This 9:3:3:1 ratio is known as a dihybrid ratio and is the result of segregation, independent assortment, and random fertilization. *See* Genetics. [M.R.C.]

Meninges In mammals, the three membranes that cover the brain and spinal cord: the dura mater, the arachnoid membrane, and the pia mater. The outermost, the dura mater, is a tough, fibrous, double-layered structure that is adherent to the skull. The inner layer of the dura mater sends separating sheets between the cerebral hemispheres and between the cerebrum and cerebellum. It also contains large venous sinuses and forms sheaths for nerves leaving the skull. The middle layer, the arachnoid, is a delicate serous layer loosely investing the brain. Below this is the spongy subarachnoid cavity which contains the circulating cerebrospinal fluid. The innermost layer, the pia mater, is a vascular layer which closely follows each convolution of the brain. Together the meninges furnish protection, blood supply, drainage, and cerebrospinal channels for the brain. *See* Nervous system (vertebrate). [T.S.P.]

Meningitis Inflammation of the meninges. Certain types of meningitis are associated with distinctive abnormalities in the cerebrospinal fluid. With certain types of meningitis, especially bacterial, the causative organism can usually be recovered from the fluid. *See* Meninges.

Meningeal inflammation in most cases is caused by invasion of the cerebrospinal fluid by an infectious organism. Noninfectious causes also occur. For example, in immune-mediated disorders antigen-antibody reactions can cause meningeal inflammation. Other noninfectious causes of meningitis are the introduction into the cerebrospinal fluid of foreign substances such as alcohol, detergents, chemotherapeutic agents, or contrast agents used in some radiologic imaging procedures. Meningeal inflammation brought about by such foreign irritants is called chemical meningitis. Inflammation also can occur when cholesterol-containing fluid or lipid-laden material leaks into the cerebrospinal fluid from some intracranial tumors.

Bacterial meningitis is among the most feared of human infectious diseases because of its possible seriousness, its rapid progression, its potential for causing severe brain damage, and its frequency of occurrence. Most cases of bacterial meningitis have an acute onset. Common clinical manifestations are fever, headache, vomiting, stiffness of the neck, confusion, seizures, lethargy, and coma. Symptoms of brain dysfunction are caused by transmission of toxic materials from the infected cerebrospinal fluid into brain tissue and the disruption of arterial perfusion and venous drainage from the brain because of blood vessel inflammation. These factors also provoke cerebral swelling, which increases intracranial pressure. Before antibiotics became available, bacterial meningitis was almost invariably fatal. *See* Antibiotic.

Most types of acute bacterial meningitis are septic-borne in that they originate when bacteria in the bloodstream (bacteremia, septicemia) gain entrance into the cerebrospinal fluid. Meningitis arising by this route is called primary bacterial meningitis. Secondary meningitis is that which develops following direct entry of bacteria into the central nervous system, which can occur at the time of neurosurgery, in association with trauma, or through an abnormal communication between the external environment and the cerebrospinal fluid.

Many viruses can cause meningeal inflammation, a condition referred to as viral aseptic meningitis. The most common viral causes include the enteroviruses, the various herpesviruses, viruses transmitted by arthropods, the human immunodeficiency virus type I (HIV-1), and formerly, the mumps virus. If the virus attacks mainly the brain rather than the spinal cord, the disorder is termed viral encephalitis. *See* Animal virus; Arboviral encephalitides; Enterovirus; Herpes.

Fungal, parasitic, and rickettsial meningitis are less common in the United States than are bacterial and viral. These infections are more likely to be subacute or chronic than those caused by bacteria or viruses; in most cases, the meningeal inflammation is associated with brain involvement. An acute form of aseptic meningitis can occur in the spirochetal diseases, syphilis and Lyme disease. *See* Lyme disease; Medical mycology; Medical parasitology; Rickettsioses; Syphilis. [W.E.B.]

Meningococcus A major human pathogen belonging to the bacterial genus *Neisseria*, and the cause of meningococcal meningitis and meningococcemia. The official designation is *N. meningitidis*. The meningococcus is a gram-negative, aerobic, nonmotile diplococcus. It is fastidious in its growth requirements and is very susceptible to adverse physical and chemical conditions.

Humans are the only known natural host of the meningococcus. Transmission occurs by droplets directly from person to person. Fomites and aerosols are probably unimportant in the spread of the organism. The most frequent form of host-parasite relationship is asymptomatic carriage in the nasopharynx.

The most common clinical syndrome caused by the meningococcus is meningitis, which is characterized by fever, headache, nausea, vomiting, and neck stiffness and has a fatality rate of 15% (higher in infants and adults over 60). Disturbance of the state of consciousness quickly occurs, leading to stupor and coma. Many cases also have a typical skin rash consisting of petechiae or purpura. *See* Meningitis. [R.Go.]

Menopause The irreversible cessation of regular monthly uterine bleeding in the adult human female, marking the end of her ability to become pregnant. Menopause commonly occurs in the United States between the ages of 47 and 53. It probably occurs because the ovary runs out of eggs and the cyclic rise and fall of brain and ovarian hormones designed to prepare the uterus to receive and nourish pregnancy no longer occur.

Menopause is one event in the climacteric, the period of time during which the reproductive machinery slows down and finally stops. The biochemical hallmark of this period is a reduction in estrogen production by the ovary. Some estrogen continues to be produced by the adrenal gland and the fatty tissues throughout the body, but this amount is very small compared with premenopausal levels. Estrogen has widespread effects on both genital and extragenital systems, and the withdrawal of estrogen accounts for many of the signs and symptoms attributed to menopause, although these are influenced by both hereditary and social factors. Many psychological problems have been attributed to estrogen deprivation, but well-documented proof of those relationships is lacking.

While estrogen can reverse or halt many of the physical changes described, it will not prevent aging or restore reproductive ability. Treatment of menopausal symptoms should be undertaken on an individual basis, with careful discussion of the risks and benefits currently known. *See* ESTROGEN; MENSTRUATION. [G.Gu.]

Menstruation Periodic sloughing of the uterine lining in women of reproductive age. Menstrual bleeding indicates the first day of the menstrual cycle, which lasts an average of 27–30 days, although ranges of 21–60 days have been recorded. Menarche, the onset of menstruation, occurs between the ages of 9 and 16. The majority of females begin menstruating at ages 12–14. During the first few years, the duration and intensity of menstrual flow and the total cycle length may be quite variable, but regularity is gradually established. Cessation of menses, or menopause, occurs at an average age of 51, with a range of 42–60 years.

The menstrual cycle consists of cyclic changes in both the ovary and the uterus. These changes are controlled by the interaction of several hormones including follicle-stimulating hormone (FSH) and luteinizing hormone (LH), which are secreted by the anterior pituitary, and the steroid hormones estrogen and progesterone, which are secreted by follicles in the ovary. At the beginning of the cycle, the follicle is stimulated by FSH. In response, it grows and secretes estrogen. The amount of estrogen secretion increases rapidly near the middle of the cycle. Estrogen, in turn, stimulates growth of the uterine lining (mucosa), which becomes thicker and fills with blood vessels. In midcycle, the rapid increase in estrogen causes a massive surge of LH release and a smaller release of FSH from the pituitary. This surge causes ovulation, which is the release of the ovum from the follicle. After ovulation, the follicle undergoes rapid changes and is then called a corpus luteum, which secretes progesterone in response to LH stimulation. Progesterone and estrogen together cause a further thickening of the uterine mucosa, preparing the uterus for pregnancy. If pregnancy does not occur, the corpus luteum degenerates, the uterine mucosa sloughs off, and the cycle begins again.

There is no menstrual bleeding during pregnancy, as the uterine mucosa is needed for the maintenance of pregnancy. This amenorrhea, or lack of normal ovarian function, sometimes continues during nursing. [J.M.Ba.]

Mental retardation A developmental disability characterized by significantly subaverage general intellectual functioning, with concurrent deficits in adaptive behavior. The causes are many and include both genetic and environmental factors as well as interactions between the two. In most cases the diagnosis is not formally made until children have entered into school settings. In the preschool years, the diagnosis is more likely to be established by evidence of delayed maturation in the areas of sensory-motor, adaptive, cognitive, social, and verbal behaviors. By definition, evidence of mental retardation must exist prior to adulthood, where vocational limitation may be evident, but the need for supervision or support may persist beyond the usual age of social emancipation.

From the aspect of etiology, mental retardation can be classified by prenatal, perinatal, or postnatal onset. Prenatal causes include genetic disorders, syndromal disorders, and developmental disorders of brain formation. Upward of 700 genetic causes have been suggested as associated with the development of mental retardation. Many environmental influences on the developing fetus, for example, infection, and other unknown errors of development may account for mental retardation.

Perinatal causes include complications at birth, extreme prematurity, infections, and other neonatal disorders. Postnatal causes include trauma, infections, demyelinating and degenerative disorders, consequences of seizure disorders, toxic-metabolic disorders, malnutrition, and environmental deprivation. Often no specific cause can be identified for the mental retardation of a particular individual.

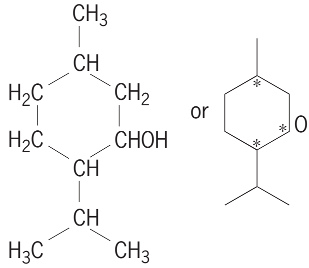
Individuals with mental retardation are typically subclassified in terms of the manifest severity of cognitive disability as reflected by the ratio of mental age to chronological age, or intelligence quotient (IQ). Subaverage intellectual functioning is defined as an IQ score of at least two standard deviations below the mean, or approximately 70 to 75 or below. Mild, moderate, severe, and profound degrees of mental retardation refer to two, three, four, or five standard deviations below the normal IQ for the general population.

Limitations in adaptive behavior must also be demonstrable in order to satisfy diagnostic criteria for mental retardation. This criterion is important because certain artistic or other gifts may not be revealed by formal IQ testing, and different levels of learning difficulty may be accentuated by the demands of specific environments. Outside such environments, an individual may navigate a normal course in life.

A specific genetic or other cause of mental retardation may also predispose to other medical or neurologic conditions. In these circumstances, the comorbid medical conditions may increase the likelihood of emotional or behavioral problems, or contribute to the challenges with which a given child must contend. Thus, the identification of cause can be important in planning for the medical, educational, and treatment needs of a particular individual.

Considerable progress has been made in both prevention and treatment. Diet is a method of treatment following early detection of phenylketonuria; warnings regarding alcohol consumption during pregnancy, lead exposure in infancy, and disease immunization and therapy are measures for prevention of retardation. Advances in prenatal, obstetrical, and neonatal care and genetic counseling have had the effect of reducing the incidence or the severity of various conditions. Energetic training and the application of psychosocial techniques have resulted in improved social performance and adaptive behavior in many persons with mental retardation. [B.H.Ki.]

Menthol A monocyclic, saturated, secondary terpene alcohol with the formula below. Menthol contains three asymmetric carbon atoms (starred in the formula). It can exist in four



externally compensated and eight optically active forms. The only forms encountered in nature are the L-menthol and D-neomenthol. Commercial l-menthol is isolated principally from the oil of *Mentha arvensis*. It possesses a distinct peppermint flavor and gives the impression of cooling the mouth and skin. *See* TERPENE. [W.Mos.]

Mercaptan One of a group of organosulfur compounds which are also called thiols or thio alcohols and which have the general structure RSH. Aromatic thiols are called thiophenols, and biochemists often refer to thiols as sulfhydryl compounds. The unpleasant odor of volatile thiols causes them to be classed as stenches, but the odors of many solid thiols are not unpleasant.

Mercaptans (1) form salts with bases, (2) are easily oxidized to disulfides and higher oxidation products such as sulfonic acids, (3) react with chlorine (or bromine) to form sulfenyl chlorides (or bromides), and (4) undergo additions to unsaturated compounds, such as olefins, acetylenes, aldehydes, and ketones. The insoluble mercury salts (mercaptides) are used to isolate and identify mercaptans. *See* ORGANOSULFUR COMPOUND. [N.K.]

Merchant ship A power-driven ship employed in commercial transport on the oceans and large inland bodies of water such as the Great Lakes. The relatively small craft used for inland waterway transportation are not commonly referred to as ships.

Commodities transported by water are classified as breakbulk, unitized, or bulk (dry or liquid) cargoes. Generally, water cargo transportation is cheaper per ton-mile than land or air transportation; approximately 90% of the United States overseas trade revenue is waterborne, while the rest is airborne. *See* MARINE CONTAINERS.

A passenger ship, as defined by International Safety of Life at Sea (SOLAS) rules, carries more than 12 passengers on international voyages. Passenger vessels that also transport cargo are called passenger-cargo ships. [A.M.D'A.]

Mercury (element) A chemical element, Hg, atomic number 80 and atomic weight 200.59. Mercury is a silver-white liquid at room temperature (melting point −38.89°C or −37.46°F); it boils at 357.25°C (675.05°F) under atmospheric pressure. It is a noble metal that is soluble only in oxidizing solutions. Solid mercury is as soft as lead. The metal and its compounds are very toxic. With some metals (gold, silver, platinum, uranium, copper, lead, sodium, and potassium, for example) mercury forms solutions called amalgams. *See* AMALGAM; PERIODIC TABLE; TRANSITION ELEMENTS.

In its compounds, mercury is found in the 2+, 1+, and lower oxidation states, for example, $HgCl_2$, Hg_2Cl_2, or $Hg_3(AsF_6)_2$. Often the mercury atoms are doubly covalently bonded, for example, Cl—Hg—Cl or Cl—Hg—Hg—Cl. Some mercury(II) salts, for example, $Hg(NO_3)_2$, or $Hg(ClO_4)_2$, are quite soluble in water and dissociate normally. The aqueous solutions of these salts react as strong acids because of hydrolysis. Other mercury(II) salts, for example, $HgCl_2$ or $Hg(CN)_2$, also dissolve in water, but exist in solution as only slightly dissociated molecules. There are compounds in which mercury atoms are bound directly to carbon or nitrogen atoms, for example, $H_3C—Hg—CH_3$ or $H_3C—CO—NH—Hg—NH—CO—CH_3$. In complex compounds, for example, $K_2(HgI_4)$, mercury often has three or four bonds.

Metallic mercury is used as a liquid contact material for electrical switches, in vacuum technology as the working fluid of diffusion pumps, for the manufacture of mercury-vapor rectifiers, thermometers, barometers, tachometers, and thermostats, and for the manufacture of mercury-vapor lamps. It finds application for the manufacture of silver amalgams for tooth fillings in dentistry. Of importance in electrochemistry are the standard calomel electrode, used as the reference electrode for the measurement of potentials and for potentiometric titrations, and the Weston standard cell.

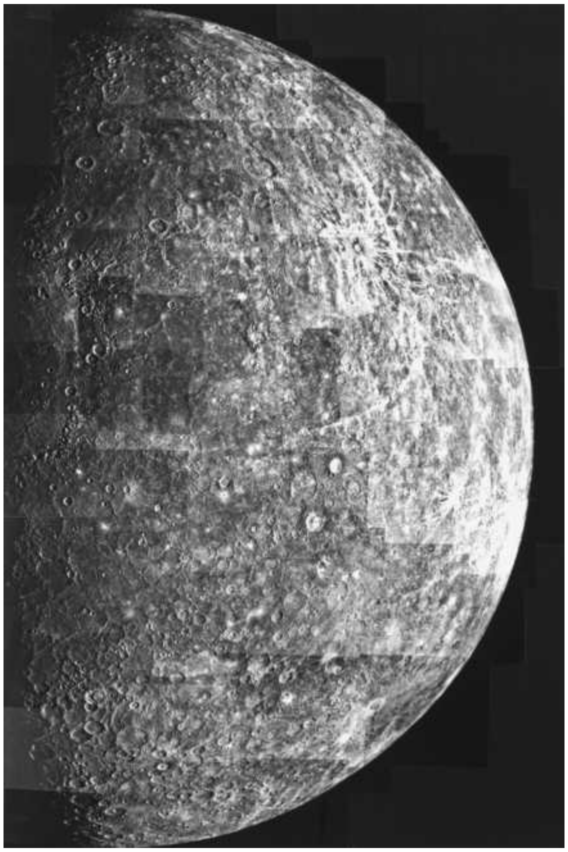
Mercury is commonly found as the sulfide, HgS, frequently as the red cinnabar and less often as the black metacinnabar. A less common ore is the mercury(I) chloride. Occasionally the mercury ore contains small drops of metallic mercury. *See* CINNABAR.

The surface tension of liquid mercury is 484 dynes/cm, six times greater than that of water in contact with air. Hence, mercury does not wet surfaces with which it is in contact. In dry air metallic mercury is not oxidized. After long standing in moist air, however, the metal becomes coated with a thin layer of oxide. In air-free hydrochloric acid or in dilute sulfuric acid, the metal does not dissolve. Conversely, it is dissolved by oxidizing acids (nitric acid, concentrated sulfuric acid, and aqua regia). [K.B.]

Mercury (planet) The planet closest to the Sun. It is visible to the unaided eye only shortly after sunset or shortly before sunrise, when it is near its greatest angular distance from the Sun (28°). Its diameter is 3031 mi (4878 km), and its mass is 0.055 times the mass of the Earth. Most detailed knowledge of Mercury is derived from data returned by the *Mariner 10* spacecraft, which flew by the planet three times in 1974 and 1975. The coverage and resolution is somewhat comparable to Earth-based telescopic coverage and resolution of the Moon before the advent of space flight.

Mercury has the most eccentric (0.205) and inclined (7°) orbit of any planet in the solar system except Pluto. The rotation period is 58.646 Earth days, and the orbital period, 87.969. Therefore, Mercury makes exactly three rotations around its axis for every two orbits around the Sun. Thus, a solar day (sunrise to sunrise) lasts two Mercurian years (176 Earth days).

Mercury experiences the greatest range in surface temperature (1130°F or 627°C) of any planet or satellite in the solar system because of its proximity to the Sun, its long solar day, and its lack of an insulating atmosphere. Its maximum surface temperature



Photomosaic of Mercury as seen by the outgoing *Mariner 10* spacecraft in March 1974. The terminator, the boundary between the lighted and unlighted halves of the planet, runs vertically along the left side of the photograph. The Caloris Basin is on the terminator, slightly above the middle. It is surrounded and filled by younger smooth plains. (*Jet Propulsion Laboratory*)

is 800°F (427°C) at perihelion on the equator, hot enough to melt zinc. At night, however, the unshielded surface plunges to below −300°F (−183°C).

Mercury's internal structure is unique in the solar system. The planet's mean density is 5.44 g/cm^3 (5.44 times that of water), which is larger than that of any other planet or satellite except Earth (5.52 g/cm^3). Because of Earth's large internal pressures, however, its uncompressed density is only 4.4 g/cm^3 compared to Mercury's uncompressed density of 5.3 g/cm^3. This means that Mercury contains a much larger fraction of iron than any other planet or satellite in the solar system. The iron core must be about 75% of the planet diameter, or 42% of Mercury's volume. It is surrounded by a silicate mantle and crust only about 370 mi (600 km) thick. *Mariner 10* discovered an intrinsic dipole magnetic field with a dipole moment equal to about 0.004 that of the Earth, which indicates that the core is at least partly molten at present. A light alloying element in the core must have lowered the melting point and retained a partially molten core over geologic history (4.5×10^9 years); otherwise the core would have solidified long ago. Sulfur is the most reasonable candidate for this alloying element. Mercury probably has between about 0.2 and 7% sulfur in its core. The origin of Mercury and how it acquired such a large percentage of iron is a major unsolved problem. *See* EARTH.

Mercury's atmosphere is very tenuous and is essentially exospheric in that its atoms rarely collide with each other. The atmospheric surface pressure is 10^{12} times less than Earth's. *Mariner 10*'s ultraviolet spectrometer identified hydrogen, helium, oxygen, and argon in the atmosphere, all of which are probably derived largely from the solar wind. Earth-based telescopic observations in 1985 discovered that Mercury is surrounded by a tenuous atmosphere of sodium and potassium that is probably derived from its surface.

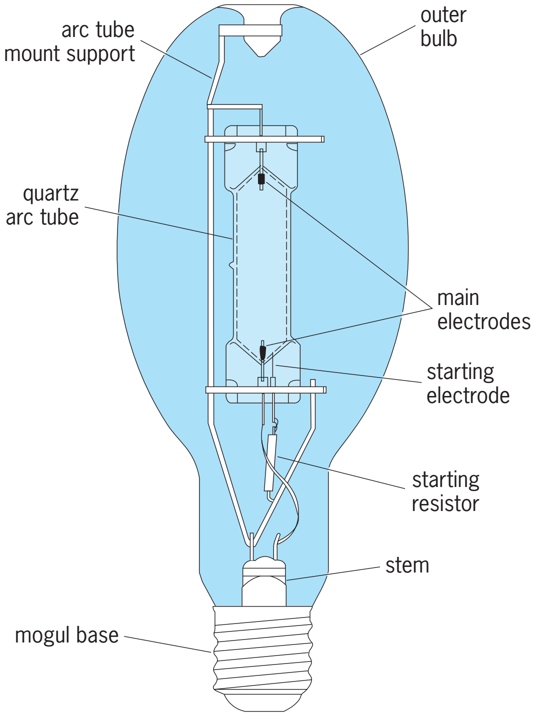
The surface of Mercury superficially resembles that of the Moon (see illustration). It is heavily cratered, with large expanses of younger smooth plains (similar to the lunar maria) that fill and surround major impact basins. Unlike the Moon surface, Mercury's heavily cratered terrain is interspersed with large regions of gently rolling intercrater plains, the major terrain type on the planet. Also unlike the Moon surface, a system of thrust faults, unique in the solar system, transects the surface viewed by *Mariner 10*. The largest structure viewed by *Mariner 10* is the 800-mi-diameter (1300-km) Caloris impact basin. Infrared temperature measurements from *Mariner 10* indicate that the surface is a good thermal insulator and, therefore, must be covered with porous soil or rock powder like the lunar regolith. This is expected on a planet whose surface is shattered and stirred by meteorite impacts. *See* PLANET; PLANETARY PHYSICS. [R.G.S.]

Mercury-vapor lamp A vapor or gaseous discharge lamp in which the arc discharge takes place in mercury vapor. This lamp is widely used for roadway and all other forms of illumination, and as a source of ultraviolet radiation for industrial applications.

The arc discharge takes place in a transparent tube of fused silica, or quartz, and this quartz tube is usually mounted inside a larger bulb of glass (see illustration). The outer bulb reduces the ultraviolet radiation of the inner arc tube, encloses and protects the mount structure, and can be coated with phosphors that greatly improve the color of the light emitted.

The arc tube has electrode assemblies mechanically sealed into each end, At one end of the arc tube, a smaller starting electrode is located close to the main electrode. The starting electrode is connected through a high resistance to the opposite electric polarity of the adjacent main electrode. The arc tube itself is filled with argon gas and a small amount of pure mercury before being sealed.

Radiation from the mercury arc is confined to four specific wavelengths in the visible portion of the spectrum and several strong lines in the ultraviolet. The visible radiation from clear mercury lamps provides light with a distinct blue-green appearance and poor color rendition. Red objects, for example, look brown or black, and human skin looks unattractive. For this reason, most mercury lamps have a phosphor color-correcting coating, and clear bulbs are used only where appearance of colors is secondary to some gain in efficiency. *See* ILLUMINATION; LAMP; ULTRAVIOLET LAMP; VAPOR LAMP. [T.F.N.]



High-pressure mercury-vapor lamp.

Meridian A line of longitude on Earth or in the sky, perpendicular to the Equator, and extending between the North and South poles.

A meridian of longitude on Earth marks a system of location and timekeeping whose zero was set at Greenwich, England, in the nineteenth century, when it was necessary to regularize time signals in the era of railway transportation. *See* LATITUDE AND LONGITUDE; TIME.

Meridians of celestial longitude are the extensions into space of meridians of longitude on Earth. Each celestial meridian is the half of a great circle that goes between the north and south celestial poles and crosses the celestial equator perpendicularly. The unique line known as the celestial meridian is the great circle going from north pole to south pole through a given observer's zenith, the point directly overhead. It thus marks the north-south line, and celestial objects going through it are said to be at their meridian transits or at their culminations. *See* ASTRONOMICAL COORDINATE SYSTEMS. [J.M.P.]

Merogony The normal or abnormal development of a part of an egg following cutting, shaking, or centrifugation of the egg before or after fertilization. Depending on the character of the nucleus present in the egg fragment, the following types of merogony are recognized: (1) diploid merogony, the nucleus being the normal fusion product of the egg and sperm nuclei and thus diploid; (2) andromerogony, development with the haploid sperm nucleus; (3) gynomerogony, development of a fragment of a fertilized egg with the haploid egg nucleus; (4) parthenomerogony, development of a nucleated fragment of an unfertilized egg following parthenogenetic stimulation. [G.Fa.]

Meromictic lake A lake whose water is permanently stratified and therefore does not circulate completely throughout the basin at any time during the year. Normally lakes in the temperate zone mix completely during the spring and autumn when water temperatures are approximately the same from top to bottom. In meromictic lakes there are no periods of overturn or complete mixing because seasonal changes in the thermal gradient are either small or overridden by the stability of a chemical gradient, or the deeper waters are physically inaccessible to the mixing energy of the wind. Most commonly, the vertical stratification is stabilized by a chemical gradient in meromictic lakes.

The upper stratum of water in a meromictic lake is mixed by the wind and is called the mixolimnion. The bottom, denser stratum, which does not mix with the water above, is referred to as the monimolimnion. The transition layer between these strata is called the chemocline.

Of the hundreds of thousands of lakes on the Earth, only about 120 are known to be meromictic. In general, meromictic lakes in North America are restricted to: sheltered basins that are proportionally very small in relation to depth and that often contain colored water, basins in arid regions, and isolated basins in fiords. *See* Fresh-water ecosystem; Lake; Limnology. [G.E.Li.]

Merostomata A class of the phylum Arthropoda, subphylum Chelicerata. Merostomes are aquatic chelicerates, characterized by abdominal appendages bearing respiratory organs. Most merostomes are extinct; only the horseshoe crabs, comprising four species and three genera (*Carcinoscorpio* and *Tachypleus* of eastern Asia and *Limulus polyphemus* of eastern North America) survive.

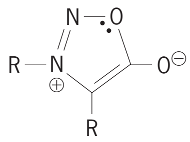
The body of a merostome consists of a prosoma, or head, which lacks antennae, has a pair of compound eyes and a pair of simple median eyes, and bears the chelicerae (pincers) and five pairs of uniramous walking legs with gnathobases for mastication. The opisthosoma, or trunk, consists of 12 or fewer segments which may be freely articulating or partly or entirely fused into a solid shield; the opisthosoma bears the respiratory appendages. The telson (tail) is a solid, usually spikelike, structure. *See* Chelicerata; Living fossils. [N.E.]

Mesogastropoda The largest and most diverse order of gastropod mollusks in the subclass Prosobranchia. Mesogastropods are all single-gilled and thus monotocardiac, that is, with only one auricle and asymmetry of other cardiac, renal, and genital structures. Mesogastropods with a wide variety of marine lifestyles are found burrowing in soft muds and living exposed to air near high-tide level. There are also estuarine, fresh-water, and terrestrial species in the order. The anatomical asymmetry makes possible a functional separation of genital from renal ducts, which in turn allows the development of internal fertilization, of large eggs, of ovoviviparity, and of true viviparity (all features advantageous for the evolution of nonmarine stocks).

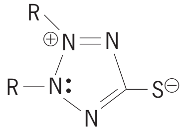
Mesogastropods are structurally diverse, and most classifications divide them into 13 superfamilies, 4 of which number several thousand species and encompass some of the world's most abundant, ubiquitous, and cosmopolitan marine snails. *See* Gastropoda; Prosobranchia. [W.D.R.-H.]

Meso-ionic compound A member of a class of five-membered ring heterocycles (and their benzo derivatives) which possess a sextet of π electrons in association with the atoms composing the ring but which cannot be represented satisfactorily by any one covalent or polar structure.

Two main types, depending formally upon the origin of the electrons in the π system, have been identified; they are exemplified by compounds (**1**) and (**2**). In structure (**1**) the nitrogen and oxygen atoms, 1,3 to each other, are shown as donating two electrons each to the total of eight electrons in the whole π system, whereas in structure (**2**) the two middle nitrogen atoms, 1,2 to each other, are the two-electron donors.



(**1**)



(**2**)

The term "satisfactorily" in the definition refers to the fact that the charge in the ring cannot be associated exclusively with one ring atom. Thus, these compounds are in sharp contrast with other dipolar structures, such as ylides, and such compounds are not considered meso-ionic.

There has been considerable interest in the pharmacological activity of meso-ionic compounds, and derivatives have shown a variety of antibiotic, anthelminthic, antidepressant, and anti-inflammatory properties. *See* Heterocyclic compounds. [J.P.Fr.]

Mesometeorology That portion of meteorology comprising the knowledge of intermediate-scale atmospheric phenomena, that is, in the size range of approximately 1–1200 mi (2–2000 km) and with time periods typically, but not always, less than 1 day. Unlike the larger weather systems on synoptic scales (the scales resolved by current weather reporting station networks) which typically produce significant changes over periods of days, most mesoscale phenomena have interdiurnal periods (less than 1 day), and consequently their changes are often more startling. In addition to time and space criteria for defining mesoscale, dynamical considerations can be used.

For observing mesoscale phenomena over midlatitude land masses, the average spacing between atmospheric sounding stations is about 180–360 mi (300–600 km) and soundings are taken twice each day. Consequently, only the largest mesoscale phenomena, with wavelengths greater than about 600 mi (1000 km), are routinely observed (resolved) by this network. Information with higher time-and-space resolution is available from aircraft observations and networks of radar stations, profilers, and satellite imagery. The profiler is a ground-based hybrid observing system of vertically pointing radar and microwave radiometry. The remote-sensing platforms often show that mesoscale weather systems are distinct components of larger synoptic-scale cyclones (low-pressure systems) and anticyclones (high-pressure systems).

Although the satellite imagery and radar data provide extensive areal coverage and clearly reveal the presence of the mesoscale systems, they do not provide measurements of certain atmospheric parameters (such as temperature, moisture, and pressure) in a form in which mesoscale structures and circulations can be readily quantified and understood. Thus, while mesoscale phenomena can be "observed," they cannot be studied and predicted (in the conventional manner) as easily as synoptic-scale systems. *See* Meteorological satellites; Radar meteorology; Weather forecasting and prediction.

Mesoanalysis is the analysis of meteorological data in a manner that reveals the presence and characteristics of mesoscale phenomena. Because sounding stations are so widely spaced, only the largest of mesoscale systems can be resolved by the free-air (sounding) data. On the other hand, the density of surface observing stations is often satisfactory for identifying mesoscale features or circulations. Probably the most common application of mesoanalysis is for forecasting convective (thunderstorm) weather systems. *See* Thunderstorm.

Modern weather-forecasting techniques rely heavily upon predictions made from computers. These predictions, commonly called numerical model forecasts, require as input the three-dimensional initial state of the atmosphere. Normally, this initial condition is produced from the previous forecast and the most recent observations from the network of atmospheric soundings. For many mesoscale phenomena, it has been possible to develop relationships between the large-scale (synoptic) environment and the occurrence of particular types of mesoscale events. By using these relationships, the prediction of the synoptic-scale environment by the numerical models is then used to infer the likelihood of specific mesoscale events. Using satellite, radar, and conventional surface observations, the onset of an event is readily detected and appropriate adjustments to local forecasts are implemented. These adjustments usually come in the form of very short-term forecasts, commonly called nowcasts, and typically are valid for only about 3 h. However, depending upon the particular mesoscale phenomena, longer-term (3–12 h) forecasts sometimes are possible. *See* Meteorology; Nowcasting; Storm detection. [J.Mi.F.]

Meson The generic name for any hadronic particle with baryon number zero. Such particles were first envisaged in 1935 by H. Yukawa, who pointed out that the main features of nuclear forces would be explained if these forces were transmitted between nucleons through an intermediate field coupled with nucleons, provided that its quanta (nuclear force mesons) were massive [200–300 electron masses (m_e)] and could carry electric charge between the nucleons. *See* Baryon; Hadron; Nuclear structure; Quantum field theory.

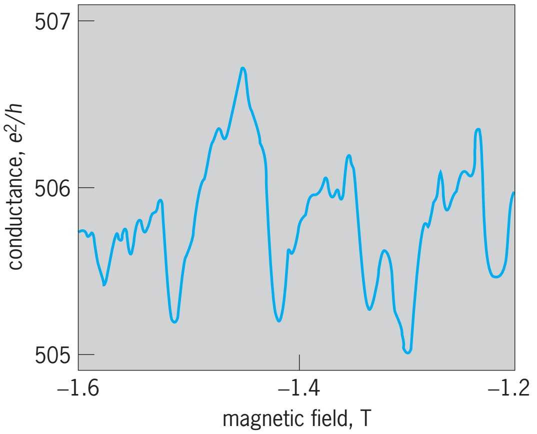
All mesons are unstable. Those with relatively long lifetimes are referred to as semistable. Nearly 200 highly unstable mesons are established, with lifetimes shorter than 10^{-22} s, and more continue to be discovered. These mesons decay to lighter mesons through the strong nuclear (hadronic) interactions, whereas the hadronic decays of the semistable mesons are forbidden or strongly suppressed. Alternative decay modes involve the weak interactions or the electromagnetic interactions, which are much weaker than the strong interactions and therefore lead to much smaller decay rates and longer lifetimes. The longest-lived mesons are those that decay only through the weak interactions; these include the charged π mesons (pions) and the K mesons (kaons), with lifetimes of about 10^{-8} to 10^{-10} s. *See* Fundamental interactions; Weak nuclear interactions.

Hadrons are now considered to be composite, consisting of spin-quarks (q), corresponding antiquarks (q), and some number of gluons (g), the last being the quanta of the intermediate field which binds the quarks and antiquarks to form hadrons. Baryon number $B = +1/3$ holds for a quark q, $B = -1/3$ for antiquark q, while $B = 0$ holds for a gluon. In this view, the simplest possibility is that each meson is a quark-antiquark ($q\overline{q}$) pair bound together by the gluon field, and this model does account quite well for most of the known mesons and their properties. However, more complicated systems (for example, consisting of two quarks with two antiquarks) can be considered and may even be required by some of the present data. The quarks must be assigned fractional charge values, relative to the proton charge. *See* Gluons; Quarks. [R.H.D.; C.G.]

Mesosauria An order of extinct aquatic reptiles, also known as Proganosauria, of latest Carboniferous or earliest Permian time, about 280,000,000 years ago. The best-known genus is *Mesosaurus*. Like many aquatic reptiles, mesosaurs have a very long snout. The teeth are numerous and long, and appear very delicate. They may have served for filter feeding on soft-bodied invertebrates.

Mesosaurs, an early offshoot of the Carboniferous “stem reptiles” or captorhinomorphs, were the first reptiles to invade marine waters, but apparently soon became extinct, leaving no descendants. *See* Reptilia. [R.L.C.]

Mesoscopic physics A subdiscipline of condensed-matter physics that focuses on the properties of solids in a size range intermediate between bulk matter and individual atoms or molecules. The size scale of interest is determined by the appearance of novel physical phenomena absent in bulk solids and has no rigid definition; however, the systems studied are normally in the range of 100 nanometers (the size of a typical virus) to 1000 nm (the size of a typical bacterium). Other branches of science, such as chemistry and molecular biology, also deal with objects in this size range, but mesoscopic physics has dealt primarily with artificial structures of metal or semiconducting material which have been fabricated by the techniques employed for producing microelectronic circuits. Thus mesoscopic physics has a close connection to the fields of nanofabrication and nanotechnology. Three categories of new phenomena in such systems are interference effects, quantum size effects, and charging effects. *See* Artificially layered structures; Nanostructure; Quantized electronic structure (QUEST); Semiconductor heterostructures.



Conductance of 2000-nm gold wire as a function of magnetic field measured at a temperature of 0.04 K. The pattern observed is reproducible over a period of days. (*After R. A. Webb and S. Washbum, Quantum interference fluctuations in disordered materials, Phys. Today, 41(12):46–55, December 1988*)

Interference effects. In the mesoscopic regime, scattering from defects induces interference effects which modulate the flow of electrons. The experimental signature of mesoscopic interference effects is the appearance of reproducible fluctuations in physical quantities. For example, the conductance of a given specimen oscillates in an apparently random manner as a function of experimental parameters (see illustration). However, the same pattern may be retraced if the experimental parameters are cycled back to their original values; in fact, the patterns observed are reproducible over a period of days.

Quantum size effects. Another prediction of quantum mechanics is that electrons confined to a particular region of space may exist only in a certain set of allowed energy levels. The spacing between these levels increases as the confining region becomes smaller. One striking phenomenon which arises from these quantum size effects is the steplike increase of the conductance of electrons flowing through a constriction of several hundred nanometers’ width. *See* Energy level (quantum mechanics).

Another mesoscopic system that shows quantum size effects consists of isolated islands of electrons that may be formed at the appropriately patterned interface between two different semiconducting materials. The electrons typically are confined to disk-shaped regions termed quantum dots. The confinement of the electrons in these systems changes their interaction with electromagnetic radiation significantly. *See* Quantized electronic structure (QUEST).

Charging effects. Isolated mesoscopic solids such as quantum dots or metallic grains on an insulating substrate also show novel effects associated with the discreteness of the charge on the electron. Devices known as single-electron transistors (SETs) are by far the most sensitive electrometers (instruments for measuring electrical charge) presently known. *See* ELECTROMETER; TRANSISTOR. [A.D.S.]

Mesosphere A layer within the Earth's atmosphere that extends from about 50 to 85 km (31 to 53 mi) above the surface. The mesosphere is predominantly characterized by its thermal structure. On average, mesospheric temperature decreases with increasing height.

Temperatures range from as high as 12°C (53°F) at the bottom of the mesosphere to as low as −133°C (−208°F) at its top. The top of the mesosphere, called the mesopause, is the coldest area of the Earth's atmosphere. Temperature increases with increasing altitude above the mesopause in the layer known as the thermosphere, which absorbs the Sun's extreme ultraviolet radiation. In the stratosphere, the atmospheric layer immediately below the mesosphere, the temperature also increases with height. The stratosphere is where ozone, which also absorbs ultraviolet radiation from the Sun, is most abundant. The transition zone between the mesosphere and the stratosphere is called the stratopause. Mesospheric temperatures are comparatively cold because very little solar radiation is absorbed in this layer. Meteorologists who predict weather conditions or study the lowest level of the Earth's atmosphere, the troposphere, often refer to the stratosphere, mesosphere, and thermosphere collectively as the upper atmosphere. However, scientists who study these layers distinguish between them; they also refer to the stratosphere and mesosphere as the middle atmosphere. *See* ATMOSPHERE; METEOROLOGY; STRATOSPHERE; THERMOSPHERE; TROPOSPHERE.

In the lower part of the mesosphere, the difference between the temperature at the summer and winter poles is of order 35°C (63°F). This large temperature gradient produces the north-south or meridional winds that blow from summer to winter. Temperatures in the upper mesosphere are colder in summer and warmer in winter, resulting in return meridional flow from the summer to the winter hemisphere. Although the temperature gradient in the upper part of the mesosphere remains large, additional complications result in wind speeds that are much slower than they are in the lower part of the mesosphere. Winds in the east-west or zonal direction are greatest at mesospheric middle latitudes. Zonal winds blow toward the west in summer and toward the east in winter. Like their meridional counterparts, zonal winds are comparatively strong near the bottom of the mesosphere and comparatively weak near the top. Thus, on average both temperature and wind speed decrease with increasing height in the mesosphere. *See* ATMOSPHERIC GENERAL CIRCULATION.

Meteors which enter the Earth's atmosphere vaporize in the upper mesosphere. These meteors contain significant amounts of metallic atoms and molecules which may ionize. Metallic ions combined with ionized water clusters make up a large part of the D-region ionosphere that is embedded in the upper mesosphere. *See* IONOSPHERE.

The upper mesosphere is also where iridescent blue clouds can be seen with the naked eye and photographed in twilight at high summer latitudes when the Sun lights them up in the otherwise darkening sky. These clouds are called noctilucent clouds (NLC). Noctilucent clouds are believed to be tiny ice crystals that grow on bits of meteoric dust.

Large-scale atmospheric circulation patterns transport tropospheric air containing methane and carbon dioxide from the lower atmosphere into the middle atmosphere. While carbon dioxide warms the lower atmosphere, it cools the middle and upper atmosphere by releasing heat to space. Methane breaks down and contributes to water formation when it reaches the middle atmosphere. If the air is sufficiently cold, the water can freeze and form noctilucent clouds. Temperatures must be below −129°C (−200°F) for noctilucent clouds to form. These conditions are common in the cold summer mesopause region at high latitudes. [M.Hag.]

Mesostigmata A suborder of the Acarina, commonly referred to as the mites. Mesostigmata are characterized by a single pair of breathing pores, or stigmata, located laterally in the middle of the idiosoma between the second and third, or third and fourth, legs. A two- or three-tined palpal claw and a tritosternum, which is located ventrally on the idiosoma just behind the gnathosoma, are also characteristic for most mesostigmatid mites. The Mesostigmata range from less than 0.008 in. (0.2 mm) to more than 0.16 in. (4 mm) in length and are cosmopolitan in distribution.

Mesostigmatid mites generally pass through an egg stage, a six-legged larval stage, two eight-legged nymphal stages, and an adult stage. In one group of these mites there is a nymphal stage which serves as a means of dispersal for the species. These nymphs attach themselves to insects and other arthropods by means of an anal pedicel and "hitchhike" to the next suitable habitat.

Many of the Mesostigmata are predacious on other small arthropods or are scavengers and fungus-feeders that make up an important segment of the soil fauna. Some members of the family Phytoseiidae are beneficial to humans as predators of the destructive spider mites, Tetranychidae. Other forms are parasitic on insects and other invertebrates. Terrestrial arthropods are the only invertebrate hosts affected by mesostigmatid mites. As a rule, phoresy is the predominant reason for the association. Vertebrate hosts are restricted to mammals, birds, and reptiles. The Mesostigmata that parasitize them are of two main sorts: They are either internal parasites of the respiratory passages, or they are ectoparasitic nidicoles; that is, they reproduce in the nests of their hosts. *See* PHORESY. [J.H.C.; R.W.St.]

Mesozoa A division of the animal kingdom sometimes ranked as intermediate between the Protozoa and the Metazoa. These animals are unassignable to any of the better-known phyla, as usually defined. In the absence of proof concerning their relationships, and in view of the disagreement among zoologists relative to their affinities and even with respect to the facts and interpretation of their structure and life cycle, they are treated as a small phylum somewhere between Protozoa and Platyhelminthes. No particular phylogenetic interpretation should be attached to this placement.

The Mesozoa comprise two orders of small, wormlike organisms, the Dicyemida and the Orthonectida. Both are parasitic in marine invertebrates. The body consists of a single layer of ciliated cells enclosing one or more reproductive cells. These body cells are rather constant in number and arrangement for any given species. The internal cells do not correspond to the entoderm of other animals, as they have no digestive function. The life cycles are complex, involving both sexual and asexual generations (metagenesis). [B.H.McC.]

Mesozoic The middle era of the three major divisions of the Phanerozoic Eon (Paleozoic, Mesozoic, and Cenozoic eras) of geologic time, encompassing an interval from 245 to 65 million years ago (Ma) based on various isotopic age dates. The Mesozoic Era is also known as the Age of the Dinosaurs and the interval of middle life. The Mesozoic Erathem (the largest recognized time-stratigraphic unit) encompasses all sedimentary rocks, body and trace fossils of organisms preserved, metamorphic rocks, and intrusive and extrusive igneous rocks formed during the Mesozoic Era. *See* GEOCHRONOMETRY.

The Mesozoic Era records dramatic changes in the geologic and biologic history of the Earth. At the beginning of the Mesozoic Era, all the continents were amassed into one large supercontinent (Pangaea), with both the marine and continental biotas impoverished from the mass extinction that marked the end of the Paleozoic Era. During the Mesozoic Era, many significant events were recorded in the geologic and fossil record of the Earth, including the breakup of Pangaea and the evolution of modern ocean basins by continental drift, the rise of the dinosaurs, the ascension of the angiosperms (flowering plants), and the appearance of the mammals. The end of the Mesozoic Era is marked by a major mass extinction (at the Cretaceous-Tertiary boundary) that records numerous meteorite impacts, the extinction of the dinosaurs, the rise to dominance of the mammals, and the beginning of the Cenozoic Era and the advanced life forms dominant today. *See* Continental drift; Plate tectonics.

The Mesozoic Era comprises three periods of geologic time: the Triassic Period (245–208 Ma), the Jurassic Period (208–146 Ma), and the Cretaceous Period (146–65 Ma). These periods are each subdivided into epochs, formal designations of geologic time designated as Early, Middle, and Late (except for the Cretaceous, which has no middle epoch). The packages of rock themselves are subdivided into series designated Lower, Middle, and Upper (except for Cretaceous). Each epoch is subdivided into ages. Likewise, each series is subdivided into stages, which are time-stratigraphic units whose boundaries are based on unconformities (erosional surfaces), on correlations to a type section (place were rocks are first described), or preferably on changes in the biota that depict true measurable time (for example, evolutionary changes). *See* Cretaceous; Jurassic; Triassic; Unconformity. [S.T.H.; R.F.Du.]

Messier catalog An early listing of nebulae and star clusters. Charles Messier (1730–1817) was primarily interested in discovering comets, so he compiled a list of objects that might be confused with comets in small telescopes. His first catalog was published in the Royal Academy of Sciences of France in 1771. The compilation contains both open and globular star clusters, diffuse galactic nebulae, so-called planetary nebulae, and external galaxies.

The New General Catalog (NGC) and the supplementary Index Catalogs (IC) published by J. L. E. Dreyer at the end of the 19th century were far more extensive than that of Messier. Consequently the NGC numbers are generally used for all except a few objects whose Messier numbers had become firmly established. *See* Galaxy, external; Nebula; Star clusters. [L.H.Al.]

Metabolic disorders Disorders of metabolism principally involve an imbalance in nucleic acids, proteins, lipids, or carbohydrates. They are usually associated with either a deficiency or excess resulting in an imbalance in a particular metabolic pathway. All metabolic disorders have a genetic background, and some of them are expressed as specific genetic diseases. Other factors affecting metabolism include internal control mechanisms that are superimposed on the genetic background. One of the most important mechanisms is the hormonal control system, which consists of the endocrine, paracrine, and autocrine systems. The second control system that has a significant effect on metabolism is the neural control system. The third control system is the immune control system, which relates to both the endocrine and neural systems. Genetic background, environmental factors, and the three major control mechanisms, in conjunction with age and sex, bring about profound changes in metabolism, which ultimately result in structural and functional alterations. *See* Endocrine mechanisms; Immunology; Nervous system (vertebrate).

Nucleic acids. Abnormalities of nucleic acid metabolism are associated with several diseases, including gout and lupus erythematosus. All genetic disease implies a defect in nucleic acids, and although some genetic diseases are classified as protein abnormalities there is always an inherent defect in the nucleotide. This is either a deficiency, an excess, or a mutation that results in an abnormal protein being formed. Similarly, although lipid storage disease results in an abnormal metabolism of lipids, it is the result of a deficiency of a particular enzyme, which also means a defect in the particular nucleic acid code. In some carbohydrate genetic storage diseases, there is a deficiency of a particular enzyme, which again results from a nucleotide defect. Certain congenital defects that result in malformations of organ systems are the result of either germ cell or somatic cell deficiencies involving differentiation genes composed of nucleic acid.

The genetic disease severe combined immunodeficiency syndrome (SCIDS) results in a deficiency of B lymphocytes, which produce antibody, and T lymphocytes, which are responsible for graft and tumor rejection as a result of their cytotoxic effect. This abnormality is associated with a deficiency of the enzyme adenosine deaminase. *See* Arthritis; Connective tissue; Disease; Gout; Human genetics; Nucleic acid.

Proteins. The diseases associated with protein abnormalities include those associated with increased production of proteins, decreased production of proteins, production of abnormal proteins, and excretion of unusual amounts of amino acids.

Often called macroglobulinemia, hyperproteinemia results in an increase in beta or gamma globulins, but possibly with less total protein. Hyperglobulinemia diseases include multiple myeloma, kala-azar, Hodgkin's disease, lymphogranuloma inguinale, sarcoidosis, cirrhosis, and amyloid disease. They usually involve stem cell lines of the bone marrow macrophages or B cells. *See* Cirrhosis; Hodgkin's disease.

A decrease in the amount of protein (hypoproteinemia) can result from a lack of amino acids for protein synthesis, a metabolic block, or other interference with normal protein synthesis. Increased excretion of protein, particularly in chronic renal disease with a loss of albumin in the urine (albuminuria), is another common cause of hypoproteinemia. Kwashiorkor is the best example of hypoproteinemia resulting from dietary deficiency. In hypogammaglobulinemia and agammaglobulinemia, which may also be classified under hypoproteinemia, the total serum albumin and globulin are not markedly depressed, but the gamma globulins may fall from a normal of 15–20% of total protein to 0.4%. *See* Agammaglobulinemia.

Many diseases are characterized by abnormal proteins, including multiple myeloma, the hemoglobinopathies, and the various amyloid disturbances. Multiple myeloma, a neoplastic growth of plasma cells, particularly in the bone marrow and lymph nodes, is representative of a disease in which an abnormal protein is produced. Another large group of abnormal proteins includes the hemoglobinopathies. Hemoglobin functions in the transport of oxygen in the blood. Scores of different hemoglobins have been identified, but sickle cell in the United States and thalassemia (Mediterranean anemia) in Europe are two of the most common hemoglobin abnormalities. A third type of abnormal protein is found in amyloid disease, of which there are many variations. *See* Amyloidosis; Hemoglobin; Sickle cell disease.

A fourth group with abnormal protein metabolism is associated with a change in particular amino acids resulting either from an overflow mechanism, where the concentration of amino acids in the serum surpasses the renal threshold of the glomerular membrane, or from defective absorption of amino acids in renal tubules. Tyrosine appears to be one of the most critical amino acids, and its metabolism is related to four key diseases including phenylketonuria, hypothyroidism, albinism, and alkaptonuria. The liver plays a major role in the deamination of amino acids. Advanced hepatitis and cirrhosis may lead to increased levels of amino acids in the blood and excretion in the urine. Other diseases with amino aciduria that are believed to be the result of defective kidney function include cystinuria (the failure to reabsorb cystine, lysine, arginine, and ornithine), Wilson's disease (a degeneration involving copper metabolism in the liver and brain), Fanconi's syndrome, galactosemia, scurvy, rickets, and lead, cresol, or benzene poisoning. *See* Kidney disorders; Liver disorders; Phenylketonuria; Protein metabolism; Sickle cell disease.

Lipids. Although lipid stores remain a secondary energy reserve in starvation, the breakdown of lipids associated with diabetes and starvation results in the production of ketone bodies in the urine with general acidosis (ketosis) in the serum. Of concern to many people is an increase in lipids associated with obesity. *See* OBESITY.

Hyperlipemia, an excess of lipid in the blood, is often secondary to uncontrollable diabetes, hypothyroidism, biliary cirrhosis, and lipoid nephrosis. Excess proliferation of fat cells is known as a lipoma, which occasionally becomes malignant, producing a liposarcoma. *See* ARTERIOSCLEROSIS.

In a large group of genetic lipid storage diseases, lipid accumulates because of a disturbance in lipid metabolism that is independent of external stimuli. These genetic diseases are inherent nucleic acid defects that result in abnormal enzymatic proteins, which then result in abnormal lipid metabolism. In these diseases, a large accumulation of lipid appears in many cells, but particularly the reticuloendothelial cells of the lymph nodes, liver, spleen, and bone marrow. Abnormal lipid storage occurs in Niemann-Pick, Gaucher's, and Tay-Sachs diseases.

The heterozygous form of the genetic disease familial hypercholesteremia results in cholesterol levels two to four times normal, and is characterized by arteriosclerotic lesions of the coronary vessels that cause myocardial infarct and death in the 35–50-year age range. In the homozygous condition, with cholesterol levels eight to ten times normal, death occurs usually before the age of 15. The defect resides in the receptor for low-density lipoprotein (LDL). *See* CHOLESTEROL; HEART DISORDERS; LIPID METABOLISM.

Carbohydrates. Abnormal carbohydrate diseases include the genetic diseases that represent a deficiency in nucleotide and eventually protein enzymatic activity. Of the six common carbohydrate storage diseases, two examples are von Gierke's disease, marked by glycogen storage in the heart, and Pompes' disease, in which the carbohydrate is stored in the liver. Variants of carbohydrate disease involve storage of mucopolysaccharides, as in Hurler's disease, and storage of galactose, as in galactosemia.

The most important disease associated with carbohydrate metabolism is diabetes mellitus. *See* CARBOHYDRATE METABOLISM; DIABETES; METABOLISM. [D.W.Ki.]

Metabolism

All the physical and chemical processes by which living, organized substance is produced and maintained and the transformations by which energy is made available for use by an organism.

In defining metabolism, it is customary to distinguish between energy metabolism and intermediary metabolism, although the two are, in fact, inseparable. Energy metabolism is primarily concerned with overall heat production in an organism, while intermediary metabolism deals with chemical reactions within cells and tissues. In general, the term metabolism is interpreted to mean intermediary metabolism. *See* ENERGY METABOLISM.

Metabolism thus includes all biochemical processes within cells and tissues which are concerned with their building up, breaking down, and functioning. The synthesis and maintenance of tissue structure generally involves the union of smaller into larger molecules. This part of metabolism, the building of tissues, is termed anabolism. The process of breaking down tissue, of splitting larger protoplasmic molecules into smaller ones, is termed catabolism. Growth or weight gain occurs when anabolism exceeds catabolism. On the other hand, weight loss results if catabolism proceeds more rapidly than anabolism, as in periods of starvation, serious injury, or disease. When the two processes are balanced, tissue mass remains the same.

The metabolism of the three major foodstuffs, carbohydrates, fats, and proteins, is intimately interrelated, so any clearcut division of the three is arbitrary and inaccurate. Thus the metabolism of protoplasm is concerned with all three of these foodstuffs. The metabolic pathways of carbohydrates, fats, and proteins cross at many points; thus certain pathways of metabolism are shared in common by fragments of these different classes of foodstuffs.

Some of the metabolic processes of the protoplasm of both plant and animal cells occur along common pathways; carbohydrate metabolism in plants is similar in many details to carbohydrate metabolism in animals. Therefore the study of metabolism in any organism is, in a sense, the study of metabolism in all protoplasm. *See* CARBOHYDRATE METABOLISM; KREBS CYCLE; LIPID METABOLISM; PROTEIN METABOLISM. [M.B.McC.]

Metal

An electropositive chemical element. Physically, a metal atom in the ground state contains a partially filled band with an empty state close to an occupied state. Chemically, upon going into solution a metal atom releases an electron to become a positive ion. Consequently in biotic systems metal atoms function prominently in ionic transport and electron exchange. In bulk a metal has a high melting point and a correspondingly high boiling temperature; except for mercury, metals are solid at standard conditions. Direct observation shows a metal to be relatively dense, malleable, ductile, cohesive, highly conductive both electrically and thermally, and lustrous. When crystals of the elements are classified along a scale from plastic to brittle, metals fall toward the plastic end. Furthermore, molten metals mixed with each other over wide ranges of proportions form, upon slowly cooling, homogeneous close-packed crystals. In contrast, a metal mixed with a nonmetal completely combines into a homogeneous crystal only in one or a few discrete stoichiometric proportions.

For detailed discussions of metals, in particular, exceptions to generic behavior, see separate articles on each metal. *See* ELEMENTS; PERIODIC TABLE. [F.H.R.]

Metal, mechanical properties of

Commonly measured properties of metals (such as tensile strength, hardness, fracture toughness, creep, and fatigue strength) associated with the way that metals behave when subjected to various states of stress. The properties are discussed independently of theories of elasticity and plasticity, which refer to the distribution of stress and strain throughout a body subjected to external forces.

