic machinery of an organism). It is therefore distinguished from duplication, which is a precise doubling of the genome preparatory to cell division, and endoreduplication, which leads to endopolyploidy.

Gene amplification results from the repeated replication of the deoxyribonucleic acid (DNA) in a limited portion of the genome, in the absence of or to a much greater extent than replication of DNA composing the remainder of the genome. Thus is formed a cell in which the genes composing a limited portion of the genome are present in relatively high copy number, while the genes composing the remainder of the genome are present in approximately normal copy number. *See* DEOXYRIBONUCLEIC ACID (DNA).

Since gene amplification increases the copy number of a specific region of the genome without altering the copy number of genes composing the remainder of the genome, it would appear to offer an alternative method for developmental control of gene expression. By increasing the number of copies of a particular gene, the number of gene copies available for transcription could thereby be increased.

In a number of instances of gene amplification, the amplification phenomenon appears to be developmentally regulated, and the amplified copies of the gene are subsequently lost from the cell. Studies on cells in culture have demonstrated “amplification” of genes involved in resistance to specific drugs. *See* GENE; GENE ACTION. [M.D.C.]

General aviation All aircraft activity not associated with major airlines or the military. Among all classifications of aviation in the United States, general aviation consists of the largest number of aircraft and pilots and accounts for the largest number of flying hours.

Of the more than 220,000 active general aviation aircraft registered by the Federal Aviation Administration (FAA), almost 80% are single-engine vehicles powered by intermittent-combustion engines. Although many of these aircraft carry fewer than three passengers at speeds below 150 mi/h (240 km/h), most can carry four to six passengers at speeds up to 200 mi/h (320 km/h). Approximately 11% of the general aviation fleet are twin-engine aircraft, powered by intermittent-combustion engines and capable of cruising at speeds of 180–250 mi/h (290–400 km/h) with six to ten passengers. *See* AIRPLANE; RECIPROCATING AIRCRAFT ENGINE.

In addition, approximately 6000 multiengine aircraft are powered by turboprop engines and 4500 by turbojet or turbofan power plants. Jet aircraft employed within general aviation usually carry from five to fifteen passengers, depending on the model, with a crew of two pilots. Turboprop aircraft may also be flown by two pilots, although this is not required for all models; passenger capacity typically ranges from six to nine. *See* JET PROPULSION; TURBOFAN; TURBOJET; TURBOPROP.

Rotorcraft number about 7000. There are also approximately 7000 gliders in the general aviation fleet. *See* GLIDER; HELICOPTER.

Business travel accounts for more flying hours than any other branch of general aviation. Approximately 70% of all general aviation is associated with some commercial activity, such as business travel, construction, aerial application of fertilizer and pesticides, or flight instruction.

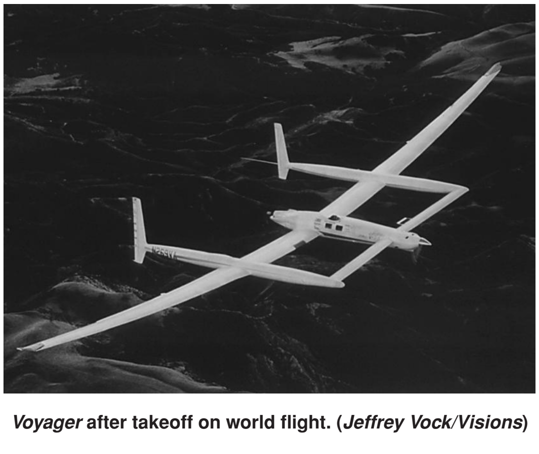
Because of the characteristics of hub-and-spoke systems, business people have increased their demand for general aviation, which also offers more control over travel arrangements. With a small single-engine aircraft accommodating four or five passengers, a business person with a private license and perhaps an instrument rating can escape many of the limitations of airline schedules based on the hub-and-spoke system.

Commuter and regional airlines supplement the hub-and-spoke scheduling typical of commercial air travel since deregulation. Small airlines offer the only scheduled service in some communities, and often cooperate with major airlines by sharing code designations used in computer reservation systems and by travel agencies. Air taxis provide on-demand air transportation for hire in a wide variety of aircraft. General aviation is widely used in agriculture; aerial seeding, fertilizing, and spraying are efficient and widely used by farmers. Flight instruction represents about 15% of all general aviation activity and is the principal source of professional pilots. *See* AGRICULTURAL AIRCRAFT.

About 30% of general aviation involves the personal use of small aircraft for transportation and leisure purposes as well as some of the proficiency flying required by the Federal Aviation Administration of pilots who wish to maintain their licenses. Most personal flying employs small single-engine craft.

General aviation has often been the testing ground for innovation. *Voyager* (see illustration) was designed and constructed to circumnavigate the globe by air without refueling, a feat that had never been accomplished. *Voyager* carried nearly 9000 lb (4000 kg) of fuel in a structure that was built of advanced composite materials and weighed less than 1000 lb (450 kg) when empty. *Voyager* took off from Edwards Air Force Base, California, on December 14, 1986, and landed there 9 days later without refueling, the crew having completed their global circumnavigation without mishap or physical injury.

Modern attempts to achieve human-powered flight were stimulated in 1959 when H. Kremer posted a prize for the first British aircraft to fly solely by means of human power, without the aid of power storage or buoyancy, around a figure-eight course. (The prize was later opened to all nationalities.) In 1977, the Kremer prize was won by the *Gossamer Condor* aircraft, which was designed by P. D. MacCready, Jr., and flown by B. Allen. The team



***Voyager* after takeoff on world flight. (*Jeffrey Vock/Visions*)**

of MacCready and Allen subsequently accomplished many significant events in human-powered flight, including the 1979 flight of the *Gossamer Albatross* across the English Channel. [J.W.O.]

Generator A machine in which mechanical energy is converted to electrical energy. Generators are made in a wide range of sizes, from very small machines with a few watts of power output to very large central-station generators providing 1000 MW or more. All electrical generators utilize a magnetic field to produce an output voltage which drives the current to the load. The electric current and magnetic field also interact to produce a mechanical torque opposing the motion supplied by the prime mover. The mechanical power input is equal to the electric power output plus the electrical and mechanical losses.

Generators can be divided into two groups, alternating current (ac) and direct current (dc). Each group can be subdivided into machines that use permanent magnets to produce the magnetic field (PM machines) and those using field windings. A further subdivision relates to the type of prime mover and the generator speed. Large generators are often driven by steam or hydraulic turbines, by diesel engines, and sometimes by electric motors. Generator speeds vary from several thousand rotations per minute for steam turbines to very low speeds for hydraulic or wind turbines. *See* Diesel engine; Hydraulic turbine; Motor; Prime mover; Steam turbine; Wind power.

The field structure of a generator establishes the magnetic flux needed for energy conversion. In small generators, permanent magnets can be used to provide the required magnetic field. In large machines, dc field windings are more economical and permit changes in the magnetic flux and output voltage. This allows control of the generated voltage, which is important in many applications. In dc generators the field structure must be stationary to permit a rotating mounting for the commutator and armature windings. However, since the field windings require low voltage and power and have only two lead wires, it is convenient to place the field on the rotating member in ac generators. *See* Electric power generation; Electric rotating machinery; Windings in electric machinery. [D.W.N.]

Genetic algorithms Search procedures based on the mechanics of natural selection and genetics. Such procedures are known also as evolution strategies, evolutionary programming, genetic programming, and evolutionary computation. Genetic algorithms are increasingly solving difficult search, optimization, and machine-learning problems that have previously resisted automated solution. They can solve hard problems quickly and reliably, are easy to interface to existing simulations and models, are extensible, and are easy to hybridize.

Motivation. Just as natural selection and genetics have filled a variety of niches by creating genotypes (sets of chromosomes) that result in well-adapted phenotypes (or organisms), so too can genetic algorithms solve many artificial problems by creating strings (artificial chromosomes) that result in better solutions. Users ultimately turn to genetic algorithms for robustness, that is, for algorithms that are broadly applicable, relatively quick, and sufficiently reliable. This emphasis on robustness contrasts starkly with the philosophy of operations research, where new algorithms must be tailored to specific problems. The need to invent a new method for each new problem class is daunting, and users look for methods that can solve complex problems without this requirement. *See* Genetics; Operations research; Organic evolution.

Mechanics. For concrete exposition, the discussion is limited to a simple genetic algorithm that processes a finite population of fixed-length, binary strings. A simple genetic algorithm consists of three operators: selection, crossover, and mutation.

Selection is the survival of the fittest within the genetic algorithm. The key notion is to give preference to better individuals. Of course, for selection to function, there must be some way of determining what is good. This evaluation can come from a formal objective function, or it can come from the subjective judgment of a human observer or critic.

If genetic algorithms were to do nothing but selection, the trajectory of populations could contain nothing but changing proportions of the strings in the original population. To do something more sensible, the algorithm needs to explore different structures. A primary exploration operator used in many genetic algorithms is crossover. Simple, one-point crossover proceeds in three steps: (1) two individuals are chosen from the population by using the selection operator, and these two structures are considered to be mated; (2) a cross site along the string length is chosen uniformly at random; and (3) position values are exchanged between the two strings following the cross site.

In a binary-coded genetic algorithm, mutation is the occasional (low probability) alteration of a bit position, and with other codes a variety of diversity-generating operators may be used. When used together with selection and crossover, mutation acts both as an insurance policy against losing needed diversity and as a hill-climbing algorithm. [D.E.Go.]

Genetic code The rules by which the base sequences of deoxyribonucleic acid (DNA) are translated into the amino acid sequences of proteins. Each sequence of DNA that codes for a protein is transcribed or copied into messenger ribonucleic acid (mRNA). Following the rules of the code, discrete elements in the mRNA, known as codons, specify each of the 20 different amino acids that are the constituents of proteins. During translation, another class of RNAs, called transfer RNAs (tRNAs), are coupled to amino acids, bind to the mRNA, and, in a step-by-step fashion provide the amino acids that are linked together in the order called for by the mRNA sequence. The specific attachment of each amino acid to the appropriate tRNA, and the precise pairing of tRNAs via their anticodons to the correct codons in the mRNA, form the basis of the genetic code. *See* Deoxyribonucleic acid (DNA); Protein; Ribonucleic acid (RNA).

The genetic information in DNA is found in the sequence or order of four bases that are linked together to form each strand of the two-stranded DNA molecule. The bases of DNA are adenine, guanine, thymine, and cytosine, which are abbreviated as A, G, T, and C. Chemically, A and G are purines, and C and T are pyrimidines. The two strands of DNA are wound about each other in a double helix that looks like a twisted ladder. Each rung of the ladder is formed by two bases, one from each strand, that pair with each other by means of hydrogen bonds. For a good fit, a pyrimidine must pair with a purine; in DNA, A bonds with T, and G bonds with C. *See* Purine; Pyrimidine.

Ribonucleic acids such as mRNA or tRNA also comprise four bases, except that in RNA the pyrimidine uracil (U) replaces thymine. During transcription a single-stranded mRNA copy of one strand of the DNA is made.

If two bases at a time are grouped together, then only 4 × 4 or 16 different combinations are possible, a number that is insufficient to code for all 20 amino acids that are found in proteins. However, if the four bases are grouped together in threes, then there are 4 × 4 × 4 or 64 different combinations. Read sequentially without overlapping, those groups of three bases constitute a codon, the unit that codes for a single amino acid.

The 64 codons can be divided into 16 families of four (see illustration), in which each codon begins with the same two bases. With the number of codons exceeding the number of amino acids, several codons can code for the same amino acid. Thus, the code is degenerate. In eight instances, all four codons in a family specify the same amino acid. In the remaining families, the two codons that end with the pyrimidines U and C often specify one amino acid, whereas the two codons that end with the purines A and G specify another. Furthermore, three of the codons, UAA, UAG, and UGA, do not code for any amino acid but instead signal the end of the protein chain.

On the ribosome, the nucleic acid code of an mRNA is converted into an amino acid sequence with the aid of tRNAs. These

	U	C	A	G
U	UUU UUC Phe UUA UUG Leu	UCU UCC UCA UCG Ser	UAU UAC Tyr UAA UAG *Stop*	UGU UGC Cys UGA — *Stop* UGG — Trp
C	CUU CUC CUA CUG Leu	CCU CCC CCA CCG Pro	CAU CAC His CAA CAG Gln	CGU CGC CGA CGG Arg
A	AUU AUC AUA Ile AUG — Met	ACU ACC ACA ACG Thr	AAU AAC Asn AAA AAG Lys	AGU AGC Ser AGA AGG Arg
G	GUU GUC GUA GUG Val	GCU GCC GCA GCG Ala	GAU GAC Asp GAA GAG Glu	GGU GGC GGA GGG Gly

Universal (standard) genetic code. Each of the 64 codons found in mRNA specifies an amino acid (indicated by the common three-letter abbreviation) or the end of the protein chain (*stop*). The amino acids are phenylalanine (Phe), leucine (Leu), isoleucine (Ile), methionine (Met), valine (Val), serine (Ser), proline (Pro), threonine (Thr), alanine (Ala), tyrosine (Tyr), histidine (His), glutamine (Gln), asparagine (Asn), lysine (Lys), aspartic acid (Asp), glutamic acid (Glu), cysteine (Cys), tryptophan (Trp), arginine (Arg), and glycine (Gly).

RNAs are relatively small nucleic acids, varying from 75 to 93 bases in length, that are folded in three dimensions to form an L-shaped molecule to which an amino acid can be attached. At the other end of the tRNA molecule, three bases are free to pair with a codon in the mRNA. These three bases of a tRNA constitute the anticodon. Each amino acid has one or more tRNAs, and because of the degeneracy of the code, many of the tRNAs for a specific amino acid have different anticodon sequences. However, the tRNAs for one amino acid are capable of pairing their anticodons only with the codon or codons in the mRNA that specify that amino acid. The tRNAs act as interpreters of the code, providing the correct amino acid in response to each codon by virtue of precise codon-anticodon pairing. The tRNAs pair with the codons and sequentially insert their amino acids in the exact order specified by the sequence of codons in the mRNA. *See* RIBOSOMES.

The rules of the genetic code are virtually the same for all organisms, but there are some interesting exceptions. In the microorganism *Mycoplasma capricolum*, UGA is not a stop codon; instead it codes for tryptophan. This alteration in the code is also found in the mitochondria of some organisms. In addition to changes in the meanings of codons, a modified system for reading codons that requires fewer tRNAs is found in mitochondria. *See* GENE; GENE ACTION; GENETICS. [P.Sc.; H.E.We.]

Genetic engineering The artificial recombination of nucleic acid molecules in the test tube, their insertion into a virus, bacterial plasmid, or other vector system, and the subsequent incorporation of the chimeric molecules into a host organism in which they are capable of continued propagation. The construction of such molecules has also been termed gene manipulation because it usually involves the production of novel genetic combinations by biochemical means. *See* NUCLEIC ACID.

Genetic engineering provides the ability to propagate and grow in bulk a line of genetically identical organisms, all containing the same artificially recombinant molecule. Any genetic segment as well as the gene product encoded by it can therefore potentially be amplified. For these reasons the process has also been termed molecular cloning or gene cloning. *See* GENE.

Basic techniques. The central techniques of such gene manipulation involve (1) the isolation of a specific deoxyribonucleic acid (DNA) molecule or molecules to be replicated (the passenger DNA); (2) the joining of this DNA with a DNA vector (also known as a vehicle or a replicon) capable of autonomous replication in a living cell after foreign DNA has been inserted into it; and (3) the transfer, via transformation or transfection, of the recombinant molecule into a suitable host.

Isolation of passenger DNA. Passenger DNA may be isolated in a number of ways; the most common of these involves DNA restriction. Restriction endonucleases make possible the cleavage of high-molecular-weight DNA. Although three different classes of these enzymes have been described, only type II restriction endonucleases have been used extensively in the manipulation of DNA. Type II restriction endonucleases are DNAases that recognize specific short nucleotide sequences (usually 4 to 6 base pairs in length), and then cleave both strands of the DNA duplex, generating discrete DNA fragments of defined length and sequence. A number of restriction enzymes make staggered cuts in the two DNA strands, generating single-stranded termini. *See* RESTRICTION ENZYME.

The various fragments generated when a specific DNA is cut by a restriction enzyme can be easily resolved as bands of distinct molecular weights by agarose gel electrophoresis. Specific sequences of these bands can be identified by a technique known as Southern blotting. In this technique, DNA restriction fragments resolved on a gel are denatured and blotted onto a nitrocellulose filter. The filter is incubated together with a radioactively labeled DNA or RNA probe specific for the gene under study. The labeled probe hybridizes to its complement in the restricted DNA, and the regions of hybridization are detected autoradiographically. Fragments of interest can then be eluted out of these gels and used for cloning. Purification of particular DNA segments prior to cloning reduces the number of recombinants that must later be screened. *See* ELECTROPHORESIS.

Another method that has been used to generate small DNA fragments is mechanical shearing. Intense sonification of high-molecular-weight DNA with ultrasound, or high-speed stirring in a blender, can both be used to produce DNA fragments of a certain size range. Shearing results in random breakage of DNA, producing termini consisting of short, single-stranded regions. Other sources include DNA complementary to poly(A) RNA, or cDNA, which is synthesized in the test tube, and short oligonucleotides that are synthesized chemically. *See* OLIGONUCLEOTIDE.

Joining DNA molecules. Once the proper DNA fragments have been obtained, they must be joined. When cleavage with a restriction endonuclease creates cohesive ends, these can be annealed with a similarly cleaved DNA from another source, including a vector molecule. When such molecules associate, the joint has nicks a few base pairs apart in opposite strands. The enzyme DNA ligase can then repair these nicks to form an intact, duplex recombinant molecule, which can be used for transformation and the subsequent selection of cells containing the recombinant molecule. Cohesive ends can also be created by the addition of synthetic DNA linkers to blunt-ended DNA molecules.

Another method for joining DNA molecules involves the addition of homopolymer extensions to different DNA populations followed by an annealing of complementary homopolymer sequences. For example, short nucleotide sequences of pure adenine can be added to the 3′ ends of one population of DNA molecules and short thymine blocks to the 3′ ends of another population. The two types of molecules can then anneal to form mixed dimeric circles that can be used directly for transformation.

The enzyme T4 DNA ligase carries out the intermolecular joining of DNA substrates at completely base-paired ends; such blunt ends can be produced by cleavage with a restriction enzyme or by mechanical shearing followed by enzyme treatment.

Transformation. The desired DNA sequence, once attached to a DNA vector, must be transferred to a suitable host. Transformation is defined as the introduction of foreign DNA into a recipient cell. Transformation of a cell with DNA from a virus is usually referred to as transfection.

Transformation in any organism involves (1) a method that allows the introduction of DNA into the cell and (2) the stable integration of DNA into a chromosome, or maintenance of the DNA as a self-replicating entity. *See* TRANSFORMATION (BACTERIA).

Escherichia coli is usually the host of choice for cloning experiments, and transformation of *E. coli* is an essential step in these experiments. *Escherichia coli* treated with calcium chloride are able to take up DNA from bacteriophage lambda as well as plasmid DNA. Calcium chloride is thought to effect some structural alterations in the bacterial cell wall. An efficient method for transformation in *Bacillus* species involves polyethylene glycol-induced DNA uptake in bacterial protoplasts and subsequent regeneration of the bacterial cell wall. Actinomycetes can be similarly transformed. Transformation can also be achieved by first entrapping the DNA with liposomes followed by their fusion with the host cell membrane. Similar transformation methods have been developed for lower eukaryotes such as the yeast *Saccharomyces cerevisiae* and the filamentous fungus *Neurospora crassa*. *See* LIPOSOMES.

Several methods are available for the transfer of DNA into cells of higher eukaryotes. Specific genes or entire viral genomes can be introduced into cultured mammalian cells in the form of a coprecipitate with calcium phosphate. DNA complexed with calcium phosphate is readily taken up and expressed by mammalian cells. DNA complexed with diethylamino-ethyl-dextran (DEAE-dextran) or DNA trapped in liposomes or erythrocyte ghosts may also be used in mammalian transformation. Alternatively, bacterial protoplasts containing plasmids can be fused to intact animal cells with the aid of chemical agents such as polyethylene glycol (PEG). Finally, DNA can be directly introduced into cells by microinjection. The efficiency of transfer by each of these methods is quite variable.

Introduction of DNA sequences by insertion into the transforming (T)-DNA region of the tumor-inducing (Ti) plasmid of *Agrobacterium tumefaciens* is a method of introducing DNA into plant cells and ensuring its integration. Because of the limitations of the host range of *A. tumefaciens*, however, alternative transformation systems are being developed for gene transfer in plants. They include the use of liposomes, as well as induction of DNA uptake in plant protoplasts. Foreign DNA has been introduced into plant cells by a technique called electroporation. This technique involves the use of electric pulses to make plant plasma membranes permeable to plasmid DNA molecules. Plasmid DNA taken up in this way has been shown to be stably inherited and expressed.

Cloning vectors. There is a large variety of potential vectors for cloned genes. The vectors differ in different classes of organisms.

Prokaryotes and lower eukaryotes. Three types of vectors have been used in these organisms: plasmids, bacteriophages, and cosmids. Plasmids are extrachromosomal DNA sequences that are stably inherited. *Escherichia coli* and its plasmids constitute the most versatile type of host-vector system known for DNA cloning. Several natural plasmids, such as ColE1, have been used as cloning vehicles in *E. coli*. In addition, a variety of derivatives of natural plasmids have been constructed by combining DNA segments and desirable qualities of older cloning vehicles. The most versatile and widely used of these plasmids is pBR322. Transformation in yeast has been demonstrated using a number of plasmids, including vectors derived from the naturally occurring 2μ plasmid of yeast.

Bacteriophage lambda is a virus of *E. coli*. Several lambda-derived vectors have been developed for cloning in *E. coli*, and for the isolation of particular genes from eukaryotic genomes. These lambda derivatives have several advantages over plasmids: (1) Thousands of recombinant phage plaques can easily be screened for a particular DNA sequence on a single petri dish by molecular hybridization. (2) Packaging of recombinant DNA in laboratory cultures provides a very efficient means of DNA uptake by the bacteria. (3) Thousands of independently packaged recombinant phages can be easily replicated and stored in a single solution as a "library" of genomic sequences. *See* BACTERIOPHAGE.

Plasmids have also been constructed that contain the phage *cos* DNA site, required for packaging into the phage particles, and ColE1 DNA segments, required for plasmid replication. These plasmids have been termed cosmids. The recombinant cosmid DNA is injected into a host and circularizes like phage DNA but replicates as a plasmid. Transformed cells are selected on the basis of a vector drug resistance marker.

Animal cells. In contrast to the wide variety of plasmid and phage vectors available for cloning in prokaryotic cells, relatively few vectors are available for introducing foreign genes into animal cells. The most commonly used are derived from simian virus 40 (SV40). Normal SV40 cannot be used as a vector, since there is a physical limit to the amount of DNA that can be packaged into the virus capsid, and the addition of foreign DNA would generate a DNA molecule too large to be packaged. However, SV40 mutants lacking portions of the genome can be propagated in mixed infections in which a "helper" virus supplies the missing function. *See* ADENO-SV40 HYBRID VIRUS.

Plant cells. Two systems for the delivery and integration of foreign genes into the plant genome are the Ti plasmid of the soil bacterium *Agrobacterium* and the DNA plant virion cauliflower mosaic virus. The Ti plasmid is a natural gene transfer vector carried by *A. tumefaciens*, a pathogenic bacterium that causes crown gall tumor formation in dicotyledonous plants. A T-DNA segment present in the Ti plasmid becomes stably integrated into the plant cell genome during infection. This property of the Ti plasmid has been exploited to show that DNA segments inserted in the T-DNA region can be cotransferred to plant DNA. *See* CROWN GALL.

Applications. Recombinant DNA technology has permitted the isolation and detailed structural analysis of a large number of prokaryotic and eukaryotic genes. This contribution is especially significant in the eukaryotes because of their large genomes. The methods outlined above provide a means of fractionating and isolating individual genes, since each clone contains a single sequence or a few DNA sequences from a very large genome. Isolation of a particular sequence of interest has been facilitated by the ability to generate a large number of clones and to screen them with the appropriate "probe" (radioactively labeled RNA or DNA) molecules.

Genetic engineering techniques provide pure DNAs in amounts sufficient for mapping, sequencing, and direct structural analyses. Furthermore, gene structure-function relationships can be studied by reintroducing the cloned gene into a eukaryotic nucleus and assaying for transcriptional and translational activities. The DNA sequences can be altered by mutagenesis before their reintroduction in order to define precise functional regions.

Genetic engineering methodology has provided means for the large-scale production of polypeptides and proteins. It is now possible to produce a wide variety of foreign proteins in *E. coli*. These range from enzymes useful in molecular biology to a vast range of polypeptides with potential human therapeutic applications, such as insulin, interferon, growth hormone, immunoglobins, and enzymes involved in the dynamics of blood coagulation. *See* BIOTECHNOLOGY.

Finally, experiments showing the successful transfer and expression of foreign DNA in plant cells using the Ti plasmid, as well as the demonstration that whole plants can be regenerated from cells containing mutated regions of T-DNA, indicate that the Ti plasmid system may be an important tool in the genetic engineering of plants. Such a system will help in the identification and characterization of plant genes as well as provide basic knowledge about gene organization and regulation in higher plants. Once genes useful for crop improvement have been identified, cloned, and stably inserted into the plant genome, it will be possible to engineer plants to be resistant to environmental stress, to pests, and to pathogens. *See* BREEDING (PLANT); GENE; GENE ACTION; SOMATIC CELL GENETICS. [P.K.M.]

Genetic homeostasis The tendency of mendelian populations to maintain a constant genetic composition in the face of external pressure. When subjected to such pressures as artificial selection (usually for some quantitative trait) or temporary environmental changes, genetic homeostatic mechanisms tend to restore to equilibrium gene frequencies that may have shifted from mean optimal values. *See* MENDELISM; POPULATION GENETICS.

The mechanisms responsible for genetic homeostasis are varied. The two most commonly invoked, which are also responsible for maintenance of genetic polymorphisms, are frequency-dependent selection and heterozygote advantage. Under the first, the selective value of a gene depends on its frequency in the gene pool with a loss of selective advantage by an allele which was rare and has become common. Under the second, when either single alleles or blocks of linked genes are involved, the relative fitness of homozygotes is lower than that of heterozygotes. *See* ALLELE; POLYMORPHISM (GENETICS). [I.M.L.]

Genetics The science of biological inheritance, that is, the causes of the resemblances and differences among related individuals.

Genetics occupies a central position in biology, for essentially the same principles apply to all animals and plants, and understanding of inheritance is basic for the study of evolution and for the improvement of cultivated plants and domestic animals. It has also been found that genetics has much to contribute to the study of embryology, biochemistry, pathology, anthropology, and other subjects. *See* BIOCHEMISTRY; EMBRYOLOGY; PATHOLOGY; PHYSICAL ANTHROPOLOGY.

Genetics may also be defined as the science that deals with the nature and behavior of the genes, the fundamental hereditary units. From this point of view, evolution is seen as the study of changes in the gene composition of populations, whereas embryology is the study of the effects of the genes on the development of the organism. *See* GENE ACTION; POPULATION GENETICS. [A.H.St.]

The field of molecular genetics describes the basis of inheritance at the molecular level. It focuses on two general questions: how do genes specify the structure and function of organisms, and how are genes replicated and transmitted to successive generations? Both questions have been answered. Genes specify organismal structure and function according to a process described by the central dogma of molecular biology: DNA is made into messenger ribonucleic acid (mRNA), which specifies the structure of a protein; the mRNA molecule then serves as a template for protein synthesis, which is carried out by complex machinery that comprises a particle called a ribosome and special adapter RNA molecules called transfer RNA. *See* DEOXYRIBONUCLEIC ACID (DNA); RIBONUCLEIC ACID (RNA); RIBOSOMES.

The structure of DNA provides a simple mechanism for genes to be faithfully reproduced: the specific interaction between the nucleotides means that each strand of the double helix carries the information for producing the other strand. *See* GENETIC CODE; GENETIC ENGINEERING; MOLECULAR BIOLOGY; MUTATION. [M.J.]

Gentianales An order of flowering plants (angiosperms) in the euasterid I group of the asterid eudicotyledons. The order consists of five families and approximately 17,500 species. The order is characterized by opposite leaves, frequent occurrence of alkaloids, and the presence of internal phloem in the wood (not in Rubiaceae).

Apocynaceae (including Asclepiadaceae), approximately 5000 species, are mostly tropical and subtropical and have a well-developed latex system, superior ovary, thickened and apically modified style, and carpels that are usually united only by the common style or stigma. Rubiaceae, approximately 11,000 species, are cosmopolitan, but particularly important in the tropics. They have stipulate leaves and an inferior ovary. The widespread occurrence of alkaloids makes the family economically significant; the major products are coffee (*Coffea*) and the antimalarial drug quinine (*Cinchona*). Gentianaceae, approximately 1200 species, are principally temperate and subtropical. They often contain bitter iridoid compounds, and some are used medicinally or in bitter alcoholic beverages (such as *Gentiana*, gentians). The remaining two families are relatively small but contain some genera of economic importance. *Strychnos* (Loganiaceae) is the source of strychnine and the arrow poison curare, and Gelsemiaceae include the ornamental *Gelsemium* (allspice jasmine). *See* ASTERIDAE; MAGNOLIOPSIDA; PLANT KINGDOM; RAUWOLFIA; STROPHANTHUS; STRYCHNOS. [M.W.C.]

Geochemical prospecting The use of chemical properties of naturally occurring substances (including rocks, glacial debris, soils, stream sediments, waters, vegetation, and air) as aids in a search for economic deposits of metallic minerals or hydrocarbons. In exploration programs, geochemical techniques are generally integrated with geological and geophysical surveys. *See* GEOCHEMISTRY; GEOPHYSICAL EXPLORATION.

General principles. Mineral deposits represent anomalous concentrations of specific elements, usually within a relatively confined volume of the Earth's crust. Most mineral deposits include a central zone, or core, in which the valuable elements or minerals are concentrated, often in percentage quantities, to a degree sufficient to permit economic exploitation. The valuable elements surrounding this core generally decrease in concentration until they reach levels, measured in parts per million (ppm) or parts per billion (ppb), which appreciably exceed the normal background level of the enclosing rocks. These zones or halos afford means by which mineral deposits can be detected and traced; they are the geochemical anomalies being sought by all geochemical prospectors.

The zone surrounding the core deposit is known as a primary halo or anomaly, and it represents the distribution patterns of elements which formed as a result of primary dispersion. Primary dispersion halos vary greatly in size and shape as a result of the numerous physical and chemical variables that affect fluid movements in rocks. Some halos can be detected at distances of hundreds of meters from their related ore bodies; others are no more than a few centimeters in width.

Abnormal chemical concentrations in weathering products are known as secondary dispersion halos or anomalies and are more widespread. They are sometimes referred to as dispersion trains. The shape and extent of secondary dispersion trains depend on a host of factors, of which topography and groundwater movement are perhaps most important. Groundwaters frequently dissolve some of the constituents of mineralized bodies and may transport these for considerable distances before eventually emerging in springs or streams. Further dispersion may ensue in stream sediments when soil or weathering debris that has anomalous metal content becomes incorporated through erosion in stream sediment. Analysis of the fine sand arid silt of stream sediment can be a particularly effective method for detection of mineralized bodies within the area drained by the stream.

Survey design. The degree of success of a geochemical survey in a mineral exploration program is often a reflection of the amount of care taken with initial planning and survey design. This phase of activity is often referred to as an orientation survey; its practical importance cannot be overstressed.

When a geochemical prospecting survey is contemplated, four basic considerations must be addressed: the nature of the mineral deposits being sought; the geochemical properties of the elements likely to be present in the target mineral deposit; geological factors likely to cause variations in geochemical background; and environmental, or landscape, factors likely to influence the geochemical expression of the target mineral deposit. Elucidation of these factors in an orientation survey will permit design of a geochemical prospecting survey that is most likely to prove effective under the prevailing conditions. *See* PROSPECTING.

Geochemical prospecting surveys fall into two broad categories, strategic or tactical, which may be further subdivided according to the material sampled. Strategic surveys imply coverage of a large area (generally several thousands of square kilometers) where the primary objective is to identify districts of enhanced mineral potential; tactical surveys comprise the more detailed follow-up to strategic reconnaissance. Typically the area covered by a tactical survey is divided into discrete areas of high mineral potential within the general anomalous district.

Soil and glacial till surveys have been used extensively in geochemical prospecting and have resulted in the discovery of a number of ore bodies. Generally, such surveys are of a detailed nature and are run over a closely spaced grid.

Biogeochemical surveys are of two types. One type utilizes the trace-element content of plants to outline dispersion halos, trains, and fans related to mineralization; the other uses specific plants or the deleterious effects of an excess of elements in soils on plants as indicators of mineralization. The latter type of survey is often referred to as a geobotanical survey.

Rock geochemical surveys are reconnaissance surveys carried out on a grid or on traverses of an area, with samples taken of all available rock outcrops or at some specific interval. One or several rock types may be selected for sampling and analyzed for various elements. Geochemical maps are compiled from the analyses, and contours of equal elemental values are drawn. These are then interpreted, often by using statistical methods. Under favorable conditions, mineralized zones or belts may be outlined in which more detailed work can be concentrated. If the survey is executed over a large expanse of territory, geochemical provinces may be outlined.

Isotopic surveys are applicable to elements which exist in two or more isotopic forms. They employ the ratios between isotopes such as ^{204}Pb, ^{206}Pb, ^{207}Pb, ^{208}Pb, or ^{32}S and ^{34}S to "fingerprint" or indicate certain types of mineral deposits which may share a common origin. Isotopic ratios may also be used to determine the ages of minerals or given rock types and may, thus, assist in elucidating questions of ore formation.

Geochemistry applied to hydrocarbon exploration differs from that in the search for metallic mineral deposits; the former chiefly involves detection and study of organic substances found during drilling; the latter, detection and study of inorganic substances at the surface. Once hydrocarbon accumulations have been discovered, their classification into geochemical families is important. The final stages of detailed exploration may involve complex multivariate computer-aided modeling of all available geological, geochemical, geophysical, and hydrological data—to determine the ultimate hydrocarbon potential of a given basin.

[R.F.H.]

Geochemistry A field that encompasses the investigation of the chemical composition of the Earth, other planets, and the solar system and universe as a whole, as well as the chemical processes that occur within them. The discipline is large and very important because basic knowledge about the chemical processes involved is critical for understanding subjects as diverse as the formation of economically valuable ore deposits, safe disposal of toxic wastes, and variations in the Earth's climate.

Isotope geochemistry is based on the fact that the isotopic compositions of various chemical elements may reveal information about the age, history, and origin of terrestrial and extraterrestrial materials. Isotopes of an element share the same chemical properties but have slightly different nuclear makeups and therefore different masses. Some naturally occurring isotopes are radioactive and decay at known rates to form daughter isotopes of another element; for example, radioactive uranium isotopes decay to stable isotopes of lead. Radioactive decay is the basis of geochronology, or age determination: the age of a sample can be found by measuring its content of the daughter isotope. Both radioactive decay and the processes that enrich or deplete materials in certain isotopes cause different parts of the Earth and solar system to have different, characteristic isotopic compositions for some elements. These differences serve as fingerprints for tracing the origins of, and characterizing the interactions between, various geochemical reservoirs. *See* DATING METHODS; ELEMENTS, GEOCHEMICAL DISTRIBUTION OF; GEOCHRONOMETRY; ISOTOPE; LEAD ISOTOPES (GEOCHEMISTRY).

Cosmochemistry deals with nonearthly materials. Typically, cosmochemists use the same kinds of analytical and theoretical approaches as other geochemists but apply them to problems involving the origin and history of meteorites, the formation of the solar system, the chemical processes on other planets, and the ultimate origin of the elements themselves in stars. *See* COSMOCHEMISTRY; METEORITE; SOLAR SYSTEM.

Organic geochemistry deals with carbon-containing compounds, largely those produced by living organisms. These are widely dispersed in the outer part of the Earth—in the oceans, the atmosphere, soil, and sedimentary rocks. Organic geochemistry is important for understanding many of the chemical cycles that occur on Earth because biology often plays a major role. Organic geochemists are also active in investigating such areas as the origin of life, the formation of some types of ore deposits that may be biologically mediated, and the origin of coal, petroleum, and natural gas. *See* BIOGEOCHEMISTRY; COAL; NATURAL GAS; ORGANIC GEOCHEMISTRY; PETROLEUM; PREBIOTIC ORGANIC SYNTHESIS.

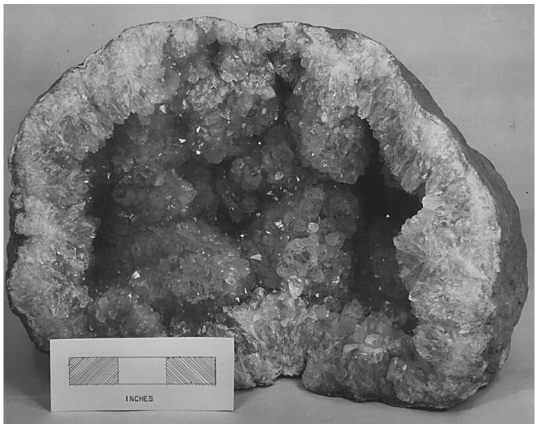
In recent years there has been widespread application of geochemical techniques to problems in paleoclimatology and paleoceanography. In this approach, ocean sediments, sedimentary rocks on land, ice cores, and other continuous records of the Earth's history are analyzed for fossil chemical evidence of past climates or seawater composition. As in most areas of geochemistry, precise and accurate analytical methods for determining the isotopic and elemental composition of the samples are critical. *See* EARTH SCIENCES; PALEOCEANOGRAPHY; PALEOCLIMATOLOGY.

[J.D.MacD.]

Geochronometry The measurement of the age of rocks, minerals, water, and biological materials. Measurements are based primarily on the radioactive decay or fission of such naturally occurring isotopes as ^{238}U, ^{235}U, ^{232}Th, ^{187}Re, ^{176}Lu, ^{147}Sm, ^{87}Rb, ^{40}K, ^{129}I, ^{36}Cl, ^{26}Al, ^{14}C, and ^{10}Be. These radioactive isotopes can be divided into two groups: primordial isotopes that are residual from early nucleosynthesis, and cosmogenic isotopes that are continuously produced by cosmic-ray-induced spallation reactions primarily within the Earth's atmosphere or on the surfaces of meteorites. For the first group, the relative amounts of the radioactive parent and radiogenic daughter are used as a measure of age. Age is determined for the second group by the amount of radioactive isotope remaining after the object is isolated from further intake—for example, by death of an organism participating in the carbon-oxygen cycle, or by trapping of the cosmogenic isotope in sediment or ice. Tree-ring dating (dendrochronology), which is based on the counting of annual rings, may also be used and provides a very precise measure of age of the last eight millennia. *See* DENDROCHRONOLOGY; LEAD ISOTOPES (GEOCHEMISTRY); NUCLEOSYNTHESIS; RADIOCARBON DATING.

There are also methods of establishing the relative sequence of events in time, most importantly, the use of unidirectional biologic evolution upon which the boundaries of the Phanerozoic time scale are based (5.5×10^8 years to the present). The virtues of isotopic dating are its applicability to the full range of geologic time, including the Precambrian for which an adequate paleontologic time scale does not exist; better resolution of events during the Cenozoic (6.5×10^7 years to present); and provision of the fourth physical dimension of astronomic time to quantify rates and energies involved in geologic processes. These isotopic chronometers have been used to measure the age of the Earth, Moon, and meteorites (4.5×10^9 years), the age of the oldest datable rocks (3.7×10^9 years), and many other significant geologic events such as the advance and retreat of continental glaciers. They have also been used to establish a Precambrian time scale, to calibrate the Phanerozoic time scale in solar years, and to provide a chronology for significant biologic, cultural, and environmental events related to the evolution of the human race. On a much shorter time scale, these methods have been used to determine rates of flow of water through aquifers and rates of material (aerosols) transport through the atmosphere. *See* Amino acid dating; Dating methods; Earth, age of; Geologic time scale; Rock age determination. [P.E.Da.]

Geode A roughly spheroidal hollow body, lined on the inside with inward-projecting small crystals (see illustration). Geodes are found most frequently in limestone beds but may occur in some shales. Typically, a geode consists of a thin outer shell of dense chalcedonic silica and an inner shell of quartz crystals. Many geodes are filled with water; others, having been exposed for some time at the surface, are dry. Calcite or dolomite crystals line the interior of some geodes, and a host of other minerals are less commonly found. In some geodes there is an alternation of layers of silica and calcite, but almost all geodes show some banding suggestive of rhythmic precipitation. *See* Chalcedony. [R.Si.]



Geode, lined with quartz crystals, keokuk, Iowa. (*Brooks Museum, University of Virginia*)

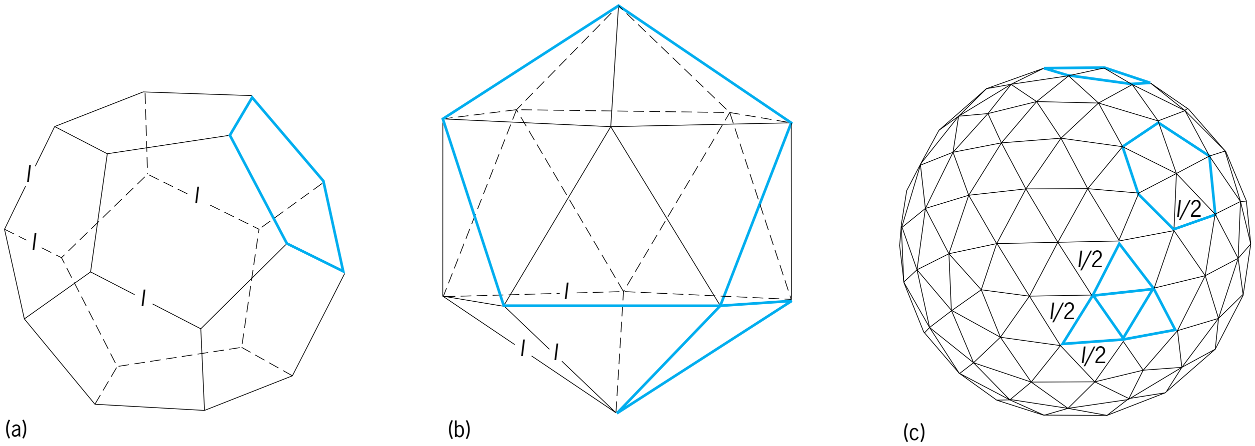
Geodesic dome A curved lattice grid dome that utilizes the equilateral triangle as the basis of its surface grid geometry. R. Buckminster Fuller, the inventor and champion of the geodesic dome, obtained a patent in 1954 that described a method of dividing a spherical surface into equilateral triangles. The two regular polyhedra that can be inscribed in a sphere are the dodecahedron (12 faces, each of which is a regular polygon; illus. *a*) and the more utilized icosahedron (20 faces, each of which is an equilateral triangle; illus. *b*). *See* Polyhedron.

The geodesic dome has been used for everything from great exhibition spaces and halls to outdoor tent supports and jungle gyms. By utilizing the icosahedron as the basic building block of the geodesic dome, larger domes are possible with additional triangular subdivisions. This subdivision is known as the frequency. The first frequency is to interconnect the projected midpoints of the struts of each equilateral triangle of the icosahedron as they will project on the spherical surface. The result is four almost equilateral triangles where there was one before. The resulting lattice has similar but not exactly equilateral triangles if the grid is to remain on the spherical surface. This subdivision process can continue. The resulting grids have both triangular and hexagonal grids as a by-product within the basic geodesic dome geometry, with pentagons around the apex of the basic underlying icosahedron framework (illus. *c*). [I.P.L.]

Geodesy The science of measuring the size, shape, and gravity field of the Earth. Geodesy supplies positioning information about locations on the Earth, and this information is used in a variety of applications, including civil engineering, boundary demarcations, navigation, resource management and exploration, and geophysical studies of the dynamics of the Earth. *See* Earth.

The conventional measurement systems in geodesy are triangulation and trilateration for determining horizontal positions, and leveling for determining heights. These techniques depend on the Earth's gravity field, and so a major part of geodesy has been not only position determination but also the measurement of the Earth's gravity field. *See* Earth, gravity field of.

Two major measurement systems were developed in the late 1970s and early 1980s: satellite laser ranging (SLR) systems, which could measure the distance from the ground to a satellite equipped with special corner-cube mirrors; and very long baseline interferometry (VLBI), which could measure the difference in arrival times between radio signals from extragalactic radio sources. With these systems it is possible to measure accurately (within a few centimeters) the distances between points located on different continents, making possible the creation of



Geometry of geodesic domes. (*a*) Dodecahedron: a regular pentagon is typical of each face; every point is an apex because all apexes are on the sphere; each strut (*l*) is the same length. (*b*) Icosahedron: an apex is above the center of each polygon and on the surface of the sphere; the equilateral triangle typical of each face is highlighted; each strut is the same length. (*c*) Larger dome based on the icosahedron: subdivision is formed by connecting mid points of struts of equilateral triangles (each half strut is labeled *l*/2); the original pentagon is shown at the top, and a formed hexagon is also shown.

truly global coordinate systems. Both systems were deployed around the world to measure not only the positions of locations but also the changes in those positions; and thus it was confirmed that the Earth is not a static but a highly dynamic body, with much of this dynamism causing catastrophic events such as earthquakes and volcanic eruptions. The more recent Global Positioning System (GPS) offers much of the capability of SLR and VLBI. *See* RADIO ASTRONOMY; SATELLITE NAVIGATION SYSTEMS.

The most recent development in geodetic techniques is interferometric synthetic aperture radar (InSAR). This technique is used to measure heights of the topography or, if the topography is already known, the changes in the topography between two synthetic aperture radar (SAR) images. Heights measured with InSAR are far less accurate than normal geodetic height measurements, but since InSAR is an imaging system, large areas can be measured easily. If the InSAR instrument is on an orbiting spacecraft, global topography can be measured. The measurement of changes in topography with InSAR has been widely used to measure the surface displacements after earthquakes (by comparing before and after SAR images) and for monitoring volcanic deformations. *See* RADAR.

Some of the major impacts of modern geodetic measurements have been in the study of the dynamics of the Earth. The measurement systems enable the observation of many of the minute motions of the Earth, such as those associated with plate tectonics and other geophysical processes, and changes in the rotation of the Earth. [T.He.]

Geodynamics The branch of geophysics that studies the processes leading to deformation of planetary mantle and crust and the related earthquakes and volcanism that shape the structure of the Earth and other planets. On the largest scale, these processes are a consequence of the transfer of heat out of planetary interiors due to cooling at their surfaces. Rock contracts as it cools, so that its density increases. The cool surface layer is heavier than the interior and has a tendency to sink into it. At the same time, cooling and solidification of the metallic core heats the deepest portion of the surrounding rocky mantle, causing it to become buoyant. The resulting flow of the mantle causes deformation at the surface. Volcanism arises from the partial melting of hot mantle that rises toward the surface from the deeper interior, in response either to buoyancy or to surface deformation. Surface deformation also results from external loads, such as the distribution of ice and water, tidal loads due to the gravitational attraction of nearby planetary bodies, and meteor impacts. *See* EARTH, CONVECTION IN; EARTH, HEAT FLOW IN; GEOPHYSICS; VOLCANO.

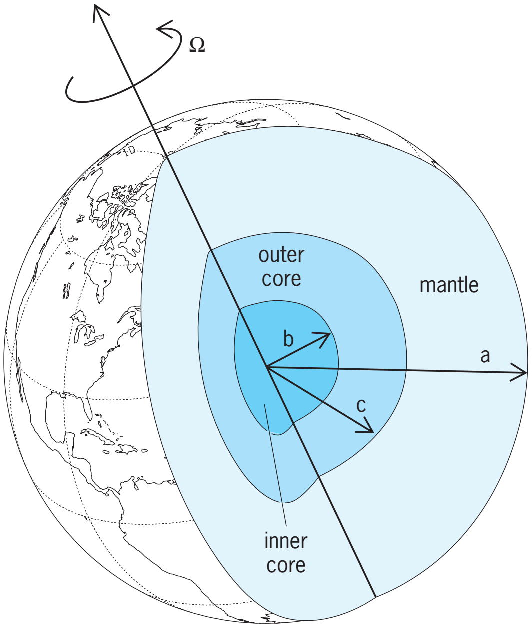
A planet's response to its internal heat flow depends largely on the rheology of deforming rock. At low temperatures, near the surface, rock behaves as a brittle-elastic material, allowing the propagation of seismic waves and the support of surface loads by elastic stresses. Deformation occurs by the formation of cracks or faults. On geologic time scales and at the higher temperatures of the deeper interior, thermally activated creep allows the solid, rocky mantle to flow like a viscous fluid. But even at these high temperatures, rock behaves elastically on short time scales so that elastic shear waves propagate through the slowly flowing mantle. In the case of the Earth in its current stage of evolution, plate tectonics describes how the surface behaves: large, cold, relatively rigid plates move laterally across the surface while the deeper mantle flows by creep. In the cold plates, deformation is largely confined to boundary faults between the plates. Faults slip with a stick-slip behavior, giving rise to large earthquakes that occur primarily on the plate boundaries. *See* EARTHQUAKE; PLATE TECTONICS; RHEOLOGY; ROCK MECHANICS.

Given the difficulty of direct observation and the wide range of scales involved in phenomena of interest, multiple approaches are needed to understand geodynamic processes. Laboratory experiments on relatively small samples of rock are used to characterize the rock's physical properties, such as its rheology, at high pressures and temperatures. The rate of deformation due to creep in nature is much too slow to measure directly in the laboratory. Field studies of rocks once deep in the interior and brought to the surface by uplift and erosion provide evidence of the processes that have affected them. But the interior of the Earth where the processes of interest are actually occurring is not directly accessible for study. Thus geodynamicists must design large-scale observational experiments that allow them to create conceptual and physical images of the interior, using combinations of seismic, gravitational, electromagnetic, and heat-flow measurements. Variations in global gravity and corresponding surface topography can be remotely sensed from orbiting spacecraft. *See* EARTH CRUST; EARTH INTERIOR; GEODESY; GEOMAGNETISM; SEISMOLOGY. [E.M.P.]

Geodynamo The mechanism thought to be responsible for the generation of the Earth's magnetic field through the convection of conducting fluids in the Earth's core.

Paleomagnetic measurements suggest that the Earth has possessed a magnetic field for at least 3.5 billion years. Geophysicists generally accept that the ambient magnetic field measured at the Earth's surface is due to electric currents flowing in its liquid iron core (see illustration). In the absence of electromotive forces, like those of chemical batteries, electric currents will decay as magnetic energy is converted to heat. Without some regenerative process to offset such natural ohmic dissipation in the Earth's core, any electric currents and the associated magnetic field would vanish in about 15,000 years. Regeneration of the field is necessary. In the Earth it is thought that the magnetic field is maintained by dynamo action, whereby the kinetic energy of convective motion in the Earth's liquid core is converted into magnetic energy. Since this process operates without an external energy source, the geodynamo is said to be self-sustaining. *See* GEOELECTRICITY; GEOMAGNETISM; PALEOMAGNETISM.

It is not obvious how a simply connected conducting fluid body, like the Earth's core, functions as a dynamo without the induced currents simply short-circuiting and eliminating field generation. In fact, the electric current in a dynamo and the magnetic field that it sustains cannot be too simple; a theorem, due to T. G. Cowling, says that no axisymmetric, or even two-dimensional,



Anatomy of the Earth. The rocky mantle has a radius $a =$ 6371 km (3959 mi), the liquid iron outer core has a radius $c = 3485$ km (2165 mi), and the solid inner core has a radius $b = 1215$ km (755 mi). The Earth's rotational vector is Ω.

dynamo magnetic field can exist. Although the magnetic north and south poles usually are nearly coincident with the geographic poles, indicating that the rotation arising from the Coriolis force plays an important role in the core's dynamics, it is no accident that the compass does not point toward true north everywhere on the Earth's surface—an inherent lack of symmetry. As a result, theoretical progress has been slow since scientists often take advantage of symmetry, should it be present, when solving mathematical equations. *See* Coriolis acceleration; Magnetohydrodynamics.

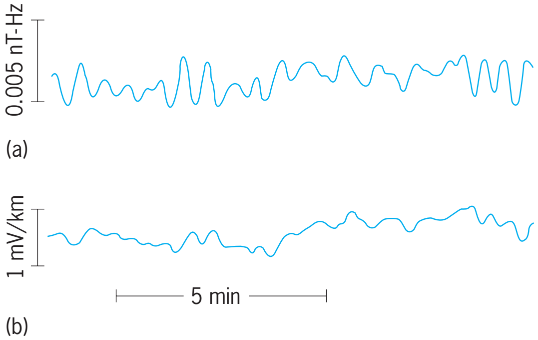
Geophysicists do, however, have a good qualitative understanding of how the geodynamo works. In the 1940s and 1950s, W. M. Elsasser and E. N. Parker first elucidated the so-called α-ω (alpha-omega) mechanism, by which core fluid motion can act as a dynamo if it consists of a combination of differential rotation and convective helical motion. Since then it has been shown mathematically that dynamo regeneration can arise from the turbulent motion of a rotating fluid. Although the α-ω mechanism probably describes how the field is amplified, it is the dynamics that ultimately governs the strength of the field.

There are two possible sources of the energy sustaining the fluid convection in the outer core—thermal and compositional. Thermal convection is perhaps most familiar, with heat sources, such as radioactive potassium, distributed over the volume of the outer core. With sufficient internal heating, the fluid is gravitationally unstable and, as a result, convection is sustained. Compositional convection is currently favored by most geophysicists as the energy source of the geodynamo. Although the core is primarily of iron, there are probably light impurities, such as sulfur. Due to the effects of pressure, as the Earth slowly cools, iron solidifies at the inner-core boundary. This causes the inner core to grow and leaves the lighter constituents behind in the fluid at the base of the outer core, supplying the buoyancy that drives the convection. *See* Convection (heat).

The Sun is a familiar dynamo, and it reverses regularly almost every 11 years. So, why does the Earth's magnetic field not display such regularity? The difference is thought to be due to the presence in the Earth of a solid electrically conducting inner core, where the magnetic field can change only rather slowly by diffusion. Recent calculations suggest that because the inner core is electromagnetically coupled to the outer core, its presence acts to stabilize the magnetic field, so that only particularly large fluctuations of the field in the outer core are sufficient to overcome the damping effect of the inner core. *See* Diffusion; Electromagnetism; Geophysics; Magnetic reversals. [J.J.Lo.]

Geoelectricity Electromagnetic phenomena and electric currents, mostly of natural origin, that are associated with the Earth. Geophysical methods utilize natural and artificial electric currents to explore the properties of the Earth's interior and to search for natural resources (for example, petroleum, water, and minerals). Geoelectricity is sometimes known as terrestrial electricity. All electric currents (natural or artificial, local or worldwide) in the solid Earth are characterized as Earth currents. The term telluric currents is reserved for the natural, worldwide electric currents whose origins are almost entirely outside the atmosphere. Geoelectromagnetism is a more comprehensive term than geoelectricity. Time variations of any magnetic field are associated with an electric field that induces electric currents in conducting media such as the Earth.

Magnetic fields, electric fields, and electric currents are the constituents of electromagnetism, and are related by Maxwell's equations. For instance, the illustration shows the time variations of the natural magnetic and electric fields simultaneously measured at one location at the surface of the Earth. These two traces are related to each other, not only by Maxwell's equations but also by the physical properties of the subsurface rocks in the vicinity of the measuring site. Either one of the two traces may be computed synthetically from the other if the properties of the subsurface rocks are known. Conversely, the two traces together can yield geologic information; this is a form of geophysical exploration or prospecting. Thus, the terms geoelectricity, geomagnetism, and geoelectromagnetism are essentially interchangeable, although each one may have a somewhat different emphasis. For example, the term geomagnetism is sometimes used for the study of the Earth's quasistationary main magnetic field. *See* Geomagnetism; Geophysical exploration. [S.H.Y.]



Time variations of the horizontal orthogonal components of the natural (*a*) magnetic and (*b*) electric fields, simultaneously measured at one site at the surface.

Geographic information systems Computer-based technologies for the storage, manipulation, and analysis of geographically referenced information. Attribute and spatial information is integrated in geographic information systems (GIS) through the notion of a data layer, which is realized in two basic data models: raster and vector. The major categories of applications comprise urban and environmental inventory and management, policy decision support, and planning; engineering and defense applications; and scientific analysis and modeling.

A geographic information system differs from other computerized information systems in two major respects. First, the information in this type of system is geographically referenced (geocoded). Second, a geographic information system has considerable capabilities for data analysis and scientific modeling, in addition to the usual data input, storage, retrieval, and output functions.

A geographic information system is composed of software, hardware, and data. The notion of data layer (or coverage) and overlay operation lies at the heart of most software designed for geographic information systems.

Two fundamental data models, the vector and raster models, embody the overlay idea in geographic information systems. In a vector geographic information system, the geometrical configuration of a coverage is stored in the form of points, arcs (line segments), and polygons, which constitute identifiable objects in the database. In a raster geographic information system, a layer is composed of an array of elementary cells of pixels, each holding an attribute value without explicit reference to the geographic feature of which the pixel is a part. *See* Computer graphics; Electronic display; Image processing.

A data layer or coverage integrates two kinds of information: attribute and spatial (geographic). The functionality of a geographic information system consists of the ways in which that information may be captured, stored, manipulated, analyzed, and presented to the user. Spatial data capture (input) may be from primary sources such as remote sensing scanners, radars, or global positioning systems, or from scanning or digitizing images and maps derived from remote sensing. Output (whether as a display on a cathode-ray tube or as hard copy) is usually in map or graph form, accompanied by tables and reports linking spatial and attribute data. The critical data management and analysis functions fall into four categories: retrieval, classification, and measurement; overlay functions; neighborhood operations; and connectivity functions. *See* Digital computer; Remote sensing. [H.Co.]

Business applications of geographic information systems are increasingly widespread and include market analysis, store location, and agribusiness (for example, determining the correct amount of fertilizers or pesticides needed at each point of a cultivated field). Engineers use geographic information systems when modeling terrain, building roads and bridges, maintaining cadastral maps, routing vehicles, drilling for water, determining what is visible from any point on the terrain, integrating intelligence information on enemy targets, and so forth. Such applications have been facilitated through the integration of geographic information systems with global positioning systems. *See* Coordinate systems; Satellite navigation systems.

Among the earliest and still most widespread applications of the technology are land information and resource management systems (for example, forest and utility management). Other common uses of geographic information systems in an urban policy context include emergency planning, determination of optimal locations for fire stations and other public services, assistance in crime control and documentation, and electoral and school redistricting. Uses of geographic information systems have spread well beyond geography, the source discipline, and now involve most applied sciences, both social and physical, that deal with spatial data. The nature of the applications of geographic information systems in these areas ranges from simple thematic mapping for illustration purposes to complex statistical and mathematical modeling for the exploration of hypotheses or the representation of dynamic processes. [H.Co.]

Geography The study of physical and human landscapes, the processes that affect them, how and why they change over time, and how and why they vary spatially. Geographers consider, to varying degrees, both natural and human influences on the landscape, although a common division separates human and physical geography. Physical geographers may study landforms (geomorphology), water (hydrology), climate and meteorology (climatology), the biotic environment (biogeography), or soils (pedology). Human geographers include urban, regional, and environmental planners; cultural geographers; regional and area specialists; economic geographers; political geographers; transportation analysts; location analysts; and specialists in the spatial nature of ethnic or gender issues. *See* Biogeography; Climatology; Geomorphology; Hydrology; Pedology.

Many geographers are involved with the development of techniques and applications that support spatial analytical studies or the display of spatial information and data. Maps, whether printed, digital, or conceptual, are the basic tools of geography. Geographers are involved in map interpretation and use, as well as map production and design. Cartographers supervise the compilation, design, and development of maps, globes, and other graphic representations. *See* Cartography.

A geographic information system (GIS) is a relatively new technology that combines the advantages of computer-assisted cartography with those of spatial database management. It facilitates the storage, retrieval, and analysis of spatial information in the form of digital map "overlays," each representing a different landscape component (terrain, hydrologic features, roads, vegetation, soil types, or any mappable factor). Each of these data layers can be fitted digitally to the same map scale and map projection—in any combination—permitting the analysis of relationships among any combination of environmental variables for which data have been input into the geographic information systems. *See* Geographic information systems.

Many geographers are applied practitioners, solving problems using a variety of tools, including computer-assisted cartography, statistical methods, remotely sensed imagery, the Global Positioning System (GPS), and geographic information systems. Today, nearly all geographers, regardless of their subdisciplinary emphases, employ some or all of these techniques in their professional endeavors. *See* Earth resource patterns; Physical geography; Terrain areas. [J.F.P.]

Geologic thermometry The measurement or estimation of temperatures at which geologic processes take place. Methods used can be divided into two groups, nonisotopic and isotopic. Nonisotopic methods involve measurements of earth temperatures either directly by surface and near-surface features or indirectly from various properties of minerals and fossils. The isotopic methods involve the determination of distribution of isotopes of the lighter elements between pairs of compounds in equilibrium at various temperatures, and application of these data to problems of the temperature at which these compounds (commonly minerals) form in nature. [E.I.]

Geologic time scale An ordered, internally consistent, internationally recognized sequence of time intervals, each distinct in its own history and record of life on Earth, including the assignment of absolute time in years to each geologic period. The geologic time scale (see table) has a relative scale, consisting of named intervals of geologic history arranged in historical sequence; and a numerical (or absolute) time scale, providing absolute ages for the boundaries of these intervals.

Geologic time scale

Eon Era Period [system] Epoch [series]	Age at beginning of interval, 10^6 years	Interval length, 10^6 years
Phanerozoic		
Cenozoic		65
Quaternary (Q)[*]		1.8
Recent	0.01	0.01
Pleistocene	1.8	1.79
Tertiary (T)	65	63.2
Pliocene (Tpl)	5.3	3.5
Miocene	23.8	18.5
Oligocene (To)	33.7	9.9
Eocene (Te)	54.8	21.1
Paleocene (Tp)	65	10.2
Mesozoic	250	185
Cretaceous (K)	144	79
Jurassic (J)	206	62
Triassic (Tr)	250	44
Paleozoic	543	297
Permian (P)	290	40
Carboniferous (M, P)	354	64
Devonian	417	63
Silurian	443	26
Ordovician	490	47
Cambrian	543	53
Precambrian		
Proterozoic	2500	1957
Late (Z)[†] (Neoproterozoic)	900	357
Middle (Y) (Mesoproterozoic)	1600	700
Early (X) (Paleoproterozoic)	~2500	900
Archean	3800	
Late (W)	3000	500
Middle (U)	3400	400
Early (V)	>3800	>400

[*] In parentheses are the symbols for the periods and epochs used on geologic maps and figures in North America, as well as other parts of the world.

[†] Letter designations of Precambrian age intervals are used by the U.S. Geological Survey.

In order to establish a geologic time scale, an independent means of dating rocks is required. Before the discovery of radioactivity, crude estimates of the length of a geologic history were made based on the total thicknesses of sedimentary rock and assumed rates of erosion and sedimentation. These estimates varied by as much as a factor of 10.

The modern geologic time scale is based on many measurements of various rock types by quantitative isotopic chronometers such as uranium-lead (U-Pb) and potassium-argon (K-Ar). *See* Rock age determination. [A.R.P.; J.W.Gei.; J.L.K.]

Geology The science of the Earth. The study of the Earth's materials and of the processes that shape them is known as physical geology. Historical geology is the record of past events. *See* Earth; Earth sciences.

Geology is an interdisciplinary subject that overlaps and depends on other scientific disciplines. Physical geology is concerned primarily with the Earth's materials (minerals, rocks, soils, water, ice, and so forth) and the processes of their origin and alteration. Chemistry and physics are the two scientific disciplines most closely related—study of the chemistry of the Earth's materials is geochemistry, and study of the physical properties of the Earth is geophysics. *See* Geochemistry; Geophysics; Structural geology.

Historical geology is based on two complementary disciplines, stratigraphy and paleontology. Stratigraphy is the systematic study of stratified rocks through geologic time. The stratigraphic record reveals the sequence of events that have affected the Earth through eons of time. Absolute dates for the stratigraphic record are provided from geochemical studies of naturally occurring radioactive isotopes. Paleontology is the study of fossilized plants and animals with regard to their distribution in space and time. Paleontology is closely related to biology. The distinctions between physical and historical geology are more matters of convenience than substance, because it is increasingly clear, within the framework of plate tectonics, that all aspects of geology are interrelated. *See* Paleontology; Plate tectonics; Stratigraphy.

Mineralogy concerns the study of natural inorganic substances (minerals), the basic building blocks of rocks. About 3600 minerals have been identified, but fewer than 50 are common constituents in the types of rocks that are abundant in the Earth. The most common minerals in the crust are feldspars, quartz, micas, amphiboles, pyroxenes, olivine, and calcite. Modern laboratories have effective devices for resolving the mineral content of rock materials; even the ultramicroscopic particles in clays are clearly defined under the electron microscope. *See* Crystal structure; Electron microscope; Mineral; Mineralogy.

Petrology is the study of rocks, their physical and chemical properties, and their modes of origin. The primary families are igneous rocks, which have solidified from molten matter (magma); sedimentary rocks, made of fragments derived by weathering of preexisting rocks, of chemical precipitates from sea or lake water, and of organic remains; and metamorphic rocks derived from igneous or sedimentary rocks under conditions that brought about changes in mineral composition, texture, and internal structure (fabric). The secondary rock families are pyroclastic rocks, which are partly igneous and partly sedimentary rocks because they are composed largely or entirely of fragments of igneous matter erupted explosively from a volcano; diagenetic rocks are transitional between sedimentary and metamorphic rocks because their textures or compositions were affected by low-temperature, postsedimentation processes below conditions of metamorphism; migmatites are transitional between metamorphic and igneous rocks because they form when metamorphic rocks are raised to temperatures and pressures so that small localized fractions of the rock start to melt but the melting is insufficient for a large body of magma to develop. *See* Petrography; Petrology; Rock.

A general knowledge of geology has many practical applications, and large numbers of geologists receive special training for service in solving problems met in the mining of metals and nonmetals, in discovering and producing petroleum and natural gas, and in engineering projects of many kinds. Human use of materials has become so great that waste materials are influencing natural geological processes. As a result, a new discipline, environmental geology, is starting to emerge. *See* Engineering geology; Petroleum geology. [B.J.S.]

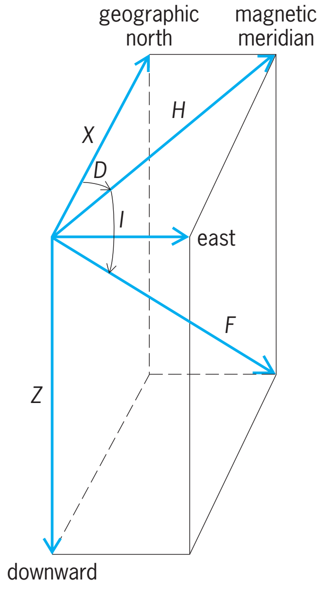
Geomagnetic variations Variations in the natural magnetic field measured at the Earth's surface. This field changes with periodicities from about 0.3 s to thousands of years. Many of these variations of observed field—the very short-period, daily, seasonal, semiannual, and solar-cycle (11-year) variations—arise from sources that are external to the Earth but are superposed upon the larger main dipolar field of the Earth by the typical measuring instruments. The daily and seasonal atmospheric motions cause field variations that are smooth in form and relatively predictable, given the time and location of the observation. During occasions of high solar-terrestrial disturbance activity that give rise to auroras at high latitudes, very large geomagnetic variations occur that mask the quiet daily changes. These geomagnetic variations are so spectacular in size and global extent that they have been named geomagnetic storms. *See* Aurora; Geomagnetism; Ionosphere; Magnetosphere; Solar wind; Sun. [W.H.Ca.]

Geomagnetism The magnetism of the Earth; also, the branch of science that deals with the Earth's magnetism. Formerly called terrestrial magnetism, geomagnetism involves any topic pertaining to the magnetic field observed near the Earth's surface, within the Earth, and extending upward to the magnetospheric boundary. Modern usage of the term is generally confined to historically recorded observations to distinguish it from the sciences of archeomagnetism and paleomagnetism, which deal with the ancient magnetic field frozen respectively in archeological artifacts and geologic structures. *See* Paleomagnetism; Rock magnetism.

The primary component of the magnetic field observed at the Earth's surface is caused by electric currents flowing in its liquid core, and is called the main field. Vectorially added to this component are the crustal field of magnetized rocks, transient variations imposed from external sources, and the field from electric currents induced in the Earth from these variations.

The geomagnetic field is specified at any point by its vector $\mathbf{F}$. Its direction is that of a magnetized needle perfectly balanced before it is magnetized, and freely pivoted about that point, when in equilibrium. The north pole of such a needle is the one that at most places on the Earth takes the more northerly position. Over most of the Northern Hemisphere, that pole dips downward (see illustration). The elements used to describe the vector $\mathbf{F}$ are H, the component of the vector projected onto a horizontal plane; its north and east components X and Y, respectively; Z the vertical component; F the magnitude of the vector $\mathbf{F}$; the angles I, the dip of the field vector below the horizontal; and D the magnetic declination or deviation of the compass from geographic north. By convention, Z and I are positive downward, and D is positive eastward (or may be indicated as east or west of north). These elements can be related to each other by trigonometric equations. *See* Magnetic compass.

A magnetic pole is a location where the field is vertically



Elements of the geomagnetic field. D = declination, I = inclination, H = horizontal intensity, X = north intensity, Y = east intensity, Z = vertical intensity, F = total intensity.

aligned, $H = 0$. Due to the presence of sometimes strong (for example, >1000 nanoteslas) magnetic anomalies at the Earth's surface, there are a number of locations where the field is locally vertical. However, those field components that extend to sufficient altitude to control charged particles can be accurately located by using the computations from a spherical harmonic expansion using degrees up to only about $n = 10$. Indeed, a pole can be defined by using only the main dipole ($n = 1$), or many terms. *See* AURORA.

The $n = 1$ poles are sometimes referred to as the geomagnetic poles, and those computed using higher terms as dip poles. The term geomagnetic could also refer to the eccentric geomagnetic pole, which can be computed from $n = 1$ and $n = 2$ harmonics so as to be the best representation of a dipole offset from the center of the Earth. The latter has been used as a simplified field model at distances of 3 or 4 earth radii. Due to the more rapid fall-off of the higher terms with distance from the Earth, the two principal poles approach those of the $n = 1$ term with increasing altitude, until the distortions due to external effects begin to predominate. *See* MAGNETOSPHERE.

The distribution of the dip angle I over the Earth's surface can be indicated on a globe or map by contours called isoclines, along which I is constant. The isocline for which $I = 0$ (where a balanced magnetized needle rests horizontal) is called the dip equator. The dip equator is geophysically important because there is a region in the ionospheric E layer in which small electric fields can produce a large electric current called the equatorial electrojet. *See* GEOMAGNETIC VARIATIONS; IONOSPHERE.

A magnetized compass needle can be weighted so as to rest and move in a horizontal plane at the latitudes for which it is designed, thus measuring the declination D. The lines on the Earth's surface along which D is constant are called isogonic lines or isogones. The compass points true geographic north on the agonic lines where $D = 0$. At nonpolar latitudes, D is a useful tool for marine and aircraft navigational reference. Indeed, isogones appear on navigation charts, electronic navigational aids are referenced to D, and airport runways are marked with D/10. A runway painted with the number 11 indicates that its direction has a compass heading of 110°. The compass needle becomes less reliable in polar regions because the horizontal component H becomes smaller as the magnetic poles are approached. *See* NAVIGATION.

The intensity of the field can also be represented by maps, and the lines of equal intensity are called isodynamic lines. The dipole dominates the patterns of magnetic intensity on Earth in that the intensity is about double at the two poles compared to the value near the Equator. However, it can also be seen that the next terms of the spherical harmonic expansion also have a significant effect, in that there is a second maximum in Siberia, and an area near Brazil that is weaker than any other. This so-called Brazilian anomaly allows charged particles trapped in the magnetic field to reach a low altitude and be lost by collisions with atmospheric gases. The highest intensity of this smooth field is about 70 microteslas near the south magnetic pole in Antarctica, and the weakest is about 23 μT near the coast of Brazil.

The term magnetic anomaly has become clearer than it was previously because it is recognized that the geomagnetic field has a continuous spectrum but with two distinct contributors. Originally, the term meant a field pattern that was very local in extent; the modern definition is that portion of the field whose origin is the Earth's crust. The sizes of the strong and easily observable features are generally up to only a few tens of kilometers. Their intensity ranges typically from a few hundred nanoteslas up to several thousand, and they are highly variable depending on the geology of the region.

The main or core component of the geomagnetic field undergoes slow changes that necessitate continual adjustment of the model coefficients and redrawing of the isomagnetic maps. In any magnetic element at a particular place, the variation may be an increase or a decrease and is not constant in either magnitude or sign. This distribution of the rate for any element can be indicated on isoporic maps by lines (isopors) along which the rate is constant. Typically, the pattern of isopors is more complex than that of the isomagnetic lines for the same element, partly because the spectrum of such change is not dominated by the dipole as is the case of the static field.

Studies indicate that the dipole component of the field 2000 years ago was about 50% stronger than the present. Its average decay rate has averaged about 0.05% per year (15 nanoteslas per year) since about 1840 when absolute measurements were first begun, but accelerated from 1970 to its 1994 value of 0.08% per year (24 nT/yr). However, there is also evidence that the decade of the 1940s showed a rate of only about 10 nT per year. A linear projection of the present rate would have the dipole decreasing to zero in less than 1500 years. Although archeomagnetic evidence indicates that the field has indeed decayed to near zero level within the last 50,000 years with a subsequent return to the present polarity, and paleomagnetic results show that the field has reversed its polarity many times since the Earth's formation (the last time, about a million years ago), there is no model that can predict the future course of field change.

Deriving a suitable model that explains the source of the Earth's magnetic field has been one of the most frustrating problems that theoreticians have faced. Starting with the physical laws that should govern the behavior of a highly conducting, rotating, spherical fluid and coming up with a model of the geomagnetic field is exceedingly difficult. Dynamo means that a current is generated as an electrical conductor is moved through a magnetic field, as in a dynamo supplying electrical power. *See* GEODYNAMO.

The main source of data for magnetic maps and models before the advent of satellites was fixed magnetic observatories. These stations, numbering about 140, provided the continuous record of changes in the magnetic field at their location. Their data are generally accurate and an excellent indicator of both secular change and the transient variations, but their global coverage is too sparse for a determination of the whole field. Spherical harmonic analyses based only on such data produce distorted results because of the large gaps in coverage, especially because of the sparseness of observing locations in southern oceanic regions. *See* MAGNETISM. [J.Cai.]

Geometric phase A unifying mathematical concept that describes the relation between the history of internal states of a system and the system's resulting orientation in space. Under various aspects, this concept occurs in geometry, astronomy, classical mechanics, and quantum theory. In geometry it is known as holonomy. In quantum theory it is known as Berry's phase, after M. Berry, who isolated the concept (which was already known in special cases) and explained its wide-ranging significance.

A system is envisioned whose possible states can be visualized as points in a suitable abstract space. At the same time, the system has some position or orientation in another space. A history of internal states can be represented by a curve in the first space; and the effect of this history on the disposition of the system, by a curve in the second space. The mapping between these two curves is described by the geometric phase. Especially interesting is the case when a closed curve (cycle) in the first space maps onto an open curve in the second, for then there is no net change in internal state, yet the disposition of the system with respect to the outside world is altered.

The power of the geometric phase ideas is that they make it possible, in complex dynamical problems, to find some simple universal regularities without having to solve the complete equations. Significant uses of these ideas include demonstrations of the fractional electric charge and quantum statistics of the quasiparticles in the quantum Hall effect, and of the occurrence of anomalies in quantum field theory. *See* ANYONS; HALL EFFECT; QUANTUM FIELD THEORY. [F.Wil.]

Geometrical optics The geometry of light rays and their images, through optical systems. In the modern view of the wave nature of light, geometrical optics as a model is simply wrong. In spite of this geometrical optics is remarkably robust, remaining as a most practical tool in the solution of optical problems where at first glance it would seem to be totally inappropriate. The principal application of geometrical optics remains in the field of optical design.

Light is a form of energy which flows from a source to a receiver. It consists of particles (corpuscles) called photons. The speed with which the particles travel depends on the medium. In a vacuum this speed is 3×10^8 m · s^{-1} (1.86×10^5 mi · s^{-1}) for all colors. In a material medium, whether gas, liquid, or solid, light travels more slowly. Moreover, different colors travel at different rates. The ratio of the speed in a vacuum to the speed in the medium is called the refractive index of the medium. The variation in refractive index with color is called dispersion. *See* Color; Dispersion (radiation); Refraction of waves.

The paths that particles take in going from the source to the receiver are called rays. The product of the refractive index and the path length is called the optical path length along the ray. The optical path length is equal to the distance that the particle would have traveled in a vacuum in the same time interval.

A point source is an infinitesimal region of space which emits photons. An extended source is a dense array of point sources. Each point source emits photons along a family of rays associated with it. For each such family of rays there is also a family of surfaces each of which is a surface of constant transit time from the source for all the particles, or alternatively, a surface of constant optical path length from the source. These surfaces are called geometrical wavefronts, because they are often good approximations to the wavefronts predicted by a wave theory.

The ray path which any particle takes as it propagates is determined by Fermat's principle, which states that the ray path between any two points in space is that path along which the optical path length is stationary (usually a minimum) among all neighboring paths. In a homogeneous medium (one with a constant refractive index) the ray paths are straight lines.

In a system that consists of a sequence of separately homogeneous media with different refractive indices and with smooth boundaries between them (such as a lens system), the ray paths are straight lines in each medium, but the directions of the ray paths will change in passing through a boundary surface. This change in direction is called refraction, and is governed by Snell's law, which states that the product of the refractive index and the sine of the angle between the normal to the surface and the ray is the same on both sides of a surface separating two media. The normal in question is at the point where the ray intersects the surface.

The primary area of application of geometrical optics is in the analysis and design of image-forming systems. An optical image-forming system consists of one or more optical elements (lenses or mirrors) which when directed at a luminous (light-emitting) object will produce a spatial distribution of the light emerging from it which more or less resembles the object. The latter is called an image. *See* Optical image.

In order to judge the performance of the system, it is first necessary to have a clear idea of what constitutes ideal behavior. Departures from this ideal behavior are called aberrations, and the purpose of optical design is to produce a system in which the aberrations are small enough to be tolerable. *See* Aberration (optics).

In an ideal optical system the rays from every point in the object space pass through the system so that they converge to or diverge from a corresponding point in the image space. This corresponding point is the image of the object point, and the two are said to be conjugate to each other (object and image functions are interchangeable).

The geometry of the object and image spaces must be connected by some mapping transformation. The one generally used to represent ideal behavior is the collinear transformation. If three object points lie on the same straight line, they are said to be collinear. If the corresponding three image points are also collinear, and if this relationship is true for all sets of three conjugate pairs of points, then the two spaces are connected by a collinear transformation. In this case, not only are points conjugate to points, but straight lines and planes are conjugate to corresponding straight lines and planes.