Stress states. Stress is the internal resistance, per unit area, of a body subjected to external forces. The forces may be distributed over the surface of a body (surface forces) or may be distributed over the volume (body forces); examples of body forces are gravity, magnetic forces, and centrifugal forces. Forces are generally not uniformly distributed over any cross section of the body upon which they act; a complete description of the state of stress at a point requires the magnitudes and directions of the force intensities on each surface of a vanishingly small body surrounding the point. All forces acting on a point may be resolved into components normal and parallel to faces of the body surrounding the point. When force intensity vectors act perpendicular to the surface of the reference body, they are described as normal stresses. When the force intensity vectors are parallel to the surface, they describe a state of shear stress. Normal stresses are positive, when they act to extend a line (tension). Shear stresses always occur in equal pairs of opposite signs.

A complete description of the state of stress requires knowledge of magnitudes and directions of only three normal stresses, known as principal stresses, acting on reference faces at right angles to each other and constituting the bounding faces of a reference parallelepiped. Three such mutually perpendicular planes may always be found in a body acted upon by both normal and shear forces; along these planes there is no shear stress, but on other planes either shear or shear and tensile forces will exist.

The shear stress is a maximum on a plane bisecting the right angle between the principal planes on which act the largest and smallest (algebraic) principal stresses. The largest normal stress in the body is equal to the greatest principal stress. The magnitude and orientation of the maximum shear stress determine the direction and can control the rate of the inelastic shear processes, such as slip or twinning, which occur in metals. Shear stresses also play a role in crack nucleation and propagation, but the magnitude and direction of the maximum normal stress more often control fracture processes in metals capable only of limited plastic deformation.

It is often useful to characterize stress or strain states under boundary conditions of either plane stress (stresses applied only in the plane of a thin sheet) or plane strain (stresses applied to relatively thick bodies under conditions of zero transverse strain). These two extreme conditions illustrate that strains can occur in the absense of stress in that direction, and vice versa.

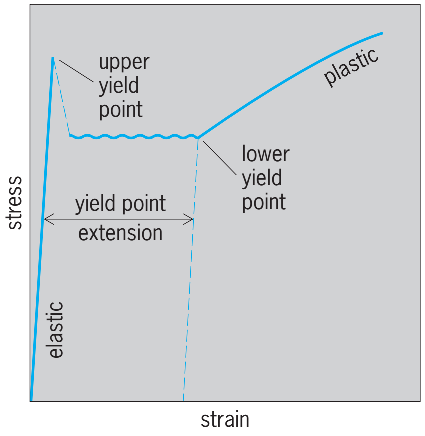
Tension and torsion. In simple tension, two of the three principal stresses are reduced to zero, so that there is only one principal stress, and the maximum shear stress in numerically half the maximum normal stress. Because of the symmetry in simple tension, every plane at 45° to the tensile axis is subjected to the maximum shear stress. For other kinds of loading, the relationship between the maximum shear stress and the principal stresses are obtained using the same method, with the results depending upon the loading condition.

For example, in simple torsion, the maximum principal stress is inclined 45° to the axis of the bar being twisted. The least principal stress (algebraically) is perpendicular to this, at 45° to the bar axis, but equal to and opposite in sign to the first principal stress—that is, it is compressive. Both of these are in a plane perpendicular to the radial direction, the direction of the intermediate principal stress, which in this case has the magnitude zero. Every free external surface of a body is a principal plane on which the principal stress is zero. In torsion, the maximum shear stress occurs on all planes perpendicular to and parallel with the axis of the twisted bar. But because the principal stresses are equal but of opposite sign, the maximum shear stress is numerically equal to the maximum normal stress, instead of to half of it, as in simple tension. This means that in torsion one may expect more ductility (the capacity to deform before fracture) than in tension. Materials that are brittle (exhibiting little capacity for plastic deformation before rupture) in tension may be ductile in torsion. This is because in tension the critical normal stress for fracture may be reached before the critical shear stress for plastic deformation is reached; in torsion, because the maximum shear stress is equal to the maximum normal stress instead of half of it as in tension, the critical shear stress for plastic deformation is reached before the critical maximum normal stress for fracture.

Tension test. To achieve uniformity of distribution of stress and strain in a tension test requires that the specimen be subjected to no bending moment. This is usually accomplished by providing flexible connections at each end through which the force is applied. The specimen is stretched at a controllable rate, and the force required to deform it is observed with an appropriate dynamometer. The strain is measured by observing the extension between gage marks adequately remote from the ends, or by measuring the diameter and calculating the change in length by using the constancy of volume that characterizes plastic deformation. Diameter measurements are applicable even after necking-down has begun. The elastic properties are seldom determined since these are structure-insensitive.

Yield strength. The elastic limit is rarely determined. Metals are seldom if ever ideally elastic, and the value obtained for the elastic limit depends on the sensitivity of strain measurement. The proportional limit, describing the limit of applicability of Hooke's law of linear dependence of stress on strain, is similarly difficult to determine. Modern practice is to determine the stress required to produce a prescribed inelastic strain, which is called the yield strength.

Tensile strength. Tensile strength, usually called the ultimate tensile strength, is calculated by dividing the maximum load by the original cross-sectional area of the specimen. It is, therefore, not the maximum value of the true tensile stress, which increases continuously to fracture and which is always higher than the nominal tensile stress because the area continuously diminishes. For ductile materials the maximum load, upon which the tensile strength is based, is the load at which necking-down begins. Beyond this point, the true tensile stress continues to increase, but the force on the specimen diminishes. This is because the rate of strain hardening has fallen to a value less than the rate at which the stress is increasing because of the diminution of area.



Yield point, mild steel.

Yield point. A considerable number of alloys, including those of iron, molybdenum, tungsten, cadmium, zinc, and copper, exhibit a sharp transition between elastic and plastic flow. The stress at which this occurs is known as the upper yield point. A sharp drop in load to the lower yield point accompanies yielding, followed, in ideal circumstances, by a flat region of yield elongation; subsequently, normal strain hardening is observed (see illustration).

Elongation. The tensile test provides a measure of ductility, by which is meant the capacity to deform by extension. The elongation to the point of necking-down is called the uniform strain or elongation because, until that point on the stress-strain curve, the elongation is uniformly distributed along the gage length. The strain to fracture or total elongation includes the extension accompanying local necking. Since the necking extension is a fixed amount, independent of gage length, it is obvious that the total elongation will depend upon the gage length, and will be greater for short gage lengths and less for long gage lengths.

Ductile-to-brittle transition. Many metals and alloys, including iron, zinc, molybdenum, tungsten, chromium, and structural steels, exhibit a transition temperature, below which the metal is brittle and above which it is ductile. The transition temperature very clearly is sensitive to alloy content, but it will vary even for the same material, depending upon such external test conditions as stress state and strain rate, and microstructural variables such as purity and grain size. The ductility transition frequently is accompanied by a change in the mechanism of fracture (as in iron and steels or zinc), but this need not be so.

Notch tensile test. Notch sensitivity in metals cannot be detected by the ordinary tension test on smooth bar specimens. Either a notched sample may be used in a tension test or a notched-bar impact test may be conducted. Notches produce triaxial stresses under the notch root as tensile forces are applied, thereby decreasing the ratio of shear stress to normal stress and increasing the likelihood of fracture. Materials are evaluated by a quantity, notch strength, which is the analog of the ultimate tensile strength in an ordinary tensile test. The notch strength is defined as the maximum load divided by the original cross-sectional area at the notch root.

Compression test. Very brittle metals, or metals used in products which are formed by compressive loading (rolling, forging), often are tested in compression to obtain yield strength or yield point information. Compression test specimens are generally in the form of solid circular cylinders. The ratio of specimen length to diameter is critical in that high ratios increase the likelihood of buckling during a test, thereby invalidating the test results. Proper specimen alignment is important for the same reason. In addition, care must be taken to lubricate specimen ends to avoid spurious effects from friction between the specimen ends and the testing machine. In the case of a metal which fails in compression by a shattering fracture (for example, cast iron), a quantity known as the compressive strength may be reproducibly obtained by dividing the maximum load carried by the specimen by its cross-sectional area. For materials which do not fail in compression by shattering, the compressive strength is arbitrarily defined as the maximum load at or prior to a specified compressive deformation.

Notched-bar impact test. Notched-bar impact tests are conducted to estimate the resistance to fracture of structures which may contain defects. The common procedure is to measure the work required to break a standardized specimen, and to express the results in work units, such as foot-pounds or newton-meters. The notched-bar impact test does not provide design information regarding the resistance of a material to crack propagation. Rather, it is a comparative test, useful for preliminary screening of materials or evaluation of processing variables. The notch behavior indicated in a single test applies only to the specimen size, notch geometry, and test conditions involved and is not generally applicable to other specimen sizes and conditions. The test is most useful when conducted over a range of temperatures so that the ductile-to-brittle transition can be determined.

Notched-bar tests are usually made in either a simple beam (Charpy) or a cantilever beam (Izod) apparatus, in both of which the specimen is broken by a freely swinging pendulum; the work done is obtained by comparing the position of the pendulum before it is released with the position to which it swings after striking and breaking the specimen. In the Izod test, the specimen is held in a vise, with the notch at the level of the top of the vise, and broken as a cantilever beam in bending with the notch on the tension side. In the Charpy test, the specimen is laid loosely on a support in the path of the pendulum and broken as a beam loaded at three points; the tup (striking edge) strikes the middle of the specimen, with the notch opposite the tup, that is, on the tension side. Both tests give substantially the same result with the same specimen unless the material is very ductile, a situation in which there is little interest.

Hardness testing. When the only information that is needed is the comparison of the resistance to deformation of a particular sample or lot with a standard material, indentation hardness tests are used. They are relatively inexpensive and fast. They tell nothing about ductility and little about the relationship between stress and strain, for in making the indent the stress and strain are nonuniformly distributed.

In all hardness tests, a standardized load is applied to a standardized indenter, and the dimensions of the indent are measured. This applies to such methods as scratch hardness testing, in which a loaded diamond is dragged across a surface to produce, by plastic deformation, a furrow whose width is measured, and the scleroscope hardness test, in which an indent is produced by dropping a mass with a spherical tup onto a surface. The dimensions of the indent are proportional to the work done in producing it, and the ratio of the height of rebound to the height from which the tup was dropped serves as an indirect measure of the hardness.

Fatigue. Fatigue is a process involving cumulative damage to a material from repeated stress (or strain) applications (cycles), none of which exceed the ultimate tensile strength. The number of cycles required to produce failure decreases as the stress or strain level per cycle is increased. The fatigue strength or fatigue limit is defined as the stress amplitude which will cause failure in a specified number of cycles. For a few metals, notably steels and titanium alloys, an endurance limit exists, below which it is not possible to produce fatigue failures no matter how often stresses are applied.

Creep and stress rupture. Time-dependent deformation under constant load or stress is measured in a creep test. Creep tests are those in which the deformation is recorded with time, while stress rupture tests involve the measurement of time for fracture to occur. Closely related are stress relaxation tests, in which the decay of load with time is noted for a body under a fixed state of strain. Test durations vary from seconds or minutes to tens of thousand of hours. Appreciable deformation occurs in structural materials only at elevated temperatures, while pure metals may creep at temperatures well below room temperature.

Since creep deformation and rupture time are temperature- and stress-dependent, it is usually necessary to test a material at several stresses and temperatures in order to establish the creep or stress-rupture properties in adequate detail. *See* METAL; METALLURGY. [N.S.S.]

Metal-base fuel A fuel containing a metal of high heat of combustion as a principal constituent. High propellent performance in either a rocket or an air-breathing engine is obtained when the heat of combustion of the fuel is high. Chemically, high heats of combustion are attained by the oxidation of the low-atomic-weight metals in the upper left-hand corner of the periodic table. The generally preferred candidates are lithium, beryllium, boron, carbon, magnesium, and aluminum.

The metallized additive can be used in either a liquid or solid propellent. When the pure metal is added to liquid fuels, an emulsifying or gelling agent is employed which maintains the particles in uniform suspension. When used in composite solid rocket propellents, the metal powder is usually mixed with the oxidizer and unpolymerized fuel, and the propellant is then processed in the usual way.

Early compounding of metallized propellents employed the free metal itself. As a result of extensive research in metalloorganic compounds, however, several classes of metallic compounds have been employed. Two major reasons for the use of such compounds are that the solubility of the metal in the fuel can be realized, resulting in a homogeneous propellant, and performance higher than that for the pure metal can be obtained in some cases.

The major classes of metallic compounds of interest as high-performance propellents include the hydrides, amides, and hydrocarbons. Additional classes include mixtures either of two metals or of two chemical groups, such as an amine hydrocarbon.

Most metallic fuels are costly and many, because of particle-size requirements or synthesis in a specific compound, are in limited supply. The combustion gases all produce smoky exhausts which may be objectionable in use. Engine development problems are also increased because of the appearance of smoke and deposits in the engine. [D.Al.]

Metal carbonyl A complex of a transition metal combined with carbon monoxide (CO). In a metal carbonyl, the CO groups form sigma bonds to the metal through lone pairs of electrons on carbon; the metal, in turn, donates electrons to antibonding pi orbitals on CO. In so doing, the metal usually attains the electronic configuration of an inert gas (the 18-electron rule). Thus elemental chromium (Cr^0), with six valence electrons, combines with six molecules of CO, each donating two electrons, to afford chromium hexacarbonyl [$Cr(CO)_6$], in which Cr has 18 valence electrons and is isoelectronic to krypton (Kr). *See* CHEMICAL BONDING; COORDINATION COMPLEXES; VALENCE.

Metal carbonyls usually are electrically neutral and nonpolar, exhibiting many of the physical properties of organic compounds. Typically they are volatile solids or liquids, soluble in common organic solvents but insoluble in water. They are highly toxic.

Anionic and cationic species also are known. Metal carbonyls also may contain one (mononuclear) or more (polynuclear) metal atoms. Polynuclear metal carbonyls may exhibit covalent metal-metal bonds, and in them CO also may function as bridging or capping ligands, forming bonds to two or three metal atoms, respectively. Mononuclear metal carbonyls tend to exhibit geometries expected on the basis of minimization of interligand repulsions (valence shell electron-pair repulsion model); their polynuclear analogs often may be envisioned structurally as arising from the fusion of mononuclear polyhedra. Thus nickel tetracarbonyl [$Ni(CO)_4$], iron pentacarbonyl [$Fe(CO)_5$], and chromium hexacarbonyl [$Cr(CO)_6$] exhibit tetrahedral, trigonal bipyramidal, and octahedral geometries, respectively [structures (**1**)–(**3**)]. The polynuclear manganese carbonyl [$Mn_2(CO)_{10}$] has a structure obtained by joining two octahedra at a vertex [structure (**4**)], and the structure of diiron enneacarbonyl [$Fe_2(CO)_9$] is viewed as two octahedra sharing three bridging carbonyls at a face [structure (**5**)].

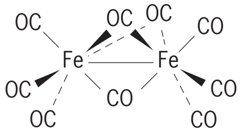
(4)



(5)

Metal carbonyls react in solution under relatively mild conditions to form a variety of substitution products, with Lewis bases such as amines, phosphines, sulfides, and nitric oxide and with organic molecules such as alkenes, alkynes, arenes, and other aromatic compounds. Reactions of metal carbonyls can also afford derivatives containing alkyl, acyl, allyl, halide, hydride, carbene, carbyne, and other substituents. They thus are the most important precursors to the synthesis of organotransition metal complexes. Their thermal decomposition can afford pure metals and CO. [G.R.B.]

Metal casting A metal-forming process whereby molten metal is poured into a cavity or mold and, when cooled, solidifies and takes on the characteristic shape of the mold. Casting offers several advantages over other methods of metal forming: it is adaptable to intricate shapes, to extremely large pieces, and to mass production; it can provide parts with uniform physical and mechanical properties throughout; and depending on the particular material being cast, the design of the part, and the quantity being produced, it can be more economical.

The two broad categories of metal-casting processes are ingot casting and casting to shape. Ingot castings are produced by pouring molten metal into a permanent or reusable mold. Following solidification, the ingots (bars, slabs, or billets) are processed mechanically into many new shapes. Casting to shape involves pouring molten metal into molds in which the cavity provides the final useful shape, followed by heat treatment and machining or welding, depending upon the specific application.

While design factors are important for producing sound castings with proper dimensions, factors such as the pouring temperature, alloy content, mode of solidification, gas evolution, and segregation of alloying elements control the final structure of the casting and therefore its mechanical and physical properties. Typically, pouring temperatures are selected within 100–300°F (60–170°C) of an alloy's melting point. Exceedingly high pouring temperatures can result in excessive mold metal reactions, producing numerous casting defects.

Almost all metals and alloys used by engineering specialists have at some point been in the molten state and cast. Metallurgists have in general lumped these materials into ferrous and nonferrous categories. Ferrous alloys, cast irons and steels, constitute the largest tonnage of cast metals. Aluminum-, copper-, zinc-, titanium-, cobalt-, and nickel-base alloys are also cast into many forms, but in much smaller quantity than cast iron and steel. Selection of a given material for a certain application will depend upon the physical and chemical properties desired, as well as cost, appearance, and other special requirements. *See* Metal, mechanical properties of; Metal forming. [K.R.]

Metal cluster compound A compound in which two or more metal atoms are bonded to one another. Metal cluster compounds bridge the gap between the solid-state chemistry of the metals—or their lower-valent oxides, chalcogenides, and related salts—and the complexes of the metals in which each metal ion is completely surrounded by and bonded to a set of ligands or ions. The latter group comprises the classical coordination chemistry of metal ions. *See* Coordination chemistry; Coordination complexes; Solid-state chemistry.

Interest in metal cluster compounds arises from unique features of their chemistry:break (1) Cluster compounds provide models for studying fundamental reactions on surfaces. (2) There is a hope that cluster compounds may provide entry to new classes of catalysts that may be tailored to specific syntheses and may thus be more selective than existing processes. (3) The nature of the bonding in cluster compounds is an area wherein experiment and theory are continuously challenging each other. (4) The systematic synthesis of mixed metal clusters may provide for the development of new types of supported catalysts (the discrete clusters are deposited on supports such as alumina, silica, or zeolites). *See* Atom cluster; Nanostructure. [M.H.Ch.]

Metal coatings Thin films of material bonded to metals in order to add specific surface properties, such as corrosion or oxidation resistance, color, attractive appearance, wear resistance, optical properties, electrical resistance, or thermal protection. This article discusses various methods of applying either metallic coatings or nonmetallic coatings, such as vitreous enamel and ceramics, and the conversion of surfaces to suitable reaction-product coatings. For other methods for the protection of metal surfaces *see* Cladding; Electroless plating; Electroplating of metals; Lacquer; Paint.

Hot-dipped coatings of low-melting metals provide inexpensive protection to the surfaces of a variety of steel articles. Thoroughly cleaned work is immersed in a molten bath of the coating metal. The coating consists of a thin alloy layer together with relatively pure coating metal that adheres to the work as it is withdrawn from the bath.

Sprayed coating permits the coating of assembled steel structures to obtain corrosion resistance, the building up of worn machine parts for rejuvenation, and the application of highly refractory coatings with melting points in excess of 3000°F (1650°C).

Cementation coatings are surface alloys formed by diffusion of the coating metal into the base metal, producing little dimensional change. Parts are heated in contact with powdered coating material that diffuses into the surface to form an alloy coating, whose thickness depends on the time and the temperature of treatment.

In vapor deposition a thin specular coating is formed on metals, plastics, paper, glass, and even fabrics. Coatings form by condensation of metal vapor originating from molten metal, from high-voltage discharge between electrodes (cathode sputtering), or from chemical means such as hydrogen reduction or thermal decomposition (gas plating) of metal halides.

Immersion coatings are produced either by direct chemical displacement or for thicker coatings by chemical reduction (electroless coating). Metal ions plate out of solution onto the workpiece.

Vitreous enamel coatings are glassy but noncrystalline coatings for attractive durable service in chemical, atmospheric, or moderately high-temperature environments. In wet enameling, a slip is prepared of a water suspension of crushed glass, flux, suspending agent, refractory compound, and coloring agents or opacifiers. The slip is applied by dipping or flow coating; it is then fired at a temperature at which it fuses into a continuous vitreous coating. Dry enameling is used for castings, such as bathtubs. The casting is heated to a high temperature, and then dry enamel powder is sprinkled over the surface, where it fuses. *See* FRIT.

Essentially crystalline, ceramic coatings are used for high-temperature protection above 1100°C (2000°F). The coatings may be formed by spraying refractory materials such as aluminum oxide or zirconium oxide, or by the cementation processes for coatings of intermetallic compounds such as molybdenum disilicide. *See* CERMET.

Surface-conversion coatings provide an insulating barrier of low solubility formed on steel, zinc, aluminum, or magnesium without electric current. The article to be coated is either immersed in or sprayed with an aqueous solution, which converts the surface into a phosphate, an oxide, or a chromate.

Anodic coatings of protective oxide may be formed on aluminum or magnesium by making them the anode in an electrolytic cell. If permanent color is required, the coating is impregnated with a dye before sealing. *See* CORROSION. [W.W.Br.]

Powder coating is a process whereby organic polymers such as acrylic, polyester, and epoxies are applied to substrates for protection and beautification. It is essentially an industrial painting process which uses a powdered (25–50-μm particle size) resin rather than the solvent solution. The powders are applied to electrically grounded substrates, usually by means of an electrostatic spray gun. The powder particles are attracted to and adhere to the substrate until it can be transported to an oven, where the powder particles melt, coalesce, flow, and form a smooth coating. Outdoor lawn and patio furniture coated in this process display good weathering and abuse resistance. Powder-coated electrical transformers are insulated electrically and provided with corrosion protection. Powder coatings have also been developed for finishing major appliances and for automotive coatings. *See* SURFACE COATING. [R.F.Fa.]

Metal forming Manufacturing processes by which parts or components are fabricated from metal stock. In the specific technical sense, metal forming involves changing the shape of a piece of metal. In general terms, however, it may be classified roughly into five categories: mechanical working, such as forging, extrusion, rolling, drawing, and various sheet-forming processes; casting; powder and fiber metal forming; electroforming; and joining processes. *See* DRAWING OF METAL; EXTRUSION; FORGING; METAL CASTING; METAL ROLLING; POWDER METALLURGY; SHEET-METAL FORMING. [S.Ka.]

Metal halide lamp A high-pressure discharge lamp that is enclosed in a quartz envelope containing metal halides, usually iodides, and produces high-efficacy white light. These lamps are widely used for sports stadiums, roadways, commercial interiors, and industrial applications. The singular lamp feature is the compact geometry and high efficacy of nearly white light. *See* LUMINOUS EFFICACY.

The metal halide lamp requires a high voltage in order to start. Once the arc discharge is ignited, the internal vapor pressure begins to increase until it reaches a preset value, usually around 5 atm (500 kilopascals). These lamps are always connected to an auxiliary power supply called the ballast which supplies the proper voltage and current for starting and operating the lamps. The light output gradually increases over approximately 2 min as the various ingredients begin to vaporize and emit light. The light from the arc discharge comes from the metal components of the iodide compounds, which are typically a mixture of sodium, thallium, indium, scandium, dysprosium, and occasionally tin iodide. A combination of these metals produces a pleasing white light of very high efficiency, between 80 and 120 lumens per watt or even higher. *See* ARC DISCHARGE.

Special ingredients can be used inside these lamps to make them suitable for plant growth, photocopying, and scientific usages. Certain types of compact metal halide lamps are ideal for use with movie and slide projection. In these cases, the ingredients chosen (usually indium) are used because they produce a small, intense high-brightness arc. The spectra of these lamps are nearly continuous and approach the spectra found in an incandescent lamp. *See* CINEMATOGRAPHY; INCANDESCENT LAMP; OPTICAL PROJECTION SYSTEMS.

In cases where a more diffuse light source is desired, the outer jacket of the lamp can be coated with a white phosphor in order both to diffuse the light and to change the color of the output and in some cases actually improve the efficiency. [G.H.R.]

Metal hydrides A compound in which hydrogen is bonded chemically to a metal or metalloid element. The compounds are classified generally as ionic, transition metal, and covalent hydrides. Covalent hydrides are of two subtypes, binary and complex. Certain hydrides have achieved a position of modest industrial importance, but most are of theoretical interest only.

Under extreme conditions such as in electric discharges, many metals form volatile, short-lived transient hydrides of the general formula type MH. Although some of these can be prepared experimentally, most are observed only by their spectra. They are important in studying molecular bonding. The action of atomic hydrogen at low temperatures forms surface films of unstable hydrides with many metals. *See* HYDRIDO COMPLEXES; HYDROGEN. [J.C.W.]

Metal matrix composite A material in which a continuous metallic phase (the matrix) is combined with another phase (the reinforcement) that constitutes a few percent to around 50% of the material's total volume. In the strictest sense, metal matrix composite materials are not produced by conventional alloying. This feature differentiates most metal matrix composites from many other multiphase metallic materials, such as pearlitic steels or hypereutectic aluminum-silicon alloys. *See* ALLOY.

The particular benefits exhibited by metal matrix composites, such as lower density, increased specific strength and stiffness, increased high-temperature performance limits, and improved wear-abrasion resistance, are dependent on the properties of the matrix alloy and of the reinforcing phase. The selection of the matrix is empirically based, using readily available alloys; and the major consideration is the nature of the reinforcing phase.

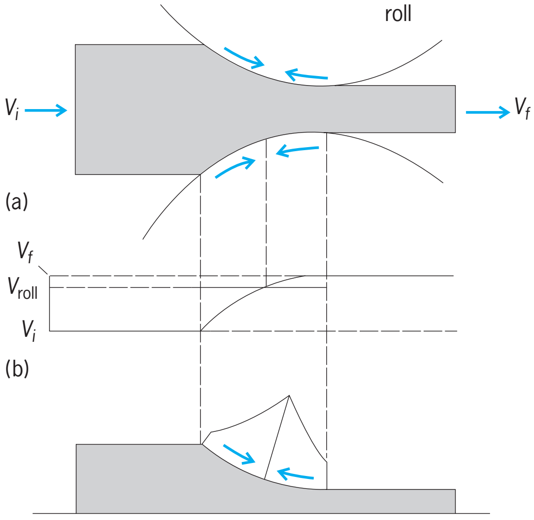
A large variety of metal matrix composite materials exist. The reinforcing phase can be fibrous, platelike, or equiaxed (having equal dimensions in all directions); and its size can also vary widely, from about 0.1 to more than 100 micrometers. Matrices based on most engineering metals have been explored, including aluminum, magnesium, zinc, copper, titanium, nickel, cobalt, iron, and various aluminides. This wide variety of systems has led to an equally wide spectrum of properties for these materials and of processing methods used for their fabrication. Reinforcements used in metal matrix composites fall in five categories: continuous fibers, short fibers, whiskers, equiaxed particles, and interconnected networks.

Composite properties depend first and foremost on the nature of the composite; however, certain detailed microstructural features of the composite can exert a significant influence on its behavior. Physical properties of the metal, which can be significantly altered by addition of a reinforcement, are chiefly dependent on the reinforcement distribution. A good example is aluminum-silicon carbide composites, for which the presence of the ceramic increases substantially the elastic modulus of the metal without greatly affecting its density. However, the level of improvement depends on the shape and alignment of the silicon carbide. Also, it depends on the processing of the reinforcement: for the same reinforcement shape (continuous fibers), microcrystalline polycarbosilane-derived silicon carbide fibers yield much lower improvements than do crystalline β-silicon carbide fibers. Other properties, such as the strength of metal matrix composites, depend in a much more complex manner on composite microstructure. The strength of a fiber-reinforced composite, for example, is determined by fracture processes, themselves governed by a combination of microstructural phenomena and features. These include plastic deformation of the matrix, the presence of brittle phases in the matrix, the strength of the interface, the distribution of flaws in the reinforcement, and the distribution of the reinforcement within the composite. Consequently, predicting the strength of the composite from that of its constituent phases is generally difficult. *See* BRITTLENESS; PLASTIC DEFORMATION OF METAL.

The combined attributes of metal matrix composites, together with the costs of fabrication, vary widely with the nature of the material, the processing methods, and the quality of the product. In engineering, the type of composite used and its application vary significantly, as do the attributes that drive the choice of metal matrix composites in design. For example, high specific modulus, low cost, and high weldability of extruded aluminum oxide particle-reinforced aluminum are the properties desirable for bicycle frames. High wear resistance, low weight, low cost, improved high-temperature properties, and the possibility for incorporation in a larger part of unreinforced aluminum are the considerations for design of diesel engine pistons. *See* COMPOSITE MATERIAL; HIGH-TEMPERATURE MATERIALS. [M.M.S.]

Metal rolling Reducing or changing the cross-sectional area of a workpiece by the compressive forces exerted by rotating rolls. The original material fed into the rolls is usually an ingot from a foundry. The largest product in hot rolling is called a bloom; by successive hot- and then cold-rolling operations the bloom is reduced to a billet, slab, plate, sheet, strip, and foil, in decreasing order of thickness and size. The initial breakdown of the ingot by rolling changes the coarse-grained, brittle, and porous structure into a wrought structure with greater ductility and finer grain size.

A schematic presentation of the rolling process, in which the thickness of the metal is reduced as it passes through the rolls, is shown in illus. *a*. The speed at which the metal moves during rolling changes, as shown in illus. *b*, to keep the volume rate of flow constant throughout the roll gap. Hence, as the thickness decreases, the velocity increases; however, the surface speed of a point on the roll is constant, and there is therefore relative sliding between the roll and the strip. The normal pressure distribution on the roll and hence on the strip is of the form shown in illus. *c*. Because of its particular shape this pressure distribution is known as the friction hill.



The rolling process, (*a*) Direction of friction forces in the roll gap. (*b*) Velocity distribution, (*c*) Normal pressure acting on the strip in the roll gap. V_i = initial velocity, V_f = final velocity, V_{roll} = velocity during rolling operation.

A great variety of roll arrangements and equipment are used in rolling. The proper reduction per pass in rolling depends on the type of material and other factors; for soft, nonferrous metals, reductions are usually high, while for high-strength alloys they are small. Requirements for roll materials are mainly strength and resistance to wear. Common roll materials are cast iron, cast steel, and forged steel. [S.Ka.]

Metallic glasses Alloys having amorphous or glassy structures. A glass is a solid material obtained from a liquid which does not crystallize during cooling. It is therefore an amorphous solid, which means that the atoms are packed in a more or less random fashion similar to that in the liquid state. The word glass is generally associated with the familiar transparent silicate glasses containing mostly silica and other oxides of aluminum, magnesium, sodium, and so on. These glasses are not metallic; they are electrical insulators and do not exhibit ferromagnetism. Glass having metallic properties is obtained from a melt containing metallic elements instead of oxides. However, liquid metals and alloys crystallize so rapidly on cooling that it was not until 1960 that the first true metallic glass, an alloy of gold and silicon ($Au_{80}Si_{20}$), containing 80 at. % Au and 20 at. % Si, was obtained. *See* AMORPHOUS SOLID.

The effect of adding solute atoms to a pure metal, especially if they are of a size and chemical character different from those of the host atoms, is to suppress the freezing temperature, so that the probability of solidifying the melt without crystallization is increased. Accordingly, the alloy systems for which glass formation occurs most readily are those manifesting either one or more eutectics. Those compositions with the lowest liquidus temperature, that is, near eutectic compositions, thus form a glass most easily. The known glass-forming families are alloys of transition metals or noble metals that contain about 10–30% semimetal [for example, platinum/phosphorus ($Pt_{75}P_{25}$) or iron/boron ($Fe_{80}B_{20}$)], alloys of early-transition metals only [for example, zirconium/palladium ($Zr_{70}Pd_{30}$) or niobium/rhodium ($Nb_{60}Rh_{40}$)], alloys containing metals from group 2 in the periodic table [for example, magnesium/zinc ($Mg_{70}Zn_{20}$) or calcium/magnesium ($Ca_{70}Mg_{30}$)], and alloys of rare-earth metals and transition metals [for example, gadolinium/cobalt ($Gd_{70}Co_{30}$) or yttrium/iron ($Y_{60}Fe_{40}$)]. In a few cases, the glass-forming composition does not fall at the eutectic point but in a composition range richer in the minor element, such as alloys of aluminum (Al) and rare-earth metals (for example, $Al_{90}Y_{10}$ or $Al_{90}Gd_{10}$). Binary alloy glasses can be obtained only as thin foils about 0.002 in. (50 μm) thick, because a critical quenching rate of 1.8×10^5 °F/s (10^5 K/s) is required to retain the glassy phase. When further solute is substituted, the stability and glass-forming tendency can be drastically enhanced. Ternary alloy glasses, for example, palladium/copper/silicon ($Pd_{77}Cu_6Si_{17}$), palladium/nickel/phosphorus ($Pd_{40}Ni_{40}$-P_{20}), and platinum/nickel/phosphorus ($Pt_{60}Ni_{15}P_{25}$), have been prepared as cylindrical rods of 0.100 in. (2.5 mm) in diameter at a quenching rate of 1.8×10^2 °F/s (10^2 K/s) or less. *See* PHASE EQUILIBRIUM.

The electrical properties of crystalline metals and alloys are generally well understood. The absence of a crystal lattice in metallic glasses results in substantial changes in their electrical properties and has theoretical applications in studies of transport properties in solids.

The electrical resistivity of metallic glasses is high, for example 100 $\mu\Omega$-cm and higher, which is in the same range as the familiar nichrome alloys widely used as resistance elements in electric circuits. Another interesting characteristic of the electrical resistivity of metallic glasses is that it does not vary much with temperature. Because of their insensitivity to temperature variations, metallic glasses are suitable for applications in electronic circuits for which this property is an essential requirement.

The first superconducting metallic glass was reported in 1975. This was an alloy containing 80 at. % lanthanum (La) and 20 at. % Au. Some superconducting metallic glasses contain only two metals, such as $Zr_{75}Rh_{25}$, and some are more complex alloys in which there is approximately 20% of metalloid elements, mostly B, Si, or P. One of the main reasons for continuing research on new superconducting glasses is their projected usefulness in high-field electromagnets, which will be required to contain the high-temperature plasma in fusion reactors. *See* Superconductivity.

The ferromagnetic properties of metallic glasses have received a great deal of attention, probably because of the possibility that these materials can be used as transformer cores.

Ferromagnetic amorphous alloys had been prepared before the technique of rapid cooling from the liquid state was developed. Electrolytic deposits of NiP alloys are slightly ferromagnetic for P concentrations less than 17 at. %. Amorphous CoP alloys can be electrodeposited in the amorphous state for P concentrations from 18 to 25 at. % Co and are also ferromagnetic. Ferromagnetism was also measured in alloys of Co with Au in the form of vapor-deposited thin films. These results suggested that it should be possible to obtain a ferromagnetic metallic glass from a liquid alloy containing a high enough percentage of ferromagnetic metals. The choice of alloying elements was guided by trying to satisfy the low-melting-point eutectic composition of the original AuSi glass, and Fe was the most obvious choice for the metal constituent.

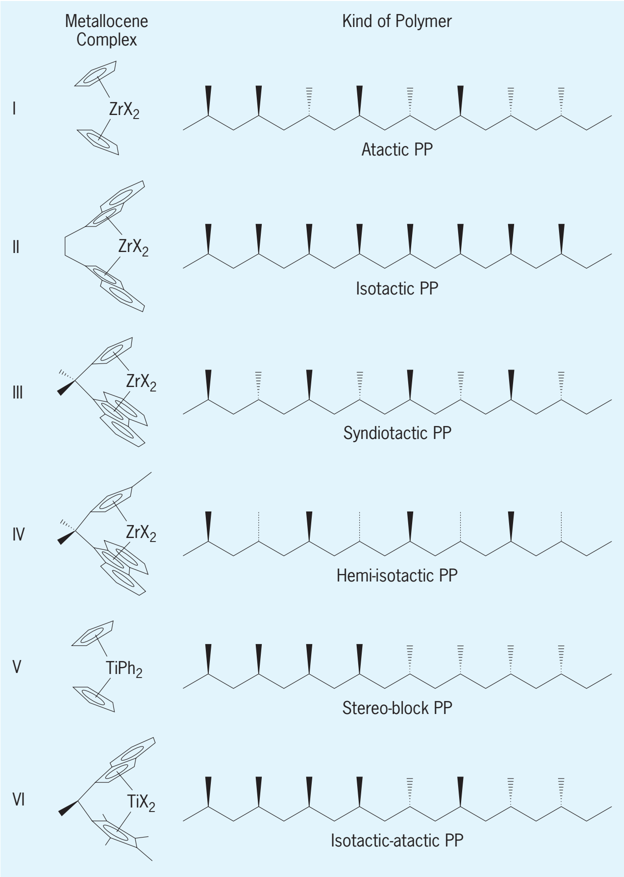
The interest in the mechanical properties of metallic glasses is motivated by their high rupture strength and toughness. The fracture strength of metallic glasses approaches a theoretical strength that is about 1/50 of Young's modulus. Iron-based glasses have a fracture strength of 5×10^5 lb/in.^{2} (3.4 GPa), which is comparable to the best hard-drawn piano wires. Remarkably, despite their high strength, metallic glasses exhibit a high toughness contrary to the brittle behavior inherent in nonmetallic and high-strength crystalline metals. The ductility and toughness of Fe-based glasses, however, are very sensitive to thermal annealing. A complete loss in ductility of Fe glasses may occur after annealing without crystallization. In contrast, glass-forming alloys of Ni, Pd, and Pt as well as metal-metal alloys (Nb-Ni,Zr-Cu) remain ductile even in a partially crystalline state. The causes of embrittlement are still not clear. *See* Young's modulus.

Possible applications of metallic glasses have already been demonstrated on audio and video magnetic tape recording heads, sensitive and quick-response magnetic sensors or transducers, security systems, motors, and power transformer cores. The combination of excellent strength, resistance to corrosion and wear, and magnetic properties may lead to interesting applications, for example, the use of such glasses as inductors in magnetic separation equipment. [P.E.D.; H.S.C.]

Metallocene catalyst A transition-metal atom sandwiched between ring structures having a well-defined single catalytic site and well-understood molecular structure used to produce uniform polyolefins with unique structures and physical properties. *See* Catalysis; Coordination chemistry; Coordination complexes; Metallocenes; Organometallic compound.

In the early 1980s, W. Kaminsky discovered that an appropriate co-catalyst activated metallocene compounds of group 4 metals, that is, titanium, zirconium, and hafnium, for alpha-olefin polymerization, attracting industrial interest. This observation led to the synthesis of a great number of metallocene compounds for the production of polymers already made industrially, such as polyethylene and polypropylene, and new materials. Polymers produced with metallocene catalysts represent a small fraction of the entire polyolefin market, but experts agree that such a fraction will increase rapidly in the future. *See* Polymer; Polymerization; Polyolefin resins.

The simplest metallocene precursor has the formula Cp_2MX_2, where M is one of the group 4 metals (mainly Zr and Ti) and X are halogen atoms (mainly chlorine, Cl). The latter are known as mobile ligands because during polymerization they are substituted or removed. A typical co-catalyst, in the absence of which the activity is very low, is methylaluminoxane (MAO), an oligomeric compound described by the formula $(CH_3AlO)_n$, whose structure is not yet fully understood. MAO plays several roles: it alkylates the metallocene precursor by replacing chlorine atoms with methyl groups; it produces the catalytic active ion pair $Cp_2MCH_3^+/MAO^-$, where the cationic moiety is considered responsible for polymerization and MAO^- acts as weakly coordinating anion.

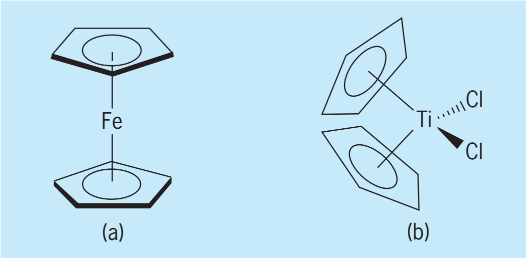


Correlation between the metallocene structure and the obtained polymer microstructure. PP = polypropylene.

The simplest metallocene structures are easily modified by replacing the Cp ligands with other variously substituted derivatives. In this way, a great number of catalysts with different steric and electronic properties are generated. The catalysts contain two C5 ring derivatives, always lying on tilted planes, which can be bridged or unbridged. Some examples are shown in the illustration, where the influence of the metallocene structure on the microstructure of the polymer product is also shown.

Because activity, stereospecificity, regiospecificity, and relative reactivity toward different monomers depend on the catalysts' characteristics, the metallocene systems offer the advantage of controlling the product through modifications of their chemical structure. [R.F.; F.G.; L.Lo.]

Metallocenes Bis-cyclopentadienyl derivatives of transition metals whose bonding involves overlap of *ns*, $(n - 1)d$, and *np* orbitals of the metal with molecular orbitals of appropriate symmetry of each cyclopentadienyl ring. The resulting complexes often possess two parallel rings (sandwich structure), but in some cases, for example those involving the titanium subgroup of metals, the rings are canted (see illustration). Metals in the periodic table commonly known to form metallocene complexes



Metallocene structures. (*a*) Staggered sandwich structure of ferrocene. (*b*) Canted cyclopentadienyl ring structure of titanocene dichloride. The distribution of the ligands about the Ti atom is tetrahedral.

are titanium, zirconium, hafnium, vanadium, chromium, molybdenum, tungsten, manganese, iron, ruthenium, osmium, cobalt, rhodium, and nickel. *See* COORDINATION COMPLEXES.

The reactions of metallocenes can be divided into two classes: the first is typified by the iron triad, and comprises essentially the reactions of aromatic molecules; the second consists of the reactions of the other metallocenes where the 18-electron rare-gas configuration is not found. Reactions in these latter systems often lead to a product where the 18-electron rule is obeyed.

Ferrocene is a very electron-rich system, and undergoes electrophilic substitution with great rapidity. For example, acylation proceeds about 10^6 times faster than that of benzene under similar conditions. Ferrocene also undergoes several other typical aromatic substitution reactions besides acylation, including sulfonation, dimethylaminomethylation (Mannich reaction), metalation, and the like. Bis substitution tends to factor a product where each ring is monosubstituted, although several cases are known where two substituents are introduced into one ring. Ferrocene is oxidized and deactivated under conditions for nitration and halogenation.

Uses of metallocenes include reaction of chromocene with alumina to make a polymerization catalyst for ethylene. Ferrocene and some alkyl-substituted ferrocenes have been used as moderators in high-temperature combustions such as occur in solid rocket fuels. A cyclopentadienyl complex, $CH_3C_5H_4Mn(CO)_3$, briefly replaced tetraethyllead as an octane booster and antiknock agent in liquid fuels. *See* ORGANOMETALLIC COMPOUND. [D.W.Sl.]

Metallochaperones A family of proteins that shuttle metal ions to specific sites within a cell. The target sites for metal delivery include a number of metalloenzymes, or proteins that bind metal ions, such as copper, zinc, or iron, and use these ions as cofactors to carry out essential biochemical reactions. Metallochaperones escort the ion to a specific intracellular location and facilitate incorporation of the metal into designated metalloenzymes. *See* BIOINORGANIC CHEMISTRY; CELL (BIOLOGY).

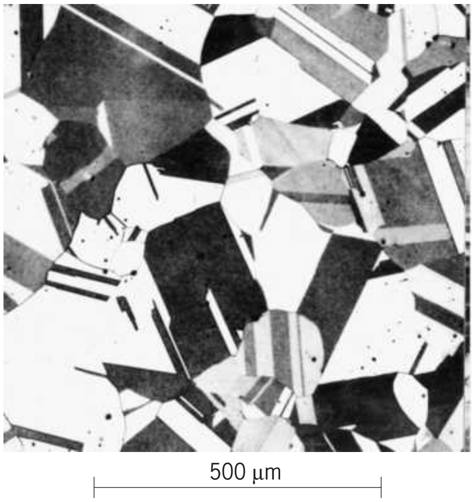
The bulk of current knowledge on metallochaperones is restricted to copper, although it is reasonable to assume that a distinct class of proteins is responsible for the incorporation of other metal ion cofactors into metalloenzymes. Among the metallochaperones that have been studied in detail are a family of three copper chaperones. These molecules operate in eukaryotic (nucleated) cells to direct copper to distinct intracellular locations: the mitochondria, the secretory pathway, and the cytosol. The first copper chaperone identified, COX17, is a small protein that specifically directs copper to the mitochondria. The copper delivered by COX17 is inserted into the metalloenzyme cytochrome oxidase, needed for respiration. A second copper chaperone identified was ATX1, which carries copper to the secretory pathway, a cellular compartment that functions to shuttle proteins toward the cell surface. The metal delivered by ATX1 is incorporated into copper enzymes destined for the cell surface or the extracellular milieu. The most recently identified copper chaperone is CCS, which specifically delivers copper to a single metalloenzyme, superoxide dismutase. This copper-requiring enzyme is located in the soluble cytosolic compartment of the cell and acts to detoxify harmful reactive oxygen species. *See* MITOCHONDRIA.

Intracellular copper is normally present at exquisitely low levels, and activation of copper enzymes is wholly dependent upon copper chaperones. Copper not only is an essential nutrient but also is quite toxic to living cells, and elaborate detoxification mechanisms prevent the free metal ion from accumulating to any substantial degree. The copper-requiring metalloenzymes cannot compete for these vanishingly low levels of available metal, explaining the requirement for the copper metallochaperones. [V.C.C.]

Metallography The study of the structure of metals and alloys by various methods, especially light and electron microscopy. Light microscopy of metals is conducted with reflected light on surfaces suitably prepared to reveal structural features. The method is often called optical microscopy or light optical microscopy. A resolution of about 200 nanometers and a linear magnification of at most 2000× can be obtained. Electron microscopy is generally carried out by the scanning electron microscope (SEM) on specimen surfaces or by the transmission electron microscope (TEM) on electron-transparent thin foils prepared from bulk materials. Magnifications can range from 10× to greater than 1,000,000×, sufficient to resolve individual atoms or planes of atoms.

Metallography serves both research and industrial practice. Light microscopy has long been a standard method for observing the morphology of phases resulting from industrial processes that involve phase transformations, such as solidification and heat treatment, and plastic deformation and annealing. Microscopy, both light and electron, is also indispensable for the analysis of the causes of service failures of components and products.

In light microscopy, microstructural features observed in photomicrographs include the size and shape of the grains (crystals) in single-phase materials (see illustration), the structure of alloys containing more than one phase such as steel, the effects of deformation, microcracking, and the effects of heat treatment. Other structural features investigated by light microscopy include the morphology and size of precipitates, compositional inhomogeneities (microsegregation), microporosity, corrosion, thickness and structure of surface coatings, and microstructure and defects in welds.



Photomicrographs of typical microstructures of annealed brass (70% Cu–30% Zn). ***(Courtesy of W. R. Johnson)***

The electron microscope offers improved depth of field and higher resolution than the light microscope, as well as the possibility of in-place spectroscopy techniques. The scanning electron microscope images the surface of a material, while the transmission electron microscope reveals internal microstructure. Images produced by the scanning electron microscope are generally easier to interpret; in addition, the instrument operates at lower voltages, offers lower magnification, and requires less specimen preparation than is necessary for the transmission electron microscope. Consequently it is important to view a specimen with light microscopy and often with the scanning electron microscope before embarking on transmission electron microscopy.

However there are some disadvantages. Electron microscope specimens are viewed under vacuum, the instruments cost significantly more than light microscopes, electron beam damage is always a danger, and representative sampling becomes more difficult as the magnification increases. *See* ELECTRON MICROSCOPE.

The ionizing nature of electron irradiation means that x-ray spectrometry and electron spectrometry, both powerful tools in their own right, can be performed in both scanning electron microscopy and transmission electron microscopy. The various signals detected spectroscopically can also be used to form images of the specimen, which reveal elemental distribution among other information. In particular, the characteristic x-ray signal can be detected and processed to map the elemental distribution quantitatively on a micrometer scale in the scanning electron microscope and a nanometer scale in the transmission electron microscope. Electron spectroscopic signals permit not only elemental images to be formed but also images that reveal local changes in bonding, dielectric constant, thickness, band gap, and valence state. *See* ELECTRON SPECTROSCOPY; METALLURGY. [D.A.T.; D.B.Wi.]

Metalloid An element which exhibits the external characteristics of a metal but behaves chemically both as a metal and as a nonmetal. Arsenic and antimony, for example, are hard crystalline solids that are definitely metallic in appearance. They may, however, undergo reactions that are characteristic of both metals and nonmetals. However, only when this dualistic chemical behavior is very marked and the external appearance metallic is the element commonly called a metalloid. *See* METAL; NONMETAL. [F.J.J.]

Metallurgy The technology and science of metallic materials. Metallurgy as a branch of engineering is concerned with the production of metals and alloys, their adaptation to use, and their performance in service. As a science, metallurgy is concerned with the chemical reactions involved in the processes by which metals are produced and the chemical, physical, and mechanical behavior of metallic materials.

The field of metallurgy may be divided into process metallurgy (production metallurgy, extractive metallurgy) and physical metallurgy. In this system metal processing is considered to be a part of process metallurgy and the mechanical behavior of metals a part of physical metallurgy.

Process metallurgy, the science and technology used in the production of metals, employs some of the same unit operations and unit processes as chemical engineering. These operations and processes are carried out with ores, concentrates, scrap metals, fuels, fluxes, slags, solvents, and electrolytes. Different metals require different combinations of operations and processes, but typically the production of a metal involves two major steps. The first is the production of an impure metal from ore minerals, commonly oxides or sulfides, and the second is the refining of the reduced impure metal, for example, by selective oxidation of impurities or by electrolysis. *See* ELECTROMETALLURGY; HYDROMETALLURGY; IRON METALLURGY; ORE DRESSING; PYROMETALLURGY; STEEL MANUFACTURE.

Physical metallurgy investigates the effects of composition and treatment on the structure of metals and the relations of the structure to the properties of metals. Physical metallurgy is also concerned with the engineering applications of scientific principles to the fabrication, mechanical treatment, heat treatment, and service behavior of metals. *See* ALLOY; HEAT TREATMENT (METALLURGY).

The structure of metals consists of their crystal structure, which is investigated by x-ray, electron, and neutron diffraction, their microstructure, which is the subject of metallography, and their macrostructure. Crystal imperfections, which provide mechanisms for processes occurring in solid metals, are investigated by x-ray diffraction and metallographic methods, especially electron microscopy. The microstructure is determined by the constituent phases and the geometrical arrangement of the microcrystals (grains) formed by those phases. Macrostructure is important in industrial metals. It involves chemical and physical inhomogeneities on a scale larger than microscopic. Examples are flow lines in steel forgings and blowholes in castings. *See* METALLOGRAPHY; X-RAY DIFFRACTION.

Phase transformations occurring in the solid state underlie many heat-treatment operations. The thermodynamics and kinetics of these transformations are a major concern of physical metallurgy. Physical metallurgy also investigates changes in the structure and properties resulting from mechanical working of metals.

For more information on metallurgy and some associated techniques see articles on individual metals and their metallurgy. *See* ELECTROPLATING OF METALS; METAL COATINGS; METAL FORMING. [M.B.B.]

Metameres The serial repetition of parts along the length of the body axis in bilaterally symmetrical animals. The successive subdivisions are called metameres, somites, or segments, hence the synonym, segmentation. Common examples are the muscles and spinal nerves in the human body and in the body and tail of many mammals, snakes and lizards, salamanders, and fishes. It also occurs in other chordates, and in arthropods and annelid worms. It never involves reproductive organs, and thus differs from strobilization in tapeworms and certain jellyfish. Metamerism arises either from a bilateral series of coelomic pouches which form the segmental muscles, kidneys, and body cavities of lower forms, or from mesoblastic somites which form the skeletal and muscular segments of vertebrates. Repetitive features of the nervous system are acquired secondarily through the influence of mesodermal metameres upon adjoining ectodermal tissues. Several primitive embryonic somites become fused in the heads of adult arthropods and vertebrates. *See* ANIMAL SYMMETRY; COELOM; MUSCULAR SYSTEM; NEURULATION. [H.L.Ha.]

Metamict state The state of a special class of amorphous materials that were initially crystalline. W. C. Broegger first used the term *metamikte* in 1893 to describe minerals that were optically isotropic with a "glasslike" fracture but still retained well-formed crystal faces. In 1914 A. Hamburg correctly attributed the transition from the periodic, crystalline state to the aperiodic, metamict state as induced by alpha-decay damage. In minerals, this damage is the result of the decay of naturally occurring radionuclides and their daughter products in the uranium and thorium (^{238}U, ^{235}U, and ^{232}Th) decay series. A wide variety of complex oxides, silicates, and phosphates are reported as occurring in the metamict state. All of these structures can accommodate uranium and thorium. *See* ALPHA PARTICLES; AMORPHOUS SOLID; RADIOACTIVITY.

The presence of uranium and thorium distinguishes metamict minerals from other naturally occurring amorphous materials that have not experienced this radiation-induced transformation. Lanthanide elements are also common (in some cases over 50 wt %) and water of hydration may be high (up to 70 mol %).

The radiation damage caused by the alpha-decay event is the result of two separate but simultaneous processes: (1) An alpha particle with an energy of approximately 4.5 MeV and a range of

10,000 nanometers dissipates most of its energy by ionization; however, at low velocities near the end of its track, it displaces several hundred atoms, creating Frenkel defect pairs. (2) The alpha-recoil atom with an energy of approximately 0.09 MeV and a range of 10 to 20 nm produces several thousand atomic displacements, creating tracks of disordered material. These two damaged areas are separated by thousands of unit cell distances and have different effects on the crystalline structure. Local point defects cause an increase in the distortion; therefore, there is an increase in the strain in the structure. Alpha-recoil tracks create regions of aperiodic material that at high enough alpha-decay doses (usually 10^{24} to 10^{25} alpha-decay events/m^3) overlap and finally lead to the metamict state. The former causes broadening of x-ray diffraction maxima and an increase in unit cell volume (and a decrease in the density); the latter causes a decrease in diffraction peak intensities. The radiation-induced transition from the crystalline to the metamict state occurs over a narrow range of alpha-decay dose (10^{24}–10^{25} alpha decays/m^3), which corresponds to 0.1 to 1.0 displacements per atom (dpa). *See* CRYSTAL DEFECTS; RADIATION DAMAGE TO MATERIALS.

A renewed interest in the metamict state has been stimulated by concern for the long-term stability of crystalline materials (nuclear waste forms) that will serve as hosts for actinides (for example, plutonium, americium, curium, and neptunium). Various crystalline materials (phases) may appear in a single waste form; each phase may or may not suffer radiation damage. For some nuclear waste-form phases, the radiation-induced transformation to the metamict state has been stimulated by doping phases with highly radioactive plutonium-238 or curium-244. [R.C.EW.]

Metamorphic rocks Preexisting rock masses in which new minerals, textures, or structures are formed at higher temperatures and greater pressures than those normally present at the Earth's surface. *See* IGNEOUS ROCKS; SEDIMENTARY ROCKS.

Two groups of metamorphic rocks may be distinguished; cataclastic rocks, formed by the operation of purely mechanical forces; and recrystallized rocks, or the metamorphic rocks properly so called, formed under the influence of metamorphic pressures and temperatures. Cataclastic rocks are mechanically sheared and crushed. They represent products of dynamometamorphism, or kinetic metamorphism. Chemical and mineralogical changes generally are negligible. The rocks are characterized by their minute mineral grain size. Each mineral grain is broken up along the edges and is surrounded by a corona of debris or strewn fragments. *See* METAMORPHISM.

Metamorphic rocks, properly so called, are recrystallized rocks. The laws of recrystallization are not the same as those of simple crystallization from a liquid, because the crystals can develop freely in a liquid, but during recrystallization the new crystals are encumbered in their growth by the old minerals. Consequently, the structures which develop in metamorphic rocks are distinctive and of great importance, because in many ways they reflect the physiochemical environment of recrystallization and thereby the genesis and history of the metamorphic rock.

The metamorphic minerals may be arranged in an idioblastic series (crystalloblastic series) in their order of decreasing force of crystallization as follows: (1) sphene, rutile, garnet, tourmaline, staurolite, kyanite; (2) epidote, zoisite; (3) pyroxene, hornblende; (4) ferrogmagnesite, dolomite, albite; (5) muscovite, biotite, chlorite; (6) calcite; (7) quartz, plagioclase; and (8) orthoclase, microcline. Crystals of any of the listed minerals tend to assume idioblastic outlines at surfaces of contact with simultaneously developed crystals of all minerals of lower position in the series.