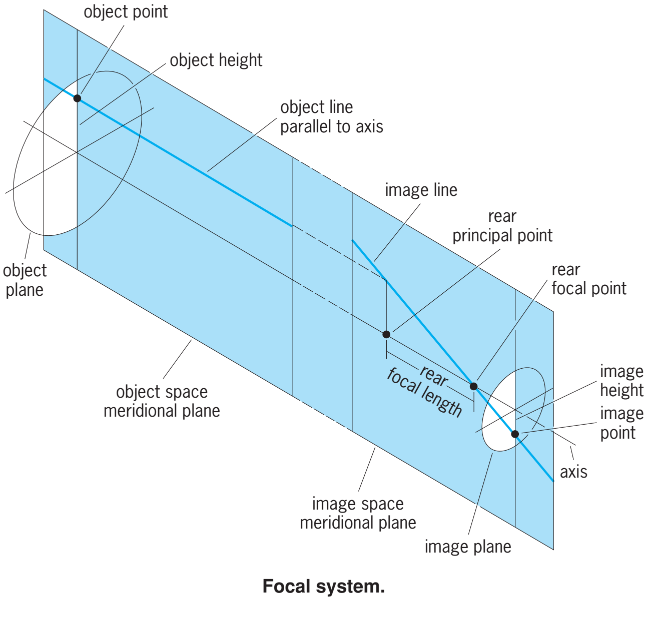
Another feature usually incorporated in the ideal behavior is the assumption that all refracting or reflecting surfaces in the system are figures of revolution about a common axis, and this axis of symmetry applies to the object-image mapping as well. Every object plane containing the axis, called a meridional plane, has a conjugate which is a meridional plane coinciding with the object plane. In addition, every object plane perpendicular to the axis must have a conjugate image plane which is also perpendicular to the axis, because of axial symmetry. In the discussion below, the terms object plane and image plane refer to planes perpendicular to the axis.

An object line parallel to the axis will have a conjugate line which either intersects the axis in image space or is parallel to it. The first case is called a focal system, and the second an afocal system.

The point of intersection of the image-space conjugate line of a focal system with the axis is called the rear focal point (see illustration). It is conjugate to an object point on axis at infinity. The image plane passing through the rear focal point is the rear focal plane, and it is conjugate to an object plane at infinity. Every other object plane has a conjugate located at a finite distance from the rear focal point, except for one which will have its image at infinity. This object plane is the front focal plane, and its intersection with the axis is the front focal point.

Now take an arbitrary object plane and its conjugate image plane. Select a point off axis in the object plane and construct a line parallel to the axis passing through the off-axis point. The conjugate line in image space will intersect the axis at the rear focal point and the image plane at some off-axis point. The distance of the object point from the axis is called the object height, and the corresponding distance for the image point is the image height. The ratio of the image height to the object height is called the transverse magnification, and is positive or negative according to whether the image point is on the same or the opposite side of the axis relative to the object point.

Every pair of conjugate points has associated with it a unique transverse magnification. The conjugate pair which have a transverse magnification of +1 are called the (front and rear) principal planes. The intersections of the principal plane with the axis are called the principal points. The distance from the rear principal point to the rear focal point is called the rear focal length, and likewise for the front focal length. *See* Focal length.



Focal system.

The focal points and principal points are four of the six gaussian cardinal points. The remaining two are a conjugate pair, also on axis, called the nodal points. They are distinguished by the fact that any conjugate pair of lines passing through them make equal angles with the axis. The function of the cardinal points and their associated planes is to simplify the mapping of the object space into the image space.

In addition to the transverse magnification, the concept of longitudinal magnification is useful. If two planes are separated axially, their conjugate planes are also separated axially. The longitudinal magnification is defined as the ratio of the image plane separation to the object plane separation.

In the case of afocal systems, any line parallel to the axis in object space has a conjugate which is also parallel to the axis. The transverse and longitudinal magnifications are constant for the system. Cardinal points do not exist for afocal systems.

The most common use of an afocal system is as a telescope, where both the object and the image are at infinity. The angular magnification is defined as the ratio of the transverse magnification to the longitudinal magnification. The power of a telescope or a pair of binoculars is the magnitude of the angular magnification. *See* MAGNIFICATION; TELESCOPE.

Real optical systems cannot obey the laws of the collinear transformation, and departures from this ideal behavior are identified as aberrations. However, if the system is examined in a region restricted to the neighborhood of the axis, the so-called paraxial region, where angles and their sines are indistinguishable from their tangents, a behavior is found which is exactly congruent with the collinear transformation. Paraxial ray tracing can therefore be used to determine the ideal collinear properties of the system.

The above discussion does not take into account the fact that the sizes of the elements of any optical system are finite, and the light that can get through the system to form the image is limited. A circular aperture which limits the cone of rays from an axial object point that gets through the system and participates in image formation is called the aperture stop of the system. An observer who looks into the front of the system from the axial object point sees not the aperture stop itself (unless it is in front of the system), but the image of it formed by the elements preceding it. This image of the aperture stop is called the entrance pupil, and is situated in the object space on the system. The image of the aperture stop formed by the rear elements is the exit pupil, and is situated in the image space of the system.

[R.V.S.]

Geometry A branch of mathematics concerned with the properties of space, including points, lines, curves, planes and surfaces in space, and figures bounded by them. For discussion of various branches of geometry *see* ALGEBRAIC GEOMETRY; DIFFERENTIAL GEOMETRY; EUCLIDEAN GEOMETRY; PROJECTIVE GEOMETRY; RIEMANNIAN GEOMETRY. [J.S.F.]

Geomorphology The study of landforms, including the description, classification, origin, development, and history of planetary surface features. Emphasis is placed on the genetic interpretation of the erosional and depositional features of the Earth's surface. However, geomorphologists also study primary relief elements formed by movements of the Earth's crust, topography on the sea floor and on other planets, and applications of geomorphic information to problems in environmental engineering.

Geomorphologists analyze the landscape. Their purview includes the structural framework of landscape, weathering and soils, mass movement and hillslopes, fluvial features, eolian features, glacial and periglacial phenomena, coastlines, and karst landscapes. Processes and landforms are analyzed for their adjustment through time, especially the most recent portions of Earth history. Geomorphologists consider processes from the perspectives of pedology, soil mechanics, sedimentology, geochemistry, hydrology, fluid mechanics, remote sensing, and other sciences. The complexity of geomorphic processes has required this interdisciplinary approach, but it has also led to a theoretical vacuum in the science. At present many geomorphologists are organizing their studies through a form of systems analysis. The landscape is conceived of as a series of elements linked by flows of mass and energy. Process studies measure the inputs, outputs, and transfers for these systems. Systems analysis provides an organizational framework within which geomorphologists are developing models to predict selected phenomena.

[V.R.B.]

Geophagia Soil ingestion by animals. Grazing animals such as sheep and cattle ingest varying amounts of soil when they graze herbage contaminated with it. Pastures become contaminated with soil when livestock walk across the herbage, particularly in wet conditions.

The amount of soil ingested by sheep and cattle is influenced by soil type, stock density, earthworm activity, management practices, and various seasonal factors. Soils that are well drained and have a strong structure do not break up so readily and contaminate the herbage as is the case for poorly drained, weak-structured soils. When the density of stock grazing in a given area of herbage is increased, the amount of treading is increased, while the herbage is grazed more closely. The overall effect is that more soil is transferred to the herbage and ingested.

Geophagia is subject to seasonal variations. The wetter and cooler conditions of autumn and winter result in muddier herbage and an increase in soil ingestion by grazing animals. During the spring and summer, the greater growth of the herbage and drier conditions result in cleaner herbage, and there is a marked decrease in intake of soil.

Soil can be a source of mineral nutrients. Since soils are higher than herbage in iron, manganese, zinc, copper, cobalt, selenium, and iodine, they may contribute to the mineral nutrition of the grazing animals. *See* AGRICULTURE; SOIL CHEMISTRY. [N.D.G.]

Geophysical exploration Making, processing, and interpreting measurements of the physical properties of the Earth with the objective of practical application of the findings. Most exploration geophysics is conducted to find commercial accumulations of oil, gas, or other minerals, but geophysical investigations are also employed with engineering objectives, in studies aimed at predicting the nature of the Earth for the foundations of roads, buildings, dams, tunnels, nuclear power plants, and other structures, and in the search for geothermal areas, water resources, archeological ruins, and so on.

Geophysical exploration is also called applied geophysics or geophysical prospecting. The physical properties and effects of subsurface rocks and minerals that can be measured at a distance include density, electrical conductivity, thermal conductivity, magnetism, radioactivity, elasticity, and other properties. Exploration geophysics is often divided into subsidiary fields according to the property being measured, such as magnetic, gravity, seismic, electrical, thermal, or radioactive properties.

Magnetic exploration. Rocks and ores containing magnetic minerals become magnetized by induction in the Earth's magnetic field so that their induced field adds to the Earth's field. Magnetic exploration involves mapping variations in the magnetic field to determine the location, size, and shape of such bodies. The magnetic susceptibility of sedimentary rock is generally orders of magnitude less than that of igneous or metamorphic rock. Consequently, the major magnetic anomalies observed in surveys of sedimentary basins usually result from the underlying basement rocks. Determining the depths of the tops of magnetic bodies is thus a way of estimating the thickness of the sediments. *See* GEOMAGNETISM; MAGNETOMETER; ROCK MAGNETISM.

Except for magnetite and a very few other minerals, mineral ores are only slightly magnetic. However, they are often associated with bodies such as dikes that have magnetic expression so that magnetic anomalies may be associated with minerals empirically. For example, placer gold is often concentrated in stream channels where magnetite is also concentrated.

Gravity exploration. Gravity exploration is based on the law of universal gravitation: the gravitational force between two bodies varies in direct proportion to the product of their masses and in inverse proportion to the square of the distance between them. Because the Earth's density varies from one location to another, the force of gravity varies from place to place. Gravity exploration is concerned with measuring these variations to deduce something about rock masses in the immediate vicinity. Gravity surveys are used more extensively for petroleum exploration than for metallic mineral prospecting. The size of ore bodies is generally small; therefore, the gravity effects are quite small and local despite the fact that there may be large density differences between the ore and its surroundings. *See* GRAVITY METER; PROSPECTING.

Seismic exploration. Seismic exploration is the predominant geophysical activity. Seismic waves are generated by one of several types of energy sources and detected by arrays of sensitive devices called geophones or hydrophones. The most common measurement made is of the travel times of seismic waves, although attention is being directed increasingly to the amplitude of seismic waves or changes in their frequency content or wave shape. *See* SEISMOLOGY.

Electrical and electromagnetic exploration. Variations in the conductivity or capacitance of rocks form the basis of a variety of electrical and electromagnetic exploration methods, which are used primarily in metallic mineral prospecting. Both natural and induced electrical currents are measured. Direct currents and low-frequency alternating currents are measured in ground surveys, and ground and airborne electromagnetic surveys involving the lower radio frequencies are made. *See* GEOELECTRICITY.

Radioactivity exploration. Natural radiation from the Earth, especially of gamma rays, is measured both in land surveys and airborne surveys. Natural types of radiation are usually absorbed by a few feet of soil cover, so that the observation is often of diffuse equilibrium radiation. The principal radioactive elements are uranium, thorium, and potassium; radioactive exploration has been used primarily in the search for uranium and other ores, such as columbium, which are often associated with them. The Geiger counter and scintillation counter are instruments generally used to detect and measure the radiation. *See* GEIGER-MÜLLER COUNTER; SCINTILLATION COUNTER.

Remote sensing. Measurements of natural and induced electromagnetic radiation made from high-flying aircraft and earth satellites are referred to collectively as remote sensing. This comprises both the observation of natural radiation in various spectral bands, including both visible and infrared radiation, such as by photography and measurements of the reflectivity of infrared and radar radiation. *See* REMOTE SENSING.

Well logging. A variety of types of geophysical measurements are made in boreholes, including self-potential, electrical conductivity, velocity of seismic waves, natural and induced radioactivity, and temperature variations. Borehole logging is used extensively in petroleum exploration to determine the characteristics of the rocks which the borehole has penetrated, and to a lesser extent in mineral exploration. *See* WELL LOGGING.

[R.E.Sh.]

Geophysical fluid dynamics

The branch of physics that studies the dynamics of naturally occurring large-scale flows in the atmosphere and oceans. Examples of such flows are weather patterns, atmospheric fronts, and ocean currents. The fluids are either air or water in a moderate range of temperatures and pressures.

Because of their large scale (from tens of kilometers up to the size of the planet), geophysical flows are strongly influenced by the diurnal rotation of the Earth, which is manifested in the equations of motion as the Coriolis force. Another fundamental characteristic is stratification, that is, density heterogeneity within the fluid in the presence of the Earth's gravitational field, which is responsible for buoyancy forces. Thus, geophysical fluid dynamics may be considered to be the study of rotating and stratified fluids. It is the common denominator of dynamical meteorology and physical oceanography. *See* CORIOLIS ACCELERATION; EARTH; METEOROLOGY; OCEANOGRAPHY.

The first of the two distinguishing attributes of geophysical fluid dynamics is the effect of the Earth's rotation. Because geophysical flows are relatively slow and spread over long distances, the time taken by a fluid particle (be it a parcel of air in the atmosphere or water in the ocean) to traverse the region occupied by a certain flow structure is comparable to, and often longer than, a day. Thus, the Earth rotates significantly during the travel time of the fluid, and rotational effects enter the dynamics. Fluid flows viewed in a rotating framework of reference are subject to two additional types of forces, namely the centrifugal force and the Coriolis force. (Properly speaking, these originate not as actual forces but as acceleration terms to correct for the fact that viewing the flow from a rotating frame—the rotating Earth in the case of geophysical fluid dynamics—demands a special transformation of coordinates.) Contrary to intuition, the centrifugal force plays no role on fluid motion because it is statically compensated by the tilting of the gravitational force caused by the departure of the Earth's shape from sphericity. Thus, of the two, only the Coriolis force acts on fluid parcels.

Variations of moisture in the atmosphere, of salinity in the ocean, and of temperature in either can modify the density of the fluid to such an extent that buoyancy forces become comparable to other existing forces. The fluid then has a strong tendency to arrange itself vertically so that the denser fluid sinks under the lighter fluid. The resulting arrangement is called stratification, the second distinguishing attribute of geophysical fluid dynamics. The greater the stratification in the fluid, the greater the resistance to vertical motions, and the more potential energy can affect the amount of kinetic energy available to the horizontal flow.

A quantity central to the understanding of geophysical flows, which are simultaneously rotating and stratified, is the potential vorticity, q. This quantity incorporates both rotation and stratification. Geophysical flows are replete with vortices, resulting from baroclinic instability. Their interactions generate highly complex flows not unlike those commonly associated with turbulence. Unlike classical fluid turbulence, however, geophysical flows are wide and thin (with, furthermore, a high degree of vertical rigidity as a result of rotational effects), and their turbulence is nearly two-dimensional.

In meteorology, geophysical fluid dynamics has been the key to understanding the essential properties of midlatitude weather systems, including the formation of cyclones and fronts. Geophysical fluid dynamics also explains the dynamical features of hurricanes and tornadoes, sea and land breezes, the seasonal formation and break-up of the polar vortex that is associated with high-latitude stratospheric ozone holes, and a host of other wind-related phenomena in the lower atmosphere. *See* CYCLONE; HURRICANE; TORNADO.

In oceanography, successes of geophysical fluid dynamics include the explanation of major oceanic currents, such as the Gulf Stream. Coastal river plumes, coastal upwelling, shelf-break fronts, and open-ocean variability on scales ranging from tens of kilometers to the size of the basin are among the many other marine applications. The El Niño phenomenon in the tropical Pacific is rooted in processes that fall under the scope of geophysical fluid dynamics. *See* EL NIÑO; GULF STREAM. [B.C.R.]

Geophysics

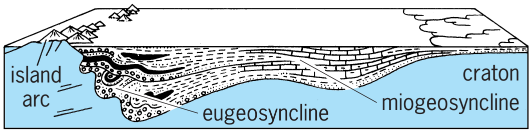
Those branches of earth sciences in which the principles and practices of physics are used to study the Earth. Geophysics is considered by some to be a branch of geology, by others to be of equal rank. It is distinguished from the other earth sciences largely by its use of instruments to make direct or indirect measurements of the parts of the Earth being studied, in contrast to the more direct observations which are typical of geology. *See* Geology.

Geophysics consists of several principal fields plus parallel and subsidiary divisions. These are commonly considered to include plutology, with geodesy, geothermometry, seismology, and tectonophysics as subdivisions; hydrospheric studies, hydrology (groundwater studies), oceanography, and glaciology; atmospheric studies, meteorology, and aeronomy; and several fields of geophysics which overlap one another, including geomagnetism and geoelectricity, geochronology, geocosmogony, and geophysical exploration and prospecting. Planetary sciences, the study of the planets and satellites aside from the Earth, are usually considered a branch of geophysics because the techniques used have been, until the first landings on each, entirely instrumental rather than directly observational. *See* Geochronometry; Geodesy; Geoelectricity; Geologic thermometry; Geomagnetism; Glaciology; Hydrology; Meteorology; Oceanography; Seismology. [B.F.H.]

Geostrophic wind A hypothetical wind based upon the assumption that a perfect balance exists between the horizontal components of the Coriolis force and the horizontal pressure gradient force per unit mass, with the implication that viscous forces and accelerations are negligible. The geostrophic wind blows parallel to the isobars (lines of equal pressure) with lower pressure to the left of the direction of the wind in the Northern Hemisphere and to the right in the Southern Hemisphere. It represents a good approximation to the actual wind at elevations greater than about 3000 ft (900 m), except in instances of strongly curved flow and in the vicinity of the Equator.

The term thermal wind denotes the net change in the geostrophic wind over some specific vertical distance. This change arises because the rate of change of pressure in the vertical is different in two air columns of different air density, so that the horizontal component of the pressure gradient force per unit mass varies in the vertical. The thermal wind is directed approximately parallel to the isotherms of air temperature with cold air to the left and warm air to the right in the Northern Hemisphere, and vice versa in the Southern Hemisphere. Thus, for example, the increasing predominance of westerly winds aloft may be viewed as a consequence of the warmth of tropical latitudes and the coldness of polar regions. *See* Coriolis acceleration; Gradient wind; Wind; Wind stress. [F.S.]

Geosyncline A linear part of the crust of the Earth that sagged deeply through time, that is, a great trough hundreds of kilometers long and tens of kilometers wide that subsided as it received thousands of meters of sedimentary and volcanic rocks through millions of years. Thicknesses are roughly 10 times greater than synchronous strata in adjacent stable regions. Linear geosynclinal belts were great subsiding tectonic divisions of the crust that lay between more stable parts of continents (cratons) or the deep abyssal ocean basins of their time, or both. Geosynclines generally contain volcanic (eugeosynclinal) and nonvolcanic (miogeosynclinal) zones (see illustration). Although defined on the basis of thickness and types of rocks, the geosyncline has always been so closely linked with the origin of mountains that it has little meaning in any other context. *See* Cordilleran belt; Orogeny; Syncline. [R.H.Dot.]



Diagrammatic section of Cordilleran geosyncline in southeastern Alaska and British Columbia at the close of Permian time (about 230 million years ago). (*After A. J. Eardley, J. Geol., 55:319–342, 1947*)

Geosynthetic Any synthetic material used in geotechnical engineering. *See* Manufactured fiber.

Geotextiles are used with foundations, soils, rock, earth, or other geotechnical material as an integral part of a manufactured project, structure, or system. These textile products are made of synthetic fibers or yarns and constructed into woven or nonwoven fabrics that weigh from 3 to 30 oz/yd^2 (100 to 1000 g/m^2). Geotextiles are more commonly known by other names, for example, filter fabrics, civil engineering fabrics, support membranes, and erosion control cloth.

Permeable geotextiles perform three basic functions in earth structures: separation, reinforcement, and filtration. Such geotextiles can thus be adapted to numerous applications in earthwork construction. The major end-use categories are stabilization (for roads, parking lots, embankments, and other structures built over soft ground); drainage (of subgrades, foundations, embankments, dams, or any earth structure requiring seepage control); erosion control (for shoreline, riverbanks, steep embankments, or other earth slopes to protect against the erosive force of moving water); and sedimentation control (for containment of sediment runoff from unvegetated earth slopes). [R.G.C.]

A geomembrane is any impermeable membrane used with soils, rock, earth, or other geotechnical material in order to block the migration of fluids. These membranes are usually made of synthetic polymers in sheets ranging from 0.01 to 0.14 in. (0.25 to 3.5 mm) thick. Geomembranes are also known as flexible membrane liners, synthetic liners, liners, or polymeric membranes.

Early liners included clay, bentonite, cement-stabilized sand, and asphalt. Modern geomembranes are commonly made of medium-density polyethylenes that are very nearly high-density polyethylenes (HDPE), several types of polyvinyl chloride (PVC), chlorosulfonated polyethylene (a synthetic rubber), ethylene propylene diene monomer (EPDM), and several other materials. Some geomembranes require reinforcement with an internal fabric scrim for added strength, or plasticization with low-molecular-weight additives for greater flexibility. *See* Polymer.

Geomembranes are able to contain fluids, thus preventing migration of contaminants or valuable fluid constituents. Since they prevent the dispersal of materials into surrounding regions, geomembranes are often used in conjunction with soil liners, permeable geotextiles, fluid drainage media, and other geotechnical support materials. The major application of geomembranes has been containment of hazardous wastes and prevention of pollution in landfill and surface impoundment construction. They are also used to a large extent in mining to contain chemical leaching solutions and the precious metals leached out of ore, in aquaculture ponds for improved health of aquatic life and improved harvesting procedures, in decorative pond construction, in water and chemical storage-tank repair and spill containment, in agriculture operations, in canal construction and repair, and in construction of floating covers for odor control, evaporation control, or wastewater treatment through anaerobic digestion. *See* Hazardous waste. [M.Cad.; H.P.]

Geothermal power Thermal or electrical power produced from the thermal energy contained in the Earth (geothermal energy). Use of geothermal energy is based thermodynamically on the temperature difference between a mass of subsurface rock and water and a mass of water or air at the Earth's surface. This temperature difference allows production of thermal energy that can be either used directly or converted to mechanical or electrical energy.

Commercial exploration and development of geothermal energy to date have focused on natural geothermal reservoirs—volumes of rock at high temperatures (up to 662°F or 350°C) and with both high porosity (pore space, usually filled with water) and high permeability (ability to transmit fluid). The thermal energy is tapped by drilling wells into the reservoirs. The thermal energy in the rock is transferred by conduction to the fluid, which subsequently flows to the well and then to the Earth's surface.

There are several types of natural geothermal reservoirs. All the reservoirs developed to date for electrical energy are termed hydrothermal convection systems and are characterized by circulation of meteoric (surface) water to depth. The driving force of the convection systems is gravity, effective because of the density difference between cold, downward-moving, recharge water and heated, upward-moving, thermal water. A hydrothermal convection system can be driven either by an underlying young igneous intrusion or by merely deep circulation of water along faults and fractures. Depending on the physical state of the pore fluid, there are two kinds of hydrothermal convection systems: liquid-dominated, in which all the pores and fractures are filled with liquid water that exists at temperatures well above boiling at atmospheric pressure, owing to the pressure of overlying water; and vapor-dominated, in which the larger pores and fractures are filled with steam. Liquid-dominated reservoirs produce either water or a mixture of water and steam, whereas vapor-dominated reservoirs produce only steam, in most cases superheated.

Although geothermal energy is present everywhere beneath the Earth's surface, its use is possible only when certain conditions are met: (1) The energy must be accessible to drilling, usually at depths of less than 2 mi (3 km) but possibly at depths of 4 mi (6–7 km) in particularly favorable environments (such as in the northern Gulf of Mexico Basin of the United States). (2) Pending demonstration of the technology and economics for fracturing and producing energy from rock of low permeability, the reservoir porosity and permeability must be sufficiently high to allow production of large quantities of thermal water. (3) Since a major cost in geothermal development is drilling and since costs per meter increase with increasing depth, the shallower the concentration of geothermal energy the better. (4) Geothermal fluids can be transported economically by pipeline on the Earth's surface only a few tens of kilometers, and thus any generating or direct-use facility must be located at or near the geothermal anomaly.

Equally important worldwide is the direct use of geothermal energy, often at reservoir temperatures less than 212°F (100°C). Geothermal energy is used directly in a number of ways: to heat buildings (individual houses, apartment complexes, and even whole communities); to cool buildings (using lithium bromide absorption units); to heat greenhouses and soil; and to provide hot or warm water for domestic use, for product processing (for example, the production of paper), for the culture of shellfish and fish, for swimming pools, and for therapeutic (healing) purposes. [J.P.M.]

The use of geothermal energy for electric power generation has become widespread because of several factors. Countries where geothermal resources are prevalent have desired to develop their own resources in contrast to importing fuel for power generation. In countries where many resource alternatives are available for power generation, including geothermal, geothermal has been a preferred resource because it cannot be transported for sale, and the use of geothermal energy enables fossil fuels to be used for higher and better purposes than power generation. Also, geothermal steam has become an attractive power generation alternative because of environmental benefits and because the unit sizes are small (normally less than 100 MW). Moreover, geothermal plants can be built much more rapidly than plants using fossil fuel and nuclear resources, which, for economic purposes, have to be very large in size. Electrical utility systems are also more reliable if their power sources are not concentrated in a small number of large units.

The most common process is the steam flash process, which incorporates steam separators to take the steam from a flashing geothermal well and passes the steam through a turbine that drives an electric generator. A more efficient utilization of the resource can be obtained by using the binary process on resources with a temperature less than 360°F (180°C). This process is normally used when wells are pumped. The pressurized geothermal brine yields its heat energy to a second fluid in heat exchangers and is reinjected into the reservoir. The second fluid (commonly referred to as the power fluid) has a lower boiling temperature than the geothermal brine and therefore becomes a vapor on the exit of the heat exchangers. It is separately pumped as a liquid before going through the heat exchangers. The vaporized, high-pressure gas then passes through a turbine that drives an electric generator. *See* ELECTRIC POWER GENERATION. [T.C.Hi.]

Geraniales An order of flowering plants, division Magnoliophyta (Angiospermae), in the superorder Rosidae of Eudicotyledon. The order consists of 6 families (Francoaceae, Geraniaceae, Greyiaceae, Ledocarpaceae, Melianthaceae, Vivianiaceae), 15 genera, and approximately 700 species. The Geraniaceae constitute the vast majority of the order and are temperate herbs or soft shrubs with deeply cleft or compound leaves (see illus.). The other families are mainly woody and are found in South America or Africa. Flowers typically have 5 sepals and petals, 10 stamens, and 5 fused carpels that separate from the central axis of the pistil when in fruit. Many of the species possess volatile compounds, as in *Pelargonium* (Geraniaceae) and *Melianthus* (Melianthaceae). *See* MAGNOLIOPHYTA; PLANT KINGDOM; ROSIDAE. [K.J.Sy.]

A common eastern United States species of geranium (*Geranium maculatum*), which is characteristic of the order Geraniales. (*A. W. Ambler, National Audubon Society*)

Gerbil The common name for 106 species of rodents, known as the sand rats, composing the subfamily Gerbillinae in the family Muridae. They inhabit the more arid regions of Africa and Asia. All species have light, soft fur and hindlegs that are longer than the front ones, enabling them to hop kangaroo fashion, although most frequently they run like typical rodents. These animals are active nocturnally and remain in their burrows during the heat of the day. In captivity they are gregarious and make good pets. *See* RODENTIA. [C.B.C.]

Germ layers The primitive cell layers, or first tissues, which appear early in the development of animals and from which the embryo body and its auxiliary membranes, when present, are constructed. These are more or less distinct anatomically, but do not necessarily have sharp boundaries of demarcation. Germ layers are almost universal among animal embryos and appear to establish discontinuities of architectural importance without complete loss of continuity. Three kinds of germ layers are recognizable: (1) the ectoderm or outer skin, (2) the endoderm or inner skin, and (3) the mesoderm or middle skin. The layers have been named in accordance with their positions in the spherical type of gastrula such as that of the sea urchin or amphibian. The terms epiblast, mesoblast, and hypoblast are sometimes used as synonyms for ectoderm, mesoderm, and endoderm, respectively. The three primary germ layers are present as a basic structural plan in all Metazoa with the exception of the coelenterates and the Porifera, in which a distinct mesodermal layer is absent. *See* GASTRULATION. [N.T.S.]

Germanium A brittle, silvery-gray, metallic chemical element, Ge, atomic number 32, atomic weight 72.59, melting point 937.4°C (1719°F), and boiling point 2830°C (5130°F), with properties between silicon and tin. Germanium is distributed widely in the Earth's crust in an abundance of 6.7 parts per million (ppm). Germanium is found as the sulfide or is associated with sulfide ores of other elements, particularly those of copper, zinc, lead, tin, and antimony. *See* PERIODIC TABLE.

Germanium has a metallic appearance but exhibits the physical and chemical properties of a metal only under special conditions since it is located in the periodic table where the transition from nonmetal to metal occurs. At room temperature there is little indication of plastic flow and consequently it behaves like a brittle material.

As it exists in compounds, germanium is either divalent or tetravalent. The divalent compounds (oxide, sulfide, and all four halides) are easily reduced or oxidized. The tetravalent compounds are more stable. Organogermanium compounds are many in number and, in this respect, germanium resembles silicon. Interest in organogermanium compounds has centered around their biological action. Germanium in its derivatives appears to have a lower mammalian toxicity than tin or lead compounds.

The properties of germanium are such that there are several important applications for this element, especially in the semiconductor industry. The first solid-state device, the transistor, was made of germanium. Single-crystal germanium is used as a substrate for vapor-phase growth of GaAs and GaAsP thin films in some light-emitting diodes. Germanium lenses and filters are used in instruments operating in the infrared region of the spectrum. Mercury-doped and copper-doped germanium are used as infrared detectors; synthetic garnets with magnetic properties may have applications for high-power microwave devices and magnetic bubble memories; and germanium additives increase usable ampere-hours in storage batteries. [P.S.G.]

GERT A procedure for the formulation and evaluation of systems using a network approach. Problem solving with the GERT (graphical evaluation and review technique) procedure utilizes the following steps:

1. Convert a qualitative description of a system or problem to a generalized network similar to the critical path method—PERT type of network.
2. Collect the data necessary to describe the functions ascribed to the branches of a network.
3. Combine the branch functions (the network components) into an equivalent function or functions which describe the network.
4. Convert the equivalent function or functions into performance measures for studying the system or solving the problem for which the network was created. These might include either the average or variance of the time or cost to complete the network.
5. Make inferences based on the performance measures developed in step 4.

Both analytic and simulation approaches have been used to perform step 4 of the procedure. GERTE was developed to analytically evaluate network models of linear systems through an adaptation of signal flow-graph theory. For nonlinear systems, involving complex logic and queuing situations, *Q*-GERT was developed. In *Q*-GERT, a simulation of the network is performed in order to obtain statistical estimates of the performance measures of interest.

GERT networks have been designed, developed, and used to analyze the following situations: claims processing in an insurance company, production lines, quality control in manufacturing systems, assessment of job performance aids, burglary resistance of buildings, capacity of air terminal cargo facilities, judicial court system operation, equipment allocation in construction planning, refueling of military airlift forces, planning and control of marketing research, planning for contractk negotiations, risk analysis in pipeline construction, effects of funding and administrative strategies on nuclear fusion power plant development, research and development planning, and system reliability. *See* DECISION THEORY; PERT; SIMULATION. [A.A.B.P.]

Gestation period In mammals, the interval between fertilization and birth. It covers the total period of development of the offspring, which consists of a preimplantation phase (from fertilization to implantation in the mother's womb), an embryonic phase (from implantation to the formation of recognizable organs), and a fetal phase (from organ formation to birth).

There is widespread confusion over the duration of the gestation period in humans because of the way in which it is defined medically. The time of ovulation, and hence the time of fertilization, is difficult to determine in humans, so for purely practical reasons doctors measure the duration of pregnancy as the interval between the last menstrual period and birth, which is typically about 40 weeks or 280 days. For comparison with other mammals, however, the true gestation period between fertilization and birth in humans is about 267 days.

The length of the gestation period in mammals depends primarily on body size and the state of development of the offspring at birth. Large-bodied mothers have big offspring that take longer to develop, and development is also prolonged for offspring that are born at an advanced stage of development. Compared to all other mammals, human beings are found to have one of the longest gestation periods relative to body size.

One remarkable feature of mammalian gestation periods is that they show very little variability within a species. After excluding exceptional cases, departures from the average usually lie in a range of no more than ±4%. This is one of the smallest degrees of variability found in any biological dimension. *See* FERTILIZATION; PREGNANCY; REPRODUCTIVE SYSTEM. [R.D.Ma.]

Geyser A natural spring or fountain which discharges a column of water or steam into the air at more or less regular intervals. Perhaps the best-known area of geysers is in Yellowstone Park, Wyoming, where there are more than 100 active geysers and more than 3000 noneruptive hot springs.

The eruptive action of geysers is believed to result from the existence of very hot rock not far below the surface. The neck of the geyser is usually an irregularly shaped tube partly filled with water which has seeped in from the surrounding rock. Far down the pipe the water is at a temperature much above the boiling point at the surface, because of the pressure of the column of water above it. Its temperature is constantly increasing, because of the volcanic heat source below. Eventually the superheated water changes into steam, lifting the column of water out of the hole. [A.N.S./R.K.Li.]

Ghost image (optics) An undesired image appearing at the image plane of an optical system. Each surface of an optical system divides the incoming light into two parts: (1) the reflected light, which returns into the first medium, and (2) the refracted light. The reflected light is again divided into two parts when it in turn strikes another dividing surface. The light thus reflected twice forms an image which may be near the plane of the primary image. This may be a false image of the object or an out-of-focus image of a bright source of light in the field of the optical system. Thus a large number of undesired or ghost images may appear. *See* OPTICAL IMAGE; REFLECTION OF ELECTROMAGNETIC RADIATION; REFRACTION OF WAVES.

If the ghost images are far out of focus, they only diminish the contrast in the primary image, a condition known as flare. But if the ghost images are near the focal plane, they are very disturbing. This effect is especially noticeable if there is a bright light source in the field of the instrument, since the ghost image of the light source may have an even greater brightness than the image of the desired object. The coating of lenses with layers of fluorite and other materials has nearly eliminated ghost images from modern optical systems. [M.J.H.]

Giant nuclear resonances Elementary modes of oscillation of the whole nucleus, closely related to the normal modes of oscillation of coupled mechanical systems. Giant nuclear resonances occur systematically in most, if not all, nuclei, with oscillation energies typically in the range of 10–30 MeV. Among the best-known examples is the giant electric dipole (E1) resonance, in which all the protons and all the neutrons oscillate with opposite phase, producing a large time-varying electric dipole moment which acts as an effective antenna for radiating gamma rays. *See* GAMMA RAYS.

Giant resonances are usually classified in terms of three characteristic quantum numbers: L, S, and T, where L is the orbital angular momentum, S is the (intrinsic) spin, and T is the isospin carried by the resonance oscillation. The number L is also the multipole order, with possible values $L = 0$ (monopole), $L = 1$ (dipole), $L = 2$ (quadrupole), $L = 3$ (octupole), and so on. The spin quantum number S is either 0 or 1. The $S = 0$ resonances are often called electric, and the $S = 1$ ones magnetic (EL or ML, where L is the multipole order), stemming from the fact that these giant resonances have strong decay modes involving the emission of either electric (for EL resonances) or magnetic (for ML resonances) multipole photons of the same multipole order as the resonance. A giant resonance with $S = 0$ corresponds to a purely spatial oscillation of the nuclear mass (or charge density), while one with $S = 1$ corresponds to a spin oscillation. The isospin quantum number T, which is also either 0 or 1, determines the relative behavior of neutrons versus protons; in a $T = 0$ or isoscalar giant resonance, the neutrons and protons oscillate in phase, whereas in a $T = 1$ or isovector resonance the neutrons and protons oscillate with opposite phase. *See* MULTIPOLE RADIATION; NUCLEAR MOMENTS.

These resonances are called giant because of their great strength, 50–100% of the theoretical limit, concentrated in a compact energy region. The oscillation energy is characteristic of the type of giant resonance and is determined by the restoring force and the nuclear mass; the force is due to the nuclear attraction between nucleons, the most important part being the component of the same multipole order as the giant resonance.

The giant electric dipole (E1) resonance is the oldest and best known of the nuclear giant resonances. It is the dominant feature in reactions initiated by gamma rays. The absorption of a gamma ray induces the giant E1 oscillation, which breaks up, in this case, by emitting neutrons. This resonance is also the dominant feature in the reverse process, in which gamma rays are produced by proton and neutron bombardments of nuclei. The resonance is isovector ($L = 1$, $S = 0$, $T = 1$).

The isoscalar giant E0 (electric monopole; $L = 0$, $S = 0$, $T = 0$) resonance lies very close in energy to the giant E1 resonance, whereas the isoscalar giant E2 (electric quadrupole; $L = 2$, $S = 0$, $T = 0$) resonance lies somewhat lower. Both are strongly excited in forward-angle inelastic scattering of energetic alpha particles.

The isoscalar E0 resonance is called the breathing mode, as the whole nucleus undergoes a purely radial oscillation, alternately expanding and contracting. The isoscalar E0 resonance energy is important in determining the nuclear compressibility.

In ordinary nuclear beta decay, a neutron inside a nucleus is transformed into a proton, and an electron and an antineutrino are produced. In one of the simplest types of beta decay, called Gamow-Teller decay, the transformed neutron is otherwise undisturbed, except that its spin may be reversed. As a result, the nucleus usually gains a small amount of energy. If beta decay involved a higher energy transfer to the nucleus, it would drive the giant Gamow-Teller resonance, which is a pure spin oscillation where the neutron spin and the proton spin oscillate out of phase ($L = 0, S = 1, T = 1$). A giant Gamow-Teller resonance is a strong feature in the (p, n) reaction in which neutrons emerge at 0° from nuclei struck by energetic protons. This reaction substitutes a proton for a neutron in the nucleus via a spin-dependent interaction, in a manner analogous to beta decay but with a much larger energy transfer.

The properties of the giant Gamow-Teller resonance are important in certain problems in nuclear astrophysics.

Studies of the giant electric dipole resonance have been extended to highly excited hot nuclei. These studies provide unique information about the properties of such nuclei, in particular their shape. The shape sensitivity arises from the resonance splitting in a deformed nucleus. The size of the splitting gives the magnitude of the deformation, whereas the relative strength of the components determines the sense of the deformation: prolate (football-shaped) or oblate (doorknob-shaped).

Giant resonances play an important role in energetic nuclear reactions occurring in nature. Among the best examples are supernovae explosions. The rate of electron capture reactions, which cool the core of the massive star involved in the explosion and accelerate its gravitational collapse, depends on the properties of the giant Gamow-Teller resonance. The strength of the shock wave created by the collapse is directly related to the nuclear compressibility discussed above in the context of the giant isoscalar E0 resonance. Higher-energy neutrinos from the central region of the star travel outward and heat the nuclei in the mantle via inelastic scattering reactions which excite various giant resonances. Certain elements found in nature may have been produced primarily as giant resonance decay products in these reactions. *See also* GRAVITATIONAL COLLAPSE; NEUTRINO; NEUTRON STAR; NUCLEAR REACTION; NUCLEAR SPECTRA; NUCLEAR STRUCTURE; RESONANCE (QUANTUM MECHANICS); SUPERNOVA. [K.A.Sn.]

Giant star An intermediate state in the evolution of a star in which it swells to enormous proportions before its death. During the longest and most stable phase of a star's life, the star, like the Sun, derives its energy from the thermonuclear fusion of hydrogen into helium deep in its dense, hot core. When the hydrogen fuel is exhausted, the core contracts and heats under the action of gravity, fresh hydrogen is ignited in a shell that surrounds the spent core, and the star becomes much more luminous, larger, and cooler at its surface. The lower surface temperature produces a redder color, hence the common term red giant. Stars like the Sun brighten by a factor of 100 and grow in radius by a factor of nearly 50.

There are actually two separate giant states. The first, described above, is terminated when the core temperature climbs so high that the helium ignites and fuses into carbon. This event stabilizes the star, but when this helium is exhausted, the earlier behavior is repeated. The star then swells to enormous proportions, perhaps two astronomical units (1.8×10^8 mi or 3×10^8 km), becoming even redder than before. It may pulsate and loses much or most of its mass through a strong wind. *See* HERTZSPRUNG-RUSSELL; STELLAR EVOLUTION. [J.B.Ka.]

Giardiasis A disease caused by the protozoan parasite *Giardia lamblia*, characterized by chronic diarrhea that usually lasts 1 or more weeks. The diarrhea may be accompanied by one or more of the following: abdominal cramps, bloating, flatulence, fatigue, or weight loss. The stools are malodorous and have a pale greasy appearance. Infection without symptoms is also common.

Giardiasis occurs worldwide. In community epidemics caused by contaminated drinking water, as many as 50 to 70% of the residents have become infected. Outbreaks also occur among backpackers and campers who drink untreated stream water. Both human and animal (beaver) fecal contamination of stream water has been implicated as the source of *Giardia* cysts in waterborne outbreaks. *Giardia* species in dogs and possibly other animals are also considered infectious for humans. Epidemics resulting from person-to-person transmission occur in day-care centers for preschool-age children and institutions for the mentally retarded. Infants and toddlers in day-care centers are more commonly infected than older children who have been toilet-trained. *See* EPIDEMIOLOGY. [D.D.J.]

Gibberellin Any of the members of a family of higher-plant hormones characterized by the *ent*-gibberellane skeleton. Some of these compounds have profound effects on many aspects of plant growth and development, which indicates an important regulatory role.

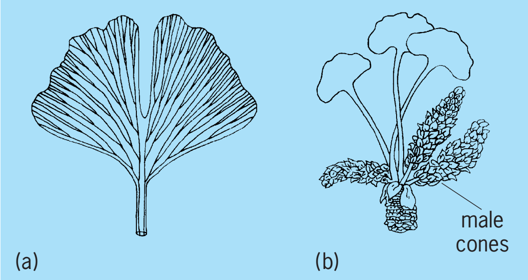
There are two classes of gibberellins: the 19-carbon gibberellins and the 20-carbon gibberellins. The 19-carbon gibberellins, formed from 20-carbon gibberellins, are the biologically active forms. Gibberellins also vary according to the position and number of hydroxyl groups linked to the carbon atoms of the *ent*-gibberellane skeleton. Hydroxylation has a profound influence on biological activity.

Probably the best-defined role for gibberellins in regulating the developmental processes in higher plants is stem growth. The cellular basis for gibberellin-induced stem growth can be either an increase in the length of pith cells in the stem or primarily the production of a greater number of cells. Applied gibberellins can often promote germination of dormant seeds, a capability suggesting that gibberellins are involved in the process of breaking dormancy. Gibberellins are intimately involved in other aspects of seed germination as well. Applied gibberellins promote or induce flowering in plants that require either cold or long days for flower induction. Gibberellin is probably not the flowering hormone or floral stimulus, because the floral stimulus appears to be identical or similar in all response types. The application of gibberellins often modifies sex expression, usually causing an increase in the number of male flowers. *See* DORMANCY; FLOWER; PLANT GROWTH; SEED.

Although gibberellins have limited use in agriculture compared with other agricultural chemicals such as herbicides, several important applications have been developed, including the production of seedless grapes. Application of gibberellin at bloom results in increased berry size and reduced berry rotting. Gibberellins are also used to increase barley malt yields for brewing and to reduce the time necessary for the malting process to reach completion. Gibberellins have found significant applications in plant breeding. Other uses for gibberellin in agriculture include reduction of rind discoloration in citrus fruits, increased yield in sugarcane, stimulation of fruit set in fruit trees, and increased petiole growth in celery. *See* PLANT HORMONES. [J.D.Me.]

Ginger An important spice or condiment; also the plant from which it is obtained, *Zingiber officinale*, of the ginger family (Zingiberaceae). The plant is a native of southeastern Asia. It is an erect perennial herb having thick, scaly, branched rhizomes which contain starch, gums, an oleoresin (gingerin) responsible for the pungent taste, and an essential oil which imparts the aroma. Ginger is used in medicine, in culinary preparations, and for flavoring beverages such as ginger ale and ginger beer. The plant is grown in China, Japan, Sierra Leone, Jamaica, Australia (Queensland), and Indonesia. *See* ZINGIBERALES. [P.D.St./E.L.C.]

Ginkgoales An order of nearly extinct gymnosperms (Pinophyta) having only one living species, the maidenhair tree (*Ginkgo biloba*). The fan-shaped leaves resemble those of the maidenhair fern. The leaves are dichotomously veined (fork-veined) and often more or less lobed (see illustration). The species is dioecious; that is, the male and female reproductive structures occur on separate trees. *Ginkgo* is widely planted on street borders, on home grounds, and in city parks. *See* PINOPHYTA. [A.Cr.]



Essential features of *Ginkgo*. (*a*) Leaf showing dichotomous venation of blade. (*b*) Spur branch with mature male cones. (*After G. M. Smith et al., A textbook of General Botany, 5th ed., Macmillan, 1953*)

Ginkgoopsida A class of largely extinct gymnosperms (Pinophyta). Included orders are Calamopityales, Callistophytales, Arberiales, Peltaspermales, Ginkgoales, Leptostrobales, Caytoniales, Pentoxylales, and Ephedrales. The most ancient taxa, Calamopityales and Callistophytales, lived during the Carboniferous; the Arberiales, from late Carboniferous into the Triassic; the Peltaspermales, from Permian through Jurassic; the Leptostrobales and Caytoniales, from Triassic into the Cretaceous; and Ginkgoales, predominantly, from Triassic into the Cretaceous periods, with one species, *Ginkgo biloba*, persisting to the present. Ephedrales is the only largely extant group, but has a pollen fossil record beginning in the Upper Triassic. *See* CAYTONIALES; EPHEDRALES; GINKGOALES.

These taxa, divergent in many characteristics, are unified by the presence in all of platyspermic (bilaterally symmetrical) seeds lacking cupules. In the most primitive, and some other, taxa of ginkgoopsids, the seeds and microsporangia are thought to have been borne on pinnately (featherlike) branched fertile structures. During the evolution of more advanced taxa, the individual microsporangia aggregated, fused to form synangia, and shifted onto leaves, causing additional changes to the microsporophylls and phyllosperms (seed-bearing leaves). In particular, the phyllosperms became greatly modified, often into peltate structures (as in advanced Peltaspermales) and stemlike structures (as in *Ginkgo*). *See* PINOPHYTA; PLANT KINGDOM. [C.B.B.]

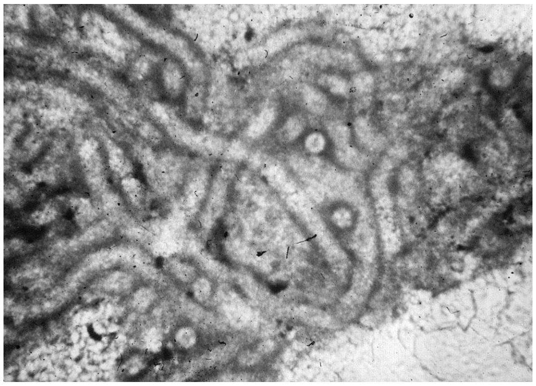
Ginseng The common name of the genus *Panax*, a group of perennial herbs of the aralia family (Araliaceae), native to the woodlands of the North Temperate Zone. *Panax schinseng* of Manchuria, extensively cultivated, was in such demand among the Chinese that the supply became insufficient. Then *P. quinquefolius* of eastern North America was discovered, and soon it was being exported to China in large quantities. The price paid for the dried roots was so high that in a relatively short time the collectors nearly exterminated the plants. Ginseng is used as a general panacea for many ills, but there is no evidence that the drug has therapeutic value. *See* APIALES. [P.D.St.; E.L.C.]

Giraffe Member of the family Giraffidae represented by a single species, *Giraffa camelopardalis*. The giraffe occurs in the savanna regions of tropical Africa. Giraffes are ruminants and belong to the mammalian order Artiodactyla (even-toed ungulates). The giraffe is the tallest of all mammals and may reach a height of 18 ft or 5.5 m. There are two prominent horns on the forehead which are bony outgrowths covered by skin, and there is a short mane along the back of the neck.

The giraffe lives in small herds with many females and usually one mature and several immature males. Gestation for the giraffe lasts about 15 months, and a single young is born. The young is about 6 ft (1.8 m) tall at the time of birth. *See* ARTIODACTYLA. [C.B.C.]

Girvanella

Girvanella A genus of fossil algae. *Girvanella* is characterized by flexuous, tubular filaments of uniform diameter, composed of thick, calcareous walls (see illus.). External diameters average between 10 and 30 micrometers. Filaments may occur free (unattached), but usually occur in groups, twisted together to form nodules and encrusting masses on various objects. The genus is intergrown with encrusting foraminifers in some Paleozoic limestones.



Girvanella **in a thin section of Cambrian limestone. Tube diameter is about 20 μm.**

Girvanella is now generally placed in the bluegreen algae (Cyanophyta). This genus is a very common fossil, with a worldwide distribution. Occurring mainly in marine rocks, it has been reported from the Cambrian to Cretaceous. The apparent absence of *Girvanella* in rocks younger than Cretaceous age has not been satisfactorily explained. *See* ALGAE. [J.L.Wr.]

Glacial epoch

Glacial epoch An informal reference to a time during the history of the Earth when there were larger ice sheets (continental size) and mountain glaciers than today. The most recent glacial epoch, better known as the Pleistocene glacial epoch, and also by the older term Quaternary period, encompassed at least the last 3,000,000 years.

Many side effects resulted from the existence of these ice sheets and glaciers, including climate changes, sea-level rise and fall, depressions of the Earth's crust, and large-scale migrations of plants, animals, and humans as well as mass extinctions. Mountain landscapes were sculptured by glaciers, and erosional and depositional landforms were formed. Ocean temperatures were cold during glaciations and warm at times of interglacials. Early human evolution, development, and migrations resulted from the ever-changing climates closely related to glacier advances and retreats.

Glacial epochs seem to recur at intervals of 200,000,000 to 250,000,000 years. In overall occurrence, all the glacial epochs that have ever occurred occupy only 5 to 10% of all geologic time. During major glacial epochs, great ice sheets formed in the high latitudes and spread out to cover as much as 40% of the Earth's land surface. Accompanying drops in temperature during some glacial epochs may have been as much as 25°F (14°C) in the mid-latitudes. During a glacial epoch, major glaciations are short-lived, each lasting less than 10,000 years, with the interglacials persisting for only about 10,000 years, so that for most of an epoch, the ice sheets either grow or diminish in size. The Pleistocene glacial epoch was distinguished by seven or eight glacial advances within the last 700,000 years. Its last glaciation ended about 9000 years ago in Fennoscandia, and less than 8000 years ago in north-central Canada. *See* GLACIAL GEOLOGY; GLACIOLOGY; PLEISTOCENE. [S.E.Wh.]

Glacial geology

Glacial geology The scientific study of the effects of glaciers on the broad land areas, on the oceans, and on climate, of their erosion and deposition, and of their modification of the Earth's surface in detail. Included in the realm of glacial geology is the history of glacial theory, consideration of the origin of glacial ages, extent and times of past glaciations, erosion and sculpturing of plains and mountains, deposition of ice-contact and meltwater sediments, and the consequences of glaciers on worldwide climate, and also on local climate around their edges. Quite distinct from glacial geology, however, is the separate, growing subscience of glaciology, the study of glaciers themselves. *See* GLACIOLOGY.

Features on the Earth's surface explained by former worldwide glaciation are numerous, embracing, for example, glacially eroded and molded valleys and mountains; ice-transported and deposited sediments and nonglacial sediments; abandoned stream channels with associated floodwater deposits; elevated silts and clays that collected around continental edges when sea level was higher; valleys eroded across and into continental shelves and slopes when sea level was much lower; communities of plants and animals similar to each other but separated by shallow seaways where land bridges once existed; fossil shells and microorganisms in deep-sea sediments reflecting colder or warmer water temperatures than today; vegetated sand dunes aligned to wind systems no longer operating; ancient shorelines and beach ridges ringing dry empty lake basins far inland; and orderly patterns of stones and fine sediments next to glacier margins in polar regions and high mountains. *See* CIRQUE; DRUMLIN; GLACIAL EPOCH; MORAINE. [S.E.Wh.]

Glaciology

Glaciology A broad field encompassing all aspects of the study of ice, specifically glaciers, the largest ice masses on Earth.

Glaciers are classified principally on the basis of size, shape, and temperature. Cirque glaciers occupy spectacular steep-walled, overdeepened basins a few square kilometers (1 km^2 = 0.36 mi^2) in area, called cirques. Most cirques are in high mountain areas that have been repeatedly inundated by ice. The cirques and the deep valleys leading away from them were, in fact, eroded by larger glaciers over the past 3 million years. *See* CIRQUE.

As a cirque glacier expands, it is usually constrained, at least initially, to move down such a valley. It then becomes a valley glacier (see illustration). Where such a valley ends in a deep fiord in the sea, the glacier is called a tidewater glacier. *See* FIORD.

In contrast, some glaciers are situated on relatively flat topography. Such glaciers can spread out in all directions from a central dome. When small, on the order of a few tens of kilometers across, these are called ice caps. Large ones, like those in Antarctica and Greenland, are ice sheets. *See* ANTARCTICA; ICE FIELD.

Thermally, glaciers are usually classified as either temperate or polar. In the simplest terms, a temperate glacier is one that is at the melting point throughout. The term melting point is used in this context rather than 0°C (32°F), because the temperature at which ice melts decreases as the pressure increases. Thus, the temperature at the base of a temperate glacier that is 500 m (1700 ft) thick will be about −0.4°C (31.2°F), but if heat energy is added to the ice, it can melt without an increase in temperature. Most valley glaciers are temperate.

In polar glaciers the temperature is below the melting point nearly everywhere. The temperature of a polar glacier increases

Storglaciären, a small valley glacier in northern Sweden.

with depth, however, because the deeper ice is warmed by heat escaping from within the Earth and by frictional heat generated by deformation of the ice. Thus, at its base, a polar glacier may be frozen to the substrate or may be at the melting point. Ice caps and ice sheets are normally polar, as are some valley glaciers in high latitudes.

As was the case with the classification based on size and shape, there is a continuum of thermal regimes in glaciers. The most common intermediate type has a surficial layer of cold ice, a few tens of meters (1 m = 3.28 ft) thick in its lower reaches, but is temperate elsewhere. Such glaciers are sometimes called subpolar or polythermal.

Glaciers exist because there are places where the climate is so cold that some or all of the winter snow does not melt during the following summer. The next winter's snow then buries that remaining from the previous winter, and over a period of years a thick snow pack or snowfield develops. Deep in such a snow pack the snow is compacted by the weight of the overlying snow. In addition, evaporation of water molecules from the tips of snowflakes and condensation of this water in intervening hollows results in rounding of grains. These processes of compaction and metamorphism gradually transform the deeper snow, normally known as firn, into ice. Melt water percolating downward into this firn may refreeze, accelerating the transformation. *See* SNOWFIELD AND NÉVÉ.

When, during a given year, the mass of snow added in the accumulation area of a glacier exceeds the mass of ice lost from the ablation area, the glacier is said to have had a positive mass balance. If such a situation persists for several years, the glacier will advance to lower elevations or more temperate latitudes, thus increasing the size of its ablation area and the mass loss. Conversely, persistent negative mass balances lead to retreat. Contrary to one implication of the word retreat, a retreating glacier does not flow backward. Rather, a glacier retreats when the ice flow toward the terminus is less than the melt rate at the terminus.

Under certain rather rare circumstances, the high subglacial water pressures that develop in the spring do not dissipate quickly but persist for weeks. This occurs under glaciers that have been thickening for several years or decades but have not advanced appreciably as a result of the thickening. On these occasions, the increase in sliding speed resulting from the increased water pressure inhibits development of an integrated subglacial conduit system, so water pressures remain high. The glacier then may advance at speeds of meters to tens of meters per day, in what is known as a surge.

Ice stream flow occurs in some parts of the Antarctic Ice Sheet. These high flow rates occur in streams of ice tens of kilometers wide and hundreds of kilometers long, and are sustained for centuries. These streams are bounded not by valley sides but by ice that is moving much more slowly. Ice Stream B, for example, which drains to the Ross Ice Shelf in West Antarctica, has a maximum speed of 825 m/yr, while ice on either side of it is moving at only 10–20 m/yr. The high speeds of these ice streams are attributed to slippery conditions at the bed, where high water pressures reduce friction between the ice and the bed. Changes in paths of water flow at the bed are believed to be responsible for the changes in ice stream activity.

Among the hazards associated with glaciers are jökulhlaups, or sudden releases of water from lakes dammed by glaciers. Jökulhlaup is an Icelandic word; it has entered the vocabulary of geology because such floods are common in Iceland where localized volcanic heat is responsible for the presence of deep lakes surrounded by ice. In other regions, the lakes are more commonly formed where a glacier in a trunk valley extends across the open mouth of a tributary valley. *See* GLACIAL GEOLOGY.

[R.LeB.H.]

Gland A structure which produces a substance or substances essential and vital to the existence of the organism and species. Glands are classified according to (1) the nature of the product; (2) the structure; (3) the manner by which the secretion is delivered to the area of use; and (4) the manner of cell activity in forming secretion. A commonly used scheme for the classification of glands follows.

I. Morphological criteria
  A. Unicellular (mucous goblet cells)
  B. Multicellular
    1. Sheets of gland cells (choroid plexus)
    2. Restricted nests of gland cells (urethral glands)
    3. Invaginations of varying degrees of complexity
      a. Simple or branched tubular (intestinal and gas-tric glands)—no duct interposed between surface and glandular portion
      b. Simple coiled (sweat gland)—duct interposed between glandular portion and surface
      c. Simple, branched, acinous (sebaceous gland)—glandular portion spherical or ovoid, connected to surface by duct
      d. Compound, tubular glands (gastric cardia, renal tubules)—branched ducts between surface and glandular portion
      e. Compound tubular-acinous glands (pancreas, parotid gland)—branched ducts, terminating in secretory portion which may be tubular or acinar
II. Mode of secretion
  A. Exocrine—the secretion is passed directly or by ducts to the exterior surface (sweat glands) or to another surface which is continuous with the external surface (intestinal glands, liver, pancreas, submaxillary gland)
  B. Endocrine—the secretion is passed into adjacent tissue or area and then into the bloodstream directly or by way of the lymphatics; these organs are usually circumscribed, highly vascularized, and usually have no connection to an external surface (adrenal, thyroid, parathyroid, islets of Langerhans, parts of the ovary and testis, anterior lobe of the hypophysis, intermediate lobe of the hypophysis, groups of nerve cells of the hypothalamus, and the neural portion of the hypophysis)
  C. Mixed exocrine and endocrine glands (liver, testis, pancreas)
  D. Cytocrine—passage of a secretion from one cell directly to another (melanin granules from melanocytes in the connective tissue of the skin to epithelial cells of the skin)
III. Nature of secretion
  A. Cytogenous (testis, perhaps spleen, lymph node, and bone marrow)—gland "secretes" cells
  B. Acellular (intestinal glands, pancreas, parotid gland)—gland secretes noncellular product

IV. Cytological changes of glandular portion during secretion
   A. Merocrine (sweat glands, choroid plexus)—no loss of cytoplasm
   B. Holocrine (sebaceous glands)—gland cells undergo dissolution and are entirely extruded, together with the secretory product
   C. Apocrine (mammary gland, axillary sweat gland)—only part of the cytoplasm is extruded with the secretory product
V. Chemical nature of the product
   A. Mucous goblet cells (submaxillary glands, urethral glands)—the secretion contains mucin
   B. Serous (parotid gland, pancreas)—the secretion does not contain mucin [O.E.N.]

Glanders A contagious zoonosis affecting primarily horses, mules, and donkeys and caused by the bacterium *Burkholderia (Pseudomonas) mallei*. Glanders (farcy) was once common throughout the world but is now found only in parts of Africa, Russia, and Asia. *Burkholderia mallei* is a gram-negative, non-acid-fast, nonsporulating, nonmotile, unencapsulated bacillus occasionally showing bipolar staining; it is obligately aerobic and oxidase-positive. *Burkholderia mallei* is highly infectious for humans, who may acquire it by handling or treating glanderous animals or during laboratory investigations. *See* ZOONOSES.

Glanders is usually contracted by ingestion of contaminated food or water, by contact, and by inhalation of infectious droplets. All equids are highly susceptible. The disease is usually acute and often fatal in donkeys and mules, and chronic in horses, some of which may ultimately recover but continue to carry *B. mallei*. It is characterized by formation of nodules and ulcerations of the skin and respiratory membranes and by granulomatous nodules in the lungs, lymphatic channels, and lymph nodes.

Although *B. mallei* is sensitive to sulfonamides and tetracyclines, affected horses are not usually treated since destruction of cases has been found to be extremely effective in control and eradication. Essential components of diagnosis include clinical examinations at frequent intervals to detect the cutaneous and nasal forms; immunological tests to detect serum antibody; and skin and intradermopalpebral (within the skin of the eyelid) injection of mallein, a glycoprotein of *B. mallei*, to detect hypersensitivity. *See* AGGLUTINATION REACTION; COMPLEMENT-FIXATION TEST; HYPERSENSITIVITY. [J.F.T.]

Glass Materials made by cooling certain molten materials in such a manner that they do not crystallize but remain in an amorphous state, their viscosity increasing to such high values that, for all practical purposes, they are solid. Materials having this ability to cool without crystallizing are relatively rare, silica, SiO_2, being the most common example. Although glasses can be made without silica, most commercially important glasses are based on it. The most important properties are viscosity; strength; index of refraction; dispersion; light transmission (both total and as a function of wavelength); corrosion resistance; and electrical properties.

Chemically, most glasses are silicates. Silica by itself makes a good glass (fused silica), but its high melting point (1723°C or 3133°F) and its high viscosity in the liquid state make it difficult to melt and work. To lower the melting temperature of silica to a more convenient level, soda, Na_2O, is added in the form of sodium carbonate or nitrate, for example. This has the desired effect, but unfortunately the resulting glass has no chemical durability and is soluble even in water (water glass). To overcome this problem, lime, CaO, is added to the glass to form the basic soda-lime-silica glass composition which is used for the bulk of common glass articles, such as bottles and sheet (window) glass. Although these are the main ingredients, commercial glass contains other oxides (aluminum and magnesium oxides) and ingredients to help in oxidizing, fining, or decolorizing the glass batch.

Special kinds of glass have other oxides as major ingredients. For example, boron oxide is added to silicate glass to make a low-thermal-expansion glass for chemical glassware which must stand rapid temperature changes, for example, Pyrex glass. Also, lead oxide is used in optical glass because it gives a high index of refraction. [J.F.McM.]

Glass switch A glassy, solid-state device used to control the flow of electric current. Useful solid-state devices can be made from glassy as well as crystalline semiconductors. A glass is a special case of a noncrystalline class of materials, namely, amorphous solids. These do not exhibit long-range order, although they tend to have the same local structure (that is, short-range order) as the corresponding crystal. A glass is an amorphous solid that is formed by cooling rapidly from the liquid phase.

The first applications of glassy semiconductors were switches made from chalcogenide (that is, alloys containing tellurium, selenium, or sulfur) glasses. The two basic structures are known as the Ovonic Threshold Switch (OTS) and the Ovonic Memory Switch (OMS). They are active devices consisting simply of a thin film (about 10–100 nanometers thick) of glass between two metallic contacts. The device characteristics depend on the bulk properties of the semiconductor material rather than on the contacts. Consequently, the switches are symmetrical in that they respond identically to voltages and currents of both polarities. The OMS and OTS differ in terms of the composition of their amorphous semiconductor thin-film materials and their functional performance.

Amorphous semiconductors can be formulated so they can be doped by adding small amounts of impurities to change their electrical properties in the same way as crystalline semiconductors, or they can be designed to be insensitive to the effects of impurities. The glass switches typically use impurity-independent material compositions, and they are also highly resistant to the effects of radiation.

Both the OTS and OMS show a rapid and reversible transition between a highly resistive and a conductive state effected by applied electric fields. The main difference between the two devices is that, after being brought from the highly resistive state to the conducting state, the OTS returns to its highly resistive state when the current falls below a holding current value. On the other hand, the OMS remains in the conducting state until a current pulse returns it to its highly resistive state. The OMS thereby remembers the last applied switching command, and it is from this property that the device receives its name.

Integrated arrays of OMSs can be used as electrically erasable programmable read-only memories (EEPROMs). Readout of these devices is extremely rapid, limited only by the readout circuit's characteristics; and, because of the capability of the OMS to be programmed into a number of selected conductivity states, more than one bit of data can be stored in each memory cell. *See* COMPUTER STORAGE TECHNOLOGY; SEMICONDUCTOR MEMORIES.

The OMS can be used as an electrically reconfigurable electrical interconnection in neural networks. In this application it provides a simple, high-density means to accomplish the many thousands or millions of programmable electrical interconnections required in practical neural-network circuits that can exhibit artificial intelligence. *See* NEURAL NETWORK.

A transistor, using an OTS as the emitter, has been developed. This can be used as a threshold amplifier, as a threshold latching amplifier, or as the basis for a computer using ternary logic. Other promising application areas include ac control and microwave generation. *See* AMORPHOUS SOLID; GLASS; SEMICONDUCTOR. [S.R.O.; D.A.]

Glass transition The transition that occurs when a liquid is cooled to an amorphous or glassy solid. This can occur only if the cooling rate is fast enough to prevent crystallization which would otherwise occur if time had been sufficient for the sample to reach true equilibrium at each temperature. Since the crystal is invariably the thermodynamically stable low-temperature phase, the glass transition corresponds to a transition from a high-temperature liquid into a nonequilibrium metastable low-temperature solid. *See* AMORPHOUS SOLID; CRYSTAL; VISCOSITY.

For many organic and polymeric systems, the difficulty of molecular packing and the steric hindrances are sufficient to prevent crystallization, and glass formation in these systems is relatively easy. In other systems, for example, metallic systems, rapid quench rates on the order of 10^6 K/s (2×10^6 °F/s) may be necessary to avoid crystallization, suggesting that any system can be quenched from the liquid state to an amorphous glassy state assuming that the system can be cooled rapidly enough. *See* GLASS; METALLIC GLASSES. [G.S.G.]

Glaucoma A disease of the eye in which damage is caused by elevated pressure within the eye. The incidence in persons over the age of 40 is about 0.5%, making glaucoma one of the most common and serious eye disorders, surpassed in the United States only by cataracts as a cause of blindness. *See* CATARACT; VISUAL IMPAIRMENT.

The normal pressure within the eye measures 10–20 mmHg (1.3–2.7 kilopascals) and is maintained by a delicate balance between the inflow and outflow of fluid called aqueous humor. *See* EYE (VERTEBRATE).

Four major types of glaucoma have been identified: (1) congenital or infantile glaucoma, which is evident at birth or shortly thereafter; (2) primary open-angle glaucoma, the most common kind, which is usually painless and is marked by a blockage in the outflow channels; (3) primary (acute) angle-closure glaucoma, in which the root of the iris interrupts drainage and causes a sudden painful blockage and acute rise in internal pressure; and (4) subacute or chronic angle-closure glaucoma, in which the root or base of the iris falls across the drain temporarily but repeatedly, resulting in transient increases in pressure but with scarring after each episode until the drain can no longer become unblocked. Secondary glaucoma results from inflammation, injury, surgery, or eye diseases such as swollen cataract.

Infantile glaucoma often enlarges the eye because of a lack of rigidity in its white coat, known as the sclera; the condition is called buphthalmos. Angle-closure glaucoma is marked by pain, sudden visual loss, and a steamy or cloudy cornea; the semidilated and fixed pupil does not respond to changes in light intensity. In chronic angle-closure glaucoma, the periodic rises in pressure are accompanied by the above symptoms and also by halo vision, that is, the person sees haloes around a light source. In the most common type of glaucoma, the asymptomatic open-angle form, the chief threat is a gradual, imperceptible loss of vision. The disease is bilateral, with progressive field loss mostly in the periphery where it escapes notice.

Blindness can usually be prevented by early treatment to maintain normal eye pressure. Eye drops or oral medication is usually effective, reducing the flow of aqueous humor into the eye and increasing its outflow. If medication fails, as in angle-closure glaucoma, or if sudden complete blockage occurs, surgery is indicated. [J.Hart.]

Glauconite The term glauconite as currently used has a two-fold meaning. It is used as both a mineralogic and morphologic term. The mineral glauconite is defined as an illite type of clay mineral. A fundamental characteristic of glauconite is that the unit cell is composed of a single silicate layer rather than the double layer of most other dioctahedral micas. *See* CLAY MINERALS; ILLITE.

Glauconite is known to occur in flakes and as pigmentary materials. When used in the morphological sense, the term glauconite often refers to small, green, spherical, earthy pellets. Some of these pelletal varieties are composed solely of the mineral described above, others are a mixed-layer association of this mineral and other three-layer structures.

Glauconite forms during marine diagenesis, in relatively shallow water, and at times of slow or negative deposition. Glauconite has been identified in both recent and ancient sediments. It is a major component in some “greensand” deposits and has been used commercially for the extraction of potassium from such sources. *See* AUTHIGENIC MINERALS; DIAGENESIS; MARINE SEDIMENTS. [F.M.W.; R.E.Gr.]

Glaucophane A monoclinic sodic amphibole with composition close to $Na_2(Mg_3Al_2)Si_8O_{22}(OH)_2$. This mineral exhibits a characteristic blue color with distinct pleochroism from colorless to lavender blue when viewed in thin section by plane-polarized light. Outcrops of glaucophane-rich metamorphic rocks are commonly blue and tend to have good foliation; these rocks are called blueschists. *See* BLUESCHIST; PLEOCHROISM.

Glaucophane is an index mineral of blueschist, which is generated under unusually high pressures at low temperatures in a tectonic environment exclusively associated with a subducted lithospheric slab or related tectonic loading. The glaucophane-bearing assemblages occur in recrystallized graywackes and pelitic rocks and in metabasites and metacherts of oceanic affinity; they are typically found in subduction zone complexes at plate boundaries, a setting first recognized in the Jurassic and Cretaceous Franciscan Complex of northern California. Blueschists are most common and best developed in Mesozoic and Cenozoic terranes: some Paleozoic and even latest Precambrian blueschists have been described in Russia and China. Blueschists formed earlier in geologic time may have been eroded or been recrystallized under normal geothermal conditions. The preservation of glaucophane in blueschists of continental or island arc margins indicates either rapid uplift or maintenance of low geothermal gradients by steady-state subduction for tens of million years. *See* GRAYWACKE; SUBDUCTION ZONES. [J.G.L.; R.Y.Z.; S.Maru.]

Glazing The application of finely ground glass, or glass-forming materials, or a mixture of both, to a ceramic body and heating (firing) to a temperature where the material or materials melt, forming a coating of glass on the surface of the ware. Glazes are used to decorate the ware, to protect against moisture absorption, to give an easily cleaned sanitary surface, and to hide a poor body color.

Glazes are classified and described by the following characteristics: surface—glossy or matte; optical properties—transparent or opaque; method of preparation—fritted or raw; composition—such as lead, tin, or boron; maturing temperature; and color. Opaque glazes contain small crystals embedded in the glass, but special glazes in which a few crystals grow to recognizable size are called crystalline glazes. *See* CERAMICS; GLASS. [J.F.McM.]

Glide-path indicator An aircraft landing instrument that provides the pilot with a set of vertical and horizontal cross pointers that indicate deviation from a radio-transmitted course to the threshold of the runway. A dual-frequency transmitter sends out one frequency to the right of the runway center line and a second frequency to the left of the runway center line. The reception of these signals in the aircraft biases the vertical needle to the left or right depending on the position of the aircraft relative to the transmitted 5° localizer path. Simultaneously, another dual-frequency transmitter causes a horizontal needle to indicate high or low as the aircraft descent path is compared to the transmitted 3° glide path. [J.W.A.]

Glider An unpowered flying device that attempts to copy the flight of soaring birds. In October 1911, Orville Wright made a gliding flight of nearly 10 min duration, and demonstrated that gliders could stay up for long periods in rising air. This condition of flight, called slope soaring, was the basic method of soaring flight until about 1930. Thermal soaring, the next step, was accomplished by flying in areas of rising convection currents. By the use of thermal flight, the modern glider can fly almost anywhere in the world for extended time and distances over 500 mi (800 km) in one flight. Other methods of soaring make use of clouds and standing-wave phenomena in the atmosphere. High-performance gliders (sailplanes) may be launched by towing behind powered aircraft or by car towing, which is used to a lesser extent. Some gliders have been fitted with a small motor and propeller, which enables them to take off and climb to an altitude where rising air permits them to soar unpowered. [F.M.R.]

Sailplane construction traditionally has been of wood and plywood, although the use of aluminum alloy has become common. The use of fiber glass as primary structure has also come into prominence, since it is possible to produce the external shapes in accurate molds with greater precision, resulting in improved performance. [E.S.]

Modern foot-launched hang gliders with aluminum tube frames have flown over 100 mi (160 km) in straight-line distance, have reached about 20,000 ft (6000 m) altitude, and have remained aloft more than 15 h. But it is not so much their performance that makes hang gliders popular, but their low cost, their convenience of folding into a small package for transport or storage, and the fact that no license is required for glider or pilot. [F.M.R.]

Global climate change The periodic fluctuations in global temperatures and precipitation, such as the glacial (cold) and interglacial (warm) cycles of the Pleistocene (a geological period from 1.8 million to 10,000 years ago). Presently, the increase in global temperatures since 1900 is of great interest. Many atmospheric scientists and meteorologists believe it is linked to human-produced carbon dioxide (CO_2) in the atmosphere.

Greenhouse effect. The greenhouse effect is a process by which certain gases (water vapor, carbon dioxide, methane, nitrous oxide) trap heat within the Earth's atmosphere and thereby produce warmer air temperatures. These gases act like the glass of a greenhouse: they allow short (ultraviolet; UV) energy waves from the Sun to penetrate into the atmosphere, but prevent the escape of long (infrared) energy waves that are emitted from the Earth's surface. *See* ATMOSPHERE; GREENHOUSE EFFECT.

Human-induced changes in global climate caused by release of greenhouse gases into the atmosphere, largely from the burning of fossil fuels, have been correlated with global warming. Since 1900, the amount of two main greenhouse gases (carbon dioxide and methane) in the Earth's atmosphere has increased by 25%. Over the same period, mean global temperatures have increased by about 0.5°C (0.9°F). The most concern centers on carbon dioxide. Not only is carbon dioxide produced in much greater quantities than any other pollutant, but it remains stable in the atmosphere for over 100 years. Methane, produced in the low-oxygen conditions of rice fields and as a by-product of coal mining and natural gas use, is 100 times stronger than carbon dioxide in its greenhouse effects but is broken down within 10 years.

Chloroflurocarbon (CFC) pollution, from aerosol propellants and coolant systems, affects the Earth's climate because CFCs act as greenhouse gases and they break down the protective ozone (O_3) layer. Other pollutants released into the atmosphere are also likely to influence global climate. Sulfur dioxide (SO_2) from car exhaust and industrial processes, such as electrical generation from coal, cool the Earth's surface air temperatures and counteract the effect of greenhouse gases. Nevertheless, there have been attempts in industrialized nations to reduce sulfur dioxide pollution because it also causes acid rain. *See* AIR POLLUTION; OZONE.

Possible impact. A rise in mean global temperatures is expected to cause changes in global air and ocean circulation patterns, which in turn will alter climates in different regions. Changes in temperature and precipitation have already been detected. In the United States, total precipitation has increased, but it is being delivered in fewer, more extreme events, making floods (and possibly droughts) more likely. *See* OCEAN CIRCULATION.

Global warming has caused changes in the distribution of a species throughout the world. By analyzing preserved remains of plants, insects, mammals, and other organisms which were deposited during the most recent glacial and interglacial cycles, scientists have been able to track where different species lived at times when global temperatures were either much warmer or much cooler than today's climate. Several studies have documented poleward and upward shifts of many plant and insect species during the current warming trend.

Changes in the timing of growth and breeding events in the life of an individual organism, called phenological shifts, have resulted from global warming. For example, almost one-third of British birds are nesting earlier (by 9 days) than they did 25 years ago, and five out of six species of British frog are laying eggs 2–3 weeks earlier.

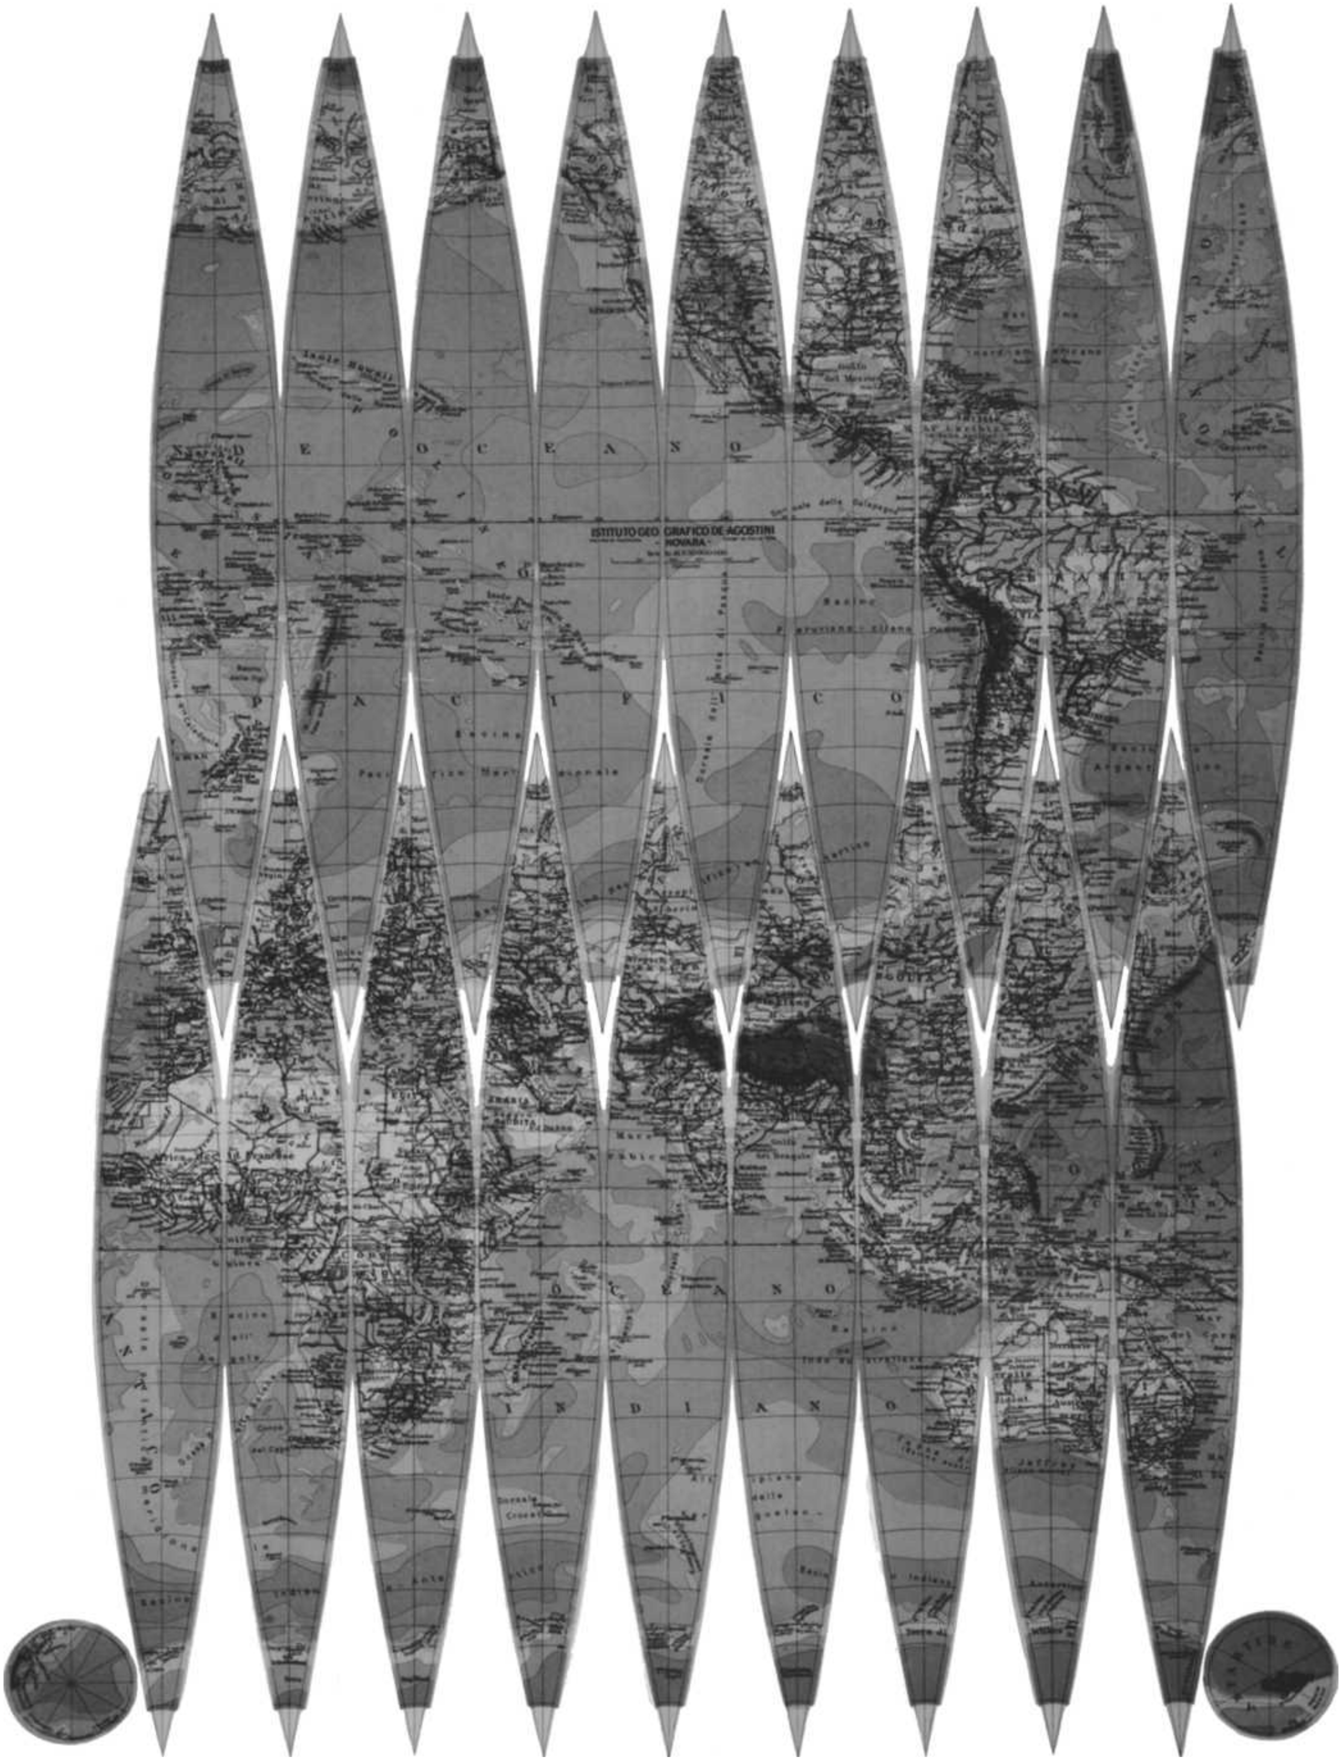
Community reassembly, changes in the species composition of communities, has resulted from climate change because not all species have the same response to environmental change.

To date, there have been no extinctions of species directly attributable to climate change. However, there is mounting evidence for drastic regional declines. For example, the abundance of zooplankton (microscopic animals and immature stages of many species) has declined by 80% off the California coast. This decline has been related to gradual warming of sea surface temperatures. *See* CLIMATE HISTORY; CLIMATE MODIFICATION; CLIMATIC PREDICTION; EXTINCTION (BIOLOGY). [C.Pa.]

Globe (Earth) A sphere on the surface of which is a map of the world. The map may be drawn, engraved, or painted directly on the surface but is more commonly prepared as a series of gores, or segments in other designs, to be affixed to the globe ball (see illustration).

Globes are both artistically interesting and scientifically useful. Their principal value is in stimulating sound concepts of worldwide patterns and in rectifying errors induced by the limitations of flat maps. All flat maps distort the Earth's surface patterns, but carefully made globes constitute truer scale models of the Earth, with correct areas, shapes, and distances as well as continuity of surface. Globes have long been used as aids in navigation, in the teaching of earth sciences, and as room ornaments.

Many modern globes have special attachments to improve their utility. A meridian ring, extending from pole to pole, may be calibrated in degrees to measure latitude. The longitude of points directly beneath that ring will be indicated at the intersection of the ring with the equatorial scale. A horizon ring at right angles to the meridian ring may be calibrated in miles or in meters, degrees, and hours to expedite distance and time measurement. A



Globe gores from collections of Library of Congress. (*Istituto Geografico de Agostini, Novara, Italy*) hinged horizon ring may be lifted to serve as a meridian ring, or placed in an oblique position to show great circle routes and distances. [A.C.G.]

Globule A small, opaque nebula seen in silhouette against a rich star field or a bright nebula. Globules were first cataloged in the 1920s. In 1947, B. J. Bok called attention to their potential significance for star formation, and since then they have been commonly known as Bok globules. A globule is a region of the interstellar medium containing a high density of interstellar grains that obscure the more distant background stars and cause the region to appear as a dark nebula in optical photographs. Only relatively nearby globules can be identified, because if there are many stars in front of the nebula the contrast with the background is too weak. *See* NEBULA.

The material contained in interstellar grains represents only a small fraction (about 1%) of the total mass of a globule; most of its mass is in gaseous form. The grains play a key role in shielding the nebular gas from the surrounding starlight, thus creating an environment in which molecules can survive and interact. Radio astronomers have been able to detect carbon monoxide (CO) emission lines in dark nebulae, and in the densest cores of nebulae heavier molecules have been identified. Dark nebulae are now commonly called molecular clouds; the most abundant molecule is molecular hydrogen, but it is difficult to detect directly. *See* INTERSTELLAR MATTER; MOLECULAR CLOUD; RADIO ASTRONOMY.

A typical (molecular core) globule has a diameter of 0.1 parsec (1 parsec $= 1.9 \times 10^{13}$ mi or 3.1×10^{13} km) and mass four times that of the Sun; larger, more massive globules are also known. The kinetic temperature in a globule is low; it is estimated to be about 10 K (−442°F).

Calculations predict that in the absence of internal support a typical globule undergoes gravitational collapse in less than a million years to produce one or more protostars. Some but not all globules have given birth to protostars, and these probably represent the youngest stars of the Milky Way. *See* PROTOSTAR; STELLAR EVOLUTION. [B.T.L.]

Globulin A general name for any member of a heterogeneous group of serum proteins precipitated by 50% saturated ammonium sulfate. *See* PROTEIN; SERUM.

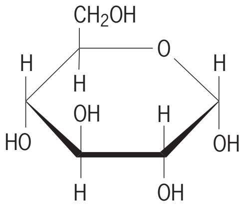
The introduction of electrophoresis during the 1930s permitted subdivision of the globulins into alpha, beta, and gamma globulins on the basis of relative mobility at alkaline pH (8.6). However, each of these subgroups, though electrophoretically homogeneous, consists of a great variety of proteins with different biological properties and markedly different sizes and chemical properties other than net charge. Thus the α_2-globulins, for example, as defined by moving boundary or paper electrophoresis, contain proteins ranging in molecular weight from approximately 50,000 to approximately 1,000,000 (α_2-macroglobulin), each with differing functions. *See* ELECTROPHORESIS; IMMUNOGLOBULIN. [H.H.F.]

Glow discharge A mode of electrical conduction in gases. Glow discharge commonly occurs under conditions of relatively low pressure and generally in the pressure range of 1–10 mm of mercury (10^2–10^3 pascals), The discharge typically gives off light, so that the region of the discharge appears to glow with considerable intensity. This glow is quite diffuse as contrasted to a higher-pressure discharge, such as a high-pressure arc. Typical currents may be of the order of tens or hundreds of milliamperes, whereas the potential drop may be of the order of 100 volts.

The most important application of the glow discharge is in the so-called voltage regulator or voltage reference tube. This device maintains a relatively constant difference of potential across itself as the current is varied over an appreciable range, and consequently is very useful in cases where a constant reference potential is required. *See* ELECTRIC SPARK; ELECTRICAL CONDUCTION IN GASES. [G.H.M.]

Glucagon The protein hormone secreted by the pancreas which is known to influence a wide variety of metabolic reactions. Glucagon, along with insulin and other hormones, plays a role in the complex and dynamic process of maintaining adequate supplies of sugar in the blood. Glucagon has often been called the hyperglycemic-glycogenolytic factor because it causes the breakdown of liver glycogen to sugar (a process known as glycogenolysis) and thereby increases the concentration of sugar in the bloodstream (a condition known as hyperglycemia). Glucagon may also be involved in the regulation of protein and fat metabolism, gastric acid secretion and gut motility, excretion of electrolytes (such as sodium, potassium and chloride) by the kidney, contractility of heart muscle, and release of insulin from the pancreas. Glucagon is used in human medicine chiefly in certain diabetic conditions when a dangerously low blood sugar must be rapidly raised. *See* CARBOHYDRATE METABOLISM; DIABETES; GLYCOGEN; HORMONE; INSULIN; PANCREAS. [W.W.Bro.]

Glucose A monosaccharide also known as D-glucose, D-glucopyranose, grape sugar, corn sugar, dextrose, and cerelose. The structure of glucose is shown in the illustration.



Structural formula for α-D-glucose.

Glucose in free or combined form is not only the most common of the sugars but is probably the most abundant organic compound in nature. It occurs in free state in practically all higher plants. It is found in considerable concentrations in grapes, figs, and other sweet fruits and in honey. In lesser concentrations, it occurs in the animal body fluids, for example, in blood and lymph. Urine of diabetic patents usually contains 3–5%.

Cellulose, starch, and glycogen are composed entirely of glucose units. Glucose is also a major constituent of many oligosaccharides, notably sucrose, and of many glycosides. It is produced commercially from cornstarch by hydrolysis with dilute mineral acid. The commercial glucose so obtained is used largely in the manufacture of confections and in the wine and canning industries. *See* CELLULOSE; GLYCOGEN; STARCH.

D-Glucose is the principal carbohydrate metabolite in animal nutrition; it is utilized by the tissues, and it is absorbed from the alimentary tract in greater amounts than any other monosaccharide. Glucose could serve satisfactorily in meeting at least 50% of the entire energy needs of humans and various animals.

Glucose enters the bloodstream by absorption from the small intestine. It is carried via the portal vein to the liver, where part is stored as glycogen, the remainder reentering the circulatory system. Another site of glycogen storage is muscle tissue.

Glucose is readily fermented by yeast, producing ethyl alcohol and carbon dioxide. It is also metabolized by many bacteria, resulting in the formation of various degradation products, such as hydrogen, acetic and butyric acids, butyl alcohol, acetone, and many others. *See* CARBOHYDRATE; MONOSACCHARIDE.

Gluons The hypothetical force particles believed to bind quarks into "elementary" particles. Although theoretical models in which the strong interactions of quarks are mediated by gluons have been successful in predicting, interpreting, and explaining many phenomena in particle physics, free gluons remain undetected in experiments (as do free quarks). According to prevailing opinion, an individual gluon cannot be isolated.

According to quantum chromodynamics (QCD), the mediators of the strong interaction are eight massless vector bosons, which are named gluons because they make up the "glue" that binds quarks together. It is hoped that the infinite range of the forces mediated by the gluons may help to explain why free quarks have not been isolated. The gluons themselves carry color. Hence, strong interactions among gluons will also occur through the exchange of gluons. It is therefore believed that gluons, as well as quarks, may be permanently confined. According to this view, only colorless objects may exist in isolation. *See* ELEMENTARY PARTICLE; QUANTUM CHROMODYNAMICS; QUARKS. [C.Q.]

Glycerol The simplest trihydric alcohol, with the formula $CH_2OHCHOHCH_2OH$. The name glycerol is preferred for the pure chemical, but the commercial product is usually called glycerin. It is widely distributed in nature in the form of its esters, called glycerides. The glycerides are the principal constituents of the class of natural products known as fats and oils.

When pure, glycerin is a colorless, odorless, viscous liquid with a sweet taste. It is completely soluble in water and alcohol but is only slightly soluble in many common solvents, such as ether, ethyl acetate, and dioxane. Glycerin is insoluble in hydrocarbons. It boils at 290°C (554°F) at atmospheric pressure and melts at 17.9°C. Its specific gravity is 1.262 at 25°C (77°F) referred to water at 25°C, and its molecular weight is 92.09. It has a very low mammalian toxicity.

Glycerin is used in nearly every industry. With dibasic acids, such as phthalic acid, it reacts to make the important class of products known as alkyd resins, which are widely used as coating and in paints. It is used in innumerable pharmaceutical and cosmetic preparations; it is an ingredient of many tinctures, elixirs, cough medicines, and anesthetics; and it is a basic medium for toothpaste. In foods, it is an important moistening agent for baked goods and is added to candies and icings to prevent crystallization. It is used as a solvent and carrier for extracts and flavoring agents and as a solvent for food colors. Many specialized lubrication problems have been solved by using glycerin or glycerin mixtures. Many millions of pounds are used each year to plasticize various materials.

Several grades of glycerin are marketed, including high gravity, dynamite, yellow distilled, USP (U.S. Pharmacopoeia), and CP (chemically pure). USP grade is water-white and suitable for use in foods, pharmaceuticals, and cosmetics, or for any purpose where the product is designed for human consumption. *See* ALCOHOL; FAT AND OIL; POLYOL. [P.H.C.]

Glycogen The primary reserve polysaccharide of the animal kingdom. It is found in the muscles and livers of all higher animals, as well as in the cells of lower animals. Because of its close relationship to starch, it is often called animal starch, although glycogen is found in some lower plants, fungi, yeast, and bacteria. *See* STARCH.

Glycogen is a nonreducing, white, amorphous polysaccharide which dissolves readily in cold water, forming an opalescent, colloidal solution. The molecular weight of glycogen is usually very high, and it varies with the source and the method of preparation; molecular weights of the order of $1-20 \times 10^6$ have been reported. Chemical studies show glycogen to possess a branched structure similar to the amylopectin starch fraction.

In its biochemical reactions, glycogen is similar to starch. It is attacked by the same plant amylases that attack starch, and like starch, it is degraded to maltose and dextrins. Both glycogen and starch are broken down by animal or plant phosphorylase enzyme in the presence of inorganic phosphate with the production of α-D-glucose-1-phosphate. *See* CARBOHYDRATE METABOLISM.

The metabolic formation of glycogen from glucose in the liver is frequently termed glycogenesis. In fasted animals, glycogen formation can be induced by the feeding, not only of materials that can be hydrolyzed to glucose and other monosaccharides, such as fructose, but also of various other materials. A number of L-amino acids, such as alanine, serine, and glutamic acid, upon deamination in the liver give rise to substances, such as pyruvic acid and α-ketoglutaric acid, that can be converted in the liver to glucose units which are subsequently converted to glycogen. Furthermore, substances such as glycerol derived from fats, dihydroxyacetone, or lactic acid can all be utilized for glycogen synthesis in the liver. Such noncarbohydrate precursors are termed glycogenic compounds. The process of glycogen formation from these precursors is known as glyconeogenesis. The term glycogenolysis is used to connote glycogen breakdown. *See* POLYSACCHARIDE. [W.Z.H.]

Glycolipid One of a class of compounds having solubility properties of a lipid and containing one or more molecules of a covalently attached sugar.

Glycosphingolipids, the most abundant and structurally diverse type of glycolipids in animals, are glycosides of ceramide, a fatty acid amide of the amino alcohol sphingosine. Galactosyl ceramide is enriched in brain tissue and is a major component of the myelin sheaths around nerves. Glucosyl ceramide is present in the cell membranes of many cell types and is abundant in serum.

Larger, neutral glycosphingolipids containing more than one sugar include lactosyl ceramide, abundant in leukocyte membranes; globosides; and other oligosaccharyl ceramides, some of which are important antigens defining blood groups. Gangliosides are oligosaccharyl ceramides, abundant in brain, spleen, erythrocytes, liver, and kidney, that contain glucose, galactose, *N*-acetylglucosamine, and sialic acids.

Glycosphingolipids carry blood group antigens and define tumor-specific or developmental antigens. In addition, they serve as receptors for many microorganisms and toxins, as modulators of cell surface receptors that mediate cell growth, and as mediators of cell adhesion. *See* ANTIGEN; CELLULAR ADHESION.

Glycosyl phosphatidylinositols are a class of glycolipids that serve as membrane anchors for a multitude of proteins in organisms ranging from yeast to protozoa to humans. Glycosyl phosphatidylinositol–core structures can have many different modifications, depending upon the protein and cell type. Lipophosphoglycans are glycosyl phosphatidylinositols attached to large polysaccharide structures that coat the surfaces of many parasitic protozoa, such as *Leishmania donovani*, the causative agent of visceral leishmaniasis (kala azar). Lipophosphoglycans appear to protect these organisms from host defenses.

Mannosylphosphoryl dolichol, glucosylphophoryl dolichol, and oligosaccharyl phosphoryl dolichols are glycolipids with sugars attached to large polyisoprenoids by phosphate esters. Dolichols are structurally related to cholesterol. Saccharylphosphoryl dolichols serve as important biosynthetic intermediates in the assembly of both asparagine-linked glycoproteins and glycosyl phosphatidylinositols. *See* GLYCOPROTEIN.

Glycosyl glycerides are glycolipids that have a structure analogous to phospholipids. They are the major glycolipids of plants and microorganisms but are rare in animals.

Bacteria produce a wide variety of glycolipids not easily categorized. Examples include fatty acid esters of carbohydrates, such as cord factor. Cord factor is a toxic component of the waxy capsular material of virulent strains of *Mycobacterium tuberculosis*, the causative agent of tuberculosis. Mycosides, glycolipids that are also found in tubercle bacilli, comprise long-chain, highly branched, hydroxylated hydrocarbon terminated by a phenol group, with the sugar glycosidically attached to the phenolic hydroxyl. *See* Lipid; Sphingolipid; Tuberculosis. [G.W.Ha.]

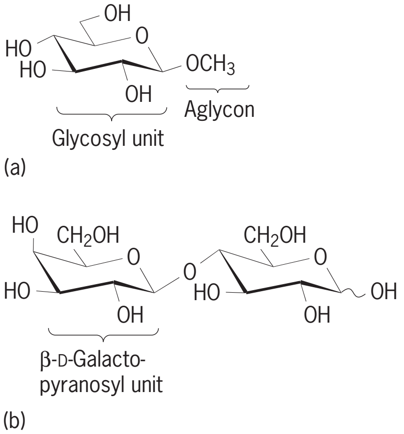
Glycoprotein A compound in which carbohydrate (sugar) is covalently linked to protein. The carbohydrate may be in the form of monosaccharides, disaccharides, oligosaccharides, or polysaccharides, and is sometimes referred to as glycan. The sugar may be linked to sulfate or phosphate groups. In different glycoproteins, 100–200 glycan units may be present. Therefore, the carbohydrate content of these compounds varies markedly, from 1% (as in the collagens), to 60% (in certain mucins), to >99% (in glycogen). *See* Collagen; Glycogen.

Glycoproteins are ubiquitous in nature, although they are relatively rare in bacteria. They occur in cells, in both soluble and membrane-bound forms, as well as in the intercellular matrix and in extracellular fluids, and include numerous biologically active macromolecules. A number of glycoproteins are produced industrially by genetic engineering techniques for use as drugs; among them are erythropoietin, interferons, colony stimulating factors, and blood-clotting factors. *See* Genetic engineering.

In most glycoproteins, the carbohydrate is linked to the polypeptide backbone by either N- or O-glycosidic bonds. A different kind of bond is found in glycoproteins that are anchored in cell membranes by a special carbohydrate-containing compound, glycosylphosphatidylinositol, which is attached to the C-terminal amino acid of the protein. A single glycoprotein may contain more than one type of carbohydrate-peptide linkage. N-linked units are typically found in plasma glycoproteins, in ovalbumin, in many enzymes (for example, the ribonucleases), and in immunoglobulins. O-linked units are found in mucins; collagens; and proteoglycans (typical constituents of connective tissues), including chondroitin sulfates, dermatan sulfate, and heparin. *See* Albumin; Carbohydrate; Enzyme; Immunoglobulin; Monosaccharide; Oligosaccharide; Polysaccharide; Protein.

Within any organism, all molecules of a particular protein are identical. In contrast, a variety of structurally distinct carbohydrate units are found not only at different attachment sites of a glycoprotein but even at each single attachment site—a phenomenon known as microheterogeneity. For instance, ovalbumin contains one glycosylated amino acid, but over a dozen different oligosaccharides have been identified at that site, even in a preparation isolated from a single egg of a purebred hen. [N.Sh.]

Glycoside A large important class of sugar derivatives in which the sugar is combined with a nonsugar. In their cyclic forms, monosaccharides (simple sugars) possess one carbon (C) atom (the anomeric carbon) that is bonded to two oxygen (O) atoms; one oxygen atom forms a part of the ring, whereas the other is outside the ring (exocyclic) and is part of a hydroxyl (OH) group. If the oxygen atom of the anomeric hydroxyl group becomes bonded to a carbon atom, other than that of a carbonyl (C=O) group, the resulting compound is a glycoside. A glycoside thus consists of two parts (see illustration): the sugar (glycosyl) unit, which provides the anomeric carbon, and the moiety (the aglycon), which is the source of the exocyclic oxygen and carbon atoms of the glycosidic linkage. Such compounds frequently are referred to as O-glycosides to distinguish them from analogs having a sulfur (thio- or *S*-glycosides), nitrogen (amino- or N-glycosides), or carbon (anomalously called C-glycosides) as the exocyclic atom on the anomeric carbon. *See* Hydroxyl; Monosaccharide.



Structural formulas of two glycosides. (*a*) Methyl β-D-glucopyranoside. (*b*) Lactose, 4-*O*-β-D-galactopyranosyl-D-glucopyranose; the wavy bond indicates that the group may have various orientations in space.

The formation of glycosides is the principal manner in which monosaccharides are incorporated into more complex molecules. For example, lactose (illustration *b*), the most abundant disaccharide in mammalian milk, has a glycosidic bond involving the anomeric carbon of D-galactose and the C-4 hydroxyl of D-glucose. The anomeric carbon atom can exist in either of two stereoisomeric configurations, a fact which is of immense importance to the chemistry and biochemistry of glycosides. For example, the principal structural difference between cellulose and amylose is that cellulose is β-glycosidically linked whereas amylose is α-linked. Humans are able to digest amylose but are unable to utilize cellulose for food. *See* Cellulose; Lactose; Stereochemistry.

A very large number of glycosides exist in nature, many of which possess important biological functions. In many of these biologically important compounds the carbohydrate portion is essential for cell recognition, the terminal sugar units being able to interact with specific receptor sites on the cell surface.

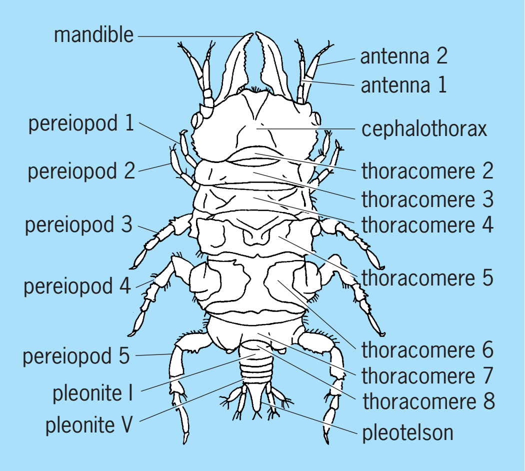
One class of naturally occurring glycosides is called the cardiac glycosides because they exhibit the ability to strengthen the contraction of heart muscles. These cardiotonic agents are found in both plants and animals and contain complex aglycons, which are responsible for most of the drug action; however, the glycoside may modify the biological activity. The best-known cardiac glycosides come from digitalis and include the drug digoxin. *See* Digitalis.

Glycosidic units frequently are found in antibiotics. For example, the important drug erythromycin A possesses two glycosidically linked sugar units. *See* Antibiotic.

Perhaps the most ubiquitous group of glycosides in nature is the glycoproteins; in many of them carbohydrates are linked to a protein by *O*-glycosidic bonds. These glycoproteins include many enzymes, hormones, such antiviral compounds as interleukin-2, and the so-called antifreeze glycoproteins found in the sera of fish from very cold marine environments. *See* Amino acids; Antifreeze (biology); Carbohydrate; Enzyme; Glycoprotein; Hormone.

Glycolipids are a very large class of natural glycosides having a lipid aglycon. These complex glycosides are present in the cell membranes of microbes, plants, and animals. *See* Glycolipid; Lipid. [G.W.Hay.]

Gnathiidea A suborder of the Isopoda. These animals are characterized as having a much reduced second thoracomere which is incorporated with the cephalothorax. The antennules are short and each has a flagellum with four or five joints; the terminal three bear single sensory palps. The antennae are also short, with flagella having five to eight joints, but generally there are seven. Thoracomeres 3–7 have a normal appearance and bear pereiopods, while the eighth thoracomere is vestigial and lacks appendages (see illustration).



***Gnathia calva*, male specimen, dorsal view. (*After W. H. Tattersall, 1921*)**

The group comprises marine forms exclusively. They are found in all latitudes and at all depths. The larvae are found as parasites on fish. *See* ISOPODA. [T.M.]

Gnathostomata A group of the subphylum Vertebrata which possesses jaws, teeth, paired appendages, and girdles (secondarily lost in some), as well as other advanced features in contrast to the more primitive Agnatha, which lack jaws and paired appendages. The Gnathostomata are divided into two major subdivisions, the superclasses Pisces and Tetrapoda, which respectively constitute roughly the aquatic and the terrestrial vertebrates. *See* PISCES (ZOOLOGY); TETRAPODA; VERTEBRATA. [W.J.B.]

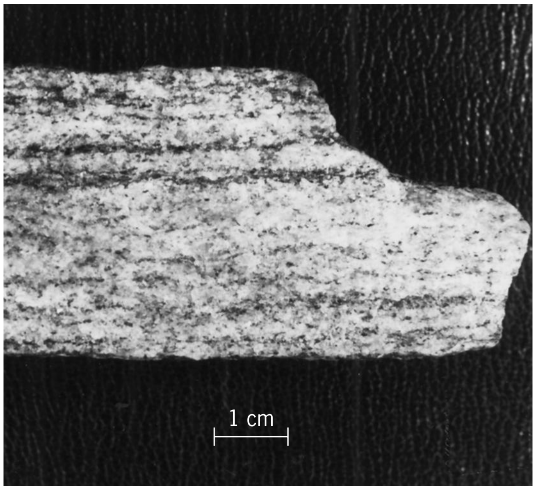
Gnathostomulida Microscopic marine worms of uncertain systematic relationship, mainly characterized by cuticular structures in the pharynx and a monociliated skin epithelium. It is the most recently described phylum of the animal kingdom. The total number of species probably exceeds 1000.

Gnathostomulids are worm-shaped, cylindrical or slightly depressed, and semitransparent (or bright red), and sometimes have the external division of head and tail. The skin is a one-layered epithelium that is completely monociliated; that is, each of the polygonal epidermal cells bears only one cilium. The sensory system usually consists of 1–2 pairs of simple and 3–4 pairs of compound bristles (frontally and laterally), and a bundle of stiff cilia (dorsally on the head). The reproductive system consists of a dorsal ovarium and in most cases two caudolateral groups of testes follicles in the same specimen. Fertilization is internal.

The distribution of gnathostomulids is worldwide, the majority of localities being known from European coasts, some from the North American east coast, and some scattered over the western Pacific. [R.J.R.; W.E.S.]

Gneiss Coarse-grained, banded crystalline rock. Gneiss is composed of mineral grains large enough to be seen with the naked eye (see illustration). Banding arises from segregation of the various minerals present, typically into dark- and light-colored layers. Individual bands are commonly 0.04 to 0.4 in. (1 mm to 1 cm) thick. Although individual mineral grains are often flattened parallel to banding, such shape orientation is not present in many gneisses. Sheetlike minerals such as micas may be present but form only a subordinate amount of the rock. Banded rock of coarse grain containing substantial amounts of such minerals is named schist. Crystalline rock which has flattened grains but lacks obvious banding is generally called leptite. *See* SCHIST.

Gneiss is defined by its texture, or arrangement of mineral grains, rather than by its mineral composition. However, the term gneiss is often taken to imply a mineral composition of granitic type, dominated by quartz and feldspar. Gneisses of other compositions are identified by qualifying terms such as compositional rock names, as in diorite gneiss and amphibolite gneiss, or a partial list of minerals present, as in biotite-plagioclase gneiss and hornblende-plagioclase gneiss. *See* FELDSPAR; QUARTZ.



Gneiss formed by metamorphism of preexisting granite. Dark minerals are mica; light-colored minerals are quartz and feldspar. The streaky nature of banding is typical of gneisses. The sample is from the Great Smoky Mountains of North Carolina.

Most gneisses are formed by recrystallization of preexisting rock during intense regional metamorphism. Shear stress present during such metamorphism causes formation of gneissic banding, although the exact mechanisms of this process are not well understood. Gneisses typically occupy large areas within the high-grade cores of regional metamorphic belts. Such terranes are often difficult to understand, because the processes which cause formation of gneissic texture are also sufficient to obscure preexisting rock structures. High temperature and shear are sufficient to cause plastic flow of gneissic rock on a gigantic scale. Such conditions of metamorphism are probably brought about by deep tectonic burial and major regional compression. Thus gneissic terranes may be expected to form in areas of convergent plate tectonics. *See* METAMORPHIC ROCKS; METAMORPHISM; METASOMATISM; PLATE TECTONICS. [D.W.Mo.]

Gnetales The only order of the class Gnetopsida in the division Gnetophyta. There are three living families, each with a single genus: Ephedraceae (*Ephedra*; 65 species in arid regions), Gnetaceae (*Gnetum*; 29 species in the tropics), and Welwitschiaceae (*Welwitschia*; 1 species in Namibia). Among the gymnosperms, Gnetales are usually considered the closest living relatives of the angiosperms. The fossil record is sparse but increasing, perhaps extending back to the Triassic Period.

Each modern genus is quite distinctive. Species of *Ephedra* (Mormon tea) somewhat resemble the spore-bearing horsetails (*Equisetum*), with scale leaves on photosynthetic, jointed stems. Most species of *Gnetum* are lianas, woody vines closely resembling the Australian flowering plant family Austrobaileyaceae. The only species of *Welwitschia* is unlike any other living plant. From its stumplike trunk, just two leaves grow ever wider and longer [upto 7 m (23 ft)], tattering at the tips. All three genera are dioecious, with separate male and female individuals. The pollen and seed cones are compound, with flowerlike buds in the axils of bracts. *See* CYCADOPSIDA; PINOPHYTA; PLANT KINGDOM. [J.E.E.]

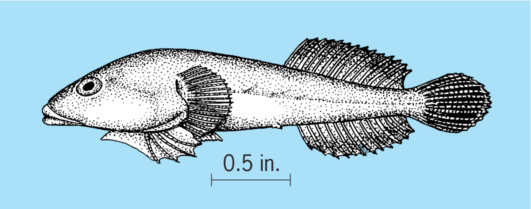
Gnotobiotics The science involved with maintaining a microbiologically controlled environment, and with the knowledge necessary to obtain and use biological specimens in this environment. The roots of the word are *gnotos*, meaning well known, and *biota*, the combined flora and fauna of a region.

All exposed surfaces of an animal are teeming with microbes. For example, the contents of the large intestine may contain 3 trillion microbes per ounce (100 billion per gram), belonging to several hundred species. Even if the animal itself is the primary interest of a researcher, there is no direct way to determine how many of an animal's normal characteristics are truly its own, and how many involve interaction with or reaction against resident microbiota. The only way to determine this is comparison with animals that have no microbiota. If differences are found, then the role of individual microbial species can be studied by inoculating pure cultures of these species into the animals without a microbiota.

Thus, gnotobiotics evolved initially to answer questions about what difference the resident microbiota makes, and which members of the microbiota make the difference. Answers become more and more essential in going beyond the effects of pathogenic microbes to the harmful or helpful long-term effects of environmental chemicals, compounds produced in the host's own metabolism, and therapeutic drugs being tested for efficacy, toxicity, or carcinogenicity. The activity of the microbiota is proportionately much greater in laboratory animals than it is in humans, and could have a decisive effect on such chemicals, especially since the chemicals are often received in small doses. For example, intestinal microbes turn a minor component of the cycad bean, a South Pacific foodstuff, into a carcinogen. One of the best drugs against parasitic schistosomes in humans is turned into a carcinogen by a single species of intestinal streptococcus. Gnotobiotic studies are designed to detect such possibilities.

Gnotobiote is the term applied to an animal (or plant) with a defined microbiota. The most simple of gnotobiotes is the animal with no microbiota. Invertebrate animals of this type are most frequently called axenic. Vertebrate animals may also be called axenic, but are more frequently called germfree. Gnotobiology is a term sometimes used to designate studies involving gnotobiotes, although it tends to suggest that there is a unified body of knowledge which results from studying gnotobiotes. In fact, the gnotobiote is a more precisely defined laboratory animal which helps elucidate biological phenomena in immunology, nutrition, physiology, oncology, gastroenterology, microbial ecology, gerontology, pathogenic microbiology, parasitology, and so on. [J.R.P.]

Gobiesociformes An order of bony fishes, also known as the Xenopterygii, or clingfishes, equipped with a thoracic sucking disk which serves for attachment to the substrate. There are single dorsal and anal fins that lack fin spines (see illustration). The body is scaleless, and there are no ribs and no swim bladder. The order consists of a single family that is classified into 8 subfamilies, 33 genera, and nearly 100 Recent species. *See* ACTINOPTERYGII. [R.M.B.]



Northern clingfish (*Gobiesox maeandricus*). (*After D. S. Jordan and B. W. Evermann, The Fishes of North and Middle America, U.S. Nat. Mus. Bull. no. 47, 1900*)

Gödel's theorem The result, proved by K. Gödel in 1931, that any sufficiently advanced mathematical system must be incomplete in that there must always be a true sentence that is not provable in the system. Roughly speaking, Gödel showed how, for each such system, a sentence could be constructed that asserted its own nonprovability in the system.

Gödel considered mathematical systems that involve numbers, sets of numbers, and other purely mathematical entities. He demonstrated a still more remarkable result for these same systems, which include the most comprehensive mathematical systems known. He showed that if these systems are consistent, they cannot prove their own consistency. This is known as Gödel's second incompleteness theorem.

Unfortunately, there are widespread misconceptions about this result. For example, Gödel's second theorem is sometimes thought to imply the impossibility of knowing that these systems are consistent. In reality, the fact that a system cannot prove its own consistency does not constitute the slightest grounds for doubting its consistency. Indeed, if a system could in fact prove its own consistency, that of course would not be any guarantee that the system was consistent, since an inconsistent system can prove anything. The consistency of the systems considered by Gödel is known rather by the self-evident nature of the axioms and the obvious correctness of the rules of reasoning. Still, it is of interest that the systems, though obviously consistent, cannot prove their own consistency.

In the eighteenth century, G. Leibniz envisioned a universal calculating machine that could solve all mathematical problems. The impossibility of such a device has been conclusively demonstrated by further ramifications of Gödel's work developed by A. Church and A. Turing. This work shows that mathematics cannot be mechanized, and that creativity and ingenuity will always be required. This is perhaps the most important consequence of Gödel's work. Another way of stating this consequence is that human beings can never eliminate the necessity of using their own intelligence, regardless of how cleverly they try. *See* LOGIC; RECURSIVE FUNCTION. [R.M.Sm.]

Goethite A mineral of composition FeO · OH, crystallizing in the orthorhombic system. Crystals are rare, and the mineral is usually in reniform or stalactitic masses which have a radiating fibrous internal structure. The luster is adamantine to dull, and the color light to dark brown. The Mohs hardness is 5.0–5.5, and the density is 4.28 for crystals and 3.3–4.3 for massive material. Most of the common, yellow-brown, earthy ferric oxides known as limonite are mixtures composed largely of cryptocrystalline goethite.

Goethite is one of the most common minerals. It is the major constituent of the gossan at the surface of metalliferous deposits rich in iron-bearing sulfides, as at Bisbee, Arizona, and of laterites, as in Cuba. Well-formed crystals are found at Pribram, Bohemia, and Cornwall, England. It is an important iron ore in Alsace-Lorraine, in the Lake Superior hematite deposits, and in the southern Appalachians. *See* LIMONITE. [L.Gr.]

Gold A chemical element, Au, atomic number 79 and atomic weight 196.967, a deep yellow, soft, and very dense metal. Gold is classed as a heavy metal and as a noble metal; commercially, it is the most familiar of the precious metals. Copper, silver, and gold are in the same group of the periodic table of elements. The Latin name for gold, *aurum* (glowing dawn), is the source of the chemical symbol Au. There is only one stable isotope of gold, that of mass number 197. *See* PERIODIC TABLE.

Uses. Consumption of gold in jewelry accounts for about three-fourths of the world's production of gold. Industrial applications, especially electronic, consume another 10–15%. The remainder is divided among medical and dental uses, coinage, and bar stock for governmental and private holdings. Gold coins and most decorative gold objects are actually gold alloys, because the metal itself is too soft (2.5–3 on Mohs scale) to be useful with frequent handling. *See* GOLD ALLOYS.

Radioactive ^{198}Au is used in medical irradiation, in diagnosis, and in a number of industrial applications as a tracer. Another tracer use is in the study of movement of sediment on the ocean floor in and around harbors. The properties of gold toward radiant energy have led to development of efficient energy reflectors for infrared heaters and cookers and for focusing and retention of heat in industrial processes.

Occurrence. Gold occurs widely throughout the world, but usually very sparsely, so that it is quite a rare element. Sea water contains low concentrations of gold, on the order of 10 μg per ton (10 parts of gold per trillion parts of water). Somewhat higher concentrations accumulate on plankton or on the ocean bottom. At present, no economically feasible process is visualized for extracting gold from the sea. Native, or metallic, gold and various telluride minerals are the only forms of gold found on land. Native gold may occur in veins among rocks and ores of other metals, especially quartz or pyrite, or it may be scattered in sands and gravel (alluvial gold). *See* GOLD METALLURGY.

Properties. The density of gold is 19.3 times that of water at 20°C (68°F), so that 1 ft^3 of gold weighs about 1200 lb (1 m^3, about 19,000 kg). Masses of gold, like those of other precious metals, are measured on the troy scale, which counts 12 oz to the pound. Gold melts at 1064.43°C (1947.97°F) and boils at 2860°C (5180°F). It is somewhat volatile well below its boiling point. Gold is a good conductor of heat and electricity. It is the most malleable and ductile metal. It can easily be made into translucent sheets 0.0000039 in. (0.00001 mm) thick or drawn into wire weighing only 0.00005 oz/ft (0.5 mg/m). The quality of gold is expressed on the fineness scale as parts of pure gold per thousand parts of total metal, or on the karat scale as parts of pure gold per 24 parts of total metal. Gold readily dissolves in mercury to form amalgams. Gold is one of the least active metals chemically. It does not tarnish or burn in air. It is inert to strong alkaline solutions and to all pure acids except selenic acid.

Compounds. Gold may be either unipositive or tripositive in its compounds. So strong is the tendency for gold to form complexes that all the compounds of the 3+ oxidation state are complex. The compounds of the 1+ oxidation state are not very stable and tend to be oxidized to the 3+ state or reduced to metallic gold. All compounds of either oxidation state are easy to reduce to the metal.

In its complex compounds gold forms bonds most readily and stably with halogens and sulfur, less stably with oxygen and phosphorus, and only weakly with nitrogen. Bonds between gold and carbon are fairly stable, as in the cyanide complexes and a variety of organogold compounds. [W.E.C.]

Gold alloys

Combinations of gold and other metals. Pure gold is soft. The addition of copper hardens the gold, and ultimately gold-copper alloys became standard for coinage. Gold coins in the United States contained 10% copper, the balance gold.

Pure gold is weak, having a tensile strength of less than 20,000 psi (138 megapascals) when annealed; however, by alloying with copper, sometimes in conjunction with silver or nickel, and often a little zinc, gold alloys with strengths of 60,000–100,000 psi (414–690 MPa) may be made. Addition of these metals changes the color of gold so that red, yellow, greenish, and white golds result. The proportion of gold in solid gold jewelry is designated in karats (k); pure gold is 24 k, 18 k is 18/24 or 75% pure gold, and 14 k is 14/24 or 58.3% pure gold.

Industrial uses of gold depend primarily upon the corrosion resistance and secondarily upon the strength that can be secured by alloying alone or by alloying and heat treating. Many alloys used in dentistry contain gold, silver, and copper, often with small amounts of platinum and palladium; these alloys can be heat-treated to develop strengths above 150,000 psi (1.0 gigapascal). The latter have good spring properties. Alloys of this type find many electrical uses as contacts, particularly where rubbing is involved. Gold electroplate, often thin, is employed on high-frequency conductors, such as those in radar equipment, because of the high electrical conductivity and tarnish resistance of gold. For the same reason gold is employed in the construction of many transistors, microcircuits, printed circuits, and integrated circuits. Most such devices are so small that the cost of gold is relatively unimportant.

Because gold does not oxidize when heated in air, appropriate gold compounds can be decomposed by heat to liberate the metal. Compounds of this type are used in the decoration of china and also for the production of printed electrical circuits on ceramics. These materials, known as liquid bright golds, are applied in the form of varnish, which is dried and then heated to redness, leaving a thin film of gold firmly attached to the underlying ceramic. *See* GOLD; GOLD METALLURGY. [C.R.M.; G.S.]

Gold metallurgy

Extracting gold from ores, refining it, and preparing it for use. Total world resources of gold are estimated at about 83,000 tons (75,000 metric tons). South Africa has about half of these resources, and Brazil, Russia, and the United States have about 12% each. The United States produces about 330 tons (300 metric tons) per year. In the United States, gold is used for jewelry and arts (70%), industry and electronics (23%), and dentistry (7%). There are only a few dozen placer mines in the United States, nearly all in Alaska. In such mines, gold is processed with the modern equivalent of gold panning—sluicing, tabling, and jigging. In addition, by-product gold from copper mining is only about 10% (historically, this source used to be much larger). There are several hundred lode mines in the United States, where the ore is mined from solid rock. This gold is often difficult to recover because it is associated with sulfide or carbonaceous minerals. As technology has improved, possibilities for processing the more difficult-to-treat (refractory) ores have expanded. A particular ore is more or less refractory depending on its combination of chemical compounds and minerals. *See* GOLD; PLACER MINING.

In the cyanide leaching process, ore is first crushed dry in a gyratory crusher and ground wet in a semiautogenous grinding mill. During the wet grinding process, cyanide and lime are added. The ore leaves the grinding mill as a slurry of muddy water. The gold gradually leaches out of each tiny ore particle (during its 20–30-h residence time) and dissolves into solution.

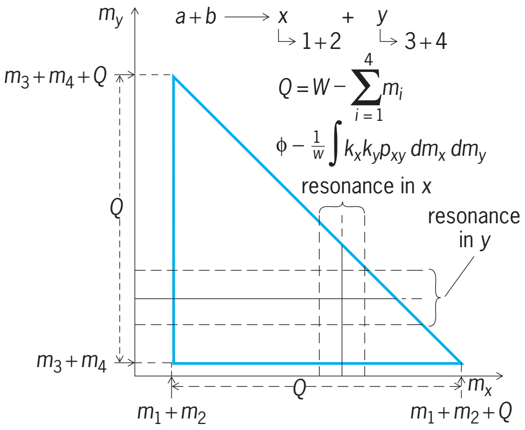
Sometimes lower-grade ore ($<$0.05 oz/ton or 1.57 g/metric ton of gold) is simply crushed and placed in heaps where it is slowly leached with cyanide solutions. Even though heap leaching gives lower gold recovery (sometimes lower than 60%), the cost is lower. Heap leaching is a form of solution mining that can also be applied to old tailings piles and mined overburden dumps. *See* SOLUTION MINING. [K.A.Pr.]

Goldhaber triangle

The phase space triangle, or Goldhaber triangle, corresponds to the kinematically allowed boundary for a high-energy reaction leading to four or more particles. In a high-energy reaction between two particles *a* and *b* yielding four particles 1, 2, 3, and 4 in the final state ($a + b \rightarrow 1 + 2 + 3 + 4$), it is convenient to consider the reaction in terms of the production of two intermediate-state quasi-particle composites *x* and *y*, which then decay into two particles each, as in expression (1).

$$\begin{array}{lll} a+b\rightarrow x & & +\,y \\ & \hookrightarrow 1+2 & \hookrightarrow 3+4 \end{array} \qquad (1)$$

Most high-energy interactions indeed proceed through such intermediate steps, in which, for specific values of the invariant masses $m_x = M_x^*$ and $m_y = M_y^*$, the quasi-particle composites may form resonances. However, the description in terms of the composites *x* and *y*, with the invariant masses m_x and m_y as variables, is valid irrespective of whether or not these composites form resonances.



Definition of the kinematical boundary of the Goldhaber triangle for four particles.

The kinematical limits in this representation are particularly simple, namely, they form a right-angle isosceles triangle. A Goldhaber triangle plot corresponds to plotting a point (m_x, m_y) for each event occurring in the above high-energy reaction. Because of the kinematical constraints, these points must all lie inside the triangle.

If one considers the general reaction given in Eq. (1), then the length of each of the two equal sides of the triangle is Q, defined in Eq. (2). Here W is the total energy in the center of mass of

$$Q = W - \sum_{i=1}^{4} m_i \tag{2}$$

particles a and b, and m_i, for $i = 1$ to 4, is the mass of the particles 1 to 4. Hence Q corresponds to the total kinetic energy available in the reaction.

In the triangle corresponding to the general reaction (see illustration), the vertical and horizontal bands indicate resonances at masses M_x^* and M_y^* with full width at half-maximum height or Γ_x and Γ_y, respectively. The bands shown of width 2Γ represent the regions usually chosen if the events corresponding to a given resonance are selected. [G.G.]

Golgi apparatus An organelle, named after the Italian histologist Camillo Golgi, found in all eukaryotic cells but absent from prokaryotes such as bacteria. It consists of flattened membrane-bounded compartments known as cisternae. In most cells, the Golgi cisternae are organized into stacks. Different cell types contain from one to several thousand Golgi stacks. The Golgi apparatus sorts newly synthesized proteins for delivery to various destinations, and modifies the oligosaccharide chains found on glycoproteins and glycolipids. *See* CELL ORGANIZATION.

The Golgi apparatus acts at an intermediate stage in the secretory pathway. A subset of the proteins synthesized by the cell are inserted into the endoplasmic reticulum. Most such proteins are then delivered to the Golgi apparatus by means of coat protein II (COPII) transport vesicles, which form at endoplasmic reticulum exit sites. Newly synthesized proteins traverse the Golgi stack until they reach the trans-most Golgi compartment, which is termed the trans-Golgi network to connote its extensive tubulation. The trans-Golgi network sorts the proteins into several types of vesicles. Clathrin-coated vesicles carry certain proteins to lysosomes. Other proteins are packaged into secretory vesicles for immediate delivery to the cell surface. Still other proteins are packaged into secretory granules, which undergo regulated secretion in response to specific signals. This sorting function of the Golgi apparatus allows the various organelles to grow while maintaining their distinct identities. *See* CELL MEMBRANES; ENDOPLASMIC RETICULUM; LYSOSOME.

The best understood of the processing reactions carried out by the Golgi apparatus is the remodeling of oligosaccharides (chains of six-carbon sugars) that are attached to glycoproteins. During insertion of a newly synthesized protein into the endoplasmic reticulum, one or more copies of a 14-sugar oligosaccharide may be attached to the amino acid asparagine at specific locations in the polypeptide chain. As the protein passes through the Golgi stack, the asparagine-linked oligosaccharides are modified to generate a diverse range of structures. Additional oligosaccharides may become linked to the amino acids serine and threonine. Although the particular oligosaccharide modifications are quite different in animal, plant, and fungal cells, the Golgi apparatus always functions as a "carbohydrate factory." *See* OLIGOSACCHARIDE.

The Golgi apparatus also carries out other processing events, including the addition of sulfate groups to the amino acid tyrosine in some proteins, the cleavage of protein precursors to yield mature hormones and neurotransmitters, and the synthesis of certain membrane lipids such as sphingomyelin and glycosphingolipids. *See* LIPID; PROTEIN. [B.S.Gl.]

Gonorrhea A common sexually transmitted disease caused by the bacterium *Neisseria gonorrhoeae*. Humans are the only natural hosts for *N. gonorrhoeae*, which directly infects the epithelium of the mucous membranes of the human genital tract, pharynx, rectum, or conjunctiva. Local epithelial cell destruction usually occurs, but the organisms may spread to adjacent organs or disseminate via the bloodstream. In women, local complications include inflammation of the uterine lining (endometritis), inflammation of the fallopian tube (salpingitis), inflammation of the abdominal wall (peritonitis), and inflammation of Bartholin's glands (bartholinitis); in men, periurethral abscess and inflammation of a duct connected to the testes (epididymitis). Systemic manifestations such as arthritis or dermatitis may develop, and rarely endocarditis or meningitis.

Women are disproportionately affected by the complications of gonorrhea. Acute pelvic inflammatory disease and salpingitis, the most serious complications of gonorrhea, result in ectopic pregnancy and infertility. Gonococcal infection during pregnancy may also predispose women to premature rupture of membranes, delivery in less than full term, and postpartum endometritis. During childbirth, the gonococcus may infect the conjunctiva of the infant and result in the infection ophthalmia neonatorum. This infection is a serious complication that remains common in less developed countries and can lead to permanent damage to the eye and blindness. *See* INFERTILITY; REPRODUCTIVE SYSTEM DISORDERS.

Gonorrhea continues to be the most commonly reported communicable disease in the United States, although incidence has declined since 1984. Risk factors that may influence the probability of infection include number of sexual partners, lack of barrier contraceptives, and young age.

Gonorrhea is an infection spread by physical contact with the mucosal surfaces of an infected person, usually a sexual partner. The risk of infection depends on the anatomic site, the amount of substance containing bacteria, and the number of exposures. Variations in host susceptibility have not been well defined. In a small but significant proportion of infections, there are no symptoms. These individuals are important in the epidemiology of this disease because gonorrhea is usually spread by carriers who have no symptoms or have ignored symptoms.

Control of gonorrhea depends on early diagnosis, effective treatment, and identification of asymptomatic individuals. The last has been accomplished, in part, through screening programs. However, complete control has not been possible because of the emergence and spread of strains that are resistant to less-expensive antimicrobial treatments such as penicillin and tetracycline.

There is no evidence that infected individuals develop long-lasting immunity to reinfection, and vaccination is not available. Thus, the prevention of gonorrhea relies on behavior modification and risk reduction, use of appropriate screening and diagnostic tests, routine use of highly effective antibiotics, early identification and treatment of sexual partners of individuals with gonorrhea, and the appropriate use of barrier methods such as condoms.

An increasing proportion of infections are due to antibiotic-resistant strains of *N. gonorrhoeae*. Chromosomally mediated resistance to multiple antibiotics as well as plasmid-mediated resistance to beta-lactam antibiotics and tetracycline occurs in strains from both developed and developing countries. Nevertheless, infections can be effectively treated with third-generation cephalosporins (for example, ceftriaxone) or fluoroquinolones (for example, ciprofloxacin or ofloxacin). *See* SEXUALLY TRANSMITTED DISEASES. [S.A.L.; S.A.Mo.]

Gonorynchiformes A small order of soft-rayed teleost fishes which at one time were included in the large order Clupeiformes (or Isospondyli). Gonorynchiforms are fusiform or moderately compressed fishes, varying from less than 2 in. (5 cm) to 5 ft (1.5 m) in length. There are single short dorsal and anal fins, and no adipose fin; the caudal fin is usually forked; and the pelvic fins are placed well back. The jaws are weak and toothless.

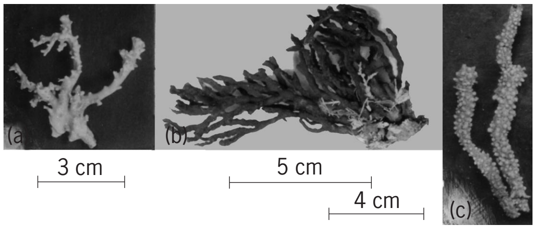
Modern gonorynchiforms are classified in 2 suborders, 4 families, 6 genera, and about 12 species. They have a wide fossil distribution that goes back to the Lower Cretaceous. *Gonorynchus* lives in marine shore waters of the Indo-Pacific area; the four genera of the Kneriidae and Phractolaemidae live in tropical African fresh waters; and the milkfish (*Chanos chanos*, family Chanidae) lives in marine and estuarine waters of the tropical Indo-Pacific. Milkfish are pond-cultured for food in Southeast Asia. *See* ACTINOPTERYGII; CYPRINIFORMES; TELEOSTEI. [R.M.B.]

Gooseberry A small fruit represented by about six species of the genus *Ribes* of the plant order Rosales. The gooseberry is a thorny, spreading bush which produces red, yellow, or green berries. The most desirable hardier types in the United States are of American parentage, or are hybrids between American and European species. Commercial culture is limited to a few states, notably Oregon, Michigan, and Washington.

The fruit is very acid and only a few European varieties, when fully ripe, are suitable for eating fresh. The fruit may be canned or frozen for use in pies or as preserves. *See* FRUIT; ROSALES. [J.H.Cl.]

Gopher The name for the North American rodents of the family Geomyidae. There are 39 species in 8 genera; 11 species are found in the United States. The distinctive name pocket gopher is applied to these animals, since they have large, furlined cheek pouches which open outward on the side of the face. Two common species are the northern pocket gopher (*Thomomys talpoides*), a small burrowing species, most numerous in the western United States and Mexico, and the prairie pocket gopher (*Geomys bursarius*). *See* RODENTIA. [C.B.C.]

Gorgonacea An order of the coelenterate subclass Alcyolaria. The Gorgonacea are the horny corals which often form fanlike or featherlike colonies with branches spread rapidly or oppositely in one plane (see illustration). They attach to objects by somewhat enlarged bases or tufts of stolons. They are more are more widely distributed than the Alcyonacea and extend from the littoral zone to some great depth. *See* ALCYONARIA. [K.At.]



Gorgonacea colonies. (*a*) Skeleton of *Corallium knojoi*. (*b*) *Melitodes sp.* (*preserved specimen*). (*c*) *Anthoplexaura dimorpha* (preserved specimen).

Gout A hereditary disease due to abnormal purine metabolism. The disease is characterized by increased amounts of blood uric acid (hyperurilcemia), acute and chronic inflammatory arthritis, tophaceous deposits of uric acid crystals, and renal insufficiency. The increase of uric acid is thought to be caused by increased production or decreased excretion of uric acid from the kidney or both. *See* ARTHRITIS; PURINE.

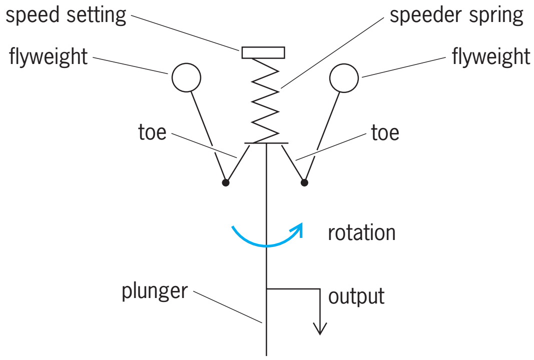
Primary gout occurs most frequently in middle-aged males and is passed as a familiar or hereditary trait which for some unknown reason does not appear as often in females. Secondary gout refers to the disease when associated with some underlying disorder causing an elevation in uric acid production (for example, myeloproliferative disorders).

The uric acid becomes deposited as urates in soft tissues, especially around the joints, in the cartilages of the ear, along the shafts of long bones, in the kidney, and occasionally on the heart valves. Such deposits, when superficial, can be seen grossly as reddish, inflamed masses called tophi. *See* PROTEIN METABOLISM; URIC ACID. [R.Se.]

Governor A device used to control the speed of a prime mover. A governor protects the prime mover from overspeed and keeps the prime mover speed at or near the desired revolutions per minute. When a prime mover drives an alternator supplying electrical power at a given frequency, a governor must be used to hold the prime mover at a speed that will yield this frequency. An unloaded diesel engine will fly to pieces unless it is under governor control. *See* PRIME MOVER.

A governor regulates the speed of a prime mover by properly varying the flow of energy to or from it. In the case of gas and steam turbines and internal combustion engines, the fuel furnishes the energy to the prime mover. For such applications, the governor usually controls the speed of the unit by regulating the rate at which fuel, and hence energy, is furnished to the prime mover. The governor controls the fuel flow so that the speed of the prime mover remains constant regardless of load and other disturbances, or changes in accordance with such operating conditions as changes in speed setting.

The speed of a prime mover is usually measured by a ballhead that contains flyweights driven at a speed proportional to the speed of the prime mover. The force from the flyweights is balanced, at least in part, by the force of compression of a speeder spring (see illustration). The upper end of this spring is positioned according to the speed setting of the governor.



Ballhead governor.

To increase the power output of a governor, a hydraulic amplifier is often employed. A governor that keeps the speed of a prime mover constant is said to be isochronous. In a simple isochronous governor, the ballhead senses the speed and strokes a pilot valve plunger that regulates the flow of fluid to a servomotor. The performance of the simple isochronous governor is often greatly improved by the introduction of a dashpot in the feedback path from the output to the ballhead. If there is little damping in the prime mover, instability often occurs when the simple isochronous governor is used, whereas this instability is removed when the dashpot is incorporated. Acceleration governors are sometimes used in place of governors with dashpots. In such governors a flywheel is employed instead of a dashpot. The prime mover drives the flywheel through a spring. [R.O.]

Graben A block of the Earth's crust, generally with a length much greater than its width, that has been dropped relative to the blocks on either side (see illustration). The size of a graben may vary. The faults that separate a graben from the adjacent rocks are inclined from 50 to 70° toward the down-thrown block and have displacements ranging from inches to thousands of feet. The direction of slip on these indicates that they are gravity faults. *See* FAULT AND FAULT STRUCTURES; HORST; RIFT VALLEY. [P.H.O.]

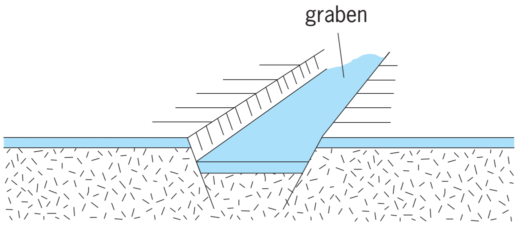


Diagram of simple graben. (*After A. K. Lobeck, Geomorphology, McGraw-Hill, 1939*)

Gradient of a scalar The result of the application of the distributive vector differential operator ∇, $\nabla = \mathrm{i}\ \partial/\partial x + \mathrm{j}\ \partial/\partial y + \mathrm{f}\ \partial\ \partial/\partial z$, to a differentiable scalar function $S(x, y, z)$; thus $\nabla S = \mathrm{i}\ \partial S/\partial x + \mathrm{j}\ \partial S/\partial y + \mathrm{f}\ \partial S/\partial z$. The letters i, j, f are symbols for the base vectors associated with x, y, z. The gradient of S is also denoted by grad S, while the symbol ∇ is usually called del and less frequently nabla. *See* CALCULUS OF VECTORS. [H.V.C.]

Gradient wind A hypothetical wind based upon the assumption that the sum of the horizontal components of the Coriolis force and the atmospheric pressure gradient force per unit mass is equivalent to a wind acceleration which is normal to the direction of the wind itself (centripetal acceleration), with the implication that there are no viscous forces acting. The direction of the gradient wind is the same as that of the geostrophic wind. The gradient wind speed is less than the geostrophic speed when the air moves in a cyclonically curved path and greater when the air moves in an anticyclonically curved path. The gradient wind is a good approximation of the actual wind and is often superior to the geostrophic wind, particularly when the flow is strongly curved in the cyclonic sense. *See* CORIOLIS ACCELERATION; GEOSTROPHIC WIND. [F.S.]

Grain boundaries The internal interfaces that separate neighboring misoriented single crystals in a polycrystalline solid. Most solids such as metals, ceramics, and semiconductors have a crystalline structure, which means that they are made of atoms which are arranged in a three-dimensional periodic manner within the constituent crystals. Most engineering materials are polycrystalline in nature in that they are made of many small single crystals which are misoriented with respect to each other and meet at internal interfaces called grain boundaries. These interfaces, which are frequently planar, have a two-dimensionally periodic atomic structure. A polycrystalline cube 1 cm on edge, with grains 0.0001 cm in diameter, would contain 10^{12} crystals with a grain boundary area of several square meters. Thus, grain boundaries play an important role in controlling the electrical and mechanical properties of the polycrystalline solid. It is believed that the properties are influenced by the detailed atomic structure of the grain boundaries, as well as by the defects that are present, such as dislocations and ledges. Grain boundaries generally have very different atomic configurations and local atomic densities than those of the perfect crystal, and so they act as sinks for impurity atoms which tend to segregate to interfaces. *See* CRYSTAL DEFECTS; CRYSTAL STRUCTURE.

Using electron microscopy and x-ray diffraction, it was determined that the grain boundary structure is frequently periodic in two dimensions. The geometry of a grain boundary is described by the rotation axis and angle, θ, that relate the orientations of the two crystals neighboring the interface, and the interface plane (or plane of contact) between the two crystals. Grain boundaries are typically divided into categories characterized by the magnitude of θ and the orientation of the rotation axis with respect to the interface plane. When θ is less than (arbitrarily) 15°, the boundary is called small-angle, and when θ is greater than 15°, the boundary is large-angle. *See* ELECTRON MICROSCOPE; X-RAY DIFFRACTION.

Because of the large differences in atomic structure and density between the grain boundary region and the bulk solid, the properties of the boundary are also quite different from those of the bulk, and have a strong influence on the bulk properties of the polycrystalline solid. The mechanical behavior of a solid, that is, its response to an applied stress, often involves the movement of dislocations in the bulk, and the presence of boundaries impedes their motion since, in order for deformation to be transmitted from one crystal to its neighbor, the dislocations must transfer across the boundary and change direction. The detailed structure at the interface influences the ease or difficulty with which the dislocations accomplish this change in direction.

Since grain boundaries in engineering materials are not in a high-purity environment, the presence of impurities dissolved in the solid may have a strong influence on their behavior. The presence of one-half of a monolayer of impurity atoms, such as sulfur or antimony in iron, at the grain boundary, can have a drastic effect on mechanical properties, making iron, which is ductile in the high-purity state, extremely brittle, so that it fractures along grain boundaries. The segregation of the impurity atoms to the boundaries has been well documented by the use of Auger electron spectroscopy, and studies have led to the suggestion that the change in properties may be related to a change in the dislocation structure of the grain boundary induced by the presence of these impurities. *See* METAL, MECHANICAL PROPERTIES OF; PLASTIC DEFORMATION OF METAL.

Since modern electronic devices are fabricated from semiconductors, which may be polycrystalline, the presence of grain boundaries and their effect on electrical properties is of great technological interest. In a semiconductor such as silicon the local change in structure at the interface gives rise to disruption of the normal crystal bonding, or sharing of valence electrons. One consequence can be the charging of the grain boundaries, which produces a barrier to current flowing across them and thus raises the overall resistance of the sample. This polycrystalline effect is exploited in devices such as zinc oxide varistors, which are used as voltage regulators and surge protectors. *See* SURGE SUPPRESSOR; VARISTOR. [S.L.S.]

Grain crops Crop plants that belong to the grass family (Gramineae), generally grown for their edible starchy seeds. They also are referred to as cereal crops and include wheat, rice, maize (corn), barley, rye, oats, sorghum (jowar), and millet. The grain of all these is used directly for human food and also for livestock, especially maize, barley, oats, and sorghum.

An important attribute of these grain crops is the easy manner in which they can be stored. The grain often dries naturally before harvest to a safe moisture content (10–12%), or can easily be dried with modern equipment. Grain placed in adequate storage facilities can then be protected against insect infestations and maintained in sound condition for years. *See* Corn; Millet; Oats; Rice; Sorghum; Wheat. [E.G.H.]

Gram-equivalent weight A quantity of a substance that contains the same number (known as the Avogadro number) of molecules as the number of atoms contained in exactly 12.000 g of carbon-12 (^{12}C). This convention stems from the concept that the central principle guiding chemical calculations is the relation of quantities of reacting substances to the numbers of molecules involved.

An added convenience in stoichiometric calculations is to incorporate the combining capacity (n), as well as the number of molecules, so that an equivalence of reacting substances is implicit without the need to examine balanced equations each time. Thus, the gram-equivalent weight of a substance is its gram-molecular weight divided by n. In acid-base reactions, n of the acid or base is given by the number of protons released or consumed in the reaction. For hydrochloric acid (HCl), ammonia (NH_3), acetic acid (CH_3COOH), and the acetate ion [CH_3COO^-; as in sodium acetate ($NaOOCCH_3$)], $n = 1$. For carbonic acid (H_2CO_3), sodium carbonate (Na_2CO_3), and ethylenediamine ($H_2NCH_2CH_2NH_2$), $n = 2$.

In precipitation and other metathetical reactions, the charge (valence) of the ion involved governs the value of n. Thus, $n = 3$ for ferric chloride ($FeCl_3$) and $n = 6$ for ferric sulfate [$Fe_2(SO_4)_3$] when precipitation yields either ferric hydroxide [$Fe(OH)_3$], barium sulfate ($BaSO_4$), or silver chloride (AgCl). When oxidation-reduction is involved, the change of valence, rather than the valence itself, defines n. When the ferric ion (Fe^{3+}) acts as an oxidant [with the ferrous ion (Fe^{2+}) as product], $n = 1$ for ferric chloride ($FeCl_3$) and $n = 2$ for ferric sulfate. When potassium permanganate ($KMnO_4$) reacts in acid medium, $n = 5$, but in neutral or basic solution $n = 3$.

Further changes in the definition arise in dealing with metal complex formation, such as FeF_6^{3-}, $FeCl_4^-$, $Zn(EDTA)^{2+}$, and $Bi(EDTA)^-$; EDTA is the polydentate metal chelating agent ethylenediaminetetraacetate ion. The combining capacity of metals in complex formation depends on their coordination number, which, as these examples demonstrate, differs with different complexing agents, or ligands. *See* Electrochemical equivalent; Equivalent weight; Ethylenediaminetetraacetic acid; Mole (chemistry); Stoichiometry; Valence. [H.Frei.]

Gram-molecular weight The molecular weight of an element or compound expressed in grams (g), that is, the molecular weight on a scale on which the atomic weight of the ^{12}C isotope of carbon is taken as 12 exactly. This replaces the earlier scale on which the atomic weight of oxygen was taken as 16.00 g. In the International System of Units, gram-molecular weight is replaced by the mole.

The ratio of the gram-molecular weights of any two elements or compounds must be identical with the ratio of the absolute weights of their individual molecules. Therefore, the gram-molecular weights of all elements or compounds contain the same number of molecules. This number, called the Avogadro number, N, is 6.022×10^{23}. *See* Avogadro number; Mole (chemistry); Molecular weight; Relative molecular mass. [T.C.W.]

Grand unification theories Attempts to unify three fundamental interactions—strong, electromagnetic, and weak—with a postulate that the three forces, with the exception of gravity, can be unified into one at some very high energy. The basic idea is motivated by the incompleteness of the electroweak theory of S. Weinberg, A. Salam, and S. Glashow, which has been extremely successful in the energy region presently accessible with the use of accelerators, and by the observation that the coupling constant for strong nuclear forces becomes smaller as energy increases whereas the fine-structure constant ($\alpha = 1/137$) for electromagnetic interactions is expected to increase with energy. *See* Gravitation; Strong nuclear interactions; Weak nuclear interactions.

The simplest grand unification theory (GUT), proposed by H. Georgi and Glashow, is based on the assumption that the new symmetry that emerges when the three forces are unified is given by a special unitary group SU(5) of dimension 24. This symmetry is not observable in the low-energy region since it is badly broken. In this model, as in most GUTs, the coupling constants for the three interactions merge into one at an energy of about 10^{14} GeV. Quarks and leptons belong to the same multiplets, implying that distinctions between them disappear at the energy of 10^{14} GeV or above. In addition to the known 12 quanta of strong, electromagnetic, and weak interactions, there appear, in this model, 12 new quanta with the mass of 10^{14} GeV. These generate new but extremely weak interactions that violate baryon- and lepton-number conservation. The most spectacular prediction of GUTs is the instability of the proton, which is a consequence of baryon-number (and lepton-number) violation. *See* Lepton; Proton; Quarks; Symmetry breaking; Symmetry laws (physics).

GUTs, in general, explain why the charge of the electron is precisely that of the proton with the opposite sign. Massive neutrinos are a distinct possibility in GUTs, and the smallness of their mass can also be understood. *See* Cosmology; Neutrino.

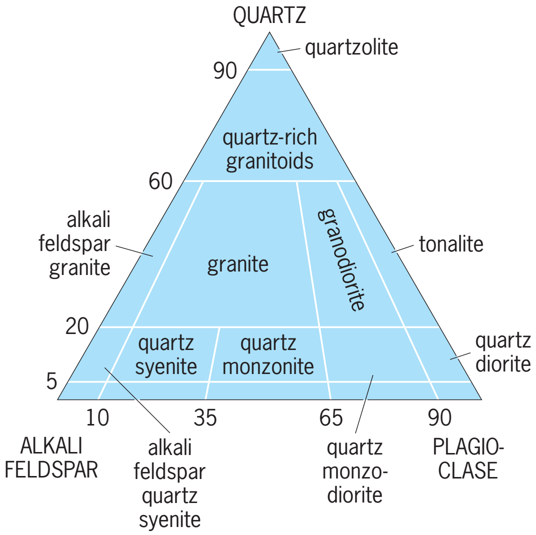
According to the scenario based on the GUTs, the universe underwent a phase transition when its temperature cooled to 10^{27} K, which corresponds to 10^{14} GeV in energy and to the first 10^{-35} s after the big bang. The phase transition caused an exponential expansion (10^{30}-fold in 10^{-32} s) of the universe, which explains why the observed 3 K microwave background radiation is uniform (the horizon problem), and why the universe behaves as if space is practically flat (the flatness problem). *See* Big bang theory; Inflationary universe cosmology; Phase transitions; Universe.

In spite of its theoretical triumph and spectacular predictions, the simple SU(5) model is practically untested by experiment and appears to be incomplete or even incorrect. No experimental evidence of proton decay has been established, and the problems which GUTs leave unsolved are numerous. *See* Elementary particle; Fundamental interactions; Supergravity; Supersymmetry. [C.W.K.]

Granite A crystalline igneous rock that consists largely of alkali feldspar (typically perthitic microcline or orthoclase), quartz, and plagioclase (commonly calcic albite or oligoclase). Its average grain size is 0.04–1.0 in. (1–25 mm); finer-grained rocks of this composition include rhyolite and aplite, and coarser-grained ones are granite pegmatite. *See* Aplite; Pegmatite; Rhyolite.

The revised nomenclature of the International Union of Geological Sciences (IUGS) subcommission defines granite as containing 80–100% by volume quartz, alkali feldspar, and plagioclase in the proportions given in the illustration, and 20–0% accessory minerals. The three essential minerals must include 20–60% quartz, and alkali feldspar must constitute 65–90% of the total feldspar. The variety alkali feldspar granite is similar except that alkali feldspar constitutes 90–100% of its total feldspar. The term granitic rocks includes granodiorite and tonalite as well as granite, and as used by some geologists may include quartz syenite to quartz diorite (*see* illustration). *See* Feldspar; Granodiorite; Hornblende; Muscovite.

Granites may be divided into three major types: calc-alkaline, peraluminous, and alkaline. Calc-alkaline granites typically are



Classification of granitic rocks by the IUGS scheme. All proportions are by volume percentages.

biotite or biotite-hornblende granites, some contain augite, and sphene is a common accessory.

Peraluminous granites, also known as S-type granites, contain aluminum in excess of that contained in feldspars and biotite; thus muscovite is an accessory mineral. Other aluminous minerals such as andalusite, sillimanite, cordierite, or garnet also may be accessory. Subalkaline to alkaline granites are characterized by iron-rich mafic minerals and relatively sodic alkali feldspar. The subalkaline type typically contains ferruginous biotite or hornblende, or both, but varieties containing ferrohedenbergite or fayalite are not uncommon. Allanite and zircon are common accessories. The alkaline type contains the Na-Fe minerals aegirine or riebeckite-arfvedsonite, or all three, and may also contain ferruginous biotite or even astrophyllite, eudialyte, or other rare minerals. *See* IGNEOUS ROCKS. [F.B.]

Granodiorite A phaneritic (visibly crystalline) plutonic rock composed chiefly of sodic plagioclase (oligoclase or andesine), alkali feldspar (microcline or orthoclase, usually perthitic), quartz, and subordinate dark-colored (mafic) minerals (biotite, amphibole, or pyroxene). Granodiorite is intermediate between granite and quartz diorite (tonalite). For convenience granite and granodiorite are commonly grouped and referred to as granite. *See* GRANITE; IGNEOUS ROCKS. [C.A.C.]

Granulite An important class of metamorphic rocks exposed at the surface of the Earth's crust, and inferred to make up a large portion of the deeper crust. Granulites are known to have formed at higher temperatures, and in many cases, higher pressures, than most other crustal rock assemblages. Thus, they are believed to have formed at considerable depths in the crust. *See* METAMORPHIC ROCKS.

Granulites may be of many different bulk compositions, inherited from precursor sedimentary, igneous, or lower-grade metamorphic rocks. The high temperatures of crystallization have resulted in very low water content, reflected in nearly anhydrous mineralogy. Characteristic minerals of granulite metabasalts are plagioclase, orthopyroxene, clinopyroxene, hornblende, and garnet. These minerals are also characteristic of granulites of intermediate to granitic composition, together with progressively greater amounts of quartz and potassium feldspar. The association of potassium feldspar with orthopyroxene is definitive for charnockite, a granulite of approximately granitic composition characteristic of ancient high-grade terrains. *See* BASALT; GRANITE.

Granulites characteristically contain CO_2-rich fluid inclusions in the mineral grains, in contrast to the more aqueous fluid inclusions of other kinds of rock. This has suggested that action of volatiles low in H_2O and rich in CO_2, probably of subcrustal origin, were important in crustal metamorphism early in the Earth's history. *See* METAMORPHISM. [R.C.N.]

Granuloma inguinale A mildly infectious, chronic, granulomatous disease principally affecting skin and subcutaneous tissues of the genital and rectal areas. The causative organism is *Calymmatobacterium granulomatis (Donovania granulomatis)*. Although rare in the United States, the disease is very common in New Guinea, the Caribbean, and other tropical and subtropical areas.

Although the method of transmission is controversial, there is a definite correlation with sexual activity and a frequent association with homosexual behavior. Tetracyclines are the drugs of choice, with streptomycin an effective alternative. [D.S.K.]

Granuloreticulosia A subclass of the Rhizopodea. These Protozoa produce reticulopodia which often fuse into networks greatly exceeding the area of the body, as in various Foraminiferida. Such nets are effective food traps and may also be important in construction of tests and cyst walls. A characteristic feature of reticulopodia is the bidirectional flow of cytoplasm. Granuloreticulosia include three orders: Athalamida, Foraminiferida, and Xenophyophorida. *See* ATHALAMIDA; FORAMINIFERIDA; RHIZOPODEA; XENOPHYOPHORIDA. [R.P.H.]

Grape The two genera of grapes are *Vitis* and *Muscadinia*. *Vitis vinifera* has intermittent forked tendrils, bark that sheds, and elongated clusters with berries that adhere to the pedicels at maturity. This species also has thin, smooth, shiny leaves with three, five, or seven lobes. Berries may be round or oval and have edible skins that adhere to the flesh. In the American species skins slip from the pulp. Many American species have a characteristic musky or foxy odor and taste. *Muscadinia* can be easily distinguished from *Vitis* by bark that does not shed and simple tendrils that do not fork.

Viticulture is the science of grape production. In a broad sense, viticulture includes studies of grape varieties; methods of culture such as trellising, pruning, and training; insect and disease control; propagation; and raisin production.

In the United States, *V. vinifera* is grown on the west coast, and most of the grapes cultivated east of the Rocky Mountains have been derived from American native species such as *V. labrusca* and *V. aestivalis*, or from crosses between them and *V. vinifera*. There is also a native Caribbean species and several Asiatic species. There are three main species of *Muscadinia* that are found mostly in the southeast portion of the United States.

Table grapes are utilized for food and decorative purposes. Some of the leading table grapes in California are Emperor, Tokay, Thompson Seedless, Cardinal, and Perlette. Some of the principal commercial American varieties are Concord, Catawba, Delaware, and Niagara. Some of the important varieties of *M. rotundifolia*, the Muscadine grape, are Scuppernong, Thomas, and Hunt.

Important wine grapes in California include Cabernet Sauvignon, Carignane, Chardonnay, Grenache, French Colombard, and Zinfandel. Many of the North American and *rotundifolia* species that are used for eating purposes are also used for wine. [R.J.W.]

Grapefruit A citrus fruit, *Citrus paradisi*. It apparently arose as a hybrid of shaddock or pummelo and sweet orange in the West Indies. Its first recorded mention was in Barbados in 1750, and the first use of the term grapefruit occurred in Jamaica in 1814. It was thought to have been introduced into Florida by Count Odelle Phillipe around 1823. The term grapefruit was derived from the tree's tendency to produce large clusters of fruit, as grape vines do.

The tree is a large evergreen, spreading in habit and becoming larger than most other edible citrus species. Fruit is relatively large and the peel thick compared to sweet oranges. Fruit shape is oblate or flattened at each end unless grown from off-bloom or under growing conditions promoting excessive vigor, in which case the fruit is often pear-shaped or sheep-nosed. The yellow peel color is not related to cool temperature as in the case of sweet oranges, but fruit picked early in the season must be degreened with ethylene to develop a satisfactory peel color. The original grapefruit were white-fleshed and extremely seedy; however, current important commercial cultivars are seedless or contain few seeds. *See* ETHYLENE; FRUIT.