Igneous magma at high temperature may penetrate into sedimentary rocks, it may reach the surface, or it may solidify in the form of intrusive bodies (plutons). Heat from such bodies spreads into the surrounding sediments, and because the mineral assemblages of the sediments are adjusted to low temperatures, the heating-up will result in a mineralogical and textural reconstruction known as contact metamorphism. *See* CONTACT AUREOLE; PLUTON.

The effects produced do not depend only upon the size of the intrusive. Other factors are amount of cover and the closure of the system, composition and texture of the country rock, and abundance of gaseous and hydrothermal magmatic emanations. The heat conductivity of rocks is so low that gases and vaporous emanations become chiefly responsible for transportation and transfer of heat into the country rock.

Crystalline schists, gneisses, and migmatites are typical products of regional metamorphism and mountain building. If sediments accumulate in a slowly subsiding geosynclinal basin, they are subject to down-warping and deep burial, and thus to gradually increasing temperature and pressure. They become sheared and deformed, and a general recrystallization results. However, subsidence into deeper parts of the crust is not the only reason for increasing temperature. It is not known what happens at the deeper levels of a live geosyncline, but obviously heat from the interior of the Earth is introduced regionally and locally, partly associated with magmas, partly in the form of "emanations" following certain main avenues, determined by a variety of factors. From this milieu rose the lofty mountain ranges of the world, with their altered beds of thick sediments intercalated with tuffs, lava, and intrusives, all thrown into enormous series of folds and elevated to thousands of feet. Thus were born the crystalline schists with their variants of gneisses and migmatites. *See* OROGENY.

Well-defined series of mineral facies have been singled out. Sedimentary rocks of the lowest metamorphic grade have recrystallized to give rocks of the zeolite facies. At slightly higher temperatures the greenschist facies develops—chlorite, albite, and epidote being characteristic minerals. A higher degree of metamorphism produces the epidote-amphibolite facies, and a still higher degree the true amphibolite facies in which hornblende and plagioclase mainly take the place of chlorite and epidote. Representative of the highest regional metamorphic grade is the granulite facies, in which most of the stable minerals are water-free, for example, pyroxenes and garnets. Any sedimentary unit will recrystallize according to the rules of the several mineral facies, the complete sequence of events being a progressive change of the sediment by deformation, recrystallization, and alteration in the successive stages: greenschist facies→epidote-amphibolite facies→amphibolite facies→granulite facies. *See* FACIES (GEOLOGY); GRANULITE.

The normal continental crust is entirely made up of metamorphic rocks; where thermal, mechanical, and geochemical equilibrium prevails, there are only metamorphic rocks. Border cases of this normal situation occur in the depths where ultrametamorphism brings about differential melting and local formation of magmas. When equilibrium is restored, these magmas congeal and recrystallize to (metamorphic) rocks. At the surface, weathering processes oxidize and disintegrate the rocks superficially and produce sediments as transient products. Thus the cycle is closed; petrology is without a break. All rocks that are found in the continental crust were once metamorphites. *See* AMPHIBOLITE; GREISEN; MARBLE; MIGMATITE; PHYLLITE; QUARTZITE; SCAPOLITE; SERPENTINITE; SOAPSTONE. [T.F.W.B.; R.C.N.]

Metamorphism The alterations and transformations in preexisting rock masses effected by temperature and pressure, but excluding changes produced by weathering and sedimentation. The changes may include the production of new minerals, structures, or textures, or all three. They give a distinctive new character to the rock as a whole, but they do not involve the loss of individuality of a rock mass, such as changes brought about by fusion. Quantitatively, the metamorphic rocks, including gneisses and migmatites, are the most important group of rocks in the crust of the continents. *See* GNEISS; METAMORPHIC ROCKS; MIGMATITE.

Different kinds of metamorphism may be defined according to genetic criteria, such as the geologic processes that were assumed to have caused the metamorphism, or the physical and chemical conditions that appear to have been predominant in determining the course of metamorphism. Using these criteria three general kinds of metamorphism are noted below.

1. Dislocation, mechanical, or dynamic metamorphism is the result of pressure (or stress) along dislocations in the Earth's crust. The deformed rocks commonly show marked zones of extremely fine-grained rocks, such as mylonites, whose structures are determined by crushing and movement of the grains without important recrystallization of old, or growth of new, minerals. This type of metamorphism is local and restricted in occurrence.

2. Contact or thermal metamorphism occurs in response to increased temperature induced by adjacent intrusions of magma. Chemical reconstitution of the rocks is due to magmatic exhalation; other conditions, such as confining pressure, exert subordinate influence.

3. Regional metamorphism, the most widespread type, is brought about by an increase in both temperature and pressure in orogenic regions, which are vast segments of the crust represented by the folded mountain ranges. Heat and pressure are mainly consequences of downwarping and deep burial. Pressure is also generated by shearing stresses accompanying the orogenic movements. *See* OROGENY. [T.F.W.B./R.C.N.]

A fluid phase plays an important role during metamorphism as an agent of heat and mass transfer. The presence of a static film of fluid around mineral grains greatly facilitates chemical reactions because the fluid film speeds the movement of matter from reactant to product minerals. Flowing fluid carries substantial quantities of materials in solution that may be precipitated far from their source. Heated rocks are cooled more rapidly, and cool rocks are more quickly heated, by flowing fluids than would otherwise be possible by heat conduction. Fluids of metamorphic rocks consist primarily of water (H_2O), variable amounts of carbon dioxide (CO_2) and methane (CH_4), and minor quantities of hydrogen sulfide (H_2S), carbon monoxide (CO), hydrogen (H_2), and sulfur dioxide (SO_2). [D.Rum.]

Metamorphosis A pronounced change in both the internal and external morphology of an animal that takes place in a short amount of time, triggered by some combination of external and internal cues. The extent of morphological change varies considerably among species. Even when morphological changes are relatively slight, metamorphosis typically brings about a pronounced shift in habitat and lifestyle. The precise morphological, physiological, and biochemical changes that constitute metamorphosis; the neural, hormonal, and genetic mechanisms through which those changes are controlled; and the ecological consequences of those changes and when they take place continue to be studied in a wide variety of animals. The hormonal and genetic control of metamorphosis has been best examined in a few species of insect, amphibian, and fish (such as flounder), but other aspects of metamorphosis have been investigated for other insect, amphibian, and fish species as well as for marine invertebrates and, indeed, representatives of essentially every animal phylum.

Amphibians exhibit extensive tissue remodeling during metamorphosis, including resorption of the tail musculature and skeletal system; major reconstruction of the digestive tract; degeneration of larval skin and pronounced alteration in skin chemical composition; growth of the hind and fore limbs; degeneration of the gills and associated support structures; shifts in mode of nitrogen excretion, from ammonia to urea; alteration in visual system biochemistry; replacement of larval hemoglobin with adult hemoglobin; and differential growth of the cerebellum. *See* AMPHIBIA.

Metamorphosis among insects is associated primarily with wing development. Bristletails and other species that do not develop wings and are not descended from winged ancestors exhibit no pronounced metamorphosis. Metamorphosis is most dramatic among holometabolous species, which pass through a distinctive and largely inactive pupal stage; in such species, all of the transformations separating the larval morphology and physiology from that of the adult take place in the pupa. Wings, compound eyes, external reproductive parts, and thoracic walking legs develop from discrete infolded pockets of tissue (imaginal discs) that form during larval development. *See* INSECTA; MOLTING (ARTHROPODA).

The most dramatic metamorphic changes in fish are seen among flounder and other flatfish: in such species, during metamorphosis a symmetrical fish larva becomes an asymmetrical adult, with both eyes displaced to the dorsal surface. The transformation of leptocephalus larvae into juvenile eels is also dramatic; such transformation includes a shift in the position of the urinary and digestive tracts from posterior to anterior. *See* EEL; PLEURONECTIFORMES.

The control of metamorphosis among crabs, barnacles, gastropods, bivalves, bryozoans, echinoderms, sea squirts, and other marine invertebrates is poorly understood, partly due to the very small size of the larvae—they rarely exceed 1 mm in length, and most are less than 0.5 mm. The larvae of some marine invertebrate species are triggered to metamorphose by specific substances associated with adults of the same species, or with the algae or animals on which they prey. *See* ANNELIDA; BIVALVIA; CRAB; DECAPODA (CRUSTACEA); ECHINODERMATA; GASTROPODA; MOLLUSCA.

Among insects, the timing of metamorphosis is influenced by environmental factors such as temperature, humidity, photoperiod, pheromone production by neighboring individuals, and the nutritional quality of the diet. In a number of species, larvae can undergo developmental arrest (a diapause) in response to unfavorable environmental conditions, so that metamorphosis can be delayed for many months or even years. The hormonal basis for such effects has been at least partly worked out for a number of insect species.

Among marine invertebrates and in at least some fish species, there is also considerable flexibility in the timing of metamorphosis. At some point in the development of marine invertebrates and apparently also in the development of some coral reef fishes, individual larvae become "competent" to metamorphose. It is not yet clear what makes larvae competent; the development of external receptor cells, or the completion of specific neural pathways, or the activation of hormonal systems or their receptors are likely possibilities. *See* ENDOCRINE MECHANISMS; ENDOCRINE SYSTEM (INVERTEBRATE); INVERTEBRATE EMBRYOLOGY. [J.A.Pe.]

Metasomatism The process by which the bulk chemical composition of a rock is changed from some previous state by the introduction of components from an external source. In contrast with metamorphism, where rocks are converted to a new set of minerals with little or no change in bulk composition, metasomatism involves the import and export of chemical components through the agency of a chemically active fluid.

Clastic rocks and mafic-to-felsic igneous rocks react in similar ways with metasomatic fluids by exchange of alkalies, alkaline earths, and hydrogen. Hydrolytic alteration dominates lower-temperature metasomatic processes. Hydrolysis involves hydrogen-ion metasomatism—exchange of hydrogen ion for potassium, sodium, and calcium.

Metasomatism of aluminum-poor rocks carbonate and ultramafic rocks generally involves addition of silica, metals, and alumina.

Metasomatism is best developed in environments characterized by extreme physical and chemical gradients and high fluid flux. At the centimeter scale, chemical contrasts along shale-limestone contacts lead to diffusive exchange of components on heating during regional or contact metamorphism. At the kilometer scale in mid-ocean rifts, island arcs, and continental-margin plutonic arcs, metasomatism results from emplacement of magma at depths of a few kilometers and infiltration of hot, saline, aqueous fluids through fractured rocks. At global scales, metasomatism accompanies mass fluxing between the crust and the mantle, such as on emplacement of mantle plumes into the lower crust or subduction of oceanic crust into the mantle. *See* ASTHENOSPHERE; EARTH CRUST; MAGMA; METAMORPHISM. [M.T.E.]

Metastable state In quantum mechanics, a state that is not truly stationary but is almost stationary.

In practice, especially in atomic and nuclear physics applications, the designation metastable state usually is reserved for states whose lifetimes are unusually long. For example, the excited states of atoms usually decay with the emission of a single photon, in a time of the order of 10^{-8} s. However, the necessity for angular momentum and parity conservation forces the second excited state ($2S_{1/2}$) of atomic hydrogen to decay by simultaneous emission of two photons; consequently, the lifetime is increased to an estimated value of 0.15 s. Thus, the $2S_{1/2}$ state of atomic hydrogen is usually termed metastable, but most other hydrogenic states are not. Similarly, emission of a gamma-ray photon by an excited nucleus usually occurs in 10^{-13} s or less; however, the lifetime of one excited state of the ^{113}In nucleus, the state that customarily is termed metastable, is about 100 min. Since radiative transition probabilities for emission of photons generally decrease rapidly with decreasing frequency, a low-lying atomic or nuclear excited state may have a lifetime longer than most excited states of atoms and nuclei and yet not be metastable in the practical sense just described, because photon emission from the state may not be hindered by any general requirement or selection rule, such as is invoked for the $2S_{1/2}$ state of hydrogen. *See* EXCITED STATE; NUCLEAR ISOMERISM; RADIOACTIVITY. [E.G.]

Metatheria An infraclass of therian mammals including a single order, the Marsupialia. The Metatheria are distinguished from the Eutheria (the placental mammals) by numerous characters. The braincase is small, the angular process of the mandible is inflected, and a pair of marsupial bones articulates with the pelvis. Almost all living marsupials have a pouch on the belly of the female in which the young are carried after birth. The early marsupials were unable to compete with the more progressive later placental forms and died out except in South America and Australia, where they were isolated by water barriers. *See* EUTHERIA; MAMMALIA; THERIA. [D.D.D./F.S.S.]

Metazoa The kingdom (or subkingdom) comprising all many-celled animals, whether constructed of simple tissue layers or of complex organs. In some five-kingdom systems and in the six-kingdom systems of classification for living organisms, metazoans constitute a separate kingdom, while in the older two-kingdom and some three-kingdom systems the subphylum Metazoa made up the greater part of the kingdom Animalia. Most usual classifications subdivide the Metazoa into about 30 phyla of many-celled animals (such as Arthropoda or Mollusca), each representing a major kind of body design. In all classifications, the only animal forms not included in the Metazoa are the single-celled protozoa (Protista) and the independently evolved sponges (Parazoa). *See* ANIMAL KINGDOM; EUKARYOTAE; PORIFERA; PROTISTA.

Metazoans are made up of eukaryotic cells, each with a membrane surrounding the nuclear material and with the mechanics of cell multiplication always involving the mitotic division of chromosomes. Cellular specialization is common. In addition to increasing functional interdependence and specialization of cells, the evolution of the higher phyla of Metazoa has involved the potentialities and penalties of increasing size, particularly those associated with the surface-mass ratio. Despite differing grades of structural and functional complexity, interdependence of organs, tissues, and cell types is diagnostic of the phyla of animals making up the kingdom (or subkingdom) Metazoa. *See* CLASSIFICATION, BIOLOGICAL; HOMEOSTASIS. [W.D.R.H.]

Meteor The luminous streak lasting seconds or fractions of a second and seen at night when a solid, natural body plunges into the Earth's (or another planet's) atmosphere. The entering object is called a meteoroid and, if any of it survives atmospheric passage, the remainder is called a meteorite. Cosmic dust particles (with masses of micrograms) entering the atmosphere and leaving very brief, faint trails are called micrometeors, with the surviving pieces known as micrometeorites. If the apparent brightness of a meteor exceeds that of the planet Venus as seen from Earth, it is called a fireball, and when a bright meteor is seen to explode, it is called a bolide. *See* METEORITE; MICROMETEORITE.

Under normal, clear atmospheric conditions and dark skies (no moonlight or artificial lights), an observer will see an average of five meteors per hour. The spatial distribution of meteoroid orbits relative to the Sun and the circumstances of their intersections with the moving Earth are responsible for pronounced variations in meteor rates.

The average meteor seen by the unaided eye starts with a meteoroid velocity of 18 mi/s (30 km/s) and leaves a luminous trail from 67 to 50 mi (110 to 80 km) high. The meteor trails are rapidly expanding columns of atoms, ions, and electrons dislodged from the meteoroid by collisions with air molecules, and can be excited to temperatures of several thousand degrees Celsius. For a time after trail formation, the free electrons are dense enough to reflect radio waves in the very high frequency range, and therefore can be used to transmit radio messages. *See* RADIO-WAVE PROPAGATION.

Under the right circumstances, particularly with high-power ultrahigh-frequency (UHF) radars, the ionization right around and moving with the meteoroid itself is seen. This is known as the head echo, and a determination of its velocity is the most accurate way to determine radar meteor speeds. *See* RADAR; RADAR ASTRONOMY.

The Earth moves around the Sun with an average speed of 18 mi/s (30 km/s). According to the laws of celestial mechanics, if a meteoroid comes from beyond the solar system, its velocity at the Earth's distance from the Sun must be greater than 26 mi/s (42 km/s). If such a meteoroid hits the Earth head-on, indications of preatmospheric speeds in excess of 45 mi/s (72 km/s) would be observed. The fact that the vast majority of observed meteoroids have orbits with Earth-approaching velocities of less than 45 mi/s indicates that most of these are comet and asteroid fragments, and are therefore long-term members of the solar system. However, in the 1980s and 1990s, a combination of spacecraft and high-power radar observations indicated that hypervelocity micrometeoids do indeed exist with seeming interstellar dust connections. *See* INTERSTELLAR MATTER.

A combination of the meteoroid's and Earth's velocities of travel around the Sun make the meteor itself seem to originate from a specific direction in the sky called the radiant. If there are numerous meteoroids in nearly the same orbit (sometimes incorrectly called meteor streams), the Earth sweeps them up at specific times of the year and a so-called meteor shower is observed. Meteor showers are named after the constellation or single star in the sky from which they appear to radiate. While shower meteoroids are really moving nearly parallel through space and result in nearly parallel meteor trails, the effects of perspective make the meteors appear to diverge from the radiant. Meteors that cannot be shown to be associated with a known shower are termed sporadic meteors.

A number of meteor showers have been observed to be in orbits that are similar to those traveled by known comets. Thus an association between shower meteors and comets has gradually become a firmly entrenched concept. There are numerous theoretical scenarios where vaporization of the more volatile cometary ices ejects small solid particles from the surface of the nucleus. A fair proportion of these fragments, particularly the smaller dust-sized ones, escape and take up their own orbits as meteoroids. Cometary nuclei have been known to split into two or more pieces and, when this occurs, it is likely that particles larger than dust size are released as well.

The strategy of photographic or electronic measurements is to place at least two cameras 10–52 mi (15–85 km) apart over a known baseline, but arranged to examine the same volume of space at a height of about 56 mi (90 km). Each camera has a rotating shutter so that the meteor trail consists of a line of bright dashes. Meteor imaging is one of the most difficult areas of astronomical detection, even with ultrafast cameras. Meteor spectroscopy is even more difficult since the light is spread out over areas hundreds of times larger than the meteor trail itself. *See* ASTRONOMICAL PHOTOGRAPHY; ASTRONOMICAL SPECTROSCOPY.

Radio and radar observations depend on the fact that the initial ion-electron densities in a meteor trail are considerably higher than the average for the ionosphere at an altitude of 56 mi (90 km). For a very high frequency (VHF) or somewhat lower-frequency radar system, the maximum reflected signal occurs when the meteor trail is at right angles to the outgoing wave, with head echoes rarely seen. At ultrahigh frequencies (UHF), radar reflections from the head-echo predominate. From these, high-accuracy radial velocities are determined directly, using the Doppler effect. *See* DOPPLER EFFECT; RADIO ASTRONOMY.

The parent comet of the Leonid stream, 1866 I, made another of its periodic (33-year intervals) approaches to the Sun in 1999. With the appearance of the comet, it was expected that the strong meteor storm that happened last in 1966 would again make a brief but spectacular appearance. However, perturbations by the outer planets (particularly by Neptune) once again played a significant role in this shower's behavior. The perturbations moved a number of thin meteoroid streams produced by the comet many orbit periods in the past into intersection range of the Earth. This produced a unique succession of strong peaks covering a span of seven years (1996–2003). The scientific yield of this extended display was much more than anyone had hoped. While meteor trails had been previously recorded from the space shuttle and other spacecraft, in 1997 the first above-atmosphere, far-ultraviolet spectrum of a bright meteor was recorded during the Leonid shower. Spectra obtained from the ground also yielded new information. The large number of fireballs in the Leonid streams enabled many details of the ablation processes at higher than average meteoroid incoming velocities to be recorded with high-speed cameras. [D.D.M.]

Meteorite A naturally occurring solid object from interplanetary space that survives impact on a planetary surface. While in space, the object is called a meteoroid, and a meteor if it produces light or other visual effects as it passes through a planetary atmosphere. Explosive surface impacts by large meteorites are believed to have created the plethora of craters on the solid planets and moons of the solar system. *See* METEOR; MICROMETEORITE.

A meteorite seen to strike a surface is known as a fall, whereas a meteorite discovered by chance is known as a find. In both cases, meteorites are named after their geographic places of recovery.

Meteorites have been broadly classified into stony, stony-iron, and iron varieties in recognition of their compositions that are dominated by silicate minerals and iron-nickel alloys either alone or as admixtures. Within each of the three categories, detailed classifications are based on distinctive mineralogical and chemical compositions and physical structures.

Meteorites represent the most ancient rocks known. Their ages, as determined by radiometric dating, extend to more than 4.5×10^9 years, which is thought to be near the time of solar system formation. As samples of primordial material, stony meteorites known as chondrites are studied for clues about how the solar system formed. In contrast, achondrites, stony-irons, and irons are samples of melt products formed during processing of solid material in planetary or preplanetary bodies. *See* DATING METHODS; SOLAR SYSTEM.

Asteroids are believed to be the sources of most meteorites. In 1982, however, it was conclusively demonstrated that a small achondrite found in Antarctica in 1981 was from the Moon. Even more exciting is the prospect that several closely related achondrites (shergottites, nakhlites, and the Chassigny meteorite), from various recovery locations around the world, are from Mars; one of them contains trapped gases that are nearly identical to those measured for the Martian atmosphere by the Viking lander in 1976. *See* ASTEROID; MARS; MOON.

Stony meteorites. Stony meteorites include a large class known as chondrites and a smaller class known as achondrites.

The stony meteorites called chondrites, which are the most abundant class of known meteorites, constitute approximately 92% of all meteorite falls. Chrondrites are divided into three major categories: ordinary, carbonaceous, and enstatite. All chondrites contain various amounts of small (generally 0.5–2 mm) beadlike objects known as chondrules.

Ordinary chondrites are the most abundant chondrites, constituting 93% of all chondrite falls. They are composed mainly of the minerals olivine, low-calcium pyroxene, plagioclase, iron-nickel (Fe-Ni) metal, and troilite. They may contain silicate glass. *See* FELDSPAR; OLIVINE; PYROXENE; PYRRHOTITE.

Chondrules are contained in a matrix of the same minerals that make up the chondrites. The difference is in texture. Chondrule minerals crystallized within molten droplets, and they show a variety of shapes consistent with a molten origin. Matrix minerals are granular and of small grain sizes. [J.L.Go.]

Carbonaceous chondrites are the most primitive of all meteorites. In addition to the major chemical elements that occur in all of the chondrite meteorites, carbonaceous chondrites contain significant amounts of carbon, hydrogen, and nitrogen, which are present in only trace amounts in ordinary chondrites. In addition to chondrules, they have a large number of other types of inclusions. Most important is the fact that the minerals that make up chondrules and inclusions are different in composition and kind from minerals that make up the surrounding matrix.

Enstatite chondrites consist of 60–80 vol % enstatite (FsO) with 10–30 vol % metal and 5–15 vol % troilite. Enstatite chondrites range from those with many chondrules to those that are free of chondrules. *See* ENSTATITE.

Chondrites contain components from two environments of origin: as results of processes that occurred under dispersed conditions in space, known as nebular; and as results of processes that occurred within parent bodies, known as planetary.

The carbonaceous chondrites have the most evident nebular components in the form of refractory mineral inclusions. These minerals formed by direct condensation from a gas cloud surrounding the primitive Sun. The minerals were accreted into small asteroidal bodies and never subjected to subsequent heat or pressure, that is, metamorphism that would have erased their primitive characteristics. The early formation and accretion histories of the ordinary chondrites and enstatite chondrites into asteroidal bodies are unknown. [E.O.]

Chondrules are the most abundant particles in chondrites, generally being $\sim$1 mm (0.04 in.) in diameter. They contain iron-magnesium silicates that crystallized from a melt.

It has become widely agreed that chondrules were formed by nebular melting of solid precursors, consisting of randomly assembled condensates, presolar relics, and chondrule debris. They were hot for only a few hours in an environment with a low ambient temperature. This requires a local heating event, rather than a nebula-wide process. Specific suggestions for melting mechanisms have ranged from lightning to frictional heating of infalling interstellar grains. [R.H.Hew.]

Achondrites are stony meteorites that have few, if any, chondrules and differ chemically from chondrites. They constitute about 8% of all meteorite falls and 1% of all finds. Although achondrites can be divided into several distinct groups based on chemical and isotopic composition, they are generally believed, based on aspects of their textures and composition, to have formed as the result of igneous processes on asteroidal or planetary bodies. Much of the interest in these meteorites derives from the fact that they provide clues into the nature of igneous processes and planetary differentiation early in the history of the solar system on planetary bodies outside the Earth-Moon system and on bodies presumed to be much smaller than the Earth and Moon.

The eucrites, howardites, and diogenites—often collectively referred to as the basaltic achondrites—are the most abundant achondritic meteorites. They appear to be samples of a series of related igneous rocks and of regolith breccias composed of fragments of these igneous rocks. They define a coherent group in terms of their oxygen isotope compositions, suggesting they are closely related. With ages near 4.5 billion years, they are products of igneous activity from the earliest history of planetary bodies in the solar system.

It is clear that igneous processes as they are known from study of terrestrial and lunar rocks were active on small bodies very soon after their formation. The heat source for such igneous activity is still under investigation, but it could be the decay of the aluminium isotope ^{26}Al or perhaps heating by electric currents induced in small planets by the passage of an intense solar wind associated with a very active early Sun (T-Tauri phase). The reflectance spectrum of the surface of the asteroid 4 Vesta closely resembles those of eucritic meteorites, and it has been suggested that this could be the source of the basaltic achondrites, although there are dynamical difficulties with such a source. *See* BASALT; IGNEOUS ROCKS; SOLAR WIND.

Shergottites, nakhlites, and chassignites (often referred to as the SNC group) are rare meteorites. Their young crystallization ages ($\sim 1.3 \times 10^9$ years), plus the similarity of the bulk compositions of the shergottites to that of the Martian soil as determined by the Viking landers, first led to the suggestion that these meteorites could be derived from Mars. It is difficult to conceive of a heat source for endogenous igneous activity (these meteorites have no features resembling known impact melts) on an asteroidal parent body at about 1.3×10^9 years ago; and given the limited choice of available larger planets, Mars seemed the most likely choice. The similarity of relative noble gas and nitrogen abundances and isotopic ratios in the Martian atmosphere and shock-produced glass in one shergottite provide strong support for this hypothesis. The very low paleomagnetic intensities of the shergottites are also consistent with a Martian origin. It is still a subject of controversy whether fragments of sufficient size to explain measured cosmic-ray exposure ages could be ejected more or less intact from Mars by impact and subsequently delivered to Earth. It is generally accepted that the question of whether or not these meteorites are from Mars will be resolved only after a sample-return mission to Mars. *See* PALEOMAGNETISM. [E.St.]

Iron meteorites. Iron meteorites are pieces of once molten metallic cores and pools in asteroids that were subsequently eroded and fragmented by impacts after slow cooling. About 650 different iron meteorites have been identified; 30 were seen to fall, and the rest fell during the last million years. The smallest iron meteorites, which weigh only 5–30 g (0.18–1.1 oz), were found in Antarctica and are aerodynamically shaped to resemble buttonlike tektites. The largest single iron meteorite weighs about 60 metric tons (66 tons) and still lies in Namibia. *See* TEKTITE.

Nine much larger iron masses also hit the Earth during the last million years, forming craters 100 to 1200 m (330 to 3900 ft) in diameter. However, each of the fragments surviving from these meteoroids weighs less than a ton. The largest and most famous crater, which is in Arizona, was formed about 50,000 years ago by the impact of a meteoroid weighing around 300,000 metric tons (330,000 tons) and measuring about 40 m (130 ft) across. The impact released energy equivalent to about 15 megatons of TNT.

Chemical and mineralogical evidence shows that iron meteorites formed from molten pools of metal that solidified and then cooled over many millions of years. This evidence is consistent with an origin for iron meteorites in the cores of asteroids that melted and differentiated. When an asteroid is partly melted, iron-nickel and iron sulfide, being denser than the associated silicates, will begin to sink to the center. With sufficient heating, a core of molten sulfur-rich metal will form. Since most iron meteorites contain no silicates and most achondrites have only trivial amounts of metal, it is likely that metallic cores are the source of many iron meteorites. [E.R.D.S.]

Isotopic anomalies. In contrast to materials from differentiated planetary bodies such as the Earth and the Moon, primitive meteorites exhibit isotopic anomalies, that is, deviations from the average solar system composition (= "normal" composition) that are not the result of processes taking place in the solar system but are of presolar origin. These anomalies provide information about the nucleosynthetic sources of the material that formed the solar system. *See* NUCLEOSYNTHESIS.

Carbon and all heavier elements are produced in stars, and their isotopic compositions reflect different nucleosynthetic reactions taking place in different stellar sources. Many different stars must have contributed to the mixture of gas and dust from which the solar system formed, and it is assumed that this mixture was originally chemically and isotopically heterogeneous. Before 1970 it was generally believed that presolar material had been completely vaporized and isotopically homogenized before the condensation of minerals and the accretion of planets. This dogma of a homogeneous solar nebula was shattered by the discovery of isotopic anomalies in an increasing number of different elements. Ample evidence has been found for the incomplete mixing of distinct isotopic components and for the survival of presolar matter in primitive meteorites.

Isotopically anomalous material constitutes only a small fraction of primitive meteorites. The largest isotopic variations are found through the analysis of small samples where the effects are not diluted by isotopically normal material.

Isotopic effects in meteorites can be divided into four classes: (1) mass-dependent fractionation due to physicochemical processes (diffusion, evaporation, condensation), although certain chemical processes can also lead to non-mass-dependent fractionation that mimics isotopic effects of nuclear origin; (2) effects due to the decay of radioactive isotopes—while effects from the decay of long-lived isotopes are also seen in terrestrial samples, meteorites in addition exhibit effects from the decay of short-lived, now extinct isotopes; (3) nuclear effects reflecting different nucleosynthetic processes in stellar sources; and (4) effects due to the irradiation of meteoritic samples by galactic and solar cosmic rays, which provide information on the exposure history of samples on their parent bodies and in interplanetary space. [E.Zi.]

Meteorite impact. The process of impact cratering was of fundamental importance for the accumulation of planets in the early solar system, the formation of planetary landscapes, and the Archean geology of the Earth. In addition, meteorite impacts have been implicated in such events as the Moon's origin and the extinction of the dinosaurs.

The precise outcome of a planetary collision depends on the size of the meteorite and conditions on the target planet. Small meteorites striking planets such as the Earth or Venus dissipate most of their energy in the atmosphere and do not strike the surface at high speed. In general, if the mass of the meteorite is small compared to the mass of atmospheric gases displaced during its entry, the meteorite will not create an impact crater. On airless bodies such as the Moon, there seems to be no lower limit on impact crater size: craters as small as a few micrometers in diameter have been discovered on the lunar rocks. On Earth, the atmosphere prevents stony meteorites or comets from making craters smaller than a few kilometers in diameter, and even iron meteorites cannot make high-speed impact craters smaller than a few hundred meters in diameter.

When a large meteorite does penetrate a planet's atmosphere, it initiates a series of swift but orderly processes that eventually create a characteristic landform, an impact crater. Three principal stages are recognized in this process.

(1) The meteorite first plunges into the surface rocks at high speed, compressing the underlying rocks and converting its initial kinetic energy into both heat and kinetic energy of the surface rocks. The high pressures produce a series of characteristic mineralogical changes in the surrounding rocks that often permits verification of the impact origin of a suspected crater. The duration of this compression state is short, however, lasting only as long as it takes the meteorite to travel a distance equal to its own diameter.

(2) Subsequently, the pent-up pressures in the compressed rocks essentially create an explosion, blasting aside the surrounding rocks as a strong shock wave radiates away from the impact site. The nearly hemispherical shock wave from the impact expands and weakens as time passes, leaving behind outward-moving rock debris that eventually excavates the crater. The maximum depth of excavation is only about 10% of the crater's diameter. The immediate result of crater excavation is called the transient crater. This is a relatively deep, steep-walled crater than beings to collapse as soon as it forms.

(3) Small transient craters are quickly filled by a lens of broken rock that forms from debris that slides down from the rim and pools at the bottom of the crater. Such bowl-shaped craters floored by broken rock are called simple craters.

In larger craters the floor rises as the rim sinks, producing central mounds that are thinly veneered with broken and melted rock. The rims of such craters, termed complex craters, are scalloped and terraced with great blocks of slumped rock. Still larger craters exhibit circular mountainous rings instead of central peaks.

The very largest impact structures, particularly on the Moon, are surrounded by inward-facing, roughly circular (but often incomplete) mountain rings that probably formed well outside the crater cavity by a process of inward flow and slumping in the fluid asthenosphere beneath the crater. They are termed multi-ring basins. These enormous structures dominate the Moon's surface and form the principal stratigraphic markers on that body. *See* ASTHENOSPHERE. [H.J.M.]

Meteorological instrumentation Devices that measure or estimate properties of the Earth's atmosphere. Meteorological instruments take many forms, from simple mercury thermometers and barometers to complex observing systems that remotely sense winds, thermodynamic properties, and chemical constituents over large volumes of the atmosphere.

Weather station measurements provide a description of conditions near the ground. In addition to the average regional conditions, these measurements also provide local information on mesoscale phenomena such as cold fronts, sea breezes, and disturbed conditions resulting from nearby thunderstorms. Traditional thermodynamic instruments are mechanical or heat-conductive devices relying on the expansion and contraction of metallic and nonmetallic liquids or solid materials as a function of temperature, pressure, and humidity. Among these are the mercury, alcohol, and bimetallic thermometers for measurement of temperature, mercury and metallic bellow (aneroid) barometers for measurement of pressure, human hair hygrometers, and wet/dry-bulb thermometers (called psychrometers) for measurement of relative humidity. Mercury barometers are simply weighing devices that balance the mass of the atmospheric column against the mass of a mercury column. On average, a column of atmosphere weighs the same as 76 cm (29.92 in.) of mercury. Psychrometers measure humidity by means of the wet-bulb depression technique. A moist thermometer is cooled by evaporation when relative humidity is less than 100%. The temperature difference between wet and dry thermometers is referred to as the wet-bulb depression, a well-known function of relative humidity at standard airflow speeds. A related method of humidity measurement is the chilled mirror technique (dewpointer). A polished surface is cooled to the temperature of water vapor saturation, at which point the cooled surface becomes fogged. Dewpoint saturation uniquely defines humidity at a known temperature and pressure. *See* BAROMETER; DEW POINT; HYGROMETER; PSYCHROMETER; TEMPERATURE MEASUREMENT; THERMOMETER.

Precipitation measurement devices may be described as precision buckets, which measure the depth or weight of that which falls into them. These gages work best for rainfall, but they are also used in an electrically heated mode for weighing snow. Rulers are routinely used for measurement of snow depth. Time-resolved measurements of rainfall are traditionally made by counting quantum amounts (0.01 in. or 0.25 mm) of rain with a small, mechanically controlled tipping bucket located beneath a large collecting orifice. Modern rain measuring is sometimes performed along short paths via drop-induced scintillations of infrared radiation, which is emitted by a laser. When the raindrop size distribution is needed, optical-shadowing spectrometers are employed, as are momentum-measuring impact distrometers, devices that measure the number density versus the size distribution of raindrops or other hydrometeors. *See* SNOW GAGE.

Wind measurements are performed by anemometers, some of which use wind-driven spinning cups for wind speed determination. Vanes are used in conjunction with cups for indication of wind direction. Alternatively, three-axis propeller anemometers may be employed to provide orthogonal components of the three-dimensional wind vector. Many hybrids of these basic approaches continue to be successfully employed. Fast-response sonic anemometers employ ultrasound transmission, where the apparent propagation speed of sound is measured. The difference between this measured speed and the actual speed for a fluid at rest is the wind speed. Such measurements are made on a time scale of 0.01 s and are used to determine the fluxes of momentum, water vapor, sensible heat, and other scalars in the planetary boundary layer. *See* ANEMOMETER; WIND MEASUREMENT.

Balloon-borne vertical profiles or soundings of temperature, humidity, and winds are central to computerized (numerical) weather prediction. Such observations are made simultaneously or synoptically worldwide on a daily basis. The temperature and humidity sensors are lightweight expendable versions of traditional surface station instruments. Balloon drift during ascent provides the wind measurement. The preferred method of tracking these rawinsondes is to use global navigation aid systems such as Omega, Loran-C, and the Global Positioning System. Parachute-borne dropsondes are often released from aircraft in data-sparse regions. *See* LORAN; SATELLITE (ASTRONOMY).

Remote sensing, principally via electromagnetic radiation, is a mainstay of modern meteorology. Such devices typically operate in the optical, infrared, millimeter-wave, microwave, and high-frequency radio regions of the electromagnetic spectrum. Passive radiometers typically operate at infrared and microwave frequencies; they are used for estimates of temperature, water vapor, cloud heights, cloud liquid water mass, and trace-gas concentrations. These observations are made from the ground, aircraft, and satellites, usually measuring naturally emitted radiation. Radarlike, active remote-sensing devices are among the most powerful tools available to meteorology. Collectively, these instruments are capable of measuring kinematic, microphysical, chemical, and thermodynamic properties of the troposphere at high spatial and temporal resolution. Active meteorological remote sensors are principally deployed on land, ships, and aircraft platforms, as well as aboard satellites. Unlike passive instruments, active remote sensors can precisely resolve the distance at which a measurement is located.

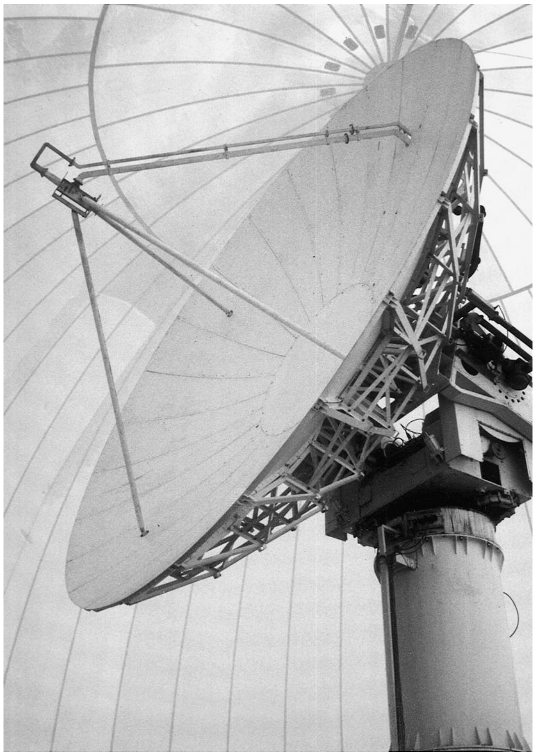
At optical frequencies, lidars measure conditions in relatively clear air. Capabilities include determining the properties of tenuous clouds; determining concentrations of aerosol, ozone, and water vapor; and measuring winds through the Doppler frequency-shift effect. Millimeter-wave radars are used to probe opaque, nonprecipitating clouds. Polarimetric and Doppler techniques reveal hydrometeor type, water mass, and air motions. *See* LIDAR.

The best-known meteorological remote sensor is the microwave weather radar. In addition to measuring rainfall and tracking movement of storms, powerful and sensitive meteorological radars can measure detailed flow fields in and around storms by using hydrometeors, insects, and blobs of water vapor as reflective targets. These radars can also distinguish between rain, hail, and snow. When Doppler measurements are combined with the atmospheric equations of motion, thermodynamic perturbation fields, such as buoyancy, are revealed inside violent convective storms. At ultrahigh and very high radio frequencies, radars known as wind profilers measure the mean wind as a function of height in the clear and cloudy air. Superior to infrequent weather balloons, radio wind profiling methods permit continuous measurement of winds with regularity and high accuracy. When radio wind profilers are colocated with acoustic transponders, the speed of sound is easily measured through radar tracking of the acoustic wave. This permits the computation of atmospheric density and temperature profiles, on which the speed of sound is strongly dependent. *See* DOPPLER RADAR; METEOROLOGY; RADAR METEOROLOGY; REMOTE SENSING. [R.E.Car.]

Meteorological optics The study of optical phenomena occurring in the atmosphere. Many light effects can be seen by looking skyward, and all of them, resulting from the interaction of light with the atmosphere, lie in the province of atmospheric optics or meteorological optics. The subject also includes the effect of light waves too long or too short to be detected by the human eye—light-type radiation in the infrared or ultraviolet regions of the spectrum. Light interacts with the different components of the atmosphere by a variety of physical processes, the most important being scattering, reflection, refraction, diffraction, absorption, and emission. *See* ABSORPTION OF ELECTROMAGNETIC RADIATION; ATMOSPHERE; OPTICS; REFLECTION OF ELECTROMAGNETIC RADIATION; SCATTERING OF ELECTROMAGNETIC RADIATION. [R.Gr.]

Meteorological radar A remote-sensing device that transmits and receives microwave radiation for the purpose of detecting and measuring weather phenomena. Radar is an acronym for radio detection and ranging. Today, many types of sophisticated radars are used in meteorology, ranging from Doppler radars, which are used to determine air motions (for example, to detect tornadoes), to multiparameter radars, which provide information on the phase (ice or liquid), shape, and size of hydrometeors. Airborne Doppler radars play a vital role in meteorological research. Radars are also used to detect hail, estimate rainfall rates, probe the clear-air atmosphere to monitor wind patterns, and study the electrification processes in thunderstorms that generate lightning discharges.

Commonly used, pulsed Doppler radar operates in the microwave region, with standard wavelengths of 10, 5, and 3 cm, referred to as S-, C-, and X-band radars, respectively. The electromagnetic radiation is focused into a narrow beam by illuminating a parabolic dish reflector with microwave energy provided by the radar transmitter. S-band radars require the use of large antennas (see illustration) to generate a narrow beam of microwave energy; transmit high power (peak power of 1 megawatt); and suffer relatively little attenuation as the radar beam passes through regions of heavy rain and hail. X-band radars use much smaller antennas to achieve similar narrow beams, and are highly portable. However, X-band radars suffer from attenuation when used to probe precipitation, which significantly limits their range. Attenuation results when the radar energy is either absorbed by the raindrops or reemitted from the raindrops in directions other than toward the radar. *See* ANTENNA (ELECTROMAGNETISM); DOPPLER RADAR; MICROWAVE.



Parabolic dish antenna of the CSU-CHILL 11-cm multiparameter Doppler radar operating at Colorado State University. The antenna is housed within a large, inflatable radome. (*P. Kennedy, Colorado State University*)

A pulsed Doppler radar typically emits 1000 electromagnetic pulses per second. These individual pulses are typically 1 microsecond (10^{-6} s) in duration. The Doppler radar provides information on the target's velocity, either toward or away from the radar when viewed along the radar beam. The Doppler shift, which is measured as a small difference between the frequency of the transmitted pulse and the frequency of the energy backscattered to the radar, provides a measure of the scatterer's radial motion. Scatterers in the case of meteorological radar include raindrops, ice particles (snowflakes), hailstones, and even insects, providing clear air returns. A Doppler radar also detects the amplitude of the backscattered signal, which can be used as a measure of storm intensity and as a means of estimating rainfall rates. *See* PRECIPITATION (METEOROLOGY); SCATTERING OF ELECTROMAGNETIC RADIATION; STORM; STORM DETECTION.

Dual-wavelength radar transmits electromagnetic energy at two wavelengths, and it also receives energy at both wavelengths. Typically, S- and X-band wavelengths are used. Dual-wavelength techniques were originally proposed to detect large hail. At S-band, hail is usually a Rayleigh target, whereas at X-band, hail is considered a Mie scatterer. Since radar energy is scattered in various directions by a Mie target, the power returned at the X-band wavelength is reduced relative to that at S-band. The presence of large hail is interpreted on the basis of the ratio of backscattered power at X-band to that at S-band. Dual-wavelength techniques are also used to estimate rainfall rates by comparing the backscattered power at a nonattenuating wavelength (S-band) to that at attenuating wavelengths (X-band). *See* HAIL.

Dual-polarization radar is able to transmit and receive both horizontally and vertically polarized radiation (the polarization of a radar beam is defined by the orientation of the electric field vector that comprises an electromagnetic wave). These radars are now used in meteorological research and have largely superseded dual-wavelength radars. A suite of multiparameter variables is being used to infer information on particle phase (ice or water), size, orientation, and shape.

Radar operating at a wavelength of 2 cm is in low Earth orbit (350 km or 210 m above the surface) and is used for mapping tropical precipitation. Understanding the amount and distribution of tropical rainfall is crucial for better understanding the Earth's climate. This space-borne radar and associated satellite was jointly developed by the United States (NASA) and Japan (National Space Development Agency); it is known as the *Tropical Rainfall Measuring Mission* (*TRMM*) satellite. Space-borne radar presents many challenging problems, including cost, size constraints, reliability issues, and temporal sampling. It is obviously impossible to continuously sample every precipitating cloud in the tropics from radar orbiting the Earth. But the *TRMM* satellite will help scientists develop a statistical distribution of rain rates within a certain area, and calculate the probability of a specific rain rate occurring. Based on this information, it will be possible to generate monthly mean rain amounts within areas of 10^5 km^2. Such information will be vital for the verification of climate models. *See* Satellite meteorology.

Radars used to probe the clear air, or regions devoid of clouds, are known as profilers. A profiler is essentially a Doppler radar that operates at much longer wavelengths compared to weather radar. Wavelengths of 6 m, 70 cm, and 33 cm are commonly used. In the case of a profiler, the reflected power is not only from hydrometeors but also from gradients in the index of refraction of air, which are caused by turbulent motions in the atmosphere. These turbulent motions in turn cause small fluctuations in air temperature and moisture content, which also change the index of refraction. A profiler can determine the airflow in the cloud-free atmosphere, roughly up to 10 km above the Earth's surface. Optical radars, called lidars, use lasers as the radiation source. At these short wavelengths (0.1–10 μm), the laser beam is scattered by small aerosol particles and air molecules, allowing air motions to be determined, especially in thin, high tropospheric clouds and in the Earth's boundary layer (approximately the lowest 1 km or 0.6 mi of the Earth's atmosphere). *See* Aerosol; Hydrometeorology; Laser; Lidar.

In the late 1990s, the weather radars used by the National Weather Service to provide warnings of impending severe weather were updated from antiquated WSR-57 and WSR-74 noncoherent radars to NEXRADs (Next Generation Weather Radars). NEXRAD (WSR-88D) radars are state-of-the-art Doppler radars operating at a wavelength of 10 cm. Using NEXRAD's Doppler capability, weather forecasters are able to warn the public sooner of approaching tornadoes and other severe weather. In severe storms, a mesocyclone first develops within the storm. The mesocyclone may be 10 km (6 mi) or more wide, and represents a deep rotating column of air within the storm. Severe and long-lasting tornadoes are often associated with mesocyclones. The mesocyclone is readily detected by a Doppler radar such as NEXRAD. The entire continental United States is covered by the NEXRAD network, consisting of more than 100 radars. NEXRADs along the Gulf Coast, in Florida, and along the eastern seaboard provide warning information on land-falling hurricanes. About 60 of the nation's busiest airports are also equipped with Doppler radars. These radars (operating at a wavelength of 5 cm, known as Terminal Doppler Weather Radars) provide weather-related warnings to air-traffic controllers and pilots. One particularly dangerous weather condition is wind shear, which often occurs as a microburst or intense downdraft. Microbursts can severely affect the flight of landing and departing aircraft, and have been identified as a factor in many aircraft accidents. *See* Radar; Radar meteorology; Tornado; Weather forecasting and prediction.

[S.A.Ru.]

Meteorological rocket A small rocket system used for extending observations of the atmosphere above feasible limits for balloon-borne and telemetering instruments. Synoptic exploration of the middle-atmospheric circulation (20–95 km or 12–60 mi altitude) through use of these systems (also known as rocketsondes) matured in the 1960s into a highly productive source of information on atmospheric structure and dynamics. Many thousands of small meteorological rockets have been launched in a coordinated investigation of the wind field and the temperature and ozone structures in the middle atmosphere region at 25–55 km (16–34 mi) altitude. These data produced dramatic changes in the scientific view of this region of the atmosphere, with a resulting alteration of the structural concepts into an atmospheric model that is primarily characterized by intense dynamics.

The development of the small meteorological rocket began in 1959 with a rocketsonde system known as ARCAS. The maximum altitude reached by this system was about 60 km (37 mi). A less wind-sensitive rocketsonde system, the Loki-Datasonde (PWN-8B), replaced the ARCAS system during the early 1970s. It was soon replaced with the Super Loki-Datasonde (PWN-11D). The PWN-11D rocketsonde motor burns for 2 s before separation from its inert dart and payload, which are thereby propelled to about 80 km (50 mi) altitude, where the payload is ejected. The payload consists of a small bead thermistor temperature sensor attached to a radio transmitter that sends the temperature data to a ground receiver, and a Starute parachute. The meteorological measurements are made during payload descent. At launch, the Super Loki-Datasonde has an overall weight of 31 kg (68 lb), and its length is approximately 4 m (13 ft).

Synoptic-scale circulation systems in the upper atmosphere are demonstrated by rocketsonde data to be very obviously keyed to the geographic and orographic structures of the Earth's surface. In winter, oceanic regions characteristically have poleward extensions of ridges of high pressure, and continental regions have shifty troughs of low pressure extending equatorward over them. This intimate relationship between the surface and 50 km (31 mi) is most likely the direct result of turbulent energy transport in the vertical direction, and a total understanding of the entire atmospheric system cannot be realized until these factors are incorporated. *See* Atmospheric general circulation; Stratosphere; Upper-atmosphere dynamics. [W.L.W.; F.J.Sc.]

Meteorological satellites Satellites dedicated to the observation of meteorological phenomena and atmospheric or surface properties used for weather forecasting. Operational meteorological satellites provide routine observations of weather conditions as well as an ever expanding range of environmental properties, such as aerosol, dust and ash clouds from volcanic eruptions, ozone, and land vegetation cover. For this reason, they are known in the United States as operational environmental satellites. *See* Meteorology; Satellite (spacecraft); Satellite meteorology.

Optical imaging sensors. The first recognized application of orbital observation was the visual exploitation of cloud images associated with weather systems. Recent instruments, such as the Advanced Very High Resolution Radiometer (AVHRR) on *NOAA* satellites, use a variety of quantitative applications, such as remote sensing of sea surface temperature, monitoring changes in land vegetation, and discriminating between different kinds of clouds. There is a pervasive trend to increase the number of spectral bands in imaging sensors, from 5 channels in the current AVHRR to 36 channels in the experimental Moderate-resolution Imaging Spectroradiometer (MODIS) developed by NASA. These channels sample the full spectrum of backscattered solar radiation in the visible, near-infrared, and longwave infrared, and a good part of the emitted terrestrial radiation spectrum (thermal infrared). This multiplicity of spectral bands allows the detection of a wide variety of features, from aerosols and smoke in the atmosphere to chlorophyll in the ocean. *See* Cloud; Remote sensing; Terrestrial radiation; Weather.

Except for observing polar regions, or providing meteorological support to operations in remote locations worldwide, the ideal platforms for cloud imaging are those in geosynchronous equatorial orbit, also known as geostationary orbit, at the precise altitude (35,900 km) where the orbital period matches the period of rotation of the Earth, so that the satellite appears to hover over a fixed location at the Equator. The international system of four to six geostationary meteorological satellites provides uninterrupted visibility of the global tropics and midlatitudes (up to 60° north and south at the satellite longitude) with the ability to monitor fast-developing weather systems that often are the most dangerous. The sharpness of cloud images (1-km picture elements in the visible), as well as the ability to scan the same scene repeatedly at time intervals as short as 5 minutes, allow for tracking the apparent motion of clouds, deducing wind velocity, and instantaneously assessing the strength of developing storms, a valuable capability in warm climate regions. *See* EARTH ROTATION AND ORBITAL MOTION; TROPICAL METEOROLOGY.

Imaging microwave radiometers. Also interesting is the detection of diverse atmospheric properties and surface features using multifrequency microwave radiometers with small antenna beams. Water molecule absorption of microwave radiation emitted by the ocean provides an accurate estimation of total precipitable water in the atmospheric column. Microwave radiation emitted by the relatively homogeneous moist atmosphere below is scattered in a recognizable way by waterdrops and ice particles in rain clouds, thus providing an indirect means to estimate precipitation rates. Microwave radiation contrast discriminates ice floes from open ocean water, and wet from dry soil. Microwave radiometry enables diagnostics of sea state and wind strength over the surface of the ocean, or the sea surface temperature. The principal design constraint of imaging microwave radiometers is the diffraction limit of the sensor—large apertures are desirable, but bulky antennas are a problem because mechanical scanning is needed to preserve radiometric accuracy. In order to achieve reasonably small footprints, microwave sensors are currently deployed in low Earth orbit. *See* MICROWAVE; PRECIPITATION (METEOROLOGY); RADIOMETRY.

Sounding sensors. The retrieval of temperature profile and water vapor information from spectral data is a difficult and not a fully determined mathematical problem. The solutions are highly sensitive to spectral resolution and small errors in radiometric measurements. The latest Atmospheric Infra-Red Sounder (AIRS) instrument developed by NASA is expected to yield temperature profiles as accurate as balloon measurements, 1°C within each successive 1-km-thick layer of the lower atmosphere. *See* HYDROMETEOROLOGY; INFRARED RADIATION.

Atmospheric sounders operate in the thermal infrared, using the absorption bands of carbon dioxide molecules (3.7–4.9 μm and 13–15 μm), and in the microwave spectrum, using the 54-GHz absorption band of oxygen. Emitted radiation is much weaker and atmospheric sounders correspondingly less sensitive in the microwave region. However, nonprecipitating clouds are largely transparent to such relatively long wavelengths, thus allowing all-weather albeit less accurate observations.

Measurements of temperature and moisture are used mainly to update numerical weather prediction computations that forecast the circulation of the global atmosphere several days in advance. For this quantitative application, a delay of a few hours is immaterial but homogeneous global coverage is essential. Thus, atmospheric sounders are principally deployed on Sun-synchronous polar orbits. The parameters of these circular low Earth orbits are selected from a discrete set of altitudes (800–1000 km) and inclinations (retrograde quasi-polar) that allow the orbital plane to drift by about 1° of longitude per day and match the change in Sun-Earth direction. Thus, a Sun-synchronous satellite crosses the Equator at (nearly) the same local time on every successive orbit.

Active sensors. Orbital systems are now powerful enough to probe the atmospheric medium or the surface with beams of electromagnetic radiation generated in space. The first operational sensor of this kind was a coarse radar or scatterometer that measured microwave radiation backscattered by the ocean surface. Backscatter is sensitive to surface roughness and thus provides a measurement of vector wind speed over the ocean (as well as a coarse all-weather mapping of sea ice).

Various radar altimeters have been used to map the changing topography of the ocean surface (principally to reconstruct the oceanic circulation from measured altitude gradients). Higher-frequency experimental radar and lidar systems are being tested to profile the distribution and optical properties of aerosol and cloud ice particles and waterdrops. The first demonstration of a space-borne precipitation radar in being conducted with the United States-Japan Tropical Rain Measuring Mission (TRMM) launched in 1997. Rain rate can be deduced from the three-dimensional distribution of ice particles and water in rain clouds, as observed by the *TRMM* satellite. *See* LIDAR; METEOROLOGICAL RADAR; RADAR METEOROLOGY.

Yet another promising technology will determine wind velocity in clear air from direct measurements of the frequency shift (Doppler effect) of multiple laser pulses backscattered by aerosol and other diffusive particles. Global wind measurements will provide an invaluable enhancement of the worldwide meteorological observing network, especially at low latitudes where the wind field cannot be deduced from atmospheric pressure. *See* DOPPLER RADAR. [P.Mo.]

Meteorology A discipline involving the study of the atmosphere and its phenomena. Meteorology and climatology are rooted in different parent disciplines, the former in physics and the latter in physical geography. They have, in effect, become interwoven to form a single discipline known as the atmospheric sciences, which is devoted to the understanding and prediction of the evolution of planetary atmospheres and the broad range of phenomena that occur within them. The atmospheric sciences comprise a number of interrelated subdisciplines. *See* CLIMATOLOGY.

Atmospheric dynamics (or dynamic meteorology) is concerned with the analysis and interpretation of the three-dimensional, time-varying, macroscale motion field. It is a branch of fluid dynamics, specialized to deal with atmospheric motion systems on scales ranging from the dimensions of clouds up to the scale of the planet itself. The activity within dynamic meteorology that is focused on the description and interpretation of large-scale (greater than 1000 km or 600 mi) tropospheric motion systems such as extratropical cyclones has traditionally been referred to as synoptic meteorology, and that devoted to mesoscale (10–1000 km or 6–600 mi) weather systems such as severe thunderstorm complexes is referred to as mesometeorology. Both synoptic meteorology and mesometeorology are concerned with phenomena of interest in weather forecasting, the former on the day-to-day time scale and the latter on the time scale of minutes to hours. *See* DYNAMIC METEOROLOGY; MESOMETEOROLOGY.