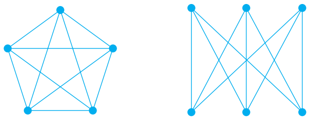
Grapefruit ripens slowly over an extended period, storing well on the tree after reaching edible quality, with fruit of a given cultivar harvested from early fall to midsummer. Composition is, therefore, important not only for indicating nutritive values but also for determining proper time of harvest. The fresh weight of grapefruit consists of 35–50% juice, with the remainder made up of peel, pulp, and seeds. The edible quality of grapefruit depends in large measure upon the ratio of sugars to acids in juice. The nutritive value of juice is in part related to its vitamin C content. The juice also contains a number of other vitamins and mineral elements required in a well-balanced human diet. The principle giving grapefruit its distinctive bitter flavor is naringin, a glucoside not found in its progenitor the pummelo or in other commercial citrus. *See* ASCORBIC ACID; CITRIC ACID. [D.P.H.T.]

Graph theory A branch of mathematics that belongs parly to combinatorial analysis and partly to topology. Its applications occur (sometimes under other names) in electrical network theory, operations research, organic chemistry, theoretical physics, and statistical mechanics, and in sociological and behavioral research. Both in pure mathematical inquiry and in applications, a graph is customarily depicted as a topological configuration of points and lines, but usually is studied with combinatorial methods. *See* COMBINATORIAL THEORY; TOPOLOGY.

A graph consists of a set of points, a set of lines, and an incidence relation that designates the end points of each line. In many applications no line starts and ends at the same point. (Such a line would be called a loop.) Also, no two lines have the same pair of end points. A graph whose lines satisfy these conditions is called simplicial. The valence of a point is the number of lines incident on it, calculated so that a loop is twice incident on its only end point. Two graphs are isomorphic if there is one-to-one correspondence from the point set and line set of one onto the point set and line set, respectively, of the other that preserves the incidence relation. An automorphism of a graph is an isomorphism of a graph with itself. Two graphs are homeomorphic if, after smoothing over all points of valence 2, the resulting graphs are isomorphic. *See* GROUP THEORY.

Drawing a graph on a surface decomposes the surface into regions. One colors the regions so that no two adjacent regions have the same color, rather like a political map of the world. It is a remarkable fact that for a given surface, there is a single number of colors that will always be enough no matter how many regions occur in a decomposition of the surface. The smallest such number is called the chromatic number of that surface. It is easy to draw a plane map that requires four colors. In 1976 K. Appel and W. Haken settled a problem dating back to about 1850, by showing that four colors are always enough for plane maps.

A graph is planar if it can be drawn in the plane so that none of its lines cross each other. Neither of the two graphs in the illustration can be drawn in the plane. K. Kuratowski proved in 1930 that a graph is planar if and only if it contains no subgraph homeomorphic to either of those two graphs.



Prototypes of all nonplanar graphs.

In a directed graph, or digraph, each line *ab* is directed from one end point *a* to the other end point *b*. There is at most one line from *a* to *b*.

An oriented graph is obtained from an ordinary graph by assigning a unique direction to every line. If there is one line between every pair of points and no loops, an ordinary graph is called complete. An oriented complete graph is called a tournament. [J.L.Gro.]

Graphic methods Procedures and techniques for visually representing on paper or a screen information pertaining to data analysis and decision making or relationships between variables by means of diagrams or charts.

Structural information is usually depicted by a bar graph, also known as a histogram, or a circle graph, also known as a sectorgram or a pie chart. Such charts are commonly used to display data. A graph representing the relation between an independent and a dependent variable is a two-dimensional line, whereas a graph representing the relation between two independent variables and a dependent variable is a three-dimensional surface. Graphical methods are frequently used to solve problems of curve fitting, correlation and regression analysis, nomographs and alignment charts, numerical integration, areas under curves, and interpolation and extrapolation.

Line graphs are by far the most important type because they can be used not only to represent functional relationships but also to solve problems. For example, the roots of an equation in one variable can be found with the help of a graph. If $f(x)$ is a function which becomes 0 for a certain value of x, that value is a root of the equation $f(x) = 0$. The equation is solved by finding the x coordinates of points where the graph of $f(x)$ crosses the x axis. *See* ROOT (MATHEMATICS). [V.K.B.]

Graphic recording instruments Instruments that make a graphic record of one or more quantities as a function of another variable, usually time. Signals representing information, such as the shape of time-varying electronic waveforms or the movements of a machine, are presented in graphical form by these devices. *See* TRANSDUCER.

Recorders are of two forms: those that plot an input variable with respect to time (denoted x-t) and those that plot two different variables (denoted x-y). Graphic recorders can also be classified as being either directly or indirectly driven by the input signal. In addition, they can be classified by their exhibiting means, recording means, number of marking devices or channels, and marking means.

Direct-acting units are suitable when the primary variable exerts sufficient and appropriate force to overcome the frictional loads of the bearings and marking means. Direct-drive recorders lack general-purpose usefulness and are, therefore, more costly to produce than indirect alternatives. In some circumstances, however, they are essential.

In the indirect form an intermediate stage is used to convert the input signal into the equivalent mechanical movements needed. Indirect-acting recorders generally accept voltage or current input signals, converting these into equivalent mechanical positions on a suitable exhibiting medium. Other input variables, such as pressure and temperature, are first transformed into electrical signals.

Such signals may range from microvolts to megavolts or from picoamperes to kiloamperes. Recorders are often supplied with adjustable input stages so that the input signal can be matched to the scale size needed for the graph.

Exhibiting means can be of either circular form or linear form, the latter being continuous strip or a single sheet.

Many different methods are used to produce the permanent trace on the recording medium. They include the use of fluid inks and fiber pens that mark in direct contact with the paper; pressure-forced ink jetting; marking with a heated stylus on heat-sensitive paper; pressure- or voltage-sensitive paper on which the stylus moves in contact; pressure of an inked ribbon onto the paper after the marking head has been positioned; exposure of heat-sensitive or photographically sensitive paper or film; and electrostatically charged images in a laser printer.

Graphic recorders (commonly referred to as plotters) are designed for use with either analog or digital electrical input signals. In the analog variation the input circuitry accepts signals that have the information to be displayed carried in terms of the variable amplitude of a voltage or current. A variable-gain input stage allows input signal magnitudes to be matched, by amplification or attenuation, to the set sensitivity of the positioning system.

In the digital plotter the digital signal (having only two states of existence for each of the bits forming the digital word equivalent to the analog alternative) can be of either serial format or parallel format. In the former a time sequence of serially occurring binary bits represents the signal amplitude. In the latter it is the state of binary signals simultaneously existing on several parallel lines that represents the amplitude. The signal lines carrying these digital signals, for purposes of interconnection, are called the communication interface.

The extensive acceptance of computer-based data logging and the general availability of hard-copy printers have contributed to a shift in usage from dedicated chart recorders to digital printers that provide permanent displays in the form of computer printouts. The plotting mechanisms incorporated within printers are similar to those of conventional graphic recording instruments, the majority being driven with stepping motors and using thermal- or laser-based printing. Dedicated graphic recording devices are still in use because it is often not economical to replace them with modern equivalents. They also find application where records need longer paper lengths than a computer printer can provide. *See* COMPUTER PERIPHERAL DEVICES; STEPPING MOTOR. [P.H.Sy.]

Graphite A low-pressure polymorph of carbon (the common high-pressure polymorph being diamond). Graphite is metallic in appearance and very soft. Crystals of graphite are infrequently encountered since the mineral usually occurs as earthy, foliated, or columnar aggregates often mixed with iron oxide, quartz, and other minerals. *See* CARBON.

The sheetlike character of the graphite atomic arrangement results in distinctive physical properties. The mineral is very soft, with hardness $1^1/_2$; it soils the fingers and leaves a black streak on paper, hence its use in pencils. The specific gravity is 2.23, often less because of the presence of pore spaces and impurities. The color is black in earthy material to steel-gray in plates, and thin flakes are deep blue in transmitted light. Graphite is a conductor of electricity.

The major sources of graphite are in gneisses and schists, where the mineral occurs in foliated masses mixed with quartz, mica, and so on. Noteworthy localities include the Adirondack region of New York, Korea, and Sri Lanka (formerly Ceylon). In Sonora, Mexico, graphite occurs as a product of metamorphosed coal beds. Graphite is also observed in meteorites. [P.B.M.]

Synthetic graphite. Commercially produced synthetic graphite is a mixture of crystalline graphite and cross-linking intercrystalline carbon. Its physical properties are the result of contributions from both sources. Thus, among engineering materials, synthetic graphite is unusual because a wide variation in measurable properties can occur without significant change in chemical composition.

At room temperature the thermal conductivity of synthetic graphite is comparable to that of aluminum or brass. An unusual property of graphite is its increased strength at high temperature. Graphite is resistant to thermal shock because of its high thermal conductivity and low elastic modulus. It is one of the most inert materials with respect to chemical reaction with other elements and compounds. It is subject to oxidation, and reaction with and solution in some metals.

Graphite has many uses in the electrical, chemical, metallurgical, nuclear, and rocket fields: electrodes in electric furnaces producing carbon steel, alloy steel, and ferroalloys; anodes for the electrolytic production of chlorine, chlorates, magnesium, and sodium; motor and generator brushes; sleeve-type bearings and seal rings; rocket motor nozzles; missile nose cones; metallurgical molds and crucibles; linings for chemical reaction vessels; and, in a resin-impregnated impervious form, for heat exchangers, pumps, pipings, valves, and other process equipment.

Graphite (carbon) fibers. Carbon fibers are filamentary forms of carbon, with a fiber diameter normally in the 6–10-micrometer range. The product is offered in the form of yarns or tows containing from 1000 to 500,000 filaments per strand. The fibers offer a unique combination of properties. They are flexible, lightweight, thermally and to a large extent chemically inert, and are good thermal and electrical conductors. In their high-performance varieties, carbon fibers are very strong and can be extremely stiff.

The principal use of high-performance carbon fibers is as the reinforcing component in structural epoxy matrix composites. Due to initially high cost, the original applications were almost exclusively for lightweight, high-stiffness, and high-strength composites for the aerospace industry. The second major usage of high-performance carbon fibers is in sporting goods, such as golf club shafts, tennis rackets, fishing rods, and sailboat structures. The major matrix material for both applications is epoxy. *See* COMPOSITE MATERIAL. [H.F.V.]

Graptolithina A group of marine organisms that were common in the early Paleozoic (the Late Cambrian to Early Devonian periods). Graptolites became extinct in the late Paleozoic Era. They were minute animals that built communal skeletons. Each graptolite colony contained from two to many hundreds of separate graptolite animals (referred to individually as zooids). All of the zooids within a single colony (a rhabdosome) were formed by asexual budding from the founder zooid, which probably grew from a fertilized egg. Thus, each colony started with a sexually produced animal and then enlarged by budding new zooids from one another. The result was a spreading rhabdosome composed of a few to many hundreds of minute tubes (thecae), each containing its own zooid. The thecae consist of the protein collagen.

With the exception of a small group of living organisms that may be relatives of the graptolites, little is known for sure of the detailed anatomy and ecology of these enigmatic organisms. Based on the shape and patterns of occurrence of their colonies, graptolites were probably suspension feeders that extracted food particles such as bacteria, algae, and other organic matter from the surrounding ocean water. Many graptolite species were very widely distributed throughout the world's oceans during the Ordovician, Silurian, and Early Devonian periods (an interval of about 110 million years in total). Graptolites evolved very rapidly. They are mainly of two sorts: bottom-living (benthic) and free-floating (planktic). Many of these benthic graptolites are grouped by graptolite taxonomists as the Dendroidea. Benthic graptolites also include several other graptolite orders (such as the Tuboidea); however, these are very small and very rare fossils. In contrast to the benthic graptolites, species of the Graptoloidea were planktonic.

Graptoloids lived mostly in the open ocean in relatively offshore or deep-water locations. Thus, they are most common in rocks deposited in outer-shelf and deep-sea environments. Most graptoloid graptolites are preserved in gray to black shales as black or silvery films flattened on the surface of the rock. Most understanding of graptolites' detailed structure comes from material of this kind. [C.E.Mi.]

Grass crops

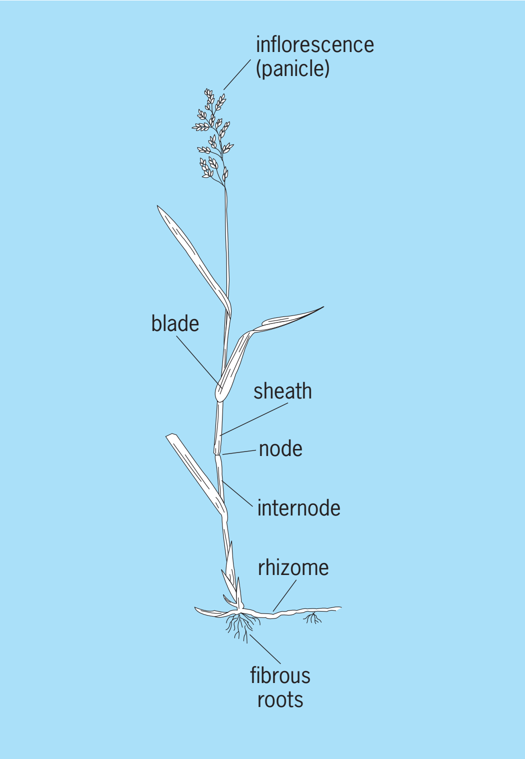
Grass crops Members of the family Gramineae cultivated as forage and grain for consumption. The grasses are the most useful of all the plants that cover the Earth. The cereal grasses supply directly three-fourths of the energy and over half of the protein in food consumed by humans. Indirectly, these cereals together with the forage grasses supply most of the food for the domestic animals that provide milk, meat, eggs, and much of the draft power required to grow crops. *See* BARLEY; CEREAL; CORN; MILLET; OATS; RICE; RYE; SORGHUM; SUGARCANE; WHEAT.

The bamboos are of vast importance in the Indo-Malay region, where they are used in building houses, bridges, furniture, rafts, water pipes, vessels for holding water, and so forth. *See* BAMBOO.

The grasses protect soil from erosion and help conserve water resources. More than any other family of plants, the sod-forming grasses blanket golf courses, athletic fields, lawns, parks, and cemeteries with a protective covering that beautifies and enhances the environment. No other family of plants in the vast plant kingdom is so useful to humans. *See* EROSION; LAWN AND TURF GRASSES; SOIL CONSERVATION.

Grass stems have solid joints (nodes) and leaves arranged in two rows, with one leaf at each joint (see illustration). The leaves consist of the sheath, which fits around the stem like a split tube, and the blade, which is commonly long and narrow. Seed heads are made up of minute flowers on tiny branchlets, often several crowded together, but always two-ranked like the leaves. The flowers are generally wind-pollinated. The seeds are enclosed between two bracts, or glumes, which remain on the seed when ripe.

The 600 genera grouped into 14 tribes that make up the grass family may be annual or perennial. Annuals and some perennial grasses are bunch grasses which spread only by seeding. Others, mostly perennials, also spread by creeping stems called stolons when above ground and rhizomes when below the soil surface. The creeping grasses form the best sods and surpass others for soil conservation; they are also the best turf grasses. All grasses have fine fibrous root systems that permeate the soil extensively to depths ranging from much less than 3 ft to more than 10 ft (1 to 3 m). The roots are short-lived, are continually being replaced, and in the process increase the organic matter content of the soil.



A typical grass plant. (*After P. D. Strausbaugh and E. L. Core, Flora of West Virginia, West Va. Univ. Bull., ser. 52, no. 12–2, pt. 1, p. 67, 1952*)

Grasses are distributed throughout the world. Annual species predominate in the adverse environments found in the deserts and the arctic areas. Temperature is the principal factor determining the distribution of perennial grasses. Perennial grasses are frequently classed as cool- or warm-season grasses depending upon the season in which they make their best growth.

Annuals and most perennial grasses reproduce sexually and are propagated by seed. Many of the grasses are cross-pollinated largely by the wind. In some species, cross-pollination is facilitated by self-incompatibility that occurs at variable frequencies. Most grasses produce perfect flowers containing both male and female organs. The male organs (anthers) must be carefully removed before they shed pollen to make controlled hybrids. A few species, largely tropical perennials, reproduce by apomixis, simply defined as vegetative reproduction through the seed. Apomictic seeds produce the same genotype as the plant that produced them. *See* FLOWER; POLLINATION; REPRODUCTION (PLANT). [G.W.Bur.]

Grassland ecosystem

Grassland ecosystem A biological community that contains few trees or shrubs, is characterized by mixed herbaceous (nonwoody) vegetation cover, and is dominated by grasses or grasslike plants. Mixtures of trees and grasslands occur as savannas at transition zones with forests or where rainfall is marginal for trees. About 1.2×10^8 mi^2 (4.6×10^7 km^2) of the Earth's surface is covered with grasslands, which make up about 32% of the plant cover of the world. In North America, grasslands include the Great Plains, which extend from southern Texas into Canada. The European meadows cross the subcontinent, and the Eurasian steppe ranges from Hungary eastward through Russia to Mongolia; the pampas cover much of the interior of Argentina and Uruguay. Vast and varied savannas and velds can be found in central and southern Africa and throughout much of Australia. *See* SAVANNA.

Grasslands occur in regions that are too dry for forests but that have sufficient soil water to support a closed herbaceous plant canopy that is lacking in deserts. Thus, temperate grasslands usually develop in areas with 10–40 in. (25–100 cm) of annual precipitation, although tropical grasslands may receive up to 60 in. (150 cm). Grasslands are found primarily on plains or rolling topography in the interiors of great land masses, and from sea level to elevations of nearly 16,400 ft (5000 m) in the Andes. Because of their continental location they experience large differences in seasonal climate and wide ranges in diurnal conditions. In general, there is at least one dry season during the year, and drought conditions occur periodically. *See* DROUGHT; PLANT-WATER RELATIONS.

Significant portions of the world's grasslands have been modified by grazing or tillage or have been converted to other uses. The most fertile and productive soils in the world have developed under grassland, and in many cases the natural species have been replaced by cultivated grasses (cereals). *See* CEREAL; GRASS CROPS.

Different kinds of grasslands develop within continents, and their classification is based on similarity of dominant vegetation, presence or absence of specific dominant species, or prevailing climate conditions.

The climate of grasslands is one of daily and seasonal extremes. Deep winter cold does not preclude grasslands since they occur in some of the coldest regions of the world. However, the success of grasslands in the Mediterranean climate shows that marked summer drought is not prohibitive either. In North America, the rainfall gradient decreases from an annual precipitation of about 40 in. (100 cm) along the eastern border of the tallgrass prairie at the deciduous forest to only about 8 in. (20 cm) in the shortgrass prairies at the foothills of the Rocky Mountains. A similar pattern exists in Europe. Growing-season length is determined by temperature in the north latitudes and by available soil moisture in many regions, especially those adjacent to deserts. Plants are frequently subjected to hot and dry weather conditions, which are often exacerbated by windy conditions that increase transpirational water loss from the plant leaves.

Soils of mesic temperate grasslands are usually deep, about 3 ft (1 m), are neutral to basic, have high amounts of organic matter, contain large amounts of exchangeable bases, and are highly fertile, with well-developed profiles. The soils are rich because rainfall is inadequate for excessive leaching of minerals and because plant roots produce large amounts of organic material. With less rainfall, grassland soils are shallow, contain less organic matter, frequently are lighter colored, and may be more basic. Tropical and subtropical soils are highly leached, have lower amounts of organic material because of rapid decomposition and more leaching from higher rainfall, and are frequently red to yellow.

Grassland soils are dry throughout the profile for a portion of the year. Because of their dense fibrous root system in the upper layers of the soil, grasses are better adapted than trees to make use of light rainfall showers during the growing season. When compared with forest soils, grassland soils are generally subjected to higher temperatures, greater evaporation, periodic drought, and more transpiration per unit of total plant biomass. *See* BIOMASS; SOIL.

Throughout the year, flowering plants bloom in the grasslands with moderate precipitation, and flowers bloom after rainfall in the drier grasslands. With increasing aridity and temperature, grasslands tend to become less diverse in the number of species; they support more warm-season species; the complexity of the vegetation decreases; the total above-ground and below-ground production decreases; but the ratio of above-ground to below-ground biomass becomes smaller.

There are many more invertebrate species than any other taxonomic group in the grassland ecosystem. Invertebrates play several roles in the ecosystem. For example, many are herbivorous, and eat leaves and stems, whereas others feed on the roots of plants. Earthworms process organic matter into small fragments that decompose rapidly, scarab beetles process animal dung on the soil surface, flies feed on plants and are pests to cattle, and many species of invertebrates are predaceous and feed on other invertebrates. Soil nematodes, small nonarthropod invertebrates, include forms that are herbivorous, predaceous, or saprophagous, feeding on decaying organic matter. *See* SOIL ECOLOGY.

Most of the reptiles and amphibians in grassland ecosystems are predators. Relatively few bird species inhabit the grassland ecosystem, although many more species are found in the flooding pampas of Argentina than in the dry grasslands of the western United States. Their role in the grassland ecosystem involves consumption of seeds, invertebrates, and vertebrates; seed dispersal; and scavenging of dead animals.

Small mammals of the North American grassland include moles, shrews, gophers, ground squirrels, and various species of mice. Among intermediate-size animals are the opossum, fox, coyote, badger, skunk, rabbit, and prairie dog; large animals include various types of deer and elk. The most characteristic large mammal species of the North American grassland is the bison, although many of these animals were eliminated in the late 1800s. Mammals include both ruminant (pronghorns) and nonruminant (prairie dogs) herbivores, omnivores (opossum), and predators (wolves).

Except for large mammals and birds, the animals found in the grassland ecosystem undergo relatively large population variations from year to year. These variations, some of which are cyclical and others more episodic, are not entirely understood and may extend over several years. Many depend upon predator–prey relationships, parasite or disease dynamics, or weather conditions that influence the organisms themselves or the availability of food, water, and shelter. *See* POPULATION ECOLOGY.

Within the grassland ecosystem are enormous numbers of very small organisms, including bacteria, fungi, algae, and viruses. From a systems perspective, the hundreds of species of bacteria and fungi are particularly important because they decompose organic material, releasing carbon dioxide and other gases into the atmosphere and making nutrients available for recycling. Bacteria and some algae also capture nitrogen from the atmosphere and fix it into forms available to plants. *See* NITROGEN FIXATION; SOIL MICROBIOLOGY.

Much of the grassland ecosystem has been burned naturally, probably from fires sparked by lightning. Human inhabitants have also routinely started fires intentionally to remove predators and undesirable insects, to improve the condition of the rangeland, and to reduce cover for predators and enemies; or unintentionally. Thus, grasslands have evolved under the influences of grazing and periodic burning, and the species have adapted to withstand these conditions. If burning or grazing is coupled with drought, however, the grassland will sustain damage that may require long periods of time for recovery by successional processes. *See* ECOLOGICAL SUCCESSION; ECOSYSTEM. [P.G.Ri.]

Gravel An unconsolidated sedimentary aggregate containing more than 50% by weight of gravel-sized particles (mean diameter greater than 0.08 in. or 2 mm). The gravel-sized particles are termed the framework; those less than 0.08 in. in diameter are the matrix. There is an important distinction between framework-supported and matrix-supported gravels. The latter may possess a muddy matrix, in which case they are termed diamictons. Typically, diamictons are unstratified internally, contain subangular framework clasts, and are deposited by mass-flow processes such as debris flow or glacial-ice transport. Water-laid gravels are typically stratified or cross-stratified and are framework-supported, with subangular to rounded clasts in a sand matrix. Less commonly, they may be sand-matrix-supported, or they may lack matrix and then are termed openwork gravels. Water-worn gravel clasts tend to conform to the shape of triaxial ellipsoids and develop preferred orientation, with long axes normal to stream flow and intermediate axes dipping gently upstream.

The consolidated equivalents of gravels are conglomerates and breccias, the latter including only angular particles. Paleoenvironmental indicators for conglomerates include stratification, size grading, particle roundness, particle orientation, and matrix–framework relations. *See* BRECCIA; CONGLOMERATE; SEDIMENTARY ROCKS. [B.R.R.]

Gravimetric analysis That branch of quantitative chemical analysis in which a desired constituent is converted (usually by precipitation) to a pure compound or element of definite, known composition, and is weighed. In a few cases, a compound or element is formed which does not contain the constituent but bears a definite mathematical relationship to it. In either case, the amount of desired constituent can be determined from the weight and composition of the precipitate.

At least two weighings are required for each analysis—the original sample, and the dried or ignited residue. From these weights, the percentage or proportion of the desired constituent may be calculated from the equation below.

$$\%A = \frac{\text{wt of residue} \times \text{factor} \times 100}{\text{wt of sample}}$$

The factor is determined from a knowledge of the chemical relationships between the weight of substance A contained in, or equivalent to, a fixed weight of residue of known composition. *See* ANALYTICAL CHEMISTRY; QUANTITATIVE CHEMICAL ANALYSIS; STOICHIOMETRY. [S.G.S.]

Gravitation

The mutual attraction between all masses and particles of matter in the universe. In a sense this is one of the best-known physical phenomena. During the eighteenth and nineteenth centuries gravitational astronomy, based on Newton's laws, attracted many of the leading mathematicians and was brought to such a pitch that it seemed that only extra numerical refinements would be needed in order to account in detail for the motions of all celestial bodies. In the twentieth century, however, A. Einstein shattered this complacency, and the subject is currently in a healthy state of flux.

Newton's law of gravitation. Newton's law of universal gravitation states that every two particles of matter in the universe attract each other with a force that acts in the line joining them, the intensity of which varies as the product of their masses and inversely as the square of the distance between them. Or, the gravitational force F exerted between two particles with masses m_1 and m_2 separated by a distance d is given by the equation below, where G is called the constant of gravitation.

$$F = \frac{Gm_1m_2}{d^2}$$

Gravitational constant. In 1774, G was determined by measuring the deflection of the vertical by the attraction of a mountain. This method is much inferior to the laboratory method in which the gravitational force between known masses is measured. In the torsion balance two small spheres, each of mass m, are connected by a light rod, suspended in the middle by a thin wire. The deflection caused by bringing two large spheres each of mass M near the small ones on opposite sides of the rod is measured, and the force is evaluated by observing the period of oscillation of the rod under the influence of the torsion of the wire (see illustration). This is known as the Cavendish experiment, in honor of H. Cavendish, who achieved the first reliable results by this method in 1797–1798. More recent determinations using various refinements yield the results: constant of gravitation $G = 6.67 \times 10^{-11}$ SI (mks) units; mass of Earth $= 5.98 \times 10^{24}$ kg. The result of the best available laboratory measurements, announced in 2002, is $G = (6.6742 \pm 0.0010) \times 10^{-11}$ in SI (mks) units.

In newtonian gravitation, G is an absolute constant, independent of time, place, and the chemical composition of the masses involved. Partial confirmation of this was provided before Newton's time by the experiment attributed to Galileo in which different weights released simultaneously from the top of the Tower of Pisa reached the ground at the same time. Newton found further confirmation, experimenting with pendulums made out of different materials. Early in this century, R. Eötvös found that different materials fall with the same acceleration to within 1 part in 10^7. The accuracy of this figure has been extended to 1 part in 10^{11}, using aluminum and gold, and to 0.9×10^{-12} with a confidence of 95%, using aluminum and platinum.

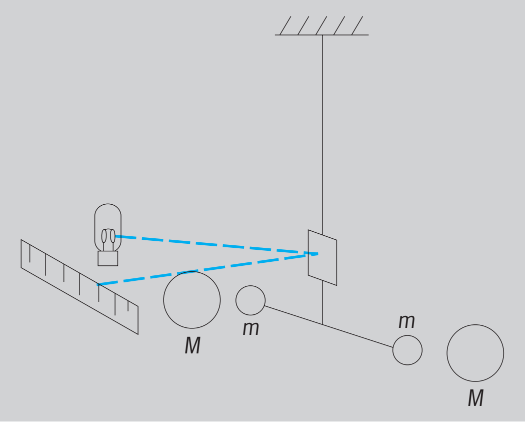


Diagram of the torsion balance.

Mass and weight. In the equations of motion of newtonian mechanics, the mass of a body appears as inertial mass, a measure of resistance to acceleration, and as gravitational mass in the expression of the gravitational force. The equality of these masses is confirmed by the Eötvös experiment. It justifies the assumption that the motion of a particle in a gravitational field does not depend on its physical composition. In Newton's theory the equality can be said to be a coincidence, but not in Einstein's theory, where this equivalence becomes a cornerstone of relativistic gravitation.

While mass in newtonian mechanics is an intrinsic property of a body, its weight depends on certain forces acting on it. For example, the weight of a body on the Earth depends on the gravitational attraction of the Earth on the body and also on the centrifugal forces due to the Earth's rotation. The body would have lower weight on the Moon, even though its mass would remain the same. *See* CENTRIFUGAL FORCE.

Gravity. This should not be confused with the term gravitation. Gravity is the older term, meaning the quality of having weight, and so came to be applied to the tendency of downward motion on the Earth. Gravity or the force of gravity is today used to describe the intensity of gravitational forces, usually on the surface of the Earth or another celestial body. So gravitation refers to a universal phenomenon, while gravity refers to its local manifestation. *See* EARTH, GRAVITY FIELD OF.

Accuracy of newtonian gravitation. A discrepancy in newtonian gravitation was discovered by U.J.J. Leverrier in the orbit of Mercury. Because of the action of the other planets, the perihelion of Mercury's orbit advances. But allowance for all known gravitational effects still left an observed motion of about 43 seconds of arc per century unaccounted for by Newton's theory. Attempts to account for this by adding an unknown planet or by drag with an interplanetary medium were unsatisfactory, and a very small change was suggested in the exponent of the inverse square of force. This particular discordance was accounted for by A. Einstein's general theory of relativity in 1916, but the final word on the subject has yet to be said. *See* RELATIVITY.

Gravitational lens. Light is deflected when it passes through a gravitational field, and an analogy can be made to the refraction of light passing through a lens. It has been suggested that a galaxy situated between an observer and a more distant source might have a focusing effect, and that this might account for some of the observed properties of quasi-stellar objects. The multiple images of the quasar (Q0957 + 561 A,B) are almost certainly caused by the light from a single body passing through a gravitational lens. While this is the best-studied gravitational lens, many other examples of this phenomenon have been discovered. *See* GRAVITATIONAL LENS; QUASAR.

Relativistic theories. In spite of his success and the absence of a reasonable alternative, Newton's theory was heavily criticized, not least with regard to its requirement of "action at a distance" (that is, through a vacuum). Newton himself considered this to be "an absurdity," and he recognized the weaknesses in postulating in his system of mechanics the existence of preferred reference systems (that is, inertial reference systems) and an absolute time.

The theory of relativity grew from attempts to describe electromagnetic phenomena in moving systems. No physical effect can propagate with a speed exceeding that of light in vacuum; therefore, Newton's theory must be the limiting case of a field theory in which the speed of propagation approaches infinity. Einstein's field theory of gravitation (general relativity) is based on the identification of the gravitational field with the curvature of space-time. The geometry of space-time is affected by the presence of matter and radiation. The relationship between mass-energy and the space-time curvature is therefore a relativistic generalization of the newtonian law of gravitation. The relativistic theory is mathematically far more complicated than Newton's. Instead of the single newtonian potential described above, Einstein worked with 10 quantities that form a tensor. *See* TENSOR ANALYSIS.

An important step in Einstein's reasoning is his "principle of equivalence": A uniformly accelerated reference system imitates completely the behavior of a uniform gravitational field. This principle requires that all bodies fall in a gravitational field with precisely the same acceleration, a result that is confirmed by the Eötvös experiment mentioned earlier. Also, if matter and antimatter were to repel one another, it would be a violation of the principle. *See* FREE FALL.

Gravitational waves. The existence of gravitational waves, or gravitational "radiation," was predicted by Einstein shortly after he formulated his general theory of relativity. They are now a feature of any relativity theory. Gravitational waves are "ripples in the curvature of space-time." In other words, they are propagating gravitational fields, or propagating patterns of strain, traveling at the speed of light. They carry energy and can exert forces on matter in their path, producing, for instance, very small vibrations in elastic bodies. The gravitational wave is produced by change in the distribution of some matter. It is not produced by a rotating sphere, but would result from a rotating body not having symmetry about its axis of rotation: a pulsar, perhaps. In spite of the relatively weak interaction between gravitational radiation and matter, the measurement of this radiation is now technically possible. [J.M.A.D.; B.Ma.]

Gravitational collapse The stage in the evolution of a star in which the pressure in the star is insufficient to maintain the star at a stable size. The material in the star or in the core of the star then falls inward under its own gravitational attraction. Depending on the mass, composition, and spin of the star, the collapse may proceed to the formation of a neutron star or black hole, possibly accompanied by a supernova explosion. *See* STELLAR EVOLUTION; SUPERNOVA.

Stars similar to the Sun maintain a stable size by continually burning nuclear fuel. In most stars, as for the Sun, this burning involves the conversion of hydrogen to helium with a release of energy as the nuclear reactions take place. This energy supplies heat to the interior of the star, which in turn keeps the core of the star hot enough so that nuclear reactions can continue. Heat is also continually transferred from the interior to the exterior of the star, where it is lost, primarily in the form of radiation.

Suppose now that the nuclear burning is turned off, as is the case if the hydrogen in the core is used up and only helium remains. Then, no more heat is supplied to the core of the star, and its temperature drops as remaining heat is transported to the surface of the star and is lost. Likewise, since the pressure in the gas depends on the temperature, the pressure in the core also drops, and more importantly, the pressure gradient decreases throughout the star. The various chunks of gas are no longer in equilibrium, and they move inward. This compression of the gas then causes a rise in temperature and the temporary reestablishment of the required temperature gradient. However, as heat is transported outward, the temperature again drops, the gas is further compressed, and so on. In this stage, the star is undergoing contraction, the heating coming from the gravitational potential energy of the star rather than nuclear reactions.

Eventually, the star condenses, and the temperature rises to a sufficiently high value that helium burning can take place. Once again, the star is in stable equilibrium until the reservoir of fuel in the core of the star is used up, after which contraction takes place until conditions are right for nuclear burning of higher elements. The contraction discussed here refers to what is going on in the core of the star; the atmosphere may actually be expanding in the process.

When the star has a core which is composed of iron, no further nuclear burning can take place, since iron is the most stable element. Continued contraction must then take place. In fact, theoretical calculations indicate that under normal conditions the temperature does not rise high enough for nuclear burning to proceed beyond carbon, at which point the star effectively runs out of fuel, and continued contraction also takes place. If, after ejection of material by the star, the mass of the star is less than about 1.2–1.4 solar masses, the limiting value known as the Chandrasekhar limit, the contraction takes place to a white dwarf. Observations suggest that stars of up to 8 solar masses can eject sufficient matter to become white dwarfs. A white dwarf is stable without any nuclear burning taking place. The pressure gradient is produced by the same kind of quantum interactions among the electrons as those which make atoms stable. *See* WHITE DWARF STAR.

Theoretical studies indicate that a star of more than about 8 solar masses will not lose enough mass in its evolution to become a white dwarf. The contracting star at some point becomes unstable; that is, the heating as a result of contraction is insufficient to produce the required pressure gradient to support the gas against gravity. This instability occurs first in the core of the star, and the core starts to fall inward on itself. This is the stage of gravitational collapse. In essence, the core is freely falling inward under its own gravitational attraction.

A collapsing core will be too condensed to form a white dwarf, even if its mass is less than the maximum allowed mass. The only other known possibilities are collapse to a neutron star and collapse to a black hole. A neutron star is a highly condensed star in which the predominant constituent of matter is in the form of neutrons. The stability of such stars is a result of the quantum-mechanical interaction of neutrons, the same kind of interaction which, for electrons, leads to stability of white dwarfs. *See* NEUTRON STAR.

Some collapsing stars are expected to end up with a core which has a mass larger than the maximum mass of a neutron star. In addition, neutron stars (and white dwarfs as well) which had been formed earlier could accrete enough matter to become more massive than the maximum mass of a neutron star. In these cases, the only known alternative is for such stars to collapse to a black hole. A black hole is a region in space in which gravity is so strong that even light cannot escape from its surface. Although black holes had been conjectured earlier, Karl Schwarzschild found the first black-hole solution of general relativity in 1916, although the significance of the solution as a black hole was not realized at the time. After suggestions that black holes might be an end point of stellar evolution, J. R. Oppenheimer and H. Snyder showed in 1939 that a black hole must result from spherically symmetric gravitational collapse if the mass of the collapsing body is large enough. At present, a black hole is believed to be the only result of a collapsing star that cannot lose enough matter to become a white dwarf or neutron star. Black holes are even more condensed than neutron stars. For example, a 1-solar-mass black hole would have a radius of about 2 mi (3 km). *See* BLACK HOLE.

Because black holes emit no light, they are intrinsically dark and directly unobservable. However, they can still have an effect on nearby matter because their gravitational field is still present. In fact, there is strong evidence that at least one condensed body in a binary star system, Cygnus X-1, is a black hole. Its gravitational field results in matter heating up sufficiently to emit x-rays, which can only be done by a highly condensed body, and its mass is determined from the orbital motion to be larger than 5 solar masses. From theory, the only known body which has these properties is a black hole. Black holes have also been identified by similar evidence in several other x-ray binaries, including LMC X-3 and A0620-00. There is no proof that such black holes came from the gravitational collapse of a star, but that is the most reasonable hypothesis. *See* Astrophysics, high-energy; Binary star; X-ray astronomy. [P.C.P.]

Gravitational lens A massive body producing distorted, magnified, or multiple images of more distant objects when its gravitational fields bend the paths of light rays. Lenses have been observed when the light from very distant quasars is affected by intervening galaxies and clusters of galaxies, producing several different images of the same quasar. A. Einstein predicted the occurrence of this phenomenon in 1936, but the discovery of real gravitational lenses did not occur until 1979. Gravitational lenses, in addition to being intrinsically interesting, can reveal the intrinsic properties of galaxies, active galaxies, and quasars, and provide information on the universe and its contents, including dark matter.

The lens phenomenon exists because gravity bends the paths of light rays, which is predicted by Einstein's general theory of relativity. Since photons, the carriers of light energy, have no mass, Newton's theory of gravity indicates that light would always travel in a straight line even if there were heavy, massive objects between the source and the observer. (Even if photons are given mass in Newton's theory, the predicted bending of light is different from the result in general relativity.) But in general relativity, gravity acts by producing curvature in space-time, and the paths of all objects, whether or not they have mass, are also curved if they pass near a massive body. *See* Gravitation; Relativity.

The discovery of gravitational lenses affects astronomers' understanding of the universe on the very largest scales. The very existence of this phenomenon indicates that nearly a dozen quasars—the ones that are being lensed—are more distant than the galaxies that are focusing their light. When quasars were first discovered, some astrophysicists argued that their redshifts were produced by exotic new physics and the quasars were just beyond the boundary of the Milky Way Galaxy. This controversy has largely subsided but has not been completely resolved. The lens phenomenon shows that at least some quasars are billions of light-years away, well beyond the edge of the Milky Way. If some quasars are billions of light-years away and others look like them, it is reasonable to conclude that all quasars are billions of light-years away at the edge of the observable universe.

Gravitational lenses can be used to determine the distance scale of the universe. Most quasars change the amount of light that they produce. In the case of a multiply imaged quasar like PG 1115 + 080, observers on Earth could see that change occur at different times because light travels on different paths to get here. The image where light travels on a more direct path would brighten first, and the one taking a more roundabout route would brighten later. The differences in the two path lengths can be used to deduce the distance to the quasar and the lensing object. Astronomers can then measure the redshifts of these distant objects and use the lens as another way to determine how fast the universe is expanding.

This seemingly easy idea is hard to implement in practice. Only one of 500 quasars is lined up in exactly the right way, and the mass distribution in the lensing object must be fully understood in order to interpret the data correctly. Sharp infrared pictures from the Hubble Space Telescope severely constrained possible models of the lens, making the interpretation much more secure. The data indicate a Hubble constant of 70 kilometers per second per megaparsec (the conventional units for measuring the Hubble constant), meaning that, if the universe has a very low density, its age is 14 billion years. *See* Cosmology; Hubble constant.

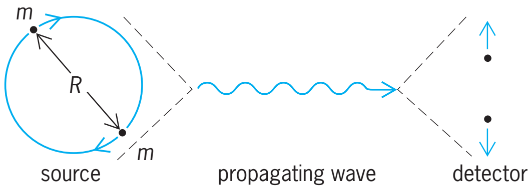
Gravitational lenses also enable the discovery of invisible objects. The speed with which stars move in galaxies and galaxies move in galaxy clusters indicates that many galaxies may be surrounded by massive dark halos. Since the matter that composes these halos cannot be seen, the name "dark matter" has been used to describe it. The dark matter could be brown dwarfs (objects not massive enough to be stars), dead stars, Jupiter-sized objects, or subnuclear particles. The more massive forms of dark matter are termed MACHOs (massive compact halo objects). *See* Brown dwarf.

If a MACHO passed directly between a distant star and the Earth, the light from the star could be temporarily brightened as the MACHO focused the starlight toward the Earth. Precise calculations of this event indicate that the brightening should last about a week. Several teams of astronomers have made repeated observations of a nearby galaxy, the Large Magellanic Cloud, in search of this phenomenon, and seven such events have been detected. These events indicate that MACHOs, which are probably low-mass white dwarf stars, make up a sizable fraction of the mass of the halo of the Milky Way Galaxy, probably at least 20% of the dark matter and possibly as much as 100%. *See* Magellanic clouds; Milky Way Galaxy. [H.L.Sh.]

Gravitational radiation A type of wave generated by accelerated masses that propagates through vacuum with the speed of light. The existence of gravitational radiation is an inescapable consequence of A. Einstein's general theory of relativity.

Properties. The general theory of relativity posits that matter (and energy) introduces curvature into four-dimensional space-time and that matter moves in response to this curvature. The degree of curvature generated by a distribution of matter can be calculated by using the Einstein field equations, which are analogous to the Maxwell field equations of electromagnetism. The Einstein equations admit solutions corresponding to weak, transverse waves that propagate in vacuum with the speed of light just like the electromagnetic waves predicted by Maxwell's equations and demonstrated experimentally by H. Hertz in 1884. However, while electromagnetic waves are fluctuations in the electric field vector which can be measured by the acceleration of a single charged particle, gravitational waves are fluctuations in the tidal gravitational force which is measured by a tensor and can be detected by the relative acceleration induced between two free test masses (see illustration). *See* Electromagnetic radiation; Maxwell's equations.

Sources. In 1974, R. Hulse and J. Taylor discovered the first binary pulsar, now known as PSR 1913+16. This is believed to comprise two neutron stars, one of which spins with a period of 59 milliseconds and emits regular radio pulses with an equal period. Radio astronomers on Earth observe a pulse period that varies slightly as the pulsar source traces an elliptical orbit around its companion due to the Doppler effect. This system emits gravitational waves with a fundamental period equal to the orbital period of 7.8 h, and these waves carry energy away from the binary, causing it to become more tightly bound. The orbital period decreases as the two stars approach one another. The fractional change in the measured orbital period agrees with the relativistic prediction to approximately 0.5%, a striking verification of general relativity. *See* Doppler effect; Neutron star; Pulsar.



Generation and detection of gravitational waves. A powerful source of these waves, such as a neutron star binary with a circular orbit, radiates with a fundamental period equal to half the orbital period. The presence of the wave can be demonstrated conceptually by measuring the relative acceleration between two free masses.

When such binary stars shrink so that their orbital periods are only a few milliseconds, the rate of radiation increases dramatically. The waves emitted by such coalescing stars may be strong enough to measure at Earth even when the stars reside in quite distant galaxies. Other proposed sources of detectable gravitational radiation include supernovae, binary black holes in active galactic nuclei, and cosmic strings. *See* BLACK HOLE; COSMIC STRING; SUPERNOVA. [R.D.Bl.]

Detectors. The direct detection of gravitational waves has not yet been achieved, though there is an active research program directed toward the construction of appropriate ultrasensitive detectors. The two classes of detectors are resonant-mass and free-mass antennas. Both types comprise a mechanical element and a transducer that converts mechanical motion to an electronic signal. *See* TRANSDUCER.

The resonant-mass antennas are commonly cylindrical bars of a few tons mass, although a mass in the shape of a icosahedron (a body with 60 faces, like a soccer ball) would be superior to a cylinder. The material most commonly used is aluminum. To reduce thermal noise, the bar is brought to cryogenic temperatures in a vacuum vessel cooled by liquid helium and is isolated against vibrations from the terrestrial environment by a series of mechanical filters. The lowest-frequency longitudinal mode of the antenna, in which the two end faces of the cylinder are displaced in opposition, is most strongly excited by a passing gravitational wave. An electromechanical transducer is attached to one end face of the bar to detect the bar's vibration.

The free-mass antennas are composed of almost inertial masses which are actually very low frequency pendulums. A common design is the arrangement of three such masses at the vertices of a right triangle with equal legs lying on the surface of the Earth. The passage of a gravitational wave in a direction perpendicular to the plane of the free-mass antenna lengthens one leg of the triangle relative to the perpendicular leg. This change in length can be detected by a laser interferometer which is composed of mirrors mounted on the masses and a high-power visible laser light source. Each mass is rigorously isolated from vibrations in the environment, and the entire system is placed in a high-vacuum chamber to eliminate light scattering by gas and dust particles. *See* INTERFEROMETRY. [M.F.B.; D.H.D.]

Gravitational redshift A shift toward longer wavelengths of spectral lines emitted by atoms in strong gravitational fields. It is also known as the Einstein shift. One of three famous predictions of the general theory of relativity, this shift results from the slowing down of all periodic processes in a gravitational field. The amount of the shift is proportional to the difference in gravitational potential between the source and the receiver. For starlight received at the Earth the shift is proportional to the mass of the star divided by its radius. In the solar spectrum the shift amounts to about 0.001 nanometer at a wavelength of 500 nm. In the spectra of white dwarfs, whose ratio of mass to radius is about 30 times that of the Sun, the shift is about 0.03 nm, which can easily be measured if it can be separated from the Doppler effect. This was first done by W. S. Adams for the companion of Sirius, a white dwarf whose true velocity relative to the Earth can be deduced from the observed Doppler effect in the spectrum of Sirius. The measured shift agreed with the prediction based on Einstein's theory and on independent determinations of the mass and radius of Sirius B. A more accurate measurement was carried out in 1954 by D. M. Popper, who measured the gravitational redshift in the spectrum of the white dwarf 40 Eridani B. Similar measurements, all confirming Einstein's theory, have since been carried out for other white dwarfs. Attempts to demonstrate the gravitational redshift in the solar spectrum have thus far proved inconclusive, because it is difficult to distinguish the gravitational redshift from so-called pressure shifts resulting from perturbations of the emitting atoms by neighboring atoms. *See* WHITE DWARF STAR.

Gravitational redshift has also been detected as temperature fluctuations in the observed cosmic microwave background. In 1967 R. K. Sachs and A. M. Wolfe showed that large-scale fluctuations in cosmic density should lead to different gravitational redshifts of observed microwave photons; the measurement of angular temperature variations therefore gives direct information about the mass distribution. This effect was observed in 1992 by the *Cosmic Background Explorer* (*COBE*) satellite, and has become a key tool in measuring the initial density perturbations from which cosmological structures are believed to have formed by gravitational instability. *See* COSMIC BACKGROUND RADIATION; COSMOLOGY; RELATIVITY. [D.La.; A.A.]

Graviton A theoretically deduced particle postulated as the quantum of the gravitational field. According to Einstein's theory of general relativity, accelerated masses (or other distributions of energy) should emit gravitational waves, just as accelerated charges emit electromagnetic waves. And according to quantum field theory, such a radiation field should be quantized; that is, its energy should appear in discrete quanta, called gravitons, just as the energy of light appears in discrete quanta, namely photons. *See* ELEMENTARY PARTICLE; GRAVITATION; QUANTUM FIELD THEORY; RELATIVITY. [C.J.G.]

Gravity The gravitational attraction at the surface of a planet or other celestial body. The quantity *g* is often referred to simply as "gravity" or "the force of gravity" of Earth, both of which are incorrect. The force of gravity means the force with which a celestial body attracts an object, that is, the weight of the object. The letter *g* represents the acceleration caused by the gravitational force and, of course, has the dimensions of acceleration. *See* GRAVITATION. [D.Br./G.M.C.]

Gravity meter A device that measures local acceleration due to the Earth's gravity; it is also called a gravimeter. Such instruments fall into two categories: relative gravity meters, which are used to determine gravity differences among a number of geographic locations or changes in gravity that occur at a single location over time; and absolute gravity meters, which can measure the true value of the acceleration due to gravity at a given location and time.

The local value of gravity is the acceleration undergone by a freely falling mass upon which gravity is the only force acting. Because the value of gravity at any particular position depends on the distribution of mass throughout the Earth (and also slightly on the Earth's rotation), measurements of the gravity field can yield information on the density of underlying rock. Thus, gravity meters are used for geologic studies and for oil and mineral exploration. Local gravity also depends on the shape of the Earth; the observation of gravity over time, then, provides a measure of deformations in the Earth that can be caused by a wide variety of phenomena, including tides, tectonic activity, and volcanism.

Nowhere on the surface of the Earth does the value of gravity differ from the nominal value of 980 Gal by more than about 0.5%. (The SI unit for gravity is the meter/second^2; the more commonly used unit is the Gal, defined as 1 cm/s^2, or the milli-Gal, which equals 0.001 Gal.) Values of gravity predicted with a latitude-and-height-dependent Earth model usually agree with observed values to within about 30 mGal. The gravitational acceleration produced by the mass of a 1-m-thick (3-ft) sheet of water (having infinite lateral extent) is 0.043 mGal.

A number of different instruments are available. One of two methods is used in all gravity meters. The first, employed by absolute gravity meters, is the direct determination of the acceleration of a test mass falling inside a vacuum chamber by using optical interferometry. The second is the observation of variations in the position of a mass supported by a mechanical or magnetic spring. This method, applied in relative gravity meters and shipboard gravity meters, is usually used in conjunction with an additional applied force (nulling force) that maintains the mass at a null position. The small nulling force is a relative measure of gravity. *See* GRAVITY. [M.A.Z.]

Graybody An energy radiator which has a blackbody energy distribution, reduced by a constant factor, throughout the radiation spectrum or within a certain wavelength interval. The designation "gray" has no relation to the visual appearance of a body but only to its similarity in energy distribution to a blackbody. Most metals, for example, have a constant emissivity within the visible region of the spectrum and thus are graybodies in that region. The graybody concept allows the calculation of the total radiation intensity of certain substances by multiplying the total radiated energy (as given by the Stefan-Boltzmann law) by the emissivity. The concept is also quite useful in determining the true temperatures of bodies by measuring the color temperature. For a discussion of the Stefan-Boltzmann law and color temperature *see* HEAT RADIATION; BLACKBODY. [H.G.S.; P.J.W.]

Graywacke A well-indurated dark gray sandstone that is characterized by abundant dark-colored detrital rock fragments and more than 15% clay matrix minerals between sand grains. Graywacke sands were deposited chiefly in marine basins near the edge of continental margins where plate subduction was taking place. Subsequent compressional deformation and uplift of rocks in the sedimentary basins results in the occurrence of most graywackes in Alpine-type (compressional) mountain ranges. *See* CLAY MINERALS; CONTINENTAL MARGIN.

Graywackes have a wide range in mineral composition, which reflects the varied source rocks from which the detritus in them was derived. They tend to be quartz-poor (10–50%), to be rich in both feldspar and unstable rock fragments, and to contain several percent of unstable accessory minerals such as micas, pyroxenes, and amphiboles. Feldspathic graywackes (those in which feldspar exceeds rock fragments) are derived chiefly from plutonic cores of denuded island arcs. Lithic graywackes (those in which rock fragments exceed feldspar) are derived either from volcanic island arcs or from sedimentary rocks in adjacent basins that were deformed and uplifted. Volcanic rock fragments characterize the former type of lithic graywackes, whereas sandstone, shale, and their weakly metamorphosed equivalents characterize the latter type.

Most graywackes were deposited in submarine fans and adjacent basin-plain environments by turbidity currents. They commonly display graded bedding, Bouma sequences, and current-formed and biogenic sole marks. The term Bouma sequence refers to five divisions of a single, ideal turbidity current deposit. Graywackes are interbedded with shale beds that were deposited by dilute turbidity currents and other marine processes. Thicknesses of several miles of interbedded turbidite graywacke and shale accumulated in many basins. Burial and subsequent compressional deformation of these sequences resulted in the generation of clay matrix, loss of porosity, and strong induration. The gray color of the sandstone is derived from rock fragments and organic-stained clay minerals. *See* ARKOSE; SANDSTONE; SEDIMENTARY ROCKS; SHALE; TURBIDITE; TURBIDITY CURRENT. [E.F.McB.]

Great circle, terrestrial A circle or near-circle representing a trace on the Earth's surface of a plane that passes through the center of the Earth and divides it into equal halves (see illustration). The Equator is a great circle, the trace of the plane that bisects and is perpendicular to the Earth's axis. Planes through the Poles cut the Earth along meridians. All meridians are great circles; actually, they are not quite circular because of the slightly flattened Earth. The equatorial diameter is 1.0034 times the size of the polar diameter. All parallels other than the Equator are called small circles, being smaller than a great circle.

Two common methods can be used to calculate the distance of a great circle arc. One method uses trigonometric functions: $\cos D = \sin a \sin b + \cos a \cos b \cos c$. Here D is the arc distance between points A and B in degrees, a is the latitude of A, b is the latitude of B, and c is the difference in longitude between A and B. After D is calculated, it can be converted to a linear distance measure by multiplying D by the length of one degree of the Equator, which is 111.32 km or 69.17 mi.

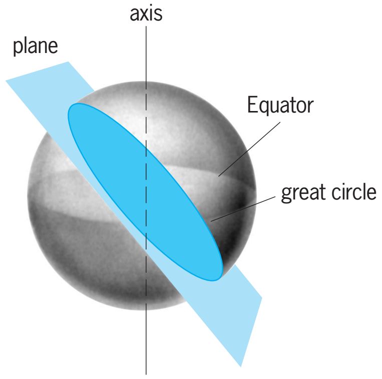


Diagram of a great circle described by a plane through the center of the Earth.

The other method uses the azimuthal equidistant projection. Unlike the gnomonic projection, the azimuthal equidistant projection can be centered at any point on the Earth's surface and can show the entire sphere. More importantly, a straight line from the center of the projection to any other point is a great circle route and the distances are at a comparable (consistent) scale between the two points. The azimuthal equidistant projection is therefore useful in showing any movement directed toward or away from a center, such as seismic waves, radio transmissions, missiles, and aircraft flights. [K.t.C.]

Greenhouse effect The ability of a planetary atmosphere to inhibit heat loss from the planet's surface, thereby enhancing the surface warming that is produced by the absorption of solar radiation. For the greenhouse effect to work efficiently, the planet's atmosphere must be relatively transparent to sunlight at visible wavelengths so that significant amounts of solar radiation can penetrate to the ground. Also, the atmosphere must be opaque at thermal wavelengths to prevent thermal radiation emitted by the ground from escaping directly to space. The principle is similar to a thermal blanket, which also limits heat loss by conduction and convection. In recent decades the term has also become associated with the issues of global warming and climate change induced by human activity. *See* ATMOSPHERE; SOLAR RADIATION.

Basic understanding of the greenhouse effect dates back to the 1820s, when the French mathematician and physicist Joseph Fourier performed experiments on atmospheric heat flow and pondered the question of how the Earth stays warm enough for plant and animal life to thrive; and to the 1860s, when the Irish physicist John Tyndall demonstrated by means of quantitative spectroscopy that common atmospheric trace gases, such as water vapor, ozone, and carbon dioxide, are strong absorbers and emitters of thermal radiant energy but are transparent to visible sunlight. It was clear to Tyndall that water vapor was the strongest absorber of thermal radiation and, therefore, the most influential atmospheric gas controlling the Earth's surface temperature. The principal components of air, nitrogen and oxygen, were found to be radiatively inactive, serving instead as the atmospheric framework where water vapor and carbon dioxide can exert their influence.

The impact of water vapor behavior was noted by the American geologist Thomas Chamberlin who, in 1905, described the greenhouse contribution by water vapor as a positive feedback mechanism. Surface heating due to another agent, such as carbon dioxide or solar radiation, raises the surface temperature and evaporates more water vapor which, in turn, produces additional heating and further evaporation. When the heat source is taken away, excess water vapor precipitates from the atmosphere, reducing its contribution to the greenhouse effect to produce further cooling. This feedback interaction converges and, in the process, achieves a significantly larger temperature change than would be the case if the amount of atmospheric water vapor had remained constant. The net result is that carbon dioxide becomes the controlling factor of long-term change in the terrestrial greenhouse effect, but the resulting change in temperature is magnified by the positive feedback action of water vapor.

Besides water vapor, many other feedback mechanisms operate in the Earth's climate system and impact the sensitivity of the climate response to an applied radiative forcing. Determining the relative strengths of feedback interactions between clouds, aerosols, snow, ice, and vegetation, including the effects of energy exchange between the atmosphere and ocean, is an actively pursued research topic in current climate modeling. *See* CLIMATE MODIFICATION. [A.A.L.]

Greenhouse technology Along with low tunnels and high tunnels, greenhouses are structures used to grow plants under protected conditions. The progression of terms shows the level (low to high) of technical sophistication in the plant-growing systems. Low tunnels, also called row covers, primarily advance the growing season for outdoor crops (for example, tomatoes, melons, strawberries, and sweet corn). Low tunnels are created using long, narrow strips of transparent plastic material (often polyethylene) buried in the ground along their outer edges to cover one or several adjacent rows of plants grown directly in the soil. High tunnels are large versions of low tunnels, raised sufficiently above the ground that people can walk within them. Greenhouse (or glass-houses) are relatively permanent structures (usually glass or plastic with aluminum or steel frames) equipped with several means of environmental modification.

Construction. Free-standing greenhouses are the most basic structural type. Cross-sectional shapes can be classified as arch, hoop, or gable (see illustration). Multispan greenhouses are typically connected by a series of roof gutters to create a single air space. Large multispan greenhouses can cover several hectares under one roof, and they are the design of choice for larger commercial greenhouse operators. Floors are frequently made of concrete, although gravel floors with concrete walkways may be used to reduce cost.

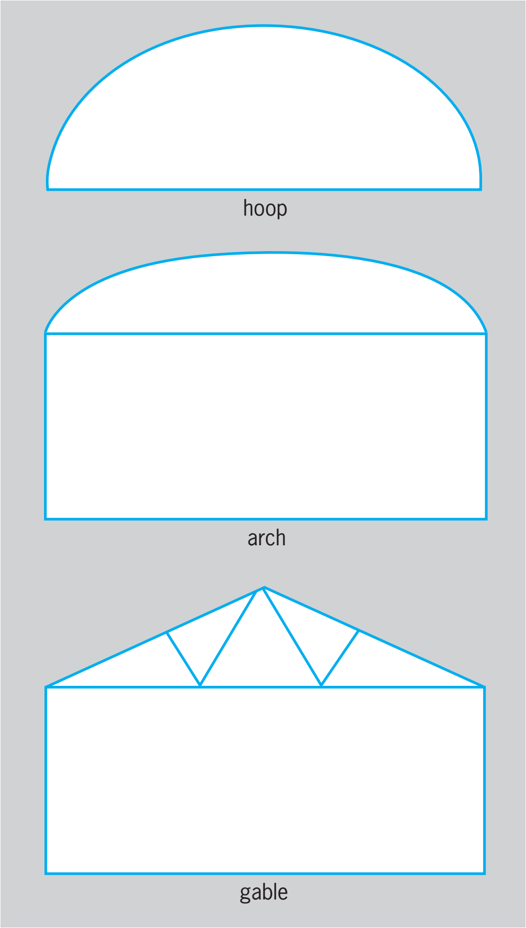
Light transmittance is important when selecting a covering material. Glass provides the most light to the plants and retains its light transmittance; however, various rigid and film plastic glazing materials are used because of initial lower costs. *See* GLASS.

Environment control. Environment control typically encompasses air temperature, supplemental light, air movement (circulation and mixing), and carbon dioxide concentration. Some degree of relative humidity control may also be included. Integrated control by computer, found in most modern greenhouses, provides the flexibility of zoned control of each environmental parameter without conflicting control signals (for example, ventilating while supplementing carbon dioxide).

Structural insulation opportunities in greenhouses are minimal and heat requirements are high in comparison to most other types of buildings. Efforts to conserve heat, such as insulating the north wall and part of the north roof, have often shown negative benefits by reducing natural light and degrading plant growth and quality. Movable, horizontal, indoor curtain systems (which also double as movable shade systems) can save approximately one-quarter of the yearly heat in a cold climate.

Greenhouses can be heated by oil or natural gas. Heat delivery is either hydronic (hot water) or by steam. *See* HEAT.

Solar loads in greenhouses are so great that mechanical cooling, as by air conditioning, is prohibitively expensive. Options for greenhouse cooling are thus limited. The most typical cooling mechanism is ventilation, either natural or mechanical. The next step of cooling is to use evaporative means. Cooling can be obtained by spraying a fine mist into the ventilation air or by pulling outside air through matrices or structures that are wetted to cool the air flowing past them.



Common commercial greenhouse shapes.

Greenhouse lighting may be used for photoperiodic reasons, or for enhancing growth. Photoperiodic lighting is a very low intensity light during the night to break the darkness period and induce plant responses representative of summer (short nights and long days). Greenhouse supplemental lighting is usually provided by high-pressure sodium (HPS) lights because of their relatively high energy efficiency. *See* LIGHT; PHOTOPERIODISM; PHOTOSYNTHESIS.

Optimum concentrations of carbon dioxide are often in the range 800–1000 ppm, which can lead to 25% greater growth provided that other inputs are not limited. Carbon dioxide can be added through carefully controlled flue gases from the greenhouse heating system, or from tanks of liquid carbon dioxide.

Mechanization and automation. Many greenhouse operations that were formerly done by hand are now mechanized or automated. Root medium is mixed, fertilized, and placed directly into flats and pots by machine. Seeding and transplanting can be by machine. Plant watering and fertilizing (termed "fertigation" when combined) can now be automated. Automatic material movement at harvest, coordinated by a computer, is no longer unusual.

Nutrition management and hydroponics. Plant fertilizers are composed of a mix of salts that are electrically conducting when dissolved into water. This characteristic leads to the use of electrical conductivity as a measure of fertilizer concentration. Computer programs have been developed that are suitable for balancing a nutrient mix to achieve close approximations to the desired molar ratios of elements. *See* PLANT MINERAL NUTRITION.

Hydroponics is defined as growing plants without using soil. However, a root medium such as sand, gravel, or rockwool may be used. Two common hydroponics systems that use no root medium are the nutrient film technique (NFT) and deep flow troughs (DFT). *See* HYDROPONICS.

Economics. Modern greenhouse technologies have mirrored developments in most of agriculture in that increased labor efficiency, larger sizes of greenhouse operations, and mass production of a few crops, or even a single crop, have become the rule to be profitable. The current dynamic in the greenhouse industry in the United States is characterized by the entry of many growers in small, specialized operations, and consolidations and mergers of large operations. *See* FLORICULTURE; PLANT GROWTH; PLANT-WATER RELATIONS. [L.D.A.]

Greenockite A mineral having composition CdS (cadmium sulfide). Greenockite usually occurs as earthy coatings with resinous luster and yellow-to-orange color. There is good prismatic cleavage; the hardness is 3 (Mohs scale) and specific gravity is 4.9. Greenockite and wurtzite, ZnS, are isostructural, and a complete solid-solution series exists between the two minerals. Although greenockite is the most common cadmium mineral, no deposits of it are sufficiently large to warrant mining it solely as a source of cadmium. *See* CADMIUM. [C.S.Hu.]

Green's function A solution of a partial differential equation for the case of a point source of unit strength within the region under examination. The Green's function is an important mathematical tool that has application in many areas of theoretical physics including mechanics, electromagnetism, acoustics, solid-state physics, thermal physics, and the theory of elementary particles. The underlying physics in each of these areas is generally described by some linear partial differential equation which relates the physical variable of interest (electrostatic potential or pressure amplitude in a sound wave, for example) to a source function. For present purposes the source may be regarded as an independent entity, although in some applications (for example, particle physics) this view masks an inherent nonlinearity. The source may be physically located within the region of interest, it may be simulated by certain boundary conditions on the surface of that region, or it may consist of both possibilities. A Green's function is a solution to the relevant partial differential equation for the particular case of a point source of unit strength in the interior of the region and some designated boundary condition on the surface of the region. Solutions to the partial differential equation for a general source function and appropriate boundary condition can then be written in terms of certain volume and surface integrals of the Green's function. *See* DIFFERENTIAL EQUATION. [P.Sh.]

Green's theorem A term used variously in mathematical literature to denote either (1) the Gauss divergence theorem,

$$\int\int\int \nabla \cdot \Im dV = \int\int \Im \cdot v dS$$

or some one of several forms or immediate consequences of this theorem, or (2) the plane case of Stokes' theorem. *See* CALCULUS OF VECTORS; GAUSS' THEOREM; STOKES' THEOREM. [H.V.C.]

Gregarinia A subclass of the class Telosporea. These protozoans occur principally as extracellular parasites in the digestive tracts and body cavities of invertebrates. There are three orders: the Archigregarinida, whose life cycle embraces both sexual and asexual phases; the Eugregarinida, which increases only by sporogony; and the Neogregarinida, whose life cycle involves schizogony and gamont formation. *See* ARCHIGREGARINIDA; EUGREGARINIDA; NEOGREGARINIDA; TELOSPOREA. [E.R.B./N.D.L.]

Greisen A type of hydrothermal wall-rock alteration and a class of tin-tungsten deposits (greisen deposits). Hydrothermal wall-rock alteration is the process whereby rocks on the margins of hydrothermal flow channels are changed from an original assemblage of minerals to a different one. This change occurs because of heat and mass exchange between water and rock.

Granitic rocks altered to greisen are known as apogranites. They are composed mainly of quartz, topaz (fluoraluminosilicate), and muscovite (white mica), accompanied by accessory minerals such as tourmaline and fluorite. Abundant veins of quartz-topaz are characteristic of intensely greisenized zones. Skarn and limestone on the margins of apogranites may also be altered to greisen (aposkarn greisen and apocarbonate greisen, respectively) with abundant fluorite. Apogranite greisen commonly is accompanied by other types of hydrothermal wall-rock alteration, including early feldspathic and late sericitic and lesser argillic.

Tin-tungsten-(beryllium-molybdenum) deposits in peraluminous granites commonly are accompanied by greisen. Ore minerals may include cassiterite, wolframite, scheelite, molybdenite, bismuth, and bismuthinite, accompanied in some deposits by pyrrhotite and sphalerite, in addition to chalcopyrite and other sulfides. *See* GRANITE.

Tin greisens represent the dominant world source of lode tin, with examples in Southeast Asia (Malaya, Indonesia, Burma, Thailand); southeast China; Tasmania, Australia; Zinnwald and Altenberg (Erzegebirge), Germany; and Cornwall-Devon, southwest England. Greisenized skarn and apocarbonate greisen, also mostly tin deposits (but including beryllium and tungsten), are found in western Tasmania, Australia; Seward Peninsula, Alaska; and Yunnan (tungsten), China. Many of the tungsten deposits of southeast China, the richest tungsten province in the world, occur in greisenized granite. *See* METASOMATISM; ORE AND MINERAL DEPOSITS; PNEUMATOLYSIS; TIN; TUNGSTEN. [M.T.E.]

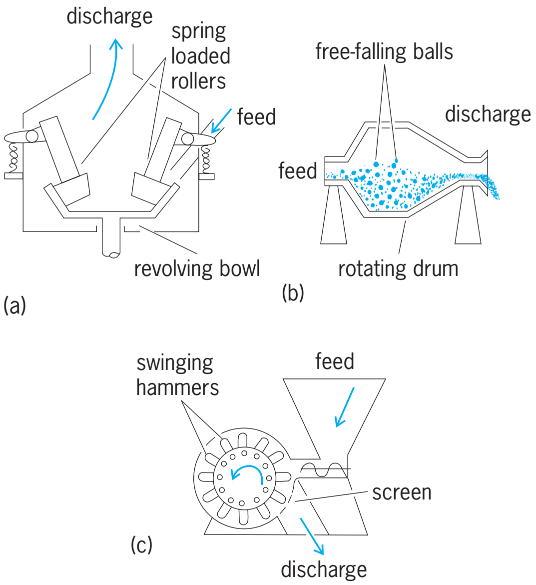
Grignard reaction A reaction between an alkyl or aryl halide and magnesium metal in a suitable solvent, usually absolute ether. The organomagnesium halides produced by this reaction are known as Grignard reagents and are useful in many chemical syntheses. The structure of a Gignard reagent is usually written RMgX, where X represents a halogen.

The scope of the Grignard reaction is extremely broad, and Grignard reagents have been prepared from many kinds of alkyl and aryl halides. In general, alkyl chlorides, bromides, and iodides and aryl bromides and iodides react readily. A few halides, such as aryl chlorides, react very sluggishly. *See* ORGANOMETALLIC COMPOUND. [P.E.F.]

Grimmiales An order of the true mosses (subclass Bryidae) which consist of two families and about five genera and generally grow in dry, exposed places, especially on rock. They are often dark, even blackish, with erect-ascending and simple or forked stems, or prostrate and freely branched stems. The leaves, in many rows, are often hair-pointed with a single and well-developed costa. The cells are generally smooth but commonly have side walls that are nodulose-thickened. The capsules are immersed to exserted (sometimes on curved setae), and are usually erect, symmetric, and sometimes ribbed. The operculum is differentiated, and the single peristome (rarely lacking) is composed of 16 teeth which are commonly perforated or variously cleft. The calyptrae are cucullate or mitrate. *See* BRYIDAE; BRYOPSIDA. [H.Cr.]

Grinding mill A machine that reduces the size of particles of raw material fed into it. The size reduction may be to facilitate removal of valuable constituents from an ore or to prepare the material for industrial use, as in preparing clay for pottery making or coal for furnace firing. Coarse material is first crushed.

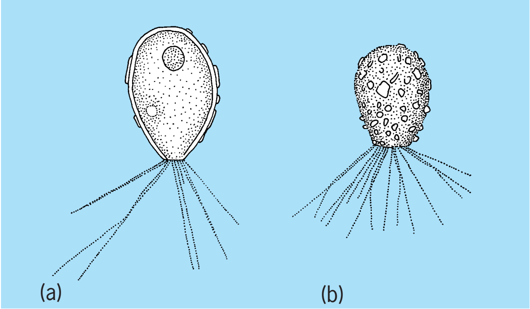
Grinding mills are of three principal types, as shown in the illustration. In ring-roller pulverizers, the material is fed past



Basic grinding mills. (*a*) Ring-roller mill. (*b*) Tumbling mill. (*c*) Hammer mill.

spring-loaded rollers. The rolling surfaces apply a slow large force to the material as the bowl or other container revolves. The fine particles may be swept by an air stream up out of the mill. In tumbling mills the material is fed into a shell or drum that rotates about its horizontal axis. The attrition or abrasion between particles grinds the material. The grinding bodies may be flint pebbles, steel balls, metal rods lying parallel to the axis of the drum, or simply larger pieces of the material itself. In hammer mills, driven swinging hammers reduce the material by sudden impacts. *See* CRUSHING AND PULVERIZING; PEBBLE MILL; TUMBLING MILL. [R.M.H.]

Gromiida An order of the subclass Filosia. The test of these protozoa is mostly chitinous in some species, rather thin and a bit flexible in others. Siliceous particles of endogenous origin, or sometimes minute platelets, may be embedded in the chitinous layer (see illustration); some species typically reinforce the test with sand grains or other extraneous particles. A few species are marine, the rest fresh-water types. Little is known about most Gromiida. *See* FILOSIA. [R.P.H.]



Representative Gromiida. (*a*) *Plagiophrys parvipunctata.* (*b*) *Pseudodifflugia fulva.* (*After R. P. Hall, Protozoology, Prentice-Hall, 1953*)

Ground-probing radar A nondestructive technique using electromagnetic waves to locate objects or interfaces buried beneath the Earth's surface or located within a visually opaque structure; also termed ground-penetrating, surface-penetrating, or subsurface radar.

Ground-probing radar (GPR) transmits a regular sequence of low power bursts of electromagnetic energy into the ground and detects the weak reflected signal from the buried target. The energy is in the form of either a very short duration impulse or a sweep over a range of frequencies. *See* MICROWAVE; RADAR.

The buried target can be a conductor of electricity, a nonconducting dielectric, or combinations of both; the surrounding host material can be soil, earth materials, rocks, ice, fresh water, or human-made materials such as concrete or brick. A typical GPR achieves a range of up to a few meters in depth, but some special systems can penetrate up to hundreds of meters. GPR will not penetrate clay or salt water because of the high absorption of electromagnetic energy by these materials. *See* ABSORPTION OF ELECTROMAGNETIC RADIATION.

GPR can be used on vehicles for rapid survey by means of an array of antennas. Other GPR systems are designed to be inserted into boreholes to provide tomographic images of the intervening rock. Most GPR systems use separate, portable, transmit-and-receive antennas which are placed on the surface of the ground and moved linearly to provide an image of the cross section of the ground traversed.

GPR technology has many applications, some well established and some still undergoing research and development, including forensic investigations, location of abandoned antipersonnel land mines, archeological exploration, and geological surveys. [D.J.Da.]

Ground proximity warning system A system carried on many aircraft to warn the pilot that the aircraft may be in danger of inadvertent contact with the ground. It is intended to reduce the occurrence of controlled-flight-into-terrain (CFIT) accidents, in which aircraft with no apparent mechanical difficulty or defect strike the ground while under the direct or indirect control of the pilot. These accidents usually occur in conditions of poor visibility due to atmospheric obscuration such as fog or rain, or darkness of night. Since 1975, federal aviation regulations have required installation of the system on large turbine-powered aircraft in commercial service.

The heart of the ground proximity warning system (GPWS) is a computer which receives inputs from several sensors on the aircraft and issues warnings to the pilot through visual and aural alerting devices. The primary sensors are the radio altimeter, the barometric altimeter, the electronic glideslope of the Instrument Landing System (ILS), and sensors which indicate aircraft configuration such as the position of flaps and landing gear. *See* ALTIMETER; INSTRUMENT LANDING SYSTEM (ILS).

The system is designed to detect and warn the pilot of excessive descent rate near the ground, excessive terrain closure rate, approaching the ground with landing gear or flaps not in the landing configuration, and descending significantly below the ILS electronic glideslope when on approach to landing. Also, during takeoff and immediately after initiating a missed-approach go-around, the system warns the pilot if the aircraft is descending when it should normally be climbing.

While GPWS has been credited with significantly reducing the incidence of CFIT accidents, it does have limitations. Its sensors cannot detect hazards which may be ahead of the aircraft such as steeply rising terrain or artificial obstacles. In addition, the effectiveness of GPWS is largely dependent on the pilot's prompt reaction to the system's warnings. *See* AIR NAVIGATION. [G.W.F.]

Ground state In quantum mechanics, the stationary state of lowest energy of a particle or a system of particles. The ground state may be bound or unbound; when bound, its energy generally is a finite amount less than the energy of the next higher or first excited state. In the typical circumstance that the potential energy is zero at infinite separation, the magnitude of the negative ground-state energy is the binding energy, that is, the energy required to separate all the particles infinitely. *See* ENERGY LEVEL (QUANTUM MECHANICS); EXCITED STATE; NUCLEAR BINDING ENERGY. [E.G.]

Ground-water hydrology The occurrence, circulation, distribution, and properties of any liquid water residing beneath the surface of the earth. Generally ground water is that fraction of precipitation which infiltrates the land surface and subsequently moves, in response to various hydrodynamic forces, to reappear once again as seeps or in a more obvious fashion as springs. Most of ground-water discharge is not evident because it occurs through the bottoms of surface water bodies. *See* SPRING (HYDROLOGY).

Ground water can be found, at least in theory, in any geological horizon containing interconnected pore space. Thus a ground-water reservoir (an analogy to an oil reservoir) can be a classical porous medium, such as sand or sandstone; a fractured, relatively impermeable rock, such as granite; or a cavernous geologic horizon, such as certain limestone beds. Ground-water reservoirs which readily yield water to wells are known as aquifers; in contrast, aquitards are formations which do not normally provide adequate water supplies, and aquicludes are considered, for all practical purposes, to be impermeable. These terms are, of course, subjective descriptions; the flow of water which constitutes an economically viable supply depends upon the intended use and the availability of alternative sources. *See* AQUIFER.

To effectively utilize ground water as a natural resource, it is necessary to be able to forecast the impact of exploitation on water availability. When ground water is used for water supply, a concern is the potential energy in the aquifer as reflected in the water levels in the producing well or neighboring wells. When a ground-water reservoir which does not readily transmit water is tapped, the energy loss associated with flow to the well can be such that the well must be drilled to prohibitively great depths to provide adequate supplies. On the other hand, in a formation able to transmit fluid easily, water levels may drop because the reservoir is being depleted of water. This is generally encountered in reservoirs of limited areal extent or those in which natural infiltration has been reduced either naturally or through human activities.

Problems involving ground-water quantity were once the primary concern of hydrologists; interest is now focused on ground-water quality. Ground-water contamination is a serious problem, particularly in the highly urbanized areas of the United States. *See* HYDROLOGY; WATER POLLUTION. [G.F.P.]

Grounding Intentional electrical connections to a reference conducting plane, which may be earth (hence the term ground), but which more generally consists of a specific array of interconnected electrical conductors, referred to as the grounding conductor. The symbol which denotes a connection to the grounding conductor is three parallel horizontal lines, each of the lower two being shorter than the one above it (Fig. 1). The electric system of an airplane or ship observes specific grounding practices with prescribed points of grounding, but no connection to earth is involved. A connection to such a reference grounding conductor which is independent of earth is denoted by use of the symbol shown in Fig. 2.

The subject of grounding may be conveniently divided into two categories: system grounding and equipment grounding. System grounding relates to a grounding connection from the electric power system conductors for the purpose of securing superior performance qualities in the electrical system. Equipment grounding relates to a grounding connection from the various electric-machine frames, equipment housings, metal raceways containing energized electrical conductors, and closely adjacent conducting structures judged to be vulnerable to contact by an energized conductor. The purpose of such equipment grounding is to avoid environmental hazards such as electric shock to area occupants, fire ignition hazard to the building or contents, and sparking or arcing between building interior metallic members which may be in loose contact with one another. The design of outdoor open-type installations presents special problems.

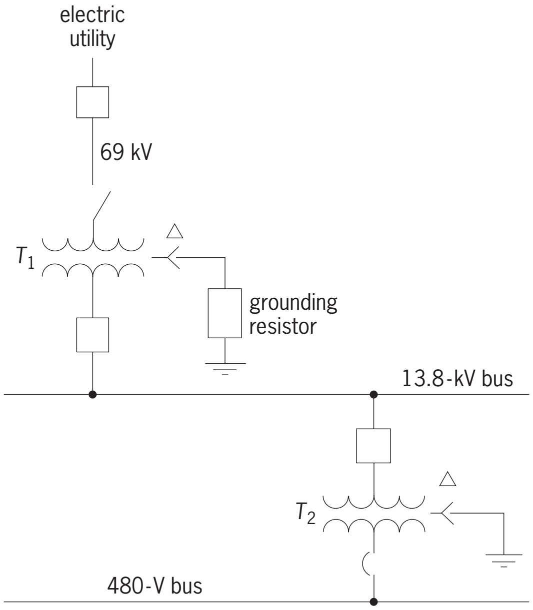


Fig. 1. Each conductively isolated portion of a distribution system requires its ground.

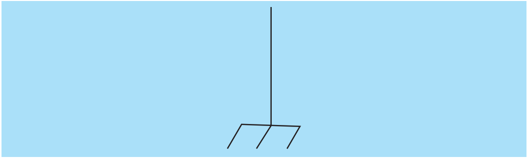

Fig. 2. Symbol to denote connection to a reference ground that is independent of earth.

Installations in which earth is used as a reference ground plane present special problems. To design an earth "floor surface" for an outdoor open-type substation which will be free of dangerous electric shock voltage exposure to persons around the station is a difficult task. [R.H.K.]

Group theory Any set of elements which is equipped with an operation (called multiplication) that is associative, has an identity element, and has an inverse element for each element of the set, is called a group. [These requirements are stated explicitly in Eqs. (1), (2), and (3) below.] Group theory is the branch of mathematics devoted to the properties of groups. Group theory has applications in the theories of relativity, quantum mechanics, and crystallography, and also in some branches of algebra and in analytic function theory.

The group operation is supposed to give for every pair of elements, for example, g and h, in the group, another element gh (called their product). Multiplication is supposed to satisfy the following requirements.

1. If g_1, g_2, and g_3 are any elements of the group, then Eq. (1) is satisfied; that is, in forming a product of three elements one

$$(g_1g_2)g_3 = g_1(g_2g_3) \tag{1}$$

obtains the same result by first multiplying g_1 and g_2 and then multiplying the result and g_3, as first mutiplying g_2 and g_3 and then multiplying g_1 and the result. This is called the associative law.

2. There is in the group an element e (called the identity) with the property that Eq. (2) is satisfied for every element g of the group.

$$eg = ge = g \tag{2}$$

3. For each element g of the group there is an element g^{-1} (called the inverse of g) which satisfies Eq. (3).

$$g^{-1}g = gg^{-1} = e \qquad (3)$$

An example of a group is the set of positive real numbers equipped with the operation of ordinary multiplication. The identity element is then the number 1, and the inverse of an element is its reciprocal. Another example of a group is the set of all real numbers equipped with the operation of ordinary addition. The identity element is then the number 0, and the inverse of an element is its negative.

Both these examples are commutative groups (also called abelian groups after the mathematician Niels Abel) because their multiplication law satisfies Eq. (4) for every g and h in the group.

$$gh = hg \qquad (4)$$

An example of a noncommutative group (also called nonabelian) is the group of rotations of a three-dimensional rigid body around a point.

These three examples are all of groups with an infinite number of elements, that is, infinite groups. There are also finite groups. A simple example is the group with two elements, the identity e and another e_1 satisfying $e_1e_1 = e$.

For infinite groups, it often occurs that a group has a natural geometry. For example, in the group of positive real numbers described above one has the geometry of the real numbers. This geometry is compatible with the group operations in the sense that the product gh is a continuous function of g and h, and the inverse g^{-1} is a continuous function of g. Generalizing this scheme to arbitrary groups, one arrives at the notion of a topological group (or less frequently a continuous group) which is a set of elements equipped not only with a group operation but also with a topology, the two notions being required to be compatible in the above sense. *See* TOPOLOGY.

There is a particular class of topological groups which is of great importance. These are the so-called Lie groups (named after the mathematician Sophus Lie). Most of the topological groups occurring in applications are Lie groups. *See* LIE GROUP.

The principal applications of group theory outside mathematics itself have to do with the classification and exploitation of symmetries in physical systems. [A.S.W.]

A symmetry may be so powerful that its possible realizations can be classified. To accomplish such classifications is the task of the theory of transformation groups. An outstanding example is the classification of possible forms of crystals. *See* CRYSTAL STRUCTURE; CRYSTALLOGRAPHY.

If a physical system is invariant under some group of transformations, then its behavior generally depends upon fewer variables than might appear in general. For instance, if the potential energy due to the interaction between two particles depends on their positions, then in general it depends upon six variables, namely three coordinates for the position of each particle. However, if this energy is invariant under both the group of spatial translations and the group of spatial rotations, then it can depend on only one parameter, the distance between the particles. In this simple example, the reduction in complexity entailed by the symmetries can be inferred rather easily, but in more complex cases, it becomes all but essential to use systematic mathematical procedures to carry out similar reductions.

A major problem in many branches of quantum mechanics is to find the energy levels of the system under study. Group theory is invaluable in predicting such energy levels. For if the fundamental laws describing a physical system have a certain symmetry, then states related by symmetry operations will all have the same energy; and if the fundamental laws are only approximately symmetric, or if some external condition breaks the symmetry, then these states will have nearly but not quite the same energy.

In modern physics, symmetry, or group theory, is increasingly used as a guide to formulating new laws. For example, the discovery that the weak interaction is not invariant under spatial inversion or parity was an important clue for formulating the proper theory of this interaction. *See* PARITY (QUANTUM MECHANICS); WEAK NUCLEAR INTERACTIONS.

A more abstract and wide-ranging symmetry postulate, gauge invariance, plays a central role in the modern theory of fundamental interactions. Roughly speaking, gauge invariance postulates not only that there is an overall symmetry among different entities, but that the symmetry transformations can be made independently at every point of space-time. When applied to the color symmetry of quarks, this powerful hypothesis leads directly to quantum chromodynamics, which is presently accepted as the fundamental theory of the strong interaction. *See* GAUGE THEORY; QUANTUM CHROMODYNAMICS. [F.Wil.]

The applications of group theory within mathematics itself are numerous and important. The part of mathematics in which the notion of group was first clearly isolated was the theory of algebraic equations. In topology, groups are used to classify the structure of various geometric objects. Group theory also plays a fundamental role in the theory of analytic functions. [A.S.W.]

Group velocity The velocity of propagation of a group of waves forming a wave packet; also, the velocity of energy flow in a traveling wave or wave packet. The pure sine waves used to define phase velocity v_p do not ever really exist, for they would require infinite extent. What do exist are groups of waves, wave packets, which are combined disturbances of a group of sine waves having a range of frequencies and wavelengths. Good approximations to pure sine waves exist, provided the extent of the media is very large in comparison with the wavelength of the sine wave. In nondispersive media, pure sine waves of different frequencies all travel at the same speed v_p, and any wave packet retains its shape as it propagates. In this case, the group velocity v_g is the same as v_p. But if there is dispersion, the wave packet changes shape as it moves, because each different frequency which makes up the packet moves with a different phase velocity. If v_p is frequency-dependent, then v_g is not equal to v_p. *See* PHASE VELOCITY; SINE WAVE; WAVE MOTION. [S.A.Wi.]

Grout A binding or structural agent used in construction and engineering applications. Grout is typically a mixture of hydraulic cement and water, with or without fine aggregate; however, chemical grouts are also produced. *See* CEMENT.

The type most commonly specified in construction and engineering is cementitious grout, which is used where its more conventional sister material, concrete, is less suited because of placing limitations or restrictions on coarse-aggregate contents. Cementitious grouts are used to fill voids and cracks in pavements, building and dam foundations, and brick and concrete masonry wall assemblies; to construct floor toppings or provide flooring underlayment; to place ceramic tile; and to bind preplaced-aggregate concrete. *See* CONCRETE.

Grout can be formulated from a variety of cements and minerals and proportioned for specific applications. Neat cement grout refers to formulations without aggregate, containing only hydraulic cement, water, and possibly admixtures. Sanded grout is any mix containing fine aggregate and it is formulated much like masonry mortar. Whether neat or sanded, cementitious grouts derive their strength and other properties from the same calcium silicate-based binding chemistry as concrete. [D.Ma.]

Growth factor Any of a group of biologically active polypeptides which function as hormonelike regulatory signals, controlling the growth and differentiation of responsive cells. Indeed, the distinction between growth factors and hormones is frequently arbitrary and stems more from the manner of their discovery than from a clear difference in function. *See* CELL DIFFERENTIATION; HORMONE.

The sequence of amino acids has been determined for several growth-factor polypeptides. This information permits a number of growth factors to be placed into families, members of which have related amino acid sequences, suggesting that they evolved from a single ancestral protein. The insulin family comprises somatemedins A and C, insulin, insulinlike growth factor (IGF), and multiplication-stimulating factor (MSF). A second family consists of sarcoma growth factor (SGF), transforming growth factors (TGFs), and epidermal growth factor (EGF). In addition, there are growth factors, such as nerve growth factor (NGF), fibroblast growth factor (FGF), and platelet-derived growth factor (PDGF), for which structural homologs have not been identified. *See* INSULIN; PROTEIN.

The stimulation of cell proliferation by several growth factors is similar in some ways to the rapid cell proliferation characteristic of tumor cells. Furthermore, the growth factor receptors are similar to the tumor-causing proteins produced by several RNA tumor viruses. It has been demonstrated that platelet-derived growth factor is virtually identical to the tumor-causing protein of the RNA tumor virus, simian sarcoma virus. Some forms of cancer involve improper function of growth factors. *See* CANCER (MEDICINE); ONCOLOGY; TUMOR VIRUSES. [M.Bo.]

Gruiformes A highly heterogeneous, worldwide order of field, marsh, and aquatic birds that may be closely related to the shorebirds and their allies. (Some taxonomists divide the gruiforms into a number of separate orders.) The order Gruiformes is arranged in 10 suborders and 20 families. *See* CHARADRIIFORMES.

The fossil record of some groups within the Gruiformes is well known from the early Eocene, including the cranes, rails, and seriemas. Other living families have either no fossil record or a poor one.

The Gruiformes range from small to very large. Some have short legs and others long, and the bill varies from short and straight to long and decurved. Some have long wings and are strong fliers, whereas others are flightless. Wading, terrestrial, or aquatic, they are usually found in open country, but some inhabit dense forests. The sexes in most species are similar in plumage, and most species are monogamous. The downy young usually leave the nest shortly after hatching and are cared for by both parents. Northern species are migratory. Some forms, including the kagu and a number of rail species, are flightless. *See* AVES. [W.J.B.]

Guava A plant, *Psidium guajava*, of tropical America. It is a shrub or low tree which belongs to the myrtle family (Myrtaceae). The fruit is a berry, yellow when ripe, and quite variable in size depending on variety and growing conditions. The guava is quite aromatic, sweet, and juicy. It is used mostly for jellies and preserves, but also as a fresh fruit. *See* FRUIT; MYRTALES. [P.D.St./E.L.C.]

Guayule A desert plant, *Parthenium argentatum*, of the composite family (Compositae), which produces rubber. It is a native perennial shrub growing in the Chihuahuan Desert of north-central Mexico and southwestern Texas. The plant is bushy with dense branches, thick clusters of silverlike leaves, a strong taproot, and a thick crown.

During the early decades of this century, guayule was cultivated as an alternative source for rubber. With the development of synthetic rubber and the end of World War 11, economic and political incentives for guayule production disappeared, and all projects were terminated by 1959. Later, in 1976, research was reinitiated as the rising price of oil and the accompanying political difficulties with oil-producing countries rekindled interest in guayule as a source of natural rubber. *See* CAMPANULALES; RUBBER. [D.D.Ru.; L.J.Ca.]

Guidance systems The algorithms and computers utilized to steer a vehicle along a path. The types of vehicles include airplanes, rockets, missiles, ships, torpedoes, drones, and material transport vehicles within factories and so forth. The means of steering depend on the vehicle and can be the rudder, elevators, and other control surfaces on an airplane, the rudder on a ship, the control surfaces on a missile or on a torpedo, the gimbal angle of the motor on a rocket, and others. In every case the guidance system utilizes knowledge of the difference between where the vehicle should be and where it is. The difference between these two vectors is processed by the guidance algorithm. The output is a steering command intended to reduce the error between the desired and the actual paths. *See* CONTROL SYSTEMS; DRONE; ELEVATOR (AIRCRAFT); FLIGHT CONTROLS; SHIP POWERING, MANEUVERING, AND SEAKEEPING.

Several important performance attributes contribute to the effectiveness of the system. These attributes are governed by the guidance system and by the other system components, including the vehicle itself and its dynamic behavior.

A primary concern is accuracy. Whether the goal is to insert a satellite into synchronous orbit or to try to intercept an enemy aircraft with an air-to-air missile, the accuracy of the sensor and the properties of the guidance system are the principal factors.

Another concern is speed of response. Here the dynamics of the vehicle itself can be a limiting factor. The guidance system must compensate to the extent possible in providing a fast, responsive system. The system should be able to recover from errors as quickly as possible and return to the desired path. In the case of homing on a target, this is crucial if the target can maneuver. Coupled with the need for a quick response is the simultaneous need for a stable response.

Another important feature of the system is its robustness. The guidance system design is based on a mathematical model of the vehicle, the autopilot, and the sensor. The guidance system must provide good overall performance despite this. *See* AUTOPILOT.

Reliability is also important. In many cases, backup components are provided for redundancy. This is frequently the case for the digital computer of the guidance system, especially for crewed space flight. *See* RELIABILITY, AVAILABILITY, AND MAINTAINABILITY. [G.C.]

Guided missile A pilotless, controlled-flight vehicle that is guided to a target by guidance and control equipment. This equipment may be carried in the missile vehicle itself, or guidance may be directed from the launch site. The term is generally reserved for aerodynamic, maneuverable missiles that may be guided to predetermined targets for military purposes.

Guided missiles are classified by launch/target mode such as air to air (AAM), air to surface (ASM), surface to air (SAM), surface to surface (SSM), and other possible modes. Missiles may be classified by range (short, medium, long) or by techniques related to tracking and guidance (radar, infrared heat seeker, optical or television, laser, radio, wire control command, acoustical). Some missiles make use of terrain following, which permits the missile to look at the terrain, compare it with a predetermined mapped route, and in effect fly a course as if by following a road map. *See* GUIDANCE SYSTEMS.

Guided missiles are generally self-propelled, and may use rocket motors (liquid or solid), air-breathing turbojet engines, ramjets, or various types of combined-cycle engines. For some missions, particularly air-to-surface missions, unpowered, gliding guided missiles may be used. *See* ION PROPULSION; JET PROPULSION; ROCKET PROPULSION.

The kill mechanism for a missile consists of some form of explosive warhead and a system for detonation (fusing and arming). Warheads are typically either high-explosive or nuclear. Warheads may be exploded upon contact with the target, by command from an external source, by a proximity fuse that senses the target, by preset timers, and so on. *See* MISSILE. [M.L.Sp.]

Guild A group of species that utilize the same kinds of resources, such as food, nesting sites, or places to live, in a similar manner. Emphasis is on ecologically associated groups that are most likely to compete because of similarity in ecological niches, even though species can be taxonomically unrelated. The term was derived from the guild in human society composed of people engaged in an activity or trade held in common.

The guild concept focuses attention on the ways in which ecologically related species differ enough to permit coexistence, or avoid competitive displacement. For example, new places to live for some plants are provided by badger mounds in dense tall-grass prairie vegetation.

The guild is also commonly used as the smallest unit in an ecosystem in studies relating to environmental impact, wildlife management, and habitat classification. A representative species of a guild may be selected for study involving the uncertain assumption that environmental impact will influence this species in the same way as other guild members. *See* Ecosystem. [P.W.P.]

Gulf of California A young, elongate ocean basin on the west coast of Mexico. It is flanked on the west by the narrow mountainous peninsula and continental shelf of Baja California, while the eastern margin has a wide continental shelf and coastal plain. The floor of the gulf consists of a series of basins 3300–12,000 ft (1000–3600 m) deep, whereas the northern gulf is dominated by a broad shelf which is the result of deltaic deposition from the Colorado River. The structural depression of the gulf continues northward into the Imperial Valley of California, which is cut off from the ocean by the delta of the Colorado River. *See* Continental margin.

Most of the gulf lies within an arid climate, with 4–6 in. (10–15 cm) of annual rainfall over Baja California and ranging on the eastern side from 4 in. (10 cm) in the north to about 34 in. (85 cm) in the southeast. No year-round streams enter the gulf on the west; a series of intermediate-size rivers flow in on the east side; and the major source of fresh-water sediment came from the Colorado River at the north prior to damming it upstream in the United States.

Water circulation is driven by seasonal wind patterns. Surface water is blown into the gulf in the summer by the southwesterly wind regime. In the winter, surface water is driven out of the gulf by the northwesterly wind regime, and upwelling occurs along the eastern margin, resulting in high organic productivity. Bottom sediments of the gulf range from deltaic sediments of the Colorado River at the north and coalesced deltas of the intermediate-size rivers on the east. A strong oxygen minimum occurs between 990 and 3000 ft (300 and 900 m) water depth, where seasonal influx of terrigenous sediments and blooms of diatoms due to upwelling produce varved sediments consisting of alternating diatom-rich and clay-rich layers. Rates of sediment accumulation are high, and total sediment fill beneath the Colorado River delta at the north may attain thicknesses of greater than 6 mi (10 km), even though the structural depression and the underlying crust are geologically young. *See* Bacillariophyceae; Delta; Marine sediments; Ocean circulation; Upwelling; Varve. [J.R.C.]

Gulf of Mexico A subtropical semienclosed sea bordering the western North Atlantic Ocean. It connects to the Caribbean Sea on the south through the Yucatan Channel and with the Atlantic on the east through the Straits of Florida. To the north, it is bounded by North America, to the west and south by Mexico and Central America, and on the east and southeast by Florida and Cuba respectively. *See* Intra-Americas Sea.

The continental shelves surrounding the gulf are very broad along the eastern (Florida), northern (Texas, Louisiana, Mississippi, Alabama), and southern (Campeche) area, averaging 125–186 mi (200–300 km) wide. The continental shelves along the western and southwestern (Mexico) and southeastern (Cuba) boundaries of the gulf are narrow, often being less than 12 mi (20 km) wide. Between the continental shelves and the Sigsbee Abyssal Plain are three steep continental slopes: the Florida Escarpment off west Florida, the Campeche Escarpment off Yucatan, and the Sigsbee Escarpment south of Texas and Louisiana. Two major submarine canyons crease the gulf's shelf areas: the De Soto Canyon near the Florida-Alabama border, and the Campeche Canyon west of the Yucatan Peninsula. *See* Continental margin; Escarpment; Glacial epoch; Holocene; Marine geology.

Compared with the North American rivers, the Mexican rivers are short, but they still provide approximately 20% of the freshwater input to the gulf because of extensive orographic rainfall from the trade winds that dominate the southern flank of the basin. Meteorologically, the Gulf of Mexico is a transition zone between the tropical wind system (easterlies) and the westerly frontal-passage-dominated weather (in winter particularly) to the north, punctuated with intense tropical storms in summer/autumn called the West Indian Hurricane. Much of the atmospheric moisture supplied to the North American heartland during spring and summer has its origin over the gulf, and thus it is a vital element in the so-called North American Monsoon. *See* Hurricane; Monsoon meteorology; Storm surge; Tropical meteorology.

The Gulf Stream System dominates the oceanic circulation in the Gulf of Mexico. The Yucatan Current, flowing northward into the eastern Gulf of Mexico, is the first recognizable western boundary current in the Gulf Stream System. North of the Yucatan Peninsula, the flow penetrates into the eastern gulf (where it is called the Gulf Loop Current) at varying distances with a distinctive chronology, loops around clockwise, and finally exits through the Straits of Florida, where it is called the Florida Current. This intense current reaches to more than 3300 ft (1000 m) depth, and transports 1.1×10^9 ft^3/s (3×10^7 m^3/s) of water, an amount 1800 times that of the Mississippi River. *See* Gulf Stream; Mediterranean Sea; Ocean circulation.

Surrounding the Gulf of Mexico are many population centers that exploit the numerous estuaries, lagoons, and oil and gas fields. Coral reefs off Yucatan, Cuba, and Florida provide important fishery and recreational activities. There are extensive wetlands along most coastal boundaries with ecological connections to many seagrass beds nearshore and coastal mangrove forests of Mexico, Cuba, and Florida. This biogeographic confluence creates one of the most productive marine areas on Earth, providing the food web for commercially important species such as lobster, demersal (bottom-dwelling) fish, and shrimp; this same ecology supports large populations of sea turtles and marine mammals. The coastal and nearshore waters also support large phytoplankton populations. The juxtaposition of these enormous marine resources and human activities has led to a distinctive anthropogenic impact on the health of the marine ecosystem. *See* Biogeography; Estuarine oceanography; Food web; Mangrove; Marine ecology; Reef; Wetlands. [G.A.Ma.]

Gulf Stream A great ocean current transporting about 70,000,000 tons (63,000,000 metric tons) of water per second (1000 times the discharge of the Mississippi River) northward from the latitude of Florida to the Grand Banks off Newfoundland. The Gulf Stream is thought of as a portion of a great horizontal circulation in the ocean, where each particle of water executes a closed circuit, sometimes moving slowly in midocean regions and other times rapidly in strong currents like the Gulf Stream. Thus the beginning and end of the Stream have arbitrary geographical limits. *See* Atlantic Ocean.

The Gulf Stream is a narrow (62 mi or 100 km) and swift (up to 5 knots or 250 cm/s) eastward-flowing current jet which is embedded in a weaker and broader mean westward flow and which is surrounded by intense eddies. As it leaves the coast at Cape Hatteras, the Stream meanders from side to side like a river.

The near-surface Gulf Stream transports warm water from southern latitudes eastward to the Grand Banks, where the flow becomes broader and weaker, separating into several branches and eddies. About half the near-surface flow continues eastward across the Mid-Atlantic Ridge, and half recirculates southwestward, with part of the recirculation consisting of a countercurrent located south of the Stream.

The Gulf Stream is predominantly driven by the large-scale wind pattern, the westerlies in the north and the trades in the south. The winds exert a torque on the ocean that, due to the shape and rotation of the Earth, causes a large western-intensified gyre. Cold, deep water is formed in northern seas and flows southward as a western boundary current; warm water flows northward and replaces it. *See* OCEAN CIRCULATION. [P.R.]

Gum A class of high-molecular-weight molecules, usually with colloidal properties, which in an appropriate solvent or swelling agent are able to produce gels at low dry-substance content. The molecules are either hydrophilic or hydrophobic. The term gum is applied to a wide variety of substances of gummy characteristics, and therefore cannot be precisely defined. *See* GEL.

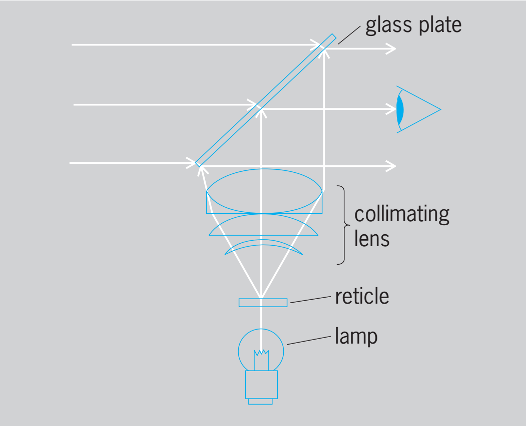
Various rubbers are considered to be gums, as are many synthetic polymers, high-molecular-weight hydrocarbons, or other petroleum products. Chicle for chewing gum is an example of a hydrophobic polymer which is termed a gum but is not frequently classified among the gums. Quite often listed among the gums are the hydrophobic resinous saps that often exude from plants and are commercially tapped in balsam (gum balsam) and other evergreen trees (gum resin). Incense gums such as myrrh and frankincense are likewise fragrant plant exudates.

Usually, however, the term gum, as technically employed in industry, refers to plant polysaccharides or their derivatives. Modern usage of the term includes water-soluble derivatives of cellulose and derivatives and modifications of other polysaccharides which in the natural form are insoluble. Usage, therefore, also includes with gums the ill-defined group of plant slimes called mucilages. *See* CELLULOSE; COLLOID; POLYSACCHARIDE.

Gums are used in foods as stabilizers and thickeners. They form viscous solutions which prevent aggregation of the small particles of the dispersed phase. In this way they aid in keeping solids dispersed in chocolate milk, air in whipping cream, and fats in salad dressings. Gum solutions also retard crystal growth in ice cream (ice crystals) and in confections (sugar crystals). Their thickening and stabilizing properties make them useful in water-base paints, printing inks, and drilling muds. Because of these properties they also are used in cosmetics and pharmaceuticals as emulsifiers or bases for ointments, greaseless creams, toothpastes, lotions, demulcents, and emollients. The adhesive properties of gums make them useful in the production of cardboard, postage stamps, gummed envelopes, and as pill binders. Other applications include the production of dental impression molds, fibers (alginate rayon), soluble surgery films and gauze, blood anticoagulants, plasma extenders, beverage-clarifying agents, bacteriological culture media, half-cell bridges, and tungsten-wire-drawing lubricants. [R.L.Wh.]

Gunsights Optical instruments which establish an optical line or axis for the purpose of aiming a weapon. The axis includes the observer's eye, a suitable mark in the instrument, and the target. Most gunsights employ as their basis either a telescope or a partially reflective mirror. *See* MIRROR OPTICS; TELESCOPE.

A typical rifle sight consists of a terrestrial telescopic system having an objective, an eyepiece, an erector lens, and a reticle. Sometimes a field lens is employed to ensure uniform illumination. Aircraft gunsights are usually of the reflector type (also known as reflex sights) and employ in their simplest form a lamp, a reticle, a collimating lens, and a glass plate or partially reflecting mirror (see illustration). The collimator images the reticle pattern at infinity, and the mirror superimposes this image over the target area. Artillery sights can assume various forms, the simplest of which is the collimator sight, consisting of an objective having a reticle at its focus. When the eye is so placed as to receive light simultaneously from the target and the reticle, the latter appears superimposed on the former and a line of sight is established. *See* LENS (OPTICS). [E.K.K.]



Reflex sight.

Gymnolaemata A class of bryozoans. Predominantly marine, gymnolaemates possess lophophores which are circular in basal outline and zooecia which are short, wide, vaselike or boxlike. Highly diverse in size and shape, most gymnolaemate colonies are small and delicate, but a few are large conspicuous growths. The individual zooids may be relatively isolated or loosely grouped side by side.

The gymnolaemates include several thousand species—mostly marine, some brackish, and a very few fresh-water—belonging to the two orders Ctenostomata and Cheilostomata. Consequently, in line with the recent approach to classification of Bryozoa, there is a tendency now to use the name Eurystomata for this class instead. Appearing early in the Early Ordovician, when they included the possible ectoproct stem group, gymnolaemates remained quite inconspicuous until the Cretaceous, when they rose to the position of dominance among bryozoans which they still maintain. *See* BRYOZOA; CTENOSTOMATA. [R.J.Cu.]

Members of the extinct order Cheilostomata have body walls that are negligibly to heavily mineralized by calcium carbonate; most are polymorphic. Feeding zooids possess tentacles that form a circular, bell-to-funnel-shaped lophophore centered on the mouth, atop a cuticular tube enclosing the initial portion of the U-shaped digestive tract. The anus is located part of the way up the cuticular tube. When the lophophore is retracted from the feeding position above the colony surface, the cuticular tube inverts and surrounds the lophophore, and the orifice is closed by a protective operculum. The operculum is a proximally hinged cuticular plate that is a thickened, sometimes mineralized part of the body wall.

Polymorphism is more prevalent in cheilostomes than in any other bryozoans. Avicularia are common cheilostome polymorphs that may be larger or much smaller than feeding zooids. They have reduced polypides and hypertrophied opercula called mandibles. Mandibles may have any shape from broad fans to bristles, but many are tapered distally to an acute point.

Colonies can be cemented to a continuous substratum, attached by rhizoids to continuous substrata or sediments, or free-living. Cemented colonies include threadlike, sheet, mound, or various erect branched morphologies; rhizoid-attached colonies are predominantly erect; and most free-living colonies are small, broadly flaring, inverted cones.

Most cheilostomes are marine, some are estuarine, and none live in fresh water. [F.K.McK.]

Gymnostomatida An order of the Holotrichia which contains a large, widely distributed group of what are believed to be the most primitive ciliate protozoans. These organisms occur abundantly in sands of intertidal zones, as well as in the more usual fresh- and salt-water habitats. The body size is frequently large; ciliation is simple and plentiful; and the oral area lacks buccal ciliature, as the name of the order implies. *See* HOLOTRICHIA. [J.O.C.]

Gypsum The most common sulfate mineral, characterized by the chemical formula $CaSO_4 \cdot 2H_2O$; it shows little variation from this composition.

Gypsum is one of the several evaporite minerals. This mineral group includes chlorides, carbonates, borates, nitrates, and sulfates. These minerals precipitate in seas, lakes, caves, and salt flats due to concentration of ions by evaporation. When heated or subjected to solutions with very large salinities, gypsum converts to bassanite ($CaSO_4 \cdot H_2O$) or anhydrite ($CaSO_4$). Under equilibrium conditions, this conversion to anhydrite is direct. The conversion occurs above 108°F (42°C) in pure water. The presence of halite (NaCl) or other sulfates in the solution lowers this temperature, although metastable gypsum exists at higher temperatures. *See* ANHYDRITE; HALITE.

Crystals of gypsum are commonly tabular, diamond-shaped, or lenticular; swallow-tailed twins are also common. The mineral is monoclinic with symmetry $2/m$. The common colors displayed are white, gray, brown, yellow, and clear. Cleavage surfaces show a pearly to vitreous luster. Gypsum is the index mineral chosen for hardness 2 on Mohs scale with a specific gravity of 2.32. In addition to free crystals, the common forms of gypsum are satin spar (fibrous), alabaster (finely crystalline), and selenite (massive crystalline).

Gypsum is used for a variety of purposes, but chiefly in the manufacture of plaster of paris, in the production of wallboard, in agriculture to loosen clay-rich soils, and in the manufacture of fertilizer. Plaster of paris is made by heating gypsum to 392°F (200°C) in air. A hemihydrate is formed as part of the water of crystallization is driven off. Later, when water is added, rehydration occurs. The interlocking, finely crystalline texture that results forms a uniform hardened mass. The slightly increased volume of the set plaster serves to fill the mold into which it has been poured. *See* PLASTER OF PARIS.

Gypsum deposits are mined throughout the world, with the United States being a world leader in gypsum production. The majority of United States gypsum is mined in Michigan, Iowa, Texas, California, and Oklahoma. Canada is the world's second largest producer. Most Canadian production is in the province of Nova Scotia. Among the other leading producers are France, Japan, Iran, Russia, Italy, Spain, and the United Kingdom. [M.L.H.; C.Sc.]

Gyrator A linear, passive, two-port electric circuit element whose transmission properties are such that it is effectively a half wavelength longer for one direction of transmission than for the other direction of transmission. Thus a gyrator is a device that causes a reversal of signal polarity for one direction of propagation but not for the other. (A two-port element has a pair of input terminals and a pair of output terminals.) This device is novel, since it violates the theorem of reciprocity. *See* RECIPROCITY PRINCIPLE.

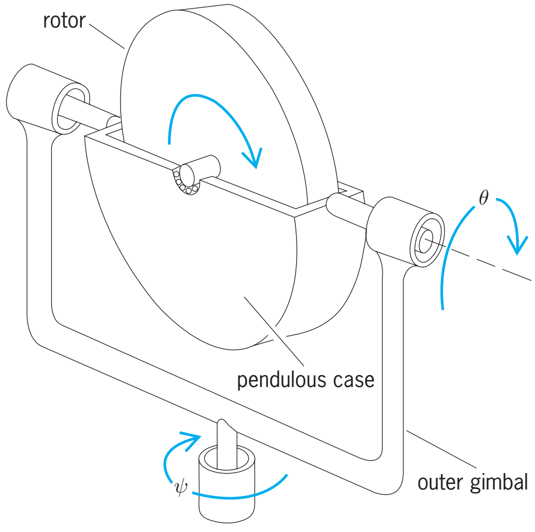
Until the early 1950s, all known linear passive electrical networks obeyed the theorem of reciprocity. However, several different types of nonreciprocal networks are now widely applied, principally at microwave frequencies. These devices are used to control the direction of signal flow and to protect or isolate components from undesired signals. One common application of a three-port nonreciprocal network, called a circulator, is to permit connection of a transmitter and a receiver to the same antenna. This is accomplished with minimum interference and virtually no power loss of either transmitted or received signal. *See* CONTINUOUS-WAVE RADAR.

Perhaps the first passive nonreciprocal system was an optical one proposed by Lord Rayleigh, making use of the rotation of the plane of polarization of light when it passed through a transparent material in the presence of a magnetic field. This phenomenon is called Faraday rotation.

The microwave analogy of Lord Rayleigh's device was proposed by C. L. Hogan. The nonreciprocal medium used is ferrite. In such a material, infinitesimal magnetic dipole moments which arise from the electronic structure of the material act gyroscopically when a steady magnetic field is applied. They precess about the applied field direction in a counterclockwise sense, thus permitting strong coupling to the component of a microwave-frequency magnetic field which is circularly polarized in the same sense. The component with the opposite sense of polarization is weakly coupled. Thus energy exchange between the magnetic dipoles and the microwave field is polarization-sensitive. *See* FERRIMAGNETISM; FERRITE. [F.J.R.]

Gyrocompass A north-seeking form of gyroscope used as a directional reference in navigation. Modern gyrocompasses are so reliable and so much more accurate than magnetic compasses that they are now used as the prime navigational instrument on nearly every ship and on major aircraft and missiles. *See* MAGNETIC COMPASS.

A gyrocompass combines the action of two devices, a pendulum and a gyroscope, to produce alignment with the Earth's spin axis. The principle is demonstrated with the model shown in the illustration, which consists of a rapidly spinning, heavy gyro rotor, a pendulous case which permits the rotor axle to nod up and down (angle θ), and an outer gimbal which permits the axle to rotate in azimuth (angle ψ). For a gyroscope positioned at the Equator of the Earth, as the Earth rotates, the gimbal moves with it. So long as the rotor's spin axis is aligned with the Earth's axis, the gyro experiences no torque from Earth rotation. If there is misalignment, however, a sequence of restoring torques is initiated. *See* GYROSCOPE; PENDULUM.



Gyrocompass model.

In a shipboard installation the system must be mounted in a complete set of gimbals to isolate it from rolling, pitching, and yawing motions of the ship. Friction must be minimized. Moreover, Schuler tuning is employed to keep horizontal accelerations of the ship from producing false torques on the pendulum; the unique combination of gyro spin speed and pendulosity is chosen so that no acceleration of the instrument can disturb its vertical reference. *See* SCHULER PENDULUM. [R.H.C.]

For many years the use of gyrocompasses in aircraft was impractical because of their high speed and large, rapid changes in attitude. The north-south component of vehicle velocity produces an error which depends on the velocity magnitude. Aircraft applications of gyrocompasses therefore use a modified version of the marine gyrocompass. The gyroscopes are mounted on a platform that is stabilized by signals from the gyroscopes. The platform is aligned to the local vertical and to north prior to takeoff by using essentially the same technique as for a marine gyrocompass. The 84-min Schuler period is shortened by amplifying signals from tilt sensors or accelerometers on the platform to rapidly remove platform tilt and align to north. Alignment times range from 5 to 30 min, depending upon the desired accuracy. The heading and vertical, once established, are "remembered" by the gyroscopes during flight. Vehicle velocity can be computed from the accelerometer data and used to correct for vehicle velocity and for dead-reckoning navigation. The need for preflight heading and vertical alignment can be eliminated by "gyrocompassing" this system in-flight by using an independent velocity sensor such as a Doppler radar. *See* Doppler radar; Inertial guidance system. [H.Bu.]

Gyrocotylidea An order of tapeworms of the subclass Cestodaria. All species are intestinal parasites of chimaeroid fishes and have an anterior end with an eversible proboscis and a posterior end with a ruffled adhesive organ. Typically, only one sexually mature worm is found in an individual host. The life history is incompletely known. *See* Cestodaria. [C.P.R.]

Gyromagnetic effect An effect arising from the relation between the angular momentum and the magnetization of a magnetic substance. It is the effect which is exploited in the measurement of the gyromagnetic ratio of magnetic materials. The gyromagnetic effect is demonstrated by a simple experiment in which a freely suspended magnetic substance is subjected to a magnetic field. Upon a change in direction of the magnetic field, the magnetization of the substance must change. In order for this to happen, the atoms must change their angular momentum. Since there are no external torques acting on the system, the total angular momentum must remain constant. Thus the sample must acquire a mass rotation which may be measured. In this way, the gyromagnetic ratio may be determined. *See* Gyromagnetic ratio. [E.A.; F.Ke.]

Gyromagnetic ratio The ratio of angular momentum to magnetic moment for atomic systems. This ratio is usually expressed in terms of the magnetomechanical factor g', as in Eq. (1). The ratio is written here in electromagnetic units; thus,

$$\frac{\text{Angular momentum}}{\text{Magnetic moment}} = \frac{2mc}{g'e} \qquad (1)$$

e/c and m are the charge and mass of the electron. The factor g' is sometimes loosely called the gyromagnetic ratio.

The magnetomechanical ratio is the inverse of the gyromagnetic ratio. It is usually denoted by γ and is equal to $g'e/2mc$. The magnetomechanical ratio of a substance identifies the origin of the magnetic moment. For example, for electron spin the angular momentum is $^1/_2\hbar$, where $\hbar$ is Planck's constant divided by 2π. The magnetic moment is the Bohr magneton $e\hbar/2mc$. Thus, the magnetomechanical ratio is given by Eq. (2). Since

$$\gamma = \frac{e\hbar/2mc}{\hbar 2} = \frac{e}{mc} \qquad (2)$$

$\gamma = g'e/2mc$, for electron spin $g' = 2$. For orbital angular momentum, $\gamma = e/mc$ and $g' = 1$. The experimental values of g' for most ferromagnetic materials are in the neighborhood of 2, showing that the major contribution to the magnetization comes from the electron spin. In superconductors, on the other hand, the fact that $g' = 1$ shows that the diamagnetic currents which cause the Meissner effect are caused by electrons. *See* Meissner effect; Superconductivity. [E.A.; F.Ke.]

Gyroscope A device that is used to define a fixed direction in space or to determine the change in angle or the angular rate of its carrying vehicle with respect to a reference frame. Gyroscopes (also called gyros) respond to vehicle angular rates, that is, rates of change of angles between vehicle axes and reference axes, from which these angles can be computed. Gyros are used for guidance, navigation, and stabilization. *See* Gyrocompass; Inertial guidance system; Navigation.

Gyros can be utilized either mounted on a stabilized platform, whose orientation in a moving vehicle remains fixed in space by a means of two, three, or four gimbals, or directly attached to the vehicle's body, so that the gyro experiences the same maneuvering as the vehicle, an operating mode referred to as strapdown. Strapdown operation is desirable because it enables a much less expensive system; it became feasible only in the 1970s and 1980s, when the very high digital computing speed required for the strapdown algorithms became available.

Gyros can be operated closed-loop or open-loop. Closed-loop means that a feedback loop from the gyro output introduces a restoring mechanism either inside the gyro (for example, torquing in mechanical gyros) or counterrotating platform motions to maintain the gyro at its null (initial) setting. In open-loop operation, the gyro is allowed to operate off its null position as it responds to the input angular rates. *See* Control systems; Servomechanism.

Gyroscopes use different physical phenomena to respond to input angular rates; for example, spinning-mass gyros sense changes in angular momentum from Coriolis acceleration; resonator gyroscopes sense deflections from Coriolis acceleration; and optical gyros sense phase shifts (the Sagnac effect) between counterpropagating beams of light. Instruments that do not have spinning masses are not technically gyros but angular rate sensors. However, the term "gyro" is commonly used for all rate-sensing devices. *See* Coriolis acceleration.

The classical spinning-mass gyroscope is based upon the phenomenon that the spin axis of a spinning mass points in a fixed direction in space unless acted upon by an external influence. However, the spin axis can be made to rotate if a torque (or rotational rate) is applied at right angles to the spin vector. The spin vector then begins to rotate (precess) about a third axis, perpendicular to the spin axis and the applied torque; that is, the spin axis tries to align itself with the applied torque. This is the law of gyroscopic precession; measurement of precession is what makes the spinning-mass gyro useful for knowing the changes in direction of the carrying vehicle.

The free gyroscope's spinning mass is isolated from the rotations of the case or the carrying vehicle so that it remains fixed in space. The relative position of the spinning mass to the gyro case is proportional to the vehicle's angle of rotation.

The rate gyro's spinning mass is forced to rotate with the vehicle rotation rate about one particular axis (for example, pitch or roll). The output torque causing the spinning mass to turn (precess) is opposed by an elastic restraint. The angle, measured by pickoffs, that the spinning mass turns through is proportional to the vehicle rotation rate. Rate gyros are used in applications in which stable errors can be tolerated.

The floated, single-degree-of-freedom, rate-integrating gyro, or floated gyro as it is commonly known, is basically a rate gyro in which the spring restraint is replaced by viscous damping. The spinning mass is contained inside a "float" which is isolated from the case by means of the viscous flotation fluid, low-restraint electromagnetic suspensions, pickoffs, and torque generators. Floated, integrating gyros went from revolutionizing military aircraft navigation in the 1950s to enabling strategic missile guidance, submarine navigation, space flight (for example, the Apollo spacecraft), and satellite stabilization (for example, the Hubble Space Telescope).

In the electrostatically suspended gyroscope (ESG), a spherical rotor is suspended in a spherical chamber in vacuum by electrostatic forces. External motor windings spin the rotor to the desired speed and are then turned off. The rotor will spin for days before requiring motor excitation. Optical or electrical techniques are used to pick off rotor position. The ESG is basically a free gyroscope and does not require a torquer to keep the rotor and case aligned. ESGs are very accurate and are used for long-term navigation of submarines and aircraft and for land surveying. A similar concept is the magnetically suspended gyro (MSG), which uses a magnetic field to suspend the rotor. *See* ELECTROSTATICS; MAGNETISM; RELATIVITY.

Optical gyros use the Sagnac effect to detect rotation. The Sagnac effect pertains to the postulate of the theory of relativity that the speed of light is constant, and independent of the motion of the source. If two identical light waves circulate in opposite directions along a closed path undergoing a rotation, then the light beam traveling in the same direction as the rotation takes longer to travel around the path than the other beam, resulting in a changed interference pattern. Optical gyroscopes include the ring laser gyro (RLG) and fiber-optic gyros (FOGs).

The ring laser gyro is widely used in tactical and navigation systems. It comprises a closed optical cavity (usually a three- or four-sided block of low-expansion-coefficient material), whose light path is defined by mirrors mounted at the corners. The light travels through holes bored in the block containing a low-pressure gas, usually a helium-neon mixture which lases when the anode and cathode are excited. Thus, the RLG is itself actually a laser (that is, it does not require an external light source), and is thus said to be an active device. *See* LASER.

The lased light propagates clockwise and counterclockwise so that there are two optical beams, each maintained in resonance (that is, each beam contains an integral number of wavelengths). Under a rotation rate about the gyro input axis, the resonant frequencies of the clockwise and counterclockwise beams change. Some light from both beams is transmitted through one of the mirrors to impinge on a detector. Because the beams have different frequencies, a changing interference pattern (fringes) appears. Measurement of the fringe pattern changes determines the external rotation rate and direction.

Fiber-optic gyros use optical fibers, in place of a lasing block, to define the optical path. The light source is external, and its light is split by a beam splitter or optical coupler to produce clockwise and counterclockwise light beams in the fiber-optic coil. FOGs are called passive devices because the optical source (a laser) is external. There are two principal types: interferometric and resonant. The interferometric fiber-optic gyro (IFOG) has up to 1 km (0.6 mi) of optical fiber wound into a coil with both ends brought into a coupler. The resonant fiber-optic gyro (RFOG) maintains the counterpropagating light beams in resonance, recirculating them in a short fiber-optic coil.

Vibrating gyroscopes use an oscillating mass in place of a spinning mass to sense rates. The mass oscillates (sinusoidally) back and forth through a fixed angle; the amplitude of the oscillation is restrained by the elastic (spring) stiffness of the vibrating structure. Nearly all such gyros oscillate at the resonant frequency of the mass-spring system since the gyro output is maximized at this frequency; hence these gyroscopes are also called resonator gyros. *See* RESONANCE (ACOUSTICS AND MECHANICS); VIBRATION. [N.Ba.]

Gyrotron One of a family of microwave generators, also called cyclotron resonance masers, in which cyclotron resonance coupling between microwave fields and an electron beam in vacuum is the basis of operation. This type of coupling has the advantage that both the electron beam and the associated microwave structures can have dimensions which are large compared with a wavelength. Thus, cyclotron resonance masers are potentially greatly superior to conventional microwave tubes with respect to power capability at short wavelengths.

The development of these power sources is particularly significant for magnetically confined plasma fusion experiments. Microwave heating is considered an attractive method of supplying the energy needed to bring a reactor to ignition temperature, and gyrotrons provide a potential means of producing sufficient microwave power at the very short wavelength required. Gyrotrons also have potential application in millimeter-wave radar and communications systems. *See* MICROWAVE TUBE; NUCLEAR FUSION; TRAVELING-WAVE TUBE. [H.R.J.]

H

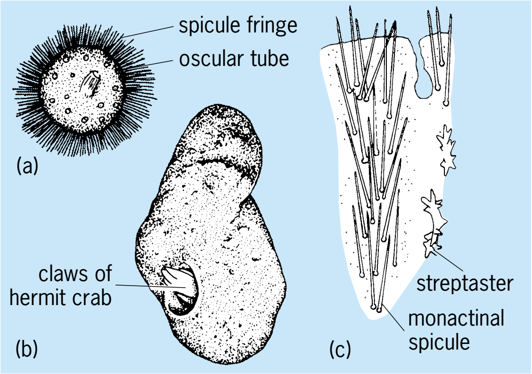
Hackberry A medium-sized to large tree, *Celtis occidentalis*. It occurs in the eastern half of the United States, except in the extreme south, and is characterized by corky or warty bark, by alternate, long-pointed serrate leaves unequal at the base, and by a small drupaceous fruit, with thin, sweet, edible flesh. Both species are used for furniture, boxes, and baskets, for shelterbelts, and as shade trees. Sugarberry (*C. laevigata*) is similar to hackberry and grows in the southeast United States. [A.H.G./K.P.D.]

Hadean The eon of geological time extends for several hundred million years from the end of the accretion of the Earth to the formation of the oldest recognized rocks. According to current models, the inner planets formed by the accretion of planetesimals in an environment where gas and volatiles had been swept away by early intense solar activity. The accretion of the Earth appears to have been completed between 50 and 100 million years (m.y.) after the beginning of the solar system (T_0) as recorded in the oldest refractory inclusions in the Allende Meteorite, whose age of 4566 ± 2 m.y., ascertained by lead isotope dating, is taken as T_0. Core formation on the Earth appears to have been coeval with accretion and so preceded the Hadean. Any primitive atmosphere was removed by early collisional events, and the present atmosphere has arisen by a combination of degassing and additions from comets. *See* EARTH, AGE OF; LEAD ISOTOPES (GEOCHEMISTRY).

The Acasta Gneiss in the Northwest Territories of Canada, dated at 3960 m.y., is often regarded as the oldest rock. However, that date refers to relict zircon crystals in the rock rather than the age of formation of the rock itself. The oldest definitely dated rocks are at Isua, Greenland, with an age of 3650–3700 m.y. Thus the Hadean Eon begins around 4500–4450 m.y. ago and extends to between 3900 and 3650 m.y. ago depending on the age assigned to the oldest rock.

Conditions on the Hadean Earth bore little resemblance to more recent times. A picture dimly appears of a hot young Earth with a thick basaltic crust, covered by an ocean. Dry land was rare. Plate tectonics had not yet begun. A few remnant zircon crystals indicate the formation of an occasional felsic rock, produced by remelting of the basalt. Sporadic disruption of the surface was caused by the collisions of basin-forming impactors that probably culminated in a spike or cataclysm around 3850–4000 m.y. ago. Such events must have frustrated the origin and development of life, which emerged in post-Hadean time. [S.R.T.]

Hadromerida An order of sponges of the class Demospongiae with monactinal megascleres that usually have a terminal knob at one end. Microscleres in the form of streptasters, asters, sigmas, or small spined diactinals may occur. Spongin is usually sparse in occurrence. In shape, hadromeridan sponges include radially symmetrical forms (see illustration) as well as encrusting, massive, or branching types. They occur in tidal and shallow waters of all seas and extend down to depths of at least 18,000 ft (5500 m). Included in the group are the limestone-excavating clionids. *See* BORING SPONGES; DEMOSPONGIAE. [W.D.H.]



Hadromerine sponges. (*a*) *Radiella sol*, deep-sea species. (*b*) *Suberites ficus* living on shell occupied by hermit crab. (*c*) Spicule arrangement of *Spirastrella*.

Hadron The generic name of a class of particles which interact strongly with one another. Examples of hadrons are protons, neutrons, the π, K, and D mesons, and their antiparticles. Protons and neutrons, which are the constituents of ordinary nuclei, are members of a hadronic subclass called baryons, as are strange and charmed baryons. Baryons have half-integral spin, obey Fermi-Dirac statistics, and are known as fermions. Mesons, the other subclass of hadrons, have zero or integral spin, obey Bose-Einstein statistics, and are known as bosons. The electric charges of baryons and mesons are either zero or ±1 times the charge on the electron. Masses of the known mesons and baryons cover a wide range, extending from the pi meson, with a mass approximately one-seventh that of the proton, to values of the order of 10 times the proton mass. The spectrum of meson and baryon masses is not understood. *See* BARYON; BOSE-EINSTEIN STATISTICS; FERMI-DIRAC STATISTICS; MESON; NEUTRON; PROTON.

Based on an enormous body of data, hadrons are now thought of as consisting of elementary fermion constituents known as quarks which have electric charges of $+\frac{2}{3}|e|$ and $\frac{1}{3}|e|$, where $|e|$ is the absolute value of the electron charge. For example, a quark-antiquark pair makes up a meson, while three quarks constitute a baryon. *See* ELEMENTARY PARTICLE; QUARKS. [A.K.M.]

Hadronic atom A hydrogenlike system that consists of a strongly interacting particle (hadron) bound in the Coulomb field and in orbit around any ordinary nucleus. The kinds of hadronic atoms that have been made and the years in which they were first identified include pionic (1952), kaonic (1966), Σ^- hyperonic (1968), and antiprotonic (1970). They were made by stopping beams of negatively charged hadrons in suitable targets of various elements, for example, potassium, zinc, or lead. The lifetime of these atoms is of the order of 10^{-12} s, but this is long enough to identify them and study their characteristics by means of their x-ray spectra. They are available for study only in the beams of particle accelerators. Pionic atoms can be made by synchrocyclotrons and linear accelerators in the 500-MeV range. The others can be generated only at accelerators where the energies are greater than about 6 GeV. *See* ELEMENTARY PARTICLE; HADRON; PARTICLE ACCELERATOR.

The hadronic atoms are smaller in size than their electronic counterparts by the ratio of electron to hadron mass. For example, in pionic calcium, atomic number $Z = 20$, the Bohr radius of the ground state is about 10 fermis (1 fermi $= 10^{-15}$ m), and in ordinary calcium it is about 2500 fermis. Thus the atomic electrons are practically not involved in the hadronic atoms, and the equations of the hydrogen atom are applicable. The close approach of the hadrons to their host nuclei suggests that hadron-nucleon and hadron-nucleus forces will be in evidence, and this is one of the motivations for studying these relatively new types of atoms.

Antiproton atoms are the latest in the series of hadronic atoms to be observed. The main research effort involving antiproton atoms has been dedicated to the investigation of the x-ray spectra of the antiprotonic hydrogen. The transitions to the ground state depend directly on the elementary antiproton-proton interaction at the threshold. If this interaction turns out to be simple enough, the antiprotonic atoms will be a future tool for measuring the matter distribution of the nuclear surface. Another source of low-energy antiprotons—the Low Energy Antiproton Ring (LEAR), which makes precision measurements on antiprotonic atoms feasible—was put into operation at CERN near Geneva, Switzerland.

There are two additional hadrons with lifetimes that are long enough to be candidates for hadronic atom formation: the negative xi (Ξ^-) and the negative omega (Ω^-), but even at the largest accelerators, these particles are too scarce for their atoms to be detected. [C.E.W.; B.Po.]

Haemophilus A genus of gram-negative, pleomorphic bacteria that are facultative anaerobes and are nonmotile and non-spore-forming.

Haemophilus influenzae was the first of the species to be isolated and is considered the type species. It was originally recovered during the influenza pandemic of 1889 and for a time was believed to be the causative agent of influenza; thus it was called the influenza bacillus. However, when this fallacy became apparent, the organism was renamed, still reflecting the historical association with influenza.

Haemophilus species are distinguished by a number of criteria. Strains of *H. influenzae* can be separated into encapsulated and nonencapsulated forms. Encapsulated strains express one of six biochemically and antigenically distinct capsular polysaccharides that are designated serotypes a through f. Nonencapsulated strains are referred to as nontypable. *See* INFLUENZA; MENINGITIS.

Haemophilus influenzae is a human-specific pathogen that inhabits the upper respiratory tract and is acquired by exposure to airborne droplets or contact with respiratory secretions. Nontypable strains can be isolated from the nasopharynx of up to 80% of normal children and adults at any given time, usually in association with asymptomatic colonization. Overall, these organisms are the leading cause of exacerbations of chronic bronchitis, and the second most common etiology of acute otitis media and sinusitis. On occasion, nontypable *H. influenzae* causes invasive disease such as meningitis, septicemia, endocarditis, epiglottitis, or septic arthritis. Invasive disease occurs most often in neonates and in patients with underlying immunodeficiency, especially when abnormalities in humoral immunity are present.

Encapsulated strains of *H. influenzae* are present in the nasopharynx of only 2–5% of children and an even smaller percentage of adults. Historically, *H. influenzae* type b strains were the primary cause of childhood bacterial meningitis and a majority of other bacteremic diseases in children. However, in recent years the incidence of disease due to *H. influenzae* type b has plummeted in the United States and other developed countries, reflecting the routine use of *H. influenzae* conjugate vaccines. These vaccines provide effective protection against disease due to *H. influenzae* type b but fail to protect against non-type b strains.

Haemophilus aphrophilus, *H. haemolyticus*, *H. parahaemolyticus*, *H. parainfluenzae*, and *H. segnis* are members of the normal flora in the human oral cavity and oropharynx and have low pathogenic potential. Among these species, *H. parainfluenzae* is the most common pathogen and has been reported in association with a variety of diseases.

Strains of *H. influenzae* are increasingly resistant to a wide variety of antibiotics. Accordingly, an extended-spectrum cephalosporin is generally recommended for empiric treatment of serious disease. *See* ANTIBIOTIC; DRUG RESISTANCE; MEDICAL BACTERIOLOGY. [G.P.Kr.; J.W.St.G.]

Haemosporina A relatively small and generally rather compact group of protozoans in the subphylum Sporozoa. Authorities differ as to the group's taxonomic status; that assigned it by the Committee on Taxonomy and Taxonomic Problems of the Society of Protozoologists is followed here: a suborder of the order Eucoccida, subclass Coccidia, class Telosporea, subphylum Sporozoa. The Haemosporina are common protozoan parasites of vertebrates, and some of them are important as causes of illness and death. The best known of the group are the four species (genus *Plasmodium*) of malarial parasites of humans. *See* MALARIA.

Transmission of these parasites is probably always effected in nature by the bite of some bloodsucking invertebrate. In the vertebrate host they reproduce asexually; sometimes this occurs in the tissues of certain internal organs, such as the lungs, liver, spleen, and brain; sometimes in the red blood cells (erythrocytes), or even in other types of blood and blood-forming cells; and often in both tissues and blood cells. The immature sex cells, gametocytes, always occur in erythrocytes or leukocytes (white blood cells). Gametocytes mature into gametes after ingestion by an intermediate host (arthropod). Fertilization ensues, with a subsequent period of development culminating in the production of numerous sporozoites. These tiny filamentous forms are infective for the vertebrate host. Since they can develop no further in the arthropod, infection in this host is self-limited, in the sense that no further buildup is possible; the insect is seldom harmed by the parasite. However, sporozoites may remain infective for a long time in the invertebrate host, perhaps as long as the insect lives. *See* SPOROZOA. [R.D.M.]

Hafnium A metallic element, symbol Hf, atomic number 72, and atomic weight 178.49. There are five naturally occurring isotopes. It is one of the less abundant elements in the Earth's crust. *See* PERIODIC TABLE.

Hafnium is a lustrous, silvery metal that melts at about 2222°C (4032°F). Reported values of the boiling point vary greatly, from about 2500 to about 5100°C (4530 to 9200°F). There are virtually no uses of the metal other than in control rods for nuclear reactors.

The chemistry of hafnium is almost identical with that of zirconium. The similarity of hafnium to zirconium is a consequence of the lanthanide contraction, which brings the ionic radii to very nearly identical values. Before (and since) the discovery of hafnium, this element was extracted with zirconium from its ores and passed with zirconium into all derivatives. Since the chemical properties are so similar, there has been no incentive to separate the hafnium except for making nuclear studies and components of nuclear reactors. *See* ZIRCONIUM. [W.B.B.]

Hail Precipitation composed of chunks or lumps of ice formed in strong updrafts in cumulonimbus clouds. Individual lumps are called hailstones. Most hailstones are spherical or oblong, some are conical, and some are bumpy and irregular. Diameters range from 0.2 to 6 in. (5 to 150 mm) or more. That is, the

Cross section of a large hailstone showing the structure of alternating rings of clear and white ice. (*Alberta Research Council, Edmonton*)

largest stones are grapefruit or softball size, and the smallest are pea size.

Very often hailstones are observed to be made of alternating rings of clear and white ice (see illustration). These rings indicate the growth processes of the hail. The milky or white portion of the growth occurs when small cloud droplets are collected by the hailstone and freeze almost instantaneously, trapping bubbles of air between the droplets and creating a milky appearance. The clear portion is formed when many droplets are collected so rapidly that a film of water spreads over the stone and freezes gradually, giving time for any trapped air bubbles to escape from the liquid.

The most favorable conditions for hail formation occur in the mountainous, high plains regions of the world. Hailstorms normally have relatively high, cool cloud bases and very strong updrafts within the clouds to carry the hailstones into the cooler regions of the cloud, where maximum growth occurs. Both small ice particles and supercooled liquid water (liquid water at temperatures below 32°F or 0°C) are needed for the ice particles to grow into hailstones. *See* CLOUD PHYSICS; PRECIPITATION (METEOROLOGY). [H.D.O.]

Hair Nonliving, specialized epidermal derivatives characteristic only of modern mammals. However, it is now thought that hair was present in at least some therapsid reptiles. It consists of keratinized cells, tightly cemented together, which arise from the matrix at the base of a follicle. A follicle is a tubular epidermal downgrowth that penetrates into the dermis and widens into a bulb (the hair root) at its deep end. The follicle, together with a lateral outgrowth called the sebaceous gland, forms the pilosebaceous system. Rapid cell production in the matrix, and differentiation in the regions immediately above, produces a hair shaft which protrudes from the follicle mouth at the skin surface. *See* GLAND.

Hairs are not permanent structures but are continually replaced throughout the life of a mammal. In some species, for example, the rat, hamster, mouse, chinchilla, and rabbit, the replacement pattern is undulant, and waves of follicular activity can be traced across the body. In other species, for example, humans, cats, and guinea pigs, each follicle appears to cycle independently of others in the immediate area. *See* INTEGUMENT. [P.F.M.]

Half-life The time required for one-half of a given material to undergo chemical reactions; also, the average time interval required for one-half of any quantity of identical radioactive atoms to undergo radioactive decay.

The concept of the time required for all of the material to react is meaningless, because the reaction goes very slowly when only a small amount of the reacting material is left and theoretically an infinite time would be required. The time for half completion of the reaction is a definite and useful way of describing the rate of a reaction.

The specific rate constant k provides another way of describing the rate of a chemical reaction. This is shown in a first-order reaction, Eq. (1), where c_0 is the initial concentration and c is

$$k = \frac{2.303}{t} \log \frac{c_0}{c} \qquad (1)$$

the concentration at time t. The relation between specific rate constant and period of half-life, $t_{1/2}$, in a first-order reaction is given by Eq. (2).

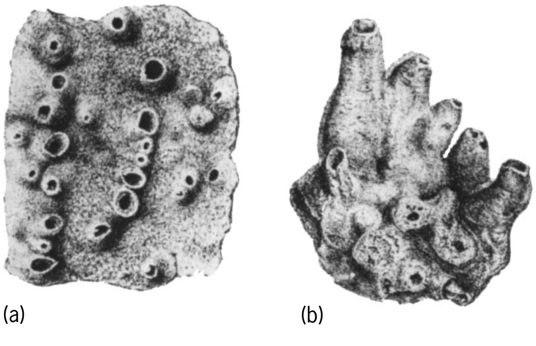
$$t_{1/2} = \frac{2.303}{k} \log \frac{1}{1/2} = \frac{0.693}{k} \qquad (2)$$

See CHEMICAL DYNAMICS. [F.D.]

The activity of a source of any single radioactive substance decreases to one-half in 1 half-period, because the activity is always proportional to the number of radioactive atoms present. For example, the half-period of ^{60}Co (cobalt-60) is $t_{1/2}$, = 5.3 years. Then a ^{60}Co source whose initial activity was 100 curies will decrease to 50 curies in 5.3 years. In 1 additional half-period this activity will be further reduced by the factor $^1/_2$. Thus, the fraction of the initial activity which remains is $^1/_2$ after one half-period, $^1/_4$ after two half-periods, $^1/_8$ after three half-periods, $^1/_{16}$, after four half-periods, and so on. The half-period is sometimes also called the half-value time or, with less justification, the half-life. *See* RADIOACTIVITY. [R.D.E.]

Halichondrida A small order of sponges of the class Demospongiae, subclass Ceractinomorpha, with a skeleton of diactinal or monactinal siliceous megascleres or both. Spongin is present in small amounts; microscleres are absent. A skinlike dermis is present and is often reinforced with tangentially placed spicules.

Halichondrid sponges are encrusting, massive, lobate, or branching in shape. Common shallow-water species, such as *Halichondria panicea*, exhibit extensive intraspecific variations in shape associated with environmental conditions (see illustration). Halichondrids inhabit all seas, occurring chiefly in tidal areas and shallow waters of the continental shelf. Some species



***Halichondria panicea*, shallow-water sponge. (*a*) Encrusting form. (*b*) Fistular form.**

occur down to depths of at least 4900 ft (1500 m). Fossil species are unknown. *See* DEMOSPONGIAE. [W.D.H.]

Halide A compound containing one of the halogens [fluorine (F), chlorine (Cl), bromine (Br), iodine (I)] and another element or organic group. Halides have the general formula M_xX_y, where M is a metal or organic group and X is a halogen. Halides are composed of almost every element in the periodic table, and they are referred to as fluorides, chlorides, bromides, or iodides. *See* HALOGEN ELEMENTS; PERIODIC TABLE.

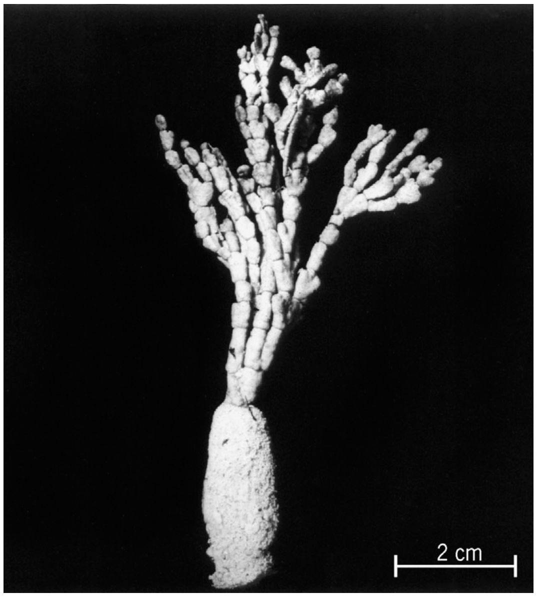
The halides are divided into classes that reflect the nature of bonding between the halogen and metal or organic species. The bonding of halides ranges from purely ionic to essentially covalent. The classes include ionic halides, molecular halides, halides and halogens that behave as ligands in coordination complexes, and organic halides.

Ionic halides such as sodium chloride (NaCl) and potassium chloride (KCl) are prepared from the vigorous reaction of the alkali and alkaline-earth metals with the halogens. These compounds possess high melting and boiling points and are soluble in very polar solvents. Ionic halides are extremely important to the chemical industry, where they are used to produce commodity chemicals such as sodium hydroxide (NaOH), hydrochloric acid (HCl, a hydrogen halide), and potassium nitrate (KNO_3).

The organic halides are divided into the alkyl halides (haloalkanes) and the aryl halides. The alkyl halides have the general formula RX, where R is any alkyl group and X is one of the halogens; for example, 1-chlorobutane ($CH_3CH_2CH_2CH_2Cl$). Halides are good leaving groups in nucleophilic substitution reactions and are good nucleophiles. The aryl halides are compounds where the halogen is attached directly to an aromatic ring and have the general formula ArX, where Ar is an aromatic group. *See* COORDINATION CHEMISTRY; COORDINATION COMPLEXES; ELECTROPHILIC AND NUCLEOPHILIC REAGENTS; HALOGENATED HYDROCARBON; HALOGENATION. [T.J.Me.]

Halimeda A genus of marine, benthic, green algae (Chlorophyta) belonging to the family Codiaceae. Plants are attached by a holdfast, generally several centimeters high, and consist of calcareous segments separated by flexible, little-calcified nodes. Most species have a distinct, erect habit (see illustration), but some deep-water species have a vinelike growth form.

Halimeda is an exclusively marine algae restricted to tropical waters, except for one or two species known from subtropical regions. These algae colonize sand and mud substrates, where rhizoids of the plant penetrate the soft bottom to develop holdfasts. They are most common at shallow depths of a few meters, especially in tropical marine shelf and lagoonal environments. *See* ALGAE; ATOLL. [J.L.Wr.]



***Halimeda* from southern Florida.**

Halite One of the group of minerals referred to as evaporites, halite is commonly known as salt. Halite is one of many substances that are essential for human life. Evaporite minerals form when ions are concentrated to their saturation point by the progressive evaporation of seawater or saline lake water. Halite precipitates after calcium sulfate, but before the highly soluble salts of potassium and magnesium. *See* HALOGEN MINERALS; SALINE EVAPORITES.

Halite (chemical formula NaCl) is composed of sodium cations and chlorine anions in equal proportion. It is the most common chloride mineral in natural sequences which proceed beyond the precipitation of sulfates. Even in sequences which contain a high percentage of potassium and magnesium salts, halite is often the most common chloride present.

Crystals of halite are generally cubic or hopper-shaped (skeletal). Although the mineral is colorless generally, impurities can color it gray, red, orange, or brown. Blue or violet halite results from exposure to radioactivity, which produces dislocations and defects in the crystal structure. Halite is characterized by a hardness of 2.5 on Mohs scale and a specific gravity of 2.16.

The deformation of bedded halite deposits is of importance to the petroleum industry. Salt rises, in part as a result of density contrasts, to form domelike structures. Hydrocarbons (oil and gas) are commonly associated with salt domes. Exploration for these structures by geophysical techniques often results in major discoveries by the petroleum industry. *See* GEOPHYSICAL EXPLORATION; PETROLEUM GEOLOGY; SALT DOME. [M.L.H.; B.C.Sc.]

Hall effect An effect whereby a conductor carrying an electric current perpendicular to an applied magnetic field develops a voltage gradient which is transverse to both the current and the magnetic field. It was discovered by E. H. Hall in 1879. Important information about the nature of the conduction process in semiconductors and metals may be obtained through analysis of this effect.

A simple model which accounts for the phenomenon is the following. For a magnetic field of strength B in the z direction (see illustration), particles flowing with speed v in the x direction suffer a Lorentz force F_L in the y direction given by Eq. (1),

$$F_L = -qvB \tag{1}$$

where q is the charge of the particles. This force deflects the particles so that a charge imbalance develops between opposite sides of the conductor. Deflection continues until the electric field E_y resulting from this charge imbalance produces a force $F_y = qE_y$ which cancels the Lorentz force. In practice, the equilibrium condition $F_L + F_y = 0$ is achieved almost instantaneously, giving a steady-state Hall field as in Eq. (2). The current density is $J_x = nqv$, where n is the carrier density. The Hall resistivity, defined by Eq. (3), is thus given by Eq. (4). The Hall coefficient, defined by Eq. (5), satisfies Eq. (6) and thus R_0 provides a measure of the

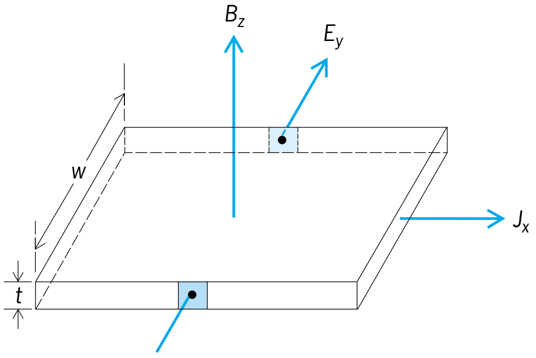
$$E_y = vB \tag{2}$$

$$\rho_{yx} = \frac{E_y}{J_x} \tag{3}$$

$$\rho_{yx} = \frac{B}{nq} \tag{4}$$

$$R_0 = \frac{\rho_{yx}}{B} \tag{5}$$

$$R_0 = \frac{1}{nq} \tag{6}$$



Configuration of fields and currents in the Hall effect experiment.

sign and magnitude of the mobile charge density in a conductor. Within the free-electron theory of simple metals, q is expected to be the electron charge $-e$, and n is taken to be $n = Zn_A$, where Z is the valence of the metal and n_A is the density of the atoms. This yields Eq. (7).

$$R_0 = \frac{-1}{n_A Z e} \qquad (7)$$

See Free-electron theory of metals.

Equation (7) is approximately valid in simple monovalent metals but fails drastically for other materials, often even giving the wrong sign. The explanation of the failures of Eq. (7) was one of the great early triumphs of the quantum theory of solids. The theory of band structure shows how collisions with the periodic array of atoms in a crystal can cause the current carriers to be holes which have an effective positive charge which changes the sign of the Hall coefficient. Band structure theory also accounts for the observed dependence of R_0 on the orientation of the current and the magnetic field relative to the crystal axes, an effect which is very useful for studying the topology of the Fermi surface. *See* Band theory of solids; Fermi surface; Hole states in solids.

In certain special field-effect transistors, it is possible to create an electron gas which is effectively two-dimensional. The Hall resistance for an idealized system in two dimensions is given by Eq. (8), where n_S is the density of electrons per unit area

$$\rho_{xy} = -\rho_{yx} = \frac{B}{n_S e} \qquad (8)$$

(rather than volume). However, if the measured value of ρ_{xy} for a high-quality (low-disorder) device is plotted as a function of B, the linear behavior predicted by Eq. (8) is observed only at low fields. At high fields the Hall resistance exhibits plateau regions in which it is a constant independent of B. Furthermore, the values of ρ_{xy} on these plateaus are given quite accurately by the universal relation of Eq. (9), where h is Planck's constant and ν

$$\rho_{xy} = \frac{h}{e^2 \nu} \qquad (9)$$

is an integer or simple rational fraction. The absolute accuracy with which Eq. (9) has been verified is better than 1 part in 10^6.

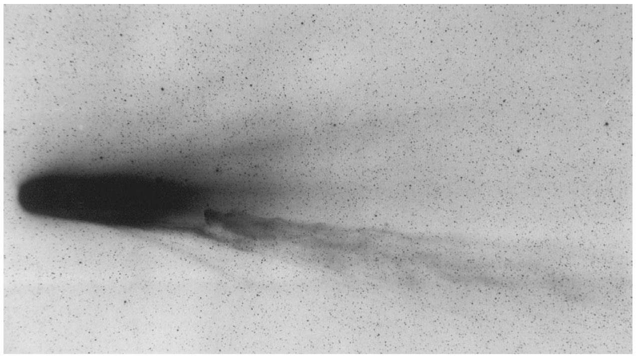
This extremely accurate quantization of ρ_{xy} allows the realization of a new standard of resistance based solely on fundamental constants of nature. In addition, the quantum unit of Hall resistance, $h/e^2 \simeq 25{,}812.80$ ohms, determines the fine-structure constant. *See* Electrical units and standards; Fundamental constants.

The explanation of this remarkable phenomenon involves several subtle quantum-mechanical effects. In the quantum regime (small ν), ρ_{xx}, which is the dissipative (longitudinal) resistivity, approaches zero on the Hall plateaus. The quantization of the Hall resistance is intimately connected with this fact. It is speculated that at zero temperature the dissipation is zero and that Eq. (9) is then obeyed exactly. *See* Quantum mechanics.

The nearly complete lack of dissipation in the quantum Hall regime is reminiscent of superconductivity. In both effects the ability of the current to flow without dissipation has its origin in the existence of a quantum-mechanical excitation gap, that is, a minimum threshold energy needed to disturb the special microscopic order in the system. *See* Entropy; Superconductivity.

In the integer quantum Hall effect [where ν in Eq. (9) in an integer], this excitation gap is a single-particle effect associated with the quantization by the strong magnetic field of the kinetic energy of the individual electrons into discrete states called Landau levels. In the fractional effect, the gap is associated with the highly collective, many-body ordering of the electrons into a quantum state which minimizes the strong Coulomb repulsion and hence lowers the overall energy. Thus, while the integer and fractional quantum Hall effects look superficially similar on a plot of resistivities versus magnetic field, their physical origins are actually quite different. *See* De Haas-van Alphen effect; Galvanomagnetic effects. [S.M.G.]

Halley's Comet The most famous of all comets; records of Halley's Comet appear at least as far back as 240 B.C. The comet's size, activity, and favorably placed orbit (with the perihelion roughly halfway between the Sun and the Earth's orbit) ensure its visibility to the naked eye at each apparition (see illustration). *See* Comet.



Halley's Comet as photographed by the United Kingdom Schmidt telescope in Australia on March 9, 1986. Dust-tail structures are visible (above), and the plasma tail (below) also shows a completely detached portion called a disconnection event. (*Copyright © by Photolabs, Royal Observatory, Edinburgh*)

This comet was the first to have its return predicted, a feat accomplished by Edmond Halley in 1705. He computed the orbits of several comets with Isaac Newton's then new gravitational theory. The orbits of comets observed in 1531, 1607, and 1682 were remarkably similar. Halley assumed that the sightings were of a single comet and predicted its return in 1758-1759. The prediction was verified, and the comet was named in his honor. The last perihelion passage of the comet was on February 9, 1986. In March 1986, six uncrewed spacecraft encountered Halley's Comet and produced data that have greatly enhanced the understanding of comets. The comet will return to its perihelion in 2061. [J.C.B.]

Halloysite A clay mineral similar in structure to kaolinite, having a 1:1 structure in which a silica tetrahedral sheet is joined to an alumina octahedral sheet. Unlike kaolinite, however, the structure is disordered in both the a and the b axis directions in successive layers, and it frequently contains water between the layers. *See* Kaolinite.

Two principal modifications exist: a less hydrous form with a composition and structure near to that of kaolinite,

$Al_2Si_2O_5(OH)_4$; and a hydrous form with the composition $Al_2Si_2O_5(OH)_4 \cdot 2H_2O$. The less hydrous form has a *c*-dimension of about 0.72 nanometer, whereas the hydrous form has a *c*-dimension of about 1.01 nm, the difference between them being roughly the thickness of a single sheet of water molecules. The hydrated form converts spontaneously and irreversibly into the less hydrous form when dried.

Electron microscopy reveals that the morphology of halloysite is usually tubular. Because the 1:1 layers in halloysite generally are separated from each other by water, halloysite has a larger cation exchange capacity, surface area, and catalytic activity than does kaolinite.

Halloysite is formed in nature from the weathering of feldspar under intense leaching conditions, and may also form in low-temperature hydrothermal systems. It has not been synthesized in the laboratory beyond doubt, although products resembling halloysite have been obtained by the artificial weathering of feldspar, and by the intercalation of kaolinite. Halloysite may precede kaolinite as a weathering product, and the transformation of halloysite into kaolinite may explain why halloysite is not common in sediments. *See* FELDSPAR; WEATHERING PROCESSES.

Halloysite is used as a catalyst and in the manufacture of ceramic products. *See* CLAY MINERALS. [D.Eb.]

Hallucination A perceptual experience in the absence of external stimulation. Hallucinations differ from illusions, which are changes in the perception of a real object. Hallucinations tend to fade with fixation or with attention to the content. Except for afterimages, which lie like a film over objects, hallucinations replace objects and object space. A hallucination is not objectlike in its realness. The conviction of reality is due to the loss of an object for comparison and the inability to disprove the image through other sensory modalities.

Hallucinations that are recognized as such by the experiencer include those resulting from sensory deprivation, drug use, and the phantom limb state. *See* SCHIZOPHRENIA.

Hallucinations may occur in a range of neurologic and psychiatric conditions, although they are usually considered hallmarks of schizophrenia. Delusional misidentification syndromes are a subtype of hallucinations and may also occur in neurological and psychiatric disease. For example, Capgras syndrome, which is commonly seen in schizophrenia, causes the individual to replace a familiar person (usually the spouse) with an imposter with the same or similar physical appearance. Frégoli syndrome is the delusional confusion of an individual as a familiar person in disguise.

Neurotransmitters are directly involved in the regulation of drug-induced and schizophrenic hallucinations, with many accounts pointing to the involvement of serotonin and dopamine. Therefore, it is possible to treat individuals with antipsychotic drugs that stabilize the chemical systems involved.

With localized damage to the brain, hallucinations are usually brief and intermittent, though in some cases, especially neurologic damage involving the brainstem, hallucinations can be chronic and sustained.

Physical input to the eyes and ears constrains and guides the construction of mental images, but the final result—the perception of an object or sound as a meaningful event occurring in the external world—also reflects very complex physiological processes. They begin in the brainstem, pass to the limbic system of the brain, and finally involve the temporal, parietal, and occipital areas of the cerebral cortex. Various types of hallucination are caused by disruptions that occur at different levels along that sequence of brain processes. *See* COGNITION.

At its earliest phase, damage to the upper brainstem produces peduncular (crepuscular) hallucinations of faces, torsos, and occasionally geometric patterns or landscapes near the viewer at the close of day. The images may be static and immobile or may change in content and affective tonality while being viewed. A smiling young boy, for example, may change into a scowling old woman. The hallucinations are often vivid and chromatic, and tend to be multimodal: they are seen, heard, and even touched, and occur over the entire visual field. Olfactory and gustatory images have also been described. Peduncular hallucinations are similar to the hypnagogic hallucinations that are experienced when falling asleep. *See* SLEEP AND DREAMING.