The complementary field of atmospheric physics (or physical meteorology) is concerned with a wide range of processes that are capable of altering the physical properties and the chemical composition of air parcels as they move through the atmosphere. It may be viewed as a branch of physics or chemistry, specializing in processes that are of particular importance within planetary atmospheres. Overlapping subfields within atmospheric physics include cloud physics, which is concerned with the origins, morphology, growth, electrification, and the optical and chemical properties of the droplets within clouds; radiative transfer, which is concerned with the absorption, emission, and scattering of solar and terrestrial radiation by aerosols and radiatively active trace gases within planetary atmospheres; atmospheric chemistry, which deals with a wide range of gas-phase and heterogeneous (that is, involving aerosols or cloud droplets) chemical and photochemical reactions on space scales ranging from individual smokestacks to the global ozone layer; and boundary-layer meteorology or micrometeorology, which is concerned with the vertical transfer of water vapor and other trace constituents, as well as heat and momentum across the interface between the atmosphere and the underlying surfaces and their redistribution within the lowest kilometer of the atmosphere by motions on scales too small to resolve explicitly in global models. Aeronomy is concerned with physical processes in the upper atmosphere (above the 50-km or 30-mi level). *See* Aeronomy; Atmospheric chemistry; Atmospheric electricity; Atmospheric general circulation; Atmospheric waves, upper synoptic; Cloud physics; Meteorological optics; Micrometeorology; Radiative transfer; Terrestrial radiation.

Although atmospheric dynamics and atmospheric physics in some circumstances can be successfully pursued as separate disciplines, important problems such as the development of numerical weather prediction models and the understanding of the global climate system require a synthesis. Physical processes such as radiative transfer and the condensation of water vapor onto cloud droplets are ultimately responsible for the temperature gradients that drive atmospheric motions, and the motion field, in turn, determines the evolving, three-dimensional setting in which the physical processes take place.

The atmospheric sciences cannot be completely isolated from related disciplines. On time scales longer than a month, the evolution of the state of the atmosphere is influenced by dynamic and thermodynamic interactions with the other elements of the climate system, that is, the oceans, the cryosphere, and the terrestrial biosphere. A notable example is the El Niño-Southern Oscillation phenomenon in the equatorial Pacific Ocean, in which changes in the distribution of surface winds force anomalous ocean currents; the currents can alter the distribution of sea-surface temperature, which in turn can alter the distribution of tropical rainfall, thereby inducing further changes in the surface wind field. On a time scale of decades or longer, the cycling of chemical species such as carbon, nitrogen, and sulfur between these same global reservoirs also influences the evolution of the climate system. Human activities represent an increasingly significant atmospheric source of some of the radiatively active trace gases that play a role in regulating the temperature of the Earth. *See* Biosphere; Maritime meteorology; Tropical meteorology.

Throughout the atmospheric sciences, prediction is a unifying theme that sets the direction for research and technological development. Prediction on the time scale of minutes to hours is concerned with severe weather events such as tornadoes, hail, and flash floods, which are manifestations of intense mesoscale weather systems, and with urban air-pollution episodes; day-to-day prediction is usually concerned with the more ordinary weather events and changes that attend the passage of synoptic-scale weather systems such as extratropical cyclones; and seasonal prediction is concerned with regional climate anomalies such as drought or recurrent and persistent cold air outbreaks. Prediction on still longer time scales involves issues such as the impact of human activity on the temperature of the Earth, regional climate, the ozone layer, and the chemical makeup of precipitation. *See* Climate modeling; Drought; Hail; Tornado.

The evolution of the atmospheric sciences from a largely descriptive field to a mature, quantitative physical science discipline is apparent in the development of vastly improved predictive capabilities based upon the numerical integration of specialized versions of the Navier-Stokes equations, which include sophisticated parametrizations of physical processes such as radiative transfer, latent heat release, and microscale motions. The so-called numerical weather prediction models have largely replaced the subjective and statistical prediction methods that were widely used as a basis for day-to-day weather forecasting. The state-of-the-art numerical models exhibit significant skill for forecast intervals as long as about a week. *See* Navier-Stokes equation.

A distinction is often made between weather prediction, which is largely restricted to the consideration of dynamic and physical processes internal to the atmosphere, and climate prediction, in which interactions between the atmosphere and other elements of the climate system are taken into account. The importance and complexity of these interactions tend to increase with the time scale of the phenomena of interest in the forecast. Weather prediction involves shorter time frames (days to weeks), in which the information contained in the initial conditions is the dominant factor in determining the evolution of the state of the atmosphere; and climate prediction involves longer time frames (seasons and longer), for boundary forcing is the dominant factor in determining the state of the atmosphere.

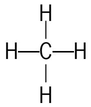
Atmospheric prediction has benefited greatly from major advances in remote sensing. Geostationary and polar orbiting satellites provide continuous surveillance of the global distribution of cloudiness, as viewed with both visible and infrared imagery. These images are used in positioning of features such as cyclones and fronts on synoptic charts. Cloud motion vectors derived from consecutive images provide estimates of winds in regions that have no other data. Passive infrared and microwave sensors aboard satellites also provide information on the distribution of sea-surface temperature, sea state, land-surface vegetation, snow and ice cover, as well as vertical profiles of temperature and moisture in cloud-free regions. Improved ground-based radar imagery and vertical profiling devices provide detailed coverage of convective cells and other significant mesoscale features over land areas. Increasingly sophisticated data assimilation schemes are being developed to incorporate this variety of information into numerical weather prediction models on an operational basis. *See* Atmosphere; Climatic prediction; Cyclone; Front; Radar meteorology; Satellite meteorology; Weather forecasting and prediction. [J.M.Wa.]

Metering orifice A thin plate that is mounted inside a pipe and has a sharp-edged aperture through which the fluid in the pipe is accelerated. The acceleration causes the local static pressure to decrease. The flow rate is sensed by taking one pressure reading upstream and one downstream of the orifice.

The orifice plate is commonly used as an instrument to meter or control the rate of flow of the most common or newtonian fluids. These comprise all gases, including air and natural gas, and many liquids, such as water, and most hydrocarbons. With no moving parts and a simple design, the orifice is easily machined, and thus has been a popular flow-measuring device. However, its pressure loss is large compared to more expensive devices such as the venturi tube.

The metering orifice is one of a class of differential-pressure-sensing devices that are used to indicate flow rate. Others in this category include flow nozzles, venturis, elbow meters, target meters, and wedge meters. In open-channel flow, such as occurs in streams and canals, the weir serves the same purpose as the orifice; however, because the flow occurs at constant pressure, the height of the fluid over the weir, rather than the pressure, is used to sense the flow rate. *See* Nozzle; Pitot tube; Venturi tube. [M.P.W.]

Methane A member of the alkane or paraffin series of hydrocarbons with the formula shown below. Methane is called



$$\begin{array}{c} \mathrm{H} \\ | \\ \mathrm{H{-}C{-}H} \\ | \\ \mathrm{H} \end{array}$$

marsh gas because it forms by anaerobic bacterial decomposition of vegetable matter in swampy land. Coal miners know it as firedamp because mixtures with air are combustible. It is a major constituent of natural gas (50–90%) and of coal gas. It forms in large amounts in sewage disposal processes, especially in anaerobic digestion. As a liquid it freezes at $-182.6^\circ\mathrm{C}$ ($-296.7^\circ\mathrm{F}$) and boils at $-161.6^\circ\mathrm{C}$ ($-258.9^\circ\mathrm{F}$).

In addition to its use as a fuel, methane is important as a source of organic chemicals and of hydrogen. Its reaction with steam at high temperatures in the presence of catalysts yields carbon monoxide and hydrogen (synthesis gas), which can be catalytically converted to liquid alkanes (Fischer-Tropsch process) or to methanol and other alcohols. *See* Alkane; Fischer-Tropsch process; Hydroformylation; Natural gas. [L.S.]

Methanogenesis (bacteria) The microbial formation of methane, which is confined to anaerobic habitats where occurs the production of hydrogen, carbon dioxide, formic acid, methanol, methylamines, or acetate—the major substrates used by methanogenic microbes (methanogens). In fresh-water or marine sediments, in the intestinal tracts of animals, or in habitats engineered by humans such as sewage sludge or biomass digesters, these substrates are the products of anaerobic bacterial metabolism. Methanogens are terminal organisms in the anaerobic microbial food chain—the final product, methane, being poorly soluble, anaerobically inert, and not in equilibrium with the reaction which produces it.

Two highly specialized digestive organs, the rumen and the cecum, have been evolved by herbivores to delay the passage of cellulose fibers so that microbial fermentation may be complete. In these organs, large quantities of methane are produced from hydrogen and carbon dioxide or formic acid by methanogens. From the rumen, an average cow may belch 26 gallons (100 liters) of methane per day.

Methanogens are the only living organisms that produce methane as a way of life. The biochemistry of their metabolism is unique and definitively delineates the group. Two reductive biochemical strategies are employed: an eight-electron reduction of carbon dioxide to methane or a two-electron reduction of a methyl group to methane. All methogens form methane by reducing a methyl group. The major energy-yielding reactions used by methanogens utilize substrates such as hydrogen, formic acid, methanol, acetic acid, and methylamine. Dimethyl sulfide, carbon monoxide, and alcohols such as ethanol and propanol are substrates that are used less frequently. *See* Archaebacteria; Bacterial physiology and metabolism; Methane. [R.S.W.]

Methanol The first member of the homologous series of aliphatic alcohols, with the formula CH_3OH. It is produced commercially from a mixture of carbon monoxide (CO) and hydrogen (H_2). Methanol is a highly flammable liquid, boiling point 64.7°C (149°F), and is miscible with water and most organic liquids. It is a highly poisonous substance; sublethal amounts can cause permanent blindness. *See* Alcohol.

Methanol is one of the major industrial organic chemicals. Its major derivatives are methyl tertiary butyl ether (MTBE), formaldehyde, and acetic acid. Other derivatives and uses include chloromethanes, methyl methacrylate, methylamines, dimethyl terephthalate, solvents (such as glycol methyl ethers), antifreeze, and fuels. [J.A.Mo.]

Methods engineering A technique used by progressive management to improve productivity and reduce costs in both direct and indirect operations of manufacturing and nonmanufacturing business organizations. Methods engineering is applicable in any enterprise wherever human effort is required. It can be defined as the systematic procedure for subjecting all direct and indirect operations to close scrutiny in order to introduce improvements that will make work easier to perform and will allow work to be done smoother in less time, and with less energy, effort, and fatigue, with less investment per unit. The ultimate objective of methods engineering is profit improvement. *See* Operations research; Productivity.

Methods engineering includes five activities: planning, methods study, standardization, work measurement, and controls. Methods engineering, through planning, first identifies the amount of time that should be spent on a project so as to get as much of the potential savings as is practical. Invariably the most profitable jobs to study are those with the most repetition, the highest labor content (human work as distinguished from mechanical or process work), the highest labor cost, or the longest life-span. Next, through methods study, methods are improved by observing what is currently being done and then by developing better ways of doing it. The standardization phase includes the training of the operator to follow the standard method. Then the number of standard hours in which operators working with standard performances can do their job is determined by measurement. Finally, the established method is periodically audited, and various management controls are adjusted with the new time data. The system may include a plan for compensating labor that encourages attaining or surpassing a standard performance. [B.W.N.]

Metric system A system of units used in scientific work throughout the world and employed in general commercial transactions and engineering applications in most of the developed nations of the world except for the United Kingdom and the United States. The basic units of the metric system define length (meter), mass (kilogram), and time (second).

The chief advantage of the metric system is that it is based on standards that have been accepted by international agreement, and it therefore provides a common basis for all scientific measurements. A second advantage of the metric system lies in the fact that only decimal multiples and submultiples of the fundamental length and mass units and of other derived units are employed. *See* Physical measurement; Time; Units of measurement. [D.Wi.]

Metzgeriales An order of liverworts in the subclass Jungermanniidae. Twelve families make up the Metzgeriales, which are also known as the Anacrogynae because of archegonia produced behind the growing apex. The gametophyte plant body is flat, elongated, and usually thallose, with no tissue differentiation or surface pores; less commonly there is a stem with two rows of leaves. Capsules dehisce by valves. *See* Bryophyta; Jungermanniidae. [H.Cr.]

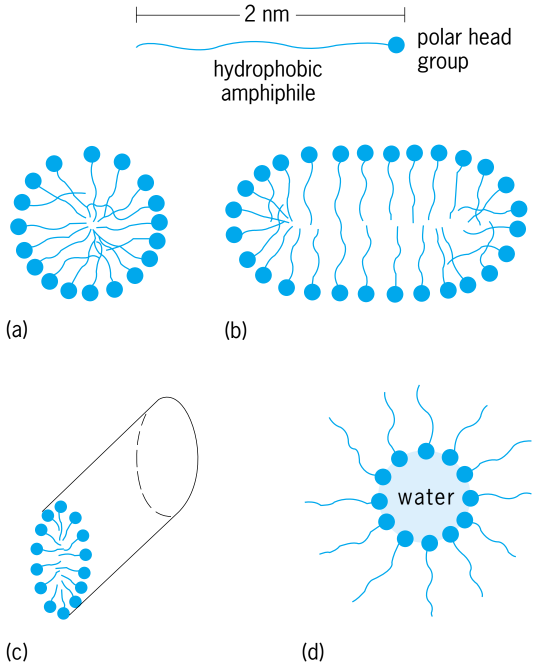
Mica Any one of a group of hydrous aluminum silicate minerals with platy morphology and perfect basal (micaceous) cleavage. The most common micas are muscovite $[KAl_2(AlSi_3O_{10})(OH)_2]$, paragonite $[NaAl_2(AlSi_3O_{10})(OH)_2]$, phlogopite $[K(Mg,Fe)_3(AlSi_3O_{10})(OH)_2]$, biotite $[K(Fe,Mg)_3(AlSi_3O_{10})(OH)_2]$, and lepidolite $[K(Li,Al)_{2.5\text{-}3.0}(Al_{1.0\text{-}0.5}Si_{3.0\text{-}3.5}O_{10})(OH)_2]$. Calcium (Ca), barium (Ba), rubidium (Rb), and cesium (Cs) can substitute for sodium (Na) and potassium (K); manganese (Mn), chromium (Cr), and titanium (Ti) for magnesium (Mg), iron (Fe), and lithium (Li); and fluorine (F) for hydroxyl (OH). The three major species, muscovite, biotite, and phlogopite, are widely distributed rock-forming minerals, occurring as essential constituents in a variety of igneous, metamorphic, and sedimentary rocks and in many mineral deposits.

Mica is commonly found as small flakes or lamellar plates without a crystal outline. Muscovite and biotite sometimes occur in thick books, tabular prisms with a hexagonal outline that can be up to several feet across. The prominent basal cleavage is a consequence of the layered crystal structure. Thin cleavage sheets of micas, particularly muscovite and phlogopite, are flexible, elastic, tough, and translucent to transparent (isinglass). They have low electrical and thermal conductivity and high dielectric strength.

Micas have Mohs hardnesses of 2–3 and specific gravities of 2.8–3.2. Upon heating in a closed tube, they evolve water. They have a vitreous-to-pearly luster. Muscovite is colorless to pale shades of brown, green, or gray. Paragonite is colorless to pale yellow. Phlogopite is pale yellow to brown. Biotite is dark green, brown, or black. Lepidolite is most often pale lilac, but it can also be colorless, pale yellow, or pale gray. *See* Biotite; Hardness scales.

Commercial mica is of two main types: sheet, and scrap or flake. Sheet muscovite, mostly from pegmatites, is used as a dielectric in capacitors and vacuum tubes in electronic equipment. Lower-quality muscovite is used as an insulator in home electrical products such as hot plates, toasters, and irons. Scrap and flake mica is ground for use in coatings on roofing materials and waterproof fabrics, and in paint, wallpaper, joint cement, plastics, cosmetics, well drilling products, and a variety of agricultural products. *See* CAPACITOR; ELECTRIC INSULATOR; SILICATE MINERALS. [L.Gr.; S.Sim.]

Micelle A colloidal aggregate of a unique number (50→100) of amphipathic molecules, which occurs at a well-defined concentration called the critical micelle concentration. In polar media such as water, the hydrophobic part of the amphiphiles forming the micelle tends to locate away from the polar phase while the polar parts of the molecule (head groups) tend to locate at the polar micelle solvent interface. A micelle may take several forms, depending on the conditions and composition of the system, such as distorted spheres, disks, or rods (see illustration). Micelles are formed in nonpolar media such as benzene, where the amphiphiles cluster around small water droplets in the system, forming an assembly known as a reversed micelle.



Form of an amphiphile and several forms of micelle: (*a*) spherical, (*b*) disk, (*c*) rod, and (*d*) reversed.

Micellar systems have the unique property of being able to solubilize both hydrophobic and hydrophilic compounds. They are used extensively in industry for detergency and as solubilizing agents. *See* DETERGENT; SOAP. [J.K.T.]

Microbial ecology The study of interrelationships between microorganisms and their living and nonliving environments. Microbial populations are able to tolerate and to grow under varying environmental conditions, including habitats with extreme environmental conditions such as hot springs and salt lakes. Understanding the environmental factors controlling microbial growth and survival offers insight into the distribution of microorganisms in nature, and many studies in microbial ecology are concerned with examining the adaptive features that permit particular microbial species to function in particular habitats.

Within habitats some microorganisms are autochthonous (indigenous), filling the functional niches of the ecosystem, and others are allochthonous (foreign), surviving in the habitat for a period of time but not filling the ecological niches. Because of their diversity and wide distribution, microorganisms are extremely important in ecological processes. The dynamic interactions between microbial populations and their surroundings and the metabolic activities of microorganisms are essential for supporting productivity and maintaining environmental quality of ecosystems. Microorganisms are crucial for the environmental degradation of liquid and solid wastes and various pollutants and for maintaining the ecological balance of ecosystems—essential for preventing environmental problems such as acid mine drainage and eutrophication. *See* ECOSYSTEM; EUTROPHICATION.

The various interactions among microbial populations and between microbes, plants, and animals provide stability within the biological community of a given habitat and ensure conservation of the available resources and ecological balance. Interactions between microbial populations can have positive or negative effects, either enhancing the ability of populations to survive or limiting population densities. Sometimes they result in the elimination of a population from a habitat. *See* RHIZOSPHERE.

The transfer of carbon and energy stored in organic compounds between the organisms in the community forms an integrated feeding structure called a food web. Microbial decomposition of dead plants and animals and partially digested organic matter in the decay portion of a food web is largely responsible for the conversion of organic matter to carbon dioxide. *See* BIOMASS; FOOD WEB.

Only a few bacterial species are capable of biological nitrogen fixation. In terrestrial habitats, the microbial fixation of atmospheric nitrogen is carried out by free-living bacteria, such as *Azotobacter*, and by bacteria living in symbiotic association with plants, such as *Rhizobium* or *Bradyrhizobium* living in mutualistic association within nodules on the roots of leguminous plants. In aquatic habitats, cyanobacteria, such as *Anabaena* and *Nostoc*, fix atmospheric nitrogen. The incorporation of the bacterial genes controlling nitrogen fixation into agricultural crops through genetic engineering may help improve yields. Microorganisms also carry out other processes essential for the biogeochemical cycling of nitrogen. *See* BIOGEOCHEMISTRY; NITROGEN CYCLE; NITROGEN FIXATION.

The biodegradation (microbial decomposition) of waste is a practical application of microbial metabolism for solving ecological problems. Solid wastes are decomposed by microorganisms in landfills and by composting. Liquid waste (sewage) treatment uses microbes to degrade organic matter, thereby reducing the biochemical oxygen demand (BOD). *See* ESCHERICHIA; SEWAGE TREATMENT; WATER PURIFICATION. [R.M.A.]

Microbiology The multidisciplinary science of microorganisms. The prefix micro generally refers to an object sufficiently small that a microscope is required for visualization. In the seventeenth century, Anton van Leeuwenhoek first documented observations of bacteria by using finely ground lenses. Bacteriology, as a precursor science to microbiology, was based on Louis Pasteur's pioneering studies in the nineteenth century, when it was demonstrated that microbes as minute simple living organisms were an integral part of the biosphere involved in fermentation and disease. Microbiology matured into a scientific discipline when students of Pasteur, Robert Koch, and others sustained microbes on various organic substrates and determined that microbes caused chemical changes in the basal nutrients to derive energy for growth. Modern microbiology continued to evolve from bacteriology by encompassing the identification, classification, and study of the structure and function of a wide range of microorganisms including protozoa, algae, fungi, viruses, rickettsia, and parasites as well as bacteria. The comprehensive range of organisms is reflected in the major subdivisions of microbiology, which include medical, industrial, agricultural, food, and dairy. *See* ALGAE; BACTERIOLOGY; BIOTECHNOLOGY; FUNGI; IMMUNOLOGY; INDUSTRIAL MICROBIOLOGY; MEDICAL BACTERIOLOGY; MEDICAL MYCOLOGY; MEDICAL PARASITOLOGY; MICROSCOPE; PROTOZOA; RICKETTSIOSES; VIRUS. [E.W.V.]

Microbiota (human) Microbial flora harbored by normal, healthy individuals. A number of microorganisms have become adapted to a particular site or ecologic niche in or on their host. Some are normal residents that are regularly found, and if disturbed will rapidly reestablish themselves; others are transient microorganisms that may colonize the host for short periods but are unable to permanently colonize. The normal fetus is sterile, but during and after birth the infant is exposed to an increasing number of microorganisms. Subsequently, those organisms best adapted to survive and colonize particular sites establish themselves and become predominant. Physiologic factors such as the availability of nutrients, temperature, moisture, pH, oxidation-reduction potential, and resistance to local antibacterial substances play an important role in determining the ability of a microorganism to become established at a particular site. The normal indigenous microbial flora is exceedingly complex, consisting of many different species of bacteria, fungi, viruses, and protozoa. The great majority of these commensal and symbiotic organisms are bacteria and fungi.

The indigenous microorganisms play an important role by protecting the normal host from invasion by microorganisms with a greater potential for causing disease. They compete with the pathogens for essential nutrients and for receptors on host cells by producing bacteriocins and other inhibitory substances, making the environment inimical to colonization by pathogens.

In the healthy individual the morphologic integrity of the body surface provides a very effective first line of defense. The intact skin is an efficient physical barrier that can be penetrated by very few microorganisms. The secretion of specific antimicrobial substances and bactericidal fatty acids by the sebaceous glands also retards microbial invasion.

Mucosal surfaces also provide a mechanical barrier in the respiratory, gastrointestinal, and genitourinary tracts. These surfaces are bathed in secretions with antimicrobial activity. In the respiratory tract, mechanical cleansing is accomplished by the cough and mucociliary action. Recurrent infections of the sinuses, middle ear, bronchial tract, and lungs occur in individuals who have an impairment of ciliary activity. These infections are usually caused by *Staphylococcus pneumoniae* and *Haemophilus influenzae*, the more virulent pus-forming organisms found in the nasopharynx. Defects in ciliary activity also cause bacterial respiratory infections in cigarette smokers and heavy alcohol drinkers. *See* Staphylococcus.

Once the natural barriers of the skin and mucous membranes are breached, the next major line of defense is the polymorphonuclear leukocytes. Individuals with disorders of these phagocytic cells have an increased incidence of serious infections with their indigenous microflora.

The complement system is another nonspecific mechanism of the body for the elimination of invading microorganisms. Complement proteins in conjunction with organs of the reticuloendothelial system (spleen, liver, and bone marrow) play a key role in the removal of encapsulated bacteria from the bloodstream. Splenectomized individuals and those with a nonfunctioning spleen because of sickle cell disease have an increased incidence of fulminating infections caused by *S. pneumoniae*, *H. influenzae*, *Neisseria meningitidis*, and recently recognized unusual organisms. *See* Complement. [H.P.W.]

Microcline Triclinic potassium feldspar, $KAlSi_3O_8$, that usually contains a few percent sodium feldspar ($Ab = NaAlSi_3O_8$) in solid solution. Its hardness is 6; specific gravity, 2.56; mean refractive index, 1.52; color, white (green varieties are called amazon stone or amazonite). Microcline is found in some relatively high-grade regional metamorphic rocks, but is much more common in pegmatites, granites, and related plutonic igneous rocks. In the last, it often occurs as a microcline perthite, containing exsolved low albite intergrowths. *See* Feldspar; Perthite. [P.H.R.]

Microcomputer A digital computer whose central processing unit consists of a microprocessor, a single semiconductor integrated circuit chip. Once less powerful than larger computers, microcomputers are now as powerful as the minicomputers and superminicomputers of just several years ago. This is due in part to the growing processing power of each successive generation of microprocessor, plus the addition of mainframe computer features to the chip, such as floating-point mathematics, computation hardware, memory management, and multiprocessing support. *See* Integrated circuits; Microprocessor; Multiprocessing.

Microcomputers are the driving technology behind the growth of personal computers and workstations. The capabilities of today's microprocessors in combination with reduced power consumption have created a new category of microcomputers: hand-held devices. Some of these devices are actually general-purpose microcomputers: They have a liquid-crystal-display (LCD) screen and use an operating system that runs several general-purpose applications. Many others serve a fixed purpose, such as telephones that provide a display for receiving text-based pager messages and automobile navigation systems that use satellite-positioning signals to plot the vehicle's position. *See* Liquid crystals; Mobile radio; Radio paging systems; Satellite navigation systems.

The microprocessor acts as the microcomputer's central processing unit (CPU), performing all the operations necessary to execute a program (see illustration).

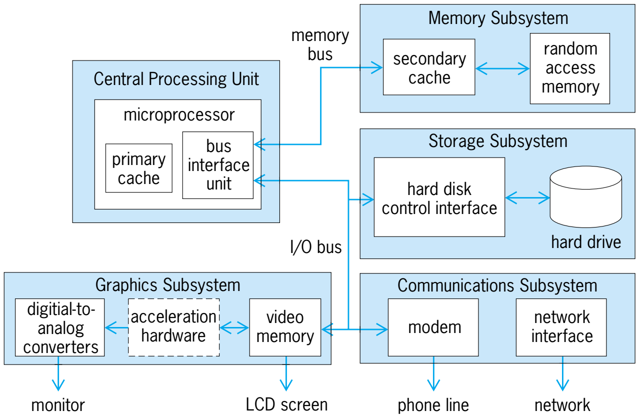
A memory subsystem uses semiconductor random-access memory (RAM) for the temporary storage of data or programs. The memory subsystem may also have a small secondary memory cache that improves the system's performance by storing frequently used data objects or sections of program code in special high-speed RAM.

The graphics subsystem consists of hardware that displays information on a color monitor or LCD screen: a graphics memory buffer stores the images shown on the screen, digital-to-analog convertors (DACs) generate the signals to create an image on an analog monitor, and possibly special hardware accelerates the drawing of two- or three-dimensional graphics. (Since LCD screens are digital devices, the graphics subsystem sends data to the screen directly rather than through the DACs.) *See* Digital-to-analog converter.

The storage subsystem uses an internal hard drive or removable media for the persistent storage of data.

The communications subsystem consists of a high-speed modem or the electronics necessary to connect the computer to a network.

Microcomputer software is the logic that makes microcomputers useful. Software consists of programs, which are sets of



Elements of a microcomputer. The various subsystems are controlled by the central processing unit. Some designs combine the memory bus and bus input/output into a single system bus. The graphics subsystem may contain optional graphics acceleration hardware.

instructions that direct the microcomputer through a sequence of tasks. A startup program in the microcomputer's ROM initializes all of the devices, loads the operating system software, and starts it. All microcomputers use an operating system that provides basic services such as input, simple file operations, and the starting or termination of programs. While the operating system used to be one of the major distinctions between personal computers and workstations, today's personal computer operating systems also offer advanced services such as multitasking, networking, and virtual memory. All microcomputers exploit the use of bit-mapped graphics displays to support windowing operating systems. *See* OPERATING SYSTEM; SOFTWARE. [T.T.]

Microdialysis sampling An approach for sampling the extracellular space of essentially any tissue or fluid compartment in the body. Continuous sampling can be performed for long periods with minimal perturbation to the experimental animal. Microdialysis provides a route for sampling the extracellular fluid without removing fluid, and administering compounds without adding fluid. The resulting sample is clean and amenable to direct analysis.

Microdialysis sampling is performed by implanting a short length of hollow-fiber dialysis membrane at the site of interest. The fiber is slowly perfused with a sampling solution (the perfusate) having an ionic composition and pH that closely matches the extracellular fluid of the tissue being sampled. Low-molecular-weight compounds in the extracellular fluid diffuse into the fiber and are swept to a collection vial for subsequent analysis. The system is analogous to an artificial blood vessel that can deliver compounds and remove the resulting metabolites. *See* DIALYSIS; MEMBRANE SEPARATIONS.

Microdialysis is a diffusion-controlled process. The perfusion rate through the probe is generally in the range of 0.5 to 5.0 ml/min. At this flow rate, there is no net flow of liquid across the dialysis membrane. The driving force for mass transport is the concentration gradient between the extracellular fluid and the fluid in the probe. *See* DIFFUSION; TRANSPORT PROCESSES.

The greatest use of microdialysis sampling has been in the neurosciences. Microdialysis probes can be implanted in specific brain regions of conscious animals in order to correlate neurochemical activity with behavior. Most studies have focused on determining dopamine or the other monoamine neurotransmitters. *See* NEUROBIOLOGY.

Microdialysis probes have been implanted in the skin of experimental animals and humans to determine the transdermal delivery of drugs from ointments. Delivery of anticancer drugs to tumors has been studied using microdialysis. *See* DRUG DELIVERY SYSTEMS; PHARMACOLOGY.

Microdialysis sampling has also been used to study the metabolism of compounds in vivo. Metabolic organs such as the liver and kidneys have been studied by microdialysis sampling. By also sampling the bile by microdialysis, complete metabolic profiles can be obtained from a single experimental animal. This approach dramatically decreases the number of experimental animals needed to assess the metabolism of a new drug. [C.E.Lu.]

Micro-electro-mechanical systems (MEMS) Systems that couple micromechanisms with microelectronics. Such systems are also referred to as microsystems, and the coupling of micromechanisms with microelectronics is also termed-break micromechatronics. Micromechanics refers to the design and fabrication of micromechanisms that predominantly involve mechanical components with submillimeter dimensions and corresponding tolerances of the order of 1 micrometer or less. The types of systems encompassed by MEMS represent the need for transducers that act between signal and information processing functions, on the one hand, and the mechanical world, on the other. This coupling of a number of engineering areas leads to a highly interdisciplinary field that is commensurately impacting nearly all branches of science and technology in fields such as biology and medicine, telecommunications, automotive engineering, and defense. Ultimately, realization of a "smart" MEMS may be desired for certain applications whereby information processing tasks are integrated with transduction tasks, yielding a device that can autonomously sense and accordingly react to the environment. *See* TRANSDUCER.

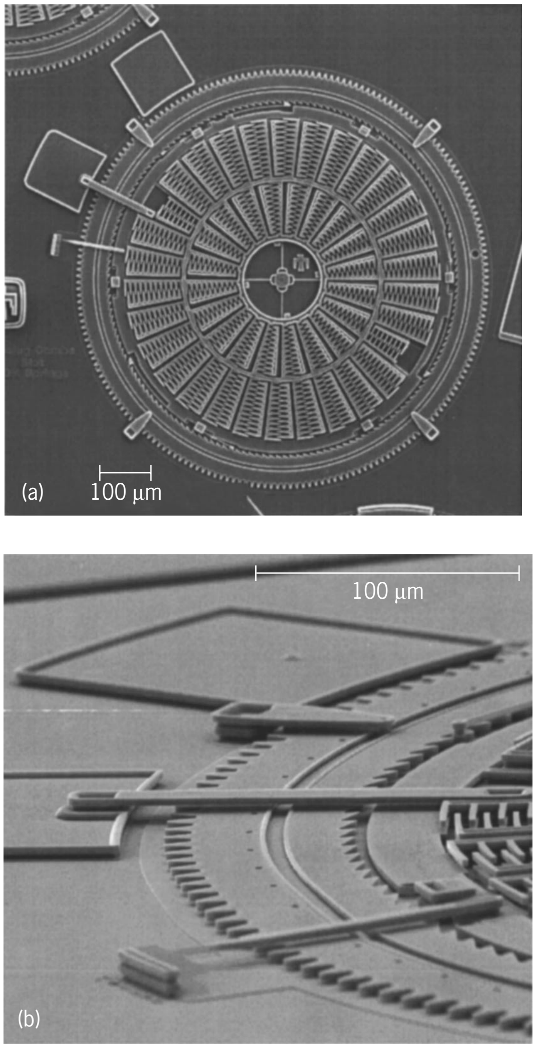


Fig. 1. Torsional ratcheting actuator fabricated by surface micromachining. (*a*) Overview. (*b*) Close-up. (*J. Jakubczala, Sandia National Laboratories*)

Motivating factors behind MEMS include greater independence from packaging shape constraints due to decreased device size. In addition, the advantages of repeatable manufacturing processes as well as economic advantages can follow from batch fabrication schemes such as those used in integrated circuit processing, which has formed the basis for MEMS fabrication. Many technical and manufacturing trade-offs, however, come into play in deciding whether an integrated approach is beneficial. In some cases, the device design with the greatest utility is based on a hybrid approach, where mechanical processing and electronic processing are separated until a final packaging step. Two broad categories of devices follow from the transduction need addressed by MEMS: the input transducer or microsensor, and the output transducer or microactuator. *See* INTEGRATED CIRCUITS.

Microfabrication technology. The development of process tools and materials for MEMS is the pivotal enabler for integration success. A material is chosen and developed for its mechanical attributes and patterned with a process amenable to co-electronic fabrication. Two basic approaches to patterning a

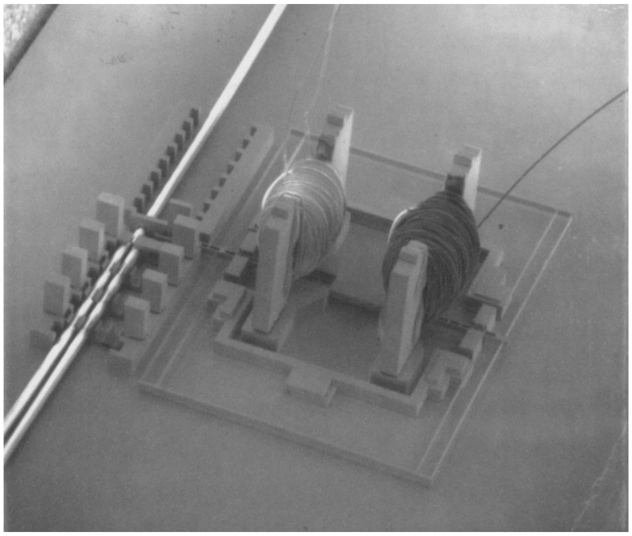

Fig. 2. Magnetic 1 × 2 optical fiber switch fabricated by deep-x-ray lithography. Total device size is approximately 4 mm × 4 mm. (*Henry Guckel, University of Wisconsin*)

material are used. Subtractive techniques pattern via removal of unwanted material, while additive techniques make use of temporary complementary molds within which the resulting structure conforms. Both approaches use a mask to transfer a pattern to the desired material. For batch processes, this step typically occurs via photolithography and may itself entail several steps. The basic process is to apply a photoresist, a light-sensitive material, and use a photomask to selectively expose the photoresist in the desired pattern. A solvent chemically develops the photoresist-patterned image, which then may be used as a mask for further processing.

Subtractive processing is accomplished via chemical etching. Wet etching occurs in the liquid phase, and dry etching or gas-phase etching may occur in a vapor phase or plasma. *See* PLASMA (PHYSICS).

A primary microfabrication technology that has been used for most commercial devices is bulk micromachining, which is the process of removing, or etching, substrate material. The important aspect of precision bulk micromachining is etch directionality. The two limiting cases are isotropic, or directionally insensitive, and anisotropic, or directionally dependent, up to the point of being unidirectional.

An alternative processing approach to bulk microfabrication was driven by the desire to reduce the fraction of the substrate area that had to be devoted to the mechanical components, thereby allowing a larger number of device dies per wafer. The approach, termed surface micromachining (SMM), realizes mechanical structures by depositing and patterning mechanical material layers in conjunction with sacrificial spacer material layers.

Applications. A highly successful device that is fabricated with both bulk and surface micromachining is the integrated pressure transducer. The process sequence uses surface micromachining techniques to form a polysilicon-plate-covered cavity. Application areas include air pressure sensing in automobile engines, environmental monitoring, and blood pressure sensing. Similar processing has resulted in the integration of surface-micromachined polysilicon inertial reference proof masses with microelectronic processing, yielding single-chip force-feedback accelerometers. *See* ACCELEROMETER.

The use of surface micromachining technology to implement microactuators has resulted in steerable micromirror arrays with as many as 1024 × 768 pixels on a chip. These arrays have revolutionized digital display technology. Further electrostatic microactuator designs are possible and may be extremely intricate, such as a torsional ratcheting actuator fabricated with five polysilicon levels (Fig. 1). These types of devices are suited for a variety of micropositioning applications. Processing based on deep-x-ray lithography has been used to produce precision magnetic microactuators. One such microactuator directly switches a single-mode optical fiber in a 1 × 2 switch configuration (Fig. 2). [T.R.C.]

Micromanipulation The technique or practice involving manipulation of objects too small to be easily seen with the unaided eye. When a microscope is used to allow the operator to visually guide the microtools used in the manipulation, the technique is called micrurgy. When an object that is not extremely small needs to be positioned with extreme precision, as when aiming a laser to make a surgical lesion, the technique is called micropositioning.

To manipulate microscopic objects, it is necessary to use a tool called a micromanipulator, which allows relatively coarse hand movements to execute proportionately slower and smaller movements of a probe or microtool. Micromanipulators are used to probe and test integrated circuit chips, to align fiber-optic communication cables, as well as to accomplish techniques in biological research.

The simplest and most common micromanipulators consist of three orthogonal mechanical slides whose position is controlled by a threaded screw or a rack and pinion. Such devices are relatively inexpensive and adequate for magnifications up to 150 power. However, the imperfections of simple machines are revealed by magnifications greater than 150 power.

There has been increasing use of electrically powered micromanipulators. The three types are direct-current-motorized, stepper-motorized, and piezoelectric. Direct-current-motor-driven micromanipulators may be operated by remote control with a joystick or single-step push button, which allows for precise control of pulse length. It is easy to adjust the ratio of movement reduction electrically. At highest magnification, however, the slight vibration of the motors begins to interfere with visualization, making direct-current-motor-driven micromanipulators best suited to medium magnifications. Micromanipulators with stepper-motor drives are the only micromanipulators capable of fast, direct movements to a specific set of coordinates, and can be directed by a computer over a preplanned route. Specialized piezoelectric micromanipulators, called cell penetrators, provide movements over a very short range of 1–10 μm. They move very abruptly but are excellent for puncturing small and hard-to-penetrate cell membranes. [C.W.Sc.]

Micrometeorite A submillimeter extraterrestrial particle that has survived entry into the atmosphere without melting. Meteoroids are natural interplanetary objects that orbit the Sun, and they range in size from small dust grains to objects that are miles in diameter. Particles below 0.04 in. (1 mm) in diameter are considered micrometeoroids, and the micrometeoroids that enter the atmosphere without melting are called micrometeorites. Micrometeorites survive entry without severe heating because they are small and they totally decelerate from cosmic velocity at high altitudes near 55 mi (90 km). Most of the mass of extraterrestrial matter that annually collides with the Earth is in the micrometeoroid size range, a total of about 10^4 tons (10^7 kg), but only a small fraction survives as micrometeorites. Usually only the particles smaller than 0.1 mm survive as true unmelted micrometeorites, although the survival of an individual micrometeorite depends on entry velocity, angle of entry, melting point, and density as well as size. *See* METEORITE.

Micrometeorites are of particular interest because they are samples of comets and asteroids, small primitive bodies that have survived without major change since the earliest history of the solar system. Some of these particles are generated by collisions in the asteroid belt, while others are released from comets when these bodies approach the Sun and ice volatilization releases dust grains and propels them into space. Once released from a parent comet or asteroid, particles survive only for a few thousand to a hundred thousand years, depending on size, before they are either destroyed or collide with a planet. Particles are destroyed either when they collide with other particles or when they spiral into the Sun because of the Poynting-Robertson drag, an effect of sunlight that causes the orbits of small particles to decay. During exposure in space, the small particles accumulate large amounts of helium implanted by the solar wind, and they also are riddled with radiation damage tracks produced by solar cosmic rays, high-energy particles accelerated from solar flares. *See* ASTEROID; COMET; COSMIC RAYS; SOLAR WIND; SUN.

The collection and laboratory analysis of micrometeorites provide an important source of information on the nature of materials in comets and asteroids. Most micrometeorites are collected in the stratosphere with aircraft such as the U2, which is capable of flying at an altitude of 12 mi (20 km) where terrestrial particles as large as 10 μm are rare. Micrometeorites are collected from the stratosphere by direct impact onto sticky plates that are extended from aircraft wings into the ambient airstream. After a cumulative exposure of many hours, the plates are returned to a clean room where the microscopic particles are picked off with needles and placed onto mounts where they can be studied by electron microscopes, mass spectrometers, and other instruments. The collection of micrometeorites in the stratosphere is usually limited to the size range from 2 to 100 μm in diameter. Most particles larger than this limit melt to form cosmic spherules during atmospheric entry and are not true micrometeorites. *See* COSMIC SPHERULES. [D.E.Br.]

Micrometeorology

Micrometeorology The study of small-scale meteorological processes associated with the interaction of the atmosphere and the Earth's surface. The lower boundary condition for the atmosphere and the upper boundary condition for the underlying soil or water are determined by interactions occurring in the lowest atmospheric layers. Momentum, heat, water vapor, various gases, and particulate matter are transported vertically by turbulence in the atmospheric boundary layer and thus establish the environment of plants and animals at the surface. These exchanges are important in supplying energy and water vapor to the atmosphere, which ultimately determine large-scale weather and climate patterns. Micrometeorology also includes the study of how air pollutants are diffused and transported within the boundary layer and the deposition of pollutants at the surface.

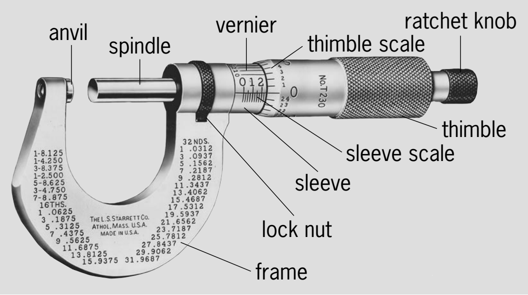
In many situations, atmospheric motions having time scales between 15 min and 1 h are quite weak. This represents a spectral gap that provides justification for distinguishing micrometeorology from other areas of meteorology. Micrometeorology studies phenomena with time scales shorter than the spectral gap (time scales less than 15 min to 1 h and horizontal length scales less than 2–10 km or 1–6 mi). Some phenomena studied by micrometeorology are dust devils, mirages, dew and frost formation, evaporation, and cloud streets. *See* AIR POLLUTION; ATMOSPHERE; MESOMETEOROLOGY.

Much of the early understanding of micrometeorology was obtained by studying conditions in large, flat, uniform areas that are relatively simple situations. Micrometeorologists have turned their attention to more complex situations that represent conditions over more of the Earth's surface. The micrometeorology of complex terrain, that is, hills and mountains, is important for air pollution in many towns and cities and for visibility in national parks and for locating wind generators. Another interest is the study of micrometeorology in areas of widely varied surface conditions. For instance, several different crops, dry unirrigated lands, lakes, and rivers may be located near one another. In these cases it is important to understand how the micrometeorology associated with each of these surfaces interacts to produce the overall heat and moisture fluxes of the region so that these areas can be correctly included in weather and climate forecast computer programs. *See* CLIMATOLOGY; MOUNTAIN METEOROLOGY; WEATHER FORECASTING AND PREDICTION.

Microscale meteorological features are too small to be observed by the standard national and international weather observing network. Generally, micrometeorological phenomena must be studied during specific experiments by using specially designed instruments. Instruments used to study turbulent fluxes must be able to respond to very rapid fluctuations. Special cup anemometers are made from very light materials, and high-quality bearings are used to minimize drag. Other anemometers use the speed of sound waves or measure the temperature of heated wires to measure wind. Tiny thermometers are used, so that time constants are short. Instruments are usually placed on towers or in aircraft, or are suspended in packages from tethered balloons. Instruments have been developed that can measure turbulence remotely. Wind speed and boundary-layer convection can be measured with Doppler radar, lidar devices using lasers, and sodar (sound detection and ranging) using sound waves. *See* ATMOSPHERIC ACOUSTICS; LIDAR; METEOROLOGICAL INSTRUMENTATION; METEOROLOGICAL RADAR; METEOROLOGY. [S.A.St.]

Micrometer

Micrometer A precision instrument used to measure small distances and angles. A common use is on a machinist's caliper, as in the illustration. *See* CALIPER.



Machinist's outside caliper with micrometer reading 0.250 in. (*L. S. Sfarrett Co.*)

The spindle of the caliper is an accurately machined screw, which is rotated by the thimble or the ratchet knob until the object to be measured is in contact with both spindle and anvil. The ratchet slips after correct pressure is applied, ensuring consistent, accurate gaging. The number 1 on the sleeve represents 0.1 in.; the smallest divisions are 0.025 in. A vernier scale allows accurate reading to 0.0001 in. *See* VERNIER. [F.H.R.]

Micro-opto-electro-mechanical systems (MOEMS)

Micro-opto-electro-mechanical systems (MOEMS) A class of microsystems that combine the functions of optical, mechanical, and electronic components in a single, very small package or assembly. MOEMS devices can vary in size from several micrometers to several millimeters. MOEMS may be thought of as an extension of micro-electro-mechanical systems (MEMS) technology by the provision of some optical functionality. This optical functionality may be in the form of moving optical surfaces such as mirrors or gratings, the integration of guided-wave optics into the device, or the incorporation of optical emitters or detectors into the system. The term may be confused with micro-opto-mechanical systems (MOMS), which more properly refers to microsystems that do not include electronic functions at the microsystem location. MOEMS is a rapidly growing area of research and commercial development with great potential to impact daily life. The basic concept is the miniaturization of combined optical, mechanical, and electronic functions into an integrated assembly, or monolithically integrated substrate, through the use of micromachining processes derived from those used by the microelectronics industry. These processes, utilizing microlithography and various etch (subtractive) or deposition (additive) steps on a planar substrate, enable the production of extremely precise shapes, structures, and patterns in various materials. *See* Integrated circuits; Integrated optics; Micro-electro-mechanical systems (MEMS); Micro-opto-mechanical systems (MOMS).

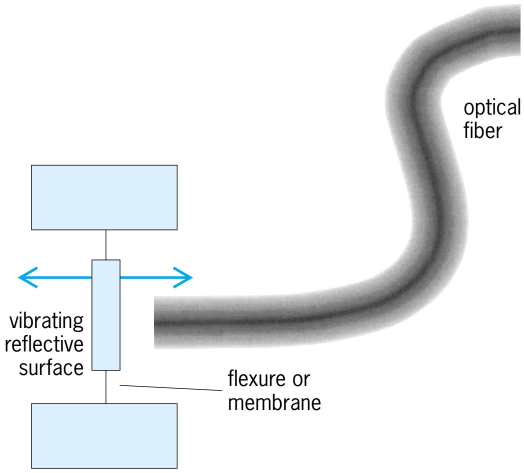
The microsystems realized by these techniques can have many unique capabilities. The miniaturization that is realized is useful in itself, allowing the systems to be utilized as sensors or actuators in environments that were not previously accessible, including inside living organisms, in hand-held instruments, or in small spacecraft. The miniaturization also allows for high-speed operation of the system, as the operating speed of mechanical systems is related to their inertial and frictional properties as well as the actuating forces. Optomechanical systems have been historically constrained in this area because of the mass required for stable optical elements and the extremely precise alignment requirements of most opto-mechanical systems, which limits the forces that can be tolerated for rapid motion. In the more integrated forms of MOEMS, the systems are prealigned by the precise fabrication processes, eliminating one of the more expensive aspects of assembling conventional optical systems. The miniaturization along with the scalability of microfabrication processes allows the development of massively parallel opto-mechanical systems, with millions of moving parts, that would not be possible in conventional technologies. MOEMS can incorporate detection and drive electronics in close proximity to provide improvements in signal-to-noise ratio for sensors and simplified interfaces for actuated systems. Ultimately, these electronics may be monolithically integrated in some technologies. Because of the production volumes achievable with micromachining techniques, MOEMS are potentially much less expensive than their conventional counterparts. [M.E.Wa.]

Micro-opto-mechanical systems (MOMS)

Miniaturized optome-chanical devices or assemblies that are typically formed using micromachining techniques that borrow heavily from the microelectronics industry. The term may be used to distinguish devices and microsystems that combine optical and mechanical functions without the use of internal electronic devices or signals. Systems that use electronic devices as part of the microsystem may be referred to as MOEMS (micro-opto-electro-mechanical systems). In some cases, these terms may be used synonymously. A related area is MEMS (micro-electro-mechanical systems), in which electronic and mechanical functions are combined in a miniature device or system, but not necessarily implementing optical functions. The progress of MOMS technology has been greatly enabled by the simultaneous development of microelectronics and optical fiber-based telecommunications technology. *See* Integrated circuits; Micro-electro-mechanical systems (MEMS); Micro-opto-electro-mechanical systems (MOEMS); Optical communications.

Advantages. Although similar in concept to MOEMS technologies, MOMS has unique advantages for some applications. The use of only optical energy and signals gives MOMS an inherent immunity to electromagnetic interference (EMI) that is important for applications in electrically noisy or high-voltage environments. The absence of semiconductor electronic devices greatly increases the high-temperature tolerance of the system. MOMS devices can be designed to work immersed in liquids, which is of great importance for chemical sensing and biomedical applications. The fact that the power and signal sources can be remotely provided via an optical fiber, allowing the sensor to be passive, is of great utility and reduces the impact of a MOMS sensor on its local environment. MOMS can be used safely in flammable and explosive environments, making them uniquely valuable in the petrochemical industry.

Applications. Some examples of MOMS technology include optical pressure transducers—microphones or hydrophones that have a thin mechanical membrane that is one surface in a Fabry-Perot interferometer formed by the reflection from the membrane surface and the reflection from the end of the fiber. (A similar arrangement for sensing vibration is shown in the illustration.) Other versions have a planar optical waveguide on the surface of a sensitive membrane that is one arm of a two-beam Mach-Zehnder interferometer. Another example is an accelerometer in which a small mass is suspended from flexure attachments to the substrate. Optical fibers are positioned with a small gap in which the moving mass can interrupt the transfer of light from one fiber to another to modulate the light intensity transmitted through the fibers. One of the most well developed MOMS applications is optical sensing of the position of small cantilevers used in scanning tip microscopy processes such as atomic force microscopy. *See* Accelerometer; Microphone; Pressure transducer; Scanning tunneling microscope. [M.E.Wa.]

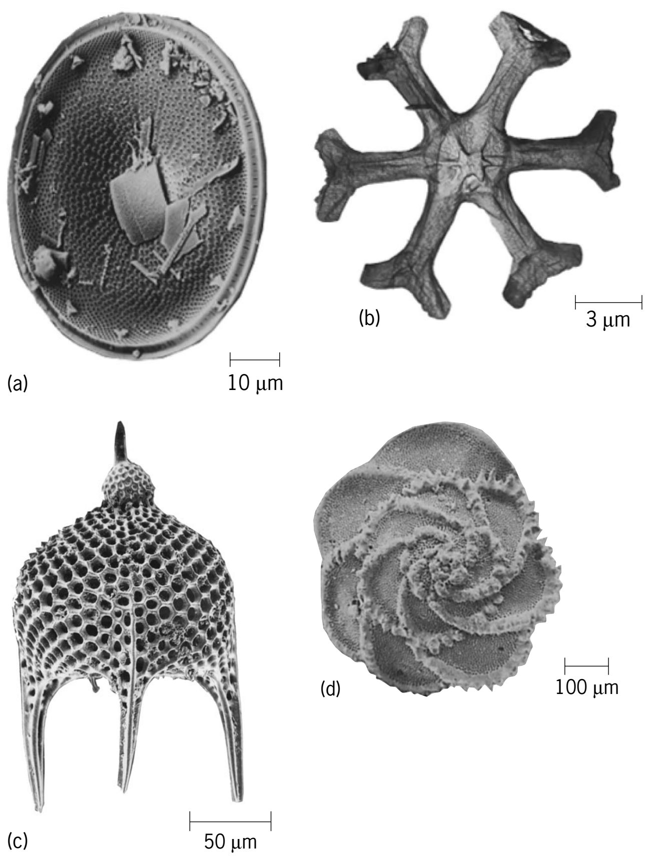


A simplified MOMS sensor using a reflecting surface on a flexible mount or membrane and the end face of an optical fiber to form an optical interferometer that can sense vibration. The vibration of the flexible membrane allows the reflecting surface to move, changing the resonance wavelength of the interferometer, modulating the intensity of the light that is reflected back into the interferometer. At the other end of the interferometer is a light source and a detector.

Micropaleontology

A branch of paleontology dealing with the fossilized microscopic organic remains (microfossils) of the geologic past, their structure, biology, phylogenetic relations, and distribution in space and time. The study of these microfossils has become an independent scientific field largely because: (1) The size of these fossils requires special methods for collection and examination. (2) Their abundance in geologic formations makes it possible to analyze their spatial distribution and the rates of morphological changes during the course of evolution by means of statistical methods which can be used only under exceptional circumstances in the study of larger fossils. (3) Microfossils have become indispensable tools in certain branches of applied geology, especially in the exploration for oil-bearing strata, because countless numbers of these minute fossils may be obtained from small pieces of subsurface rock recovered from drill holes. (4) The diversity of microfossils, their wide spatial distribution in varied environments, and their distinctive steps in evolution and the ease of studying them have contributed to make micropaleontology one of the most actively studied branches of the earth sciences.

The material subjected to micropaleontological studies forms a spectrum from primitive plants to advanced vertebrates (see illustration). The only prerequisite for organisms to become the subject of micropaleontological studies is their possession of resistant skeletal components ensuring their preservation in sedimentary strata as fossilized remains even after biological, chemical, or mechanical processes have destroyed the organisms' soft parts.



Representative microfossils. (*a*) Diatom; (*b*) asterolith, a calcareous nannoplankton; (*c*) radiolarian; and (*d*) planktonic foraminiferan.

Most major groups of organisms incorporate, besides organic compounds, hard resistant materials that serve for structural support or protection. The more common substances found among the microfossils are calcium carbonate, silicon dioxide (or silica), calcium phosphate in the form of the mineral apatite (typical of bones and teeth), sporonine (principal constituent of pollen and spore walls), and various complex organic compounds. [T.S.]

Microphone An electroacoustic device containing a transducer which is actuated by sound waves and delivers electric signals proportional to the sound pressure. Microphones are usually classified with respect to the transducer principle used. Their directional characteristics are also of interest, that is, the voltage output as a function of the direction of incidence for constant sound pressure. *See* DIRECTIVITY; SOUND; SOUND PRESSURE; TRANSDUCER.

In addition to directional characteristics, some other important characteristics of microphones include open-circuit sensitivity, equivalent noise level, dynamic range, and vibration sensitivity.

Open-circuit sensitivity is defined as the ratio of open-circuit output voltage and sound pressure. The pressure sensitivity refers to the actual pressure acting upon the diaphragm of the microphone, while the free-field sensitivity refers to the pressure that existed in the sound field before insertion of the microphone. Pressure sensitivity and free-field sensitivity are equal at low frequencies. Sensitivities are measured in volts/pascal (V/Pa).

Equivalent noise level is equal to the level of a sound pressure which generates an output voltage of the microphone corresponding to its inherent A-weighted noise voltage. It is measured in dB(A).

Dynamic range is defined as the range of sound pressure levels in decibels (dB) extending from the equivalent noise level to the level where the nonlinear distortion reaches 3%.

Vibration sensitivity is defined as the ratio of the output voltage of the microphone as a result of acceleration of its case to the magnitude of the acceleration. Vibration sensitivities are measured in volts/g, where g is the acceleration of the Earth's gravity, or in volts/(m/s^2).