Neurologic damage involving limbic and temporal-lobe structures yields hallucinations of faces or formed scenes laden with meaning and affect. Changes in size (micropsia, macropsia) and shape (metamorphopsia) may occur. Déjà vu, derealization, and dreamy states are common. Auditory hallucinations are usually of speech or music. Microscopic (Lilliputian) and autoscopic (out-of-the-body) hallucinations also occur with temporal-lobe lesions. Exposure to a wide range of drugs and many psychiatric disorders, especially schizophrenia, can lead to hallucinations whose form suggests dysfunction involving limbic or temporal-lobe structures. *See* PSYCHOTOMIMETIC DRUG.

Damage to the parietal lobe leads to illusory distortions of shape, size, and motion, whereas occipital lesions or stimulation—or migraine—gives elementary hallucinations of sparks, flames, lines, or simple patterns. These hallucinations share features with afterimages. Palinopsia, the hallucinatory persistence of an object after the viewer has turned away, is a form of pathological afterimagery. *See* PERCEPTION.

[J.W.Br.; K.L.C.]

Halo Either of two large circles of light surrounding the Sun or Moon that result from the refraction of sunlight by small, hexagonal ice crystals falling slowly through the air. Light passing through the side faces of a hexagonal prism is refracted by an amount that depends on the orientation of the crystal; but a collection of many crystals refracts light passing through two side faces by an average angle of about 22°. If such crystals tumble randomly as they fall, they will produce the 22° halo, a circle around the Sun with an angular radius of 22°. Rays that pass through a side face and an end face of the prism similarly produce the larger and fainter 46° halo. The halos sometimes have a red inner edge and otherwise appear nearly white.

Many similar effects result from rays passing through ice crystals that assume special orientations as they fall, and from rays undergoing combination of reflection and refraction in an ice crystal. Usually, all of these effects are referred to as halo effects. *See* METEOROLOGICAL OPTICS; SUN DOG. [R.Gr.]

Halocyprida An order of the subclass Myodocopa, class Ostracoda, characterized by biramous antennae with the endopod and exopod of similar size, reduction or absence of the seventh pair of appendages, an unpaired male copulatory organ, and the absence of a median eye. The taxon is subdivided into two suborders, Halocypridina and Cladocopina; each has both Recent and fossil representatives. Extant halocyprids are small ostracods, measuring less than 0.4 in (10 mm).

With the exception of one brackish-water representative, halocyprids are marine, cosmopolitan in all oceans, and found from surface waters to abyssal depths. Most are planktonic species, although a few are epibenthic or benthic, and they include filter feeders, carnivores, and possibly detritus feeders. *See* CRUSTACEA; MYODOCOPA. [P.A.McL.]

Halogen elements The halogen family consists of the elements fluorine, F; chlorine, Cl; bromine, Br; iodine, I; and astatine, At. All the halogen elements except astatine exist in the Earth's crust and atmosphere. *See* HALOGEN MINERALS.

The halogens are the best-defined family of elements. They have an almost perfect gradation of physical properties. The increase in atomic weight from fluorine through iodine is paralleled by increases in density, melting and boiling points, critical temperature and pressure, heats of fusion and vaporization, and even in progressively deeper color (fluorine is pale yellow; chlorine, yellow-green; bromine, dark red; and iodine, deep violet).

Although all halogens generally undergo the same types of reactions, the extent and ease with which these reactions occur vary markedly. Fluorine in particular has the usual tendency of the lightest member of a family of elements to exhibit reactions not comparable to the other members. Each halogen must be considered individually, both in its preparation and in its reaction. *See* ASTATINE; BROMINE; CHLORINE; FLUORINE; HALIDE; HALOGENATION; IODINE. [R.J.C.; A.A.G.]

Halogen minerals Naturally occurring compounds containing a halogen as the sole or principal anionic constituent. There are over 70 such minerals, but only a few are common and can be grouped according to the following methods of formation.

1. Saline deposition by evaporation of seawater or salt lakes. Halite (rock salt), NaCl, is the most important of this type. Of the other minerals associated with halite, sylvite, KCl, and carnallite, $KMgCl_3 \cdot 6H_2O$, are the most important. *See* SALINE EVAPORITE.

2. Hydrothermal deposition. Fluorite, CaF_2, is the chief representative of this type. Cryolite, Na_3AlF_6, may be of primary deposition or may result from the action of fluorine-bearing solutions on preexisting silicates. *See* CRYOLITE; FLUORITE.

3. Secondary alteration. Chlorides, iodides, or bromides of silver, copper, lead, or mercury may form as surface alterations of ore bodies carrying these metals. The most common are cerargyrite, AgCl, and atacamite, $CU_2(OH)_3Cl$. *See* CERARGYRITE.

4. Deposition by sublimation. Halides formed as sublimation products about volcanic fumaroles include sal ammoniac, NH_4Cl; malysite, $FeCl_3$; and cotunnite, $PbCl_2$. At Mount Vesuvius, Italy, is the most noted occurrence of such minerals. *See* HALIDE.

5. Meteorites. Lawrencite, $FeCl_2$, has been found in iron meteorites. [C.S.H.]

Halogenated hydrocarbon An aliphatic or aromatic hydrocarbon in which one or more hydrogen atoms are substituted by halogen. *See* HALOGEN ELEMENTS; HALOGENATION.

Alkyl halides are compounds in which one hydrogen of an alkane has been replaced by halogen [fluorine (F), chlorine (Cl), bromine (Br), or iodine (I)], for example, bromoethane (ethyl bromide; CH_3CH_2Br). Many alkyl halides have been prepared; the chlorides and bromides are most useful and most common. Alkyl halides are important starting materials for the preparation of many other functionally substituted compounds. A general reaction for chlorides, bromides, and iodides is nucleophilic substitution, in which an ion or molecule with an available electron pair (a nucleophile) displaces a halide ion. *See* QUATERNARY AMMONIUM SALTS.

Compounds with halogen bonded directly to a benzene or other aromatic ring are called aryl halides. Halogen is introduced by electrophilic substitution, with a Lewis acid catalyst such as $FeCl_3$ or $FeBr_3$ to enhance the positive character of the halogen.

In fluorocarbons, every hydrogen atom is replaced by fluorine. Fluorocarbons can be named simply by using the prefix perfluoro- with the parent name. Because of the small atomic radius and high electronegativity of fluorine, these compounds are chemically inert and have properties quite unlike those of other halogenated organic compounds. *See* FLUORINE; FLUOROCARBON.

Hydrofluorocarbons contain combinations of fluorine and hydrogen to satisfy the valency requirement of carbon. Hydrofluorocarbons are also known as HFCs. The development of specific molecules for particular applications, previously satisfied by chlorofluorocarbons, has been international in scope. Because they contain hydrogen, hydrofluorocarbons are more likely to be degraded in the lower regions of the atmosphere. Since they do not contain chlorine, these compounds do not contribute to ozone depletion.

Perfluorocarbons contain only carbon and fluorine. They are named by using the prefix perfluoro- along with the name of the equivalent hydrocarbon. Perfluorocarbons are chemically very inert and also have excellent thermal stability. This inertness and the resulting long atmospheric lifetime is reflected in higher global warming potentials compared to hydrofluorocarbons, hydrochlorofluorocarbons, and chlorofluorocarbons. This is due, partly, to the high strength of the C-F bond. The electronegativity of fluorine shields the carbon backbone from chemical attack. Under normal conditions, perfluorocarbons are unaffected by strong acids or bases and by oxidizing or reducing agents. *See* ELECTRONEGATIVITY.

A number of compounds with two or more halogen atoms are of special importance. Methane (CH_4) can be substituted with as many as four halogen atoms to give compounds such as CH_2Cl_2, CHI_3, and CF_3Br. Several polyhalomethane, -ethane, and -ethylene derivatives have major uses, and they are industrial chemicals produced in large quantities.

Chlorination of methane leads to mixtures of mono-, di-, tri-, and tetrachloro products. The relative amounts can be controlled by adjusting the ratio of starting materials. Methyl chloride is manufactured by this chlorination process and also by reaction of methanol and HCl. Methylene chloride, CH_2Cl_2, is the major product from methane, and is utilized primarily as a cleaning solvent or as a blowing agent for plastic foam. Methylene chloride is more volatile and much less toxic than $CHCl_3$ or CCl_4.

Chlorofluorocarbons are methane and ethane derivatives with all hydrogen atoms replaced by combinations of chlorine and fluorine. Chlorofluorocarbons are known collectively as CFCs. The first of these compounds, dichlorofluoromethane (CCl_2F_2), was introduced as a nontoxic, nonflammable working fluid in refrigeration equipment to replace ammonia and sulfur dioxide. Other compounds were developed to meet the requirements of specific uses such as air-conditioning equipment in buildings and vehicles, and propellants for aerosols.

Hydrochlorofluorocarbons contain combinations of hydrogen, chlorine, fluorine, and carbon to satisfy the valency requirement of carbon. Also known as HCFs, the hydrochlorofluorocarbons have been developed as interim substitutes for chlorofluorocarbons. Since they have at least one hydrogen atom in the molecule, they are more likely to be degraded in the troposphere by reaction with hydroxyl (OH) radicals. Thus, the potential that hydrochlorofluorocarbons have to deplete ozone by migration to the stratosphere is reduced. [J.A.Mo.; V.N.M.R.]

Halogenation A chemical reaction or process which results in the formation of a chemical bond between a halogen atom and another atom. Reactions resulting in the formation of halogen-carbon bonds are especially important. The halogenated compounds produced are employed in many ways, for example, as solvents, intermediates for numerous chemicals, plastic and polymer intermediates, insecticides, fumigants, sterilants, refrigerants, additives for gasoline, and materials used in fire extinguishers. *See* HALOGEN ELEMENTS.

Halogenation reactions can be subdivided in several ways, for example, according to the type of halogen (fluorine, chlorine, bromine, or iodine), type of material to be halogenated (paraffin, olefin, aromatic, hydrogen, and so on), and operating conditions and methods of catalyzing or initiating the reaction.

Halogenation reactions with elemental chlorine, bromine, and iodine are of considerable importance. Because of high exothermocities, fluorinations with elemental fluorine tend to have high levels of side reactions. Consequently, elemental fluorine is generally not suitable for direct fluorination. Two types of reactions are possible with these halogen elements, substitution and addition.

Substitution halogenation is characterized by the substitution of a halogen atom for another atom (often a hydrogen atom) or group of atoms (or functional group) on paraffinic, olefinic, aromatic, and other hydrocarbons. A chlorination reaction of importance that involves substitution is that between methane and chlorine. *See* SUBSTITUTION REACTION.

Addition halogenation involves a halogen reacting with an unsaturated hydrocarbon. Chlorine, bromine, and iodine react readily with most olefins; the reaction between ethylene and chlorine to form 1,2-dichloroethane is of considerable commercial importance, since it is used in the manufacture of vinyl chloride.

Addition reactions with bromine or iodine are frequently used to measure quantitatively the number of —CH=CH— (or ethylenic-type) bonds in organic compounds. Bromine numbers or iodine values are measures of the degree of unsaturation of the hydrocarbons.

Substitution halogenation on the aromatic ring can be made to occur via ionic reactions. The chlorination reactions with elemental chlorine are similar to those used for addition chlorination of olefins. *See* HALOGENATED HYDROCARBON. [L.F.A.]

Halophilism (microbiology) The requirement of high salt (NaCl) concentrations for growth of microorganisms. Microorganisms (mainly bacteria) can be classified by their physiological tolerance to salt. Most normal eubacteria, such as *Escherichia coli* and *Pseudomonas fluorescens*, and most freshwater microorganisms, are nonhalophiles (best growth at less than 1.2% NaCl). Slight halophiles (1.2–3% NaCl) include many marine microorganisms. Moderate halophiles (3–15% NaCl) include *Vibrio costicola*, *Paracoccus halodenitrificans*, and many others. Borderline extreme halophiles (9–25% NaCl) include the photosynthetic bacterium *Ectothiorhodospira halophila*, the actinomycete *Actinopolyspora halophila*, and the halophylic archaebacteria *Halobacterium volcanii* and *H. mediterranei*. Extreme halophiles (require at least 10% NaCl; optima 15–30% NaCl) are *Halobacterium salinarium* and *Halococcus morrhuae*. *See* METHANOGENESIS (BACTERIA).

The halophilic aerobic archaebacteria give a striking red color to hypersaline waters. They are found in the Dead Sea, the Great Salt Lake, Lake Magadi in Kenya, and other alkaline salt lakes, and in solar salterns where salt is prepared by evaporating seawater. Their red color is due to carotenoid pigments (bacterioruberins), which seem to protect them from strong sunlight in their natural environments. *See* CAROTENOID.

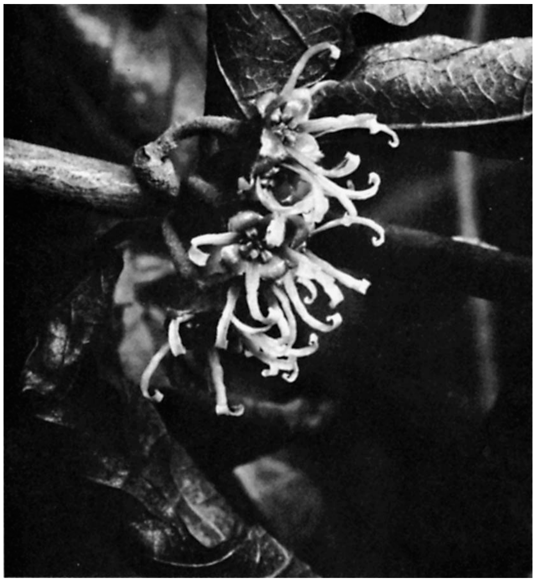
Microorganisms that live in high concentrations of salt or other solutes do not exclude solutes from the interior of the cell. However, the internal solute composition is quite different from the outside composition. *Dunaliella* species have internal glycerol concentrations corresponding to the external concentration of NaCl. Other salt-tolerant algae and yeasts also have high internal concentrations of glycerol, or other polyols. Solutes which maintain osmotic equilibrium between inside and outside of the cell without interfering with the cell's physiological processes are called compatible solutes. *See* OSMOREGULATORY MECHANISMS.

Mechanisms of adaptation to a highly saline environment have been best characterized in aerobic halophilic bacteria whose enzymes are able to function in high salt concentrations; indeed, most of them require such salt concentrations for activity, stability, or both. For a number of enzyme systems, KCl rather than NaCl is required. Other parts of the cells of these bacteria also require high salt concentrations for function or stability. Halobacteria lyse and their cell walls may completely dissolve unless salt concentrations are high. NaCl is specifically required for active transport of ions and nutrients in all halophilic bacteria. [D.J.K.]

Haloragales An order of flowering plants, division Magnoliophyta (Angiospermae), in the subclass Rosidae of the class Magnoliopsida (dicotyledons). The order consists of 2 families, with about 150 species in all. The Haloragales are herbs with perfect or often unisexual, more or less reduced flowers. Many of the species are aquatic. Pollen is commonly distributed by wind or water. The aquarium plant called parrot's feather (*Myriophyllum*, family Haloragaceae) and the very large-leaved plant *Gunnera*, (family Gunneraceae) are well-known members of the Haloragales. *See* MAGNOLIOPHYTA; MAGNOLIOPSIDA; PLANT KINGDOM; ROSIDAE. [A.Cr.; T.M.Ba.]

Hamamelidae A small subclass of the class Magnoliopsida (dicotyledons) in the division Magnoliophyta (Angiospermae), the flowering plants, consisting of 11 orders (Trochodendrales, Hamamelidales, Daphniphyllales, Didymelales, Eucommiales, Urticales, Leitneriales, Juglandales, Myricales, Fagales, and Casuarinales), 24 families, and about 3400 species. They have strongly reduced, often unisexual flowers with poorly developed or no perianth. With the notable exception of some of the Urticales, they are all woody plants. Pollination is usually by wind. Many of the families formerly grouped under the Amentiferae belong to the Hamamelidae. See articles on each order. *See* MAGNOLIOPHYTA; MAGNOLIOPSIDA; PLANT KINGDOM. [A.Cr.; T.M.Ba.]

Hamamelidales A small order of flowering plants, division Magnoliophyta (Angiospermae), which gives its name to the subclass Hamamelidae in the class Magnoliopsida (dicotyledons). The family Hamamelidaceae contains about 100 species and the Platanaceae about 6 species; the other 3 families have only 2 species each. Within its subclass, the order is more advanced than the Trochodendrales in having vessels in the wood, but less advanced than the other orders in that the gynoecium consists either of separate carpels or of united carpels that open at maturity to release the seeds. Witch hazel (*Hamamelis*; see illustration), sweet gum (*Liquidambar*, family Hamamelidaceae), and the plane tree or sycamore (*Platanus*) are familiar members of the Hamamelidales. *See* HAMAMELIDAE; MAGNOLIOPHYTA; PLANT KINGDOM; TROCHODENDRALES. [A.Cr.; T.M.Ba.]



American witch hazel (*Hamamelis virginiana*), a characteristic member of the family Hamamelidaceae and order Hamamelidales. The flowers of this species open in the autumn, when the leaves are already beginning to deteriorate. (*John H. Gerard, National Audubon Society*)

Hamilton's equations of motion The motion of a mechanical system may be described by a set of first-order ordinary differential equations known as Hamilton's equations. Because of their remarkably symmetrical form, they are often referred to as the canonical equations of motion of a system. They are equivalent to Lagrange's equations, but the fact that they are of first order and highly symmetrical makes them advantageous for general discussions of the motion of systems. *See* LAGRANGE'S EQUATIONS.

Hamilton's equations can be derived from Lagrange's equations. Let the coordinates of the system be q_j ($j = 1, 2, \ldots, f$), and let the dynamical description of the system be given by the lagrangian $L(q, \dot{q}, t)$, where q denotes all the coordinates and a dot denotes total time derivative. Lagrange's equations are then given by Eq. (1). The momentum p_j canonically conjugate to q_j is defined by Eq. (2).

$$\frac{d}{dt}\frac{\partial L}{\partial \dot{q}_j} - \frac{\partial L}{\partial q_j} = 0 \qquad (1)$$

$$p_j = \frac{\partial L}{\partial \dot{q}_j} \qquad (2)$$

The hamiltonian H is defined by Eq. (3). Then Hamilton's canonical equations are Eqs. (4).

$$H = \sum_{j=1}^{f} p_j \dot{q}_j - L(q, \dot{q}, t) \qquad (3)$$

$$\dot{q}_j = \frac{\partial H(q, p, t)}{\partial p_j} \quad \dot{p}_j = -\frac{\partial H(q, p, t)}{\partial q_j} \qquad (4)$$

As they stand, Hamilton's equations are no easier to integrate directly than Lagrange's. Hamilton's equations are of great advantage in more general discussions, and they permit the making of canonical transformations which can lead to simplifications. *See* CANONICAL TRANSFORMATIONS.

The hamiltonian function H of classical mechanics is used to form the quantum-mechanical hamiltonian operator. [P.M.S.]

Hamilton's principle A variational principle from which can be derived the equations of motion of a classical dynamical system in which friction or other forms of dissipation of energy do not occur. In the original formulation of Newton's laws of motion, the position of each particle of the system of interest is specified by the cartesian coordinates of that particle. In many cases, these coordinates are not all independent of each other or do not reflect the structure of the system in a convenient way. It is then advantageous to introduce a system of generalized coordinates which are independent of each other and do reflect any special features of the system such as its symmetry about some center. The number of degrees of freedom of the system, f, is the number of such coordinates required to specify the configuration of the system at any time. *See* DEGREE OF FREEDOM (MECHANICS).

The problem of determining how a system moves may be formulated in the following way: If the configuration of the system at time t_1 is specified by the generalized coordinates $q_1(t_1), \ldots, q_f(t_1)$ and at the time t_2 by $q_1(t_2), \ldots, q_f(t_2)$, then it is required to find the trajectory along which the system travels from the initial to the final configuration. Hamilton's principle addresses this problem similarly to the way that a geometer addresses the problem of finding the shortest path lying in a curved surface between two given points on the surface. The geometer specifies the distance ds between any two close-lying points in terms of the coordinates q_i of the two points and their differences, the coordinate differentials dq_i, as in Eq. (1). The path length D between the two

$$(ds)^2 = \sum_{i,j=1}^{f} g_{ij}(q_1, \ldots, q_f)\, dq_i\, dq_j \qquad (1)$$

$$D = \int_{t_1}^{t_2} ds \qquad (2)$$

specified points, given by the integral in Eq. (2), is then required to be a minimum. Hamilton defined a characteristic function Φ, analogous to D, by Eq. (3), using the lagrangian function

$$\Phi = \int_{t_1}^{t_2} L(q, \dot{q}, t)\, dt \qquad (3)$$

$L(q, \dot{q}, t)$ of the system in a way analogous to the geometer's g. Hamilton's principle states that the system follows the trajectory that makes the integral in Eq. (3) have a minimum value, provided the time interval between times t_1 and t_2 is not too great. It can be shown that this principle implies Lagrange's equations of motion for the system, and that it follows from Lagrange's equations. *See* DIFFERENTIAL GEOMETRY; LAGRANGE'S EQUATIONS; LAGRANGIAN FUNCTION; LEAST-ACTION PRINCIPLE; MINIMAL PRINCIPLES; VARIATIONAL METHODS (PHYSICS). [P.St.]

Hamster The common name for any of 14 species of rodents in the family Cricetidae. The natural range of most of these species is Asia but a few, such as the common hamster (*Cricetus cricetus*), are found in Europe.

The common hamster is a solitary, aggressive animal with interesting burrowing and hoarding habits. The burrows are not deep, rarely more than 2 ft (0.6 m), and consist of a large central chamber with radiating side chambers for special purposes, such as for hoarding food, for living quarters, and for excretion. A so-called summer chamber is used for breeding. The hamster goes into its burrow in the autumn, closes off the entrance, and goes to sleep. It does not hibernate deeply and wakes up from time to time to eat. *See* HIBERNATION.

The golden hamster (*Mesocricetus auratus*) is extensively used as a laboratory animal for experimental purposes, especially in studies of the physiological aspects of hibernation. *See* RODENTIA. [C.B.C.]

Haplopoda An order of carnivorous branchiopod crustaceans formerly included in the order Cladocera. Only one species, the fresh-water *Leptodora kindti*, is included.

The body is about 9 mm (0.4 in.) long. *Leptodora* is among the most transparent of multicellular freshwater animals. It swims slowly by means of enormous antennae and seizes its prey with its six pairs of segmented, grasping, thoracic limbs. The mandibles are styliform and of a type unique within the Branchiopoda. There is a single, median sessile eye. The carapace is reduced to a dorsal brood pouch and does not protect the body.

Parthenogenetic eggs and young are carried in the brood pouch in summer. In autumn, fertilized resting eggs are carried there which are shed freely, and the eggs overwinter. They hatch in spring as nauplii, a stage eliminated from the parthenogenetic phase of the life cycle.

Leptodora is widely distributed in the plankton of larger lakes of the Holarctic region. *See* BRANCHIOPODA. [G.Fr.]

Haplosclerida An order of sponges of the class Demospongiae, including species with a skeleton made up of a single category of siliceous megascleres embedded in spongin fibers or joined together in a network by a spongin cement. Microscleres (never asters) are present or absent. A modified dermal skeleton is absent. Many species form large upright branching colonies, the branches often being hollow.

Haplosclerid sponges inhabit all seas and are especially abundant in tidal and shallow waters of the continental shelf. Some species occur down to depths of 6600 ft (2000 m). The family Spongillidae is restricted to fresh water except for a few species which have secondarily invaded brackish water. *See* DEMOSPONGIAE. [W.D.H.]

Haplosporea A class of protozoa, often known as Acnidosporidia, in the subphylum Sporozoa. Haplosporea are distinguished from other similar groups by the production of spores lacking polar filaments. The spores are enclosed in a membrane, and each spore contains a single sporozoite.

Two orders make up the class according to the scheme proposed by the Committee on Taxonomy and Taxonomic Problems of the Society of Protozoologists. These are the Haplosporida and Sarcosporida. Haplosporida are parasites of invertebrates and primitive chordates (Ascidia). Sarcosporida are muscle parasites of vertebrates, particularly warm-blooded ones. *See* HAPLOSPORIDA; SPOROZOA. [R.D.M.]

Haplosporida A group of Protozoa usually regarded as an order within the class Haplosporea. The chief distinguishing characteristic of the Haplosporida, and the one from which their name is derived, is the production of uninucleate spores that lack polar capsules and polar filaments.

Haplosporida are mainly parasites of invertebrates, such as rotifers, annelids, crustacea, insects, and mollusks, but they also occur in the bodies of Ascidia (tunicates), which are primitive chordates. If the genus *Icthyosporidium* is properly included in the order, Haplosporida also parasitize fish. One species causes "neon" fish disease.

It is of considerable biological interest that some species of Haplosporida are hyperparasites, that is, parasitic on other parasites. They have been found in gregarines parasitizing annelids, and also in flukes. *See* HAPLOSPOREA; SPOROZOA. [R.D.M.]

Harbors and ports A harbor is any body of water of sufficient depth for ships to enter and find shelter from storms or other natural phenomena. The modern harbor is a place where ships are built, launched, and repaired, as well as a terminal for incoming and outgoing ships. There are four principal classes of harbors; commercial, naval, fishery, and refuge for small craft. Most harbors are situated at the mouth of a river or at some point where it is easy to transfer cargoes inland by river barges, railroads, or trucks. Harbors may be land-locked, natural harbors protected from the sea by a narrow inlet; unprotected harbors at which ships may dock even though subjected to the hazards of changing tides, ocean waves, fogs, and ice; and artificial harbors carved out at sites where the natural features are unfavorable. The latter are fashioned by dredging and by constructing jetties, breakwaters, and sea basins to protect ships against unusually high or low tides. *See* COASTAL ENGINEERING.

A port is a harbor with the necessary terminal facilities to expedite the moving of cargo and passengers at any stage of a journey. A good harbor must have a safe anchorage and a direct channel to open water, and must be deep enough for large ships. An efficient port must have enough room for docks, warehouses, and loading and unloading machinery. Geographically, a port or harbor is usually limited to a comparatively small area of usable berthing space rather than an extended coastline. Some ports along exposed coastal areas, for example, the western coast of South America, have little harbor area. [B.J.W.]

Hardness scales Arbitrarily defined measures of the resistance of a material to indentation under static or dynamic load, to scratch, abrasion, or wear, or to cutting or drilling. Standardized tests compare similar materials according to the particular aspect of hardness measured by the test. Widely used tests for metals are Brinell, Rockwell, and Scleroscope tests, with modifications depending upon the size or condition of the material. Indentation tests compare species of wood or flooring materials, and abrasion tests serve as an index of performance of stones and paving materials.

Hardness tests are important in research and are widely used for grading, acceptance, and quality control of manufactured articles. The hardness designation or scale is associated with the test method or instrument used.

Resistance to scratching is defined by comparison with 10 selected minerals, which are numbered in the order of increasing hardness. This mineralogical scale, called Mohs scale, is 1, talc; 2, gypsum; 3, calcite; 4, fluorite; 5, apatite; 6, orthoclase; 7, quartz; 8, topaz; 9, corundum; and 10, diamond. Minerals lower in the scale are scratched by those with higher numbers.

Materials are differentiated qualitatively according to resistance to scratching or cutting by files especially selected for the purpose. Whether or not a visible scratch is produced on the material indicates its hardness in comparison with a sample of desired hardness.

Resistance to indentation by a hardened steel or tungsten carbide ball under specified load is the basis for Brinell hardness. Brinell hardness number (Bhn), expressed in kilograms per square millimeter, is obtained by dividing the load by the spherical surface area of the impression.

Indentation of a square-based diamond pyramid penetrator with an angle between opposite faces of 136° measures Vickers hardness. Vickers hardness number, also called diamond pyramid hardness, is equal to the load divided by the lateral area of the pyramidal impression.

Depth of indentation of either a steel ball or a 120° conical diamond with rounded point, called a brale, under prescribed load is the basis for Rockwell hardness. The depth of impression is indicated on a dial whose graduations represent the hardness number.

The pressure in kilograms per square millimeter required to embed a 0.75-mm (0.0295-in.) hemispherical diamond penetrator to a depth of 0.046 mm (0.0018 in.), producing an impression 0.36 mm (0.014 in.) in diameter, is the measure of Monotron hardness.

Height of rebound of a diamond-tipped weight or hammer falling within a glass tube from a height of 10 in. (25.4 cm) and striking the specimen surface measures Shore Scleroscope hardness.

Resistance to indentation over very small areas (as on small parts, the constituents of metal alloys, or for exploration of hardness variations) is called microhardness. [W.J.K./W.G.B.]

Hardy-Weinberg formula A basic mathematical relation used in population genetics. It gives the proportion of the various genotypes in a randomly mating population in terms of the frequencies of the genes. The formula was discovered independently in 1908 by G. H. Hardy, a British mathematician, and W. Weinberg, a German physician. *See* HUMAN GENETICS; POPULATION GENETICS.

In its simplest form the Hardy-Weinberg formula may be stated thus: If p is the proportion of gene A in the population and $q(= 1 - p)$ is the proportion of gene a, then after one generation of random mating the three genotypes AA, Aa, and aa will occur in the proportions p^2, $2pq$, and q^2. In other words the genotypes are given by the appropriate terms in the expansion of the binomial $(p + q)^2$. The extension to multiple alleles is direct.

The formula holds only for an infinite population and assumes random mating in the absence of significant mutation pressure or gene transfer between populations. However, it is an accurate approximation in many populations. *See* GENETICS. [J.F.Cr.]

Harmonic (periodic phenomena) A sinusoidal quantity having a frequency that is an integral multiple of the frequency of a periodic quantity to which it is related. *See* MODE OF VIBRATION.

A harmonic series of sounds is one in which the basic frequency of each sound is an integral multiple of some fundamental frequency. The name exists for historical reasons, even though according to the usual mathematical definition such frequencies form an arithmetic series. An ideal string (or air column) can vibrate as a whole or in a number of equal parts, and the respective periods of vibration are proportional to the lengths. These increasingly shorter lengths or periods form a harmonic series. The name came from the harmonious relation of such sounds, and the science of musical acoustics was once called harmonics. Nowadays, it is customary to deal with ratios of frequency rather than ratios of length and, because frequency is the reciprocal of period, the definition of harmonic in acoustics becomes that given here. *See* Harmonic analyzer; Musical acoustics. [R.W.Y.]

Harmonic motion A periodic motion that is a sinusoidal function of time. It is often called simple harmonic motion (SHM). It is the simplest possible type of vibratory motion. The motion is symmetric about its midpoint, at which the velocity is greatest and the acceleration is zero. At the extreme displacements or turning points, the velocity is zero, and the acceleration is a maximum. The motion is characterized by a unique frequency (without overtones).

Harmonic motion may be present in very simple mechanisms. For example, if a wheel is rotating at a constant speed about a fixed axis, the projection on any fixed line of the motion of a point on the wheel is simple harmonic. Harmonic motion may also result from the response of a vibrating system to a periodic—in particular a sinusoidal—force. Harmonic motion is the typical motion of most simple systems that have been displaced from a position of stable equilibrium and then released, provided that the damping is negligible. The motion of a pendulum is approximately simple harmonic for small amplitudes. *See* Pendulum.

The realization that atoms are continually vibrating in motions that are nearly harmonic is essential for understanding many properties of matter, including molecular spectra, heat capacity, and heat conduction. *See* Damping; Forced oscillation; Harmonic oscillator; Lattice vibrations; Molecular structure and spectra; Periodic motion; Vibration; Wave motion. [J.M.Ke.]

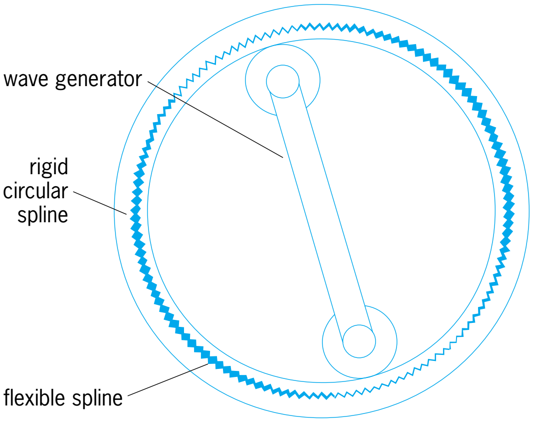
Harmonic oscillator Any physical system that is bound to a position of stable equilibrium by a restoring force or torque proportional to the linear or angular displacement from this position. If such a body is disturbed from its equilibrium position and released, and if damping can be neglected, the resulting vibration will be simple harmonic motion, with no overtones. The frequency of vibration is the natural frequency of the oscillator, determined by its inertia (mass) and the stiffness of its restoring force.

The harmonic oscillator is not restricted to a mechanical system, but might, for example, be electric. Typical electronic oscillators, however, are only approximately harmonic.

If a harmonic oscillator, instead of vibrating freely, is driven by a periodic force, it will vibrate harmonically with the period of the force; initially the natural frequency will also be present, but any damping will eventually remove the natural motion. *See* Damping; Forced oscillation; Harmonic motion.

In both quantum mechanics and classical mechanics, the harmonic oscillator is an important problem. It is one of the few rigorously soluble problems of quantum mechanics. The quantum-mechanical description of electromagnetic, electronic, mesonic, and other fields is usually carried out in terms of a (time) Fourier analysis. The individual Fourier components of noninteracting fields are independent harmonic oscillators. *See* Anharmonic oscillator. [J.M.Ke.]

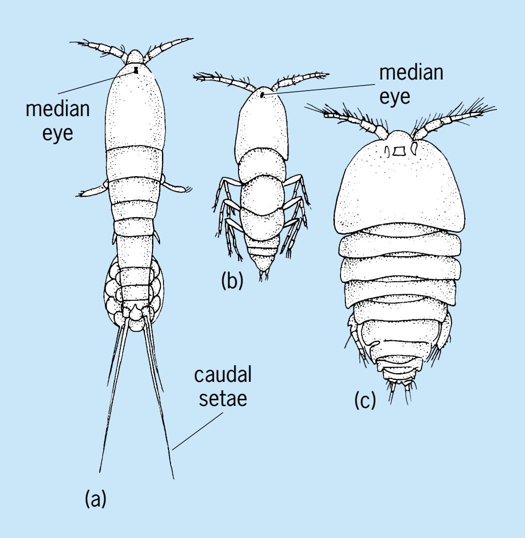
Harmonic speed changer A mechanical-drive system used to transmit rotary, linear, or angular motion at high ratios and with positive motion. In the rotary version, shown schematically in the illustration, the drive consists of a rigid circular spline, an input wave generator, and a flexible spline. Any one of these can be fixed, used as the input, or used as the output. Any combination (fixed, driver, or driven) may be used. *See* Splines.



Rotary-to-rotary harmonic speed changer.

The advantages of this drive are (1) high-ratio gearing in small space, (2) speed reduction (or increase) in fixed ratio up to 1000:1 in one unit, (3) negligible wear of teeth, (4) balanced bearing loads, (5) negligible backlash, (6) efficiency of approximately 80% in a gear ratio of 400:1, and (7) adaptability to rotary-to-rotary, rotary-to-linear, and linear-to-linear drives. *See* Gear drive. [P.H.B.]

Harpacticoida An order of the Copepoda, with about 1700 species known. Their form is variable but is generally linear and more or less cylindrical (see illustration). These animals are minute and vary in length from 1/64 to 1/8 in. (0.4 to 3 mm). As a rule, the first thoracic segment is incorporated with the cephalothorax, and the last thoracic segment is included in the abdomen.



Some typical harpacticoids. (*a*) *Harpacticus chelifer*. (*b*) *Parategastes spaericus*. (*c*) *Alteutha interrupta*.

Harpacticoids have a worldwide distribution. They occur in all kinds of aquatic habitats, especially marine, but also among moss and leaves. In the sea they range from the shore to abyssal depths. In general, they are free-living and benthonic; some species are pelagic, parasitic, or commensal. *See* Copepoda. [K.L.]

Hassium A chemical element, symbol Hs, atomic number 108. It was synthesized and identified in 1984 by using the Universal Linear Accelerator (UNILAC) at Darmstadt, West Germany, by the same team (led by P. Armbruster and G. Müzenberg) which first identified bohrium and meitnerium. The isotope ^{265}Hs was produced in a fusion reaction by bombarding a ^{208}Pb target with a beam of ^{58}Fe projectiles. *See* Periodic table.

The discovery of bohrium and meitnerium was made by detection of isotopes with odd proton and neutron numbers. In this region, odd-odd nuclei show the highest stability against fission. Elements with an even atomic number are intrinsically less stable against spontaneous fission. The isotopes of hassium were expected to decay by spontaneous fission—which explains why meitnerium was synthesized before hassium.

As in the case of bohrium and meitnerium, the isotope was produced by fusion in a one-neutron deexcitation channel; in this case the compound system was ^{266}Hs. The reaction mechanism again was cold fusion. The isotope ^{265}Hs has a half-life of about 2 ms and decays by emission of an alpha particle of 10.36 MeV.

The elements bohrium, hassium, and meitnerium are stabilized by shell effects against spontaneous fission; this special stability may occur because these nuclei may prefer a sausage shape which is predicted to be energetically most favorable for them. *See* BOHRIUM; MEITNERIUM; TRANSURANIUM ELEMENTS. [P.Ar.]

Hatchettite Mountain tallow, a yellow-white to yellow-green hydrocarbon occurring in Belgian coal seams; it is also called hatchettine. Hatchettite is translucent but darkens on exposure to air. It is soft, has no odor, is greasy to the touch, and consists of 85.5% carbon and 14.5% hydrogen. Its index of refraction is 1.47–1.50; it melts at 46–47°C (115–117°F), is sparingly soluble in alcohol or ether, decomposes in concentrated sulfuric acid, and has a specific gravity of 0.89–0.98. [I.A.B.]

Hausmannite A mineral with composition $Mn^{2+}Mn_2^{3+}O_4$. Hausmannite is most frequently massive-granular and possesses one perfect basal cleavage. The color is black, and streak dark brown. Hardness is 5.5 on Mohs scale, and the specific gravity is 4.81. It is an occasional ore of manganese, and it most frequently occurs in metamorphosed sedimentary manganese ore deposits, such as some small deposits in central Sweden and in the Central Provinces, India. [P.B.M.]

Hazardous waste Any solid, liquid, or gaseous waste materials that, if improperly managed or disposed of, may pose substantial hazards to human health and the environment. Every industrial country in the world has had problems with managing hazardous wastes. Improper disposal of these waste streams in the past has created a need for very expensive cleanup operations. Efforts are under way internationally to remedy old problems caused by hazardous waste and to prevent the occurrence of other problems in the future.

A waste is considered hazardous if it exhibits one or more of the following characteristics: ignitability, corrosivity, reactivity, and toxicity. Ignitable wastes can create fires under certain conditions; examples include liquids, such as solvents, that readily catch fire, and friction-sensitive substances. Corrosive wastes include those that are acidic and those that are capable of corroding metal (such as tanks, containers, drums, and barrels). Reactive wastes are unstable under normal conditions. They can create explosions, toxic fumes, gases, or vapors when mixed with water. Toxic wastes are harmful or fatal when ingested or absorbed. When they are disposed of on land, contaminated liquid may drain (leach) from the waste and pollute groundwater. *See* GROUND-WATER HYDROLOGY; WATER POLLUTION.

Hazardous wastes may arise as by-products of industrial processes. They may also be generated by households when commercial products are discarded. These include drain openers, oven cleaners, wood and metal cleaners and polishes, pharmaceuticals, oil and fuel additives, grease and rust solvents, herbicides and pesticides, and paint thinners.

The predominant waste streams generated by industries in the United States are corrosive wastes, spent acids, and alkaline materials used in the chemical, metal-finishing, and petroleum-refining industries. Many of these waste streams contain heavy metals, rendering them toxic. Solvent wastes are generated in large volumes both by manufacturing industries and by a wide range of equipment maintenance industries that generate spent cleaning and degreasing solutions. Reactive wastes come primarily from the chemical industries and the metal-finishing industries. The chemical and primary-metals industries are the major sources of hazardous wastes.

There is a growing acceptance throughout the world of the desirability of using waste management hierarchies for solutions to problems of hazardous waste. A typical sequence involves source reduction, recycling, treatment, and disposal. Source reduction comprises the reduction or elimination of hazardous waste at the source, usually within a process. Recycling is the use or reuse of hazardous waste as an effective substitute for a commercial product or as an ingredient or feedstock in an industrial process.

Treatment is any method, technique, or process that changes the physical, chemical, or biological character of any hazardous waste so as to neutralize such waste; to recover energy or material resources from the waste; or to render such waste nonhazardous, less hazardous, safer to manage, amenable for recovery, amenable for storage, or reduced in volume. Disposal is the discharge, deposit, injection, dumping, spilling, leaking, or placing of hazardous waste into or on any land or body of water so that the waste or any constituents may enter the air or be discharged into any waters, including groundwater.

There are various alternative waste treatment technologies, for example, physical treatment, chemical treatment, biological treatment, incineration, and solidification or stabilization treatment. These processes are used to recycle and reuse waste materials, reduce the volume and toxicity of a waste stream, or produce a final residual material that is suitable for disposal. The selection of the most effective technology depends upon the wastes being treated.

There are abandoned disposal sites in many countries where hazardous waste has been disposed of improperly in the past and where cleanup operations are needed to restore the sites to their original state. Cleaning up such sites involves isolating and containing contaminated material, removal and redeposit of contaminated sediments, and in-place and direct treatment of the hazardous wastes involved. As the state of the art for remedial technology improves, there is a clear preference for processes that result in the permanent destruction of contaminants rather than the removal and storage of the contaminating materials. [H.M.F.]

Head The region of the body consisting of the skull, its contents, and related structures. Its two principal parts are the cranium, or braincase, and the face.

The skin, hair, and subcutaneous tissues over the top of the skull are collectively known as the scalp. The regions of the cranium take their names from the underlying bones, for example, the temporal, parietal, frontal, and occipital regions.

The intracranial contents include the brain and uppermost portion of the spinal cord with their coverings (meninges), blood vessels, and the important cranial nerves, as well as the cerebrospinal fluid system. Many openings, or foramina, afford means of passage from within the skull for nerves and blood vessels. [T.S.P.]

Headache Pain within the head. It is probably the most common complaint for which people seek a physician's help. Headaches can be grouped into three primary categories: vascular, muscle-contraction, and organic.

Vascular headaches include classic and common migraine as well as cluster, toxic, and hypertensive headaches. All are caused by dilation of cerebral blood vessels. Constriction of the blood vessels may also occur in any part of the cerebral vascu-lature and cause the neurologic symptoms associated with some forms of vascular headache. Migraine affects one side of the head but may be bilateral. Nerologic symptoms, especially visual disturbances, are common. Cluster headache is the occurrence of migraines in groups or series. The cluster headache is characterized by its one-sided, excruciating attack that is usually localized around one eye. Other forms of vascular headache may be caused by systemic infection or fever, which causes dilation of the blood vessels. The ingestion of alcohol, poisons, or some medications used to treat hypertension or cardiac disease may produce adverse effects, including vascular headaches. *See* HYPERTENSION.

The most common form of headache is the muscle-contraction or tension headache. It is characterized by dull, constricting pain that can either occur intermittently or continue for days, months, or years. Muscle-contraction headaches usually affect both sides of the head and may be described as having a hat-band distribution of pain.

Very few headaches have an organic cause, such as brain tumor or aneurysm. Headache is not a prominent symptom of brain tumor: if present, headache will become progressively worse and constant, and it may not appear until late in the course of the tumor development. The headache associated with an aneurysm is usually mild until the aneurysm is at the point of rupture. If a patient complains of an exceptionally severe headache, organic disease, such as aneurysm, must be ruled out. *See* ANEURYSM.

Acute sinus headache is characterized by nasal congestion and fever. The headache is minimal in the morning and increases in severity through the day. Temporomandibular joint (TMJ) disease involves a faulty bite or misalignment of the teeth and can cause a headache. Eye conditions may also cause headache. The increased intraocular pressure of glaucoma, for example, may cause a headache, and so complaints of a recent onset of headache, particularly in the elderly, should prompt a screening for glaucoma. *See* GLAUCOMA; PAIN. [S.D.]

Health physics A branch of the environmental and occupational safety health sciences and professions concerned with the protection of people and the environment from possibly harmful effects of radiation, while providing for the utilization of radiation for the benefit of society. Health physicists are interdisciplinary radiation protection and safety specialists whose expertise draws from environmental science, mathematics, medicine, radiological health, radiation biology, chemistry, and physics. The subject requires understanding of the generation, measurement, and characteristics of radiation; environmental transport of radionuclides; dosimetry; effects of radiation in biological systems; and the regulations and recommendations governing the use of radiation. The field has expanded to include nonionizing as well as ionizing sources of radiation. *See* DECONTAMINATION OF RADIOACTIVE MATERIALS; DOSIMETER; ENVIRONMENTAL RADIOACTIVITY; NUCLEAR MEDICINE; RADIATION INJURY (BIOLOGY); RADIATION SHIELDING; RADIOACTIVE TRACER; RADIOACTIVITY; RADIOACTIVITY AND RADIATION APPLICATIONS; RADIOECOLOGY; RADIOGRAPHY; RADIOLOGY; RADON. [M.Gol.]

Hearing (human) The general perceptual behavior and the specific responses that are made in relation to sound stimuli. The auditory system consists of the ear and the auditory nervous system. The ear comprises outer, middle, and inner ear. The outer ear, visible on the surface of the body, directs sounds to the middle ear, which converts sounds into vibrations of the fluid that fills the inner ear. The inner ear contains the vestibular and the auditory sensory organs. *See* EAR (VERTEBRATE).

The auditory part of the inner ear, known as the cochlea because of its snaillike shape, analyzes sound in a way that resembles spectral analysis. It contains the sensory cells that convert sounds into nerve signals to be conducted through the auditory portion of the eighth cranial nerve to higher brain centers. The neural code in the auditory nerve is transformed as the information travels through a complex system of nuclei connected by fiber tracts, known as the ascending auditory pathways. They carry auditory information to the auditory cortex, which is the part of the sensory cortex where perception and interpretation of sounds are believed to take place. Interaction between the neural pathways of the two ears makes it possible for a person to determine the direction of a sound's source. *See* BINAURAL SOUND SYSTEM; BRAIN.

Role of the ear. The pinna, the projecting part of the outer ear, collects sound, but because it is small in relation to the wavelengths of sound that are important for human hearing, the pinna plays only a minor role in hearing. The ear canal acts as a resonator: it increases the sound pressure at the tympanic membrane in the frequency range between 1500 and 5000 Hz. The difference between the arrival time of a sound at each of the two ears and the difference in the intensity of the sound that reaches each ear are used by the auditory nervous system to determine the location of the sound source.

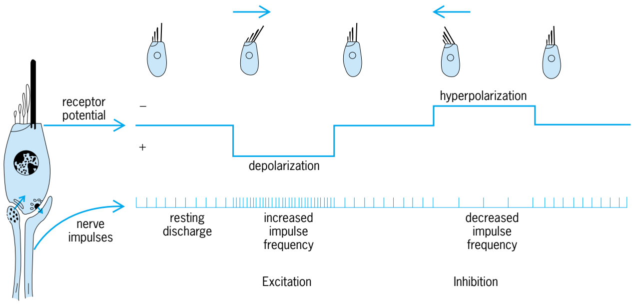
Sound that reaches the tympanic membrane causes the membrane to vibrate, and these vibrations set in motion the three small bones of the middle ear: the malleus, the incus, and the stapes. The footplate of the stapes is located in an opening of the cochlear bone—the oval window. Moving in a pistonlike fashion, the stapes sets the cochlear fluid into motion and thereby converts sound (pressure fluctuations in the air) into motion of the cochlear fluid. Motion of the fluid in the cochlea begins the neural process known as hearing.

There are two small muscles in the middle ear: the tensor tympani and the stapedius muscles. The former pulls the manubrium of the malleus inward, while the latter is attached to the stapes and pulls the stapes in a direction that is perpendicular to its pistonlike motion. The stapedius muscle is the smallest striated muscle in the body, and it contracts in response to an intense sound. This is known as the acoustic middle-ear reflex. The muscle's contraction reduces sound transmission through the middle ear and thus acts as a regulator of input to the cochlea. Perhaps a more important function of the stapedius muscle is that it contracts immediately before and during a person's own vocalization, reducing the sensitivity of the speaker's ears to his or her own voice and possibly reducing the masking effect of an individual's own voice. The role of the tensor tympani muscle is less well understood, but it is thought that contraction of the tensor tympani muscle facilitates proper ventilation of the middle-ear cavity. These two muscles are innervated by the facial (VIIth) nerve for the stapedius and the trigeminal (Vth) nerve for the tensor tympani. The acoustic stapedius reflex plays an important role in the clinical diagnosis of disorders affecting the middle ear, the cochlea, and the auditory nerve.

Vibrations in the cochlear fluid set up a traveling wave on the basilar membrane of the cochlea. When tones are used to set the cochlear fluid into vibration, one specific point on the basilar membrane will vibrate with a higher amplitude than any other. Therefore, a frequency scale can be laid out along the basilar membrane, with low frequencies near the apex and high frequencies near the base of the cochlea.

The sensory cells that convert the motion of the basilar membrane into a neural code in individual auditory nerve fibers are located along the basilar membrane. They are also known as hair cells, because they have hairlike structures on their surfaces. The hair cells in the mammalian cochlea function as mechanoreceptors: motion of the basilar membrane causes deflection of the hairs, starting a process that eventually results in a change in the discharge rate of the nerve fiber connected to each hair cell. This process includes the release of a chemical transmitter substance at the base of the hair cells that controls the discharge rate of the nerve fiber (see illustration).

The frequency selectivity of the basilar membrane provides the central nervous system with information about the frequency or spectrum of a sound, because each auditory nerve fiber is "tuned" to a specific frequency. The frequency of a sound is also represented in the time pattern of the neural code, at least for frequencies up to 5 kHz. Thus, the frequency or spectrum of a



Schematic illustration of the excitation in hair cells. A deflection of hairs in one direction results in an increase in the neural discharge rate in the nerve fiber associated with the hair cell, whereas a deflection in the opposite direction causes inhibition, or slowing, of this discharge rate. (*After A. Fiock, Transducing mechanisms in lateral line canal organ receptors, Proceedings of the Cold Spring Harbor Symposia on Quantitative Biology, 30:133–146, 1965*)

sound can be coded for place and time in the neural activity in the auditory nervous system. *See* Audiometry; Pitch.

Auditory nervous system. The ascending auditory nervous system consists of a complex chain of clusters of nerve cells (nuclei), connected by nerve fibers (nerve tracts). The chain of nuclei relays and transforms auditory information from the periphery of the auditory system, the ear, to the central structures, or auditory cortex, which is believed to be associated with the ability to interpret different sounds. Neurons in the entire auditory nervous system are, in general, organized anatomically according to the frequency of a tone to which they respond best, which suggests a tonotopical organization in the auditory nervous system and underscores the importance of representations of frequency in that system. However, when more complex sounds were used to study the auditory system, qualities of sounds other than frequency or spectrum were found to be represented differently in different neurons in the ascending auditory pathway, with more complex representation in the more centrally located nuclei. Thus, the response patterns of the cells in each division of the cochlear nucleus are different, which indicates that extensive signal processing is taking place. Although the details of that processing remain to be determined, the cells appear to sort the information and then relay different aspects of it through different channels to more centrally located parts of the ascending auditory pathway. As a result, some neurons seem to respond only if more than one sound is presented at the same time, others respond best if the frequency or intensity of a sound changes rapidly, and so on.

Another important feature of the ascending auditory pathway is the ability of particular neurons to signal the direction of sound origination, which is based on the physical differences in the sound reaching the two ears. Certain centers in the ascending auditory pathway seem to have the ability to compute the direction to the sound source on the basis of such differences in the sounds that reach the ears.

Knowledge of the descending auditory pathway is limited to the fact that the most peripheral portion can control the sensitivity of the hair cells. *See* Hearing impairment; Loudness; Masking of sound; Phonoreception; Signal detection theory; Sound.
[A.R.Mø.]

Hearing (vertebrate) The ability to perceive sound arriving from distant vibrating sources through the environmental medium (such as air, water, or ground). The primary function of hearing is to detect the presence, identity, location, and activity of distant sound sources. Sound detection is accomplished using structures that collect sound from the environment (outer ears), transmit sound efficiently to the inner ears (via middle ears), transform mechanical motion to electrical and chemical processes in the inner ears (hair cells), and then transmit the coded information to various specialized areas within the brain. These processes lead to perception and other behaviors appropriate to sound sources, and probably arose early in vertebrate evolution.

Sound is gathered from the environment by structures that are variable among species. In many fishes, sound pressure reaching the swim bladder or another gas-filled chamber in the abdomen or head causes fluctuations in volume that reach the inner ears as movements. In addition, the vibration of water particles that normally accompany underwater sound reaches the inner ears to cause direct, inertial stimulation. In land animals, sound causes motion of the tympanic membrane (eardrum). In amphibians, reptiles, and birds, a single bone (the columella) transmits tympanic membrane motion to the inner ears. In mammals, there are three interlinked bones (malleus, incus, and stapes). Mammals that live underground may detect ground-borne sound via bone conduction. In whales and other sea mammals, sound reaches the inner ears via tissue and bone conduction.

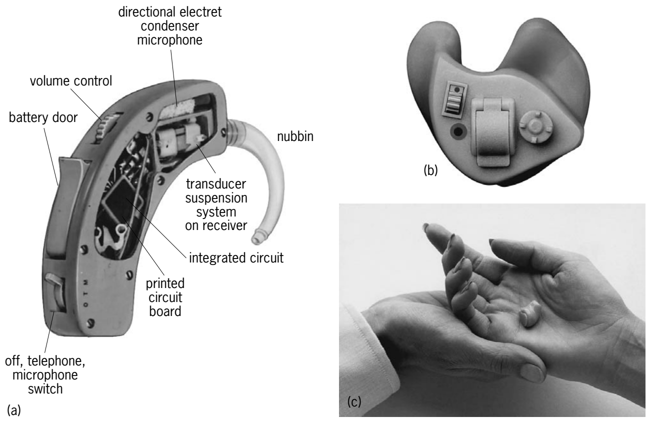
The inner ears of all vertebrates contain hair-cell mechanoreceptors that transform motion of their cilia to electrochemical events resulting in action potentials in cells of the eighth cranial nerve. Patterns of action potentials reaching the brain represent sound wave features in all vertebrates. All vertebrates have an analogous set of auditory brain centers. *See* Ear (vertebrate); Physiological acoustics.

Experiments show that vertebrates have more commonalities than differences in their sense of hearing. The major difference between species is in the frequency range of hearing, from below 1 Hz to over 100,000 Hz. In other fundamental hearing functions (such as best sensitivity, sound intensity and frequency discrimination acuity, time and frequency analysis, and source localization), vertebrates have much in common. All detect sound within a restricted frequency range. All species are able to detect sounds in the presence of interfering sounds (noise), discriminate between different sound features, and locate the sources of sound with varying degrees of accuracy.

The sensitivity range is similar among all groups, with some species in all groups having a best sensitivity in the region of −20 to 0 dB. Fishes, amphibians, reptiles, and birds hear best between 100 and 5000 Hz. Only mammals hear at frequencies above 10,000 Hz. Humans and elephants have the poorest high-frequency hearing.
[R.R.F.]

Hearing aid A device worn by a person with a hearing loss to amplify sound so that the individual can better recognize the phonetic components of speech, and so communicate orally. A typical hearing aid consists of a microphone, an amplifier, a volume control, an earphone (receiver), a power source, and a coupling to the ear (earmold). When both ears are draining, a vibrator held by a spring headband is utilized to deliver amplified sound by bone conduction. *See* Amplifier; Earphones; Microphone.

Hearing aids are designed in various forms. The body type, also known as the conventional or pocket type, is worn in a garment bag or clipped to the clothing and has a cord connecting the amplifier and receiver. The postauricular or over-the-ear type fits behind the ear; a sound tip attached to plastic tubing conducts sound through an earmold to the ear canal. All components of the in-the-ear type fit into the concha of the ear. This type of hearing aid is normally custom made from an impression taken of the ear. The eyeglass-temple type has all components fitted into the temples of eyeglasses and is made with a receiver and customized earmolds or with vibrators for bone conduction. This type can also be employed for special fittings such as the CROS (contralateral routing of signal) or BICROS (one hearing aid with a microphone in each temple) for people with unilateral profound hearing losses. The components of the all-in-the-canal type fit into a customized shell that is placed in the ear canal. Deep canal fittings are customized canal aids so miniaturized that



Hearing aids. (*a*) Over-the-ear aid with case open to show internal components. (*b*) In-the-ear aid. (*c*) In-the-canal aid. (*Belltone Electronics Corp.*)

they can be inserted into the bony section of the ear canal close to the eardrum; these hearing aids are completely concealed in the ear canal and provide improved response at high frequencies (see illustration).

The performance characteristics of a hearing aid, namely gain, frequency response, and maximum pressure output, are determined from the audiometric profile of the hearing-impaired individual. Prescriptive procedures have been suggested, based on threshold-of-hearing levels or most-comfortable-loudness levels, for computing the gain and frequency-response characteristics for maximum speech intelligibility for the user. A threshold of uncomfortable loudness at critical frequencies of 500, 1000, 2000, and 4000 Hz is determined so that the selected maximum output of the hearing aid will not exceed discomfort levels. Directional microphones can be employed in hearing aids to reduce background noise and favor speech in the foreground. Speech recognition is enhanced when the hearing aid responds to frequencies in the range 200–6500 Hz and the frequency-response curve is smooth. Potentiometers can be inserted in hearing aids to adjust the gain (amplification factor), frequency response, and maximum pressure output. Compression amplification, a type of automatic gain control, adjusts the gain of the amplifier to amplify weak sounds more than strong ones. The automatic volume control enables the intensity range of speech to be delivered to the hearing-impaired ear within its tolerable or comfortable range of hearing. *See* Automatic gain control (AGC); Gain; Potentiometer; Response; Volume control systems. [E.Z.]

Hearing impairment Any alteration of hearing capacity. Hearing impairment can be of various degrees, including mild, moderate, severe, profound, or total. The degree of impairment typically is categorized by the loss of hearing sensitivity, that is, how loud sounds must be for a listener to hear them. The degree of impairment can refer either to the loss of hearing sensitivity for individual pitches of sounds for each ear separately, or to an overall loss of hearing sensitivity for both ears. Hearing impairment is further defined as unilateral if present in only one ear, and as bilateral if present in both ears.

Hearing impairment may be present at birth or acquired later in life. Congenital hearing loss greatly interferes with normal language and speech development if it is bilateral and of severe or greater magnitude over the pitch range that covers speech sounds. Acquired hearing loss can occur gradually or suddenly at any time of life and therefore can also be defined in relation to the development of language and speech. Hearing impairment is often termed prelingual, perilingual, or postlingual if the hearing loss occurred prior to, during, or after the development of language and speech.

The term deafness has two meanings. If it refers only to a total lack of hearing function, a lowercase d is used. If it refers to an individual with a bilateral hearing loss who does not use oral language and speech, an uppercase D is used.

Hearing loss can be classified by the part of the auditory system that is defective. Conductive hearing loss results from abnormalities or diseases of the outer or middle ear; sensorineural hearing loss results from abnormalities or diseases of the inner ear or auditory nerve; and central hearing impairment results from abnormalities or diseases of the auditory portions of the central nervous system. Combined conductive and sensorineural hearing loss is referred to as mixed hearing loss. *See* Audiometry; Ear (vertebrate).

Conductive hearing loss impairs sensitivity to sound; if the sound is amplified, the impairment can usually be overcome. *See* Acoustic noise; Loudness.

In sensorineural hearing loss, the abnormality can affect different portions of the inner ear so that often hearing sensitivity may be normal or nearly so for low-pitched tones but falls off sharply for higher tones. In addition, what is heard may be distorted. The speech of the hearing-impaired person may deteriorate over time because the high-pitched speech sounds cannot be heard. *See* Speech disorders.

In most cases of sensorineural or mixed hearing loss, both sensitivity and clarity are impaired, so the perceived sound is weak and distorted. A hearing aid that amplifies sound fails to correct the distortion, and so the difficulty of understanding speech is only partially remedied. Speech deteriorates for adults who suffer this type of hearing loss after speech has developed normally. For children born with severe or profound bilateral sensorineural hearing loss, special education is required for the acquisition of speech and language. *See* Hearing aid.

Other symptoms characterize sensorineural hearing loss. Tinnitus—head noise or ringing in the ears that is heard with no related acoustic stimulus—may occur continuously or intermittently, and is described as a rushing or roaring noise. Vertigo and nausea may accompany the hearing deficit if the abnormality affects the vestibular system, as in Ménière's disease. In double hearing, or diplacusis, a single tone is heard at a different pitch in each ear, or simple tones may sound fuzzy or rough. Loudness recruitment, an abnormal increase in perceived loudness as a sound is intensified, may be associated with a low tolerance for loud noises.

Prevention is the best approach to possible loss. Immunization for viral and bacterial diseases, early medical intervention for upper respiratory infections or earaches, keeping both nostrils open when blowing the nose, control of allergies, avoidance of ototoxic drugs, and reduced exposure to loud sounds are desirable preventive measures. Routine hearing tests are also advisable.

Antibiotic control of ear infections is a common treatment for conductive hearing loss, and surgical procedures are also available. Many of these procedures for conductive hearing loss allow hearing to return to normal.

Measures to correct sensorineural deafness are varied. Tranquilizing and antivertiginous drugs, vasodilative agents, and low-salt diets are among the treatments prescribed for the symptomatic management of Ménière's disease, but they have met with only moderate success. The cochlear implant seeks to restore hearing in the completely deaf ear by direct electrical stimulation of the auditory nerve, thereby producing an auditory sensation that can represent environmental sounds and certain speech sounds. Success is not universal, but some with postlingual deafness have improved substantially.

Nonmedical aural rehabilitation for persons with hearing impairment includes the use of hearing aids, special auditory training to use this amplification, and instruction in speech reading (lip reading). Devices that convert sound to skin sensations are sometimes useful when hearing aids fail to provide any benefit. [G.R.Po.]

Heart (invertebrate) Hearts of invertebrates can be categorized according to the source of the electrical rhythmicity that underlies their beat. Rhythmic electrical activity can arise in the muscle itself (myogenic hearts) or in neurons that drive the heart muscle (neurogenic hearts). Most mollusks and some insects appear to have purely myogenic hearts; these hearts beat normally when isolated from neural inputs. Conversely, the hearts of the higher crustaceans and the xiphosuran *Limulus* are usually considered to be purely neurogenic: motor neurons impose their rhythmic electrical activity on heart muscle fibers by means of direct excitatory synapses. Without neural input, the heart ceases to beat. Other invertebrates, including gnathobdellid leeches and some insects, have hearts that can produce a myogenic beat but require rhythmic neural input to coordinate that beat and maintain the proper rate.

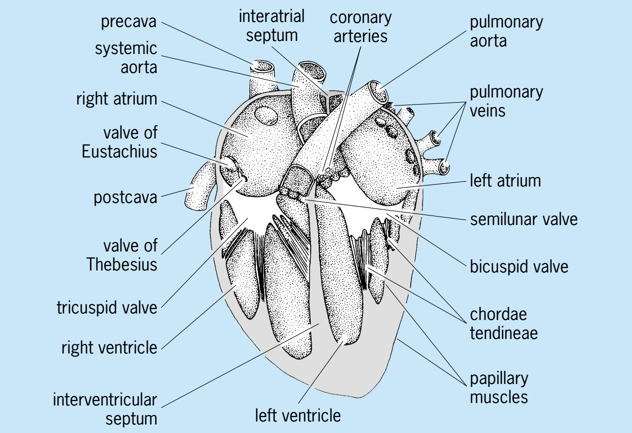
In the marine snail *Aplysia*, an organism with a myogenic heart, a muscular heart consisting of an auricle and a ventricle is located in a dorsal pericardial cavity. The rhythmic contractions of the auricle fill the ventricle with hemolymph, which is then pumped through the open circulatory system by the rhythmic contractions of the ventricle. The normal heartbeat period lasts about 3 s. A pair of semilunar valves prevents backflow of hemolymph into the auricle during ventricular contraction. Three arteries issue from the ventricle toward the anterior, and a single semilunar valve prevents backflow from them during ventricular expansion. The arteries carry the hemolymph to the various body organs, where they end in tissue spaces. The hemolymph then collects in the hemocoel and returns to the heart by two parallel veins, one through the kidney and one through the gill. Although the Aplysia heart is innervated, its normal beat persists after denervation.

The lobster is an example of an organism with a neurogenic heart. A muscular heart pumps hemolymph through the open circulatory system. This heart is located dorsally along the thoracic midline and is suspended within a pericardial cavity by ligaments. The heartbeat period lasts about 2 s. Large anterior- and posterior-going arteries, which branch extensively to supply various body organs, issue from the heart. Semilunar valves, located at the juncture of each artery with the heart, prevent backflow of blood into the heart when it relaxes. Hemolymph enters the heart from the pericardial sinus through six ostia, which have valves to ensure unidirectional flow. The rhythmic discharge of motor neurons innervating the heart by way of excitatory chemical synapses produces the heartbeat. These motor neurons are located in the cardiac ganglion on the inner dorsal surface of the heart. The cardiac ganglion contains only nine neurons, which generate a simple two-phased rhythm of electrical activity. The four posterior small cells (cells 6–9) are interneurons, and the five anterior large cells (cells 1–5) are the motor neurons. *See* NERVOUS SYSTEM (INVERTEBRATE). [R.L.Ca.; C.S.Co.]

Heart (vertebrate) The muscular pumping organ of the cardiovascular system. The heart typically lies ventrally, near the anterior end of the trunk; it is ventral and medial to the gills in fish and at the base of the neck or in the chest region of tetrapods. In humans it is located behind the breastbone and ribs between the third and fifth costal cartilages. Its anterior portion or base is directed to the right and dorsally and is the area where the great vessels enter and leave the heart. The lower muscular portion ends in a blunt apex which lies behind the fifth costal cartilage on the left.

The muscular wall of the heart, the myocardium, is lined by an inner endocardium and is covered externally by membranous visceral pericardium. There are coronary arteries and veins to and from the heart, which has a specialized neuromuscular conducting system and autonomic nerve supply.

In fishes the heart is basically a simple tube which becomes subdivided into four successive chambers, the sinus venosus, atrium, ventricle, and conus arteriosus. Blood from the body enters the sinus and leaves the conus to go to the gills to be oxygenated. The ventricle supplies the main pumping force.



Internal structure of four-chambered mammalian heart, ventral view. (*After C. K. Weichert, Anatomy of the Chordates*, 2d ed., *McGraw-Hill, 1958*)

When lungs are introduced into the system in lungfish and tetrapods, the mixing of oxygenated and nonoxygenated blood becomes a problem. In brief, the sinus venosus and conus arteriosus disappear, becoming incorporated into the other chambers or the bases of the great vessels. At the same time the atrium and later the ventricle become divided into right and left chambers by a median septum.

In birds and mammals including humans (see illustration) the medial fibromuscular septum divides the heart into two lateral halves, each consisting of a thin-walled receiving chamber or atrium and a thicker, muscular pumping chamber or ventricle. Blood enters the right atrium from the superior and inferior venae cavae which drain most of the body. It passes through the tricuspid valve to the right ventricle and is pumped to the lungs during systole, or contraction of the heart. Blood returns from the lungs by way of the pulmonary veins to the left atrium, passes into the left ventricle through the mitral valve, and during contraction is pumped out into the aorta. *See* CARDIOVASCULAR SYSTEM. [T.S.P.]

Heart disorders Pathologies of the heart and its blood vessels. Almost all cardiovascular disorders eventually progress to serious debilitating stages characterized by heart failure (reduced pumping function), dysrhythmias (abnormal electrical rhythms), and sudden death. Coronary atherosclerosis, a disease causing obstruction of the arteries that supply nutrient blood to heart muscle, is the leading cause of cardiovascular mortality. Hypertension (high blood pressure) is another important cause. Valvular heart disease, cardiomyopathies (disease of heart muscle), and congenital heart disease are less common.

Coronary disease. The coronary arteries carry oxygen and nutrients to the heart muscle. Obstructive disease of these arteries is almost always caused by atherosclerosis, a pathologic process that produces a fatty deposition and thickening of the inner surface of the artery, eventually restricting the flow of blood through the artery. The capacity to deliver blood to the heart muscle is increasingly limited. Heart muscle function declines, and the individual experiences characteristic discomfort in the chest called angina pectoris. Angina pectoris is relieved by rest or medications that improve the balance between myocardial oxygen demands and coronary blood (and oxygen) supply. *See* ARTERIOSCLEROSIS.

Coronary artery disease can be complicated by the abrupt formation of a blood clot (thrombus) at the site of an atherosclerotic plaque. When the artery is incompletely obstructed, unstable angina or angina at rest may develop. This is a dynamic condition that is complicated by spasms of the involved artery. When the artery becomes completely occluded, a myocardial infarction or heart attack results, causing irreversible injury to the heart muscle (myocardium) supplied by the occluded artery. Complications and deaths are directly related to the size of the infarction. *See* INFARCTION; THROMBOSIS.

Several characteristics or risk factors are associated with a high likelihood that coronary disease will develop. They include cigarette smoking, elevated levels of blood cholesterol, hypertension, and a family history of the disease. Other risk factors include diabetes, a lack of exercise, and obesity. By modifying or eliminating these factors, the risk of developing coronary disease can be reduced. *See* CHOLESTEROL; DIABETES; HYPERTENSION; OBESITY.

Hypertensive heart disease. High blood pressure results in an excessive cardiac work load. The heart responds to the high pressure through a growth process called hypertrophy. As a result, the mass of the heart muscle is increased, and the work requirement of each unit of heart muscle returns toward normal. Unfortunately, this compensatory increase in cardiac mass eventually results in heart failure and other morbid cardiovascular events. Antihypertensive drugs are effective in the treatment of hypertension and its consequences.

Valvular heart disease. Heart valves ensure an efficient forward blood flow through the heart. Disease of these valves can be caused by rheumatic fever or degenerative noninflammatory processes.

Congenital heart disease. About 1% of all newborns have a structural abnormality of the heart or adjacent blood vessels. Such congenital heart disease can be caused by maternal rubella, or it may be inherited, as in Down syndrome. However, the cause of most congenital heart disease is unknown. Defects in the walls between the atria and the ventricles are the most common congenital malformations. A blood shunt between the pulmonary artery and the aorta also causes a recirculation of oxygenated blood through the lungs; this defect occurs when there is an abnormal persistence of the fetal connection between the two vessels. *See* CONGENITAL ANOMALIES; DOWN SYNDROME.

Cardiomyopathies. Heart muscle disease that is caused by excessive intake of alcohol, some drugs, or infections may cause depression of myocardial function and cardiac enlargement. The resulting dilated cardiomyopathy causes shortness of breath and fatigue. Less commonly, inappropriate growth of the myocardium has occurred in the absence of enlargement of the chamber. This hypertrophic cardiomyopathy causes anginalike chest pain, shortness of breath, and fainting spells.

Heart failure. Congestive heart failure is a clinical syndrome that consists of shortness of breath, fatigue, and retention of fluid. It is caused by failure of the heart as a pump; thus, heart failure can be caused by almost any form of heart disease.

Sudden cardiac death. Most cases of sudden death result from inadequate pumping and low cardiac output during a rapid cardiac dysrhythmia, such as ventricular tachycardia or ventricular fibrillation. *See* HEART (VERTEBRATE). [W.H.Ga.; F.J.V.]

Heartwater disease

A rickettsial disease, also known as cowdriosis, which is caused by the microorganism *Cowdria ruminantium* and is transmitted by ticks of the genus *Amblyomma*. The disease occurs in wild and domestic ruminants, primarily cattle, sheep, and goats, in sub-Saharan Africa and some Caribbean islands (for example, Guadeloupe, Antigua, and Marie-Galante).

Heartwater disease is characterized by fluid in the pericardium of the heart, high fever, lung edema, and nervous symptoms that range from mild incoordination and exaggerated reflexes to convulsions seen in acute infections. The course of acute heartwater disease is 2–6 days, and recovery is rare. However, young animals have a high rate of natural resistance.

The organism is susceptible to tetracycline antibiotics. However, once marked nervous symptoms have developed, recovery usually does not occur. *See* ANTIBIOTIC.

Control and prevention of heartwater is achieved by tick control or immunization. [K.M.K.]

Heartworms

Heartworm (*Dirofilaria immitus*) is a nematode parasite that resides within the host's large pulmonary arteries and right heart chambers. It primarily infests dogs but may also infest foxes, wolves, coyotes, ferrets, sea lions, horses, and cats. A dog can be infested with one to several hundred adult heartworms, which can grow to 12 in. (30 cm). During their 3–5-year life-span, heartworms can cause serious and often life-threatening damage to the heart and lungs. Endemic areas require a reservoir of infected animals (usually dogs) and the presence of mosquitoes, the intermediate host, which transmit the larval stages to a new host.

Adult female heartworms release their microscopic offspring called microfilariae into the bloodstream. A mosquito becomes infested with these circulating microfilariae while taking a blood meal from the dog. The microfilariae develop into mature larvae within the mosquito during the next 10–14 days. As the mosquito feeds again, the mature larvae are injected into the new host. Once in the dog, it takes approximately 6 months for these larvae to complete the cycle by migrating to the large arteries of the lung and right chambers of the heart.

Adult heartworms stimulate a progressive proliferation of the artery lining (endarteritis) that gradually restricts the blood flow to the lungs. The resulting increase in the pulmonary artery blood pressure (pulmonary hypertension) causes the right ventricle to pump harder, eventually leading to right heart failure. In advanced cases the lung fibrosis and heart changes may be permanent. When adult worms die either naturally or with treatment, their fragments become lodged distally in the smaller pulmonary arteries causing an exaggerated proliferation of the vessel lining, the formation of blood clots, and an intense local inflammatory reaction. Blood flow is severely restricted or totally blocked, resulting in severe coughing, coughing up blood, and difficulty in breathing (dyspnea).

Initial signs of disease include coughing, exercise intolerance, and weight loss. As the disease progresses, these symptoms become more pronounced. With advanced disease, dogs begin to exhibit progressive signs of pulmonary disease and associated heart failure, including fainting spells, collapse, difficulty in breathing, coughing up blood, and fluid accumulation around the lungs (hydrothorax) or within the abdominal cavity (ascites). Rarely, a rapidly fatal condition called vena caval syndrome may be observed in young dogs with massive heartworm infestation.

Heartworm infection can usually be determined by examining a blood sample for the presence of circulating microfilariae. Those infestations in which the adults produce no circulating microfilariae are termed occult infections, which can be accurately diagnosed by identifying specific circulating immunologic substances (uterine antigens) released into the blood by adult females.

All but the most advanced cases of heartworm disease can usually be treated successfully. Treatment involves multiple steps to eliminate both adult and microfilariae stages. Daily or monthly heartworm preventive medication is strongly recommended, especially during the mosquito season, in infested areas. The objective is killing the infectious larval stages before they develop into adults. Only dogs that test negative for heartworms should be placed on preventive medication because of the risk of serious reactions. [W.D.F.]

Heat

For the purposes of thermodynamics, it is convenient to define all energy while in transit, but unassociated with matter, as either heat or work. Heat is that form of energy in transit due to a temperature difference between the source from which the energy is coming and the sink toward which the energy is going. The energy is not called heat before it starts to flow or after it has ceased to flow. A hot object does contain energy, but calling this energy heat as it resides in the hot object can lead to widespread confusion. *See* ENERGY; INTERNAL ENERGY; TEMPERATURE; THERMODYNAMIC PRINCIPLES. [H.C.W.; W.A.S.]

Heat balance An application of the first law of thermodynamics to a process in which any work terms are negligible.

For a closed system, one that always consists of the same material, the first law is $Q + W = \Delta E$, where Q is the heat supplied to the system, W is the work done on the system, and ΔE is the increase in energy of the material forming the system. It is convenient to treat ΔE as the sum of changes in mechanical energy, such as kinetic energy and potential energy in a gravitational field, and of internal energy ΔU that depends on changes in the thermodynamic state of the material. Because the rates at which any changes occur are usually of interest, heat balances are often written in terms of heat flow rates (heat per unit time), sometimes denoted by a dot over the symbol, $\dot{Q}$, so that for a process with negligible work, kinetic energy and potential energy terms, $\dot{Q} = \dot{Q}_{\mathrm{IN}} - \dot{Q}_{\mathrm{OUT}} = dU/dt$, the rate of change of internal energy with time.

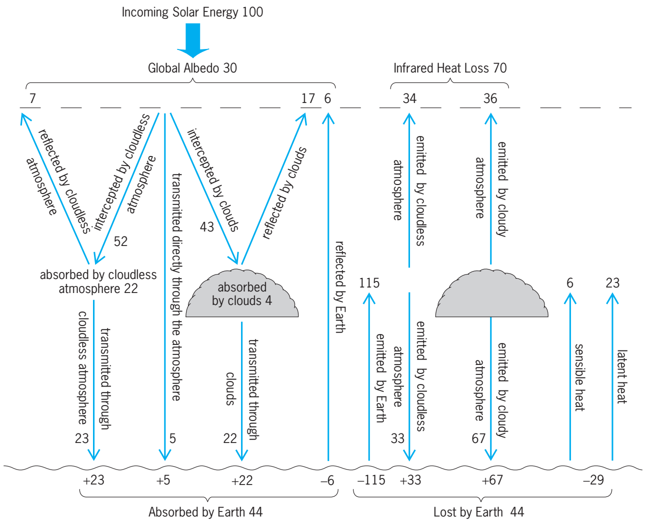
Often it is more convenient to apply the first law or a heat balance to an open system, a fixed region or control volume across the boundaries of which materials may travel and inside which they may accumulate, such as a building, an aircraft engine, or a section of a chemical process plant. Then the first law is expressed by the equation below, where $\dot{W}_S$ is the rate of doing shaft work on the system; is the mass flow rate of any stream entering or

$$\dot{Q} + \dot{W}_S = \sum \dot{m}\left(h + c^2/2 + gz\right)_{\mathrm{OUT}} - \sum \dot{m}\left(h + c^2/2 + gz\right)_{\mathrm{IN}} + dE/dt$$

leaving the control volume; h is the enthalpy per unit mass; c is the velocity; gz is the gravitational potential for each stream at the point of crossing the boundary of the control volume; and E is the energy of all material inside the control volume. When conditions inside the control volume do not change with time, although they need not be spatially uniform, $dE/dt = 0$, and the balance equation is known as the steady-flow energy equation.

Enthalpy is a thermodynamic property defined by $h = u + pv$, where u is the specific internal energy (enthalpy per unit mass), p the pressure, and v the specific volume. It is used, along with shaft work, because the derivation of the first-law equation for a control volume from the more fundamental equation for a closed system involves work terms pv that are not available for use outside the control volume. Changes in enthalpy occur because of changes in temperature, pressure, physical state (for example, from liquid to vapor), and changes in chemical state. *See* Enthalpy; Thermodynamic principles; Thermodynamic processes. [D.B.R.K.]

Heat balance, terrestrial atmospheric The balance of various types of energy in the atmosphere and at the Earth's surface. At the top of the atmosphere, the incoming solar radiation that is absorbed by the Earth-atmosphere system is approximately balanced by the terrestrial radiation emitted from this system over long periods of time. The flux of solar energy (energy per time) across a surface of unit area normal to the solar beam at the mean distance between the Sun and the Earth is referred to as the solar constant. Based on recent satellite measurements, a value of 1365 watts per square meter (W/m^2) for the solar constant has been suggested. Because the area of the spherical Earth is four times that of its cross section facing the parallel solar beam, the top of the Earth's atmosphere receives an average of about 341 W/m^2. Based on measurements from satellite radiation budget experiments, about 30% of this is reflected back to space, and is referred to as the global albedo. The reflecting power of the Earth-atmosphere system includes the scattering of molecules, aerosols, and various types of clouds, as well as reflection by different surfaces. Thus, only about 70% of the incoming solar flux, that is, about 239 W/m^2, is absorbed within the Earth-atmosphere system. For this system to be in thermodynamic equilibrium or balance, it must emit the same amount of thermal infrared radiation. *See* Albedo; Solar constant; Solar energy.



Heat balance of the Earth-atmosphere system. The incoming solar energy is taken to be 100 units. On a climatic scale, the incoming solar energy at the top of the atmosphere is approximately balanced by the reflected solar energy and thermal infrared heat loss. At the surface, the heat balance involves sensible and latent heat components, in addition to net radiative energy.

For the presentation of internal heat balance components, the effective solar constant of 341 W/m^2 may be arbitrarily represented by 100 units (see illustration). Of these units, roughly 26 are absorbed within the atmosphere, including 22 by clear column and 4 by clouds. A total of 30 units are reflected back to space, including about 7 from clear column, 17 from cloudy atmospheres, and 6 directly from the Earth's surface. The remaining 44 units are absorbed by the surface. The Earth-atmosphere system emits terrestrial radiation according to its temperature and composition distributions. The upward flux from the warmer surface accounts for about 115 units. The colder troposphere emits both upward and downward fluxes, with about 70 and 100 units at the top and surface, respectively. The clear and cloudy portions are 34 and 36 at the top and 33 and 67 at the surface, respectively. The net upward flux at the surface, representing the difference between the flux emitted by the surface and the downward flux from the atmosphere reaching the surface, is about 15 units. *See* Heat balance; Terrestrial radiation.

As a result of thermal emission, the atmosphere loses 55 units. With absorption of the incoming solar flux contributing only 26 units, the net radiative loss from the atmosphere amounts to about 29 units. This deficit is balanced by convective fluxes of sensible and latent heat associated with temperature gradient and evaporation. Based on statistical analyses, the average annual ratio of sensible to latent heat loss at the surface has a global value of about 0.27. It follows that the latent and sensible heat components are about 23 and 6 units, respectively, in order to produce an overall heat balance at the surface (see illustration). The atmosphere experiences a net radiative cooling that must be balanced by the latent heat of condensation released in precipitation processes and by the convection and conduction of sensible heat from the underlying surface. [K.N.L.]

Heat capacity The quantity of heat required to raise a unit mass of homogeneous material one unit in temperature along a specified path, provided that during the process no phase or chemical changes occur, is known as the heat capacity of the material in question. Moreover, the path is so restricted that the only work effects are those necessarily done on the surroundings to cause the change to conform to the specified path. The path is usually at either constant pressure or constant volume.

In accordance with the first law of thermodynamics, heat capacity at constant pressure C_p is equal to the rate of change of enthalpy with temperature at constant pressure $(\partial H/\partial T)_p$. Heat capacity at constant volume C_v is the rate of change of internal energy with temperature at constant volume $(\partial U/\partial T)_v$. Moreover, for any material, the first law yields the relation

$$C_p - C_v = \left[P + \left(\frac{\partial U}{\partial V}\right)\right]_T \left(\frac{\partial U}{\partial T}\right)_P$$

See ENTHALPY; INTERNAL ENERGY; THERMODYNAMIC PRINCIPLES. [H.C.W.]

Heat exchanger A device used to transfer heat from a fluid flowing on one side of a barrier to another fluid (or fluids) flowing on the other side of the barrier.

When used to accomplish simultaneous heat transfer and mass transfer, heat exchangers become special equipment types, often known by other names. When fired directly by a combustion process, they become furnaces, boilers, heaters, tube-still heaters, and engines. If there is a change in phase in one of the flowing fluids—condensation of steam to water, for example—the equipment may be called a chiller, evaporator, sublimator, distillation-column reboiler, still, condenser, or cooler-condenser.

Heat exchangers may be so designed that chemical reactions or energy-generation processes can be carried out within them. The exchanger then becomes an integral part of the reaction system and may be known, for example, as a nuclear reactor, catalytic reactor, or polymerizer.

Heat exchangers are normally used only for the transfer and useful elimination or recovery of heat without an accompanying phase change. The fluids on either side of the barrier are usually liquids, but they may also be gases such as steam, air, or hydrocarbon vapors; or they may be liquid metals such as sodium or mercury. Fused salts are also used as heat-exchanger fluids in some applications.

Most often the barrier between the fluids is a metal wall such as that of a tube or pipe. However, it can be fabricated from flat metal plate or from graphite, plastic, or other corrosion-resistant materials of construction.

Heat exchangers find wide application in the chemical process industries, including petroleum refining and petrochemical processing; in the food industry, for example, for pasteurization of milk and canning of processed foods; in the generation of steam for production of power and electricity; in nuclear reaction systems; in aircraft and space vehicles; and in the field of cryogenics for the low-temperature separation of gases. Heat exchangers are the workhorses of the entire field of heating, ventilating, air-conditioning, and refrigeration. *See* CONDUCTION (HEAT); CONVECTION (HEAT); COOLING TOWER; DISTILLATION; EVAPORATOR; FURNACE; HEAT RADIATION; HEAT TRANSFER; TUBE-STILL HEATER; VAPOR CONDENSER. [R.F.Fr.]

Heat insulation Materials whose principal purpose is to retard the flow of heat. Thermal- or heat-insulation materials may be divided into two classes, bulk insulations and reflective insulations. The class and the material within a class to be used for a given application depend upon such factors as temperature of operation, ambient conditions, mechanical strength requirements, and economics.

Examples of bulk insulation include mineral wool, vegetable fibers and organic papers, foamed plastics, calcium silicates with asbestos, expanded vermiculite, expanded perlite, cellular glass, silica aerogel, and diatomite and insulating firebrick. They retard the flow of heat, breaking up the heat-flow path by the interposition of many air spaces and in most cases by their opacity to radiant heat.

Reflective insulations are usually aluminum foil or sheets, although occasionally a coated steel sheet, an aluminized paper, or even gold or silver surfaces are used. Refractory metals, such as tantalum, may be used at higher temperatures. Their effectiveness is due to their low emissivity (high reflectivity) of heat radiation. *See* EMISSIVITY.

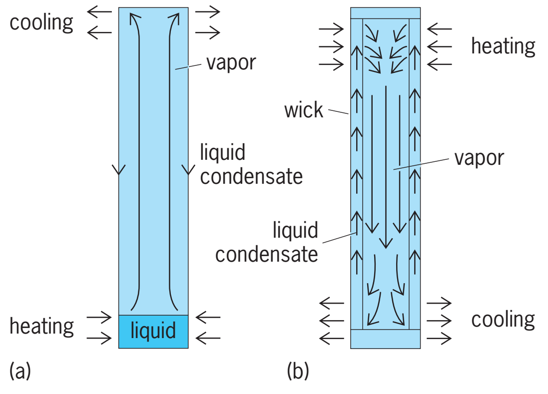
The distinguishing property of bulk thermal insulation is low thermal conductivity. For a given thickness of material exposed to a given temperature difference, the rate of heat flow per unit area is directly proportional to the thermal conductivity of the material. *See* CONDUCTION (HEAT). [H.F.R.]

Heat pipe A device for transferring heat efficiently between two locations by using the evaporation and condensation of a fluid contained therein. Heat pipes have many applications in areas where reliable performance and low cost are of prime importance—for example, in electronics and heat exchangers. *See* HEAT EXCHANGER.

The heat pipe, the idea of which was first suggested in 1942, is similar in many respects to the thermosiphon. A large proportion of applications do not use heat pipes as strictly defined below, but employ thermosiphons (illus. *a*), sometimes known as gravity-assisted heat pipes. A small quantity of liquid is placed in a tube from which the air is then evacuated, and the tube is sealed. The lower end of the tube is heated, causing liquid to vaporize and the vapor to move to the cooler end of the tube, where it condenses. The condensate is returned to the evaporator section by gravity. Since the latent heat of evaporation is generally high, considerable quantities of heat can be transported with a very small temperature difference between the two ends. Thus the structure has a high effective thermal conductance. The thermosiphon, also known as the Perkins tube, has been used for many years. A wide variety of working fluids have been employed, ranging from helium to liquid metals.

One limitation of the basic thermosiphon is that in order for the condensate to be returned by gravitational force to the evaporator region, the latter must be situated at the lowest point. The heat pipe is similar in construction to the thermosiphon, but in this case provision is made for returning the condensate against a gravity head. A wick, for example a few layers of fine gauze, is commonly used. This is fixed to the inside surface of the tube, and capillary forces return the condensate to the evaporator (illus. *b*). Since the evaporator position is not restricted, the heat pipe may be used in any orientation. If the heat pipe evaporator happens to be in the lowest position, gravitational forces will assist the capillary force. Alternative techniques, including centripetal forces and osmosis, may be used for returning the condensate to the evaporator.

Capillary forces are by far the most common form of condensate return employed, but a number of rotating heat pipes are used for cooling of electric motors and other rotating machinery. In some applications a mechanical pump is used to return condensate in two-phase run-around coil heat recovery systems. While this may be regarded as a retrograde step, it is a much

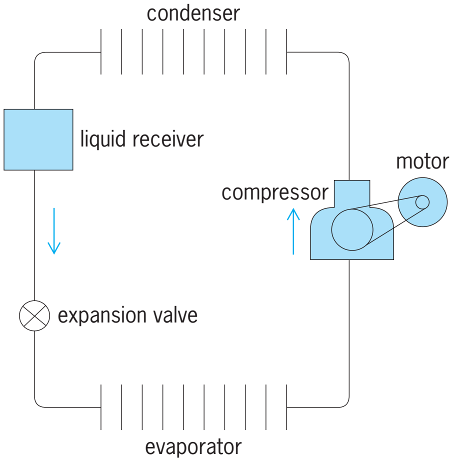


Heat transfer devices. (*a*) Thermosiphon. (*b*) Heat pipe; it can be in any position, not just vertical as shown.

more effective method for condensate return than reliance on capillary forces.

Applications are related to five principal functions of the heat pipe: separation of heat source and sink, temperature flattening, heat flux transformation, temperature control, and action as a thermal diode or switch. The two major applications, cooling of electronic components and heat exchange, can involve all of these features. In the case of electronics cooling and temperature control, all features can be important. In heat exchangers employing heat pipes, the separation of heat source and sink, and the action as a thermal diode or switch, are most significant. [D.A.Re.]

Heat pump The thermodynamic counterpart of the heat engine. A heat pump raises the temperature level of heat by means of work input. In its usual form a compressor takes refrigerant vapor from a low-pressure, low-temperature evaporator and delivers it at high pressure and temperature to a condenser (see illustration). The pump cycle is identical with the customary vapor-compression refrigeration system. *See* REFRIGERATION CYCLE.



Basic flow diagram of heat pump with motor-driven compressor. For summer cooling, condenser is outdoors and evaporator indoors; for winter heating, condenser is indoors and evaporator outdoors.

This dual purpose is accomplished, in effect, by placing the low-temperature evaporator in the conditioned space during the summer and the high-temperature condenser in the same space during the winter. Thus, if 70°F (21°C) is to be maintained in the conditioned space regardless of the season, this would be the theoretical temperature of the evaporating coil in summer and of the condensing coil in winter. The actual temperatures on the refrigerant side of these coils would need to be below 70°F in summer and above 70°F in winter to permit the necessary transfer of heat through the coil surfaces. If the average outside temperatures are 100°F (38°C) in summer and 40°F (40°C) in winter, the heat pump serves to raise or lower the temperature 30° (17°C) and to deliver the heat or cold as required.

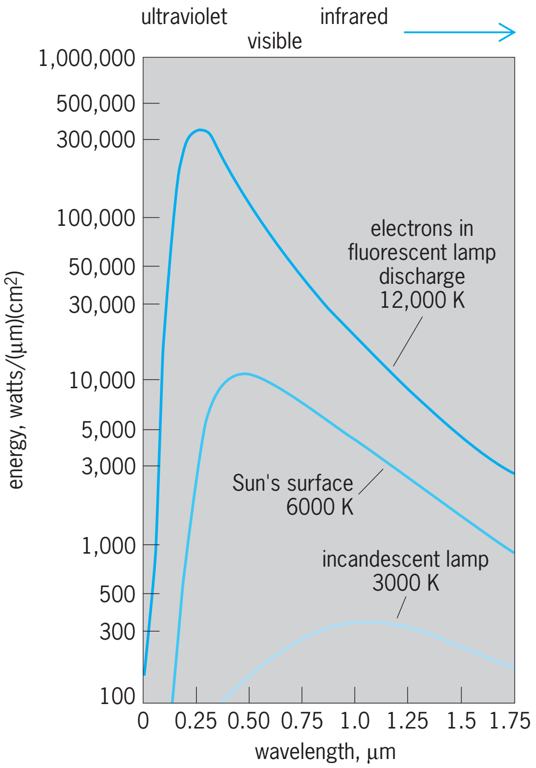
The heat pump is also used for a wide assortment of industrial and process applications such as low-temperature heating, evaporation, concentration, and distillation. [T.Ba.]

Heat radiation The energy radiated by solids, liquids, and gases as a result of their temperature. Such radiant energy is in the form of electromagnetic waves and covers the entire electromagnetic spectrum, extending from the radio-wave portion of the spectrum through the infrared, visible, ultraviolet, x-ray, and gamma-ray portions. From most hot bodies on Earth this radiant energy lies largely in the infrared region. *See* ELECTROMAGNETIC RADIATION; INFRARED RADIATION.

Radiation is one of the three basic methods of heat transfer, the other two methods being conduction and convection. *See* CONDUCTION (HEAT); CONVECTION (HEAT); HEAT TRANSFER.

A hot plate at 260°F (400 K) may show no visible glow; but a hand which is held over it senses the warming rays emitted by the plate. A temperature of more than 1300°F (1000 K) is required to produce a perceptible amount of visible light. At this temperature a hot plate glows red and the sensation of warmth increases considerably, demonstrating that the higher the temperature of the hot plate the greater the amount of radiated energy. Part of this energy is visible radiation, and the amount of this visible radiation increases with increasing temperature. A steel furnace at 2800°F (1800 K) shows a strong yellow glow. If a tungsten wire (used as the filament in incandescent lamps) is raised by resistance heating to a temperature of 4600°F (2800 K), it emits a bright white light. As the temperature of a substance increases, additional colors of the visible portion of the spectrum appear, the sequence being first red, then yellow, green, blue, and finally violet. The violet radiation is of shorter wavelength than the red radiation, and it is also of higher quantum energy. In order to produce strong violet radiation, a temperature of almost 5000°F (3000 K) is required. Ultraviolet radiation necessitates even higher temperatures. The Sun emits considerable ultraviolet radiation; its temperature is about 10,000°F (6000 K). Such temperatures have been produced on Earth in gases ionized by electrical discharges. The mercury-vapor lamp and the fluorescent lamp emit large amounts of ultraviolet radiation. Temperatures up to 36,000°F (20,000 K), however, are still much too low to produce x-rays or gamma radiation. A gas maintained at temperatures above 2×10^{6}°F (1×10^{6} K), encountered in nuclear fusion experiments, emits x-rays and gamma rays. *See* NUCLEAR FUSION; SUN; ULTRAVIOLET RADIATION.

A blackbody is defined as a body which emits the maximum amount of heat radiation. Although there exists no perfect blackbody radiator in nature, it is possible to construct one on the principle of cavity radiation. *See* BLACKBODY.



Graphs of Planck's law for various temperatures.

A cavity radiator is usually understood to be a heated enclosure with a small opening which allows some radiation to escape or enter. The escaping radiation from such a cavity has the same characteristics as blackbody radiation.

Kirchhoff's law correlates mathematically the heat radiation properties of materials at thermal equilibrium. It is often called the second law of thermodynamics for radiating systems. Kirchhoff s law can be expressed as follows: The ratio of the emissivity of a heat radiator to the absorptivity of the same radiator is a function of frequency and temperature alone. This function is the same for all bodies, and it is equal to the emissivity of a blackbody. A consequence of Kirchhoff's law is the postulate that a blackbody has an emissivity which is greater than that of any other body. *See* Kirchhoff's laws of electric circuits.

Planck's radiation law represents mathematically the energy distribution of the heat radiation from 1 cm^2 of surface area of a blackbody at any temperature. Formulated by Max Planck early in the twentieth century, it laid the foundation for the advance of modern physics and the advent of quantum theory. Equation (1)

$$R_\lambda = 37,418/\lambda^5[e^{14.388(\lambda T)} - 1] \qquad (1)$$

is the mathematical expression of Planck's radiation law, where R_λ is the total energy radiated from the body measured in watts per square centimeter per unit wavelength, at the wavelength λ. The wavelength in this formula is measured in micrometers. The quantity T is the temperature in kelvins, and e is the base of the natural logarithms. The illustration presents graphs of Planck's law for various temperatures and shows substances which attain these temperatures. It should be noted that these substances will not radiate as predicted by Planck's law since they are not blackbodies themselves.

The Stefan-Boltzmann law states that the total energy radiated from a hot body increases with the fourth power of the temperature of the body. This law can be derived from Planck's law by the process of integration and is expressed mathematically as Eq. (2), where R_T is the total amount of energy radiated from a

$$R_T = 5.670 \times 10^{-10} T^4 \qquad (2)$$

blackbody in watts per square centimeter. When R_T is multiplied by the total emissivity, the total energy radiated from a real heat radiator is obtained. [H.G.S.; P.J.W.]

Heat transfer Heat, a form of kinetic energy, is transferred in three ways: conduction, convection, and radiation. Heat transfer (also called thermal transfer) can occur only if a temperature difference exists, and then only in the direction of decreasing temperature. Beyond this, the mechanisms and laws governing each of these ways are quite different. *See* Conduction (heat); Convection (heat); Heat radiation.

By utilizing a knowledge of the principles governing the three methods of heat transfer and by a proper selection and fabrication of materials, the designer attempts to obtain the required heat flow. This may involve the flow of large amounts of heat to some point in a process or the reduction in flow in others. All three methods operate in processes that are commonplace.

In industry, for example, it is generally desired to extract heat from one fluid stream and add it to another. Devices used for this purpose have passages for each of the two streams separated by a heat-exchange surface in the form of plates or tubes and are known as heat exchangers. The automobile radiator, the hot-water heater, the steam or hot-water radiator in a house, the steam boiler, the condenser and evaporator on the household refrigerator or air conditioner, and even the ordinary cooking utensils in everyday use are all heat exchangers. *See* Heat; Heat exchanger. [R.H.L.]

Heat treatment (metallurgy) A procedure of heating and cooling a material without melting. Plastic deformation may be included in the sequence of heating and cooling steps, thus defining a thermomechanical treatment. Typical objectives of heat treatments are hardening, strengthening, softening, improved formability, improved machinability, stress relief, and improved dimensional stability. Heat treatments are often categorized with special names, such as annealing, normalizing, stress relief anneals, process anneals, hardening, tempering, austempering, martempering, intercritical annealing, carburizing, nitriding, solution anneal, aging, precipitation hardening, and thermomechanical treatment.

All metals and alloys in common use are heat-treated at some stage during processing. Iron alloys, however, respond to heat treatments in a unique way because of the multitude of phase changes which can be induced, and it is thus convenient to discuss heat treatments for ferrous and nonferrous metals separately. *See* Iron; Steel.

Ferrous metals. Annealing heat treatments are used to soften the steel, to improve the machinability, to relieve internal stresses, to impart dimensional stability, and to refine the grain size.

Hardening treatments are used to harden steels by heating to a temperature at which austenite is formed and then cooling with sufficient rapidity to make the transformation to pearlite or ferrite unfavorable.

Some heat treatments are used to alter the chemistry at the surface of a steel, usually to achieve preferential hardening of a surface layer. Carburizing consists of subjecting the steel to an atmosphere of partially combusted natural gas which has been enriched with respect to carbon. In the nitriding treatment, nitrogen diffusing to the surface of the steel forms nitrides. Chromizing involves the addition of chromium to the surface by diffusion from a chromium-rich material packed around the steel or dissolved in molten lead. *See* Surface hardening of steel.

Nonferrous metals. Many nonferrous metals do not exhibit phase transformations, and it is not possible to harden them by means of simple heating and quenching treatments as in steel. Unlike steels, it is impossible to achieve grain refinement by heat treatment alone, but it is possible to reduce the grain size by a combination of cold-working and annealing treatments.

Some nonferrous alloys can be hardened, but the mechanism is one by which a fine precipitate is formed, and the reaction is fundamentally different from the martensitic hardening reaction in steel. There are also certain ferrous alloys that can be precipitation hardened. However this hardening technique is used much more widely in nonferrous than in ferrous alloys. In titanium alloys, the β phase can transform in a martensitic reaction on rapid cooling, and the hardening of these alloys is achieved by methods which are similar to those used for steels. [B.L.A.]

Heating system An apparatus consisting of an energy source, a method of converting that energy to heat, and a transport system to convey the energy and heat to the point of use. Most heating systems include some manual or automatic method of controlling the heat output and delivery.

There are many sources of energy for use in heating. The earliest source, and still most common in developing countries, comprises wood and wood products such as paper, wood chips, and sawdust; peat is used in some cultures. Solar use for heating and electrical generation has become widespread, although economics discourages more general use. The generation of electrical energy requires the use of fossil fuels, water power, geothermal energy, or nuclear energy. Fossil fuels are used directly in furnaces and boilers. *See* Electric power systems; Energy sources; Heat pump; Solar energy.

The energy source is converted into heat by various means. Wood and fossil fuels are converted by burning, or the combustion process. Electrical energy can be converted directly into heat by resistance heaters. Solar energy requires collectors, with conversion to heat or electricity.

Many methods deliver heat to the point of use. Radiation systems take several forms. Cast-iron column radiators, using steam or hot water, have largely been superseded by convector radiators using steam, hot water, or electricity. Panel-type radiators are also used in ceilings or in floors. All require a piping or electrical distribution system. Forced-air warm-air heating, using electric motor-driven circulating fans, is common. *See* Central heating and cooling; Comfort heating; District heating; Hot-water heating system; Panel heating and cooling; Radiant heating; Solar heating and cooling; Steam heating; Warm-air heating system. [R.W.Hai.]

Heavy minerals Minerals with a density greater than 2.9 g/cm^3. The term is most commonly used to denote high-density components of siliciclastic sediments. Most heavy mineral studies are undertaken to determine sediment provenance, because heavy mineral suites provide important information on the mineralogical composition of source areas. Since heavy minerals rarely constitute more than 1% of sandstones, their study normally requires them to be concentrated. This is achieved by disaggregation of the sandstone, followed by mineral separation using dense liquids such as bromoform, tetrabromoethane, or the more recently developed nontoxic polytungstate liquids. *See* Density; Provenance (geology); Sandstone.

Geographic and stratigraphic variations in heavy mineral suites within a sedimentary basin can be used to infer differences in sediment provenance. Such differences result either from the interplay between a number of sediment transport systems draining different source regions, or from erosional unroofing within a single source area. Heavy mineral data therefore play an important role in the understanding of depositional history and paleogeography. In some cases, sophisticated mathematical and statistical treatment of heavy mineral data may be required to elucidate the interplay between multiple sediment transport systems. *See* Depositional systems and environments; Paleogeography; Sedimentology; Stratigraphy.

Heavy minerals have important economic applications. Their use in paleogeographic reconstructions, especially in elucidating sediment transport pathways, is of particular value in hydrocarbon exploration, and their use in correlation has important applications in hydrocarbon reservoir evaluation and production. Recent advances have made it possible to utilize the technique on a real-time basis at the well site, where it is used to help steer high-angle wells within the most productive reservoir horizons. Heavy minerals may become concentrated naturally by hydrodynamic sorting, usually in shallow marine or fluvial depositional settings. Naturally occurring concentrates of economically valuable minerals are known as placers, and such deposits have considerable commercial significance. Cassiterite, gold, diamonds, chromite, monazite, and rutile are among the minerals that are widely exploited from placer deposits. *See* Dating methods; Monazite; Placer mining; Well; Zircon. [A.Mor.]

Heavy water A form of water in which the hydrogen atoms of mass 1 (^{1}H) ordinarily present in water are replaced by deuterium (D or ^{2}H), the heavy stable isotope of hydrogen of mass 2. The molecular formula of heavy water is D_2O (or ^2H_2O). *See* Deuterium.

Because the mass difference between ^{1}H and ^{2}H is the largest for any pair of stable (nonradioactive) isotopes in the periodic table, many of the physical and chemical properties of the pure isotopic species and their respective compounds differ to a significant extent. Selected physical properties of ^1H_2O and ^2H_2O are compared in the table.

Heavy water, judging from its higher melting and boiling points, its higher viscosity, and its surprisingly high temperature of maximum density, is a distinctly more structured liquid than is ordinary water. Heavy water is more extensively hydrogen-bonded, and the hydrogen bonds formed by ^{2}H are somewhat stronger than are those of ^{1}H.

The only large-scale use of heavy water in industry is as a moderator in nuclear reactors. Small amounts of heavy water are used to grow fully deuterated organisms, which serve as a source of fully deuterated compounds of biological importance. These are finding increasing use in research techniques such as small-angle neutron scattering, in high-resolution nuclear magnetic resonance spectroscopy of immobilized samples, and in the study of isotope effects. *See* Isotope (stable); Separation; Nuclear reactor; Water. [J.J.K.]

Physical properties of ordinary and heavy water

Property	^1H_2O	^2H_2O (D_2O)
Molecular weight, ^{12}C scale	18.015	20.028
Melting point, °C	0.00	3.81
Normal boiling point, °C	100.00	101.42
Temperature of maximum density, °C	3.98	11.23
Density at 25°C, g/cm^3	0.99701	1.1044
Critical constants		
Temperature, °C	374.1	371.1
Pressure, mPa	22.12	21.88
Volume, cm^3/mol	55.3	55.0
Viscosity at 55°C, mPa·s	0.8903	1.107
Refractive index, n_D^{20}	1.3330	1.3283

Hederellida A marine bryozoan order in the class Stenolaemata. It is recorded from scattered localities in the Ordovician through Permian systems of the Paleozoic Era but is found prominently in Devonian strata. The colonies comprise tubular zooecia that commonly occur on brachiopod shells, echinoderm plates and columnals, and the outer surfaces of corals. Although usually encrusting, the colonies sometimes may be erect structures. The initial zooecium is a bulbous ancestrula, which gives rise to a tubular zooecium. Succeeding tubular zooecia bud one at a time from the lateral wall of the preceding zooecium. The tubular zooecia have perforated walls, and the distal opening of the zooecium is commonly sealed by a plate (possibly perforate). The zooecial wall apparently consisted of two layers, but it lacks the distinctive laminate structures of the order Trepostomata (Stenolaemata) and shows no additional thickening in the outer parts of the colony.

The simple, perforate tubular zooecia, in which the commonly oval zooecial opening is the same diameter as the zooecial tube, and the lack of accessory tubes or structures separate the hederellids from the Paleozoic cyclostomes. There are six recognized genera, including *Hederella*, *Reptaria*, *Hederopsis*, and *Clonopora*. [J.R.P.R.]

Hedgehog Members of the family Erinaceidae (order Insectivora), which includes 7 genera and 19 species of medium- to large-size animals generally characterized by spines on their back and sides. This family, however, is subdivided into two subfamilies, the spiny hedgehog group which includes the European hedgehog (*Erinaceus europaeus*); and the hairy hedgehog or gymnuras, long-tailed species which lack spines. The typical spiny hedgehog (see illustration) has well-developed eyes and a rudimentary to moderately long tail. In most species, there

Hedgehog (*Erinaceus europaeus*).

are five toes on each foot, although in some species these are reduced to four on the hindfeet. The spines can be erected by strong muscles, and serve as a protection for the naked or hairy belly, head, and limbs when the animal rolls itself into a ball. *See* INSECTIVORA. [C.B.C.]

Helicity (quantum mechanics) A fundamental quantized variable used in quantum mechanics to specify the relative orientations of spin and linear momentum of massless particles. It is a requirement of fundamental Dirac quantum mechanics that such particles have their spins aligned either parallel or antiparallel to their linear momentum. Particles having parallel alignment are arbitrarily assigned helicity $+1$; those having antiparallel alignment, -1. *See* MOMENTUM; SPIN (QUANTUM MECHANICS).

In a classic experiment on *K* electron capture by ^{152}Eu, M. Goldhaber, L. Grodzins, and A. Sunyar first showed that the neutrino emitted in the weak nuclear interaction had negative helicity—that its spin was aligned antiparallel to its momentum. An equivalent description of this situation is that these neutrinos are left-handed. Symmetry requires that antineutrinos be right-handed and have positive helicity. *See* ELECTRON CAPTURE; ELEMENTARY PARTICLE; NEUTRINO; QUANTUM MECHANICS; SYMMETRY LAWS (PHYSICS). [D.A.B.]

Helicobacter A genus of gram-negative bacilli whose members are spiral shaped, showing corkscrewlike motility generated by multiple, usually polar flagella. *Helicobacter* species require low concentrations of oxygen for maximum growth and produce the enzymes oxidase, catalase, and urease.

Different species of *Helicobacter* are found in the stomachs of different animals: *H. felis* in cats and dogs, *H. mustelae* in the domestic ferret, *H. nemestrinae* in the pigtailed macaque, and *H. acinonyx* in captive cheetahs with gastritis. *Helicobacter pylori*, found in the human stomach, is extremely common. In the United States and similarly developed countries, its prevalence increases at about 1% per year of age so that the majority of adults above age 50 are infected. In less developed countries, infection rates are dramatically higher, with up to 80% of children infected.

Helicobacter pylori is present in virtually all cases of chronic gastritis, which progresses slowly (years or decades) from asymptomatic to atrophic gastritis with impaired acid secretion. Virtually all individuals with duodenal ulcers are infected with *H. pylori*, which colonizes sites in the duodenum. The termination of treatment for duodenal ulcers leads to a high rate of recurrence of the ulcers, but ulcer treatment plus eradication of *H. pylori* from the stomach usually leads to a permanent cure. A significant proportion of individuals with *H. pylori*-associated atrophic gastritis develop intestinal-cell metaplasia in the stomach, a condition which is known to represent a precancerous state. *See* CANCER (MEDICINE); ULCER.

Helicobacter pylori virulence factors include its shape and its ability to rapidly move into and through the gastric mucous coating, which protects the organism from stomach acid; its surface-associated urease enzyme which neutralizes stomach acid near the organism; a cytotoxin; and a fibrillar adhesin which binds the organism to the surface of gastric epithelial cells. *Helicobacter pylori* can survive in large numbers in spite of antibodies which are secreted into the stomach and the host immune cell response (inflammatory response) characteristic of gastritis. [D.J.Ev.]

Helicoplacoidea A small class of spindle-shaped, spirally pleated, primitive echinoderms in the subphylum Echinozoa, from the Early Cambrian (*Nevadella* Zone) in eastern California, western Nevada, and eastern British Columbia. Since their discovery in the early 1960s, three genera and six species have been described based on nearly 600 complete specimens, making helicoplacoids the most diverse and abundant echinoderm class known from the Early Cambrian. The unusual plating and spiral symmetry of helicoplacoids separate them from all other classes of echinoderms. *See* ECHINODERMATA; ECHINOZOA. [J.Sp.]

Helicopter An aircraft characterized by its large-diameter, powered, rotating blades. The helicopter can lift itself vertically by the reactive force generated as the rotating blades accelerate air downward. It can both lift and propel itself by accelerating air downward at an angle to the vertical. The helicopter is the most successful vertical takeoff and landing (VTOL) aircraft developed, by virtue of its relatively high efficiency in performing hovering and low-speed flight missions.

The key to understanding the operation and control of a helicopter lies in a knowledge of the forces and resultant motion of each rotor blade as momentum is imparted to the air. Unlike a fixed-wing aircraft, which derives its lift from the translational motion of the fuselage and airfoil-shaped wing relative to the air, the helicopter rotates its wings (or rotor blades) about a vertical shaft and thus is able to generate lift when the fuselage remains stationary.

Many different rotor arrangements have been used, and most of the early attempts at vertical flight were made with machines having multiple or coaxial counterrotating rotors. Most modern helicopters employ the single rotor or the tandem rotor configurations.

In addition to the selection of the number and location of the lifting rotors, designers have developed varied methods for attaching the blades to the rotor hub. Very early experiments conducted with the blades rigidly attached to the hub were unsatisfactory because of the excessive moments applied to the rotor mast. Based on the success achieved by the introduction of hinged attachments for the rotor blades, several configurations have been successfully manufactured. The teetering rotor used on two-bladed configurations has one central hinge which allows the blades to move in unison (one up, one down) like a seesaw. The gimbaled rotor is essentially equivalent to the teetering rotor and has been used on rotors with three or more blades. The articulated rotor has each blade attached to the hub by its own flapping hinge.

The growth of the helicopter industry in the United States is founded in the uses made by the armed forces. The technology which evolved to meet the needs of the military provided the base for an impressive growth in commercial applications. With such diverse operations as crop spraying, logging, construction, police and ambulance service, and passenger and corporate transportation, the industry has responded with a variety of commercial helicopters. *See* VERTICAL TAKEOFF AND LANDING (VTOL). [J.L.J.]

Helicosporida An order of protozoa in the class Myxosporidea (subphylum Cnidospora). It is characterized by production of spores with a relatively thick, single intrasporal filament and three uninucleate sporoplasms. *Helicosporidium parasiticum* is the only species in the order. The parasite infests the body cavity, fat bodies, and ganglia of mites (*Hericia hericia*) and the body cavity of fly larvae (*Dasyhelea obscura* and *Mycetobia pallipes*) found in the sap of horse chestnut and elm trees. *See* MYXOSPORIDEA. [R.F.N.]

Helimagnetism A property possessed by some metals, alloys, and salts of transition elements in which the atomic magnetic moments, at sufficiently low temperatures, are arranged in a spiral or helix. Simple antiferromagnets and ferromagnets can be considered as nonconical helimagnets with helical angles of 180 and 0°, respectively. In the same way, nonconical helimagnets may be considered as conical helimagnets with cone angle of 0°. Some typical helimagnets are listed in the table. The

Some representative helimagnets

Substance	Magnetic structure	Temperature, K
MnO_2	Nonconical helix	$0 < T < 84$
$MnAu_2$	Nonconical helix	$0 < T < 363$
Dy	Nonconical helix	$85 < T < 179$
	Ferromagnet	$0 < T < 85$
$MnCr_2O_4$	Simple ferrimagnet	$18 < T < 43$
	Complex conical helix	$0 < T < 18$
Er	Conical helix	$0 < T < 20$
	Complex oscillation	$20 < T < 53$
	Sinusoidal antiferromagnet	$53 < T < 85$

magnetic structures have been detected by neutron diffraction. [F.Ke.]

Helioseismology A technique for probing the interior of the Sun, using methods akin to terrestrial seismology. The Sun, although the nearest star by far, is a typical star, so what can be learned of its interior through helioseismology is of broad importance to the stars in general.

Like terrestrial seismology, helioseismology entails the analysis of many "seismic" wave modes to determine the structure of the interior. However, although terrestrial seismic waves are initiated by a singular event such as an earthquake, waves within the Sun are continuously excited, probably by the turbulent convective motions in its outer layers. Thus the solar waves are always present at all points within the Sun and on its surface. The Sun is "ringing" like a bell, but not like one struck by a clapper; it vibrates more like a bell suspended in a sandstorm, continuously struck by tiny grains of sand. *See* SEISMOLOGY.

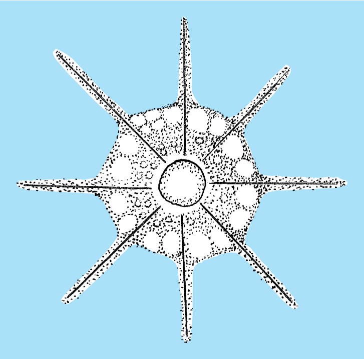
The solar waves are seen at the surface as up-and-down motions of the gases with a speed of about 0.3 mi/s (0.5 km/s) and a vertical displacement of about 30 mi (50 km). These waves are detected through the Doppler shift of the wavelength of absorption lines in the solar spectrum. They have periods clustering near 5 min (that is, with a frequency of one cycle in 5 min or about 0.003 cycle per second). As a result, the solar surface undulates up and down in a so-called five-minute oscillation. The oscillation is actually the superposition of as many as 10^7 individual modes of oscillation of the Sun as a whole, where each mode has its own characteristic frequency (near, but not exactly at, 0.003 cycle per second) and spatial pattern on the solar surface.

Precise observations of the solar oscillations are difficult. A nearly continuous stream of data extending over days is needed to separate the many individual modes with nearly identical oscillation frequencies. Ground-based observations are hampered by the day-night cycle. This restriction has been overcome by making observations from near the South Pole during the austral summer, through networks of similar telescopes spaced at several longitudes around the globe, and from spacecraft located in orbits experiencing continuous sunlight.

Helioseismology offers insight into the structure of the solar interior and also into its rotation. Waves propagating with or against the direction of rotation are carried by it, and their effective propagation speed and frequency are increased or decreased. The frequency shift for any mode depends on the average rotation rate within the resonant cavity for that mode, and comparison of the shift for many modes with different cavities makes it possible to determine how the rotation varies with depth.

The surface of the Sun has long been known to rotate differentially with latitude; that is, at the Equator the surface rotation period is about 25 days while near the Poles it is about 34 days. Roughly speaking, the increase of rotation period from Equator to Pole persists throughout the convection zone, which constitutes the outer 30% of the solar radius. However, at all latitudes the rotation period decreases slightly over the outer 10% of the solar radius, and then increases again to approximately its surface value at the bottom of the convection zone. At the bottom of the convection zone there is an abrupt transition to a deeper interior, which seems to rotate nearly uniformly and at the same speed as surface latitudes of about 35°. *See* STELLAR ROTATION; SUN. [R.W.N.]

Heliozoia A subclass of the Actinopodea. Unlike Radiolaria, these protozoans have no central capsule. Most species live in fresh water. Pseudopodia may be either slender with an axial filament surrounded by cytoplasm (axopodia) or filamentous (filopodia). Certain floating species can roll along on the tips of their axopodia and also swim by moving their axopodia. Some species are naked; others have skeletal elements ranging from siliceous scales or spicules embedded in a gelatinous capsule to a reticulate chitinous skeleton often impregnated with silica. A centroplast may or may not be present. The subclass has three orders: Actinophryida (see illustration), Centrohelida, and Desmothoracida. *See* ACTINOPODEA. [R.P.H.]



Actinophryida type of Heliozoia. (*After R. P. Hall, Protozoology, Prentice-Hall, 1953*)

Helium A gaseous chemical element, He, atomic number 2 and atomic weight 4.0026. Helium is one of the noble gases in group 18 of the periodic table. It is the second lightest element. The world's chief source of helium is a group of natural gas fields in the United States. *See* INERT GASES; PERIODIC TABLE.

Helium is a colorless, odorless, and tasteless gas. It has the lowest solubility in water of any known gas. It is the least reactive element and forms essentially no chemical compounds. The density and the viscosity of helium vapor is very low. Thermal conductivity and heat content are exceptionally high. Helium can be liquefied, but its condensation temperature is the lowest of any known substance. The properties of helium are given in the table. *See* LIQUID HELIUM.

Helium was first used as a lifting gas in balloons and dirigibles. This use continues for high-altitude research and for weather balloons. The principal use of helium is in inert gas–shielded

Properties of helium

Property	Value
Atomic number	2
Atomic weight	4.0026
Melting point* at 25.2 atm pressure	−272.1°C (1.1 K)
Triple point (solid, helium I, helium II)	−271.37°C (1.78 K)
Triple point = λ-point (helium gas, helium I, helium II)	−270.96°C (2.19 K)
Boiling point at 1 atm pressure	−268.94°C (4.22 K)
Gas density at 0°C and 1 atm pressure, g/liter	0.17847
Liquid density at its boiling point, g/ml	0.1249
Solubility in water at 20°C, ml helium (STP)/1000 g water at 1 atm partial pressure of helium	8.61

*The melting point varies with the pressure.

arc welding. The greatest potential for helium use continues to emerge from extreme-low-temperature applications. Helium is the only refrigerant capable of reaching temperatures below 14 K (−434°F). The chief value of ultralow temperature is the development of the state of superconductivity, in which there is virtually zero resistance to the flow of electricity. Other helium applications include use as a pressurizing gas in liquid-fueled rockets, in helium-oxygen breathing mixtures for divers, as a working fluid in gas-cooled nuclear reactors, and as a carrier gas for chemical analysis by gas chromatography.

Terrestrial helium is believed to be formed in natural radioactive decay of heavy elements. Most of this helium migrates to the surface and enters the atmosphere. The atmospheric concentration of helium (5.25 parts per million at sea level) could be expected to be higher. However, its low molecular weight permits helium to escape into space from the upper atmosphere at a rate roughly equal to its formation. Natural gases contain helium at concentrations higher than in the atmosphere. [A.W.F.]

Helium is an element with a closed electronic shell, a large ionization potential, and a low polarizability, which makes it a very unlikely candidate to form chemical bonds. However, solid helium compounds have been found to form at high pressure, one with nitrogen [$He(N_2)_{11}$] and one with neon [$Ne(He)_2$]. These compounds belong to a class known as van der Waals compounds. *See* INTERMOLECULAR FORCES.

Other helium compounds have also been observed in a clathrate hydrate, $He(H_2O)_{6+\delta}$, and helium has been detected inside the carbon molecule buckminsterfullerene (C_{60}), forming HeC_{60}. Mixtures of helium and other components prevail under conditions of high pressure in the outer planets of the solar system and their satellites. Therefore, it is believed that helium compounds are important in the modeling of the interiors of such celestial bodies. The formation of helium compounds at high pressures illustrates that under such conditions different chemical behavior occurs compared to that observed under ambient conditions. *See* CHEMICAL BONDING; CLATHRATE COMPOUNDS; FULLERENE. [W.L.V.]

Helium-3 is a rare stable isotope of helium was discovered by L. W. Alvarez and R. Cornog in 1939. Its concentration in nature is so low, approximately one part per hundred million in well helium, that it was 1951 before sufficient quantities of pure gas became available for experimentation. The gas was then, and continues to be, obtained as a by-product from the decay of tritium, the heavy isotope of hydrogen. Tritium is produced in a nuclear reactor from the reaction between lithium and a neutron.

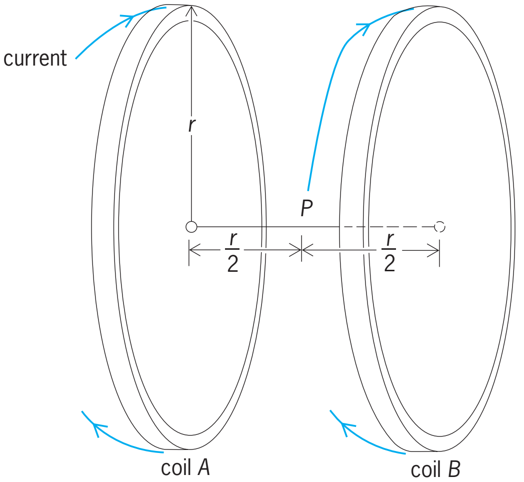
The ^3He nucleus is composed of two protons and one neutron, one fewer than for ^4He; as a consequence, ^3He is a fermion whereas ^4He is a boson. The two isotopes are the exemplars of Fermi-Dirac and Bose-Einstein systems, respectively. It is principally for this reason that helium, an apparently featureless chemical element, has been studied intensively. *See* BOSE-EINSTEIN STATISTICS; FERMI-DIRAC STATISTICS; TRITIUM. [B.M.A.]

Helix

Helix Any nonplanar curve all of whose tangents make the same angle with a fixed line. Other characteristic properties are that all principal normals are parallel to a plane and that the ratio of torsion to curvature is constant. If a helix has constant curvature (and hence constant torsion), it is a circular helix; it lies on a circular cylinder whose elements it cuts at a constant angle. *See* ANALYTIC GEOMETRY; DIFFERENTIAL GEOMETRY. [L.M.Bl.]

Helmholtz coils

Helmholtz coils A pair of flat circular coils with equal numbers of turns and equal diameters, arranged with a common axis, and connected in series to have a common current (see illustration). The purpose of the arrangement is to obtain a magnetic field that is more nearly uniform than that of a single coil without the use of a long solenoid. The optimum arrangement is that in which the distance between the two coils is equal to the radius of one of the coils. *See* SOLENOID (ELECTRICITY). [K.V.M.]



Helmholtz coils separated by distance *r*, resulting in a nearly uniform field of point *P*. (*After L. B. Loeb, Fundamentals of Electricity and Magnetism, 3d ed., 1947*)

Hematite

Hematite The most important ore of iron, with composition α-Fe_2O_3. The crystals are thick tabular, usually flattened parallel to the base, and are frequently platy in habit. Hematite usually occurs as rouge-red earthy masses of finely divided particles. It is the major red-coloring agent in rocks and is a common interstitial cement in sediments. When mixed with quartzite or finely divided quartz, the mixture is called jasper, jaspilite, or taconite. Botryoidal masses are called "kidney ore," and splinters of these masses are "pencil ore."

The color is steel gray, blood red in thin fragments, and streak and powder are rouge red; hardness is 6 on Mohs scale and specific gravity is 5.25. The mineral is only weakly magnetic.

Hematite is the most widespread iron mineral. The most important ores are in low-to-medium-grade metamorphic rocks of sedimentary origin. Enormous beds occur in the Great Lakes region of the United States. Hematite also occurs in contact metamorphic and metasomatic deposits, often derived from the oxidation of magnetite and frequently associated with limestones.

Nearly every country in the world mines some hematite ore; the most important occurrences outside of the United States include India, Cuba, China, Chile, north African nations, and Russia. *See* IRON METALLURGY; REDBEDS. [P.B.M.]

Hematologic disorders

Hematologic disorders Those disorders marked by aberrations in structure or function of the blood cells or the blood-clotting mechanism. Although many other diseases may be reflected by the blood and its constituents, the abnormalities of red cells, white cells, platelets, and clotting factors are considered to be primary hematologic disorders. *See* BLOOD.

Red-cell abnormalities are principally represented by the anemias and polycythemias. The anemias are marked by a decrease in the hemoglobin concentration, and may be due to blood loss or decreased production or excessive destruction of red cells. Polycythemias are disorders characterized by an increase in the numbers of circulating red cells and usually by a concomitant increase in hemoglobin. Secondary polycythemias result from a compensatory increase in the formation of red cells following hypoxia of the bone marrow. Primary polycythemia or polycythemia vera is a chronic and ultimately fatal disease of middle and old age in which there is a gradual increase in the number of red cells and usually an increase in the number of platelets and leukocytes. *See* ANEMIA; HEMOGLOBIN.

In a wide variety of conditions the many forms of white cell present in the circulation, bone marrow, and lymphoid tissues of the body may be altered in form or number. The suffixes -philia and -penia denote increases and decreases, respectively, for the cells named. Leukopenia, neutrophilia, eosinophilia, and pancytopenia are examples of the wide range of possibilities. The absolute or relative increases or decreases of one or more types of leukocytes are often characteristic of certain disease states. There may also be changes in the proportions of the different cells, and immature or atypical forms may be present. The leukemias represent a special kind of malignancy in which there is usually an uncontrolled proliferation of one or more types of leukocytes, often reflected by great increases in the white cell count of the peripheral blood. *See* LEUKEMIA.

The hemorrhagic disorders result from a large number of known and unknown causes or contributing factors, often of a diverse nature. A decrease or abnormality of the von Willebrand factor, a reduction in the number of platelets, a qualitative defect in platelets, or a defect in the vascular wall can all result in failure of the primary hemostatic mechanism, with spontaneous bleeding; this is referred to as purpura. Blood vessel damage may occur as a result of direct or indirect damage by microorganisms during infections, as the result of vitamin C deficiency (scurvy), and following hereditary defects in blood vessel development. There are several forms of thrombocytopenia, all of which are characterized by a decrease in thrombocytes or platelets in the circulation. A defect in fibrin or clot formation gives rise to the type of bleeding seen in hemophilia, in which the primary hemostatic plug is formed normally but breaks down several hours or days later owing to lack of adequate fortification by fibrin. Defects in the clotting process that result in excessive bleeding may be due to an acquired or hereditary deficiency or abnormality of a clotting factor, as in hemophilia A or B. *See* HEMOPHILIA; HEMORRHAGE. [C.Ho.]

Hematopoiesis The process by which the cellular elements of the blood are formed. The three main types of cells are the red cells (erythrocytes), which serve to carry oxygen, the white cells (leukocytes), which function in the prevention of and recovery from disease, and the thrombocytes, which function in blood clotting. The formation of these cells is one of the most active and important processes in the body. Most of the circulating cells live only for a short time and must be replaced in order to maintain life. For instance, in the human adult a red blood cell has a life of 120 days; 250 billion new red cells have to be produced daily to replace those that are destroyed.

Blood cells originate in the reticuloendothelial tissue, which is a loose, fibrous, highly vascularized mesh of fibers, endothelial cells, and macrophages. Within the spaces of the tissue are found the precursor (blast) cells of the definitive adult types. For the sake of convenience, the reticuloendothelial tissue is divided into two general but imprecise types: lymphoid and myeloid tissue. Lymphoid tissue is primarily localized in the lymph nodes of the lymphatic system and is also in the spleen, thymus, and bone marrow. Several classes of white cells are produced, including the lymphocytes, macrophages, and monocytes. *See* CELLULAR IMMUNOLOGY; LYMPHATIC SYSTEM.

Myeloid tissue is normally limited in humans to the red bone marrow of the ribs, sternum, vertebrae, and proximal ends of the long bones of the body. It is concerned with the production of the erythrocytes and certain types of leukocytes. The latter are the granular leukocytes (called eosinophils, basophils, and neutrophils on the basis of the affinity of granules in their cytoplasm for certain dyes) and megakaryocytes. Fragments of megakaryocytes form the blood platelets (thrombocytes), which are necessary for blood clotting. *See* BLOOD. [F.Wi.]

Hemiascomycetes A class of the phylum Ascomycota that includes the yeasts and yeastlike fungi. These are morphologically simple fungi; no ascoma is formed, and the asci are produced free on the host or substrate. Asexual reproduction occurs by the formation of blastospores (budding) or, less frequently, by fission arthrospores. Two main orders are recognized, the Saccharomycetales and the Taphrinales. *See* YEAST.

The vegetative body (thallus) of the Saccharomycetales may be either unicellular (true yeasts) or mycelial. In unicellular species, asci form when two vegetative cells fuse, and then the fused cell undergoes meiosis to form ascospores. In mycelial species, the hyphae are not very extensive. Sexual reproduction occurs when adjacent cells extend short lateral branches that fuse to form the asci. Variations on these modes of ascus formation, however, are common among the yeasts.

The Saccharomycetales are common on substrates high in sugars, such as plant exudates, ripe fruits, and flower parts. Because they are microscopic, they are recognized mainly from cultures that have a homogeneous appearance and a characteristic odor. The most important genus is *Saccharomyces; S. cerevisiae* is the common bakery and brewery yeast, and *S. ellipsoideus* is used in winemaking. An important mycelial species is *Nematospora coryli*, which causes yeast spot disease of various crops.

The order Taphrinales includes the leaf curl disease fungi. The most widely recognized species are *Taphrina deformans*, cause of leaf curl of peach and almond trees, and *T. caerulescens*, cause of leaf blister of oaks. These fungi produce a well-developed mycelium in the host tissue but, when grown in culture, form only a yeastlike colony of single cells. Asci are produced when special binucleate hyphal cells beneath the host cuticle undergo nuclear fusion and the resulting diploid cell elongates to form an ascus on the leaf surface. The nucleus undergoes meiosis, and ascospores are formed. *See* ASCOMYCOTA; EUMYCOTA; FUNGI.

On the basis of molecular data, some workers now propose separating the Taphrinales and the fission yeast, *Schizosaccharomyces*, into a new class, Archiascomycetes. These fungi are considered to be more primitive and phylogenetically basal to the rest of the ascomycetes. [R.T.Ha.]

Hemicellulose A term designating plant cell components which are made soluble by dilute alkali or which go into solution quite readily in hot dilute mineral acids with the formation of simple sugars. Hemicelluloses constitute about one-fourth of perennial plants and about one-third of annual plants. The term is usually applied to those polysaccharides in the cell wall of land plants which are extractable by dilute alkaline solutions. The term has also been used to include all the polysaccharide components of the cell wall other than cellulose. *See* CELL WALLS (PLANT); CELLULOSE.

Hemicelluloses extracted from different plant sources are rarely identical. In fact, many different hemicelluloses usually occur intermixed with each molecular type representing different degrees of polymerization. Because of this heterogeneity, few hemicelluloses have been isolated in a homogeneous state. Therefore, relatively little is known of the structure of these compounds that compose almost one-third of the carbohydrates in woody tissue.

D-Xylose is the dominant building unit of the hemicelluloses of most woods and annual plants. D-Mannose is also very abundant in hemicelluloses; the mannose content of softwoods is usually higher than that of hardwood. Often it occurs as a polymer, mannan, or in combination with D-glucose or D-galactose as a glucomannan, galactomannan, or galactoglucomannan. *See* MANNANS.

Hemicelluloses are important to the paper industry. In chemical wood pulps, hemicellulose is needed for satisfactory pulp quality. Its presence aids the swelling of the pulp, the bonding of the fibers, the bursting strength, tensile strength, tear resistance, folding endurance, opacity, and specific surface of the pulp sheet.

Hemicelluloses also serve as nutrients for yeasts, and they can be used for raw material in the production of furfural and ethyl alcohol. [R.L.Wh.]

Hemichordata A group of deuterostome animals that includes the classes Enteropneusta, Pterobranchia, and Planctosphaeroidea. The last, a monospecific class, is represented by *Planctosphaera pelagica*, a planktonic larva that occupies low depths and resembles the larval tornaria of Enteropneusta. *See* ENTEROPNEUSTA; PTEROBRANCHIA.

The hemichordates have a slender tubular diverticulum that projects forward into the protosome from the roof of the buccal cavity. That organ, also called a stomochord or buccal diverticulum, is a supporting axial rod of the protosome and resembles the notochord of Chordata, but it does not have the same position, structure, origin, or function, and so they are not homologous. *See* CHORDATA.

The hemichordates are not plentiful animals. All are marine species that live in a wide range of habitats and depths, from intertidal to abyssal, and show a worldwide distribution. They vary in size from a fraction of an inch to 7 ft or more. The members of the phylum differ widely. The enteropneusts are vermiform and solitary, whereas the pterobranchs are sacciform and colonial.

The hemichordates are a primitive group, having a tripartite body and coelom; their embryonic development resembles the echinoderms, with which they also share a primitive nervous system. The Hemichordata, therefore, may be a group at a low level of evolution, between echinoderms and chordates. [J.Ben.]

Hemicidaroida An extinct paraphyletic order of regular sea urchins (Echinoidea), identified by having a plain, unsculptured test and tubercles that are perforate and crenulate. They almost certainly include ancestors of later groups that developed imperforate and noncrenulate tuberculation and are thus paraphyletic. Two families are generally placed within the order, Hemicidaridae and Pseudodiadematidae. The oldest hemicidaroid is Late Triassic (Upper Norian) and the youngest comes from the Upper Cretaceous (Campanian). They appear to have been epifaunal grazers. *See* ECHINOIDEA. [A.Sm.]

Hemidiscosa An order of the subclass Amphidiscophora in the class Hexactinellida. These sponges are distinguished from the order Amphidiscosa in that the birotulates are hemidiscs with asymmetrical ends. *See* AMPHIDISCOPHORA; AMPHIDISCOSA. [W.D.H.]

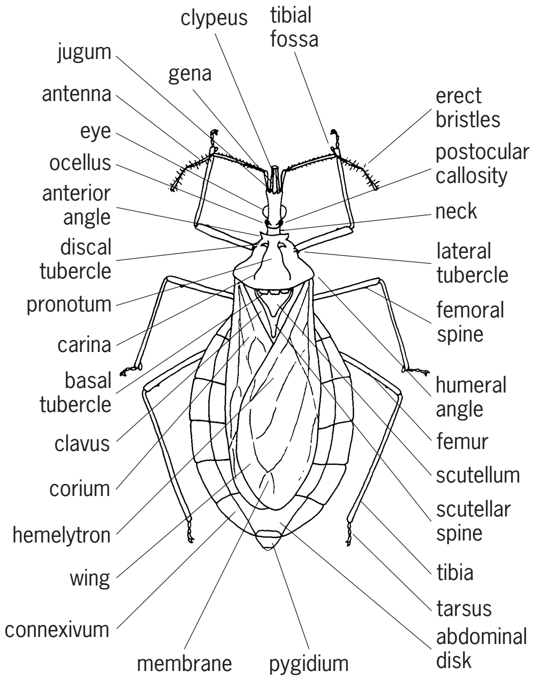
Hemimorphite A mineral sorosilicate having the composition $Zn_4Si_2O_7(OH)_2.H_2O$; an ore of zinc. Crystals are usually colorless and the aggregates white, but in some cases there are faint shades of green, yellow, and blue. The mineral has a vitreous luster, a hardness of $4\frac{1}{2}$ to 5 on Mohs scale, and a specific gravity of 3.45.

Hemimorphite has a wide distribution and has been mined in Belgium, Germany, Romania, England, Algeria, and Mexico. In the United States it is found at Sterling Hill, New Jersey; Friedensville, Pennsylvania; and Elkhorn Mountains, Montana. *See* SILICATE MINERALS. [C.S.Hu.]

Hemiptera An order of the class Insecta sometimes referred to as the Heteroptera. Both these names refer to the forewings, which are differentiated into a thickened basal area and a membranous apical region. These are the true bugs. Included in Hemiptera are such common insects as the bedbugs, stink bugs, plant bugs, lace bugs, and backswimmers.

The true bugs number about 25,000 species. They are known from all continents except Antarctica and occur on most islands. Hemiptera range in size from small aquatic and ground-inhabiting forms approximately 0.04–0.08 in. (1–2 mm) in length to giant water bugs 4 in. (100 mm) or more.

In habits, the true bugs range from strictly phytophagous types attached to a single host plant, to general predators on other insects, and even to specialized ectoparasites of bats. Many species are of economic importance as plant pests or vectors of disease. They occur in vegetation, on the ground, in and on the water, and in the nests of termites. Most water bugs depend on surface air held to the body by air spaces and hairs on the abdomen. As oxygen is depleted in the air bubble, it is replaced from the surrounding medium by diffusion.



External anatomy of a bug.

Most Hemiptera are bisexual and oviparous, but parthenogenesis is known. Mating usually takes place on vegetation or on the ground, the pairing being end-to-end in stink bugs, squash bugs, chinch bugs, and similar species, and with the male above the female in most others.

Morphology. In Hemiptera the mouthparts are elongate and slender, forming a sucking mechanism. The beak arises from the anterior part of the head and the head is commonly directed forward or downward.

Hemiptera are further characterized (see illustration) by antennae, usually of four or five segments, a pair of compound eyes, and often two ocelli. The thorax consists of a prominent pronotum, a triangular mesothoracic scutellum, and a broad metathorax which is partly fused with the first abdominal segment. The mesothoracic wings, or hemelytra, overlap at their membranous apices when at rest. The hindwings are hitched to the forewings in flight by grooves and pegs. Wings are sometimes reduced to short pads and may be lacking in certain groups or even in members of a single species. The front legs are frequently enlarged and sometimes chelate in predacious forms, and the middle and hindlegs are adapted for swimming in some groups. The abdomen is of 10–11 segments, but only seven are commonly seen.

Subdivisions. Families of the Hemiptera and their distinguishing characteristics are listed in the table under the respective subdivisions.

Hydrocorisae. This subdivision contains nine families of water bugs with concealed antennae and without a bulbus ejaculatorius in the male. Many species are predaceous.

Corixoidea is a superfamily which contains the single family Corixidae, or water boatmen. Corixidae lack ocelli and have a unique type of mouthpart. Corixids swim with the dorsal side uppermost, using the oarlike middle and hind legs. Eggs are stalked and there are five nymphal instars. Adults sometimes fly to lights in great numbers.

Families of Hemiptera

Family	Common name	Distribution	Number of species
Subdivision Hydrocorisae			
Corixidae	Water boatmen	General	300
Nepidae	Water scorpions	General	170
Belostomatidae	Giant water bugs	General	140
Notonectidae	Backswimmers	General	170
Pleidae	None	General	20
Helotrephidae	None	Tropical	20
Naucoridae	Creeping water bugs	General	200
Gelastocoridae	Toad bugs	Tropical and subtropical	80
Ochteridae	Velvety shore bugs	Tropical and subtropical	20
Subdivision Amphibicorisae			
Gerridae	Water striders	General	300
Veliidae	Smaller water striders	General	200
Hydrometridae	Marsh treaders	General	50
Mesoveliidae	Water treaders	General	20
Hebridae	Velvety water bugs	General	40
Subdivision Geocorisae			
Superfamily Leptopodoidea			
Saldidae	Shore bugs	General	200
Leptopodidae	None	Tropical and subtropical	20
Leotichidae	None	Asian	2
Superfamily Dipsocoroidea			
Dipsocoridae	None	General	
Schizopteridae	Jumping ground bugs	Tropical and subtropical	
Superfamily Cimicimorpha			
Cimicidae	Bat, bed, bird bugs	General	80
Anthocoridae	Flower bugs	General	300
Polyctenidae	Bat bugs	Tropical and subtropical	20
Miridae	Plant bugs	General	5000
Microphysidae	None	Palearctic	30
Plokiophilidae	None	Tropical	20
Nabidae	Damsel bugs	General	250
Tingidae	Lace bugs	General	700
Vianaidae	None	Neotropical	2
Thaumastocoridae	Palm bugs	Tropical	11
Superfamily Enicocephaloidea			
Enicocephalidae	Gnat bugs	General	300
Superfamily Reduvioidea			
Reduviidae	Assassin bugs	General	3500
Superfamily Aradoidea			
Aradidae	Flat bugs	General	800
Termitaphididae	Termite bugs	Tropical	10
Superfamily Pentatomorpha			
Idiostolidae	None	Chilean	2
Lygaeidae	Lygaeid bugs	General	2000
Thaumastellidae	None	Ethiopian	1
Colobathristidae	None	Tropical	70
Berytidae	Stilt bugs	General	100
Malcidae	None	Ethiopian, Asian	30
Piesmatidae	Ash-gray leaf bugs	General but discontinuous	20
Pyrrhocoridae	Pyrrhocorid bugs	General	300
Largidae	None	General	100
Coreidae	Coreid bugs	General	2000
Rhopalidae	None	General	300
Stenocephalidae	None	Old World, Neotropical	20
Hyocephalidae	None	Australia	1
Pentatomidae	Stink bugs	General	2500
Phloeidae	Bark bugs	Neotropical	5
Plataspidae	None	Old World	400
Lestoniidae	None	Australia	1
Cydnidae	Ground or burrower bugs	General	600
Urostylidae	None	Asian and Australian	50
Aphylidae (not placed)	None	Australian	2
Joppeicidae	None	Mediterranean	1

In the superfamily Nepoidea, the Nepidae, or water scorpions, have a long breathing tube at the tip of the abdomen, through which they obtain air directly from the surface. The beak is short and stout to suck the juices of other insects on which they prey. Belostomatidae, or electric-light bugs, have short, straplike respiratory appendages at the tip of the abdomen. Giant water bugs of the genus *Lethocerus* are pests in fish ponds where they attack fry. They can inflict a painful bite when handled carelessly.

The superfamily Notonectoidea includes the Notonectidae or backswimmers: they swim ventral side uppermost, the hindlegs serving as oars. Breathing is facilitated by an air bubble, obtained by touching the tip of the abdomen to the surface.

The minute bugs of the families Pleidae and Helotrephidae (superfamily Pleoidea) are suboval, with legs not fitted for rowing.

The creeping water bugs (superfamily Naucoroidea) are sometimes separated into the Naucoridae and Aphelocheiridae. They are suboval in body form. Respiration is either by an air bubble or by means of a plastron; in the Old World genus *Aphelocheirus*, the plastron consists of an ultramicroscopic hair pile which acts as a physical gill; the bug is thus able to remain submerged permanently.

In the superfamilies Gelastocoroidea and Ochteroidea, the Gelastocoridae, or toad bugs, and the Ochteridae (or Pelogonidae) are shore-line or mud inhabitants. Both have ocelli. The former are cryptically colored, resembling the sand or mud background. Ochterids are black with a silky sheen.

Amphibicorisae. This subdivision contains surface water bugs with antennae exposed and without a bulbus ejaculatorius in the male. Only the single, diverse superfamily Gerroidea has been proposed for the surface water bugs. All have conspicuous antennae, and the body is clothed with hydrofuge hairs. All Gerroidea are predacious.

Gerridae are the large water striders with long middle and hind legs and a median scent gland opening on the metasternum. The claws are inserted before the tips of the tarsi. The marine forms are always wingless but all others are polymorphic, with fully winged forms occurring together with short-winged or apterous types.

Veliidae are small water striders which have shorter legs and a longitudinal groove between the eyes. The claws are preapical. Like the Gerridae, these are pond inhabitants, stream-riffle bugs, and marine types, but the last are found only near shore in tropical reefs.

Hydrometridae are long, slender marsh treaders in which the head is longer than the thorax. The claws are apical.

Mesoveliidae and Hebridae are two small families which differ from others in having the well-developed ocelli and the single dorsal abdominal scent gland openings of the nymphs.

Geocorisae. This subdivision contains the land bugs with conspicuous antennae and an ejaculatory bulb in the male reproductive system. This subdivision can be divided into seven groups, each of which may be equivalent in rank to the Hydrocorisae and Amphibicorisae. Superfamilies that do not fit the above groupings are the Reduvioidea, the Saldoidea, the Aradoidea, and the Enicocephaloidea and Dipsocoroidea, of isolated position in the system.

The superfamily Saldoidea comprise the shore bugs which have three pairs of trichobothria on the vertex and a single nymphal scent gland opening. Dipsocoroidea is a group of minute ground inhabitants, of which the Schizopteridae live in leaf mold and the Dipsocoridae are predators on small insects under bark or in rotten wood or amid stones at the edge of streams.

Enicocephaloidea is a unique group in which the head is bilobed, the pronotum trilobed, and the wings completely membranous. They live under stones, beneath bark, and in leaf mold and are predators. Some species are wingless; others can cast off their wings.

Reduvioidea includes only the assassin bugs or conenose bugs of the family Reduviidae. Nearly all have a stridulatory furrow on the prosternum, which is scraped by the rostrum to produce a squeaking sound. Ocelli are generally present and the beak is three-segmented.

Among the Aradoidea are flat bugs of the family Aradidae and their specialized relatives, Termitaphididae. They lack ocelli and have four-segmented antennae. Most, if not all, are fungus feeders. The Termitaphididae have no wings. They are known from termite nests in the Old and New World tropics. Aradidae are nearly cosmopolitan and fully winged, brachypterous, stenopterous, or apterous.

Cimicimorpha is the largest group of the Geocorisae and is divided into three superfamilies, the Cimicoidea, Tingoidea, and Thaumastocoroidea.

1. Cimicoidea. Anthocoridae, or the flower bugs, are small predators on thrips, mites, and similar species in vegetation, in stored products, and in the nests of birds. The ocelli are distinct, and the front wings have a marginal fracture. Cimicidae contains the bedbugs, which lack ocelli, and have the short wings reduced to pads. The food consists of blood of birds and mammals. The Polyctenidae are bat ectoparasites which lack eyes and have ctenidia and strong claws. The Miridae family contains a majority of the species of Hemiptera. Included are plant bugs of both herbivorous and predacious type. Ocelli are lacking, the antennae are four-segmented, and there is only one dorsal abdominal scent gland opening in nymphs. Two small families, the Plokiophilidae and Microphysidae, are predacious. The Plokiophilids live in the webs of spiders and embiids.

Nabidae are the long "damsel" bugs which are slender predators on other insects. The ocelli are well developed, and the rostrum is four-segmented. The tropical Velocipedidae are related but differ in the broader form and darker coloration.

2. Tingoidea. This superfamily contains the lace bugs of the family Tingidae which have wings with many lacelike areolae. They lack ocelli, have four segments in the antennae and beak, and commonly have one or more bulbous or hoodlike elevations on the thorax. Pests are known on ornamental plants.

3. Thaumastocoroidea. The only family, the Thaumastocoridae, occurs in Australia and the New World tropics; it includes the royal palm bug of Florida.

Pentatomorpha includes the superfamilies Lygaeoidea, Pyrrhocoroidea, Coreoidea, and Pentatomoidea.

1. Lygaeoidea. This is the first of the superfamilies with ventral trichobothria (bristles) on the abdomen. The antennae are four-segmented. Ocelli are present. The Lygaeidae include the chinch bug, the false chinch bugs, and the milkweed bugs. Small families related to the lygaeids are the thread-legged Neididae (Berytidae), the small Piesmidae, and the tropical Colobathristidae. Some of the last have a unique method of stridulation with a filelike arch on the sides of the head.

2. Pyrrhocoroidea. This group includes the cotton stainers, which attack cotton bolls in the southwestern United States and over most of the tropics, and stout, dark bugs with a reddish border.

3. Coreoidea. The squash bugs and their relatives include the Coreidae, Rhopalidae, Alydidae, and Hyocephalidae. They have four-segmented antennae, a beak, distinct ocelli, and many veins in the membrane.

4. Pentatomoidea. This large group has marginal trichobothria. The antennae are usually five-segmented and the beak is four-segmented. Scutelleridae, or shield bugs, are not injurious in the United States. Cydnidae include the ground-burrowing bugs, which attack strawberries in sandy soil, and the negro bugs. Smaller families of little or no economic importance in the United States are the large tropical Tessaratomidae, the Acanthosomatidae, the Dinidoridae, the Aphylidae, the Urostylidae, the barklike Phloeidae, the shining, oval Plataspidae, and the Lestoniidae. The true stink bugs, Pentatomidae, include the black-and-red harlequin cabbage bug, and several green stink bugs on cotton and other crops. *See* INSECTA. [P.W.W.]

Hemispheric laterality The human brain is a bilaterally symmetrical structure which is for the most part richly interconnected by two main bridges of neurons called the corpus callosum and anterior commissure. These structures can be surgically sectioned in humans in an effort to control the spread of epileptic seizures. Although there is no apparent change in everyday behavior of these patients, dramatic differences in cognitive function can be demonstrated under specialized testing conditions. In normal humans these cerebral commissures are largely responsible for behavioral unity; the neural mechanism keeps the left side of the body up to date with the activities of the right side, and vice versa.

Changes in behavioral responses of persons whose cerebral commissures have been sectioned are almost undetectable. The person walks, talks, and behaves in a normal fashion. Dramatic effects are observed only under testing conditions which utilize stimuli that are lateralized exclusively to one hemisphere or the other. For example, if a picture of an apple is flashed in the right visual field, the person describes the object normally. However, if the same picture is flashed in the left visual field, in the early days of postoperative testing the person denies that the stimulus was presented at all. After many test sessions the person may have the impression that something was flashed, but is unable to say what. This disparity of recognition in the two sides of the visual field occurs because the information is projected to the right hemisphere, which is incapable of speech. Because the right hemisphere is now disconnected from the left, information arriving in the right hemisphere cannot be communicated by means of speech.

When tests are used which do not require a spoken response, numerous mental abilities are observed to be present in the "disconnected" right hemisphere. For example, even though the person is unable to describe a picture of an orange flashed to the left field, when the left hand searches through a field of objects placed out of view, it correctly retrieves the orange. If asked what the object is, the person would say he does not know. Here again the left hemisphere controls speech but cannot solve the problem. The right hemisphere solves the problem but cannot elicit speech.

Despite its linguistic superiority, the left hemisphere does not excel over the right in all tasks. Tests have demonstrated that in some specialized functions the right hemisphere is decidedly superior to the left. In the area of emotional reactions there appears to be equal reactivity in the two hemispheres.

Tests have been conducted on subjects in which the cerebral commissure had not been entirely sectioned (because it is now believed total commissure section is not necessary to stop the interhemispheric spread of some kinds of seizure activity). These persons showed dramatic breakdown in interhemispheric transfer. When the posterior part of the callosum is sectioned, visual aspects of the syndrome appear. When it is spared and more interior regions are cut, tactile and auditory communications are blocked, but not visual ones. It also appears that no fundamental reorganization of the interhemispheric transfer system takes place, since years after surgery these same deficits are present and are not compensated for in any way.

There appears to be a large variation in the lateralized talents of each half-brain. While the right hemisphere frequently appears to have some language talent, not all split-brain persons have language skills in the right hemisphere. Similarly, visual spatial skills, which are usually present exclusively in the right hemisphere, are frequently bilaterally represented and sometimes represented only in the left speech hemisphere. There is even some evidence that the commissure system itself varies in what is transferred where. *See* Brain; Psychology. [M.S.G.]

Hemlock The genus *Tsuga* of the pine family, characterized by flattened needles with two white lines beneath the needlelike leaves, which have distinct short stalks. The cones are small and pendent.

Eastern hemlock (*T. canadensis*) occurs in eastern Canada, the Great Lakes states, and the Appalachians. Minutely toothed leaves are characteristic of this species. The wood is hard and strong, and is used for construction, boxes, crates, and paper pulp. The bark is one of the principal domestic sources of tannin. The eastern hemlock is a common ornamental tree.

Carolina hemlock (*T. caroliniana*), a species found in the southern Appalachians, has entire needles and is sometimes grown as an ornamental. The western hemlock (*T. heterophylla*) grows in the extreme Northwest and in Alaska. Its needles resemble those of the eastern hemlock, but the white lines beneath are not so distinct. It is an important lumber tree, with uses similar to these of the eastern species. *See* Finales. [A.H.G./K.P.D.]

Hemoglobin The oxygen-carrying molecule of the red blood cells of vertebrates. This protein represents more than 95% of the solid constituents of the red cell. It is responsible for the transport of oxygen from the lungs to the other tissues of the body and participates in the transport of carbon dioxide in the reverse direction.

Each molecule of hemoglobin comprises four smaller subunits, called polypeptide chains. These are the protein or globin parts of hemoglobin. A heme group, which is an iron-protoporphyrin complex, is associated with each polypeptide subunit and is responsible for the reversible binding of one molecule of oxygen. The polypeptide chains and the heme are synthesized and combine together in nucleated red cells of the bone marrow. As these cells mature, the nuclei fragment and the cells, now called reticulocytes, begin to circulate in the blood. After sufficient hemoglobin has been formed in the reticulocyte, all nuclear material disappears and the cell is then called an erythrocyte, or red blood cell. Each hemoglobin molecule lasts as long as the red cell, which has an average life of 120 days. *See* Porphyrin.

Normal adult males and females have about 16 and 14 g, respectively, of hemoglobin per 100 ml of blood; each red cell contains about 29×10^{-12} g of hemoglobin. Red cells normally comprise 40–45% of the volume of whole blood.

The reversible combination of hemoglobin and oxygen can be represented by the reaction shown below. The equilibrium constants for each step are not the same because an oxygen molecule on one heme group changes the affinity of the other hemes for additional oxygen molecules. This alteration in binding affinity during oxygenation is called heme-heme interaction and is due to small changes in the three-dimensional structure of the molecule.

$$\mathrm{Hb} + 4\mathrm{O_2} \overset{K_1}{\rightleftharpoons} \mathrm{HbO_2} + 3\mathrm{O_2} \overset{K_2}{\rightleftharpoons} \mathrm{Hb(O_2)_2} + 2\mathrm{O_2} \overset{K_3}{\rightleftharpoons} \mathrm{Hb(O_2)_3} + \mathrm{O_2} \overset{K_4}{\rightleftharpoons} \mathrm{Hb(O_2)_4}$$

Hemoglobin combines reversibly with carbon monoxide about 210 times more strongly than with oxygen. This strong affinity for carbon monoxide accounts for the poisoning effects of this gas.

Hemoglobin binds carbon dioxide by means of free amino groups of the protein but not by the heme group. The reversible combination with carbon dioxide provides part of the normal blood transport of this gas. Hemoglobin serves also as a buffer by reversible reactions with hydrogen ions. The acidic property of oxyhemoglobin is greater than deoxygenated hemoglobin. The extra binding of hydrogen ion by deoxyhemoglobin promotes the conversion of tissue carbon dioxide into bicarbonate ion and thus increases the amount of total carbon dioxide which can be transported by blood. *See* Blood; Respiration. [R.T.J.]

Hemophilia A rare, hereditary blood disorder marked by a tendency toward excessive bleeding. It is almost entirely restricted to males, and is transmitted as a sex-linked mendelian recessive trait passing from an affected male through an unaffected or very mildly affected daughter to appear again in a grandson. Queen Victoria was a carrier, and several of her male descendants were affected. *See* Human genetics; Sex-linked inheritance.

Classical hemophilia (hemophilia A) is due to a deficiency of the antihemophilic factor or factor VIII, a clotting factor which is normally present in the blood in trace amounts and is essential for normal fibrin formation. Hemophilia B is a similar sex-linked bleeding disorder affecting males but characterized by a deficiency of another blood clotting factor, factor IX. It can only be distinguished from hemophilia A, which it closely resembles, by laboratory tests. Hereditary deficiencies of other clotting factors may give rise to bleeding disorders similar to hemophilia, but they are inherited as autosomal dominant or recessive characteristics.

Treatment consists in the intravenous administration of potent concentrates of factor VIII or IX prepared from human plasma and they are very effective in the management of hemophilia A and B, respectively. *See* Blood; Hemorrhage. [C.Ho.]

Hemorrhage The escape of blood from within the vascular system. Hemorrhage may result from either trauma or disease of the vessel wall. The escape of blood following rupture of a vessel wall as a result of trauma is obvious and needs no further explanation. The causes other than trauma can be divided into three main groups. The first group consists of these conditions in which there is a chronic disease process affecting the vessel wall, such as atherosclerosis or aneurysm formation. Either of these conditions, in association with an elevated blood pressure, can result in a break in the wall and subsequent hemorrhage. An infarct, or tissue death from any cause, may also result in hemorrhage. The second group consists of those causes in which there is an acute process affecting the vessel wall, such as septicemia, bacterial toxins, or anoxia. The third group consists of those hemorrhagic conditions which result from some defect in the blood itself. Under this heading are leukemia, thrombocytopenia, and the clotting disorders. *See* ANEURYSM; ARTERIOSCLEROSIS; INFARCTION; LEUKEMIA.

Petechiae are hemorrhages no larger than the head of a pin. Hemorrhages of greater size are termed ecchymoses. A localized mass of blood in tissue is a hematoma. Spontaneous hemorrhaging into the skin and mucosal surfaces is termed purpura. This usually denotes a disease of the vascular system or of the blood itself, such as a deficiency of blood platelets. *See* HEMATOLOGIC DISORDERS.