Electrostatic (condenser) microphones. These consist of a fixed electrode (the backplate), a movable electrode (the diaphragm), and an air gap between the electrodes. To decrease the acoustic stiffness of the airgap, which is generally about 20 to 30 micrometers (0.8 to 1.2 mils) thick, the backplate is often perforated with holes connecting the air gap to a larger air cavity. The diaphragm is a thin [typically 4 to 6 μm thick (0.16 to 0.24 mil)] foil under mechanical tension. *See* CAPACITANCE; CAPACITOR; ELECTRICAL IMPEDANCE.

Condenser microphones are renowned for their excellent acoustic qualities such as flat frequency response, high sensitivity, large dynamic range, and small vibration sensitivity. Also important is their suitability for miniaturization, with the smallest units having dimensions of only about 0.12 × 0.12 × 0.08 in. (3 × 3 × 2 mm). They can be designed as precision instruments and as such are widely used in measurement and in high-fidelity sound production. *See* HEARING AID; MAGNETIC RECORDING; SOUND RECORDING; TELEPHONE.

Piezoelectric microphones. These consist of a material having piezoelectric properties. A deformation of the material leads to the generation of a voltage which corresponds to the deformation. Piezoelectric materials can be crystals, polycrystalline ceramics, or semicrystalline polymers. The best-known piezoelectric crystals are quartz and ammonium dihydrogen phosphate (ADP). Representative of polycrystalline ceramics are lead zirconate titanate (PZT) and barium titanate, which are initially electrostrictive; they have to be poled, that is, exposed to a high electric field at elevated temperatures, to become piezoelectric. An example of a semicrystalline polymer is poly(vinylidenefluoride) [PVDF]. It is also made piezoelectric by poling. *See* ELECTRET; ELECTROSTRICTION; PIEZOELECTRICITY.

Well-designed piezoelectric microphones have acceptable quality. A drawback is the relatively high vibration sensitivity. They are still in occasional use in telephones in some countries and are also employed in the near-ultrasonic range at frequencies up to about 100 kHz.

Dynamic microphones. These consist of a conductor located in the gap of a permanent magnet. Motion of the conductor produces a voltage proportional to its velocity. In the moving-coil microphone the coil, often referred to as voice coil, is connected to a diaphragm actuated by the sound waves. Motion of the coil induces a voltage proportional to its velocity. To obtain a frequency-independent sensitivity, the coil must respond to the sound pressure with frequency-independent velocity. This is accomplished by resistance-controlling the system: the acoustical resistance is made larger in magnitude than the acoustical reactance due to the mass of the diaphragm and coil and due to the compliance of the suspension. A silk cloth or a piece of felt placed behind the voice coil is used for this purpose. In modern moving-coil microphones, the diaphragm is made of a plastic film. The impedance of the voice coil is typically 200 to 1000 ohms. *See* ACOUSTIC IMPEDANCE.

Dynamic microphones are relatively complicated systems. If well designed, they are of good quality. Drawbacks are the difficulties encountered in miniaturization and the relatively high vibration sensitivity. Moving-coil microphones are still widely used in high-fidelity, radio, television, and concert applications. In many other areas they have been replaced by electret-based condenser microphones.

Magnetic microphones. These consist of a diaphragm connected to an armature which, when vibrating, varies the reluctance in a magnetic field. The variation in reluctance leads to a variation in the magnetic flux through a surrounding coil and therefore to an induced voltage. This voltage is proportional to the velocity of the armature. To obtain a frequency-independent sensitivity, the velocity of the armature in response to the sound pressure must be independent of frequency. As in dynamic microphones, this is accomplished by resistance-controlling the system, for example, by placing an acoustic resistance behind the diaphragm.

Magnetic microphones are relatively complicated and have poor frequency response and high vibration sensitivity. While never extensively used, they have now disappeared completely. However, the magnetic principle is still used in telephone receivers and in earphones employed in hearing aids. *See* EARPHONES.

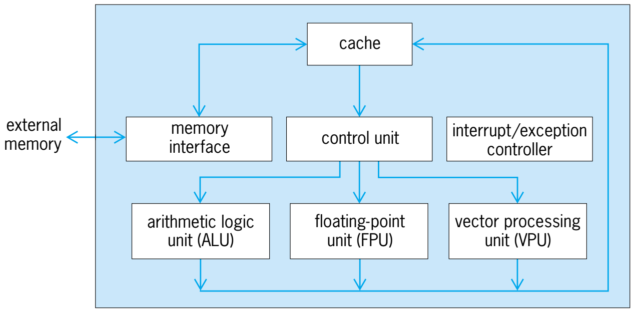
Silicon microphones. The methods of silicon technology make it possible to fabricate batch-processed, high-performance microphones. Utilizing the transducer principles outlined above, many types of such micromachined acoustic sensors have been built. In addition, new concepts of transducer design, such as the modulation of the drain current of a field-effect transistor or the modulation of light propagation in an optical waveguide by the sound waves, have been realized in silicon. Closest to commercial application are the silicon microphones based on the condenser and piezoelectric principles. *See* FIBER-OPTIC SENSOR; TRANSISTOR.

Silicon microphones have several advantages as compared to conventional microphones. They can be made considerably smaller with membrane areas of only about 1 mm^2, as opposed to about 5 mm^2 for the smallest conventional transducers. They also have very low vibration sensitivity due to the use of thin diaphragms. They are thus not susceptible to pickup from vibration sources such as motors in cassette recorders or camcorders. Furthermore, they can be produced together with proper signal-processing electronics on the same chip with the same semiconductor methods. Finally, they can be made inexpensively through batch-processing techniques. [G.M.Se.]

Microprocessor A device that integrates the functions of the central processing unit (CPU) of a computer onto one semiconductor chip or integrated circuit (IC). In essence, the microprocessor contains the core elements of a computer system, its computation and control engine. Only a power supply, memory, peripheral interface ICs, and peripherals (typically input/output and storage devices) need be added to build a complete computer system. *See* COMPUTER PERIPHERAL DEVICES.

A microprocessor consists of multiple internal function units. A basic design has an arithmetic logic unit (ALU), a control unit, a memory interface, an interrupt or exception controller, and an internal cache. More sophisticated microprocessors might also contain extra units that assist in floating-point match calculations, program branching, or vector processing (see illustration).

The ALU performs all basic computational operations: arithmetic, logical, and comparisons.



A microprocessor consists of multiple independent function units. The memory interface fetches instructions from, and writes data to, external memory. The control unit issues one or more instructions to other function units. These units process the instructions in parallel to boost performance.

The control unit orchestrates the operation of the other units. It fetches instructions from the on-chip cache, decodes them, and then executes them. Each instruction has the control unit direct the other function units through a sequence of steps that carry out the instruction's intent. The execution path taken by the control unit can depend upon status bits produced by the arithmetic logic unit or the floating-point unit (FPU) after the instruction sequence completes. This capability implements conditional execution control flow, which is a critical element for general-purpose computation. *See* BIT.

The memory interface enables the microprocessor to maintain two-way communication with off-chip semiconductor memory, which stores programs and data. This interface typically supports memory reads and writes in blocks of words (the number of bits that the processor operates on at one time). The block size facilitates burst data transfers to and from the chip's internal cache. *See* SEMICONDUCTOR MEMORIES.

The interrupt or exception controller enables the microprocessor to respond to requests from the external environment or to error conditions by allowing interruptions of the ongoing operation. An interrupt might be an external peripheral requesting service, while an exception typically consists of a floating-point math error or an unrecognized instruction. The interrupt controller can prioritize and selectively handle these interrupts.

The internal cache is an on-chip memory storage area that holds recently used data values or instruction sequences that are likely to be used again in the near future. Since this information is already on-chip, it can be accessed rapidly, thereby accelerating the computation rate. Items not in the cache can take several or more extra operations to access, which significantly degrades the computation rate. Software writers often organize a program's code and data structures so that the most frequently used elements often occupy the cache, thus maintaining a high level of computational throughput. *See* COMPUTER STORAGE TECHNOLOGY; COMPUTER SYSTEMS ARCHITECTURE.

The design of instruction sets (the commands that produce basic work when executed by the microprocessor) often influences the design of the microprocessor itself. Instruction sets—and as a consequence, the microprocessor architecture—are of two types: reduced instruction set computers (RISC) and complex instruction set computers (CISC). Because of the limits of early computer technology, most computers were by necessity RISC machines. Since most of the software was written in assembly language (that is, a programming language that represented the program's intent in actual machine instructions), there was a drive to build instruction sets of greater sophistication and complexity. These new CISC instruction sets made assembly language programming easier, but they also made it difficult to build high-speed computer hardware. First, CISC instructions were harder to decode. In addition, since CISC instructions involved long and complex operation sequences, they incurred a major cost by requiring more complicated logic to implement. Second, such instructions were also difficult to interrupt or abort if an exception occurred. Finally, such instructions usually carried many data dependencies that made it more difficult to support advanced architectural techniques. By returning to a RISC design, much faster computers can be built. In fact, an enhancement in performance by a factor of 2 to 3 has been attributed to this simple organizational change. To achieve these efficiencies, most of the RISC microprocessor's function units must be kept as busy as possible. This requires optimizing compilers that can translate a program's high-level source code and then reorder the resulting low-level instructions in such a way as to ensure the high throughput. *See* COMPUTER PROGRAMMING; PROGRAMMING LANGUAGES.

Microprocessors are found in virtually every consumer product that requires electric power, such as microwave ovens, automobiles, video recorders, cellular telephones, digital cameras, and hand-held computers. High-performance microprocessors implement the servers that store and distribute Web content, such as streaming audio and video, desktop computers, and the high-speed network switches that constitute the Web's infrastructure. More modest-powered microprocessors are at the heart of notebook computers and electronic games. Low-power microprocessors provide the control and flow logic of hand-held devices, digital cameras, cellular and cordless phones, pagers, and the diagnostic and pollution control of automobile engines. *See* Internet; Video games; Wide-area networks; World Wide Web. [T.T.]

Micropygoida An order of regular echinoids belonging to the Diadematacea, established for the two recognized species of *Micropyga*. They have an aulodont lantern with grooved teeth. Test plating is imbricate, and ambulacra are composed of trigeminate compound plates in which upper and lower elements are reduced to demiplates. Pore pairs are biserially arranged in ambulacral columns, and there are unique umbrellalike aboral tube feet. *Micropyga* is a deep-water echinoid, found between 480 and 4290 ft (150 and 1340 m) depth in the Indo-West Pacific. There are no fossils that can be placed in this taxon with certainty, but it is possible that the Upper Jurassic *Pedinothuria* may belong here. *See* Diadematacea; Echinodermata. [A.B.S.]

Microradiography The process of producing enlarged images of the interior of thin, usually small specimens by penetration of low-energy (0.1–10 keV) x-rays. The magnification can be obtained geometrically during the exposure by subsequent enlargement of the initial image by optical or electronic means, or by a combination of both processes. As with radiography on other size scales, microradiography shows the spatial distribution of mass and elemental composition of the sample. If a pulsed (flash) source or time-gated detector is employed, radiographs also provide stop-motion details of fast-changing objects. Microradiography has numerous applications in biology, material science, the characterization of fabricated microstructures, and assessment of plasma-driven compression of thermonuclear fuel.

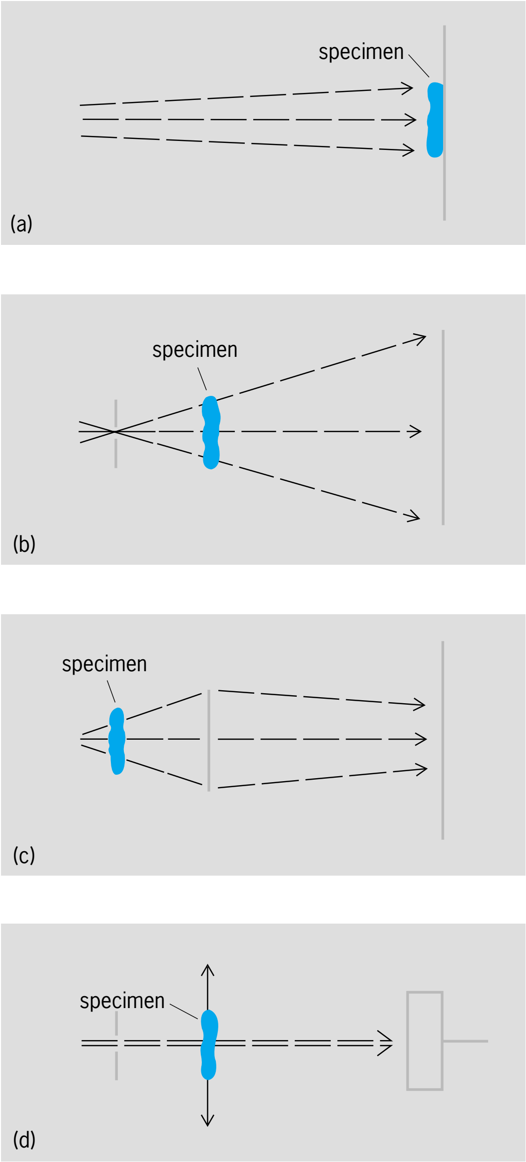
Microradiography is largely synonymous with x-ray microscopy, both techniques being concerned with producing enlarged images of opaque objects by using x-rays. However, x-ray microscopy of defects in crystals can be performed by using diffraction, rather than simple absorption, in a technique termed x-ray topography. Microradiography by x-ray absorption is complementary, or related to a variety of other techniques for characterization of microstructures. *See* X-ray diffraction; X-ray microscope.

There are three classes of sources employed for microradiography: electron-impact devices, storage ring sources of synchrotron radiation, and multimillion-degree plasmas. The first microradiography measurements, and most studies since then, have been done with electron-impact sources. These contain an electron-emitting cathode and an anode in a high vacuum, between which a high voltage is applied. *See* X-ray tube.

High-energy (of the order of gigaelectronvolts) electrons orbiting within an evacuated toroid, called a storage ring, produce intense continuum radiation which is tightly collimated and polarized. Such synchrotron radiation is emitted in nanosecond pulses at MHz rates, and can be 1000 or more times as intense as the x-rays from electron-impact sources. The use of synchrotron radiation for microradiography began in 1977 and has rapidly expanded. *See* Synchrotron radiation.

Very high-temperature plasmas can be heated by high-power lasers or electrical discharges. They are typically 10 μm to 1 mm in size. Multimillion-degree plasmas emit uncollimated line and continuum spectra predominantly in the soft x-ray region, below a few kiloelectronvolts, with pulse lengths of 0.1–100 ns. Stop-motion microradiographs were first made with plasma x-radiation in 1980. *See* Plasma (physics).

X-ray micrographs may be obtained by four geometrically different techniques (see illustration). Two of them, the contact and the projection methods, have been in use for decades. However, they have undergone significant development because of the availability of bright synchrotron radiation and plasma radiation sources. The other two techniques, the true imaging and the scanning methods, require the bright sources.



Schematics of techniques for x-ray microradiography. X-ray paths are indicated by broken lines. (*a*) Contact. (*b*) Projection. (*c*) Imaging. (*d*) Scanning.

Microradiography was developed in order to observe fine details in the interior of opaque natural (for example, biological) and manufactured (for example, metallurgical) samples. Optical microscopy has long been available to observe the surfaces of opaque specimens, or the interior of clear samples, with spatial resolutions approaching 200 nm. Early interest in microradiography waned for two reasons: weak sources required long exposure times, and electron beam techniques which provide submicrometer details were developed. The availability of bright soft x-ray sources, especially synchrotron radiation, has led to a resurgence of interest in microradiography, especially for cellular samples. Sub-100-nm resolution of live specimens is needed to understand biological structures with sizes between those observable with light microscopes (down to about 200 nm) and the molecular level (about 1 nm) probed by diffraction from ordered arrays of molecules. Microradiography of inorganic natural, manufactured, and dynamic structures remains of interest. *See* ELECTRON MICROSCOPE; OPTICAL MICROSCOPE. [D.J.Na.]

Microsauria A diverse order of small, extinct amphibians, known only from the Pennsylvanian and lower Permian of North America and Europe. They range from obligatorily aquatic, perennibranchiate genera with lateral-line canal grooves, to fully terrestrial lizardlike forms. Several families include long-bodied, possibly burrowing, species. Limbs are always retained, and the tail is never specialized as a swimming organ. Microsaurs are recognized by the possession of a broad, strap-shaped occipital condyle, and no more than a single bone in the temporal series. The trunk vertebrae are spool-shaped.

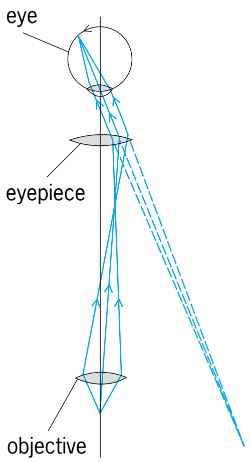
The specific origin of the group remains unknown. Although intermediate forms are not known, microsaurs appear to be the most probable group of Paleozoic amphibians from which two modern amphibian orders, the apodans and the salamanders, have evolved. *See* AMPHIBIA; LEPOSPONDYLI. [R.L.C.]

Microscope An instrument used to obtain an enlarged image of a small object. The image may be seen, photographed, or sensed by photocells or other receivers, depending upon the nature of the image and the use to be made of the information of the image.

A simple microscope, hand lens, or magnifier usually is a round piece of transparent material, ground thinner at the edge than at the center, which can form an enlarged image of a small object. Commonly, simple microscopes are double convex or planoconvex lenses, or systems of lenses acting together to form the image.

The compound microscope utilizes two lenses or lens systems. One lens system forms an enlarged image of the object and the second magnifies the image formed by the first. The total magnification is then the product of the magnifications of both lens systems (see illustration).

The typical compound microscope consists of a stand, a stage to hold the specimen, a movable body-tube containing the two lens systems, and mechanical controls for easy movement of the body and the specimen. The lens system nearest the specimen is called the objective; the one nearest the eye is called the eyepiece or ocular. A mirror is placed under the stage to reflect light into the instrument when the illumination is not built into the stand. For objectives of higher numerical aperture than 0.4, a condenser is provided under the stage to increase the illumination of the specimen. Various optical and mechanical attachments may be added to facilitate the analysis of the information in the doubly enlarged image. *See* ELECTRON MICROSCOPE; FLUORESCENCE MICROSCOPE; INTERFERENCE MICROSCOPE; LENS (OPTICS); OPTICAL MICROSCOPE; PHASE-CONTRAST MICROSCOPE; REFLECTING MICROSCOPE; X-RAY MICROSCOPE. [O.W.R.]



Compound microscope diagram. (***After F. A. Jenkins and H. E. White, Fundamentals of Optics, 4th ed., McGraw-Hill, 1976***)

Microsensor A very small sensor with physical dimensions in the submicrometer to millimeter range. A sensor is a device that converts a nonelectrical physical or chemical quantity, such as pressure, acceleration, temperature, or gas concentration, into an electrical signal. Sensors are an essential element in many measurement, process, and control systems, with countless applications in the automotive, aerospace, biomedical, telecommunications, environmental, agricultural, and other industries. The stimulus to miniaturize sensors lies in the enormous cost benefits that are gained by using semiconductor processing technology, and in the fact that microsensors are generally able to offer a better sensitivity, accuracy, dynamic range, and reliability, as well as lower power consumption, than their larger counterparts.

Mechanical microsensors form perhaps the largest family of microsensors because of their widespread availability. Microsensors have been produced to measure a wide range of mechanical properties, including force, pressure, displacement, acceleration, rotation, and mass flow. Force sensors generally use a sensing element that converts the applied force into the deformation of the elastic element.

Applications for chemical and biochemical microsensors are environmental monitoring and medicine. Applications in the medical industry may involve monitoring blood, urine, and breath, which contain a wealth of information about the patient's state of health. Only a few such devices now exist. Examples include a glucose biochemical microsensor and ion-selective field-effect devices used to measure blood pH. The use of microsensors to gather medical diagnostic information is an attractive proposition, and eventually there may even be implanted microsensors to diagnose health problems, using smell-sensitive array devices. *See* BIOELECTRONICS. [A.C.P.; C.J.W.; J.W.Ga.]

Microsporidea A class of Cnidospora characterized by the production of minute spores with a single intrasporal or one or two intracapsular filaments and a single sporoplasm. The spore membrane of these protozoans is usually a single piece. Microsporidians are mainly intracellular parasites of arthropods and fishes. Microsporida is the only order of this class. *See* CNIDOSPORA. [R.F.N.]

Microtechnique The art of preparing objects for examination under the microscope and of preserving objects so prepared. Few objects yield useful information if examined without such preparation, which may involve, in addition to preliminary preservation, hardening, rendering transparent, selective coloration of parts, and cutting into thin slices.

The four types of microscope slide commonly made are wholemounts, smears, squashes, and sections. The last three methods are merely devices to make thinner, or smaller, objects unsuitable for the first method. In all four methods, the objects are permanently preserved in a mounting medium between a glass slide, about 0.04 in. (1 mm) thick, and a glass cover slip 0.04 to 0.008 in. (1 to 0.2 mm) thick. Preliminary fixation and preservation, staining, and the final mounting media are common to all four types. [P.Gr.]

Microwave Electromagnetic energy with wavelengths in free space ranging roughly from 0.3 to 30 cm. Corresponding frequencies range from 1 to 100 GHz. Frequency and wavelength are related by $f\lambda = c$, where f is the frequency, λ is the free-space wavelength, and c is the velocity of light in vacuum, approximately 3×10^8 m/s. *See* ELECTROMAGNETIC RADIATION; FREQUENCY (WAVE MOTION); WAVE MOTION; WAVELENGTH.

Characteristic transmission media for microwaves are hollow-pipe waveguides, where the cross-sectional dimensions are of the order of the wavelength and thus are of convenient size. Coaxial transmission lines are also used, however, especially in the lower-frequency bands, and various stripline techniques are used on microwave integrated circuits. Resonant cavities are commonly used as circuit elements, and radiation or reception of the energy is typically by horns, parabolic reflectors, or arrays. *See* ANTENNA (ELECTROMAGNETISM); CAVITY RESONATOR; COAXIAL CABLE; ELECTROMAGNETIC WAVE TRANSMISSION; TRANSMISSION LINES; WAVEGUIDE.

Generation. For most applications, microwaves are generated in electronic devices that produce oscillations at microwave frequencies. The devices may be single-frequency or tunable, and continuous-wave (cw) or pulsed. Vacuum-tube generators include klystrons, magnetrons, and backward-wave oscillators; solid-state generators include tunnel diodes, Gunn diodes, IMPATT diodes, transistor oscillators, masers, and harmonic generators using varactor diodes. The vacuum-tube generators are used to produce higher powers, which can be as much as thousands of kilowatts. Solid-state generators were formerly limited in power to a few watts, but their power capabilities are continually increasing and now may reach hundreds of watts. *See* GYROTRON; KLYSTRON; MAGNETRON; MICROWAVE SOLID-STATE DEVICES; MICROWAVE TUBE; TRAVELING-WAVE TUBE.

Circuit elements. Physical elements which produce specific effects on microwaves are called circuit elements.

The most common method of microwave transmission within a system is through hollow circular or rectangular metal tubes of uniform cross section called waveguides. The microwave energy is confined within these tubes and guided along them.

Various forms of stripline are used in interconnecting components on a dielectric or semiconductor substrate when microwave devices are integrated. One important example is the microstrip, in which a metallic strip or ribbon is placed on a thin dielectric, which is in turn backed by a conducting ground plane. Striplines have more losses than hollow-pipe waveguides but are generally used over very short distances.

Filters are needed in communication or information-processing systems for blocking of high frequencies (low-pass), blocking of low frequencies (high-pass), elimination of undesired bands (band elimination), or passing of desired bands while attenuating others (band pass). All of these may be made for microwaves by adding periodic perturbations, such as posts, irises, diaphragms, or dimensional variations, to the wave-guide or other transmission system. *See* ELECTRIC FILTER; MICROWAVE FILTER.

A thin sheet of plastic can be used to alter the amplitude or phase of microwaves. If the sheet is coated with powdered carbon with appropriate electrical conductivity and placed in a waveguide with the lossy material parallel to the lines of electrical intensity, it will absorb microwave power. Variable attenuation can be achieved by mechanically inserting more or less of the lossy strip into the path of the wave. *See* ATTENUATION (ELECTRICITY).

A phase shifter changes the phase of a microwave without changing its amplitude. It can be constructed in the same manner as an attenuator without the lossy material.

An attenuator which has a very large loss and is closed at one end is called a termination; it absorbs all the power transmitted into it, reflecting none.

The most common microwave detector is a silicon diode designed for high frequencies and mounted in a waveguide or a stripline. The diode rectifies the microwave signal, producing an average current which can be indicated by a direct-current meter connected between the diode terminals. If the microwave signal is modulated in amplitude, the modulation will appear in the output current. *See* AMPLITUDE MODULATION; SEMICONDUCTOR DIODE.

The bolometer is a detector which absorbs microwave power, causing a temperature increase and a corresponding change in resistance. The bolometer does not respond fast enough to detect high-frequency modulation. It is often used as one arm of a resistance bridge circuit in microwave power meters. *See* BOLOMETER; MICROWAVE POWER MEASUREMENT.

A transmitting antenna takes microwave power from a waveguide and converts it into a plane wave that propagates through space to a distant receiving antenna. Two important characteristics of antennas are efficiency and directivity, efficiency being the ratio of the power delivered into space to the power available in the waveguide. High directivity is accomplished by large antennas which focus the microwave energy in the same way a searchlight focuses a beam of light.

The gyrator is a lossless, nonreciprocal, two-port circuit which has 180° more phase shift in one direction than in the other. This principle is used in the broadband microwave circulator. The three-port circulator has the property that all the power into port 1 exits at port 2, all the power into port 2 exits at port 3, and all the power into port 3 exits at port 1. The nonreciprocal phase shift is achieved in a magnetic ferrite placed in the waveguide junction and magnetized with an external permanent magnet. An isolator is a circulator with one port terminated, resulting in a circuit which transmits power in one direction and not the other. The input circuit is thus isolated from the output circuit. When the terminated port is internal, the isolator appears to be a two-port element. *See* GYRATOR.

A varactor is a solid-state diode whose capacitance changes with applied voltage. Varactors are used as harmonic generators to obtain microwave power efficiently from lower-frequency sources such as quartz crystal-controlled oscillators in the 10–100-MHz range. Varactors are also used in up-converters and down-converters performing the same functions as similar circuits using resistive diodes, but more efficiently and at the expense of narrower bandwidth. *See* OSCILLATOR; VARACTOR.

A microwave amplifier converts a low-power input signal to a higher-power output signal while preserving one or more characteristics. A linear amplifier preserves the amplitude, frequency, and phase of the input signal. When a linear amplifier is overloaded, it becomes saturated: the output amplitude tends to remain constant and the envelope of the input signal becomes distorted.

High power output is achieved with klystron and traveling-wave tube (TWT) amplifiers, both of which can be operated in the linear or saturated modes. Moderate power can be achieved with transistor amplifiers, and these are continually being extended in their frequency range of usefulness. Very low noise levels are achieved in the maser and the parametric amplifier, both of which require power at a single frequency to pump the active element. *See* AMPLIFIER; MASER; PARAMETRIC AMPLIFIER.

Microwave integrated circuits. Microwave integrated circuits (MICs) are of two types, hybrid MICs and monolithic microwave integrated circuits (MMICs). In the hybrid circuits, some or all of the active and passive devices are added to a dielectric or semiconducting substrate and interconnected by striplines as discussed above. For MMICs, all of the active and passive devices of the functional unit are formed on the substrate, and interconnected by striplines through a variety of microfabrication techniques, including photolithography, epitaxy, ion implantation, etching, diffusion, sputtering, and evaporation. *See* INTEGRATED CIRCUITS.

Receiver. The first active element in nearly all microwave receivers is a silicon diode operated as a down-converter. In this type of receiver, a strong, continuous-wave local oscillator signal is used to pump the diode over its nonlinear resistance range. In this manner, the local oscillator and the input signal are mixed, shifting the input signal down to an intermediate frequency, which is the difference between the frequencies of the local oscillator signal and the received signal. Intermediate frequencies of a few tens of megahertz are common. Frequency, phase, or amplitude modulation on the received signal appears in the detector output at the intermediate frequency. A bandpass intermediate-frequency amplifier, providing most of the gain of the receiver, follows the detector, after which a demodulator converts the modulation on the intermediate-frequency signal to usable form, for example, an audio or a television signal. *See* Radio receiver.

Transmitter. The main components of a microwave transmitter are a microwave power source, a modulator, and, if necessary, a power amplifier. The modulation can be done directly at microwave frequencies or it can be performed at intermediate frequency and shifted to the microwave frequency in an up-converter, which is very much like a down-converter.

Propagation. In free space, microwaves travel in straight lines as do optical waves. Near the Earth, however, the atmosphere has an index of refraction which normally decreases with distance above the Earth and causes the wave to travel in a circular path which bends slightly toward the Earth. Microwaves are reflected and refracted by objects just as are optical waves. *See* Microwave optics.

Occasionally during the summer, atmospheric conditions cause microwaves transmitted from an antenna to travel to a receiver via two or more paths. These waves interfere at the receiver and may cause large decreases in the received signal amplitude. This phenomenon, called multipath fading, is a serious problem in microwave transmission parallel to the surface of the Earth. Other atmospheric conditions can result in what is known as earth-bulge fading. When microwaves are directed well above the horizon, neither of these two problems occurs. Thus satellite microwave systems do not suffer from either multipath or earth-bulge fading.

At frequencies above about 10 GHz, rain absorbs microwave energy, resulting in large signal losses. Both satellite and point-to-point microwave systems are seriously affected by rain attenuation. For most frequencies the attenuation of microwaves by the Earth's atmosphere is very small. *See* Radio-wave propagation.

Applications. Areas in which microwave radiation is applied include radar, communications, radiometry, medicine, physics, chemistry, and cooking food.

Radar is used in military applications, commercial aviation, remote sensing of the atmosphere, and astronomy. The high antenna directivity and the excellent propagation characteristics of microwaves in the atmosphere make this the preferred band for radar applications. Microwaves are also used in electronic countermeasures to radar. *See* Electronic warfare; Radar.

There is at least 100 times as much frequency space available for communications in the microwave band as in the entire spectrum below microwaves. In addition, the high directivity obtainable at microwave frequencies allows reuse of these frequencies many times in the same area, a practice not possible at lower frequencies. The high directivity also makes possible communication to satellites and deep-space probes. *See* Communication satellite; Radio spectrum allocations; Space communications.

All objects, including liquids and gases, emit electromagnetic radiation in the form of noise, the amount of the noise being proportional to the absolute temperature of the object. A noise temperature can be assigned to the object corresponding to the amount of noise radiating from it. A microwave radiometer is a sensitive receiver which measures the noise power received by an antenna; from this measurement, the noise temperature of the source object can be determined. Radiometers are used extensively for remote sensing. Microwave radiometers are used to study astronomical sources of noise and to observe planets from deep space probes. *See* Passive radar; Radiometry; Remote sensing.

Applications of microwaves in medicine include (1) thermography, the measurement of tissue temperature; (2) hyperthermia, microwave heating used in the treatment of cancer and in the treatment of hypothermic subjects; and (3) biomedical imaging, the use of microwaves to study the structure of tissue beneath the skin. *See* Radiology.

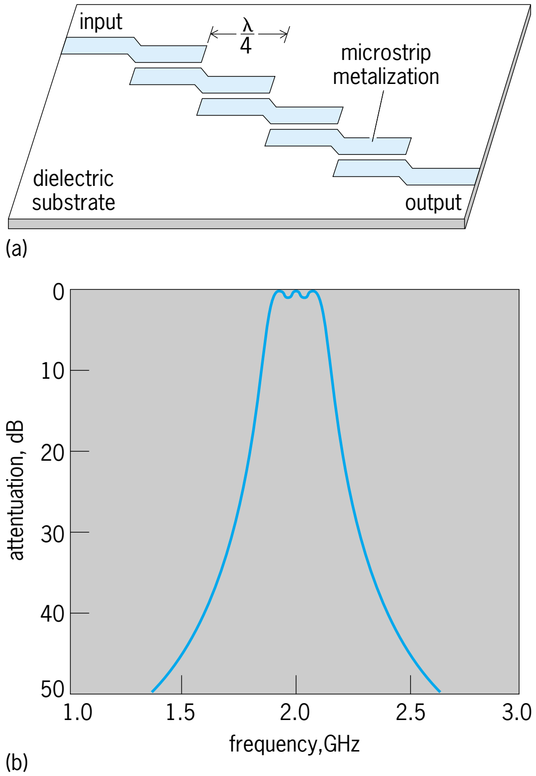
Physics and chemistry. Microwave energy is used in large particle accelerators to accelerate charged particles such as electrons and protons to very high energies and cause them to collide. Knowledge of the structure of matter is also obtained from microwave spectroscopy. *See* Microwave spectroscopy; Particle accelerator.

Microwave energy is absorbed in most foods and has been found to be a source of quick, uniform heating or cooking. Microwave ovens based upon this principle are now widely used. Microwaves are also used for the industrial heating of foodstuffs and other materials. [C.L.Ru.; J.R.W.]

Microwave filter

A two-port component used to provide frequency selectivity in satellite and mobile communications, radar, electronic warfare, metrology, and remote-sensing systems operating at microwave frequencies (1 GHz and above). Microwave filters perform the same function as electric filters at lower frequencies, but differ in their implementation because circuit dimensions are on the order of the electrical wavelength at microwave frequencies. Thus, in the microwave regime, distributed circuit elements such as transmission lines must be used in place of the lumped-element inductors and capacitors used at lower frequencies. This can make microwave filter design more difficult, but it also introduces a variety of useful coupling and transmission effects that are not possible at lower frequencies.

The majority of modern microwave filters are designed by using the insertion-loss method, whereby the amplitude response of the filter is approximated by using network synthesis techniques that have been extended to accommodate microwave distributed circuit elements. A general four-step procedure is followed: determination of filter specifications, design of a low-pass prototype filter, scaling and transforming the filter, and implementation (conversion of lumped elements to distributed elements).



Third-order (four-section) microwave band-pass filter. (*a*) Layout of the parallel coupled stripline filter. (*b*) Calculated frequency response of the filter, with center frequency of 2 GHz and 0.5-dB equal-ripple passband.

Microwave filters are implemented in many ways. Waveguide cavity band-pass filters have very low insertion loss, making them preferred for frequency multiplexing in satellite communication systems. Coaxial low-pass filters, made with sections of coaxial line with varying diameters, are compact and inexpensive. Planar filters in microstrip or stripline form (see illus.) are important for integration with hybrid or monolithic microwave integrated circuits. While planar filters are usually more cost effective than waveguide versions, their insertion loss is usually greater. Computer-aided design procedures are used in the synthesis of more sophisticated amplitude and phase responses, and active microwave devices (field-effect transistors) are used to provide filters with gain or tunable response characteristics. *See* COAXIAL CABLE; COMPUTER-AIDED DESIGN AND MANUFACTURING; ELECTRIC FILTER; MICROWAVE SOLID-STATE DEVICES; TRANSMISSION LINES; WAVEGUIDE. [D.M.Po.]

Microwave free-field standards The means for setting up electromagnetic fields of precisely determined intensity at microwave frequencies in unbounded regions of space. Such standards are used to evaluate field probes and antennas for measuring field strength and power density. The standardization of these devices is necessary before they are used for determining the performance of radar and communications systems or for assessing such systems for health and safety risks or electromagnetic compatibility. *See* ELECTROMAGNETIC RADIATION; MICROWAVE.

Antennas used in free-field standards are usually either half-wave dipoles or wave-guide horns. The half-wave dipole is a collinear device with a length of approximately one-half of the free-space wavelength of the radiated wave. The gain and pattern characteristics of a pyramidal horn can be calculated to accuracies of about ±2 dB; however, the reflections at the throat and aperture discontinuities significantly influence the gain-frequency characteristic and calibration is usually necessary. *See* WAVEGUIDE.

The ideal environment for making measurements on antennas is a large unobstructed volume which is free of reflecting objects and electromagnetically interfering signals—that is, a free-space condition. A practical solution is to use an anechoic chamber to set up simulated free-space conditions in a bounded environment. Low reflection of electromagnetic signals from the walls of such a chamber is achieved by the use of an electromagnetic wave absorbent layer covering all of the reflecting surfaces within the room or chamber, the outer shell of which is a metallic structure to give shielding against interfering signals encroaching on the test region.

Clear open sites can be used at low frequencies, or for high-gain antennas where far-field measurements require such large distances that enclosed or anechoic environments are impractical. However, since electromagnetic waves are strongly reflected by a ground plane, this effect must be accommodated, and one of two courses can be adopted. One is to do measurements as far above the ground as possible. The alternative is to make use of the ground plane by working close to it—if necessary, enhancing its reflection with a metal ground plane or grid—and by making allowance for the reflection in the analysis of performance. *See* ANECHOIC CHAMBER.

Probably the single most important parameter of a standard antenna, when considered for metrological applications, is the boresight or maximum gain, and a number of methods of determining this parameter have been devised. The three-antenna method involves measurement of the transmission between two polarization-matched antennas. Only the product of the antenna gains can be obtained from this measurement; however, with three antennas the measured combinations will yield the gain of each antenna uniquely. The extrapolation method involves determining the transmission characteristic between two antennas as the transmission path is increased through about 4 to 10 Rayleigh distances. With good metrology it is possible to get a sufficiently accurate characterization to allow extrapolation to the true far-field range. Antenna metrology has increasingly concentrated on near-field scanning techniques with the objective of improving antenna characterization. In this method a probe antenna is used to sample the magnitude and phase, for orthogonal polarizations, of the radiated fields over a well-defined surface, which can be a plane, a cylinder, or a sphere, a few wavelengths from the antenna under test.

The essential requirement for the calibration of devices for measuring power flux density or field strength is the creation of a substantially plane wave of known power density which encompasses the effective aperture of the device to be tested. This is effected by launching a known power through an antenna or transverse-electromagnetic cell of known characteristics and calculating the field strength or power density from the appropriate equation. [R.W.Ye.]

Microwave landing system (MLS) An aircraft landing-guidance system that operates at microwave frequencies and provides deviations from the landing runway centerline using time-referenced scanning beam (TRSB) technology. The MLS was standardized in 1988 and approved for use in international civil aviation. The instrument landing system (ILS) is also standardized internationally and approved for use. Standards for a third landing system, based on Global Positioning System (GPS) technology, are expected. *See* INSTRUMENT LANDING SYSTEM (ILS); SATELLITE NAVIGATION SYSTEMS.

The operating frequencies for MLS lie in a portion of the C-band (5030–5091 MHz) designated for use in aeronautical telecommunications. This frequency choice allows a 12-ft (3.6-m) antenna to generate the 1° beamwidth pattern needed to exclude most reflections.

As with ILS, the MLS equipment is sited near the primary runway, with the azimuth transmitter and distance-measuring equipment (DME) transponder located near the runway stop end, and the elevation transmitter located alongside the runway near landing threshold. With this geometry, the approach course and glide path, generated by the ground equipment, are monitored at the landing runway. Also, the aircraft lateral and vertical displacements due to guidance errors become vanishingly small as the runway is approached and the angular guidance converges to its origin. Unlike ILS, the 50-times higher frequency of the MLS allows generation of narrow beams by relatively small equipment. Because of this 50:1 scale factor, a 1° beamwidth antenna for MLS requires a 12-ft (3.6-m) antenna, while for ILS a 600-ft (180-m) antenna would be required. *See* ANTENNA (ELECTROMAGNETISM); DISTANCE-MEASURING EQUIPMENT.

The large coverage volume of MLS is provided by scanning the narrow beams clockwise then counterclockwise for azimuth functions and up then down for elevation functions. This scanning is electronically controlled at a precise rate of 20,000°/s and fills a lateral sector of 60° (maximum) on each side of the runway center line and a vertical sector of 30° (maximum). The angular position of the aircraft is decoded by the airborne receiver, which measures the time elapsed between successive passages of azimuth or elevation beams.

The antennas typically used are phased arrays where beam scanning is accomplished by a stored set of commands which, at the appropriate time in the transmission sequence, are directed to variable signal-delay devices (phase shifters) associated with each radiating element of the array. *See* AIR NAVIGATION; ELECTRONIC NAVIGATION SYSTEMS. [D.B.V.]

Microwave measurements A collection of techniques particularly suited for development of devices and monitoring of systems where physical size of components varies from a significant fraction of an electromagnetic wavelength to many wavelengths. *See* MICROWAVE.

Virtually all microwave devices are coupled together with a transmission line having a uniform cross section. The concept of traveling electromagnetic waves on that transmission line is fundamental to the understanding of microwave measurements. *See* MICROWAVE TRANSMISSION LINES.

At any reference plane in a transmission line there are considered to exist two independent traveling electromagnetic waves moving in opposite directions. One is called the forward or incident wave, and the other the reverse or reflected wave. The electromagnetic wave is guided by the transmission line and is composed of electric and magnetic fields with associated electric currents and voltages. Any one of these parameters can be used in considering the traveling waves, but the measurements in the early development of microwave technology made principally on the voltage waves led to the custom of referring only to voltage. One parameter in very common use is the voltage reflection coefficient Γ, which is related to the incident, V_i, and reflected, V_r voltage waves by Eq. (1).

$$\Gamma = \frac{V_r}{V_i} \tag{1}$$

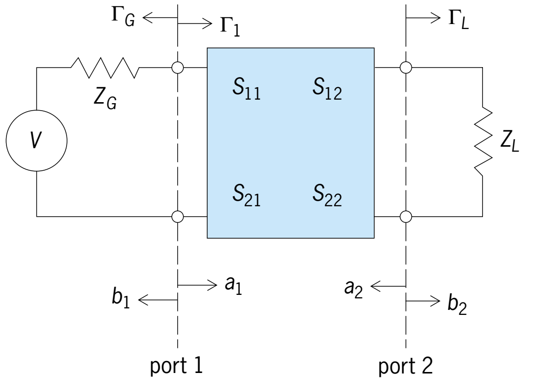
Impedance. The voltage reflection coefficient Γ is related to the impedance terminating the transmission line and to the impedance of the line itself. If a wave is launched to travel in only one direction on a uniform reflectionless transmission line of infinite length, there will be no reflected wave. The input impedance of this infinitely long transmission line is defined as its characteristic impedance Z_0. An arbitrary length of transmission line terminated in an impedance Z_0 will also have an input impedance Z_0. *See* ELECTRICAL IMPEDANCE.

If the transmission line is terminated in the arbitrary complex impedance load Z_L, the complex voltage reflection coefficient Γ_L at the termination is given by Eq. (2).

$$\Gamma = \frac{Z_L - Z_0}{Z_L + Z_0} \tag{2}$$

Even when there is no unique expression for Z_L and Z_0 such as in the case of hollow uniconductor waveguides, the voltage reflection coefficient Γ has a value because it is simply a voltage ratio. In general, the measurement of microwave impedance is the measurement of Γ. Both amplitude and phase of Γ can be measured by direct probing of the voltage standing wave set up along a transmission line by the two opposed traveling waves, but this is a slow technique. Directional couplers have been used for many years to perform much faster swept frequency measurement of the magnitude of Γ, and more recently the use of automatic network analyzers under computer control has made possible rapid, accurate measurements of amplitude and phase of Γ over very broad frequency ranges. *See* DIRECTIONAL COUPLER.

Power. A required increase in microwave power is expensive whether it be the output from a laboratory signal generator, the power output from a power amplifier on a satellite, or the cooking energy from a microwave oven. To minimize this expense, absolute power must be measured. Most techniques involve conversion of the microwave energy to heat energy which, in turn, causes a temperature rise in a physical body. This temperature rise is measured and is approximately proportional to the power dissipated. The whole device can be calibrated by reference to low-frequency electrical standards and application of appropriate corrections. *See* RADIOMETRY.



A two-port inserted between a load and a generator. S_{nm} are the scattering coefficients of the two-port.

The power sensors are simple and can be made to have a very broad frequency response. A power meter can be connected directly to the output of a generator to measure available power P_A, or a directional coupler may be used to permit measurement of a small fraction of the power actually delivered to the load.

Scattering coefficients. While the measurement of absolute power is important, there are many more occasions which require the measurement of relative power which is equivalent to the magnitude of voltage ratio and is related to attenuation. Also there arises frequently the need to measure the relative phase of two voltages. Measurement systems having this capability are referred to as vector network analyzers, and they are used to measure scattering coefficients of multi-port devices. The concept of scattering coefficients is an extension of the voltage reflection coefficient applied to devices having more than one port. The most simple is a two-port. Its characteristics can be specified completely in terms of a 2 × 2 scattering matrix, the coefficients of which are indicated in the illustration. The incident voltage at the reference plane of each port is defined as a, and the reflected voltage is b. Voltages a and b are related by matrix equation (3), where (S_{nm}) is the scattering matrix of the junction. Writing Eq. (3) out for a two-port device gives Eqs. (4) and (5). Examination of Eq. (4) shows, for example, that S_{11} is the voltage reflection coefficient looking into port 1 if port 2 is terminated with a Z_0 load ($a_2 = 0$). *See* MATRIX THEORY.

$$(b_n) = (S_{nm})(a_m) \tag{3}$$

$$b_1 = S_{11}a_1 + S_{12}a_2 \tag{4}$$

$$b_2 = S_{21}a_1 + S_{22}a_2 \tag{5}$$

Heterodyne. The heterodyne principle is used for scalar attenuation measurements because of its large dynamic range and for vector network analysis because of its phase coherence. The microwave signal at frequency f_s is mixed with a microwave local oscillator at frequency f_{LO}, in a nonlinear mixer. The mixer output signal at frequency $f_s - f_{LO}$ is a faithful amplitude and phase reproduction of the original microwave signal but is at a low, fixed frequency so that it can be measured simply with low-frequency techniques. One disadvantage of the heterodyne technique at the highest microwave frequencies is its cost. Consequently, significant effort has been expended in development of multiport network analyzers which use several simple power detectors and a computer analysis approach which allows measurement of both relative voltage amplitude and phase with reduced hardware cost. *See* HETERODYNE PRINCIPLE.

Noise. Microwave noise measurement is important for the communications field and radio astronomy. The measurement of thermal noise at microwave frequencies is essentially the same as low-frequency noise measurement, except that there will be impedance mismatch factors which must be carefully evaluated. The availability of broadband semiconductor noise sources having a stable, high, noise power output has greatly reduced the problems of source impedance mismatch because an impedance-matching attenuator can be inserted between the noise source and the amplifier under test. *See* ELECTRICAL NOISE; ELECTRICAL NOISE GENERATOR; MICROWAVE NOISE STANDARDS.

Use of computers. The need to apply calculated corrections to obtain the best accuracy in microwave measurement has stimulated the adoption of computers and computer-controlled instruments. An additional benefit of this development is that measurement techniques that are superior in accuracy but too tedious to perform manually can now be considered. For a discussion of attenuation in microwave circuits *see* ATTENUATION (ELECTRICITY).

[R.F.Cl.]

Microwave noise standards Electrical noise generators which produce calculable noise intensities at microwave frequencies, and which are used to calibrate other noise sources by using comparison methods. Noise standards are based upon the blackbody or thermal radiator and generate noise power according to Planck's radiation law. The practical realization of a blackbody in the microwave region consists of a microwave absorber with unity absorptivity. This can be achieved by using a transmission line terminated in its characteristic impedance, or in microwave terminology a matched termination. *See* HEAT RADIATION; MICROWAVE TRANSMISSION LINES; TRANSMISSION LINES.

The range of sources which require calibration and the desire to obtain low uncertainties dictate that microwave thermal noise standards are required with temperatures both above and below the ambient temperature. Sources have been developed with temperatures in the range from 4 to 1300 K (−452 to 1900°F). The low temperatures are normally achieved by immersion of the matched termination in a cryogenic liquid of which liquid nitrogen (77 K or −321°F) is the most common. Standards for measurement of high-temperature sources have the termination in a heated oven. A transition section supports the temperature gradient from the thermal termination to the ambient temperature output which connects to the measurement system. *See* MICROWAVE; MICROWAVE MEASUREMENTS; RADIOMETRY. [M.W.S.]

Microwave optics The study of those properties of microwaves which are analogous to the properties of light waves in optics. The fact that microwaves and light waves are both electromagnetic waves, the major difference being that of frequency, already suggests that their properties should be alike in many respects. But the reason microwaves behave more like light waves than, for instance, very low-frequency waves for electrical power (50 or 60 Hz) is primarily that the microwave wavelengths are usually comparable to or smaller than the ordinary physical dimensions of objects interacting with the waves.

As is the case with light, a beam of microwaves propagates along a straight line in a perfectly homogeneous infinite medium. This phenomenon follows directly from a general solution of the wave equation in which the direction of a wave normal does not change in a homogeneous medium. *See* WAVE EQUATION.

With some modification the laws of reflection and refraction can be applied to the propagation of microwaves inside a dielectric-filled metallic waveguide. Another interesting application is associated with the microwave analog of total internal reflection in optics. A properly designed dielectric rod (without metal walls) can serve as a waveguide by totally reflecting the elementary plane waves. Still another case of interest is that of a microwave lens. *See* ANTENNA (ELECTROMAGNETISM); REFLECTION OF ELECTROMAGNETIC RADIATION; REFRACTION OF WAVES; WAVEGUIDE.

In an analogous manner to light, a microwave undergoes diffraction when it encounters an obstacle or an opening which is comparable to or somewhat smaller than its wavelength. *See* MICROWAVE. [C.K.J.]

Microwave solid-state devices Semiconductor devices used for the detection, generation, amplification, and control of electromagnetic radiation with wavelengths from 30 cm to 1 mm (frequencies from 1 to 300 GHz). The number and variety of microwave semiconductor devices, used for wireless and satellite communication and optoelectronics, have increased as new techniques, materials, and concepts have been developed and applied. Passive microwave devices, such as *pn* and PIN junctions, Schottky barrier diodes, and varactors, are primarily used for detecting, mixing, modulating, or controlling microwave signals. Step-recovery diodes, transistors, tunnel diodes, and transferred electron devices (TEDs) are active microwave devices that generate power or amplify microwave signals. *See* MICROWAVE; SEMICONDUCTOR DIODE.

Typical high-frequency semiconductor materials include silicon (Si), germanium (Ge), and compound semiconductors, such as gallium arsenide (GaAs), indium phosphide (InP), silicon germanium (SiGe), silicon carbide (SiC), and gallium nitride (GaN). In general, the compound semiconductors work best for high-frequency applications due to their higher electron mobilities. *See* GALLIUM; GERMANIUM; SEMICONDUCTOR; SILICON.

Passive devices. A PIN (*p*-type/intrinsic/*n*-type) diode is a *pn* diode that has an undoped (intrinsic) region between the *p*- and *n*-type regions. The use of an intrinsic region in PIN diodes allows for high-power operation and offers an impedance at microwave frequencies that is controllable by a lower frequency or a direct-current (DC) bias. The PIN diode is one of the most common passive diodes used at microwave frequencies. PIN diodes are used to switch lengths of transmission line, providing digital increments of phase in individual transmission paths, each capable of carrying kilowatts of peak power. PIN diodes come in a variety of packages for microstrip and stripline packages, and are used as microwave switches, modulators, attenuators, limiters, phase shifters, protectors, and other signal control circuit elements. *See* JUNCTION DIODE.

A Schottky barrier diode (SBD) consists of a rectifying metal-semiconductor barrier typically formed by deposition of a metal layer on a semiconductor. The SBD functions in a similar manner to the antiquated point contact diode and the slower-response *pn*-junction diode, and is used for signal mixing and detection. The point contact diode consists of a metal whisker in contact with a semiconductor, forming a rectifying junction. The SBD is more rugged and reliable than the point contact diode. The SBD's main advantage over *pn* diodes is the absence of minority carriers, which limit the response speed in switching applications and the high-frequency performance in mixing and detection applications. SBDs are zero-bias detectors. Frequencies to 40 GHz are available with silicon SBDs, and GaAs SBDs are used for higher-frequency applications. *See* SCHOTTKY EFFECT.

The variable-reactance (varactor) diode makes use of the change in capacitance of a *pn* junction or Schottky barrier diode, and is designed to be highly dependent on the applied reverse bias. The capacitance change results from a widening of the depletion layer as the reverse-bias voltage is increased. As variable capacitors, varactor diodes are used in tuned circuits and in voltage-controlled oscillators. For higher-frequency microwave applications, silicon varactors have been replaced with GaAs. Typical applications of varactor diodes are harmonic generation, frequency multiplication, parametric amplification, and electronic tuning. Multipliers are used as local oscillators, low-power transmitters, or transmitter drivers in radar, telemetry, telecommunication, and instrumentation. *See* VARACTOR.

Active devices. Transistors are the most widely used active microwave solid-state devices. At very high microwave frequencies, high-frequency effects limit the usefulness of transistors, and two-terminal negative resistance devices, such as transferred-electron devices, avalanche diodes, and tunnel diodes, are sometimes used. Two main categories of transistors are used for microwave applications: bipolar junction transistors (BJTs) and field-effect transistors (FETs). In order to get useful output power at high frequencies, transistors are designed to have a higher periphery-to-area ratio using a simple stripe geometry. The area must be reduced without reducing the periphery, as large area means large interelectrode capacitance. For high-frequency applications the goal is to scale down the size of the device. Narrower widths of the elements within the transistor are the key to superior high-frequency performance. *See* TRANSISTOR.

A BJT consists of three doped regions forming two *pn* junctions. These regions are the emitter, base, and collector in either an *npn* or *pnp* arrangement. Silicon *npn* BJTs have an upper cutoff frequency of about 25 GHz (varies with manufacturing improvements). The cutoff frequency is defined as the frequency at which the current amplification drops to unity as the frequency is raised. The primary limitations to higher frequency are base and

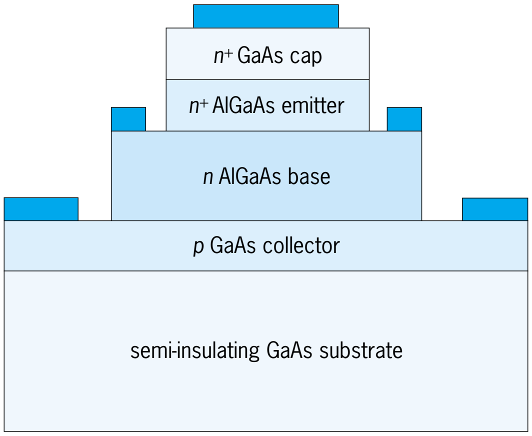


Fig. 1. Materials composition for a heterojunction bipolar transistor (HBT).

emitter resistance, capacitance, and transit time. To operate at microwave frequencies, individual transistor dimensions must be reduced to micrometer or submicrometer size. To maintain current and power capability, various forms of internal paralleling on the chip are used. Three of these geometries are interdigitated fingers that form the emitter and base, the overlaying of emitter and base stripes, and the matrix approach. Silicon BJTs are mainly used in the lower microwave ranges. Their power capability is quite good, but in terms of noise they are inferior to GaAs metal semiconductor field-effect transistors (MESFETs) at frequencies above 1 GHz and are mainly used in power amplifiers and oscillators. They may also be used in small-signal microwave amplifiers when noise performance is not critical. *See* ELECTRICAL NOISE.

Heterojunction bipolar transistors (HBTs) have been designed with much higher maximum frequencies than silicon BJTs. HBTs are essentially BJTs that have two or more materials making up the emitter, base, and collector regions (Fig. 1). In HBTs, the major goal is to limit the injection of holes into the emitter by using an emitter material with a larger bandgap than the base. The difference in bandgaps manifests itself as a discontinuity in the conduction band or the valence band, or both. For *npn* HBTs, a discontinuity in the valence band is required. In general, to make high-quality heterojunctions, the two materials should have matching lattice constants. For very thin layers, lattice matching is not absolutely necessary as the thin layer can be strained to accommodate the crystal lattice of the other material. Fortunately, the base of a bipolar transistor is designed to be very thin and thus can be made of a strained layer material. Combinations such as AlGaAs/InGaAs and Si/SiGe are possible. *See* BAND THEORY OF SOLIDS; ELECTRICAL CONDUCTIVITY OF METALS; HOLE STATES IN SOLIDS; SEMICONDUCTOR HETEROSTRUCTURES.

Field-effect transistors (FETs) operate by varying the conductivity of a semiconductor channel through changes in the electric field across the channel. The three basic forms of FETs are the junction FET (JFET), the metal semiconductor FET (MESFET), and the metal oxide semiconductor FET (MOSFET). All FETs have a channel with a source and drain region at each end and a gate located along the channel, which modulates the channel conduction (Fig. 2). Microwave JFETs and MESFETs work by channel depletion. The channel is *n*-type and the gate is *p*-type for JFETs and metal for MESFETs. FET structures are well suited for microwave applications because all contacts are on the surface to keep parasitic capacitances small. The cutoff frequency is mainly determined by the transit time of the electrons under the gate; thus short gate lengths (less than 1 μm) are used.

Power devices consist of a number of MESFETs in parallel with air bridges connecting the sources. GaAs MESFET devices are used in low-noise amplifiers (LNAs), Class C amplifiers, oscillators, and monolithic microwave integrated circuits. The performance of a GaAs FET is determined primarily by the gate width and length. The planar structure of a MESFET makes it straightforward to add a second gate which can be used to control the amplification of the transistor. Dual-gate MESFETs can be used as mixers (with conversion gain) and for control purposes. Applications include heterodyne mixers and amplitude modulation of oscillators. *See* AMPLIFIER; HETERODYNE PRINCIPLE; MIXER; OSCILLATOR.

The MOSFET has a highly insulating silicon dioxide (SiO_2) layer between the semiconductor and the gate; however, silicon MOSFETs are not really considered microwave transistors. Compared with the GaAs MESFET, MOSFETs have lower electron mobility, larger parasitic resistances, and higher noise levels. Also, since the silicon substrate cannot be made semi-insulating, larger parasitic capacitances result. MOSFETs therefore do not perform very well above 1 GHz. Below this frequency, MOSFETs find application mainly as radio-frequency (RF) power amplifiers.

A disadvantage of the MESFET is that the electron mobility is degraded since electrons are scattered by the ionized impurities in the channel. By using a heterojunction consisting of *n*-type AlGaAs with undoped GaAs, electrons move from the AlGaAs to the GaAs and form a conducting channel at the interface. The electrons are separated from the donors and have the mobility associated with undoped material. A heterojunction transistor made in this fashion has many different names: high electron mobility transistor (HEMT), two-dimensional electron gas FET (TEGFET), modulation-doped FET (MODFET), selectively doped heterojunction transistor (SDHT), and heterojunction FET (HFET). The HEMT has high power gain at frequencies of 100 GHz or higher with low noise levels.

A monolithic microwave integrated circuit (MMIC) can be made using silicon or GaAs technology with either BJTs or FETs. For high-frequency applications, GaAs FETs are the best choice. A MMIC has both the active and passive devices fabricated directly on the substrate. MMICs are typically used as low-noise amplifiers, as mixers, as modulators, in frequency conversion, in phase detection, and as gain block amplifiers. Silicon MMIC devices operate in the 100-MHz to 3-GHz frequency range. GaAs FET MMICs are typically used in applications above 1 GHz.

Active microwave diodes. Active microwave diodes differ from passive diodes in that they are used as signal sources to generate or amplify microwave frequencies. These include step-recovery, tunnel, Gunn, avalanche, and transit time diodes, such as impact avalanche and transit-time (IMPATT), trapped plasma avalanche triggered transit-time (TRAPATT), barrier injection transit-time (BARITT), and quantum well injection transit time (QWITT) diodes.

A step recovery diode is a special PIN type in which charge storage is used to produce oscillations. When a diode is switched from forward to reverse bias, it remains conducting until the stored charge has been removed by recombination or by the electric field. A step recovery diode is designed to sweep out the carriers by an electric field before any appreciable recombination has taken place. Thus, the transition from the conducting to the nonconducting state is very fast, on the order of picoseconds. Because of the abrupt step, this current is rich in

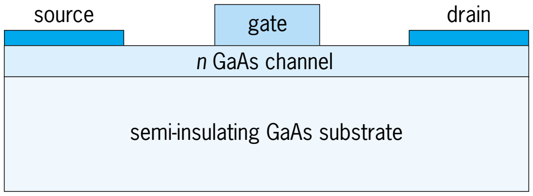

Fig. 2. Gallium arsenide metal semiconductor field-effect transistor (MESFET).

harmonics, so these diodes can be used in frequency multipliers. *See* FREQUENCY MULTIPLIER.

For microwave power generation or amplification, a negative differential resistance (NDR) characteristic at microwave frequencies is necessary. NDR is a phenomenon that occurs when the voltage (*V*) and current (*I*) are 180° out of phase. NDR is a dynamic property occurring only under actual circuit conditions; it is not static and cannot be measured with an ohmmeter. Transferred electron devices (TEDs), such as Gunn diodes, and avalanche transit-time devices use NDR for microwave oscillation and amplification. TEDs and avalanche transit-time devices today are among the most important classes of microwave solid-state devices. *See* NEGATIVE-RESISTANCE CIRCUITS.

The tunnel diode uses a heavily doped abrupt *pn* junction resulting in an extremely narrow junction that allows electrons to tunnel through the potential barrier at near-zero applied voltage. This results in a dip in the current-voltage (*I-V*) characteristic, which produces NDR. Because this is a majority-carrier effect, the tunnel diode is very fast, permitting response in the millimeter-wave region. Tunnel diodes produce relatively low power. The tunnel diode was the first semiconductor device type found to have NDR. *See* TUNNEL DIODE; TUNNELING IN SOLIDS.

Avalanche diodes are junction devices that produce a negative resistance by appropriately combining impact avalanche breakdown and charge-carrier transit time effects. Avalanche breakdown in semiconductors occurs if the electric field is high enough for the charge carriers to acquire sufficient energy from the field to create electron-hole pairs by impact ionization. The avalanche diode is a *pn*-junction diode reverse-biased into the avalanche region. By setting the DC bias near the avalanche threshold, and superimposing on this an alternating voltage, the diode will swing into avalanche conditions during alternate half-cycles. The hole-electron pairs generated as a result of avalanche action make up the current, with the holes moving into the *p* region, and the electrons into the *n* region. The carriers have a relatively large distance to travel through the depletion region. At high frequencies, where the total time lag for the current is comparable with the period of the voltage, the current pulse will lag the voltage. By making the drift time of the electrons in the depletion region equal to one-half the period of the voltage, the current will be 180° out of phase. This shift in phase of the current with respect to the voltage produces NDR, so that the diode will undergo oscillations when placed in a resonant circuit.

A Gunn diode is typically an *n*-type compound semiconductor, such as GaAs or InP, which has a conduction band structure that supports negative differential mobility. Although this device is referred to as a Gunn diode, after its inventor, the device does not contain a *pn* junction and can be viewed as a resistor below the threshold electric field (E_{thres}). For applied voltages that produce electric fields below E_{thres}, the electron velocity increases as the electric field increases according to Ohm's law. For applied voltages that produce electric fields above E_{thres}, conduction band electrons transfer from a region of high mobility to low mobility, hence the general name "transferred electron device." Beyond E_{thres}, the velocity suddenly slows down due to the significant electron transfer to a lower mobility band producing NDR. For GaAs, E_{thres} is about 3 kV/cm. The Gunn effect can be used up to about 80 GHz for GaAs and 160 GHz for InP. Two modes of operation are common: nonresonant bulk (transit-time) and resonant limited space-charge accumulation (LSA). *See* ELECTRIC FIELD.

Impact avalanche and transit-time diodes (IMPATTs) are NDR devices that operate by a combination of carrier injection and transit time effects. There are several versions of IMPATT diodes, including simple reverse-biased *pn* diodes, complicated reverse-biased multidoped *pn* layered diodes, and reverse-biased PIN diodes. The IMPATT must be connected to a resonant circuit. At bias turn-on, noise excites the tuned circuit into a natural oscillation frequency. This voltage adds algebraically across the diode's reverse-bias voltage. Near the peak positive half-cycle, the diode experiences impact avalanche breakdown. When the voltage falls below this peak value, avalanche breakdown ceases. A 90° shift occurs between the current pulse and the applied voltage in the avalanche process. A further 90° shift occurs during the transit time, for a total 180° shift which produces NDR. An IMPATT oscillator has higher output power than a Gunn equivalent. However, the Gunn oscillator is relatively noise-free, while the IMPATT is noisy due to avalanche breakdown.

A trapped plasma avalanche triggered transit-time (TRAPATT) diode is basically a modified IMPATT diode in which the holes and electrons created by impact avalanche ionization multiplication do not completely exit from the transit domain of the diode during the negative half-cycle of the microwave signal. These holes and electrons form a plasma which is trapped in the diode and participates in producing a large microwave current during the positive half-cycle.

A barrier injection transit-time diode (BARRITT) is basically an IMPATT structure that employs a Schottky barrier formed by a metal semiconductor contact instead of a *pn* junction to create similar avalanche electron injection.

A variety of approaches have been investigated to find alternative methods for injecting carriers into the drift region without relying on the avalanche mechanism, which is inherently noisy. Quantum well injection transit-time diodes (QWITT) employ resonant tunneling through a quantum well to inject electrons into the drift region. The device structure consists of a single GaAs quantum well located between two AlGaAs barriers in series with a drift region of made of undoped GaAs. This structure is then placed between two n^+-GaAs regions to form contacts. [L.P.S.]

Microwave spectroscopy The study of the interaction of matter and electromagnetic radiation in the microwave region of the spectrum. *See* MICROWAVE; SPECTROSCOPY.

The interaction of microwaves with matter can be detected by observing the attenuation or phase shift of a microwave field as it passes through matter. These are determined by the imaginary or real parts of the microwave susceptibility (the index of refraction). The absorption of microwaves may also trigger a much more easily observed event like the emission of an optical photon in an optical double-resonance experiment or the deflection of a radioactive atom in an atomic beam. *See* MOLECULAR BEAMS.

At room temperature, the relative population difference between the states involved in a microwave transition is a few percent or less. The population difference can be close to 100% at liquid helium temperatures, and microwave spectroscopic experiments are often performed at low temperatures to enhance population differences and to eliminate certain line-broadening mechanisms. The population differences between the states involved in a microwave transition can also be enhanced by artificial means. When the molecules or atoms with inverted populations are placed in an appropriate microwave cavity, the cavity will oscillate spontaneously as a maser (microwave amplification by stimulated emission of radiation). *See* MASER.

The magnetic dipole and electric quadrupole interactions between the nuclei and electrons in atoms and molecules can lead to energy splittings in the microwave region of the spectrum. Thus, microwave spectroscopy has been used extensively for precision determinations of spins and moments of nuclei. *See* HYPERFINE STRUCTURE; MOLECULAR BEAMS; NUCLEAR MOMENTS.

The rotational frequencies of molecules often fall within the microwave range, and microwave spectroscopy has contributed a great deal of information about the moments of inertia, the spin-rotation coupling mechanisms, and other physical properties of rotating molecules. *See* MOLECULAR STRUCTURE AND SPECTRA.

The magnetic resonance frequencies of electrons in fields of a few thousand gauss (a few tenths of a tesla) lie in the microwave region. Thus, microwave spectroscopy is used in the study of electron-spin resonance or paramagnetic resonance. *See* ELECTRON PARAMAGNETIC RESONANCE (EPR) SPECTROSCOPY; MAGNETIC RESONANCE.

The cyclotron resonance frequencies of electrons in solids at magnetic fields of a few thousand gauss (a few tenths of a tesla) lie within the microwave region of the spectrum. Microwave spectroscopy has been used to map out the dependence of the effective mass on the electron momentum.

For other applications *see* Atomic clock; Cosmic background radiation; Radio astronomy. [W.Hap.]

Microwave tube A high-vacuum tube designed for operation in the frequency region from approximately 3000 to 300,000 MHz. Two considerations distinguish a microwave tube from vacuum tubes used at lower frequencies: the dimensions of the tube structure in relation to the wavelength of the signal that it generates or amplifies, and the time during which the electrons interact with the microwave field. *See* Vacuum tube.

In the microwave region wavelengths are in the order of centimeters; resonant circuits are in the forms of transmission lines that extend a quarter of a wavelength from the active region of the microwave tube. With such short circuit dimensions the internal tube structure constitutes an appreciable portion of the circuit. For these reasons a microwave tube is made to form part of the resonant circuit. Leads from electrodes to external connections are short, and electrodes are parts of surfaces extending through the envelope directly to the external circuit that is often a coaxial transmission line or cavity. *See* Cavity resonator; Transmission lines.

At microwaves the period of signal is in the range of 0.001-1 nanosecond. Only if transit time is less than a quarter of the signal period do significant numbers of electrons exchange appreciable energy with the signal field. Transit time is reduced in several ways. Electrodes are closely spaced and made planar in configuration, and high interelectrode voltages are used.

Tubes designed by the foregoing principles are effective for wavelengths from a few meters to a few centimeters. At shorter wavelengths different principles are necessary. To obtain greater exchange of energy between the electron beam and the electromagnetic field several alternative designs have proved practical.

Instead of collecting the electron beam at a plate formed by the opposite side of the resonant circuit, the beam is allowed to pass into a field-free region before reacting further with an external circuit. The electron cloud can be deflected by a strong static magnetic field so as to revolve and thereby react several times with the signal field before reaching the plate. *See* Klystron; Magnetron.

Instead of producing the field in one or several resonant circuits, the field can be supported by a distributed structure along which it moves at a velocity comparable to the velocity of electrons in the beam. The electron beam is then directed close to this structure so that beam and field interact over an extended interval of time. *See* Microwave; Traveling-wave tube. [F.H.R.]

Mictacea A proposed order of the Peracarida established for two small crustacean species, *Hirsutia bathyalis* and *Mictocaris halope*. The two species share many features common to other peracaridans but differ sufficiently to justify their assignment to a distinct order with two monotypic families. Common peracaridan features include a brood pouch formed by basal lamellae of the perepods (oöstegites) in the female; a small movable process (lacinia mobilis) on the mandible; free thoracic somites not fused to a carapace shield; a single maxilliped of typical peracarid form; and partially immobile pereopodal basal segments.

Mictocaris is a cave-dwelling species, whereas *Hirsutia* has been found only in soft muddy sediment of the deep sea. Nothing is known about the feeding habits of these crustaceans, but with its spined first pereopod and fossorial second, *Hirsutia* is thought to be carnivorous. In contrast, the feeding appendages in *Mictocaris* resemble those of thermosbae-naceans, which scrape food particles from the substrate.

Mictacea appear to be most closely related to the Thermosbaenacea, Spelaeogriphacea, and Mysidacea. *See* Crustacea; Mysidacea; Peracarida; Spelaeogriphacea; Thermosbaenacea. [P.A.McL.]

Middle-atmosphere dynamics The motion of that portion of the atmosphere that extends in altitude roughly from 10 to 100 km (6 to 60 mi). The Earth's climate is determined by a balance between incoming solar and outgoing Earth thermal radiative energy, both of which must necessarily pass through the middle atmosphere. The lower portion, the stratosphere, contains many greenhouse gases (ozone, water vapor, carbon dioxide, methane, nitrous oxide, chlorofluorocarbons, and others); and it is predicted to cool at the same time as the lower atmosphere is warmed by the greenhouse effect. The middle atmosphere is also a focus for effects of emissions from proposed commercial fleets of stratospheric aircraft. In addition to the chemistry involved, dynamical transport modeling and measurements are needed to predict the widespread transport of these important trace gases and emissions over the globe. *See* Atmosphere; Stratosphere; Terrestrial radiation.

The stratosphere constitutes the lower part of the middle atmosphere, from about 10 to 50 km (6 to 30 mi) altitude; from about 50 to 80 km (30 to 48 mi) or so lies the mesosphere. The location of the base of the stratosphere (called the tropopause) depends on meteorological conditions, varying on average from about 10 km (6 mi) in altitude at the poles to about 16 km (10 mi) at the Equator.

Atmospheric gravity waves result from combined gravitational and pressure gradient forces. Typical characteristics are transverse polarization, vertical wavelengths of 0.1–0 km (0.06–6 mi), horizontal wavelengths of 1–100 km (0.6–60 mi) or more, and periods in the range of 5 min to several hours. These waves may be excited by airflow over orography (mountains) as standing lee waves, by growing clouds, and by large-scale storm complexes in the lower atmosphere; and then they propagate up into the middle atmosphere.

Planetary-scale Rossby waves are large and slowly moving waves affected by the Coriolis effect due to the Earth's rotation. Rossby waves are common at middle latitudes in winter, where they can propagate up into the middle atmosphere from excitation regions below. Near the Equator, hybrid Rossby-gravity waves and also Kelvin waves (a special class of eastward-propagating internal gravity waves having no north-south velocity component) have been observed in the middle atmosphere. *See* Coriolis acceleration.

A variety of global-scale normal-mode oscillations are also found in the middle atmosphere, prominent examples being wave 1, westward-moving waves with periods of about 5 and 16 days, and wave 3, a westward-moving feature with a period of about 2 days. Another observed oscillation in the middle atmosphere has been found with periods in the range 1–2 months (propagating up from the lower atmosphere).

Waves resulting from fluid dynamical instabilities are also observed: medium-scale (waves 4–7) eastward-moving waves, which are actually the tops of tropospheric storm systems, can dominate the circulation of the summer Southern Hemisphere lower stratosphere. The medium-scale waves have periods of 10–20 days. *See* Dynamic instability; Dynamic meteorology. [J.L.Sta.]

Midnight sun The phenomenon occurring when the Sun does not set, but only approaches the horizon at midnight. The effect occurs near the time of the summer solstice, on June 21, for latitudes north of the Arctic Circle. The same effect occurs near the time of the winter solstice, on December 21, for latitudes south of the Antarctic Circle. (Here "summer" and "winter" refer to the Northern Hemisphere; seasons are reversed in the Southern Hemisphere.)

The Earth orbits the Sun on a plane called the ecliptic. The Earth's Equator is inclined with the ecliptic by 23°26′. As a result, the North and South poles are in turn inclined toward the Sun for 6 months. Close to the summer solstice, on June 21, the Northern Hemisphere reaches its maximum inclination toward the Sun and the Sun illuminates all the polar area down to latitude +66°34′. As seen from the polar area, the Sun does not set, but only reaches its lowest altitude in the north at midnight. Latitude +66°34′ defines the Arctic Circle, which is the southernmost latitude in the Northern Hemisphere where the midnight sun can be observed near the summer solstice. However, atmospheric refraction raises objects on the horizon by about 34′, and the midnight sun can therefore be seen for a few days from locations 80 km (50 mi) south of the Arctic Circle. Observers at latitudes above the Arctic Circle see the midnight sun higher above the northern horizon, or correspondingly, see the midnight sun before the summer solstice. *See* EARTH ROTATION AND ORBITAL MOTION; ECLIPTIC; METEOROLOGICAL OPTICS; REFRACTION OF WAVES; SEASONS. [P.P.]

Mid-Oceanic Ridge An interconnected system of broad submarine rises totaling about 60,000 km (36,000 mi) in length, the longest mountain range system on the planet. The origin of the Mid-Oceanic Ridge is intimately connected with plate tectonics. Wherever plates move apart sufficiently far and fast for oceanic crust to form in the void between them, a branch of the Mid-Oceanic Ridge will be created. In plan view the plate boundary of the Mid-Oceanic Ridge comprises an alternation of spreading centers (or axes or accreting plate boundaries) interrupted or offset by a range of different discontinuities, the most prominent of which are transform faults. As the plates move apart, new oceanic crust is formed along the spreading axes, and the ideal transform fault zones are lines along which plates slip past each other and where oceanic crust is neither created nor destroyed. *See* PLATE TECTONICS; TRANSFORM FAULT.

Separation of plates causes the hot upper mantle to rise along the spreading axes of the Mid-Oceanic Ridge; partial melting of this rising mantle generates magmas of basaltic composition that segregate from the mantle and rise in a narrow zone at the axis of the Mid-Oceanic Ridge to form the oceanic crust. The partially molten mantle "freezes" to the sides and bottoms of the diverging plates to form the mantle lithosphere that, together with the overlying "rind" of oceanic crust, comprises the lithospheric plate. At the axis of the Mid-Oceanic Ridge the underlying column of crust and mantle is hot and thermally expanded; this thermal expansion explains why the Mid-Oceanic Ridge is a ridge. With time, a column of crust plus mantle lithosphere cools and shrinks as it moves away from the ridge axis as part of the plate. The gentle regional slopes of the Mid-Oceanic Ridge therefore represent the combined effects of sea-floor spreading (divergent plate motion) and thermal contraction. *See* LITHOSPHERE; MAGMA.

The height and thermal contraction rate of the ridge crest are relatively independent of the rate of sea-floor spreading; thus the width and regional slopes of the Mid-Oceanic Ridge depend primarily on the rate of plate separation (spreading rate). Where the plates are separating at 2 cm (0.8 in.) per year, the Mid-Oceanic Ridge has five times the regional slope but only one-fifth the width of a part of the ridge forming where the plates are separating at 10 cm (4 in.) per year. One consequence of the relation between the width and plate separation rate of the Mid-Oceanic Ridge is that more ocean water is displaced, thereby raising sea level, during times of globally faster plate motion.

Although the Mid-Oceanic Ridge exhibits little systematic depth variation along much of its length, there are several bulges (swells) of shallower sea floor. For reasons not well understood, the sea-floor bulges are more prominent along parts of the Mid-Oceanic Ridge where the rate of plate separation (spreading rate) is slower, for example, along the northern Mid-Atlantic Ridge and the Southwest Indian Ridge.

The axis of the Mid-Oceanic Ridge—that is, the active plate boundary between two separating plates—is a narrow zone only a few kilometers wide, characterized by frequent earthquakes, intermittent volcanism, and scattered clusters of hydrothermal vents where seawater, percolating downward and heated by proximity to hot rock, is expelled back into the ocean at temperatures as high as 350°C (660°F). Surrounding such vents are deposits of hydrothermal minerals rich in metals, as well as exotic animal communities including, in some vent fields, giant tubeworms and clams. *See* HYDROTHERMAL VENT; MARINE GEOLOGY; VOLCANO. [P.R.V.]

Migmatite Rocks originally defined as of hybrid character due to intimate mixing of older rocks (schist and gneiss) with granitic magma. Now most plutonic rocks of mixed appearance, regardless of how the granitic phase formed, are called migmatites. Commonly they appear as veined gneisses.

Several modes of origin have been proposed. (1) Granitic magma may be intercalated between thin layers of schist (lit-par-lit injection) to form a banded rock called injection gneiss. (2) The granitic magma may form in place by selective melting of the rock components. (3) The granitic layers may develop by metamorphic differentiation (redistribution of minerals in solid rock by recrystallization). (4) The granitic layers may represent selectively replaced or metasomalized portions of the rock. *See* METAMORPHISM; METASOMATISM. [C.A.C.]

Migratory behavior Regularly occurring, oriented seasonal movements of individuals of many animal species. The term migration is used to refer to a diversity of animal movements, ranging from short-distance dispersal and one-way migration to round-trip migrations occurring on time scales from hours (the vertical movements of aquatic plankton) to years (the return of salmon to their natal streams following several years and thousands of kilometers of travel in the open sea).

Many temperate zone species, including many migrants, are known to respond physiologically to changes in the day length with season (photoperiodism). For example, many north temperate organisms are triggered to come into breeding condition by the interaction between the lengthening days in spring and their biological clocks (circadian rhythms). Similar processes, acting through the endocrine system, bring animals into migratory condition.

To perform regular oriented migrations, animals need some mechanism for determining and maintaining compass bearings. Animals use many environmental cues as sources of directional information. Work with birds has shown that species use several compasses.

Many species of vertebrates and invertebrates possess a time-compensated Sun compass. With such a system, the animal can determine absolute compass directions at any time of day; that is, its internal biological clock automatically compensates for the changing position of the Sun as the Earth rotates during the day. Many arthropods, fish, salamanders, and pigeons can perceive the plane of polarization of sunlight, and may use that information to help localize the Sun even on partly cloudy days.

Only birds that migrate at night have been shown to have a star compass. Unlike the Sun compass, it appears not to be linked to the internal clock. Rather, directions are determined by reference to star patterns which seem to be learned early in life.

Evidence indicates that several insects, fish, a salamander, certain bacteria, and birds may derive directional information from the weak magnetic field of the Earth. *See* MAGNETIC RECEPTION (BIOLOGY).

Many kinds of animals show the ability to return to specific sites following a displacement. The phenomenon can usually be explained by familiarity with landmarks near "home" or sensory contact with the goal. For example, salmon are well known for their ability to return to their natal streams after spending several years at sea. Little is known about their orientation at sea, but they recognize the home stream by chemical (olfactory) cues in the water. The young salmon apparently imprint on the odor of the stream in which they were hatched. Current evidence indicates that birds imprint on or learn some feature of their birthplace, a prerequisite for them to be able to return to that area following migration. On its first migration, a young bird appears to fly in a given direction for a programmed distance. Upon settling in a wintering area, it will also imprint on that locale and will thereafter show a strong tendency to return to specific sites at both ends of the migratory route.

Only in birds can an unequivocal case be made for the existence of true navigation, that is, the ability to return to a goal from an unfamiliar locality in the absence of direct sensory contact with the goal. This process requires both a compass and the analog of a map. Present evidence suggests that the map is not based on information from the Sun, stars, landmarks, or magnetic field. Other possibilities such as olfactory, acoustic, or gravitational cues are being investigated, but the nature of the navigational component of bird homing remains the most intriguing mystery in this field. [K.P.A.]

Military aircraft Aircraft that are designed for highly specialized military applications. Fixed-wing aircraft, rotary-wing aircraft, free-flight balloons, and blimps have all been used in both crewed and crewless flight modes for military purposes. *See* DRONE.

Bombers are usually characterized by relatively long range, low maneuverability, and large weapon-carrying capability. The use of aerial refueling by tanker aircraft gives most bombers a global range. Bombers may be equipped to deliver conventional or nuclear weapons in day, night, or adverse weather.

Aircraft that provide airborne early warning and control include a variant of the Russian Ilyushin IL-76 and the United States E-3A. Increasing numbers of the airborne early warning and control variant of the Russian Ilyushin IL-76 aircraft (NATO codename Mainstay) have been produced for early warning against low-altitude penetration and for air battle management. The U.S. Air Force Airborne Warning and Control System (AWACS), designated E-3A, is a versatile surveillance, command, and control center, designated to provide battle management in the conduct of air warfare.

Unlike bombers and AWACS aircraft, fighters are relatively short-range, highly maneuverable, fast aircraft, designed to destroy enemy aircraft and to attack ground targets. They can carry machine guns, cannons, rockets, guided missiles, and bombs, depending upon the mission. They may be interceptor fighters, designed to shoot down enemy airplanes or missiles during day, night, or adverse weather conditions. Other fighters may be designated for close-in attack of mobile enemy ground forces to provide close support for friendly ground troops. Some fighters, called fighter-bombers, can carry conventional or nuclear weapons several hundreds of kilometers behind enemy lines to strike priority ground targets.

The United States reconnaissance program provides capabilities to meet many peacetime and wartime information collection requirements. Reconnaissance resources include strategic, tactical standoff, and penetration aircraft systems that are flexible and responsive. Reconnaissance aircraft carry photographic, infrared, radar, and television sensors. These aircraft may be specially designed or may be modified from a basic fighter or bomber type. Some are equipped with special electronic gear for such purposes as submarine detection; others serve as picket planes for early warning of an enemy approach.

Transport aircraft provide dedicated logistic support to all types of military operations. Transport aircraft carry troops and war supplies. Many are adaptations of airplanes used by commercial airlines. The aerial tanker is a special-purpose transport aircraft. Fighters, bombers, and helicopters can refuel from tankers while in flight by means of special probe and drogue fittings. Another special-purpose transport is a gunship. This aircraft is equipped with rapid-fire weapons for saturation attack on ground targets.

Helicopters deserve special mention as military aircraft. They are unexcelled for rescue work and for delivery of people and material to otherwise inaccessible areas. Some helicopters are armed and serve as attack aircraft, providing gun and rocket fire against ground targets. Other helicopters deliver assault troops to advanced combat areas and supply them with ammunition and other needs. *See* HELICOPTER.

Special-purpose research aircraft are occasionally designed, assembled, and tested in order to experiment with advanced aerodynamic, structural, avionic, or propulsion concepts that must be validated before they can be applied to other aircraft designs. Research aircraft are usually well instrumented, with performance data telemetered on radio-frequency data links to ground stations located at the test ranges where they are flown. *See* AIRCRAFT TESTING. [R.J.St.]

Military satellites Artificial satellites used for a variety of military purposes. Of approximately 4000 satellites successfully launched between 1957 and 1999, about 50% have been either specifically military or usable for military purposes. Major functions of military satellites include communications, positioning and navigation, meteorology, reconnaissance and surveillance, early warning, remote sensing, geodesy, and research.

Although only certain satellites are used continuously for military purposes, all communication satellites, including commercial, may find use during conflict. All contain the necessary equipment to transmit a signal over great distances to assist in the command, control, administration, and logistic support of military forces. Military communication satellites differ from commercial satellites only in that they contain specialized components, certain capabilities, and multiple redundant systems designed to make them less vulnerable and more effective in a hostile environment. *See* COMMUNICATIONS SATELLITE.

Military forces must be able to quickly and precisely determine their position on the ground, in the air, or at sea. The Navstar Global Positioning System (GPS) is the most accurate and reliable satellite navigation system available. It includes 25 spacecraft in semisynchronous (12-h) orbits inclined at 55° to the Equator at 11,600 mi (18,700 km) altitude. Of these, 21 are operational and 4 are spares. The inclined orbits provide worldwide coverage, including the Poles. Russia also maintains global navigation satellite systems. Its Tsikada/Nadezhda low-Earth-orbit system functions similar to the United States' decommissioned Transit system. In addition, Russia operates the GLONASS navigation system. Similar to GPS, the system is less complex, but its satellites have proven less reliable than the United States' version. Receivers are available that will accept navigational data from either GPS or GLONASS. *See* SATELLITE NAVIGATION SYSTEMS.

From orbit, it is possible to obtain a wide-field-of-view image of the Earth, its cloud formations, and their movements. This meteorological information is valuable for military planning and operations.

The *Television Infrared Observation Satellites* (*TIROS*) have, for decades, traveled in Sun-synchronous, low Earth orbits providing images of cloud cover, snow, ice, and the sea surface. The Defense Meteorological Satellite Program (DMSP) consists of several satellites in low Earth, Sun-synchronous, polar orbits at an altitude of 517 mi (833 km), spaced to provide complete coverage of the Earth at various times of the day and night.

Russia operates the Meteor system of satellites. As many as five satellites are in low Earth orbit similar to *TIROS* with an orbital inclination of 81.2°. They image in the infrared spectrum. Several other countries maintain a meteorological satellite capability that provides useful information for military operations, although not specifically designed for military use. *See* METEOROLOGICAL SATELLITES.

Military reconnaissance and surveillance satellites offer near-real-time unrestricted access over almost any area on Earth.

Operating in many parts of the electromagnetic spectrum, they can be used to observe weapons development and deployment of forces, and to provide warning of attack by ground forces as well as targeting intelligence, technical intelligence on enemy capabilities, electronic intelligence, and bomb damage assessment.

Early warning satellites provide information on missile launch and nuclear detonation that give governments time to make strategic military decisions.

Remote-sensing satellites afford a unique view of Earth, providing vital information to military forces. The images produced by these satellites are used to conduct routine reconnaissance, analyze waterways, assist in exercise and strike planning, and provide up-to-date maps for forces deploying to unfamiliar areas. Important information is gathered not only in the visible spectrum but in other bands of the spectrum. *See* REMOTE SENSING.

Geodesy. Geodesy is the study of the Earth's size and shape. Geodetic data are important to the military in that the data affect position determination, navigation, map making, and a variety of other missions. Almost all satellites can be used for geodesy, provided their position in space can be accurately determined by optical or electronic means from the Earth.

In addition to the missions discussed above, there have been hundreds of military research and technology spacecraft, as well as thousands of experimental investigations for military purposes on space vehicles launched by all space-faring nations. [D.F.M.]

Milk The lacteal secretion, practically free from colostrum, obtained by the complete milking of one or more healthy cows and containing not less than 8.25% milk solids (not fat) and not less than 3.25% milk fat. Among mammals, humans utilize milk as a source of food. The dairy cow supplies the vast majority of milk for human consumption, particularly in the United States; however, milk from goats, water buffalo, and reindeer is also consumed in other countries. Without qualification, the general term milk refers to cow's milk.

Average composition of milk is 87.2% water, 3.7% fat, 3.5% protein, 4.9% lactose, and 0.7% ash. Whole milk and skim milk are classified as excellent sources of calcium, phosphorus, and riboflavin because 10% of the daily nutritional requirement is supplied by not over 100 kcal (420 kilojoules). These two beverages are also classified as good sources of protein and thiamine; and whole milk is a good source of vitamin A. To be classified as good, the source must contribute 10% of a nutrient in not over 200 kcal (840 kilojoules). Milk is a good source of protein rich in all the essential amino acids.

Processing. Most raw milk collected at farms is pumped from calibrated and refrigerated stainless steel tanks into tank trucks for delivery to processing plants. The actual processing of raw milk begins with either separation or clarification. These machines are essentially similar except that in the clarifier the cream and skim milk fractions are not separated. Many processers have units called standardizer-clarifiers which separate only a small fraction of the fat from the raw whole milk; the amount of fat removed can be regulated. This facilitates the production of milk of standard fat content even though that in the raw product may vary.

Milk is rendered free of pathogenic bacteria by pasteurization. This is accomplished in a manner so that every particle of milk is heated to a specified temperature and held at that temperature for a specified time. *See* PASTEURIZATION.

Fat globules in fluid milk products are broken by homogenization into sizes that are 2 micrometers or less and thus are relatively unaffected by gravitational forces. The U.S. Public Health Service specifies that the fat content of the upper 6 in. (100 m]) of a quart of homogenized milk that has been undisturbed for 48 h cannot differ by more than 10% from that of the remainder.

Most milk is fortified with 400 international units (IU) of vitamin D per quart, and some skim milk is fortified also with 2000 IU of vitamin A per quart. These vitamins as concentrates are added either by automatic dispensing into a continuous flow of milk prior to pasteurization or as a single quantity in a batch operation.

Products. Many fermented or cultured products are produced from milk. These fermentations require the use of bacteria that ferment lactose or milk sugar.

Cultured buttermilk consists of skim milk or low-fat milk which is pasteurized at 180°F (82°C) for 30 min, cooled to 72°F (22°C), and inoculated with an active starter culture containing *Streptococcus lactis* and *Leuconostoc citrovorum*. The mixture is incubated at 70°F (21°C) and cooled when acidity is developed to approximately 0.8%. This viscous product is then agitated, packaged, and cooled. The desired flavor is created by volatile acids and diacetyl; the latter is produced by *L. citrovorum*.

One of the oldest fermented milks known is yogurt. Yogurt is prepared using whole or low-fat milk with added nonfat milk solids. The milk is heated to approximately 180°F (82°C) for 30 min, homogenized, cooled to 115°F (46°C), inoculated with an active culture, and packaged. Yogurt cultures are mixtures of *Streptococcus thermophilus* and *Lactobacillus bulgaricus* in a 1:1 ratio. Balance of these organisms in the culture is important for production of a quality product.

Concentrated and dried milk products. To reduce costs of transportation and handling, either part or all of the water is removed from milk. Moreover, the partly dehydrated milk can either be sterilized or dried to permit unrefrigerated storage for prolonged periods. Many different milk products (such as dry whole milk, evaporated milk, and condensed milk) are produced for these specific reasons. The composition of some of these is controlled by standards of identity and some by request of the commercial buyer. [R.L.Br.]

Milky Way Galaxy The large disk-shaped aggregation of stars, gas, and dust in which the solar system is located. The term "Milky Way" is used to refer to the diffuse band of light visible in the night sky emanating from the Milky Way Galaxy. Although the two terms are frequently used interchangeably, Milky Way Galaxy, or simply the Galaxy, refers to the physical object rather than its appearance in the night sky.

Structure and contents. The Milky Way Galaxy contains about 2×10^{11} solar masses of visible matter. Roughly 96% is in the form of stars, and about 4% is in the form of interstellar gas. The gas both inside the stars and in the interstellar medium is primarily hydrogen and helium with a small admixture of all of the heavier atoms. The mass of dust is about 1% of the interstellar gas mass and is an insignificant fraction of the total mass of the Galaxy. Its presence, however, limits the view from the Earth in the plane of the Galaxy to a small fraction of the Galaxy's diameter in most directions. *See* INTERSTELLAR MATTER.

The Milky Way Galaxy contains four major structural subdivisions: the nucleus, the bulge, the disk, and the halo. The Sun is located in the disk about half way between the center and the indistinct outer edge of the disk of stars. The currently accepted value of the distance of the Sun from the galactic center is 8.5 kiloparsecs, although some measurements suggest that the distance may be as small as 7 kpc. *See* PARSEC.

The nucleus of the Milky Way is a region within a few tens of parsecs of the geometric center and is totally obscured at visible wavelengths. The nucleus is the source of very energetic activity detected by means of radio waves and infrared radiation.

At the galactic center, there is a very dense cluster of hot stars observed by means of its infrared radiation. In 1997, astronomers confirmed the existence of a black hole with a mass of about 2.5 million times the mass of the Sun at the position of an unresolved source of radio emission known as Sgr A^* in the middle of the central star cluster. The black hole appears to be the dynamical center of the Milky Way. *See* BLACK HOLE; INFRARED ASTRONOMY; RADIO ASTRONOMY.

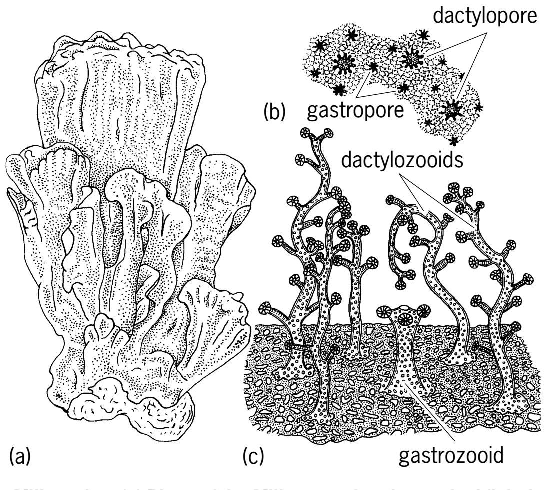
The bulge is a thick distribution of stars centered on the nucleus which extends to a distance of about 3 kpc from the center. It contains a relatively old population of stars, nearly as old as the Milky Way itself. Direct imaging with infrared satellites has demonstrated that the bulge is actually an elongated barlike structure with a length about two to three times its width. The Milky Way is thus classified as a barred spiral galaxy, a classification that includes about half of all disk-shaped galaxies. *See* STELLAR POPULATION.

The disk is a thin distribution of stars and gas orbiting the nucleus of the Galaxy. The disk of stars begins near the end of the bar and can be identified to about 16 kpc from the center of the Galaxy; the disk of gas can be identified to about twice this distance, about 35 kpc from the center. The faint, low-mass stars make up most of the mass of the disk. There is also a thick disk of stars and gas. The thin disk of stars contains most of the mass and has a thickness relative to its diameter similar to that of a commercial compact disk. The disk is the location of the spiral arms that are characteristic of most disk-shaped galaxies, as well as most of the present-day star formation.

The halo is a rarefied spheroidal distribution of stars nearly devoid of the interstellar gas and dust that surrounds the disk. The stars found in the halo are the oldest stars in the Galaxy. The stars are found individually as "field" stars as well as in globular clusters: spherical clusters of up to about a million stars with very low abundances of elements heavier than helium. The extent of the halo is not well determined, but globular clusters with distances of about 40 kpc from the center have been identified. Dynamical evidence suggests that the halo contains nonluminous matter in some unknown form, commonly referred to as dark matter. The dark matter contains most of the mass of the Galaxy, dominating even that in the form of stars. *See* STAR CLUSTERS.

Evidence suggests that the ages of the oldest stars in the Milky Way are within about 10% of the age of the universe as a whole; thus parts of the Milky Way must have formed early in the history of the universe, about 12–16 billion years ago. There is increasing evidence that the Milky Way formed as a result of the coalescence of small galaxies and protogalaxies, objects with the masses of small dwarf galaxies that are thought to have been among the first objects to form in the universe. The coalescence would have proceeded rapidly at first and then more irregularly as relatively large pieces merged to form the Milky Way. According to this picture, the formation of the Milky Way is not yet complete, and both small galaxies and clouds of gas are continuing to rain in on the Milky Way. [L.Bl.]

Milleporina An order of the class Hydrozoa of the phylum Coelenterata. These are the "string corals" of shallow tropical seas. Their structure is similar to that of hydroids except for the addition of a calcareous exoskeleton (illus. *a*). Because of this skeleton, they resemble true corals (Anthozoa). The skeleton is covered by a thin layer of tissue, is penetrated by interconnecting tubes, and is perforated by tiny holes through which the bodies of the "coral animals," or polyps, are extended (illus. *b*).



Milleporina. (*a*) Piece of dry Millepora, showing typical flabellate shape. (*b*) Same, magnified, showing pores. (*c*) Polyps of Millepora. (*After L. H. Hyman, The Invertebrates, vol. 1, McGraw-Hill, 1940*)

The polyps are of two types (illus. *c*): nutritive gastrozooids with tentacles and mouth; and protective polyps, which are long and armed with stinging cells but have no mouth. Millepores produce medusae, or jellyfish, in which sex cells develop. *See* HYDROZOA. [S.Cr.]

Millerite A mineral having composition NiS and crystallizing in the hexagonal system. Millerite usually occurs in hair-like tufts and radiating groups of slender to capillary crystals. The hardness is 3–3.5 (Mohs scale) and the specific gravity is 5.5. The luster is metallic and the color pale brass yellow. Millerite is found in many localities in Europe, notably in Germany and Czechoslovakia. In the United States it is found with pyrrhotite at the Gap Mine, Lancaster County, Pennsylvania; with hematite at Antwerp, New York; and in geodes in limestone at Keokuk, Iowa. In Canada large cleavable masses are mined as a nickel ore in Lamotte Township, Quebec. [C.S.Hu.]

Millet A common name applied to at least five related members of the grass family grown for their edible seeds: foxtail millet (*Setaria italica*), proso millet (*Panicum miliaceum*), pearl or cat-tail millet (*Pennisetum typhoideum*), Japanese barnyard millet (*Echinochloa frumentacea*), raggee or finger millet (*Eleusine coracana*), and koda millet (*Paspalum scrobiculatum*).

As a crop for human food, pearl millet is grown widely in the tropics and subtropics in regions of limited rainfall where there is a growing season of 90 to 120 days. The naked seeds are yellowish to whitish in color and about the size of wheat grain. The dried grain is usually pulverized to make a meal or flour and then cooked in soups, in porridge, or as cakes. [H.B.S.]

Mineral A naturally occurring homogeneous solid with a definite (but generally not fixed) chemical composition and a highly ordered atomic arrangement; it is usually formed by inorganic chemical processes. The fact that a mineral has a definite chemical composition implies that it can be expressed by a specific chemical formula. For example, the chemical composition of quartz (silicon dioxide) is expressed as SiO_2; its formula is definite because quartz contains no chemical elements other than silicon and oxygen. Most minerals, however, do not have such a well-defined composition. Dolomite [$CaMg(CO_3)_2$], for example, is not always a pure calcium-magnesium carbonate. It may contain considerable amounts of iron and manganese in place of magnesium, and because these amounts vary, the composition of dolomite is said to range between certain limits and is, therefore, not fixed. The description of mineral structure as a highly ordered atomic arrangement indicates that a mineral possesses an internal structural framework of atoms (or ions) arranged in a regular geometric pattern. Minerals are crystalline because this is the criterion of a crystalline solid. Under favorable conditions, crystalline materials may express their ordered internal structure by well-developed external form, also known as crystal form, or morphology. *See* APATITE; ARAGONITE; CRYSTAL STRUCTURE.

Classification. Chemical composition has been the basis for the classification of minerals, whereby they are divided into classes depending on the dominant anion or anionic group (such as oxides, halides, sulfides, or silicates). However, it was recognized early in the development of mineralogy that chemistry alone does not adequately characterize a mineral. A full appreciation of the nature of minerals evolved only after x-rays were used to determine internal structures. It has become clear that mineral classification must be based on chemical composition and internal structure, because these together represent the essence of a mineral and determine its physical properties. Major groups in the mineral classification are native elements, sulfides, sulfosalts, oxides, hydroxides, halides, carbonates, nitrates, borates, phosphates, sulfates, tungstates, and silicates. These groups are subdivided on the basis of chemical types, and may be refined further on the basis of structural similarity. *See* Borate minerals; Carbonate minerals; Halogen minerals; Hydroxide; Native elements; Nitrate minerals; Phosphate minerals; Silicate minerals; X-ray crystallography.

Names. Minerals may be given names on the basis of some physical property or chemical aspect; or they may be named after a locality, a public figure, a mineralogist, or almost any other subject considered appropriate. Some examples of mineral names and their derivations are as follows: albite ($NaAlSi_3O_8$) from the Latin albus (white) in allusion to its color; rhondonite ($MnSiO_3$) from the Greek rhodon (a rose) in allusion to its characteristically pink color; chromite ($FeCr_2O_4$) because of the presence of a large amount of chromium in the mineral; magnetite (Fe_3O_4) because of its magnetic properties; franklinite ($ZnFe_2O_4$) after Franklin, New Jersey, where it occurs as the dominant zinc mineral; sillimanite (Al_2SiO_2) after Professor Benjamin Silliman of Yale University.

Occurrence and formation. Minerals form in all geological environments, reflecting a wide range of chemical and physical conditions, such as temperature and pressure. The main categories of mineral formation are (1) igneous, or magmatic, in which minerals form as crystallization products from a melt; (2) sedimentary, in which minerals are the result of the processes of weathering, erosion, and sedimentation; (3) metamorphic, in which new minerals form at the expense of earlier ones, as a result of changing (usually increasing) temperatures, pressures, or both, on some earlier rock type; metamorphic minerals are the result of new mineral growth in the solid rock, without the intervention of a melt (as in igneous processes); and (4) hydrothermal, in which minerals are chemically precipitated from hot solutions. The first three processes generally lead to rock types in which different mineral grains are closely intergrown in an interlocking fabric. Hydrothermal solutions, and even solutions at very low temperatures such as ground water, tend to follow fracture zones in rocks that may provide open spaces for chemical precipitation of minerals from solution. It is from such open spaces, partially filled by minerals deposited from solutions, that most of the spectacular mineral specimens, seen in mineral museums worldwide, have been collected. If a mineral in the process of its growth (as a result of precipitation) is allowed to grow in a free space, it will commonly exhibit a well-developed crystal form, which adds to a specimen's esthetic beauty. Similarly, geodes, which are rounded, hollow, or partially hollow bodies, commonly found in limestones, may contain very well-formed crystals lining the central cavity. Geodes are the result of mineral deposition from solutions such as ground water. *See* Geode; Precipitation (chemistry).

Economic importance. Society today depends on minerals in countless ways—from the construction of skyscrapers to the manufacture of televisions. A few minerals such as talc, asbestos, and sulfur are used essentially as they come from the ground, but most are first processed to obtain a usable material such as bricks, glass, cement, plaster, and a score of metals ranging from iron to gold. Both forests and farms are dependent upon soils, which are composed chiefly of minerals. *See* Asbestos; Soil; Sulfur; Talc.

Metallic ores and industrial minerals are mined on every continent, wherever specific minerals are sufficiently concentrated to be extracted economically. The location of minable metal and industrial mineral deposits, and the study of the origin, size, and ore grade of these deposits are the domain of economic geologists, but a knowledge of the chemistry, occurrence, and physical properties of minerals is basic to pursuits in economic geology. *See* Mineralogy. [C.K.]

Mineralogy The science which concerns the study of natural inorganic substances, whether of terrestrial or extraterrestrial origin, called minerals. Mineralogy is a science that cannot be easily defined. It is most properly a branch of inorganic chemistry, but the discipline concentrates on the origin, description, and classification of minerals. *See* Mineral.

Thus, four main categories may be considered: crystal chemistry (composition and atomic arrangement of minerals); paragenetic mineralogy (the study of mineral association and occurrence both in natural and synthetic systems); descriptive mineralogy (the study of the physical properties of minerals and the means for their identification); and taxonomic mineralogy (mineral classification, systematization, and nomenclature).

Crystal chemistry. This is the most vital aspect of mineralogy because it is the basis for the other studies. The fields of mineralogy, crystallography, inorganic chemistry, geochemistry, petrology, and geology are connected in the domain of crystal chemistry (Fig. 1).

A particular mineral, called a mineral species, is defined on the basis of a specified chemical composition and a specified crystal structure (atomic arrangement). These two criteria provide almost sufficient knowledge for characterization of a mineral since in principle all other properties can be derived from them.

Crystalline substances, that is, periodic arrangements of matter in three dimensions, can be divided into six crystal systems: triclinic, monoclinic, orthorhombic, tetragonal, hexagonal (including the trigonal and rhombohedral subdivisions), and cubic. These crystal systems can be considered as structure cells, each of which contains a certain integral number of atoms of a substance. Figure 2 depicts these systems and offers the criteria for distinguishing them. *See* Crystallography.

Any crystalline substance has a certain integral number of its essential chemical formula units loosely called molecules) in its structure cell. Thus, each unique atomic position in the structural unit can be occupied by a particular kind (or kinds) of atom(s). Consider the ideal cell formula $(A_a)(B_b)\ldots(P_p)$. Each of

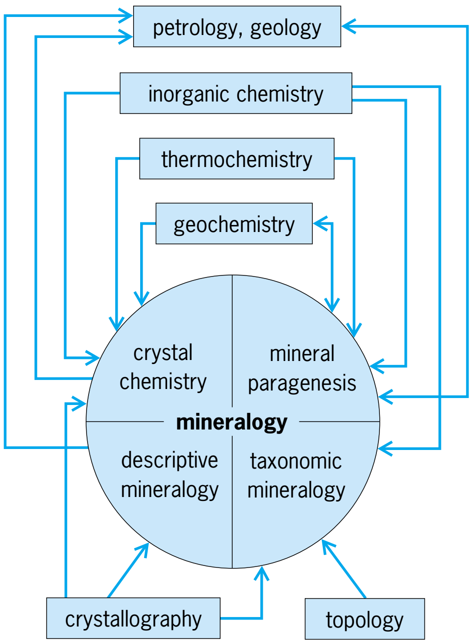


Fig. 1. Diagram showing the transmission of Information between mineralogy and some other sciences. Arrows Imply the direction of Information.

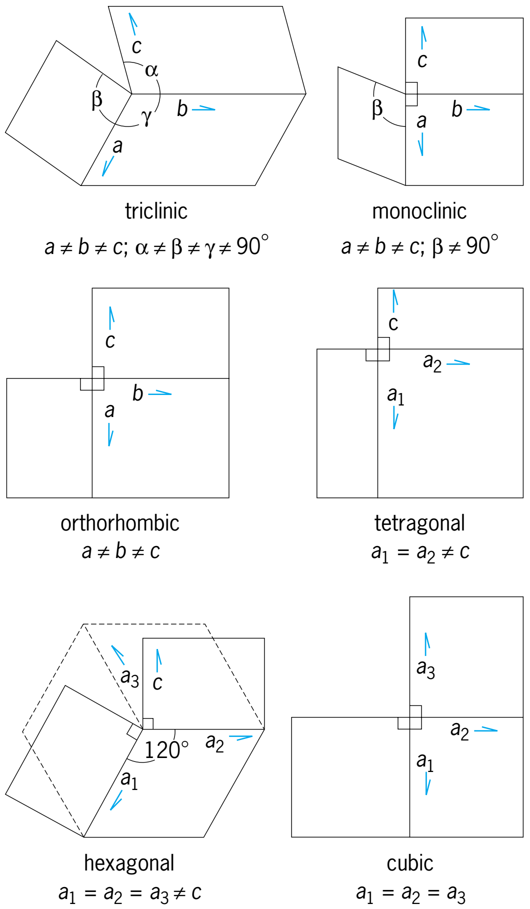


triclinic
$a \neq b \neq c$; $\alpha \neq \beta \neq \gamma \neq 90^\circ$

monoclinic
$a \neq b \neq c$; $\beta \neq 90^\circ$

orthorhombic
$a \neq b \neq c$

tetragonal
$a_1 = a_2 \neq c$

hexagonal
$a_1 = a_2 = a_3 \neq c$

cubic
$a_1 = a_2 = a_3$

Fig. 2. The cell shapes of the six crystal systems shown as their principal projections.

the parentheses specifies a unique atomic position. The capital letters specify the element present and the small subscripts the number of times it occurs in the cell. If the small subscripts have a factor in common, it is factored out and what remains is the formula unit. The ideal formula is further defined in terms of the atomic element which occurs in excess of 50 mole % within each of the parentheses. The structure type, along with the ideal formula unit, defines a mineral species.

This strict definition of a species is required since a particular mineral may have a range of compositions. The range of compositions is called a series. The ideal limiting compositions are called end members and each of the end members has a specific name.

Paragenetic mineralogy. Paragenetic mineralogy is the study of mineral paragenesis, or the association and order of crystallization of minerals. The problem may concern mineral association within a single hand specimen or may embrace a much larger region, such as an entire ore body, in which case many representative specimens are judiciously collected. This study usually accompanies the analysis of the general geological structures within and around the ore body, such as the bedding, folding, and faulting. Included among the important aspects of paragenetic mineralogy are ore mineralogy, the mineralogy of a sequence of phases crystallized from a parent magma, the sequence of minerals crystallized in a vein, and so forth. *See* GEOLOGY; PETROLOGY.

Mineral paragenesis is usually considered in relative time and the absolute difference in time between the oldest and youngest minerals is often not known. Absolute age differences can be obtained in some instances, for example, by lead isotope age dating of a sequence of crystallized lead-bearing minerals.

Descriptive mineralogy. Mineral recognition directly by the senses is very subjective and requires considerable experience. Gross features of a mineral such as color, form, hardness, and specific gravity are important criteria for identification in the field where a well-equipped laboratory is usually not available. More objective criteria such as the optical properties and x-ray powder diffraction spectra of a mineral require specialized equipment, but the results are usually certain since these data are known for most mineral species and are extensively tabulated. Older methods such as fusibility, flame tests, and blowpipe analysis have been largely abandoned.

Taxonomic mineralogy. There are approximately 3000 distinct mineral species known to science, About 60 new mineral species are discovered each year. For a new species to be properly defined, the chemical analysis, structure cell and space group, crystal morphology, powder pattern, optical data, all physical properties, and paragenesis must be given as completely as possible. [P.B.M.]

Minimal principles

In the treatment of physical phenomena, it can sometimes be shown that, of all the processes or conditions which might occur, the ones actually occurring are those for which some characteristic physical quantity assumes a minimum value. These processes or conditions are known as minimal principles. The application of minimal principles provides a powerful method of attacking certain problems that would otherwise prove formidable if approached directly from first principles.

One simple minimal principle asserts that the state of stable equilibrium of any mechanical system is the state for which the potential energy is a minimum. Other general theorems of classical dynamics that are related to minimal principles are Hamilton's principle and the principle of least action. *See* HAMILTON'S PRINCIPLE; LEAST-ACTION PRINCIPLE. [D.Wi.]

Minimal surfaces

A branch of mathematics belonging to the calculus of variations, differential geometry, and geometric measure theory. A surface, interface, or membrane is called minimal when it has assumed a geometric configuration of least area among those configurations into which it can readily deform. Soap films spanning wire frames or compound soap bubbles enclosing volumes of trapped air are common examples. *See* DIFFERENTIAL GEOMETRY; MEASURE THEORY.

Geometrically, the mean curvature of a surface S at a point is the difference between the maximum upward curvature there and the maximum downward curvature; in particular, a surface of zero mean curvature has such principal curvatures equal and opposite and hence typically appears "saddle-shaped." It turns out that S is a minimal surface; that is, it cannot be perturbed to less area leaving its boundary fixed, provided the mean curvature is zero at each of its points; such a surface could occur, for example, as a soap film spanning a wire frame. The corresponding minimal surface equation is partial differential equation. If, alternatively, S were part of a soap bubble enclosing trapped air, the mean curvature of S would be proportional to the difference in air pressure between the two sides of S. In the calculus of variations, typically area-minimizing properties of minimal surfaces are emphasized. In differential geometry, minimal surfaces are defined as surfaces of zero mean curvature; surfaces of constant mean curvature are also extensively studied.