Cerebrovascular accident, or stroke, is an acute vascular lesion of the brain. This may be the result of hemorrhage from, thrombosis in, or embolism to a cerebral vessel. *See* EMBOLISM; THROMBOSIS. [R.A.V.; I.N.]

Hemp The fiber and the plant *Cannabis sativa*. It should not be confused with Manila hemp, which is not related to true hemp. Hemp contains the drug THC (tetrahydrocannabinol). *See* ABACA; MARIJUANA.

Hemp fiber, which for many years was the major raw material used in the manufacture of rope, now is used mostly in the production of small twines, linenlike fabrics and canvases, and, to some extent, in making special types of paper. *See* NATURAL FIBER.

Hemp is an annual crop, most of which is produced in Eastern Europe and mainland China, with some production in South Korea, Turkey, Italy, and Canada. [E.G.N.]

Henequen A fiber obtained from the leaves of *Agave fourcroydes*. It is produced only in Mexico, Cuba and El Salvador. Henequen is sometimes incorrectly called sisal, which is a closely related plant grown in Brazil and Africa. *See* SISAL.

The greatest quantity of henequen fiber goes into farm twine, followed by industrial tying twine and then light-duty rope. Padding for innerspring mattresses is made from the lowest grades of fiber and from flume tow, the short, tangled fiber that can be recovered from the cleaning operation. Henequen is exported as manufactured twine, rope, or padding, not as raw fiber. *See* NATURAL FIBER. [E.G.N.]

Heparin A highly sulfated mucopolysaccharide with blood anticoagulant activity, isolated from mammalian (chiefly beef) tissues. Heparin was first found in abundance in the liver, hence the name, but it is present in substantial amounts in the spleen, muscle, and lung as well. In the blood of most mammals, heparin is an antagonist to thrombin, prothrombin, and thromboplastin. It lessens the tendency of platelets to agglutinate. It is used in the treatment of venous thrombosis, embolism, myocardial infarction, and certain types of cerebral thrombosis. *See* POLYSACCHARIDE. [F.W.]

Hepaticopsida A class of lower green plants called liverworts that belong to the division Bryophyta. The class is divided into approximately 225 genera and 8500 species. Although there is a great diversity of external form, most of the gametophytes (gamete-producing plants) are dorsoventrally differentiated. These plants are considered among the most primitive of the existing land plants. Fossil remains of liverworts have been found in both the Devonian and Carboniferous. Since the fossils found do not differ significantly from modern liverworts, they are of little value in ascertaining phylogenetic relationships. Liverworts are widely distributed over the world, but have their greatest diversity in the tropics of the Americas and East Indies.

Except when the plants occur in masses, they are quite inconspicuous and are usually confused with mosses, which they resemble somewhat in their external appearance. In the presence of adequate moisture, they grow on soil, rocks, and tree trunks. Usually the plant body is a thin, prostrate thallus, sometimes having a short central axis with leaflike appendages. On the lower surface are rhizoids (rootlike structures) which function in anchorage and absorption. *See* BRYOPHYTA; BRYOPSIDA. [P.A.V.]

Hepatitis An inflammation of the liver caused by a number of etiologic agents, including viruses, bacteria, fungi, parasites, drugs, and chemicals. The most common infectious hepatitis is of viral etiology. All types of hepatitis are characterized by distortion of the normal hepatic lobular architecture due to varying degrees of necrosis of individual liver cells or groups of liver cells, acute and chronic inflammation, and Kupffer cell enlargement and proliferation. There is usually some degree of disruption of normal bile flow, which causes jaundice. The severity of the disease is highly variable and often unpredictable. *See* LIVER.

A frequently occurring form of hepatitis is caused by excessive ethyl alcohol intake and is referred to as alcoholic hepatitis. It usually occurs in chronic alcoholics and is characterized by fever, high white blood cell count, and jaundice. Some drugs are capable of damaging the liver and can occasionally cause enough damage to produce clinical signs and symptoms. Among these drugs are tetracycline, methotrexate, anabolic and contraceptive steroids, phenacetin, halothane, chlorpromazine, and phenylbutazone.

Clinical features of hepatitis include malaise, fever, jaundice, and serum chemical tests revealing evidence of abnormal liver function. In most mild cases of hepatitis, treatment consists of bedrest and analgesic drugs. In those individuals who develop a great deal of liver cell necrosis and subsequently progress into a condition known as hepatic encephalopathy, exchange blood transfusions are often used. This is done with the hope of removing or diluting the toxic chemicals thought to be the cause of this condition. Chronic hepatitis is a condition defined clinically by evidence of liver disease for at least 6 consecutive months. *See* ALCOHOLISM; LIVER DISORDERS. [S.P.H.]

Hepatitis C is a disease of the liver caused by the hepatitis C virus (HCV). The prevalence of HCV infection worldwide is 3% (170 million people), with infection rates in North America ranging from 1 to 2% of the population. A simulation analysis estimated that in the period from 1998 to 2008 there will be an increase of 92% in the incidence of cirrhosis of the liver, resulting in a 126% increase in the incidence of liver, failures and a 102% increase in the incidence of hepatocellular carcinoma (HCC), all attributed to HCV.

Hepatitis C virus can be transmitted only by blood-to-blood contact. With the institution of screening of blood, intravenous drug use has become the major source of transmission in North America. Approximately 89% of people who use intravenous drugs for one year become infected with HCV.

Management strategies can be divided into three main areas: surveillance of patients with chronic HCV infection who have not developed cirrhosis; surveillance of patients with established cirrhosis; and strategies to eradicate HCV. [N.Ar.; N.G.; G.L.]

Herbarium A collection of pressed and dried plant specimens, and a description of when, where, and by whom they were collected, arranged in a systematic manner, and serving as a permanent physical record of the occurrence of an individual plant at a specific place and time. Herbaria may contain specimens from the full range of organisms that have classically been considered plants: fungi, lichens, algae, bryophytes, ferns and their allies, gymnosperms, and angiosperms. Many herbaria also accumulate and manage special collections such as liquid-preserved parts for anatomical studies, wood, seeds, or specially preserved material suitable for extraction of deoxyribonucleic acid (DNA) or other chemical constituents. Many groups of plants, especially those with succulent or fleshy parts, are not suitable for preservation as dry, flat specimens because they lose many of their important features in the drying process. Consequently, these plants are often preserved in liquid. Specimens are used in taxonomic and ecological research, such as morphological studies, and for comparative identification and verification of unknown specimens. *See* PLANT GEOGRAPHY; PLANT TAXONOMY. [J.C.So.]

Herbicide Any chemical used to destroy or inhibit plant growth, especially of weeds or other undesirable vegetation. There are well over a hundred chemicals in common usage as herbicides. Many of these are available in several formulations or under several trade names. The variety of materials are conveniently classified according to the properties of the active ingredient as either selective or nonselective. Selective herbicides are those that kill some members of a plant population with little or no injury to others. Nonselective herbicides are those that kill all vegetation to which they are applied. Further subclassification is by method of application, such as preemergence (soil-applied before plant emergence) or postemergence (applied to plant foliage). Additional terminology sometimes applied to describe the mobility of post-emergence herbicides in the treated plant is contact (nonmobile) or translocated (mobile—that is, killing plants by systemic action).

A rapidly expanding use for nonselective herbicides is the destruction of vegetation before seeding in the practice of reduced tillage or no tillage. Some are also used to kill annual grasses in preparation for seeding perennial grasses in pastures. Additional uses are in fire prevention, elimination of highway hazards, destruction of plants that are hosts for insects and plant diseases, and killing of poisonous or allergen-bearing plants.

Preemergence or postemergence application methods derive naturally from the properties of the herbicidal chemical. The distinction between pre- and postemergence is not always clearcut. For example, atrazine can exert its herbicidal action either following root absorption from a preemergence application or after leaf absorption from a postemergence treatment. [R.O.R.]

Herbig-Haro objects A small, bright, semistellar knot of nebular emission in one of the dark interstellar clouds of gas and dust from which stars form. Herbig-Haro objects are named for G. Herbig and G. Haro, who independently discovered them in the early 1950s. They range in size from 300 to 1000 astronomical units and can vary in intensity over periods of only a few years. Their spectra show the presence of the emission lines characteristically formed behind a radiative shock wave, and suggest masses only about a factor of 10 greater than the mass of the Earth. It is now believed that Herbig-Haro objects are manifestations of the mass-loss phenomenon associated with very young stars. *See* INTERSELLAR MATTER; MOLECULAR CLOUD.

Since the late 1970s, evidence of bipolar outflows has been detected in star-forming regions of the interstellar medium. In this dramatic phase of early stellar evolution, oppositely directed jets of high-speed gas are observed emanating from visible, pre-main-sequence T Tauri stars and, more frequently, from objects so young that their presence within their obscuring, parent clouds can be inferred only from infrared measurements. When these visible jets, which have speeds up to 400 km/s (250 mi/s), collide with the ambient interstellar gas, the violent heating and compression known as a shock wave results. Herbig-Haro objects are frequently the hot spots where the jets hit the surrounding material. Their luminous appearance is the result of excitation of the gas by the shock. *See* PROSTAR; T TAURI STAR.

However, not all Herbig-Haro objects are found at the terminal points of bipolar jets. Particularly when the source of the outflow is a much more luminous star than the Sun, Herbig-Haro objects can be scattered over a wide angular region rather than restricted to a well-defined outflow axis. Alternatively, several well-known Herbig-Haro objects with characteristic spectral emission lines are the brightest knots within individual jets, and probably reflect the presence of internal shocks. *See* STELLAR EVOLUTION. [A.I.S.]

Herbivory The consumption of living plant tissue by animals. Herbivorous species occur in most of the major taxonomic groups of animals. Herbivorous insects alone may account for one-quarter of all species. The fraction of all plant biomass that is eaten by herbivores varies widely among plants and ecosystems, ranging from less than 1% to nearly 90%. In terms of both the number of species involved and the role that herbivory plays in the flow of energy and nutrients in ecosystems, herbivory is a key ecological interaction between species.

Herbivory usually does not kill the plant outright, although there are striking exceptions (such as bark beetle outbreaks that decimate conifer trees over thousands of square kilometers). Nevertheless, chronic attack by herbivores can have dramatic cumulative effects on the size, longevity, or reproductive output of individual plants. As a consequence, plants have evolved several means to reduce the level of damage from herbivores and to amellorate the impact of damage.

Many plants possess physical defenses that interfere mechanically with herbivore feeding on or attachment to the plant. In addition, plant tissues may contain chemical compounds that render them less digestible or even toxic to herbivores. Many plant compounds even can cause death if consumed by unadapted herbivores. While natural selection imposed by herbivores was the likely force driving the elaboration of these plant chemicals, humans have subsequently found many uses for the chemicals as active components of spices, stimulants, relaxants, hallucinogens, poisons, and drugs. An exciting recent finding is that some plants possess induced resistance, elevated levels of physical or chemical defenses that are brought on by herbivore damage and confer enhanced resistance to further damage.

Herbivores can either avoid or counteract plant defenses. Many herbivores avoid consuming the plant tissues that contain the highest concentrations of toxic or antinutritive chemicals. Herbivores have also evolved an elaborate array of enzymes to detoxify otherwise lethal plant chemicals. Because few herbivores have the ability to detoxify the chemical compounds produced by all the plant species they encounter, many herbivores have restricted diets; the larvae of more than half of all species of butterflies and moths include only a single genus of plants in their diets. Some insect species that have evolved the means to tolerate toxic plant chemicals have also evolved ways to use them in their own defense. Larvae of willow beetles store plant compounds in glands along their back. When the larvae are disturbed, the glands exude droplets of the foul-smelling compounds, which deter many potential predators.

If a plant evolved the ability to produce a novel chemical compound that its herbivores could not detoxify, the plant and its descendants would be freed for a time from the negative effects of herbivory. A herbivore that then evolved the means to detoxify the new compound would enjoy an abundance of food and would increase until the level of herbivory on the plant was once again high, favoring plants that acquire yet another novel antiherbivore compound. These repeated rounds of evolution of plant defenses and herbivore countermeasures (coevolution) over long periods of time help to explain similar patterns of evolutionary relatedness between groups of plant species and the herbivorous insect species that feed on them.

Plants and their herbivores seldom occur in isolation, and other species can influence the interaction between plants and herbivores. For example, mammalian herbivores often rely on gut microorganisms to digest cellulose in the plant material they consume. Thus, herbivory occurs against a backdrop of multiple interactions involving the plants, the herbivores, and other species in the ecological community. [W.F.Mo.]

Hermaphroditism A condition in which components of both testes and ovaries are present in the same individual. Although true hermaphroditism is common among lower forms of animals such as annelids and mollusks, it is rare in humans. A more common condition in humans is pseudohermaphroditism, which simulates hermaphroditism. In female pseudohermaphroditism, or gynandry, the external sexual characteristics are in part or wholly of the male aspect, but internal female genitalia are present. In male pseudohermaphroditism, or androgyny, the individual has external sexual characteristics of female aspect, but has testes (usually undescended). *See* OVARY; REPRODUCTIVE SYSTEM DISORDERS; TESTIS. [S.P.P.]

Hernia The protrusion of an organ, part of an organ, or other structure through the wall of the body cavity normally containing it. Various organs may be involved, including the bladder, brain, esophagus, intestine, ovary, and rectum. The most common location for a hernial bulge to appear is the abdominal wall, particularly the groin.

Among the most infrequent but life-threatening hernias is a cerebral hernia in which part of the brain protrudes through an opening in the skull.

A diaphragmatic hernia, which occurs when a defect is present in the muscular diaphragm separating chest from abdomen, may be present at birth or result from an injury later in life. Abdominal organs, such as the liver, spleen, stomach, and intestine, can pass through the diaphragmatic defect and lodge in the chest cavity, so that the lungs become compressed and breathing is impaired. Hiatal or esophageal hernia results when a portion of the stomach slides into the chest cavity through the normal diaphragmatic opening for the esophagus.

Groin hernias consist of two major types, inguinal and femoral. Inguinal hernias account for 75% of all hernias of the body, and are divided into two anatomic variants, indirect and direct. Indirect inguinal hernias are caused by a weakness in the abdominal wall that corresponds to an area where the testis descended into the scrotum during embryological development. With direct inguinal hernias, the defect results mainly from strain on the abdominal muscles which have been weakened by age. Inguinal hernias are 10 times as common in men as in women. Femoral hernias are more common in women, but are infrequent. The weakness in a femoral hernia originates in the area where the major veins, arteries, and nerves pass from the abdomen into the lower extremities. A femoral hernia bulge is always located in the upper inner part of the thigh, just below the groin crease.

With rare exceptions, all hernias should be corrected surgically to prevent the possibilities of incarceration, intestinal obstruction, and strangulation. [I.M.R.]

Herpes Any virus of the herpesvirus group, which comprises a family of 70 species, 5 of which are pathogenic to humans; the term also refers to any infection caused by these viruses. Since these pathogens are ubiquitous in nature, most individuals of all populations are exposed to and thus immunized to these viruses. The five pathogenic groups include herpes simplex I and II, varicella-zoster, cytomegalovirus, and the Epstein-Barr virus.

In nonimmunized hosts, the vast majority of all herpes infections present symptoms of nonspecific viral illnesses which resolve spontaneously. However, the infections that cause clinical disease in fact may cause serious morbidity and mortality in afflicted individuals. Reactivation of herpes infection, characteristic of the immunocompromised host, is an important cause of mortality in the treatment of patients with advanced cancer, and is a potential complication of an otherwise possibly curable systemic disease.

Herpesviruses have a deoxyribonucleic acid (DNA) core and are 150 to 200 nanometers in size with icosahedral symmetry, and are coated by a protein barrier, the capsid, derived from the infected host cells. The surface of the virions in general contains protein-carbohydrate structures which allow cellular attachment and thus cellular penetration. All viruses require living cells for their replication; the virus may replicate and destroy the cell, or replicate and allow cell survival, or incorporate its viral gene structure into the host gene structure. This incorporation phenomenon is designated as latency. For example, herpes simplex virus exhibits the phenomenon of latency within nerve cells in the area of previous infection. The Epstein-Barr virus characteristically causes latent infection in lymphocytes (white blood cells in the circulating blood), and the cytomegalic virus also causes latent infection within lymphocytes and possibly within nerve cells. Once the viral genome is incorporated into the host cell, antiviral drugs are of no use, since therapeutic agents cannot selectively destroy or inhibit the viral genome. Factors which are possibly involved in the reactivation of latent virus generally revolve around some depression of the host immune response system. Viral genome incorporation into host cells is of great interest as several herpesvirus types are implicated in the development of cancer. *See* VIRUS INFECTION, LATENT, PERSISTENT, SLOW.

The foundation of therapeutic intervention for all herpesviruses involves a series of chemicals with structures similar to the base pairs which compose the viral DNA structure. The base analogs compete with or inhibit viral enzymes necessary for the assembly of DNA. *See* VIRUS.

Herpes simplex I and II infections are spread by intimate contact of mucocutaneous surfaces during the period of virus shedding from active lesions. They usually affect the genitalia, but may affect the oral mucosa, causing painful ulcerations which crust and heal. Upon healing, the virus resides in latent form within local nerve cells. Viral reactivation is poorly understood, but may relate in part to the host immune system. The type II virus has been linked to the development of uterine cervical carcinoma, however its precise role remains a question.

Herpes simplex virus I (cold sores, fever blisters) afflicts 20–40% of the population in the United States and usually affects the oropharynx, causing pharyngitis, tonsillitis, gingivostomatitis, or keratitis (eye inflammation) as primary infections. Inflammation of the mouth, eye, or brain may occur as a secondary infection.

Primary infection (airborne) due to herpes varicella-zoster usually affects preschool children, causing chickenpox, with rare complications usually affecting the immunocompromised host. Secondary infection usually afflicts the elderly when latent viral reactivation occurs, presumably due to an immune imbalance in the host, and involves the spread of virus along the skin in the anatomic distribution of nerve (this disorder is known as shingles). *See* CHICKENPOX AND SHINGLES.

Cytomegalovirus is ubiquitous, with the majority of infections remaining subclinical. Adult syndromes include a mononucleosislike syndrome and hepatitis, both of which are self-limited diseases in the normal host. However, reactivation of latent infection is a major source of morbidity and especially mortality in the compromised host, for example, the patient being treated with chemoradiotherapy for advanced malignant disease. *See* CYTOMEGALOVIRUS INFECTION; HEPATITIS.

The characteristic clinical syndrome caused by Epstein-Barr virus infection includes generalized lymphadenopathy, hepatosplenomegaly, pharyngitis, tonsillitis, and general fatigue and fever. This disorder affects individuals of all ages, but predominantly adolescents. The majority of children are subclinically infected. This mononucleosis syndrome is usually a self-limited disorder, and investigational drugs in use for prophylaxis of high-risk individuals include interferons and acyclovir. Epstein-Barr virus is suspected to be of etiologic importance in Burkitt's African lymphoma. *See* ANIMAL VIRUS; EPSTEIN-BARR VIRUS; VIRUS CHEMOPROPHYLAXIS. [D.J.D.]

Herrings The common name for a family (Clupeidae) of about 70 genera of fishes in the order Clupeiformes. They are used extensively as food all over the world, and occur in all seas except the Arctic and Antarctic.

These fishes are the most primitive of the higher bony fishes. The fins have no supporting spines and are soft-rayed. There are usually four gill clefts, with the pectoral fins behind the gill openings. Scales are present on the body but absent on the head, and the swim bladder and lateral line may be missing.

The herring *Clupea harengus* has a circumpolar distribution. About eight other species of this genus are recognized, including the sprat or brisling (*C. sprattus*), which occurs in the Mediterranean and seas of western Europe, and the gizzard shad (*Dorosoma cepedicmum*), which is a common species in the Potomac River. In Europe the herring is either salted, pickled, or smoked and cured as kippers. In Canada and the United States young herring are canned as "sardines."

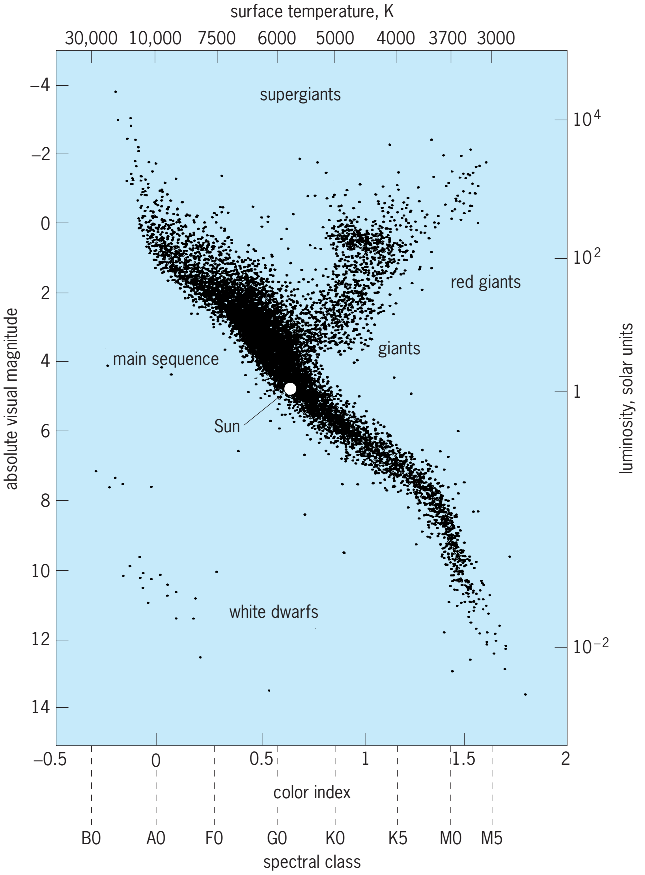
The sardine, *Sardina pilchardus*, is a herring known commonly as the pilchard and is found along the European coasts in the Atlantic. The entire fish may be processed and preserved in oil, since the bones are soft and all parts are edible. Shads, herrings of the genus *Alosa*, occur in northern waters on both sides of the Atlantic. Anchovies comprise a family of herringlike fish, the Engraudidae, which together with the Clupeidae belong to the suborder Clupoidea. These fishes are found in the Mediterranean and range along the European coast as far north as Norway. *See* CLUPEIFORMES. [C.B.C.]

Hertzsprung-Russell diagram A two-dimensional diagram used extensively in astronomy, developed independently by Ejnar Hertzsprung in 1911 and Henry Norris Russell in 1913. In its original form, the Hertzsprung-Russell (H-R) diagram was a plot of absolute visual magnitude versus spectral type (O, B, A, and so on). Variants are now commonly used, avoiding requirements of and uncertainties due to spectral classification. The vertical axis of the diagram is some suitable measure of the power output of the star, while the horizontal axis indicates the temperature (or color) of the star's visible surface, or the corresponding spectral type. Each point in the plot represents a nearby star of known distance. In any of its forms, the diagram reveals the most fundamental correlation among observed stellar properties discovered to date. *See* MAGNITUDE (ASTRONOMY); SPECTRAL TYPE.

In its observational form, also referred to as a color-magnitude diagram, absolute magnitude is used as ordinate, although apparent magnitude may be used for a collection of stars at a common distance. Brighter stars (that is, those with higher luminosities, and smaller numerical values of the magnitude) appear at the top of the diagram. The color scale is usually a color index constructed as the difference between the magnitudes measured in two chosen spectral bands. For historical reasons, the bluest color index (corresponding to the highest temperatures) appears at the left. *See* COLOR INDEX.

The illustration shows the Hertzsprung-Russell diagram for about 15,000 single stars from the compilation of nearly 120,000 stellar distances measured by the *Hipparcos* satellite. The absolute visual magnitude scale runs from −5 to 15, corresponding to a range of 10^8 in star luminosity. The color index scale corresponds to effective temperatures ranging from around 100,000 K (180,000°F) at the left to about 2500 K (4000°F).

From the upper left (blue, high-luminosity stars) to the lower right (red, low-luminosity stars) a prominent concentration of objects defines the main sequence. Stars located on the main sequence are also called dwarfs. They include stars such as Sirius, and are assigned luminosity class V in the MK stellar classification system. (In this system, two parameters, spectral type and luminosity class, categorize each star.) Along the main sequence, the luminosity of a star and its surface temperature are tightly correlated. Stellar structure theory successfully models this relationship. The main-sequence stars are at the early phases of their lives, and are powered by the fusing of hydrogen to helium in their centers. Masses of the main-sequence stars increase going toward the upper left of the diagram (reaching almost 100 times the Sun's mass) and decrease going to the lower right (to about one-tenth of the Sun's mass). Due to their higher central temperatures and pressures, the more massive stars are burning hydrogen more rapidly and are therefore brighter. *See* DWARF STAR.



Hertzsprung-Russell diagram for about 15,000 stars within a sphere of radius 100 parsecs, taken from the *Hipparcos Catalogue*. The color index and absolute visual magnitude scales are directly measured. The spectral class, surface temperature, and luminosity (in terms of solar luminosity) are approximate relationships appropriate for the main sequence.

Extending from the main sequence in the direction toward lower temperatures, and at roughly constant luminosity, are the luminosity class III giant stars (such as Vega) and the clump of more luminous red giants. Even more luminous supergiants, of luminosity class I (such as Arcturus and Procyon), are sparsely represented but occupy a broad range of color index at the very highest luminosities. They reach absolute magnitudes of less than −5, corresponding to luminosities some 10^4 times brighter than the Sun, and with radii around 1000 times that of the Sun. The lower left part of the diagram is not entirely empty and contains the white dwarfs: hotter than the Sun, but much less luminous (typically 10^4 times fainter) and of much smaller radius (about 1% of the Sun's radius). *See* GIANT STAR; SUPERGIANT STAR; WHITE DWARF STAR.

The Hertzsprung-Russell diagram says nothing, at least directly, about the mass, chemical composition, or age and state of evolution of a star. However, comparisons between observations (such as the illustration) and the predictions of stellar evolution theory allow stringent constraints to be placed on models of the structure, chemical composition, and evolution of stars. *See* STAR; STELLAR EVOLUTION. [M.A.C.P.]

Hesperornithiformes A small order of Cretaceous, toothed fossil birds that comprises the families Enaliornithidae, Baptornithidae, and Hesperornithidae. They were mostly flightless marine birds specialized for diving, whose fossils have been found through most of the Cretaceous of North America and Europe and with one species known from Chile. Although the hesperornithiforms are similar in body form and habits to the living loons, grebes, and penguins, they are not closely related and their resemblances are the result of convergent evolution. Hesperornithiformes is placed in the superorder Odontognathae with Ichthyornithiformes solely because those two orders comprise the only modern birds still possessing teeth. The relationships of the two orders must still be demonstrated with additional evidence, however. *See* Aves; Gaviiformes; Ichthyornithiformes; Odontognathae; Podicipediformes; Sphenisciformes. [W.J.B.]

Heterochrony An evolutionary phenomenon that involves changes in the rate and timing of development. As animals and plants grow from their earliest embryonic stages to the adult, they undergo changes in shape and size. This life history of an individual organism is known as its ontogeny. The amount of growth that an organism experiences during its ontogeny can be more or less than its ancestor. This can apply to the organism as a whole or to specific parts.

Evolution can be viewed as a branching tree of modified ontogenies. Heterochrony that produces these changes in size and shape may be the link between genetics at one extreme and natural selection at the other.

If a character of one species in an evolutionary sequence undergoes less growth than its ancestor, the process is known as pedomorphosis. If it undergoes more growth, the process is known as peramorphosis. Each state can be achieved by varying the timing of onset, offset, or rate of development.

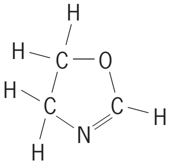
If development is stopped at an earlier growth stage in the descendant than in the ancestor (for example, by earlier onset of sexual maturity), ancestral juvenile features will be retained by the descendant adult (progenesis). If the onset of development of a particular structure is delayed in a descendant, the structure will develop less than in the ancestor (postdisplacement). The third process that produces pedomorphosis is neoteny, whereby the rate of growth is reduced.

For peramorphosis, development can start earlier in the descendant than in the ancestor (predisplacement); or the rate of development can be increased, thus increasing the allometric coefficient (acceleration); or development can be extended by a delay in the onset of sexual maturity (hypermorphosis).

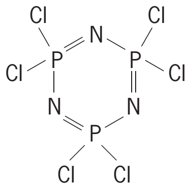
As an organism grows, the number of cells that it produces increases. Ultimately, changes to rate and timing of growth are reflections of changes to the timing of onset and rate of cell development, and the balance between cell growth and cell death. Morphogens and growth hormones play a major role in controlling development in terms of initiation, rate of division, and migration. Therefore, changes to the timing of their expression affect the shape and size of the final adult structure. Inception of hormonal activity is under the control of genes that regulate the timing of its production. [K.J.McN.]

Heterocorallia A small, extinct, late Paleozoic order of fossil corals, known from Europe, North Africa, Asia, North America, and Australia, but limited to the Late Mississippian. They are found in calcareous shales and in limestones. Their very elongate skeletons, and the hooks on the outer septal edges of some, suggest a pseudoplanktonic existence attached to seaweeds. There are but rare indications of branching. *See* Coelenterata. [D.H.]

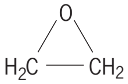
Heterocyclic compounds Cyclic compounds in which the rings include at least one atom of an element different from the rest. Most types of heterocyclic compounds studied to date are organic compounds. An example of an organic heterocyclic compound is oxazoline (**1**); an example of an inorganic heterocyclic compound is the phosphonitrilic chloride (**2**). The smallest possible ring is three-membered, for example, ethylene oxide (**3**), but very large rings are possible, as in the crown ethers, for example, 18-crown-6 (**4**). The cycle may contain only single bonds and is thus saturated; it may include one or more double bonds; or it may possess aromatic unsaturation characteristics of benzene, that is, it is heteroaromatic. Heterocyclic compounds can contain more than one ring, either heterocyclic or homocyclic.



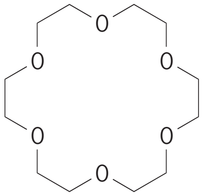
(1)



(2)



(3)



(4)

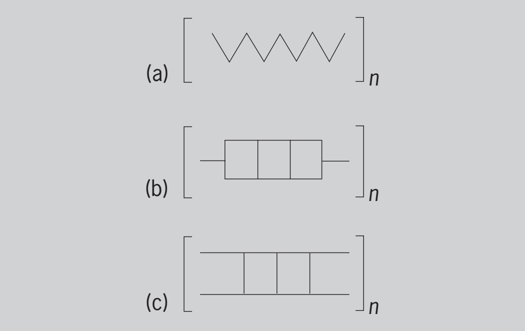
Naturally occurring heterocyclic compounds are extremely common as, for example, most alkaloids, sugars, vitamins, DNA and RNA, enzymic cofactors, plant pigments, many of the components of coal tar, many natural pigments (such as indigo, chlorophyll, hemoglobin, and the anthocyanins), antibiotics (such as penicillin and streptomycin), and some of the essential amino acids (for example, tryptophan), and many of the peptides (such as oxytocin). Some of the most important naturally occurring high polymers are heterocyclic, including starch and cellulose. The major groups of natural products that are not mainly heterocyclic are the fats and most of the terpenes, steroids, and essential α-amino acids, though exceptions do exist.

Heterocyclic compounds may be named systematically. Many heterocycles, however, have nonsystematic names that are usually preferred by practicing chemists over the systematic ones. In the systematic approach to nomenclature the ring size is denoted by the appropriate stem. For example, three-membered saturated rings without nitrogen would have a name ending in -irane. The nature of the heteroatom is denoted by such prefixes as oxa-, thia-, or aza-, for oxygen, sulfur, or nitrogen, respectively. Thus, ethylene oxide (**3**) becomes oxirane. A five-membered unsaturated ring would have a name ending in -ole. A six-membered unsaturated ring containing nitrogen would have a name ending in -ine according to this scheme. Actually, the trivial names for many systems are commonly accepted, and the systematic names are not often used.

For details about specific heterocyclic systems *see* Furan; Heterocyclic polymer; Indole; Pyridine; Pyrimidine; Pyrrole; Thiophene. [R.A.A.]

Heterocyclic polymer Essentially, linear high polymers comprising heterocyclic rings, or groups of rings, linked together by one or more covalent bonds. As the search has continued for polymeric materials having useful properties at high temperatures (500°C or 930°F, or higher), much attention has been given to heterocyclic polymers. As a group such polymers are often both mechanically rigid and inherently resistant to thermal degradation. *See* Polymer.

Some of these polymers form molecules in which the rings are fused together, as shown symbolically in the illustration (ladder



Structural units in linear polymers. (*a*) Simple linear polymer. (*b*) Stepladder polymer. (*c*) Ladder polymer.

polymers), and some form molecules in which fused rings are joined by single bonds (stepladder polymers). Similar considerations hold for simple aromatic systems, for example, linear polymers of benzene, but the heterocyclic systems have, in general, been more useful in application.

Three heterocyclic polymers have been developed to the point of commercial availability; polyimides, polybenzimidazoles, and polybenzothiazoles. At least the first two appear to have established specialized markets.

Major applications for these rather expensive polymers are as metal-to-metal adhesives and as laminating resins for fibrous composites for structural applications in the aerospace industry. Other applications requiring both strength and resistance to oxidation at elevated temperatures have developed, including valve seats, bearings, and turbine blades. *See* POLYMERIC COMPOSITE. [J.A.M.]

Heterodyne principle The basic principle underlying the operation of a superheterodyne radio, television, or other receiver, wherein two alternating currents that differ in frequency are mixed in a nonlinear device to produce two new frequencies, corresponding to the sum and the difference of the input frequencies. Only the difference frequency is commonly used in a superheterodyne receiver, where it serves as the input to the intermediate-frequency amplifier. *See* RADIO RECEIVER. [J.Mar.]

Heterogeneous catalysis A chemical process in which the catalyst is present in a separate phase. In the usual case, the catalyst is a solid and the reactants and products are in gaseous or liquid phases. *See* CATALYSIS.

Heterogeneous catalysis proceeds by the formation and subsequent reaction of chemisorbed complexes which can be considered to be surface chemical compounds. A very simple case, where A → B is slow in the absence of catalyst, is shown in the following reaction:

$$\left.\begin{array}{l} {}^{*} + \mathrm{A} \rightarrow {}^{*}\mathrm{A} \\ \mathrm{A}^{*} \rightarrow \mathrm{B}^{*} \\ \mathrm{B}^{*} \rightarrow \mathrm{B} + {}^{*} \\ \mathrm{A} \rightarrow \mathrm{B} \end{array}\right\} \text{chain propagating steps}$$

Reaction A → B is fast if the three preceding steps are fast. Here, * represents a catalytic site on the surface of the catalyst, $\mathrm{A}^{*} \rightarrow \mathrm{B}^{*}$ is called a surface reaction, $^{*} + \mathrm{A} \rightarrow {}^{*}\mathrm{A}$ represents the chemisorption of A, and $\mathrm{B}^{*} \rightarrow \mathrm{B} + {}^{*}$ represents desorption of B. *See* ADSORPTION.

With most sets of reactants, more than one reaction will be thermodynamically possible. The degree to which a given catalyst favors one reaction compared with other possible reactions is called the selectivity of the catalyst for the reaction. Two aspects of a catalyst are of particular importance: its selectivity, and its activity, which can be taken as the rate of conversion of reactants by a given amount of catalyst under specified conditions. Ideally, the rate will be proportional to the amount of catalyst.

The first important heterogeneous catalytic process to be used in the chemical industry was the manufacture of sulfuric acid from sulfur trioxide by the contact process in 1875. By the 1950s, heterogeneous catalytic processes had come to dominate the petroleum, petrochemical, and chemical industries. Today, about 70% of the crude oil refined in the United States is exposed to at least one heterogeneous catalytic process. Heterogeneous catalysis is a critical feature in energy conservation and interconversion, and is a key feature in the production of synthetic fuels from coal and oil shale. *See* COAL GASIFICATION; FISCHER-TROPSCH PROCESS.

Since catalytic activity will ordinarily be proportional to surface area, most catalysts are used in forms with large specific areas. Higher-area metal powders are often used for liquid-phase reactions in batch reactors. For example, finely divided nickel is used for the hydrogenation of unsaturated glycerides in the manufacture of margarine from vegetable oils. Supported catalysts are widely used. In these, the catalytic ingredient is dispersed in the internal porosity of such supports as silica gel, γ-alumina, and charcoals. These supports have large areas in the internal porosity, and their average pore diameters are 2–20 nm. Supported catalysts have the advantage that the area of the catalytic ingredient can be very large.

One important type of catalyst exposes strongly acidic sites in its internal porosity. Such catalysts are used to crack larger molecules of hydrocarbon into smaller ones in petroleum refining. Other catalysts, called dual-functional catalysts, have a hydrogenating catalytic ingredient on an acidic support. These are also of major importance in processing petroleum. *See* CRACKING; HYDROCRACKING; ZEOLITE. [R.L.Bu.; G.L.H.]

Heteronemertini An order of the class Anopla in the phylum Rhynchocoela, with an unarmed proboscis, a thick partly fibrous dermis, and a three-layered body musculature composed of outer longitudinal, median circular, and inner longitudinal strata. Cerebral organs, cephalic grooves and slits, and eyes are generally present. The alimentary system consists of a mouth, foregut, intestine with regular lateral diverticula but no cecum, and anus. Heteronemertini are mainly marine littoral in habit. *See* ANOPLA; RHYNCHOCOELA. [J.B.J.]

Heterophile antigen The serologic reactions of the tissue and blood-cell antigens of most animals are normally characteristic of the species. Significant serologic cross reactions usually occur only with antisera to the corresponding antigens of closely related species. The numerous groups of heterophile antigens—of which the Forssman antigens are the best studied—constitute significant exceptions. Heterophile antigens link the species hog-ox-human (blood group A), cat-horse, and dog-hog-cat-human, while several heterophile groups link otherwise diverse microorganisms. Similarities between antigens in mammalian hearts and the cell walls of the group A hemolytic streptococcus are also known. The cross reactions between the *Proteus* bacillus and the *Rickettsiae* are important in the diagnosis of typhus fever. *See* ANTIBODY; ANTIGEN; SEROLOGY. [M.J.Po.]

Heterosis Hybrid vigor or increase in size, yield, and performance found in hybrids, especially if the parents have previously been inbred. The application of heterosis has been one of the most important contributions of genetics to scientific agriculture in providing hybrid corn, and vigorous, high-yielding hybrids in other plants and in livestock. *See* BREEDING (ANIMAL); BREEDING (PLANT); GENETICS; MENDELISM.

There are two principal hypotheses to account for the association of size and vigor with heterozygosity, dominance and overdominance. The dominance hypothesis notes that any noninbred population carries a number of recessive genes that are harmful to a greater or lesser extent, but which are rendered ineffective by their dominant alleles. As they become homozygous through inbreeding, they exert their harmful effect. With hybridization, some of the detrimental recessives contributed to the hybrid by one parent are masked by dominant alleles from the other, and an increase in vigor is the result. The alternative hypothesis is that there are loci at which the heterozygote is superior in vigor to either homozygote. This, the overdominance hypothesis, also has the consequence that vigor is proportional to heterozygosity. The dominance hypothesis has been more widely accepted, but the two are very difficult to distinguish experimentally, and it is likely that overdominant loci are playing an appreciable role in heterosis, particularly in determining why one hybrid is better than another. *See* DOMINANCE. [J.F.Cr.]

Heterostraci An extinct group of ostracoderms or armored, jawless vertebrates (Agnatha). The armor has a distinctive microscopic structure, consisting of bone lacking any cavities for bone cells, surmounted by tubercles or ridges of dentine. Fragments of such armor from the Middle Ordovician of Australia and North America are the earliest remains definitely attributable to vertebrates. Heterostraci became more common toward the end of the Silurian and persisted through the Devonian.

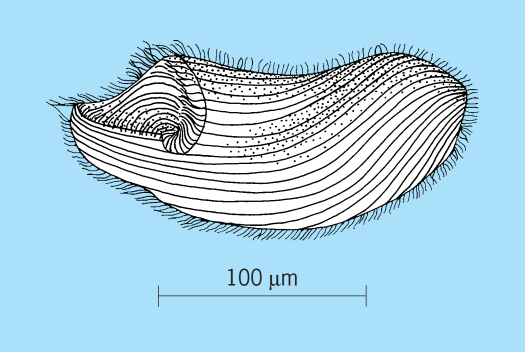
The anterior part of the body was covered with plates. The posterior part of the body and the tail were covered with thick scales. There were no jaws, but the mouth was bounded behind by a number of small plates that may have been used for nibbling. [R.H.De.]

Heterotardigrada An order of the tardigrades; the majority of genera have widely varied structure. Cephalic appendages having a sensorial function are present, as well as cirrus lateralis and clava. This order of tardigrades is divided into two suborders, Arthrotardigrada and Echiniscoidea.

Members of the suborder Arthrotardigrada have toelike terminations of the legs. The tubular middle part of the leg telescopes into the broad proximal part. These animals are marine organisms found in sand or on algae.

In the suborder Echiniscoidea the legs terminate with claws. The middle part of the leg is partially retractable into the proximal part. At least the fourth pair of legs has a distinct fold. Frequently these animals are red because of the presence of carotenoid pigments. *See* CAROTENOID; TARDIGRADA. [Ev.M.]

Heterotrichida A large order of the Spirotrichia. The buccal ciliature is well developed, although in a number of families the somatic, or body, ciliature is really holotrichous in nature. Heterotrichs have become adapted to all sorts of habitats, including the digestive tracts of a variety of invertebrate and a few vertebrate hosts. Because of their size and amazing regenerative powers, a number of heterotrichs have been widely used in experimental research. Common genera include *Stentor*, *Blepharisma*, *Folliculina*, *Condylostoma*, *Climacostomum* (see illustration), and *Spirostomum*. *See* SPIROTRICHIA. [J.O.C.]



***Climacostomum*, an example of a heterotrich.**

Heulandite A mineral belonging to the zeolite family of silicates. It usually occurs in crystals with the prominent side being pinacoid, often having a diamond shape. There is perfect side pinacoid cleavage on which the luster is pearly; elsewhere the luster is vitreous. The hardness is $3^1/_2$ to 4 on Mohs scale; specific gravity is 2.18–2.20. The mineral is usually white or colorless but may be yellow or red. *See* ZEOLITE.

Heulandite is essentially a hydrous calcium aluminum silicate, $Ca(Al_2Si_7O_{18}) \cdot 6H_2O$. Heulandite is a secondary mineral found in cavities in basalts associated with other zeolites and calcite. Notable localities are in the Faeroe Islands, India, Nova Scotia, and West Paterson, New Jersey. [C.Fr.; C.S.Hu.]

Hexactinellida A class of sponges whose skeletons are made of siliceous hexactine spicules. These exclusively marine sponges are widely distributed in modern oceans. Their fossil record extends from the late Precambrian to the Recent. The basic spicule type of the class is a triaxial hexactine, in which the three pairs of opposed rays are at right angles to each other and lie along one of the three axes of a cube. Proximal ray ends and axial filaments meet at the center of the cube. These principal spicules and variants of that form make up skeletons of the sponges.

Recent hexactinellid sponges are chiefly upper bathyal marine animals and are most common in depths of 200–2000 m (660–6560 ft), although many species are known to inhabit lower bathyal depths. Living hexactinellid sponges are commonly goblet- or vase-shaped, although branched, massive, tubular, or ropy-appearing sponges also occur in the class. Many have root tufts of long spicules that anchor them in place and support them above the sea floor.

The following classification is a combination of ones used in living and fossil sponges. *See* PORIFERA.

Class Hexactinellida
  Subclass Hexasterophora
    Order Lyssacinosida
    Order Hexactinosida
    Order Lychniscosida
  Subclass Amphidiscophora
    Order Reticulosa
    Order Amphidiscosa
    Order Hemidiscosa [J.K.Ri.]

Hexactinosa An order of the subclass Hexasterophora in the class Hexactinellida. The parenchymal megascleres in this order of sponges are united to form a rigid framework and consist wholly of simple hexactins which are arranged in parallel linear series. The members of each series are united one to another by a secondary envelope of silica. *See* HEXACTINELLIDA; HEXASTEROPHORA. [W.D.H.]

Hexasterophora A subclass of sponges of the class Hexactinellida, in which the parenchymal microscleres are typically hexasters (small, six-rayed spicules, often with branched ends). This is a diverse assemblage of sponges commonly firmly fixed to the substratum by the base, less commonly anchored by means of basal spicule tufts or mats. The spicules of the body are sometimes free and unconnected, but the parenchymal megas-cleres are often fused to form a rigidly connected skeleton. The following orders are recognized: Hexactinosa, Lychniscosa, Lyssacinosa, and Reticulosa. *See* HEXACTINOSA; LYCHNISCOSA; LYSSACINOSA; PORIFERA; RETICULOSA. [W.D.H.]

Hibernation A term generally applied to a condition of dormancy and torpor found in cold-blooded (poikilotherm) vertebrates and invertebrates. (The term is also applied to relatively few species of mammals and birds, which are warm-blooded vertebrates.) This rather universal phenomenon can be readily seen when body temperatures of poikilotherm animals drop in a parallel relation to ambient environmental temperatures.

Poikilotherm animals. Hibernation occurs with exposure to low temperatures and, under normal conditions, occurs principally during winter seasons when there are lengthy periods of low environmental temperatures. A related form of dormancy is known as estivation. Many animals estivate when they are exposed to prolonged periods of drought or during hot, dry summers. For all practical purposes, hibernation and estivation in animals are indistinguishable, except for the nature of the stimulus, which is either cold or an arid environment.

There is no complete list of animals that hibernate; however, many examples can be found among the poikilotherms, both vertebrate and invertebrate. The poikilotherms are sometimes referred to as ectothermic, because their body temperatures are not internally regulated but follow the rise and fall of environmental temperatures. During hibernation and winter torpor, body temperatures reflect the environmental temperature, often to within a fraction of a degree. Among the classic examples of hibernators or estivators are reptiles, amphibians, and fishes among the vertebrates, and insects, mollusks, and many other invertebrates.

For many ectothermic vertebrates (fishes, amphibians, and reptiles) the ability to avoid seasonal and periodic environmental rigors by entering a state of metabolic inactivity is a crucial element in their survival. Specifically, winter dormancy and summer estivation—the usual context in which these terms are applied to ectotherms—permit these animals to survive and flourish, first, by reducing the impact of seasonal extremes and, second, by significantly lowering the ectotherm's energetic costs during times that would not be favorable for activity (that is, when food is available).

Many terrestrial reptiles, such as lizards, snakes, and turtles, become dormant and hibernate by burrowing in crevices under rocks, logs, and in the ground below the frost line. Terraqueous turtles also become cold-torpid and may often be found completely submerged in mud and in ponds under ice.

Since the hibernating reptile is subject to the caprices of duration of seasonal low temperature, there is no well-defined period of dormancy. The period of hibernation may often be related to latitudinal positions as evidenced by the turtle family Emydae. Species that inhabit the northern climes will hibernate longer than their southern relatives, thus showing hibernation periods which are proportional to the length of the winter period. Hibernating reptiles show a loss of appetite and discontinue the ingestion of food. Although the metabolic rate is reduced as much as 95% in hibernating turtles, there is some utilization of stored food products. There are two principal types of reserve food: lipids and glycogen, the animal starch, which is less stable and more rapidly used than fats. Glycogen is generally localized in tissues such as liver and muscle. There is evidence that these reserve foods are selectively utilized. In hibernating turtles, the tissue glycogen is used during the initial days and weeks of hibernation; later, the lipids are utilized.

A major hazard to hibernating poikilotherms is death from freezing; ice crystals form in free protoplasmic water and ultimately destroy the cells and tissues, causing the death of the animal. Frogs, salamanders, and turtles are able to survive, despite the reduction in body temperatures to about 32 to 31°F (0 to -1°C). As winter approaches, the water content of the tissues becomes reduced and the blood more concentrated.

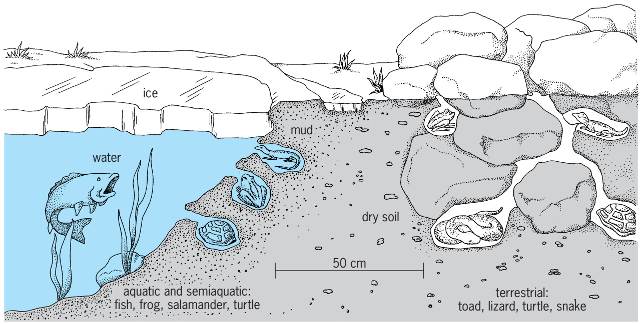
Hibernation in fishes does not occur. Many fishes do, however, spend much of the winter in a state of quiescence while partially frozen in mud and ice.

The phenomenon of estivation is best known in the dipnoans, that is, the lungfishes. These fishes are restricted to tropical regions marked by repeated seasons of drought. They survive the dry seasons by becoming dormant and torpid. The lungfishes are among the more primitive air-breathing animals possessing a lung which utilizes atmospheric oxygen. This lung becomes the primary organ of respiration during the torpidity of estivation. In general, the lungfishes follow a similar behavioral pattern as the dry seasons approach. *Protopterus*, for example, burrows in the bottom mud as the water begins to diminish during the dry season. A lifeline of air is provided by the tunnel from the burrow to the surface. In preparation for estivation, *Protopterus* secretes a slimy mucus around itself which hardens in a tight cocoonlike chamber, preventing the desiccation of the fish. There is but one opening, formed around the mouth. Thus the air from the tunnel enters the mouth and passes to the lung apparatus. At the termination of the dry season, water slowly enters the burrow, softens the contents, and awakens the lungfish. The metabolism of the lungfish is at a low ebb during estivation, with the energy for its modest life processes provided by the utilization of tissue protein.

In some snails estivation may be extended for years at a time, and among the insects and spiders the period of hibernation becomes intimately associated with a phase in the life cycle. During the winter months and during a hot dry summer, the soil contains a remarkable variety of torpid invertebrates, for example, earthworms, snails and slugs, nematodes, insects and spiders, grubs, larvae, and pupae of many insects, egg cases, and cocoons.

Insects overwinter, for the most part, in the egg or larval stage of metamorphosis. Hibernation frequently becomes integrated with the diapause, or arrested development, of the egg or larva which occurs during the winter. The familiar cocoon of the butterfly is the hibernaculum of the larva and pupa. *See also* INSECT PHYSIOLOGY.

The phenomenon of encystment is commonplace in the protozoa, or single-celled animals. Encystment is remarkably similar to estivation and hibernation, and an encysted protozoon is extremely quiescent and almost nonmetabolizing. *See* PROTOZOA.



Hibernacula of various cold-blooded vertebrates.

The hibernacula of poikilotherm vertebrates and invertebrates are as varied as the animals themselves (see illustration). The minute cysts in protozoa, the cocoon and egg case of insects and spiders, the burrows and crevices of reptiles, and the dried mucous case of the lungfish, in all instances, protect the animal from evaporation or desiccation and freezing. [X.J.M.]

Warm-blooded vertebrates. Many mammals and some birds spend at least part of the winter in hiding, but remain no more drowsy than in normal sleep. On the other hand, some mammals undergo a profound decrease in metabolic rate and physiological function during the winter, with a body temperature near 32°F (0°C). This condition, sometimes known as deep hibernation, is the only state in which the warm-blooded vertebrate, with its complex mechanisms for temperature control, abandons its warm-blooded state and chills to the temperature of the environment. Between the drowsy condition and deep hibernation are gradations about which little is known. The bear, skunk, raccoon, and badger are animals which become drowsy in winter. Although usually considered the typical hibernator, the bear's body temperature does not drop more than a few degrees.

The deep hibernators are confined to five orders of mammals: the marsupials, the Chiroptera or bats, the insectivores, the rodents, and, probably, the primates. Most, if not all, of the insect-eating bats of temperate climates not only hibernate in the winter, but also drop their body temperature when they roost and sleep. The advantage of this for a small mammal with a disproportionately large heat-losing surface is obvious when conservation of energy is considered. Many rodents are deep hibernators, including ground squirrels, woodchucks, dormice, and hamster. The fat-tailed and mouse lemurs are primates that hibernate or estivate. Among birds, the poorwill (*Phalaenoptilus*) and some hummingbirds and swifts undergo a lowering of body temperature and metabolic rate in cold periods.

With all deep hibernators, except the bats, hibernation is seasonal, usually occurring during the cold winter months. In all cases, it occurs in animals which would face extremely difficult conditions if they had to remain active and search for food. During a preparation period for hibernation, the animals either become fat, like the woodchuck, or store food in their winter quarters, like the chipmunk and hamster. Prior to hibernation, there is a general involution of the endocrine glands, but at least part of this occurs soon after the breeding season and is not directly concerned with hibernation. Animals such as ground squirrels become more torpid during the fall, even when kept in a warm environment, indicating a profound metabolic change which may be controlled by the endocrine glands. In most hibernators lack of food has little if any effect, and the stimulus for hibernation is not known. It has been reported that an extract from the blood of an animal in hibernation will induce hibernation when infused into an active potential hibernator, indicating that the factor which produces hibernation may be bloodborne.

Hibernation in mammals is not caused by an inability to remain warm when exposed to cold, for hibernators are capable of very high metabolic rates and sometimes do not enter hibernation if exposed to cold for months at a time. When the animal is entering hibernation, heart rate and oxygen consumption decline before body temperature, indicating that the animal is actively damping its heat-generating mechanisms. The autonomic nervous system is involved in this process. As normal hibernation deepens, the heart rate, blood pressure, metabolic rate, and body temperature slowly drop, but in some animals periodic bouts of shivering and increased oxygen consumption occur, elevating the body temperature temporarily and causing a stepwise entrance into hibernation. *See* AUTONOMIC NERVOUS SYSTEM.

In deep hibernation at a steady state the body temperature is 33–35.5°F (0.5–2°C) above that of the environment, and it is a peculiarity of hibernators that the vital processes can function at lower temperatures than those of nonhibernators. The heart rate varies between 3 and 15 beats per minute. The metabolic rate is less than one-thirtieth of the warm-blooded rate at rest, and the main source of energy is fat. In spite of its low body temperature, the hibernating animal retains a remarkably rigid control of its internal environment. If the environmental temperature drops to 32°F (0°C), the hibernating animal may respond either by increasing its metabolic rate and remaining in hibernation or by a complete arousal from the hibernating state.

A hibernating mammal reduces its metabolic rate by nearly 30-fold and shifts from glycogen to lipid (that is, fat stores) as the major fuel source for metabolism. The magnitude of metabolic rate reduction is far in excess of what would be expected solely as a result of a hibernator's lowered body temperature. Moreover, suppression of glycogen metabolism during hibernation must be poised for regular and rapid relaxation during periods of arousal (which are fueled by glycolysis) as well as at the end of the hibernation period.

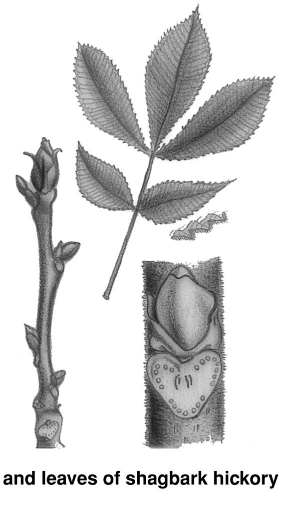
Mechanisms controlling these aspects of hibernation metabolism appear to be the relative acidification of the intracellular fluids of the hibernator. This is a consequence of the hibernator's tendency to continuously regulate its blood pH (at about pH 7.4, termed pH stat), and of the adoption of a modified breathing pattern that, although variable among species, is typified by periods of apnea lasting up to 2 h that are interspersed between 3–30 min intervals of rapid ventilation. [J.B.G.]

The hibernator is capable of waking at any time, using self-generated heat, and this characteristic clearly separates the hibernating state from any condition of induced hypothermia. During the total period of hibernation, the hibernator spontaneously wakes from time to time, usually at least once a week. In the period of wakefulness the stored food is evidently eaten, but animals which do not store food rely on their fat for the extra energy during the whole winter. The cause of the periodic arousals has not been definitely determined, but it is theorized that the arousal is due to the effect of the accumulation of a metabolite or other substance which can be neutralized only in the warm-blooded state. [C.P.L.]

As in hibernating endotherms (birds and mammals), a key factor regulating seasonal torpor in ectotherms is the continuous internal monitoring of environmental cues, such as day length, which in turn triggers temporally precise seasonally adaptive changes in systemic function, metabolism, and behavior. A second important factor is the presence in ectotherms of a bioenergetic metabolic system that, when compared to mammals and birds, operates at a much lower intensity and has less absolute dependence on molecular oxygen. The metabolic energy adaptations for seasonal torpor in ectothermic vertebrates are to a large extent similar to those required by vigorous activity or prolonged diving, and thus involve the processing or storage of intermediate metabolitics such as lactic acid, the regulation of intra- and extracellular pH, and enduring periods without access to oxygen. *See* ENERGY METABOLISM; METABOLISM. [J.B.G.]

Hickory Any species of the genus *Carya*, formerly known botanically as *Hicoria*. Hickories are mostly tall forest trees characterized by strong, terminal, scaly winter buds, pinnately compound leaves (see illustration), solid pith (not chambered), and fruit with an outer husk or exocarp which splits more or less readily into four parts, revealing a nut with a hard shell or endocarp.

The shagbark hickory (*C. ovata*) is found in the eastern half of the United States and adjacent Canada. It is the most important species because of the commercial value of its nuts, the hickory nuts of commerce, and of its wood. The pecan (*C. illinoensis*) is also a valuable species because of its commercially popular, thin-shelled, sweet nuts. Other species are the mockernut, shellbark, and pignut hickories. The remarkably tough and strong wood of



Twigs, buds, and leaves of shagbark hickory (*Carya ovata*).

all species makes it the world's best wood for tool handles. It is also used for parts of furniture, flooring, boxes, and crates, and for smoking meats. *See* Fagales. [A.H.G./K.P.D.]

Hidden variables Additional variables or parameters that would supplement quantum mechanics so as to make it like classical mechanics. Hidden variables would make it possible to unambiguously predict (as in classical mechanics) the result of a specific measurement on a single microscopic system. In contrast, quantum mechanics can give only probabilities for the various possible results of that measurement. Hidden variables would thus provide deeper insights into the quantum-mechanical probabilities. In this sense the relationship between quantum mechanics and hidden variables could be analogous to the relationship between thermodynamics (for example, temperature) and statistical mechanics (the motions of the individual molecules). *See* Statistical mechanics.

F. J. Belinfante formulated a three-section classification scheme for hidden variable theories—zeroth kind, first kind, and second kind. Most interest, both theoretically and experimentally, has been focused on hidden variable theories of the second kind, also known as local hidden variable theories.

In 1932 J. von Neumann provided an axiomatic basis for the mathematical methods of quantum mechanics. As a sidelight to this work, he rigorously proved from the axioms that any hidden variable theory was inconsistent with quantum mechanics. This was the most famous of a number of proofs, appearing as recently as 1980 and purporting to show the impossibility of any hidden variable theory. In 1966 J. S. Bell pinpointed the difficulty with von Neumann's proof—one of his axioms was fine for a pure quantum theory which makes statistical predictions, but the axiom was inherently incompatible with any hidden variable theory. The other impossibility proofs have also been found to be based on self-contradictory theories. Such theories are called hidden variable theories of the zeroth kind.

Hidden variable theories of the first kind are constructed so as to be self-consistent and to reproduce all the statistical predictions of quantum mechanics when the hidden variables are in an "equilibrium" distribution. Hidden variables of the second kind predict deviations from the statistical predictions of quantum mechanics, even for the "equilibrium" situations for which theories of the first kind agree with quantum mechanics. They are generally called local hidden variable theories because they are required to satisfy a locality condition. Intuitively, this seems to be a very natural condition. Locality requires that an apparatus at one location should operate independently of any settings or actions of a second apparatus at a spatially separated location. In the strict Einstein sense of locality, the two apparatus must be independent during any time interval less than the time required for a light signal to travel from one apparatus to the other.

The focus for much of the discussion of local hidden variable theories is provided by a famous thought experiment (a hypothetical, idealized experiment in which the experimental results are deduced) that was introduced in 1935 by A. Einstein, B. Podolsky, and N. Rosen. Their thought experiment involves an examination of the correlation between measurements on two parts of a single system after the parts have become spatially separated. They used this thought experiment to argue that quantum mechanics was not a complete theory. Although they did not refer to hidden variables as such, these would presumably provide the desired completeness. The Einstein-Podolsky-Rosen (EPR) experiment led to a long-standing philosophical controversy; it has also provided the framework for a great deal of research on hidden variable theories.

New efforts were stimulated in 1952 when Bohm did the "impossible" by designing a hidden variable theory of the first kind. Bohm's theory was explicitly nonlocal, and this fact led Bell to reexamine the Einstein-Podolsky-Rosen experiment. He came to the remarkable conclusion that any hidden variable theory that satisfies the condition of locality cannot possibly reproduce all the statistical predictions of quantum mechanics. Specifically, in Einstein-Podolsky-Rosen type experiments, quantum mechanics predicts a very strong correlation between measurements on the spatially separated parts. Bell showed that there is an upper limit on the strength of these correlations in the statistical prediction of any local hidden variable theory. Bell's result can be put in the form of inequalities which must be satisfied by any local hidden variable theory but which may be violated by the statistical predictions of quantum mechanics under appropriate experimental conditions.

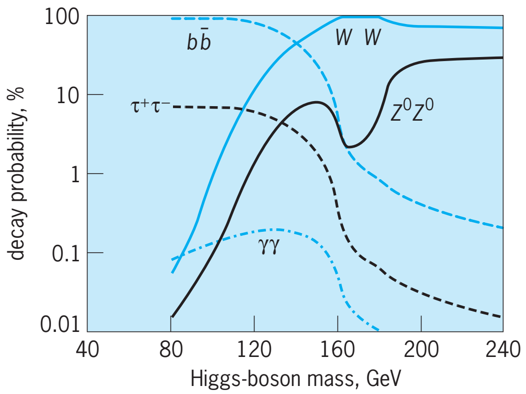
Experiments performed under conditions in which the statistical predictions of quantum mechanics violate Bell's inequalities can test the entire class of local hidden variable theories. However, all existing experiments have required supplementary assumptions regarding detector efficiencies. Due to the supplementary assumptions, small loopholes still remain, and experiments have been proposed to eliminate them. The overwhelming experimental evidence is against any theory that would supplement quantum mechanics with hidden variables and still retain the locality condition; that is, any hidden variable theory that reproduces all the statistical predictions of quantum mechanics must be nonlocal. The remarkable Einstein-Podolsky-Rosen correlations have defied any reasonable classical kind of explanation. *See* Nonrelativistic quantum theory; Quantum mechanics. [E.S.F.]

Higgs boson An elementary scalar particle in the Glashow-Weinberg-Salam theory of electromagnetic and weak interactions. At present, there is no direct experimental evidence for its existence. It is closely associated with the origin of mass for all known elementary particles, as described in the Glashow-Weinberg-Salam theory. This gives the Higgs boson distinctive properties which shape the search for it. *See* Electroweak interaction; Standard model.

The mass of the Higgs boson is uncertain theoretically, being determined by the parameters of the scalar self-interactions. It is strongly suspected, however, that the Higgs mass is between about 114 and 200 GeV/c^2 (where c is the speed of light).

The fact that the Higgs particle is closely related to the origin of mass endows it with special properties crucial in its production and detection. The illustration shows how the decay pattern of a standard-model Higgs boson depends on its mass.

The first extensive searches for the Higgs boson were carried out at the Large Electron Positron Storage Ring (LEP) and Stanford Linear Collider (SLC), e^+e^- machines with sufficient center-of-mass energy to operate at the Z resonance. The LEP was subsequently upgraded, and there were signs that experiments at center-of-mass energies up to 208 GeV/c^2 might be seeing the Higgs, but these were not sufficient to delay the machine's



Dependence of the decay probabilities of a standard-model Higgs boson on its mass.

shutdown in November 2000 to make way for the construction of the Large Hardon Collider (LHC) in the same tunnel.

The next particle accelerators to extend the Higgs search will probably be hadron colliders (proton-proton or proton-antiproton), particularly the LHC. *See* ELEMENTARY PARTICLE; PARTICLE ACCELERATOR. [A.Ch.; M.Sol.]

High magnetic fields

Magnetic fields that are large enough to significantly alter the properties of objects that are placed in them. Valuable research is conducted at high magnetic fields. *See* MAGNETISM.

High-field magnets. Research and development efforts in magnets and magnet materials have led to gradual increases in the fields available for scientific research to fields near 20 tesla from superconducting magnets, 33 T in copper-core (resistive) magnets, and 45 T for hybrid magnets. Superconducting magnets have the advantage that they use no electrical power once the field is established and the temperature is maintained at liquid-helium temperatures of 4.2 K (−452°F) or below. The disadvantage is that there is a critical magnetic field, H_{c2}, determined by the type of conductor, that limits the attainable field to about 22 T in superconducting materials currently available. Resistive magnets, which consume enormous amounts of power and are very expensive to build and operate, are confined to a few central facilities worldwide. *See* MEDICAL IMAGING; SUPERCONDUCTIVITY.

Advanced pulsed magnets that are not self-destructing provide fields beyond 70 T for about 0.1 s. Pulsed magnets using explosive magnetic flux compression have achieved fields above 500 T for periods of 10 microseconds. *See* MAGNET.

Materials research. Research at very high magnetic fields spans a wide spectrum of experimental techniques for studies of materials. These techniques include nuclear magnetic resonance (NMR) in biological molecules utilizing the highest-field superconducting magnets, while the resistive magnet research is primarily in the investigation of semiconducting, magnetic, superconducting, and low-dimensional conducting materials. *See* NUCLEAR MAGNETIC RESONANCE (NMR).

Much of the progress in semiconductor physics and technology has come from high-field studies. For example, standard techniques for mapping the allowed electronic states (the Fermi surface) of semiconductors and metals are to measure the resistance (in the Shubnikov-de Haas effect) or magnetic susceptibility (in the de Haas-van Alphen effect) as a function of magnetic field and to observe the oscillatory behavior arising from the Landau levels of the electron orbits. Measurements at low fields are limited to low impurity concentrations since the orbits are large and impurity scattering wipes out the oscillations. At high fields of 20–200 T, the orbits are smaller, and higher impurity concentrations (higher carrier concentrations) have been studied. Another area in which very high magnetic fields have an important role is in high-temperature superconductors, which have great potential for high-field applications, from magnetic resonance imaging, to magnetically levitated trains, to basic science. *See* DE HAAS-VAN ALPHEN EFFECT; FERMI SURFACE; SEMICONDUCTOR.

Studies at high magnetic fields have played an important role in advancing understanding of magnetic materials. For example, in many organic conductors the conduction electrons (or holes) are confined to one or two dimensions, leading to very rich magnetic phase diagrams. High-field phases above 20 T include spin-density waves, a modulation of the electron magnetic moments that can propagate through the crystal, modifying the conduction and magnetic properties. Another area of interest is the magnetic levitation of diamagnetic materials (the most common materials). *See* MAGNETIC MATERIALS; ORGANIC CONDUCTOR; PHASE TRANSITIONS; SPIN-DENSITY WAVE. [W.G.M.]

High-pressure chemistry

Chemistry at very high pressures, arbitrarily chosen to be above 10^4 bars (1 gigapascal), and mainly concerned with solid and liquid states. At 25°C (77°F) and 10^4 bars (1 GPa), nearly all ordinary gases are liquid or solid, and only a few liquids are not frozen; thus most high-pressure chemistry involves either higher temperatures, at which chemical reactions can occur at appreciable rates, or studies of internal arrangements in solids.

From 1 bar (10^2 kilopascals) to about 10^5 bars (10 GPa), normal low-pressure chemical behavior prevails, and only minor departures from the usual valence and coordination rules are found. However, many interesting changes in materials can be effected in this pressure range as atoms are forced into new bonding arrangements. From 10^5 to 10^9 bars (10 to 10^5 GPa), the energy added by compression becomes comparable with chemical bond energies, so that outer-shell electronic orbits are distorted and atoms and molecules change in character. A general tendency toward more metallic behavior is observed as the electrons become less strongly fixed to particular atoms, and chemical bonds may be broken. Upward of about 10^9 bars (10^5 GPa), the delocalization of electrons is extensive, and the material consists of a mixture of ions and electrons, so that chemical bonds are of little importance. The boundaries on these three pressure ranges are, of course, only approximate, and show some variation according to the temperature and the atoms involved.

The simplest effect of high pressure is the closer compression of atoms. The noble gases and alkali metals are quite compressible, whereas most oxides and the stronger metals are considerably stiffer. However, at a pressure exceeding about 10^5 bars (10 GPa), most of the easily compressed electronic clouds are tightened up, and the compressibilities of most substances approach each other.

Substances which consist of large molecules are easily stiffened or frozen by high pressures. The mobility of the molecules is sharply decreased by a sort of interlocking and tangling effect; thus for the substance to be sheared, chemical bonds must be broken, a process which requires considerable energy. This stiffening phenomenon limits the study of most reactions of organic molecules to low pressures because they are rather large and "freeze" easily, but yet are usually not stable enough to withstand the temperatures necessary for liquefaction or intermolecular reactions. [R.H.W.]

High-pressure mineral synthesis

A laboratory technique for studying the behavior of minerals under high-pressure conditions.

The nature of minerals as they exist at atmospheric pressure represents only a very limited part of their real nature. The range of pressure and temperature prevailing at the surface of the Earth is very limited compared to the ranges that exist in the other planets of the solar system. The bottom of the ocean, which is at the highest pressure that can be observed directly, is only 0.1 GPa (1 kilobar), while the pressure at the center of the Earth is 390 GPa (3900 kilobars). Pressures at the centers of large planets such as Saturn and Jupiter exceed 1000 GPa (10,000 kilobars). Therefore, to study the formation and structure of the Earth and other planets, it is essential to study the behavior of minerals under high pressure. It has become clear through high-pressure experiments that the minerals constituting the Earth's lower mantle (which extends from 650 to 2900 km or 400 to 1800 mi from the surface and occupies more than 50% of the entire volume of the Earth) are mostly so-called silicate perovskites that can never be formed on the surface of the Earth. *See* EARTH INTERIOR; JUPITER; SATURN.

Pressure is defined as a force per unit area; therefore, in order to apply a high pressure, it is necessary to concentrate a large force in a small area. Because of the limited strength of materials used to produce sample chambers, many different techniques are required, depending on the pressure range (see illustration).

A large number of phase transformations has been found in minerals under high pressure, but most of these structures have already been observed in other minerals existing under

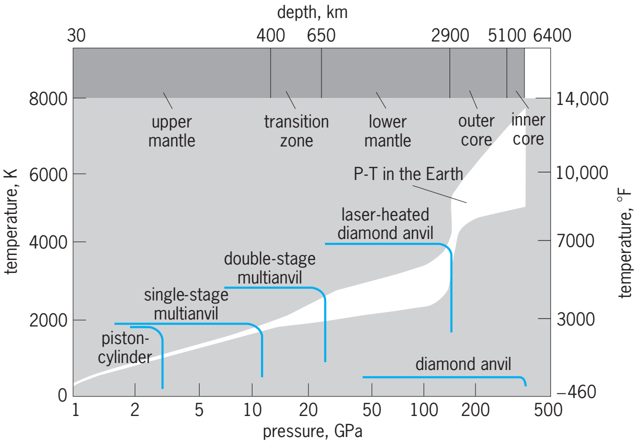


Diagram of pressure (P) and temperature (T) within the Earth, showing capabilities of various types of high-pressure apparatus. 1 GPa = 10 kilobars. 1 km = 0.6 mi.

atmospheric pressure. For example, rutile-type SiO_2 (stishovite) is formed only above 10 GPa (100 kilobars), but the same structure is obtained at atmospheric pressure when the Si ion is replaced by the larger germanium (Ge) ion. This implies that crystal structure is determined mainly by the ratio of the cation radius to that of the anion.

When the very dense structure is compressed further, the bond length becomes shorter and shorter, and the orbitals of the electrons around the ions begin to overlap. This means that the orbital electrons can move freely in the material, which changes into a so-called metallic state. This metallic transition is believed to occur in all materials when they are subjected to high enough pressure. Even hydrogen, helium, and ice are believed to exist in the metallic state in the interiors of Jupiter and Saturn. In the laboratory, however, this transformation into the metallic state under pressure has been confirmed in only a limited number of materials such as Si, Ge, and gallium arsenide (GaAs). *See* BOND ANGLE AND DISTANCE; FREE-ELECTRON THEORY OF METALS.

It has become clear that many of the major phases of silicate transform into the perovskite structure above 25 GPa (250 kilobars). Therefore it is believed that silicate perovskite is the most abundant mineral within the Earth, although it is an exotic mineral on the surface. In order to clarify the nature of the high-pressure minerals believed to be present in the interior of the Earth many studies have been made using various techniques. For this type of study, it is important to obtain a single crystal. The multianvil apparatus has been widely used for such experiments, and various single crystals of high-pressure minerals such as silicate perovskite, spinel, and stishovite have been synthesized.

High-pressure synthesis is a powerful method not only for use in earth and planetary sciences but also for the creation of new materials. Many industrial diamonds are synthesized by using high-pressure techniques, and some new high-pressure materials, such as cubic boron nitride, have found wide application. Pressure is one of the most fundamental parameters that can alter the state of materials, and research in this field is also expected to expand in the future. *See* DIAMOND; HIGH-PRESSURE CHEMISTRY; HIGH-PRESSURE PHYSICS; SILICATE PHASE EQUILIBRIA; SOLID-STATE CHEMISTRY; SOLID-STATE PHYSICS; THERMODYNAMIC PROCESSES. [T.Ya.]

High-pressure physics The study of the effects of high pressure on the properties of matter. Since most properties of matter are modified by pressure, the field of high-pressure physics encompasses virtually all branches of physics.

The “high” of high-pressure physics connotes experimental difficulty. At liquid-helium temperatures, pressures of several hundred bars are considered high. In general, however, the high-pressure range may be arbitrarily regarded as extending from about 1 kbar (100 MPa or 14,500 lb/in.^{2}) upward to the present experimental limit. Prolonged static pressures in excess of 1 megabar (100 gigapascals or 1.45×10^7 lb/in.^{2}) can be achieved in very small samples weighing about 1 microgram.

Transient pressures as high as about 10^7 bars (1000 GPa or 1.45×10^8 lb/in.^{2}) have been attained in shock waves produced by high explosives or by projectile impact.

The major effects of high pressure on matter include diminution of volume, phase transitions, changes in electrical, optical, magnetic, and chemical properties, increases in viscosity of liquids, and increases in the strength of most solids. In general solids are less compressible than liquids, and the compressibility of both solids and liquids decreases with increasing pressure.

At high pressure many solids exhibit polymorphic phase changes, that is, a rearrangement of the atoms or molecules in the solid. There are no universally applicable rules governing the number of phase changes or the kind of phase change to be expected at high pressure, but there is a thermodynamic requirement that the phase that is stable at high pressure must have a smaller volume than the phase that is stable at low pressure. *See* THERMODYNAMIC PRINCIPLES.

Frequently, dramatic changes in physical properties result from phase changes. Ferromagnetic iron transforms to a paramagnetic form at pressures somewhat above 100 kbar (10 GPa or 1.45×10^6 lb/in.^{2}). In the same pressure range, the semiconducting element germanium transforms into a metallic phase that has an electrical conductivity greater than a million times that of the semiconductor. Similar semiconductor-to-metal transitions at high pressure have been observed in the cases of silicon, indium arsenide, gallium antimonide, indium phosphide, aluminum antimonide, and gallium arsenide. *See* SEMICONDUCTOR.

Many phases that form at high pressure transform back to low-pressure phases as the pressure is released. However, some high-pressure phases may be retained in a metastable condition at low pressures, and some low-pressure phases can persist metastably at high pressure. Diamond, the high-pressure form of carbon, is thermodynamically unstable at room temperature and pressures below about 12 kbar (1.2 GPa or 1.74×10^5 lb/in.^{2}). Nonetheless diamond persists indefinitely as a metastable phase at low temperatures; it transforms to the stable form, graphite, only when heated to temperature in excess of 1800°F (1000°C) at low pressure. [R.K.L.; P.S.DeC.]

High-pressure processes Changes in the chemical or physical state of matter subjected to high pressure. The earliest high-pressure chemical process of commercial importance were the Haber synthesis of ammonia from hydrogen and nitrogen and the synthesis of diamonds from graphite. Raising the pressure on a system may result in several kinds of change. It causes a gas or vapor to become a liquid, a liquid to become a solid, a solid to change from one molecular arrangement to another, and a gas to dissolve to a greater extent in a liquid or solid. These are physical changes. A chemical reaction under pressure may proceed in such a fashion that at equilibrium more of the product forms than at atmospheric pressure; it may also take place more rapidly under pressure; and it may proceed selectively, forming more of the desired product among multiple possible products.

Pressures higher than that of the atmosphere are expressed in bars and kilobars as well as in other units. A bar is 10^5 pascals, or 10^5 newtons per square meter, which are the units for pressure in the International System of units. These units are too small for convenient use in high-pressure processes, hence the bar is used. The bar equals 0.9869 standard atmosphere, 760 mmHg.

Increasing the pressure on a gas or vapor compresses it to a higher density and so to a smaller volume. If the pressure exceeds the vapor pressure, the vapor will condense to a liquid which occupies a still smaller volume. A vapor may be condensed at a higher temperature when it is under pressure; this permits the use of cooling water to remove the latent heat instead of more costly refrigeration.

Solids also change from a less dense phase to a more dense phase under the influence of increases in pressure. The density of diamond is about 1.6 times greater than that of graphite because of a change in the spatial arrangement of the carbon atoms. The temperatures and pressures used in the commercial synthesis of diamond range up to 5000°F (3000 K) and 100,000 atm. A molten metal is required as a catalyst to permit the atomic rearrangement to take place at economical rates of conversion. Metals such as tantalum, chromium, and iron form a film between graphite and diamond.

In a manner similar to its effect during a physical change in which the volume of a system decreases, pressure also favors a chemical change where the volume of the products is less than the volume of the reactants. This is Le Chatelier's principle, which applies to systems in equilibrium. This general principle may be derived more precisely by thermodynamic reasoning, and thermodynamics is used to predict the effect of pressure on physical and chemical changes which lead to an equilibrium state.

Ammonia is formed according to the reaction shown below. At

$$N_2 + 3H_2 \rightleftharpoons 2NH_3$$

1 atm only a fraction of 1% ammonia is formed. The ammonia content increases greatly when the pressure is raised. At 100 atm and 392°F (200°C) there would be about 80% ammonia at equilibrium. However, a very long time is required to form ammonia under these conditions, and consequently commercial processes operate at higher temperatures and pressures and use a catalyst to obtain higher rates of reaction. Many combinations of pressure and temperature have been used. The largest number of plants now operate in the region of 300 atm and 840–930°F (450–500°C). A higher-pressure process is carried out at about 1000 atm and 930–1200°F (500–650°C).

Methanol is synthesized from hydrogen and carbon monoxide at 200 atm and 600°F (315°C) in a similar manner. The catalyst contains aluminum oxide, zinc oxide, chromium oxide, and copper. Higher alcohols are produced at pressures of 200–1000 atm and temperatures up to 1000°F (538°C) with a similar catalyst to which potassium carbonate or chromate has been added.