The two-dimensional surface is dominant in determining shape whenever the energy of a system is changed significantly by a displacement or a change in area of the surface. Such surfaces include the interfaces between crystals in a typical rock or metal, the film of soapy water between the air cells in a soap froth, the membrane separating the cells in living tissue, and the cracks separating basalt columns. Minimization of surface area plays a role in determining the shape of many living organisms. *See* FOAM; GRAIN BOUNDARIES. [F.J.A.]

Mining The taking of minerals from the earth, including production from surface waters and from wells. Usually the oil and gas industries are regarded as separate from the mining industry. The term mining industry commonly includes such functions as exploration, mineral separation, hydrometallurgy, electrolytic reduction, and smelting and refining, even though these are not actually mining operations. *See* HYDROMETALLURGY; METALLURGY; ORE DRESSING.

Mining is broadly divided into three basic methods: opencast, underground, and fluid mining. Opencast mining is done either from pits or gouged-out slopes or by surface mining, which involves extraction from a series of successive parallel trenches. Dredging is a type of surface mining, with digging done from barges. Hydraulic mining uses jets of water to excavate material.

Underground mining involves extraction from beneath the surface, from depths as great as 10,000 ft (3 km), by any of several methods.

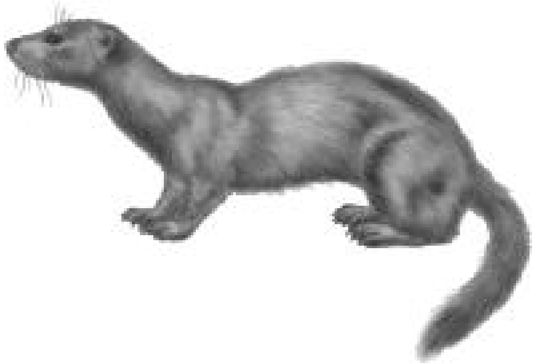
Fluid mining is extraction from natural brines, lakes, oceans, or underground waters; from solutions made by dissolving underground materials and pumping to the surface; from underground oil or gas pools; by melting underground material with hot water and pumping to the surface; or by driving material from well to well by gas drive, water drive, or combustion. Most fluid mining is done by wells. In one experimental type of well mining, insoluble material is washed loose by underground jets and the slurry is pumped to the surface. *See* COAL MINING; OPEN PIT MINING; PETROLEUM ENGINEERING; PLACER MINING; SOLUTION MINING; SURFACE MINING; UNDERGROUND MINING.

The activities of the mining industry begin with exploration, which, since accidental discoveries or surficially exposed deposits are no longer sufficient, has become a complicated, expensive, and highly technical task. After suitable deposits have been found and their worth proved, development, or preparation for mining, is necessary. For opencast mining, this involves stripping off overburden; and for underground mining, the sinking of shafts, driving of adits and various other underground openings, and providing for drainage and ventilation. For mining by wells, drilling must be done. For all these cases, equipment must be provided for such purposes as blasthole drilling, blasting, loading, transporting, hoisting, power transmission, pumping, ventilation, storage, or casing and connecting wells. Mines may ship their crude products directly to reduction plants, refiners, or consumers, but commonly, concentrating mills are provided to separate useful from useless (gangue) minerals. *See* PROSPECTING.

A unique feature of mining is the circumstance that mineral deposits undergoing extraction are "wasting assets," meaning that they are not renewable as are other natural resources. This depletability of mineral deposits requires that mining companies must periodically find new deposits and constantly improve their technology in order to stay in business. Depletion means that the supplies of any particular mineral, except those derived from oceanic brine, must be drawn from ever-lower-grade sources. [E.Ju.]

Mink Any of three species of aquatic carnivorous mammals that are members of the family Mustelidae in the genus *Mustela*. They are found in the forested areas of North America, Europe, and Siberia. The mink is an excellent swimmer, aided by its slightly webbed hindfeet, and feeds on crayfish, frogs, snakes, and fish. The body is elongate and the legs are short (see illustration).

There is one litter each year, with three or four young being born in April or May after a gestation period of about 8 weeks. The young are mature the following season. The pelts of these animals are valuable; many mink farms have been established throughout the world. This animal is a natural predator on the muskrat, over whose numbers it exerts a control. *See* BADGER; CARNIVORA; MARTEN; OTTER; SKUNK; WEASEL. [C.B.C.]



The American mink (*Mustela vison*) is the largest species of mink.

Miocene The second subdivision of the Tertiary Period (Eocene, Miocene, and Pliocene) by Charles Lyell in 1833; the fourth in a more modern sevenfold subdivision (epochs) of the Cenozoic Era; and the first epoch of the Neogene Period (which includes in successive order the Miocene, Pliocene, Pleistocene, and Holocene). The Miocene represents the interval of time from the end of the Oligocene to the beginning of the Pliocene and the rocks (series) formed during this epoch. *See* CENOZOIC; HOLOCENE; OLIGOCENE; PLEISTOCENE; PLIOCENE; TERTIARY.

The Miocene spans the time interval between 23.8 and 5.32 million years ago (Ma) based on integrated astronomical and radioisotopic dating. The Miocene/Pliocene boundary is located in Sicily, just above a major unconformity separating the youngest late Miocene (Messinian) deposits (of the Great Terminal Miocene Salinity Crisis) and the overlying white chalks of the Zanclean. *See* UNCONFORMITY.

Major orogenic and volcanic events characterize the Miocene. Plate-tectonic motions, originating in the Mesozoic, resulted in the gradual dismemberment of the Tethyan Ocean and the upthrusting of the Alpine-Himalayan orogenic belt in three major phases: the late Eocene (about 40 Ma) and the early (21–17 Ma) and mid-late Miocene (10–7 Ma). Along the eastern margins of the Pacific Ocean, the ocean crust was subducted under the North and South American continents, giving rise to major orogenic movements stretching from the Aleutians to Tierra del Fuego. The Andes range was thrust up during the later part of the Miocene. The Pacific Coast developed as a result of westward drift of North America over, and partial consumption by, the Farallon plate and collision with the Farallon Ridge. Only two relatively minor plates remain as remnants of the Farallon plate: the Juan de Fuca and Cocos plates between Mexico and Alaska. The plate margin was bounded by transform faults rather than a subduction zone, and northwestern propagation of a major transform fault issuing from the Cocos plate formed the Gulf of California in the late Miocene, and its continued extension northward is familiar to residents of the west coast as the San Andreas Fault System. The latter was responsible for the formation of many of the off- and onshore basins of southern California, some of which contain prolific petroleum resources. Subduction of the Pacific plate at the Middle America Trench during the late Paleogene and Neogene resulted in arc magmatism and eventual uplift of the Central American Isthmus into a series of archipelagos in the late Miocene (about 7 Ma) and eventual fusion into a continuous land bridge in the early Pliocene (about 3 Ma) that resulted in the separation of the Atlantic and Pacific oceans and concomitant disruption in marine faunal communities as well as transcontinental migration of vertebrate animals in the Great

American Faunal Interchange. *See* OROGENY; PLATE TECTONICS; SUBDUCTION ZONES; TRANSFORM FAULT.

Ocean circulation essentially assumed its modern form during the Miocene as enhanced refrigeration in the form of growth of the Antarctic Ice Sheet plunged the Earth inexorably deeper into an icehouse state, although there were some details that were completed during the succeeding Pliocene and Pleistocene epochs. An ice cap has been present on Antarctica, at least intermittently, since at least the early Oligocene (about 34 Ma). The opening of the Drake Passage between South America and Antarctica took place during the latest Oligocene–early Miocene (about 25–23 Ma), allowing the unhindered circulation of ocean currents around the Antarctic continent. The development of the Circum-Antarctic Current thermally isolated high southern latitude waters and the continent of Antarctica from the warmer, low-latitude waters and resulted in the replacement of calcareous oozes (comprising planktonic foraminifera and calcareous nannoplankton) by biosiliceous oozes (diatoms and radiolarians). *See* GLACIAL EPOCH.

During the Miocene, life assumed much of its modern aspect. The spread of grasses and weeds throughout this epoch, but particularly in the late Miocene, and concomitant reduction in and thinning of forests reflected the global Neogene cooling as the Earth entered deeper into an ice house state. In this environment, snakes, frogs, and murids (rats, mice) expanded in diversity and habitat; songbirds reflect the expansion of seed-bearing herbs and, like frogs, the concomitant diversification of insects, many of which are found entombed in middle Miocene amber from the Dominican Republic. Grazing animals (elephants, rodents, horses, camelids, and rhinos, for example) developed high crowned teeth to resist significant wear caused by silicon fragments in the developing grasses. Some animals assumed gigantic proportions such as *Baluchitherium*, a Eurasian rhino that stood 16 ft (5 m) at the shoulders, and the tallest camel known, a giraffelike form that was over 12 ft (3.5 m) tall.

The relatively free interchange between Eurasia and Africa between 18 and 12 Ma appears to have come to an end in the late Miocene, after which (about 8 Ma) the hominoids of Eurasia and Africa appear to have followed separate and independent lines of evolution: the pongids in Asia, and the panids and hominoids leading eventually to the true hominids in (predominantly East) Africa. This scenario has been linked, in turn, with the development of the East African Rift (and its northward extension into the Red Sea and Gulf of Suez), which would have served as a geographic barrier allowing independent evolution toward forest (panid) and savannah (hominid) adapted forms. With the late Miocene change in climate (7–5 Ma) to cooler, drier conditions and the spread of open savannah and grasslands, monkeys came to dominate the African forest at the expense of dryomorphs. There is a gap in the terrestrial fossil record during this interval of time, and it is only in the early Pliocene (about 4 Ma) that the story of human evolution resumes with the discovery of the earliest true hominids (australopithecines) in East Africa, about 1 million years older than the australopithecine footprints of Laeotili and the skeletons of Lucy and other australopithecines at Hadar in Ethiopia at about 3 million years. *See* AUSTRALOPITHECINE; FOSSIL HUMANS.

In the marine realm, major radiation of mammals including walruses, seals, sea lions, and whales occurred during the early Miocene. On the sea floor, large bivalve mollusks of the scallop family thrived in the early Miocene, and a distinct horizon of large pectenids occurs in lower Miocene rocks of Europe and North America and in corresponding levels in the deposits of the Paratethyan Sea in east-central Europe and at least as far to the east as Iran, attesting to an interval of global climatic amelioration. Among the protozoa, planktonic foraminifera experienced a major radiation in the early and middle Miocene following the drastic reduction in diversity during the middle and late Eocene, some 15–20 million years earlier. Mangroves and coral reefs flourished in a circumequatorial belt spanning the Indo-Pacific and Caribbean regions, but the latter were eliminated from the Mediterranean during the terminal Miocene Salinity Crisis, never to return with early Pliocene flushing from the Atlantic. *See* FORAMINIFERIDA; MANGROVE; MOLLUSCA; REEF. [W.A.Ber.]

Mira The first star recognized to have a periodic brightness variation. Mira (officially designated Omicron Ceti, in the constellation Cetus, the Whale) was discovered in 1596 by David Fabricius.

Mira is the prototype of an entire class of Mira-type pulsating long-period variables. Although it once resembled the Sun, Mira has evolved into a cool red giant star that is at the end of its life. *See* GIANT STAR; STELLAR EVOLUTION.

Contracting and expanding every 332 days, Mira varies in visual brightness from about magnitude 3.4 (brightest) to about 9.3 (faintest). However, an individual maximum can sometimes be as bright as second magnitude, while at other times its maximum may reach barely fifth magnitude. *See* MAGNITUDE (ASTRONOMY).

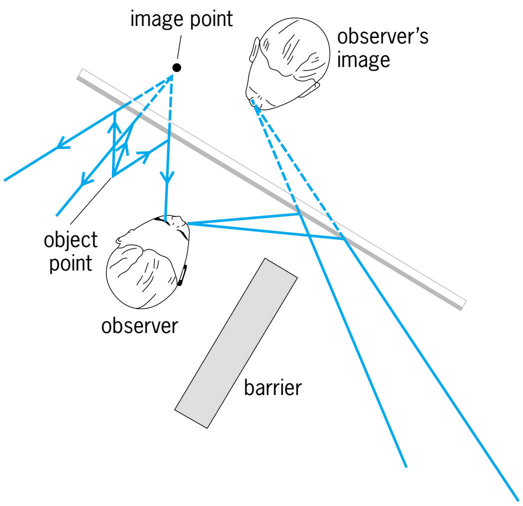
Mira is one of the few long-period variable stars with a close companion star. The companion, VZ Ceti, is also a variable star. It is a hotter, bluer, burned-out star, called a white dwarf, surrounded by material captured from Mira's wind. *See* BINARY STAR; WHITE DWARF STAR.

Hubble Space Telescope visible light images show that Mira has an odd, asymmetrical shape. In ultraviolet light, the Hubble Space Telescope has resolved a small hooklike appendage extending from Mira in the direction of the companion. The diameter of Mira is measured to be 700 times larger than the Sun. *See* STAR; ULTRAVIOLET ASTRONOMY; VARIABLE STAR. [J.A.Ma.]

Mirage A name for a variety of unusual images of distant objects seen as a result of the bending of light rays in the atmosphere during abnormal vertical distribution of air density. If the air closer to the ground is much warmer than the air above, the rays are bent in such a way that they enter the observer's eyes along a line lower than the direct line of sight. The object is then seen below the horizon, the inferior mirage. If the air closer to the ground is much colder than the air above, the rays are bent in the opposite direction, arriving at the observer's eyes above the line of sight; the object then seems to be elevated or floating in the air, the superior mirage. Mirages can be seen most frequently along an overheated highway surface; the inferior mirage of the sky gives the impression of water reflection over a wet pavement, which disappears upon a closer viewing. [Z.S.]

Mirror optics The use of plane or curved reflecting surfaces for the purpose of reverting, directing, or forming images. An optical surface which specularly reflects the largest fraction of the incident light is called a reflecting surface. Such surfaces are commonly fabricated by polishing of glass, metal, or plastic substrates, and then coating the surface of the substrate with a thin layer of metal, which may be covered in addition by a single or multiple layers of thin dielectric films. The law of reflection states that the incident and reflected rays will lie in the plane containing the local normal to the reflecting surface and that the angle of the reflected ray from the normal will be equal to the angle of the incident ray from the normal. *See* GEOMETRICAL OPTICS.

The formation of images in the plane mirrors is easily understood by applying the law of reflection. The illustration shows the formation of the image of a point formed by a plane mirror. Each of the reflected rays appears to come from a point image located a distance behind the mirror equal to the distance of the object point in front of the mirror. The face of the observer can be considered as a set of points, each of which is imaged by the plane mirror. Since the observer is viewing the facial image from the object side of the mirror, the face will appear to be reversed left for right in the virtual image formed by the mirror. The illustration also indicates the redirection of light by a plane



Formation of images by a plane mirror.

mirror, in that a viewer who cannot observe the object point directly can observe the virtual image of the point formed by the mirror. A simple optical device which is based on this principle is the simple mirror periscope, which uses two mirrors to permit viewing of scenes around an obstacle. *See* PERISCOPE.

A curved mirror, either spherical or conic in form, will produce a real or virtual image in much the same manner as a lens, but generally with reduced aberrations. There will be no chromatic aberrations since the law of reflection is independent of the color or wavelength of the incident light. *See* ABERRATION (OPTICS); OPTICAL IMAGE.

Both concave and convex spherical mirrors are commonly encountered. Convex mirrors are commonly used as wide-angle rearview mirrors in automobiles or on trucks. A common application of concave mirrors is the magnifying shaving mirror frequently found in bathrooms.

A spherical mirror will form an image which is not perfect, except for particular conjugate distances. The use of a mirror which has the shape of a rotated conic section, such as a parabola, ellipsoid, or hyperboloid, will form a perfect image for a particular set of object-image conjugate distances and will have reduced aberrations for some range of conjugate relations. The most familiar applications for conic mirrors are in reflecting telescopes. *See* OPTICAL PRISM; OPTICAL SURFACES; OPTICAL TELESCOPE; REFLECTION OF ELECTROMAGNETIC RADIATION; TELESCOPE. [R.R.S.]

Misophrioida A small but evolutionarily significant order of the subclass Copepoda, containing only a few species. Misophrioids have two subdivisions of the body, the anterior prosome and posterior urosome, articulated immediately behind the fifth thoracic somite. This feature immediately distinguishes misophrioids from calanoids. Like calanoids, some misophrioids have a dorsal heart, a character that distinguishes the taxon from both cyclopoids and harpacticoids. The misophrioids have four unique characteristics: a carapacelike posterior extension of the head region (cephalosome) that encloses the first leg-bearing segment; the absence of the nauplius eye in all life stages; the retention of the antennary gland as the functional excretory system of adults; and a single naupliar developmental stage.

The unique characteristics of the misophrioids are interpreted as having resulted from the adaptation to a bathypelagic mode of life and gorging as a feeding strategy. However, species of three newly described genera also exhibit a number of characteristics that approach those attributed to a hypothetical copepod ancestor. *See* CALANOIDA; COPEPODA; CRUSTACEA; CYCLOPOIDA; HARPACTICOIDA. [P.A.McL.]

Missile An object capable of being projected or hurled, usually with the intent of striking some distant object. More particularly, a missile is usually a weapon that is self-propelled after leaving the launching device. The term thus excludes projectiles fired from guns as well as free-failing bombs. The propulsion criterion is not an absolute test, however, since gliding bombs, especially those guided after launch, are also frequently classed as missiles.

There are two primary categories of modern missiles; unguided and guided. All missiles, to be effective, must be directed in some sense, but those subject to no further control after leaving the launching device are usually classed as unguided.

Typical of unguided missiles are the ground-launched and air-launched free-flying rockets used in enormous number in World War II.

The growth of the sciences of instrumentation, electronics, and automatic control has led to the development of devices for the guidance of missiles in flight. Certain targets contrast with their surroundings by emitting or reflecting radiation in a distinctive manner. (Airplanes and ships are typical of the targets falling into this class.) The direction, and sometimes the distance, of targets of this kind can frequently be sensed by radiation receiving instruments. These instruments, located either in the missile or on the ground, can be used to guide the missile continuously toward the target.

Other targets cannot be readily distinguished from their surroundings by nonhuman means. Guided missiles used against these are frequently directed to the predetermined geographical location of such targets. Guidance errors are likely to be substantial, particularly as the distance from the guidance station to the target becomes great. In these cases, use of nuclear warheads becomes mandatory on economic grounds.

Missiles are classified in many ways. A common classification is according to the medium from which the missile is launched and to which it is directed. Thus, there are surface-to-air missiles, surface-to-surface missiles, air-to-surface missiles, and so on. They may also be classified according to range.

Missiles are also classified according to flight profile. The two categories are aerodynamic missiles (sometimes called cruise missiles) and ballistic missiles. Cruise missiles usually have wings or enlarged fins to give lift and maneuverability. A ballistic missile has no wings. It must be aimed sufficiently high to permit it to fall freely under the influence of gravity until it reaches the target. *See* BALLISTIC MISSILE.

High-speed missiles present problems of protecting sensitive components from the high temperatures produced by aerodynamic drag and sometimes from the high inertial forces produced by high accelerations. Only during the reentry phase is heat protection necessary.

The shape of the reentering body is sometimes quite blunt. This shape causes a greater fraction of the kinetic energy of the missile to be transferred to the surrounding atmosphere. However, blunt bodies slow down greatly before striking the ground, and they also have large radar reflectivity. These qualities are undesirable if antiballistic missiles are defending the target. As a consequence, the trend is toward sharper cones, accepting the greater heat transfer by providing greater protection. The ablative heat shield has almost entirely superseded the heat-sink type. *See* NOSE CONE. [R.C.Tr.]

Mississippian The fifth period of the Paleozoic Era. The Mississippian System (referring to rocks) or Period (referring to time during which these rocks were deposited) is employed in North America as the lower (or older) subdivision of the Carboniferous, as used on other continents. The name Mississippian is derived from rock exposures on the banks of the Mississippi River between Illinois and Missouri.

The limits of the Mississippian Period are radiometrically dated. Its start (following the Devonian) is dated as 345–360 million years before the present (Ma). Its end (at the start of the next younger North American period, the Pennsylvanian) is dated as 320–325 Ma. The duration of the Mississippian is generally accepted as 40 million years (m.y.). Biochronologic dating within the Mississippian, based on a combination of conodont (phosphatic teeth of eel- or hagfish-like primitive fish), calcareous foraminiferan, and coral zones permits a relative time resolution to within about 1 m.y. *See* Carboniferous; Pennsylvanian.

The Mississippian is divided, in ascending order, into the Lower Mississippian, comprising the Kinderhookian and Osagean, and the Upper Mississippian, comprising the Meramecian and Chesterian. Kinderhookian, Osagean, Meramecian, and Chesterian are used in North America as series (for rocks) and as stages (for time). In Illinois, Valmeyeran is commonly used for the Osagean and Meramecian combined.

During much of Mississippian time, the central North American craton (stable part of the continent) was the site of an extensive marine carbonate platform on which mainly limestones and some dolostones and evaporites were deposited. This platform extended either from the present Appalachian Mountains or Mississippi Valley to the present Great Basin. The craton was covered by shallow, warm, tropical epicontinental seas that had maximum depths of only about 60 m (200 ft) at the shelf edge.

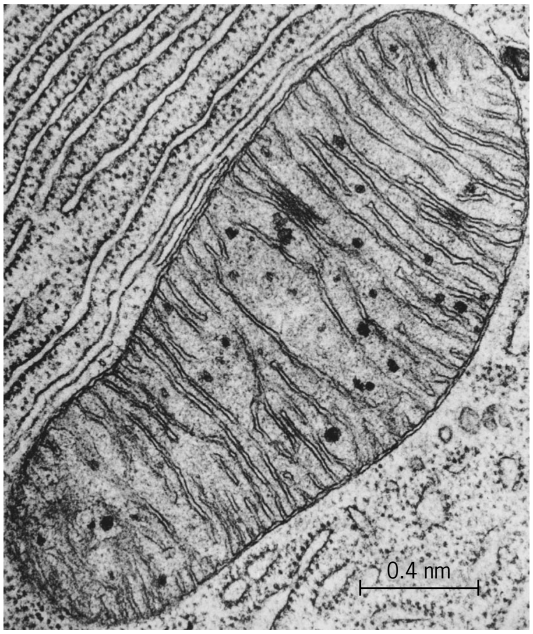
Mississippian North America was subjected to a number of sea-level rises, associated with transgressions, and sea-level falls, associated with regressions. The two major rises, which were probably eustatic (referring to worldwide change of sea level), took place during the late Kinderhookian and at the start of the middle Osagean zone. These sea-level rises caused progradation or seaward migration of carbonate platforms as organisms produced buildups that maintained their niches relative to sea level. The rises also caused stratification of the water column in deeper basins, so that bottom conditions became deficient to lacking in oxygen. *See* Anoxic zones; Basin.

Crinoids were probably the most abundant biota in Mississippian seas, but are only uncommonly used for correlation because most specific identifications require study of calyxes, which generally disarticulated after death. Corals are probably the most widely preserved Mississippian megafossil group, and they are one of the most useful biochronologic tools for constructing biostratigraphic zones for carbonate-platform rocks. The earliest Mississippian is characterized mainly by solitary corals and tubular colonial corals known as *Syringopora*, which had survived the late Frasnian mass extinction. Other colonial corals began a gradual return late in the Kinderhookian. The Late Mississippian was a heyday for reef-building colonial corals and large solitary corals. *See* Corallinales; Crinoidea; Reef.

Forests flourished during the Mississippian, and tree trunks, plant stems, roots, and spores occur commonly in terrestrial and peritidal rocks, particularly in coal beds. *Lepidodendron* trunks and *Stigmaria* roots are among the best-known plant remains. *See* Geologic time scale; Paleontology; Paleozoic. [C.A.Sa.]

Mistletoe The name given to several species of the mistletoe family (Loranthaceae). The true mistletoe of Europe is *Viscum album*, and among the early nations this was an important ceremonial plant, which probably accounts for the origin of the custom of kissing under the mistletoe. In the United States, the common representative of the group is *Phoradendron flavescens*. All of the mistletoes are green hemiparasites; that is, they obtain water and minerals from the host plant but manufacture their own food. *See* Santalales. [P.D.St./E.L.C.]

Mitochondria Specialized organelles of all eukaryotic cells that use oxygen (see illustration). Often called the powerhouses of the cell, mitochondria are responsible for energy generation by the process of oxidative phosphorylation. In this process, electrons produced during the oxidation of simple organic compounds are passed along a chain of four membrane-bound enzymes (the electron transport or respiratory chain), finally reacting with and reducing molecular oxygen to water. The movement of the electrons releases energy that is used to build a gradient of protons across the membrane in which the electron transport chain is situated. Like a stream of water that drives the turbines in a hydroelectric plant, these protons flow back through adenosine triphosphate (ATP) synthase, a membrane-bound enzyme that acts as a molecular turbine. Rotation of part of ATP synthase results in storage of energy in the form of ATP, the universal energy currency of the cell.



Electron micrograph of a thin section through the pancreas of a bat, showing a typical mitochondrion in profile. Note how the cristae are formed by extensive folding of the inner membrane. (*Courtesy of K. R. Porter*)

Besides their role in energy generation, mitochondria house numerous enzymes that carry out steps essential to metabolism. Defects in mitochondrial assembly or function generally have serious consequences for survival of the cell. In humans, mitochondrial dysfunction is the underlying cause of a wide range of degenerative diseases, with energy-demanding cells such as those of the central nervous and endocrine systems, heart, muscle, and kidney being most severely affected.

Mitochondria are bounded by two concentric membranes referred to as the outer and the inner. This creates two distinct compartments, the matrix and the intermembrane space. The outer membrane consists of a bilayer containing about 80% lipid. It is freely permeable to molecules smaller than about 5000 daltons. The inner membrane is also a lipid bilayer. It is extremely rich in protein (about 75%) and is impermeable to even the smallest of ions. The inner membrane contains the enzymes of the electron transport chain and the ATP synthase, together with a set of transporter proteins that regulate the movement of metabolites in and out of the matrix space. Mitochondria of cells that depend on a high level of ATP production are usually extensively folded to produce structures called cristae (see illustration). These greatly increase the surface area of the inner membrane, allowing many more copies of the enzymes of oxidative phosphorylation.

The intermembrane space contains enzymes capable of using some of the ATP that is transported out of the matrix to phosphorylate other nucleotides. The matrix space is packed with a hundred or so water-soluble proteins that form a sort of semisolid gel. They include enzymes of the tricarboxylic acid (Krebs) cycle and enzymes required for the oxidation of pyruvate and fatty acids, comprising steps in the biosynthesis or degradation of amino acids, nucleotides, and steroids.

Both mitochondria and chloroplasts contain DNA and the machinery necessary to express the information stored there. In both cases, the DNAs are relatively small and simple compared with DNA in the nucleus. While chloroplast DNA tends to be very similar in size in all organisms examined, mtDNA varies widely in complexity, from 16–18 kilobases in metazoa to upward of 2000 kilobases in some higher plants. In the case of higher-plant mtDNAs, some extra sequences appear to have been picked up from chloroplast and nuclear DNAs. MtDNA is generally circular, although some linear exceptions are known among the yeasts, algae, and protozoa.

The information content of most mtDNA is limited. This means that most of the several hundred proteins found in these organelles are encoded by genes located in nuclear DNA. These proteins are synthesized in the cytosol and subsequently transported specifically to the respective organelles. The contributions of the two genetic systems are usually closely coordinated, so that cells synthesize organelles of more or less constant composition.

Many organisms, including humans, show uniparental inheritance of mitochondrial genes because one parent contributes more cytoplasm to the zygote than the other. In humans, it is the egg cell provided by the mother that contributes the cytoplasm. Human mitochondrial genes are thus inherited maternally.

Recent years have seen a growing interest in human diseases that result from mitochondrial dysfunction. A number of these result from mutations in mtDNA. Others are linked to nuclear genes, whose mutation disturbs oxidative phosphorylation or impairs mitochondrial assembly. Mutations in mtDNA are remarkably frequent and lead to a wide range of degenerative, mainly neuromuscular diseases. Most of these diseases are maternally inherited, but some appear to be spontaneous, possibly resulting from error-prone replication of mtDNA. A striking feature of mtDNA-related diseases is the enormous diversity in clinical presentation. This diversity is attributable to two main factors: (1) Heterogeneity in the mtDNA population. Most human tissues contain many thousands of mtDNA molecules per cell. The severity of clinical symptoms depends on the number of mutated molecules present. (2) Dependence of a particular cell type on mitochondrial function (mainly ATP production). Cells with a high requirement for mitochondrially generated ATP are more severely affected than cells with alternative sources of ATP.

Besides their role in metabolism and energy-linked processes, mitochondria have recently been identified as important players in the initiation of apoptosis (programmed cell death). On one hand, the mitochondrial outer membrane houses a number of members of the Bcl-2 family of apoptosis regulatory proteins. On the other hand, release of certain mitochondrial proteins from the intermembrane space is instrumental in activating specialized proteases called caspases. These catalyze a degradative cascade in the cytoplasm that eventually ends in cell death.

Mammalian mtDNAs accumulate mutations at high rates and evolve correspondingly fast (up to 12–15 times faster than single-copy genes in nuclear DNA and up to 100 times faster for rRNA and tRNA genes). This behavior reflects both a high incidence of mutations and a high probability of their fixation. The first is probably related to oxidative damage to mtDNA by oxygen free radicals produced as by-products of electron transfer through the respiratory chain. The second has been attributed to the lack of efficient DNA repair (mitochondria lack nucleotide-excision repair) and to a relatively high tolerance of many mitochondrial gene products to mutational change.

The rapid rate of sequence evolution of mammalian mtDNAs makes these genomes highly sensitive indicators of recent evolutionary relationships. Unlike their nuclear counterparts, mtDNAs do not undergo recombination during sexual transmission and are strictly maternally inherited. Sequence changes in mtDNA therefore provide a clear record of the history of the female lineages through which this DNA has been transmitted. [L.A.Gr.]

Mitosis The series of visible changes that occur in the nucleus and chromosomes of non-gamete-producing plant and animal cells as they divide. During mitosis the replicated genes, packaged within the nucleus as chromosomes, are precisely distributed into two genetically identical daughter nuclei (see illustration). The series of events that prepare the cell for mitosis is known as the cell cycle. When viewed in the context of the cell cycle, the definition of mitosis is often expanded to include cytokinesis, the process by which the cell cytoplasm is partitioned during cell division.

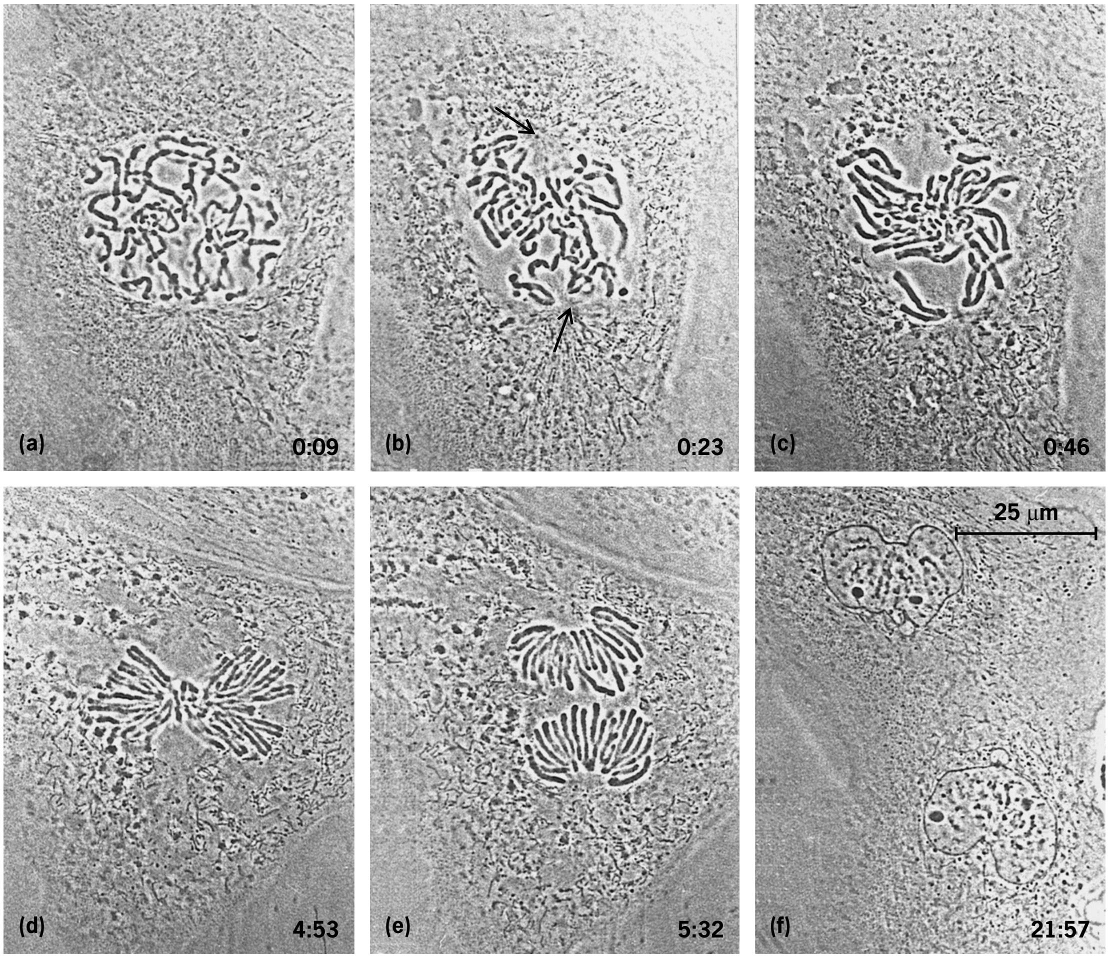
Chromosome segregation is mediated in all nonbacterial cells (that is, eukaryotes) by the transient formation of a complex structure known as the mitotic spindle. During mitosis in most higher plants and animals, the nuclear membrane surrounding the replicated chromosomes breaks down, and the spindle is formed in the region previously occupied by the nucleus (open mitosis). In lower organisms, including some protozoa and fungi, the spindle is formed and functions entirely within the nucleus which remains intact throughout the process (closed mitosis).

All spindles are bipolar structures, having two ends or poles. In animal cells, each spindle pole contains an organelle, the centrosome, onto which the spindle focuses and terminates. The polar regions of plant spindles lack centrosomes and, as a result, are much broader. In animals the bipolar nature of the spindle is established by the separation of the centrosomes, which is critical for successful mitosis; the presence of only one pole produces a monopolar spindle in which chromosome segregation is inhibited. The presence of more than two poles produces multipolar spindles which distribute the chromosomes unequally among three or more nuclei. Centrosomes are duplicated during interphase near the time that the DNA is replicated, but then act as a single functional unit until the onset of mitosis. In plants, and during meiosis in some animals, the two spindle poles are organized by the chromosomes and by molecular motors that order randomly nucleated microtubules into parallel bundles. *See* CENTROSOME; PLANT CELL.

Microtubules are the primary structural components of the mitotic spindle and are required for chromosome motion. These are 25-nanometer-diameter, hollow, tubelike structures. During interphase, microtubules are distributed throughout the cytoplasm, where they serve to maintain cell shape and also function as polarized roadways for transporting organelles and cell products. As the cell enters mitosis, the cytoplasmic microtubule network is disassembled and replaced by the mitotic spindle. The microtubules in animal cells originate from the centrosome which, like the chromosomes, was inherited during the previous mitosis where it functioned as a spindle pole. The motion associated with microtubules is mediated by several families of molecular motors which bind to and move along the wall of the microtubule. *See* CYTOSKELETON.

As mitosis begins, each replicated chromosome consists of two identical sister chromatids that are joined along their length. In most cells, chromosomes possess a unique region of highly condensed chromatin (DNA plus protein), known as the centromere, which forms an obvious constriction on the chromosome, referred to as the primary constriction. Spindle microtubules attach to a small specialized structure on the surface of the centromere known as the kinetochore. Fragments of chromosomes lacking a kinetochore do not move poleward; it is always the kinetochore that leads in the poleward motion of the chromosome. The centromere region of each replicated chromosome contains two sister kinetochores, one attached to each chromatid, that lie on opposite sides of the primary constriction.

Once initiated, mitosis is a continuous process that, depending on the temperature and organism, requires several minutes to many hours to complete. Traditionally it has been subdivided into five consecutive stages that are distinguished primarily by chromosome structure, position, and behavior. These stages are prophase, prometaphase, metaphase, anaphase, and telophase. In prophase, cell chromosomes condense within the nucleus. By



Selected phase-contrast light micrographs showing changes in chromosome position during mitosis in a living newt lung epithelial cell. (*a*) Late prophase. (*b*) Prometaphase. (*c*) Mid-prometaphase. (*d*) Metaphase. (*e*) Anaphase. (*f*) Telophase.

late prophase/early prometaphase, the nuclear envelope breaks down; kinetochore-containing primary constrictions are sometimes visible; the cytoplasmic microtubule complex is replaced by two radial astral microtubule arrays; centrosomes separate; and microtubules in each aster grow and shorten at their ends away from the centrosome. By mid-prometaphase, the kinetochores on the chromosomes interact with the asters to form the spindle. In metaphase, all of the chromosomes are aligned on the spindle equator; sister kinetochores are attached to opposite poles by kinetochore fibers. In anaphase, the sister chromatids separate and move toward their respective spindle poles; at the same time the spindle poles move farther apart. In telophase, the two groups of sister chromosomes become two well-separated sister nuclei, and the cytoplasm of the cell divides (cytokinesis). *See* CELL (BIOLOGY); CELL DIVISION; CELL NUCLEUS. [C.L.R.]

Mitteniales An order of true mosses (subclass Bryidae) found in Australia and New Zealand. The order consists of a single species. *Mittenia plumula*, which is adapted for growth in caves or cavelike places. Branches of the persistent protonema consist of spherical cells which reflect light from a backing of chloroplasts, thus providing a glow. The stems are simple and erect, and the leaves are 2–4-ranked and oblonglingulate and blunt or apiculate. The midrib ends above the midleaf, and the cells are short and smooth.

The order is remarkably similar to the Schistostegales of North Temperate distribution in protonema and habitat, but the other features of gametophyte and sporophyte are quite different. A distinctive feature is the double peristome with 32 segments derived in part from the outermost cell walls of the endothecium (that is, the inner portion of the embryonic capsule). *See* BRYIDAE; BRYOPHYTA; BRYOPSIDA; SCHISTOSTEGALES. [H.Cr.]

Mixer A device with two or more signal inputs and one common output. The two primary classes are linear (additive) and nonlinear (multiplicative) mixers. Linear mixers are used to add or blend together two or more signals, nonlinear mixers mainly to shift the spectrum (center frequency) of one signal by the frequency of a second signal.

Linear mixing is the process of combining signals additively, such as the summing of audio signals in a recording studio. This operation can be accomplished passively by simply using a resistive summing network. Although this approach appears very economical, there is a loss in signal strength and an interaction of the signal amplitudes as the gains are adjusted.

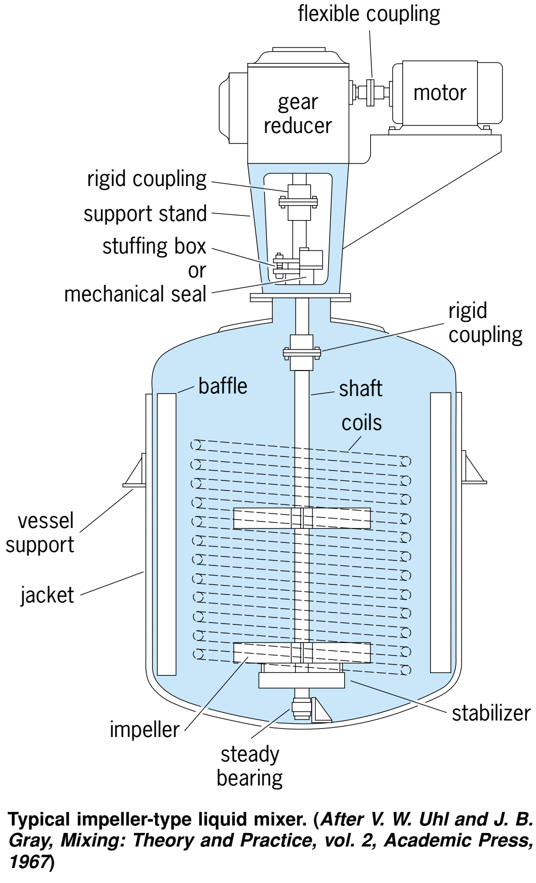
Inexpensive integrated circuits have improved this application dramatically. Operational amplifiers of reasonably high quality that will eliminate the adjustment interactions and also provide gain are readily available. The input signals are summed into the virtual ground summing node at the input of the operational amplifier. There is a sign change in the output, but that is a small drawback compared to the advantage of having the virtual ground provided by the operational amplifier. *See* AMPLIFIER; INTEGRATED CIRCUITS; LINEARITY; OPERATIONAL AMPLIFIER.

Perhaps the most familiar application of nonlinear mixers is in radio and television receivers. They are widely used in such applications as amplitude modulation (AM) and demodulation, frequency demodulation, phase detection, frequency multiplication, and single-sideband (SSB) generation. The incoming information to a receiver has been transmitted and received at a frequency far too high to permit efficient amplification and processing. Therefore the signal is translated or frequency-shifted or heterodyned by a mixer to a lower frequency, known as the intermediate frequency (IF), where amplification and processing are performed efficiently by an IF processor, sometimes referred to as the IF strip. *See* AMPLITUDE-MODULATION DETECTOR; AMPLITUDE MODULATOR; FREQUENCY-MODULATION DETECTOR; FREQUENCY MODULATOR; FREQUENCY MULTIPLIER; PHASE-ANGLE MEASUREMENT; RADIO RECEIVER; SINGLE SIDEBAND; TELEVISION RECEIVER.

A second application of a nonlinear mixer is frequency synthesis, where a stable but not easily changed signal at a high frequency is made tunable by mixing it with an easily tunable signal at a low frequency, which, perhaps, can be varied in precise increments of any size. The utility of the method is limited by the ability to filter or separate one frequency term from another, thereby determining the minimum practical value of low frequency for the application.

A mixer is an integral part of an AM-radio integrated circuit which contains virtually all AM-radio functions except filters. A particular type of mixer, the quadrature detector, is included in the frequency-modulation (FM)-radio integrated circuit. [S.A.Wh.]

Mixing A common operation to effect distribution, intermingling, and homogeneity of matter. Actually the operation is called agitation, with the term mixing being applicable when the goal is blending, that is, homogeneity. Other processes, such as reaction, mass transfer (includes solubility and crystallization), heat transfer, and dispersion, are also promoted by agitation. The type, extent, and intensity of agitation determine both the rates and adequacy of a particular process result. The agitation is accomplished by a variety of equipment.



Typical impeller-type liquid mixer. (*After V. W. Uhl and J. B. Gray, Mixing: Theory and Practice, vol. 2, Academic Press, 1967*)

Most liquid mixing is done by rotating impellers in vertical cylindrical vessels. A typical impeller-type liquid mixer with a variety of features is shown in the illustration. The internal features, including the vessel itself, are considered as a whole, that is, as the agitated system. The forces applied by the impeller develop overall circulation or bulk flow. Superimposed on this flow pattern, there is molecular diffusion, and if turbulence is present, also turbulent eddies. These provide micromixing. Solids, granular to powder, are mixed in a variety of contrivances.

Solids of different density and size are mixed in tumblers (a double cone turning end on end) or with agitators (a helical ribbon rotating in a horizontal trough). The duration of mixing is an important additional variable because classification and separation often occur after attainment of the desired distribution if the operation is carried on too long. [V.W.U.]

Mizar The second-magnitude star that marks the bend in the handle of the Big Dipper, ζ Ursae Majoris. Mizar was the first telescopic visual binary to be discovered (1650), the first ever to be photographed (1857), and the first star discovered to be a spectroscopic binary (1889). Its distance to the Sun is 24 parsecs (7.5×10^{14} km or 4.7×10^{14} mi). *See* BINARY STAR; CONSTELLATION; URSA MAJOR.

Mizar (the Horse) forms a wide visual binary with the fourth-magnitude star Alcor (the Rider), at a separation of $12'$. The two stars have nearly the same proper motion, and the pair is visible to the naked eye. Mizar itself is a close visual pair, with bluish-white components of apparent magnitude 2.27 and 3.95, approximately $14''$ apart. The spectrum of the primary star, Mizar A, shows periodic doubling of the absorption lines due to the Doppler effect, caused by the motion of two stars around their common center of mass. The orbital period of this spectroscopic binary is 20.5 days, and the stars have been resolved with an interferometer, the mean angular separation being only $0.012''$. Mizar B is also a spectroscopic binary with a period of 176 days. *See* DOPPLER EFFECT; SPECTRAL TYPE. [D.W.L.]

Mobile radio Radio communication in which one or both ends of the communication path are movable. The term mobile refers to movement of the radio rather than association with a vehicle (for example, hand-held portable radios are included by the definition). The Federal Communications Commission (FCC) licenses and regulates nonfederal government radio activity in the United States, while the National Telecommunications and Information Administration (NTIA) oversees federal government users. Other countries have similar agencies. International coordination is afforded through the International Telecommunication Union (ITU) and international treaty.

Users who lease or purchase radio equipment for personal communication fall into this category. Examples are public safety, special emergency, industrial, land transportation, and radiolocation radio services. Spectrum over a wide range of frequency bands is allocated; for example, low band (30–50 MHz), high band (150–174 MHz), ultrahigh frequency or UHF (450–512 MHz), the 800 band (806–824 MHz, paired with 851–869 MHz), and the 900 band (896–901 MHz, paired with 935–940 MHz). Dispatch is the normal mode of operation; that is, all members of the group hear all communications. To accomplish this high-power, high-site base, repeaters are generally used so that the entire area of interest is covered by a single site. Coverage radius varies with frequency band, local terrain, and permissible power levels, but values on the order of 20 mi (32 km) are commonplace. Where areas to be covered are even larger (for example, statewide police systems) or where coverage reliability must be greater than that possible from a single site (for example, for ambulance communications), multiple sites can simulcast the communications. Current technology allows for data exchanges, vehicle location, and secure, digitized voice. *See* RADIO SPECTRUM ALLOCATIONS.

Specialized mobile radio (SMR) is a type of mobile radio service in which individual users with business interests are licensed to operate their mobiles, portables, and control stations on channel pairs repeated by specialized mobile radio base stations. Full interconnection to the public switched telephone network (PSTN) is possible. To boost the spectrum efficiency of specialized mobile radios relative to shared repeaters already in use, the FCC requires that channels be trunked. Trunking in the context of radio systems means not only sharing equipment but sharing frequencies as well. Trunking channels means that when a user wishes to place a call it can be served by any one of the channel pairs that is available.

Although paging is primarily a one-way radio system, two-way operation with such functions as page acknowledgment and short message reply are available. Some types of paging receivers display digits and letters (alphanumeric displays) that allow the calling party's number or a brief message to be displayed, and a message operator becomes unnecessary. Since display of paging messages involves little information, thousands of users can share each paging channel, thus making the service extremely spectrum efficient. Other types of paging receivers provide for brief voice messages following the alert (tone and voice). *See* RADIO PAGING SYSTEMS.

Cellular technology allows hundreds of thousands of users to be handled in a single metropolitan area. Rather than link into the telephone system from a single high-power, high site that covers the entire metropolitan ares, users are linked via many low-power, low sites. A single low site, of course, can cover only a limited area, termed a cell, but many low sites taken together can cover the entire metropolitan area. Spectrum efficiency stems from reusing the same frequency at all sites that are sufficiently separated. To further limit interference caused by frequency reuse, each cell may be divided into sectors and directive antenna patterns may be used.

An attractive feature of cellular radio is the ability to vary the size of the cells in accordance with user density; hence, cell size can increase away from city centers. To sustain the reuse pattern with mixed cell sizes, power levels are tailored to produce comparable signal levels at all cell boundaries. Also, as more customers are added, radio channels can be created to serve them by constructing new base stations (hence, new cells) in geographical locations between existing cells. This concept is called cell splitting. Geographical coverage of the system can be expanded as well by constructing new base stations on the periphery of the existing system and assigning frequencies consistent with the original reuse pattern.

Automatic, continuous coverage as users move across cell boundaries is provided by the call handoff feature of cellular (also termed handover and automatic link transfer). Calls in need of handoff are recognized by monitoring call quality and comparing it to some required threshold. Handoff control procedures for first-generation analog frequency-modulation cellular systems are in operation.

The great demand for cellular phones and related wireless services has been addressed to some extent by the addition of new spectrum, by the introduction of narrow-band and digital cellular systems, and by cell splitting where practical. Acknowledging that these techniques for increasing capacity would quickly be exhausted, most countries allocated additional spectrum for mobile and portable communication. Since these frequency bands have much more spectrum than those previously allocated to cellular service, a greater variety of services are possible.

A spectrum of 120 MHz in the 1850–1910 and 1930–1990 MHz bands was allocated for licensed personal communication system (PCS) operation in the United States, and 20 MHz of spectrum in the 1910–1930 MHz band for unlicensed operation, split evenly between voice (isochronous) and data (asynchronous) applications. The spectrum allocated for licensed PCS operation is divided into six frequency blocks, three of which contain 30 MHz of spectrum and the other three, 10 MHz. It is thus possible in a given region to have as many as six competing service providers, in addition to the two 900-MHz cellular service providers. *See* DATA COMMUNICATIONS; TELEPHONE SERVICE.

[G.C.H.; J.R.Hau.]

Mode of vibration

Mode of vibration A characteristic manner in which vibration occurs. In a freely vibrating system, oscillation is restricted to certain characteristic frequencies; these motions are called normal modes of vibration.

An ideal string, for example, can vibrate as a whole with a characteristic frequency $f = (1/2L)\sqrt{T/m}$, where L is the length of string between rigid supports, T the tension, and m the mass per unit length of the string. The displacements of different parts of the string are governed by a characteristic shape function. The frequency of the second mode of vibration is twice that of the first mode. Similarly, modes of higher order have frequencies that are integral multiples of the fundamental frequency.

Because the frequencies are in the ratios 1:2:3. . . , the modes of vibration of an ideal string are properly called harmonics. Not all vibrating bodies have harmonic modes of vibration, however. *See* HARMONIC (PERIODIC PHENOMENA); VIBRATION. [R.W.Y.]

Model theory

Model theory The body of knowledge that concerns the fundamental nature, function, development, and use of formal models in science and technology. In its most general sense, a model is a proxy. A model is one entity used to represent some other entity for some well-defined purpose. Examples of models include: (1) An idea (mental model), such as the internalized model of a person's relationships with the environment, used to guide behavior. (2) A picture or drawing (iconic model), such as a map used to record geological data, or a solids model used to design a machine component. (3) A verbal or written description (linguistic model), such as the protocol for a biological experiment or the transcript of a medical operation, used to guide and improve procedures. (4) A physical object (scale model, analog model, or prototype), such as a model airfoil used in the wind-tunnel testing of a new aircraft design. (5) A system of equations and logical expressions (mathematical model or computer simulation), such as the mass- and energy-balance equations that predict the end products of a chemical reaction, or a computer program that simulates the flight of a space vehicle. Models are developed and used to help hypothesize, define, explore, understand, simulate, predict, design, or communicate some aspect of the original entity for which the model is a substitute.

Formal models are a mainstay of every scientific and technological discipline. Social and management scientists also make extensive use of models. Indeed, the theory of models and modeling cannot be divorced from broader philosophical issues that concern the origins, nature, methods, and limits of human knowledge (epistemology) and the means of rational inquiry (logic and the scientific method). *See* LOGIC; SCIENTIFIC METHODS.

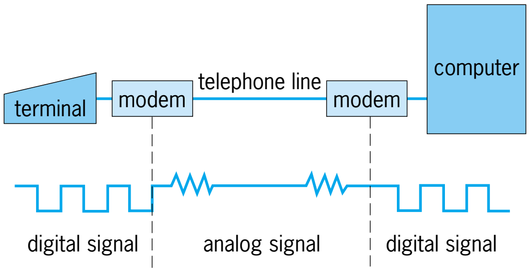
Models are usually more accessible to study than the system modeled. Changes in the structure of a model are easier to implement, and changes in the behavior of a model are easier to isolate, understand, and communicate to others. A model can be used to achieve insight when direct experimentation with the actual system is too dangerous, disruptive, or demanding. A model can be used to answer questions about a system that has not yet been observed or built, or even one that cannot be observed or built with present technologies.

Specific models developed in different disciplines may differ in subject, form, and intended use. However, basic concepts such as model description, validation, simplification, and simulation are not unique to any particular discipline. Model theory seeks a formal logical and axiomatic understanding of the underlying concepts that are common to all modeling endeavors.

General and mathematical systems theory have stimulated many of the important developments in model theory.

Mathematical models are particularly useful, because of the large body of mathematical theory and technique that exists for the study of logical expressions and the solution of equations. The power and accessibility of digital computers have increased the use and importance of mathematical models and computer simulation in all branches of modern science and technology. A great variety of programming languages and applications software are now available for modeling, computational analysis, and system simulation. *See* Digital computer; Simulation; Systems analysis; Systems engineering. [K.P.W.]

Modem A device that converts the digital signals produced by terminals and computers into the analog signals that telephone circuits are designed to carry. Despite the availability of several all-digital transmission networks, the analog telephone network remains the most readily available facility for voice and data transmission. Since terminals and computers transmit data using digital signaling, whereas telephone circuits are designed to transmit analog signals used to convey human speech, a device is required to convert from one to the other in order to transmit data over telephone circuits. The term modem is a contraction of the two main functions of such a unit, modulation and demodulation. The device is also called a data set. *See* Integrated Services Digital Network (ISDN): Modulation.



Signal conversion performed by modems. A modem converts a digital signal to an analog tone (modulation) and reconverts the analog tone into its original digital signal (demodulation).

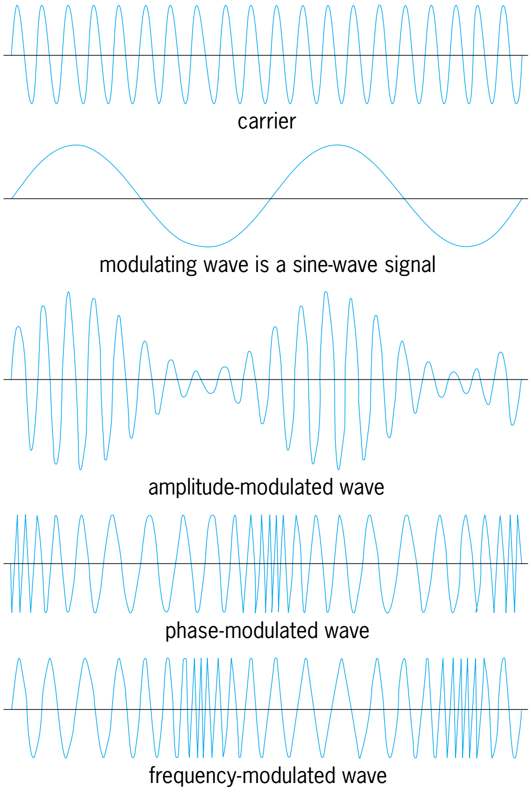
In its most basic form a modem consists of a power supply, transmitter, and receiver. The power supply provides the voltage necessary to operate the modem's circuitry. The transmitter section contains a modulator as well as filtering, wave-shaping, and signal control circuitry that converts digital pulses (often input as a direct-current signal with one level representing a digital one and another level a digital zero) into analog, wave-shaped signals that can be transmitted over a telephone circuit. The receiver section contains a demodulator and associated circuitry that is used to reverse the modulation process by converting the received analog signals back into a series of digital pulses (see illustration). *See* Data communications; Demodulator; Electric filter; Electrical communications; Electronic power supply; Modulator; Wave-shaping circuits. [G.He.]

Modulation A technique employed in telecommunications transmission systems whereby an electromagnetic signal (the modulating signal) is encoded into one or more of the characteristics of another signal (the carrier signal) to produce a third signal (the modulated signal), whose properties are matched to the characteristics of the medium over which it is to be transmitted. The encoding preserves the original modulating signal in that it can be recovered from the modulated signal at the receiver by the process of demodulation. The main purpose of modulation is to overcome any inherent incompatibilities between the electromagnetic properties of the modulating signal and those of the transmission medium. Of primary importance in this respect is the spectral distribution of power in the modulating signal relative to the passband of the medium. Modulation provides the means for shifting the power of the modulating signal to a part of the frequency spectrum where the medium's transmission characteristics, such as its attenuation, interference, and noise level, are favorable. *See* Electromagnetic wave transmission; Radio-wave propagation.

Two forms of modulation are generally distinguished, although they have many properties in common: If the modulating signal's amplitude varies continuously with time, it is said to be an analog signal and the modulation is referred to as analog. In the case where the modulating signal may vary its amplitude only between a finite number of values and the change may occur only at discrete moments in time, the modulating signal is said to be a digital signal and the modulation is referred to as digital.

In most applications of modulation the carrier signal is a sine wave, which is completely characterized by its amplitude, its frequency, and its phase relative to some point in time. Modulating the carrier then amounts to varying one or more of these parameters in direct proportion to the amplitude of the modulating signal. In analog modulation systems, varying the amplitude, frequency, or phase of the carrier signal results in amplitude modulation (AM), frequency modulation (FM), or phase modulation (PM), respectively. Since the frequency of a sine wave expressed in radians per second equals the derivative of its phase, frequency modulation and phase modulation are sometimes subsumed under the general term "angle modulation" or "exponential modulation." The illustration shows an example of an unmodulated sine-wave carrier signal and the signal resulting from modulating its amplitude, phase, or frequency with the amplitude of an analog modulating signal, which is also taken to be a sine wave.

If the modulating signal is digital, the modulation is termed amplitude-shift keying (ASK), frequency-shift keying (FSK), or phase-shift keying (PSK), since in this case the discrete amplitudes of the digital signal can be said to shift the parameter of the carrier signal between a finite number of values. For a mod-



Amplitude, phase, and frequency modulation of a sine-wave carrier by a sine-wave signal. (*After H. S. Black, Modulation Theory, Van Nostrand, 1953*)

ulating signal with only two amplitudes, "binary" is sometimes added before these terms.

Digital modulating signals with more than two amplitudes are sometimes encoded into both the amplitude and phase of the carrier signal. For example, if the amplitude of the modulating signal can vary between four different values, each such value can be encoded as a combination of one of two amplitudes and one of two phases of the carrier signal. Quadrature amplitude modulation (QAM) is an example of such a technique.

In certain applications of modulation the carrier signal, rather than being a sine wave, consists of a sequence of electromagnetic pulses of constant amplitude and time duration, which occur at regular points in time. Changing one or the other of these parameters gives rise to three modulation schemes known as pulse-position modulation (PPM), pulse-duration modulation (PDM), and pulse-amplitude modulation (PAM), in which the time of occurrence of a pulse relative to its nominal occurrence, the time duration of a pulse, or its amplitude are determined by the amplitude of the modulating signal. *See* PULSE MODULATION. [H.J.He.]

Modulator Any device or circuit by means of which a desired signal is impressed upon a higher-frequency periodic wave known as a carrier. The process is called modulation. The modulator may vary the amplitude, frequency, or phase of the carrier. *See* MODULATION.

There are many ways to accomplish amplitude modulation, but in all cases a nonlinear element or device must be employed. The modulating signal controls the characteristics of the nonlinear device and thereby controls the amplitude of the carrier. *See* AMPLITUDE MODULATION; AMPLITUDE-MODULATION DETECTOR; AMPLITUDE MODULATOR.

The frequency modulator usually changes the effective capacitance or inductance in the frequency-determining LC circuit of the oscillator. However, other techniques can be used. For example, a multivibrator can be used to generate carrier frequencies up to a few megahertz, and the multivibrator frequency can be modulated by controlling the base, gate, or grid bias supply voltage. *See* FREQUENCY MODULATION; FREQUENCY-MODULATION RADIO; FREQUENCY MODULATOR. [C.L.A.]

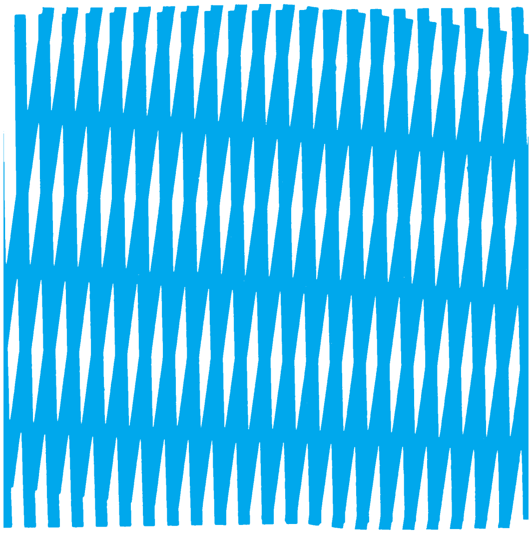
Mohair The long, lustrous hair of the Angora goat, which originated in the area around Ankara (Angora), Turkey. Mohair is a smooth, strong, durable, and resilient fiber. It enhances softness and luster in fabrics. Mohair absorbs dye evenly and brilliantly, retains color well, and permits unusual decorative effects. It is mainly used as an apparel fiber but may be used in upholstery, draperies, wigs, hairpieces, and rugs. Leather produced from the skin is useful for gloves, purses, and novelties. *See* WOOL. [C.E.T.]

Moho (Mohorovičić discontinuity) The level in the Earth where the velocity of sonic waves first increases rapidly or discontinuously to a value between 4.7 and 5.3 mi/s (7.6 and 8.6 km/s). A. Mohorovičić discovered this boundary while investigating seismograms of the Zagreb (in former Yugoslavia) earthquake of October 8, 1909. He recognized that low-velocity waves traveling directly from the earthquake source were overtaken at large distances by refracted waves traveling through the deeper, high-velocity layer. Modern determinations of the depth and nature of the Moho are commonly made in seismic refraction studies that use artificial seismic sources, such as explosions, rather than earthquakes. This method allows identification of the wave traveling in the high-velocity medium (P_n) and a wide-angle reflection (P_mP) from the boundary. The Moho is generally assumed to mark the boundary between the crust and mantle, although this need not always be the case. *See* EARTH INTERIOR. [D.M.Fo.]

While the definition of Moho in the continents is based solely on seismic refraction observations, the term has been utilized to describe a range of observations pertaining to the oceanic environment. In the strictest sense, Moho refers to the depth where material velocities, as determined from seismic refraction methods, exceed 5 mi/s (8 km/s). From geological studies of ocean crust and ophiolites (ancient oceanic sections subsequently emplaced on continents), oceanic crust is understood to originate from partial melting of mantle that upwells and decompresses in response to sea-floor spreading. The eruption and intrusion of this melt, and the formation of Moho, occurs in a very narrow zone at the axis of sea-floor spreading. Different mantle conditions can lead to different volumes of melting, accounting for most of the observed variations in crustal thickness (depth to the Moho). Very slow spreading centers, while rare, are expected to form somewhat thinner crust, largely reflecting the magma-starred nature of these areas. The Moho is a proxy for the transition from crustal materials (for example, basalts, diabase dikes, or gabbros) formed by mafic melts extracted from the mantle to the ultramafic residual mantle (for example, peridotite) that has remained at depth. *See* BASALT; DOLERITE; GABBRO; OPHIOLITE; PLATE TECTONICS. [C.Z.M.]

Moiré pattern When one family of curves is superposed on another family of curves, a new family called the moirè pattern appears.

To produce moirè patterns, the lines of the overlapping figures must cross at an angle of less than about 45°. The moirè lines are then the locus of points of intersection. The illustration shows the case of two identical figures of simple gratings of alternate black and white bars of equal spacing. When the figures are crossed at 90°, a checkerboard pattern with no moirè effect is seen. At crossing angles of less than 45°, however, one sees a moirè pattern of equispaced lines, the moirè fringes. The spacing of the fringes increases with decreasing crossing angle. This provides one with a simple method for measuring extremely small angles (down to 1 second of arc). As the angle of crossing approaches zero, the moirè fringes approach 90° with respect to the original figures.



Two simple gratings crossed at a small angle.

Even when the spacings of the original figures are far below the resolution of the eye, the moirè fringes will still be readily seen. This phenomenon provides a means of checking the fidelity of a replica of a diffraction grating. *See* DIFFRACTION GRATING.

Moiré techniques are widely used in the stress analysis of metals, in the examination of large optical surfaces, in investigating aberrations of lenses, and in determining a refractive index gradient (for example, that of sugar molecules diffusing into water). [G.O.]

Moisture-content measurement Measurement of the ratio or percentage of water present in a gas, a liquid, or a solid (granular or powdered) material. Nearly all materials contain free water, the relative amount being dependent upon the physical and chemical properties of the material. The primary purpose of determining and maintaining moisture contents within specified limits can usually be traced to economic factors, trade practices, or legal requirements.

Moisture content has a number of synonymous terms, many of which are specific to certain industries, types of product, or material. The water content in solid, granular, or liquid materials is usually referred to as moisture content on either the wet or dry basis; the wet basis is common to most industries. Specifically, moisture content on the wet basis refers to the quantity of water per unit weight or volume of the wet material. A weight basis is preferred. The textile industry uses the dry basis for moisture content of textile fibers. Often referred to as regain moisture content, the dry basis or regain refers to the quantity of water in a material expressed as a percentage of the weight of the bone-dry (thoroughly dried) material.

The moisture content in air is referred to as humidity, either absolute or relative. Absolute humidity is the number of pounds of water vapor associated with 1 Ib (0.5 kg) of dry air, also called just humidity, Relative humidity is the ratio, usually expressed as a percentage, of the partial pressure of water vapor in the actual atmosphere to the vapor pressure of water at the prevailing temperature. Relative humidity is customarily reported by the U.S. Weather Bureau because it essentially describes the degree of saturation of the air. However, air which is saturated (100% RH) at 50°F (10°C) is quite dry (19% RH) when heated to 100°F (38°C). A changing basis of this type is not convenient for many purposes such as computations used in air conditioning, combustion, or chemical processing; therefore absolute units, such as dew point or grains of water per pound of dry air, are more acceptable. Dew point is the temperature at which a given mixture of air and water vapor is saturated with water vapor. *See* DEW POINT; HUMIDITY.

Gases. The measurement of water content in gases and mixtures of air and gases is important in industry. A number of commercially manufactured instruments are available for these measurements; their principles of operation include condensation, used in dew- or fog-point indicators; dimensional change, used by hygrometers; thermodynamic equilibrium, used by wet-bulb psychrometers; and absorption methods, which serve as the basic principle for gravimetric and electric conductivity or dielectric types. *See* HYGROMETER; PSYCHROMETER; PSYCHROMETRICS.

The importance of humidity in relation to personal comfort is well known. The air conditioning industry produces equipment to maintain comfortable conditions of temperature and humidity. Considerable industrial air conditioning is also done for process reasons. Control of humidity is also important in the preservation of materials, especially those which are hygroscopic, and in the storage of food products.

Liquids and solids. The development of instrumentation for the measurement and control of moisture in liquids and solids has been due in a large part to the great need that exists in many processes where the control of a precise moisture is critical. The desirability of a specific moisture content in a product during its preliminary manufacturing process is often required. In general, however, the rigid control of moisture content occurs most frequently in the final product to assure its quality and the fulfillment of legal or trade practices for the individual product.

Instruments suitable for the measurement of moisture content may be classified as periodic and continuous. In general, only those instruments offering continuous measurement are practical for the automatic control of moisture content in a product. The periodic instrument types are generally automated versions of conventional laboratory moisture-analysis procedures.

Moisture measuring instruments may also be classified by operating principle. Those instruments employing electrical conductivity (either dc or ac), absorption of electromagnetic energy (radio-frequency regions), electrical capacitance (dielectric constant change), and infrared energy radiations are more readily adapted to continuous measurements inasmuch as the response of these instruments to moisture changes is very fast. Those instruments employing automatic oven drying, chemical titrations, equilibrium hygrometric methods, distillation methods, and so forth are usually of the intermittent, or periodic, type. [L.E.C.]

Mole (chemistry) A unit (symbolized mol) used to measure the amount of material in a chemical sample. The mole is defined by international agreement as the amount of substance (chemical amount) of a chemical system that contains as many molecules or entities as there are atoms in 12 g of carbon-12 (^{12}C). When the mole is used, the elementary entities need not be molecules, but they must always be specified. They may be atoms, molecules, ions, electrons, or specified groups of such particles.

Three obvious ways of measuring the amount of material in a given sample are to measure the mass of the sample, to measure the volume, or to count the number of molecules in the sample. Although it is more difficult to devise an experiment to count molecules, this third way of measuring amount is of special interest to chemists because molecules react in simple rational proportions (for example, one molecule of A may react with one, or two, or three molecules of B, and so forth). However, to count molecules is inconvenient in practice because the numbers are so large. For any chemical, a mass of 1 kilogram of the sample contains a large number of molecules, of the order 10^{23}–10^{24}. The mole is defined so that 1 mole of any substance always contains the same number of molecules. This number approximately 6.02×10^{23}, and is known as the Avogadro number. The mole is a more convenient unit in which to measure the amount of a chemical than counting the number of molecules, and it has the same advantages. *See* AVOGADRO NUMBER.

The amount of substance (chemical amount) of a sample, n, may be determined in practice by one of three methods.

The value of n (the amount of substance) may be determined from the mass m by dividing by the molar mass M of the sample, as in Eq. (1). If m is expressed in g and M in g/mol, then the value of n will be obtained in mol.

$$n = \frac{m}{M} \tag{1}$$

For a gas, the value of n may be determined from the volume V, pressure p, and absolute temperature T by using the ideal gas equation (2), where R is the gas constant ($R = 8.3145$ J K^{-1}

$$n = \frac{pV}{RT} \tag{2}$$

mol^{-1}). If pV is expressed in (N m^{-2}) × (m^3) = J, and RT in J mol^{-1}, then pV/RT gives the value of n in mol.

For a solution, the amount of solute (or the amount concentration of solution) is frequently determined by titration: if ν_A molecules of A react with ν_B molecules of B in the titration, then at the end point the amount of A used (n_A) is related to the amount of B (n_B) by Eq. (3), so that if one is known the other may be determined.

$$n_A = \frac{\nu_A}{\nu_B} n_B \tag{3}$$

See TITRATION.

The concentration of a solution may be recorded as (mass of solute)/(volume of solution), in units gram/liter; or as (chemical amount of solute)/(volume of solution) in units mol/liter. Because of the proportionality of chemical amount to number of molecules, the latter is the more useful measure of concentration and is generally used in chemistry and biochemistry. *See* CONCENTRATION SCALES. [I.M.M.]

Mole (zoology)

Mole (zoology) A mammal belonging to the family Talpidae. There are 19 species distributed on all continents except Australia. Moles are insectivores, feeding mainly on earthworms and insect larvae, and are highly specialized for their burrowing habits.

The body is stout and cylindrical and with a short neck (see illustration). The eyes and external ears are small or vestigial, and the conical head terminates in a long naked muzzle. The forelimbs are especially adapted for digging, having very powerful muscles and a spadelike bony structure. Mating occurs in the spring; after a gestation period of 30–40 days a litter of 3–7 young are born.

The European mole, *Talpa europaea.*

Moles are solitary animals and rarely come aboveground. Molehills are seen where temporary burrows are made, but permanent runs are made by compressing the earth so there are no molehills to betray their presence. Each mole lives in its own fortress constructed as a central chamber around which are two circular passages, one at a higher and the other at a lower level, connected by short passages. The upper passage connects with the central chamber and the lower one leads to the main exit. There is also an emergency exit leading to the main exit from below the central chamber. *See* INSECTIVORA; MAMMALIA. [C.B.C.]

Molecular adhesion The tendency of dissimilar solids or liquids to cling together as a result of the interatomic forces which they exert upon each other across their common interface. Some factors affecting molecular adhesion are the physical state of the materials, the composition and the topology of the surfaces in contact, the temperature, and the presence of foreign materials such as adsorbed gases on one or both surfaces.

Mutual forces of attraction, electrical in origin, exist between virtually all atoms and molecules. It is these forces which, under proper conditions of temperature and pressure, compel isolated atoms or molecules to condense into solids and liquids. On average, these forces are approximately equally strong in all directions and result in an atom or molecule achieving its lowest possible energy, that which is thermodynamically favored, when it is surrounded on all sides by other atoms. The presence of a real surface breaks the three-dimensional continuity of the substance, leaving atoms at the surface with an unfulfilled capacity for bonding. It is this capacity for bonding that is responsible for the phenomena of surface tension, adsorption of gases, and adhesion. *See* ADSORPTION; COHESION (PHYSICS); INTERMOLECULAR FORCES; SURFACE TENSION.

Molecular adhesion plays an especially significant role in the deposition of thin films on substrates of dissimilar composition. A particularly important example is the use of such films to form conducting paths—microscopic wires only a few tens of nanometers thick—in integrated circuits. These films must both adhere well to the underlying substrate and produce contacts with appropriate electrical properties. At present the understanding of adhesion is not sufficiently detailed to be able to predict such properties in advance of experiments. *See* INTEGRATED CIRCUITS; SPUTTERING. [R.A.We.]

Molecular anthropology The study of primate phylogeny and human evolution through the genetic information in the deoxyribonucleic acid (DNA) of genomes and in the proteins that genes encode. The first studies in molecular anthropology used immunological and biochemical methods to obtain information from proteins on the degrees of genetic similarity of humans and other primates. These results not only placed chimpanzees and gorillas closest to humans rather than to orangutans but also indicated that the very close kinship between chimpanzees and gorillas was not any closer than the relation of each to humans. Subsequent studies that extracted genetic information directly from DNA extended this original finding. Indeed, the accumulating comparative DNA sequence data provide mounting evidence that the closest genetic kinship is between chimpanzees and humans rather than chimpanzees and gorillas.

The results gathered in DNA studies of primate phylogeny challenge the traditional anthropological view that humans are very different from all other animals. DNA results show that, genetically, humans are only slightly remodeled apes. Humans share with their closest relatives, the chimpanzees and bonobos (pygmy chimpanzees), more than 98.3% identity in typical noncoding DNA and probably about 99.5% identity in the active coding sequences of functional nuclear genes. Humans share about 98.0% identity in nuclear genomic DNA with gorillas, 96.5% identity with orangutans, and 95.0% identity with the most distant ape relatives, the gibbons and siamangs. Apes and humans share with the other branch of catarrhines, the Old World monkeys, about 92% identity in nuclear genomic DNA, and with the platyrrhines, the New World monkeys, about 87% identity. Even with nonanthropoid primates, the tarsiers and strepsirhines (lemurs and loriforms, such as bushbabies), the anthropoids (platyrrhines and catarrhines) share a DNA identity in the range of 76–71%. *See* DEOXYRIBONUCLEIC ACID (DNA).

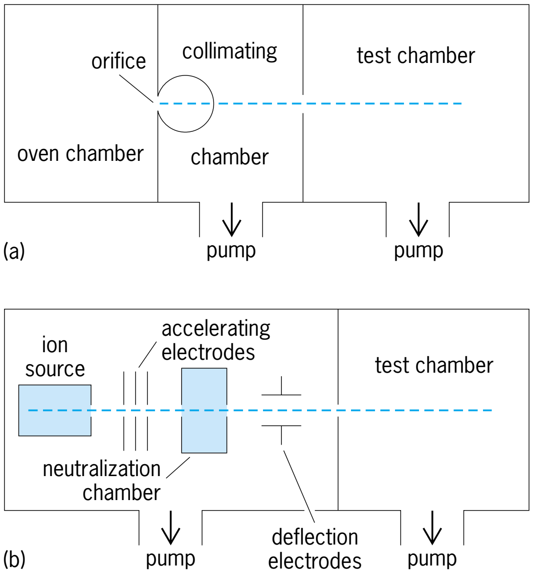
Traditional primate classifications use the vague concept of grades of evolutionary advancement to place the smaller-brained primates in the suborder Prosimii (the primitive grade) and the larger-brained primates in the suborder Anthropoidea (the advanced grade). Moreover, on viewing humans as the most advanced primates, traditional primate classifications have humans as the sole living members of family Hominidae, while the great apes of Africa (chimpanzees, bonobos, gorillas) and Asia (orangutans) are members of subfamily Ponginae of family Pongidae. In contrast, a strictly objective view based on molecular evidence, but also congruent morphological evidence from both living and fossil primates, not only places apes with humans within the family Hominidae but also within this family places chimpanzees and bonobos with humans in the genus *Homo*. *See* APES; FOSSIL APES; FOSSIL HUMANS; FOSSIL PRIMATES; MAMMALIA.

After the divergence of *Homo* (*Homo*) from *Homo* (*Pan*) *paniscus* (bonobos, or pygmy chimpanzees), humankind's emergence was marked by mutations (such as DNA sequence changes) that spread to fixation in the ancestors of all modern humans. These mutations are the human-specific factors which distinguish the human species genetically from all other species. Ongoing evolution involves mutations that have not spread to fixation, either because they occurred too recently or because natural selection has maintained a polymorphic state. These mutations occur at frequencies that occasionally differ from one human group to another. They account for the genetic diversity found in the human species. Extensive comparative data now exist on the genetic diversity due to mitochondrial genetic variants (which arise from mutations in the DNA carried by mitochondria). The species-wide distribution of mitochondrial haplotypes in present-day human populations compared to the distribution in chimpanzees reveals that humans show less DNA diversity than chimpanzees. Human populations in different ethnic groups (European Norwegians and South African hottentots) and even within the same group share 85–90% of the total species diversity. The human genetic diversity due to mutations in nuclear DNA (the DNA carried by the chromosomes of cells) also shows this same pattern in which most of the variation within the human species as a whole is contained within single populations. These findings argue that all living humans are biologically not only members of the same species but also the same subspecies and even the same race, the human race. A further inference from the data on mitochondrial genetic diversity is that the birth of the human race took place in Africa about 200,000 years ago. *See* MITOCHONDRIA. [M.Goo.]

Molecular beams Well-directed streams of atoms or molecules in vacuum. Utilization of molecular beams is a cornerstone technique in the investigation of molecular structure and interactions. Molecular beams are usually formed at sufficiently low particle density for the interaction of one beam molecule with another to be negligible. This ensemble of truly isolated molecules is available for the spectroscopic study of molecular energy levels using photon probes from the radio-frequency to optical portions of the electromagnetic spectrum. Some of the best-determined fundamental knowledge of physics comes from spectroscopic molecular-beam experiments. Beyond this, beams can be applied as probes of the multifaceted nature of gases, plasmas, surfaces, and even the structure of solids. An application intermediate in complexity is the study of molecular interactions by means of two colliding beams, where one might be a beam of charged particles such as ions or electrons. *See* SCATTERING EXPERIMENTS (ATOMS AND MOLECULES).

One simple means of forming a beam is to permit gas from an enclosed chamber to escape through a small orifice into a second chamber maintained at high vacuum by means of large pumps (illus. *a*). A useful number of molecules passes forward along the horizontal axis of the apparatus. A well-collimated beam is then formed by requiring that those molecules entering the test chamber where an experiment is to be performed pass not only through the orifice but also through a second small hole separating the collimating and test chambers.

If higher velocities are desired, a charge-exchange beam system can be used. In this scheme (illus. *b*), ions are produced by some ionizing process such as electron impact on atoms within a gas discharge. Since the ions are electrically charged, they can be accelerated to the desired velocity and focused into a beam using electric or magnetic fields. The last step in neutrally charged beam formation is to pass the ions through a neutralizing gas where electrons from the gas molecules are transferred to the beam ions in charge-exchange molecular collisions. *See* ION SOURCES.



Schematic diagrams of systems for producing molecular beams. (*a*) Conventional oven-beam system. (*b*) Charge-exchange beam system.

Much of molecular spectroscopy involves the absorption or emission of light by molecules in a gas sample. The frequency of the light photon is proportional to the separation of molecular energy levels involved in the spectroscopic transition. However, the molecule density in typical gas samples is so high that the energy levels are slightly altered by collisions between molecules, with the transition frequency no longer characteristic of the free molecule. The use of low-density molecular beams with their sensitive detection techniques can reduce this collision alteration problem, with the result that atomic properties can be measured to accuracies of parts per million or even better. If the very simplest atoms or molecules are employed, the basic electromagnetic interactions holding the component electrons and nuclei together can be precisely studied. This is of great importance to fundamental physics, since theoretical understanding of electromagnetic interactions through quantum electrodynamics represents the most successful application of quantum field theory to elementary particle physics problems. *See* QUANTUM ELECTRODYNAMICS; QUANTUM FIELD THEORY.

The development of tunable, strong laser sources of single-frequency light beams has added another dimension to molecular-beam experiments. With laser radiation resonantly tuned to excite a molecule from its normal ground state to one of its infinite number of vibrationally, rotationally, and electronically excited states, the number of possible studies and applications of excited molecular beams becomes enormous. *See* LASER SPECTROSCOPY; MOLECULAR STRUCTURE AND SPECTRA; NUCLEAR STRUCTURE. [J.E.B.]

Molecular biology The study of structural and functional properties of biological systems, pursued within the context of understanding the roles of the various molecules in living cells and the relationship between them. Molecular biology has its roots in biophysics, genetics, and biochemistry. A prime focus of the field has been the molecular basis of genetics, and with the demonstration in the mid-1940s that deoxyribonucleic acid (DNA) is the genetic material, emphasis has been on structure, organization, and regulation of genes. Initially, molecular biologists restricted their studies to bacterial and viral systems, largely because of their genetic and biochemical simplicity. *Escherichia coli* has been extensively examined because of its limited number of cellular functions and the corresponding restricted amount of genetic information encoded in the bacterial chromosome. Simple eukaryotic cells, such as protozoa and yeast, offer similar advantages and also have been studied. For these same reasons, bacteriophage and animal viruses have provided molecular biologists with the ability to study the structural and functional properties of molecules in intact cells. However, a series of conceptual and technological developments occurred rapidly during the late 1970s that permitted molecular biologists to approach a broad spectrum of plant and animal cells with experimental techniques. One of the major factors has been the development and applications of genetic engineering. Recombinant DNA technology allowed the isolation and selective modification of specific genes, thereby reducing both their structural and functional complexity and facilitating the study of gene expression in higher cells. The concepts and techniques used by molecular biologists have been rapidly and effectively employed to resolve numerous cellular, biological, and biochemical problems—becoming routine at both the basic and applied levels.

The recognition of DNA as the genetic material coupled with the discovery that genes reside in chromosomes resulted in an intensive effort to map genes to specific chromosomes. Initially genes were assigned to chromosomes on the basis of correlations between modifications in cellular function, particularly biochemical defects, and the addition, loss, or modification of specific chromosomes. *See* CHROMOSOME ABERRATION; MUTATION.

A major breakthrough was the development of somatic cell genetics. This is an approach in which, for example, human and hamster cells are fused, resulting in a hybrid cell initially containing the complement of human and hamster chromosomes. As the cells grow and divide in culture, the hamster chromosomes are retained while there is a progressive loss of human chromosomes. By correlating the loss of human biological or biochemical traits with the loss of specific human chromosomes, a number of human genes have been successfully mapped. *See* Somatic cell genetics.

The development of methods for isolating genes and for determining the genetic sequences of the DNA in which the genes are encoded, led to rapid advances in gene mapping at several levels of resolution. Localization of specific genes to chromosomes is routinely carried out with cloned genes as probes. Further information about the segment of a chromosome in which a specific gene resides can be obtained by directly determining the DNA sequences of both the gene itself and the surrounding region.

Chromosome localization of specific genes has numerous applications at both the basic and clinical levels. At the basic level, knowledge of the positions of various genes provides insight into potentially functional relationships. At the clinical level, chromosome aberrations are now routinely used in prenatal diagnosis of an extensive series of human genetic disorders, and several chromosomal modifications have been linked to specific types of cancer. Knowledge of genetic defects at the molecular level has permitted the development of diagnostic procedures that in some instances, such as sickle cell anemia, are based on a single nucleotide change in the DNA.

Recombinant DNA. Recombinant DNA technology has provided molecular biology with an extremely powerful tool. In broad terms, applications of recombinant DNA technology can be divided into four areas—biomedical, basic biological, agricultural, and industrial. Biomedical applications include the elucidation of the cellular and molecular bases of a broad spectrum of diseases, as well as both diagnostic and therapeutic applications in clinical medicine.

In a strictly formal sense, the term recombinant DNA designates the joining or recombination of DNA segments. However, in practice, recombinant DNA has been applied to a series of molecular manipulations whereby segments of DNA are rearranged, added, deleted, or introduced into the genomes of other cells.

The ability to manipulate or "engineer" genetic sequences is based on several developments.

1. *Methods for breaking and rejoining DNA*. The precise breaking and rejoining of DNA has been made possible by the discovery of restriction endonucleases, enzymes that have the ability to recognize specific DNA sequences and to cleave the double helix precisely at these sites. Also important are the ability to join fragments of DNA together with the enzyme DNA ligase, and the techniques to determine the nucleotide sequence of genes and thereby confirm the identity and location of structural and regulatory sequences.

2. *Carriers for genetic sequences*. Bacterial plasmids, that is, circular double-stranded DNA molecules that replicate extrachromosomally, have been modified so that they can serve as efficient carriers for segments of DNA, complete genes, regions of genes, or sequences contained within several different genes. Bacteriophage and animal viruses, retroviruses, and bovine papilloma virus have also been successfully utilized as DNA carriers. These carriers are referred to as cloning vectors. Host cells in which vectors containing cloned genes can replicate range from bacteria to numerous other cells, including normal, transformed, and malignant human cells.

3. *Introduction of recombinant DNA molecules*. Genetic sequences in the form of isolated DNA fragments, or chromosomes, or of DNA molecules cloned in plasmid vectors can be introduced into host cells by a procedure referred to as transfection or DNA-mediated gene transfer—a technique that renders the cell membrane permeable by a brief treatment with calcium phosphate, thereby facilitating DNA uptake. Genes cloned in viruses can also be introduced by infection of host cells.

4. *Selection of cells containing cloned sequences*. Bacterial cells containing plasmids with cloned genes can be detected by selective resistance or sensitivity to antibiotics. In addition, the presence of introduced genes in bacterial, plant, or animal cells can be assayed by a procedure known as nucleic acid hybridization.

5. *Amplification*. Amplification of genetic sequences cloned in bacterial plasmids is efficiently achieved by treatment of host cells with antibiotics which suppress replication of the bacterial chromosome, yet do not interfere with replication of the plasmid with its cloned gene. Sequences cloned in bacterial or animal viruses are often amplified by virtue of the ability of the virus to replicate preferentially. *See* Gene amplification.

6. *Expression*. Expression of cloned human genes can be mediated by regulatory sequences derived from the natural gene, from exogenous genes, or by host cell sequences.

Two clinically important genes, human insulin and human growth hormone, have been cloned and introduced into bacteria under conditions where biologically active hormones can be produced.

Progress has been made in applications of recombinant DNA technology to the resolution of agricultural problems, especially for the improvement of both crops and livestock. *See* Adenohypophysis hormone; Breeding (animal); Breeding (plant); Genetic engineering; Insulin.

Biophysical analysis. Understanding of the structural properties of molecules and the interaction between molecules that constitute biologically important complexes has been facilitated by biophysical analysis. For example, developments in the resolution offered by techniques such as electron microscopy, x-ray diffraction, and neutron scattering have provided valuable insight into the structure of chromatin, the protein-DNA complex which constitutes the genome of eukaryotic cells. These techniques have also provided clues about modifications in chromatin structure that accompany functional changes. One possible application of biophysical analysis is the diagnosis of human disorders by adaptation of nuclear magnetic resonance for tissue and whole body evaluation of soft tissue tumors, blood flow, and cardiac function. *See* Electron microscope; Nuclear magnetic resonance (NMR); X-ray diffraction.

Flow of molecular information. Information for all cellular activities is encoded in DNA; selective elaboration of this information is prerequisite to meeting both structural and biochemical requirements of the cell. In this regard, there are three major areas of investigations by molecular biologists: (1) the composition, structure, and organization of chromatin, the protein-DNA molecular complex in which genetic information is encoded and packaged; (2) the molecular events associated with the expression of genetically encoded information so that specific cellular biochemical requirements can be met; and (3) the molecular signals that trigger the expression of specific genes and the types of communication and feedback operative to monitor and mediate gene control. *See* Chromosome; Deoxyribonucleic acid (DNA); Gene; Genetic code; Nucleic acid. [G.S.S.; J.L.St.]

Molecular cloud A large and relatively dense cloud of cold gas and dust in interstellar space from which new stars are born. Molecular clouds consist primarily of molecular hydrogen (H_2) gas, with temperatures in the range 10–100 K. Molecular hydrogen is not directly observable under most conditions in molecular clouds. Therefore, almost all current knowledge about the properties of molecular clouds has been deduced from observations of trace constituents, mostly simple molecules such as carbon monoxide (CO), which have strong emission lines in the centimeter-, millimeter-, and submillimeter-wavelength portions of the electromagnetic spectrum. The majority of clouds lie in a broad Molecular Ring encircling the galactic center with an inner radius of about 3 kiloparsecs and an ill-defined outer radius extending to beyond 20 kpc. *See* Radio astronomy.

Molecular clouds are the principal sites of ongoing star formation. Therefore, they tend to be associated with young stars and star-forming regions. The nearest star-forming clouds are found in the constellations Ophiuchus, Taurus, and Perseus, at distances of 125, 140, and 300 parsecs (1 parsec = 3×10^{13} km or 2×10^{13} mi), where the nearest regions of active low- and intermediate-mass star formation are found. These cloud complexes have masses ranging from several thousand to perhaps over 10,000 times the mass of the Sun. However, most of the molecular gas in the Milky Way Galaxy is concentrated into giant clouds with masses more than 100,000 times the mass of the Sun. The nearest giant molecular clouds are located at a distance of 460 parsecs toward the constellation Orion where, over the last 10^7 years, they gave birth to tens of thousands of stars, including several dozen relatively rare high-mass stars. *See* ORION NEBULA; PROTOSTAR.

Most molecular clouds have temperatures of only 10 K. Molecular clouds are orders of magnitude more dense than the general interstellar medium, with gas densities ranging from about 10 molecules per cubic centimeter on large scales to over 10^6 molecules per cubic centimeter in cloud cores. The sizes of individual clouds range from less than 0.1 parsec for small clouds and dense cores to over 100 parsecs for giant molecular clouds. In addition to star-forming molecular clouds concentrated toward the plane of the Milky Way, there are many smaller and lower-density molecular clouds visible most clearly far away from the galactic plane, with the closest ones only about 50 parsecs from the Sun.

Molecular clouds have a very complex internal structure consisting of clumps and filaments of dense gas surrounded by interclump gas of much lower density. Individual clumps usually have supersonic internal motions with a velocity of several kilometers per second. The powerful outflows produced by young stars during the first 100,000 years of their existence may be a major source of these chaotic motions. Magnetic fields which thread molecular clouds may play a role in the longevity of turbulent motions and may support clouds against gravitational collapse.

About 100 different chemical species have been so far identified within molecular clouds, indicating that there is a rich chemistry taking place. *See* INTERSTELLAR EXTINCTION. [J.Ba.]

Molecular isomerism The property of compounds (isomers) which have the same molecular formula but different physical and chemical properties. The difference in properties is caused by a difference in molecular structure (that is, molecular architecture). A typical example is dimethyl ether, CH_3OCH_3, a chemically quite inert gas which condenses at −24°C, and ethyl alcohol, CH_3CH_2OH, a liquid of substantial chemical reactivity which boils at 78°C; both compounds have the molecular formula C_2H_6O.

Isomers may be classified as constitutional isomers or stereoisomers. Constitutional isomers differ in constitution or connectedness, relating to the question as to which atoms are linked to which others and how. Dimethyl ether and ethanol (Fig. 1) are constitutional isomers. In dimethyl ether each carbon is connected to three hydrogen atoms and the one oxygen atom; the two carbon atoms are thus equivalent. In ethyl alcohol (ethanol) one carbon is linked to three hydrogen atoms and the other carbon; the second carbon is linked to the first carbon, two hydrogens, and the oxygen atom which, in turn, is linked to the sixth hydrogen atom; the two carbon atoms are not equivalent. Stereoisomers, in contrast, have the same constitution but differ in the three-dimensional array of the atoms in space, called configuration.

Constitutional isomers. Constitutional isomers have been subdivided into functional isomers, positional isomers, and chain isomers.

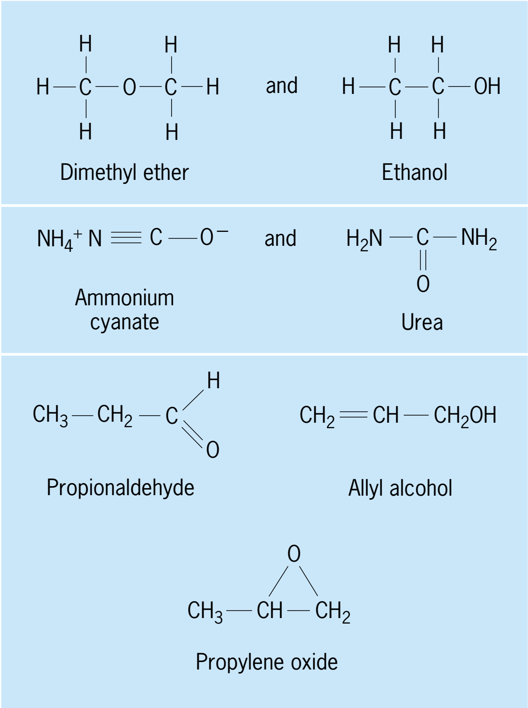


Fig. 1. Functional isomers.

Functional isomers (Fig. 1) differ in functional group, that is, the group (or groups) most material in determining chemical behavior. In the third example shown in Fig. 1 (propionaldehyde) the three compounds all correspond to the molecular formula C_3H_6O, but the first one has an aldehyde function, the second combines a double bond with an alcohol function, and the third one has an epoxide function.

Positional isomers (Fig. 2) have the same functional group but differ in its position along a chain or in a ring. Closely related are chain isomers which also have the same functional group or groups but differ in the shape of the carbon chain (Fig. 3*a*); quite

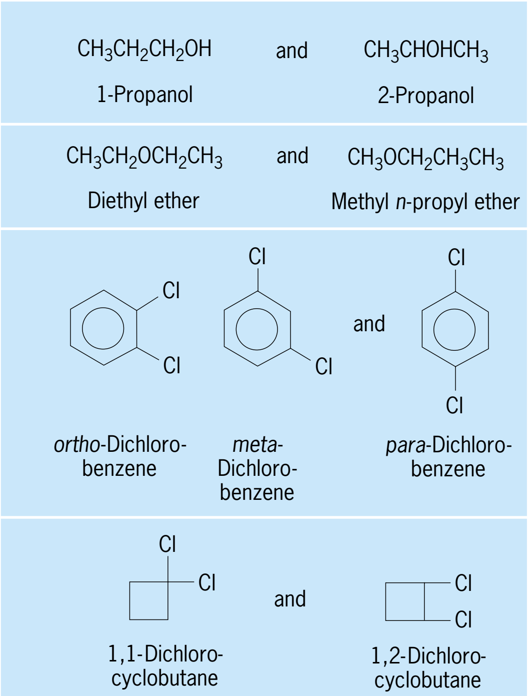

Fig. 2. Positional isomers.

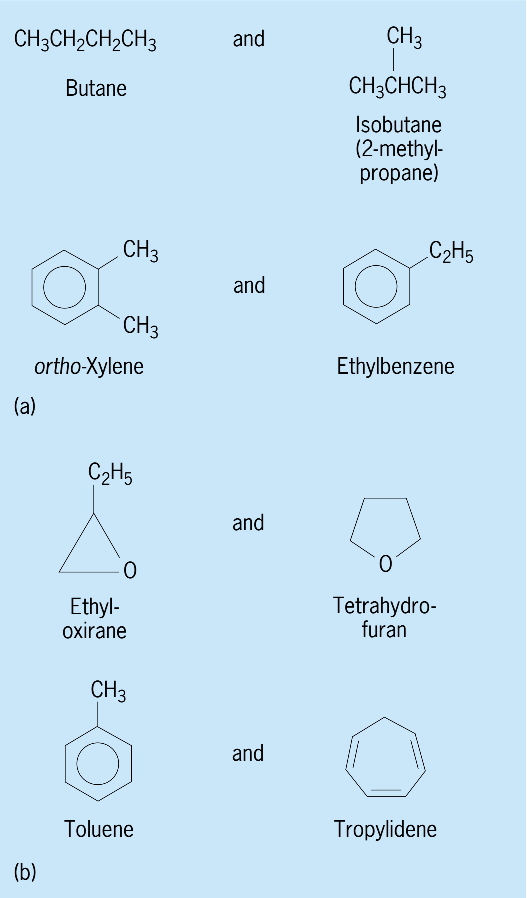

Fig. 3. Skeletal isomers. (*a*) Chain. (*b*) Ring.

similar are ring isomers (Fig. 3*b*) which differ in the size of one or more rings. Ring and chain isomers together are sometimes called skeletal isomers.

Stereoisomers. Compounds which have not only the same molecular formula but also the same constitution (connectivity of atoms) but which differ in the disposition of the atoms in space are called Stereoisomers. Stereoisomers, in turn, are subdivided into two types: those that are mirror images of each other, called enantiomers, and those which are not mirror images, called diastereomers or diastereoisomers.

Enantiomers are unique in that they always come in pairs. Either a molecule is superposable with its mirror image, in which case it does not have an enantiomer, or it is not superposable with its mirror image, in which case it has one and only one enantiomer (since an object can have only one mirror image). Molecules which are not superposable with their mirror images are called chiral; those which are so superposable are called achiral. Enantiomers are much more alike than are other sets of isomers (constitutional isomers or diastereomers); thus they have the same melting point, boiling point, free energy, spectral properties, x-ray diffraction pattern, and so on.

Diastereomers have the same constitution but different spatial arrangement and are not mirror images. They resemble constitutional isomers in that there may be more than two isomers in a set and that their physical, energetic, and spectral properties are generally quite distinct. *See* CONFORMATIONS; ANALYSIS; STEREOCHEMISTRY; TAUTOMERISM. [E.L.E.]

Molecular machine A molecular device is an assemblage of a discrete number of molecular components (that is, a supramolecular structure) designed to achieve a specific function. Each molecular component performs a single act, while the entire supramolecular structure performs a more complex function, which results from the cooperation of the various molecular components. Molecular devices operate via electronic or nuclear rearrangements. Like any device, they need energy to operate and signals to communicate with the operator. The extension of the concept of a device, so common on a macromolecular level, to the molecular level is of interest not only for basic research but also for the growth of nanoscience and nanotechnology. *See* NANOTECHNOLOGY; SUPRAMOLECULAR CHEMISTRY.

A molecular machine is a particular type of molecular device in which the component parts can display changes in their relative positions as a result of some external stimulus. Such molecular motions usually result in changes of some chemical or physical property of the supramolecular system, resulting in a "readout" signal that can be used to monitor the operation of the machine. The reversibility of the movement, that is, the possibility to restore the initial situation by means of an opposite stimulus, is an essential feature of a molecular machine. Although there are a number of chemical compounds whose structure or shape can be modified by an external stimulus (for example, photoinduced cis-trans isomerization processes), the term "molecular machines" is used only for systems showing large-amplitude movements of molecular components.

The human body can be viewed as a very complex ensemble of molecular-level machines that power motions, repair damage, and orchestrate an inner world of sense, emotion, and thought. Among the most studied natural molecular machines are those based on proteins such as myosin and kynesin, whose motions are driven by adenosine triphosphate (ATP) hydrolysis. One of the most interesting molecular machines of the human body is ATP synthase, a molecular-level rotatory motor. In this machine, a proton flow through a membrane spins a wheellike molecular structure and the attached rodlike species. This changes the structure of catalytic sites, allowing uptake of adenosine diphosphate (ADP) and inorganic phosphate, their reaction to give ATP, and then the release of the synthesized ATP. *See* ADENOSINE TRIPHOSPHATE (ATP).

An artificial molecular machine performs mechanical movements analogous to those observed in artificial macroscopic machines (for example, tweezers, piston/cylinder, and rotating rings). Analogously to what happens for macroscopic machines, the energy to make molecular machines work (that is, the stimulus causing the motion of the molecular components of the supramolecular structure) can be supplied as light, electrical energy, or chemical energy. In most cases, the machinelike movement involves two different, well-defined and stable states, and is accompanied by on/off switching of some chemical or physical signal [absorption and emission spectra, nuclear magnetic resonance (NMR), redox potential, or hydronium ion (H_3O^+) concentration]. For this reason, molecular machines can also be regarded as bistable devices for information processing (Fig. 1). *See* ACID AND BASE.

The interest in molecular machines arises not only from their mechanical movements but also from their switching aspects. Computers are based on sets of components constructed by the top-down approach. This approach, however, is now close to its intrinsic limitations. A necessary condition for further miniaturization to increase the power of information processing and computation is the bottom-up construction of molecular-level components capable of performing the functions needed (chemical computer). The molecular machines described above operate according to a binary logic and therefore can be used for switching processes at the molecular level. It has already been shown that suitable designed machinelike systems can be employed to perform complex functions such as multipole switching, plug/socket connection of molecular wires, and XOR logic operation. *See* LOGIC. [V.B.]

Molecular mechanics A non-quantum-mechanical way of computing structures, energies, and some properties of molecules. While quantum mechanics treats electrons explicitly, molecular mechanics treats electrons implicitly. For this reason, molecular mechanics calculations are much faster than quantum calculations, and this method is heavily used by scientists who need to quickly determine shapes of molecules. The goal of molecular mechanics is to build a computer model of reality. This is done with potential energy functions. Parameters are then selected for those potential functions so that molecules whose structures, energies, and properties are known can be reproduced with a specified degree of precision. Once that has been accomplished, the molecular mechanics model may be used to compute structures, energies, and properties of unknown molecules. *See* ENERGY.

Molecular mechanics considers molecules as a collection of atomic masses held together by "sticky" forces. These forces represent the electrons holding the atoms together to form molecules. A simple conception is to consider the atoms as balls connected by springs. In this model, as in all real molecules, the atoms migrate toward their lowest-energy, most stable positions. Anything that moves the atoms from their equilibrium positions increases the internal energy of the molecule. This energy, like that of a mechanical spring model, is the potential energy. If one of the bonds were elongated (or compressed) by pulling (or pushing) it from its resting length, the potential energy would increase, and a restoring force would return it to equilibrium position. The magnitude of this restoring force depends on the strength of the spring connecting the masses. This, in turn, is proportional to the strength of the bond connecting the atoms.

Molecular mechanics has several limitations. Most important, it is necessary to have access to a dataset of known, related molecules to use for parametrization. Thus the discovery of completely new molecular species with this computational method is not possible. Also, molecular mechanics cannot account for bond making or bond breaking (the essence of chemical reactions) because of the way it implicitly treats electrons. Finally, the motionless structure computed is not very realistic, so many scientists implement molecular dynamics to achieve better model molecules. *See* COMPUTATIONAL CHEMISTRY. [K.B.L.]

Molecular orbital theory A quantum-mechanical model concerned with the description of the discrete energy levels associated with electrons in molecules. One useful way to generate such levels is to assume that the molecular orbital wave function (ψ_j) may be written as a simple weighted sum of the constituent atomic orbitals (χ_i) [Eq. (1)]; this is called

$$\psi_j = \Sigma c_{ij} \chi_i \qquad (1)$$

the linear combination of atomic orbitals approximation. The c_{ij} coefficients may be determined numerically by substitution of Eq. (1) into the Schrödinger equation and application of the variational theorem. The theorem states that an approximate wave function will always be an upper bound to the true energy; thus minimization of the energy of the system given by the wave function of Eq. (1) will provide the best values of c_{ij}. Once the wave function is known, its associated energy may be calculated. The energies of the occupied orbitals in molecules may be probed by using photoelectron spectroscopy, which gives a good check on the accuracy of the theory. There are some simple concepts that contribute to a qualitative understanding of these molecular orbital energy levels and hence an insight into chemical bonding in molecules. They may be illustrated with reference to the hydrogen molecule. *See* CHEMICAL BONDING; ELECTRON SPECTROSCOPY; QUANTUM MECHANICS; SCHRÖDINGER'S WAVE EQUATION.

First, the basis orbitals (χ_i) used in the expansion of Eq. (1) can usefully be restricted to include the valence orbitals only. For molecular hydrogen (H_2) the 1*s* orbitals on the two hydrogen atoms are then the only two orbitals to be included. Second, since hydrogen atoms are chemically identical, any observable characteristic whose value might be computed with Eq. (1) must be the same for both atoms. This leads to the requirement that $c^2{}_{1j} = c^2{}_{2j}$, where the labels 1,2 refer to hydrogen atoms 1 and 2. As a consequence $c_{1j} = \pm c_{2j}$.

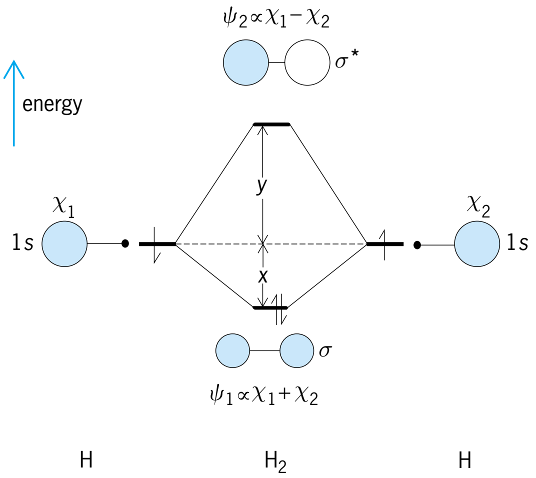

Fig. 1. Molecular orbital diagram of H_2.

When the signs of the two coefficients are the same, the two hydrogen orbitals are mixed in phase; when they are different, the two hydrogen orbitals are mixed out of phase. When the atomic orbitals are mixed in phase, electron density is built up between the two hydrogen nuclei and the potential energy of the nuclei and electrons is lowered. In fact, a reduction of kinetic energy also occurs. An electron lying in the molecular orbital is then of lower energy than an electron associated with an isolated hydrogen 1*s* orbital. It is called a bonding orbital. The increase in electron density between the two nuclei is the electronic "glue" holding the nuclei together. When the atomic orbitals are mixed out of phase, the opposite behavior occurs. Electron density is removed from the region between the two nuclei, resulting in an increase of both potential and kinetic energy of the electrons. An electron lying in such a molecular orbital would experience an energetic destabilization relative to an electron associated with an isolated hydrogen 1*s* orbital.

Such a molecular orbital is called an antibonding orbital. Figure 1 shows this information as a molecular orbital diagram. The shading convention of the orbitals has been adopted to indicate the in-phase and out-of-phase mixing of the basis orbitals. Just as the energy levels of atoms are filled in an Aufbau process, so the orbitals of the molecule may be analogously filled up with electrons, each level accommodating two electrons of opposite spin. In H_2 there are two electrons to be accounted for. They lie in the bonding orbital, and the stabilization energy relative to two isolated hydrogen atoms (the bond energy) is $2x$. Antibonding orbitals are invariably destabilized more than their bonding counterparts are stabilized. This is shown in Fig. 1 by making $y > x$. With four electrons to be accommodated in this collection of orbitals (this would correspond to the hypothetical case of the He_2 molecule), one electron pair resides in the bonding orbital and one pair in the antibonding orbital. Since $y > x$, this molecule is less stable relative to two isolated helium atoms, and as a result the molecule does not exist as a stable entity. ${He_2}^+$, however, with only three electrons is known.

The size of the interaction energy associated with two atomic orbitals (x in Fig. 1) is controlled by the extent of their spatial overlap. This overlap integral clearly depends upon the internuclear separation. The equilibrium bond length in the hydrogen molecule (and indeed in all molecules) is then a balance between the attractive forces associated with bonding orbital formation and the electrostatic repulsion between the nuclei. Such a molecular parameter is amenable to numerical calculation.

The description of the bonding in the H_2 molecule using this model is one where two electrons occupy a bonding orbital and

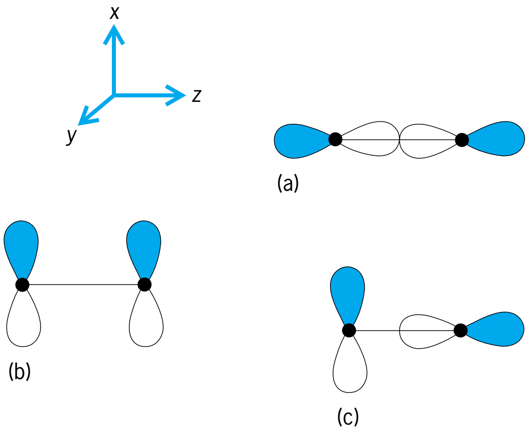

Fig. 2. Possible orientations of the *p* orbitals on adjacent atomic centers. (*a*) End-on overlap. (*b*) Sideways overlap. (*c*) Zero overlap.

give rise to a simple two-center–two-electron bond traditionally written as H—H. Since the electron density associated with the bonding orbital is cylindrically and symmetrically located about the H—H axis, this bond is called a σ bond. In Fig. 1 the bonding orbital is labeled with a σ and the corresponding antibonding orbital with a σ^*.

Ideas similar to those above are readily extended to diatomic molecules from the first row of the periodic table, such as N_2 and O_2, where the valence orbitals to be considered are the one 2*s* and the three 2*p* orbitals of the atoms. The 2*s* orbitals lie deeper in energy than the triply degenerate 2*p* orbitals. The atomic 2*s* orbitals form bonding and antibonding orbitals ($s\sigma$ and $s\sigma^*$) just as in the case of elemental hydrogen described above, but the behavior of the 2*p* orbitals is a little different. Here there are three possible types of interaction between the *p* orbitals on one center and those on the other. The end-on overlap of two *p* orbitals gives rise to a σ interaction (Fig. 2*a*), and the sideways overlap of two *p* orbitals gives rise to a π interaction (Fig. 2*b*). The interaction in Fig. 2*c* can be ignored since the overlap between the two orbitals in this orientation can be seen to be identically zero. The result is a σ-bonding orbital and a σ-antibonding orbital ($p\sigma$ and $p\sigma^*$), and a pair of π-bonding and a pair of π-antibonding orbitals (π and π^*). A larger interaction energy is associated with $p\sigma$ compared to $p\pi$, due to the larger σ overlap compared to π overlap in Fig. 2.

Filling these orbitals with electrons allows comment on the stability of the resulting diatomics. The molecule Li_2 $(s\sigma)^2$ is known and, like H_2, may be written as Li—Li to emphasize the single, two-center, two-electron bond between the nuclei. The molecule Be_2 which would have the configuration $(s\sigma)^2(s\sigma^*)^2$ is unknown since, just as in He_2, $s\sigma^*$ is destabilized more than $s\sigma$ is stabilized relative to an atomic 2*s* level. If the molecular orbital bond order is written as expression (2), then the bond order in Li_2 is one but

$$\begin{aligned}\begin{matrix}\text{Molecular}\\\text{bond order}\end{matrix} &= \left(\begin{matrix}\text{number of bonding}\\\text{electron pairs}\end{matrix}\right)\\ &\qquad - \left(\begin{matrix}\text{number of antibonding}\\\text{electron pairs}\end{matrix}\right) \qquad (2)\end{aligned}$$

the bond order in Be_2 is zero.

By filling up the molecular orbital levels derived from the 2*p* orbitals, the bond order associated with the other diatomics may be generated: $B_2(1)$, $C_2(2)$, $N_2(3)$, $O_2(2)$, $F_2(1)$, and $Ne_2(0)$. All of these species are known except Ne_2, which is predicted, like He_2 and Be_2, to have a zero bond order and therefore not to exist as a stable molecule. The molecular orbital bond orders for the three best-known diatomics are consistent with their traditional formulation as N≡N, O═O, and F—F. N_2, for example, would be described as having one σ and two π bonds. With the configuration $(s\sigma)^2(s\sigma^*)^2(p\sigma)^2$–$(\pi)^4(\pi^*)^2$, there are four bonding pairs of electrons and two antibonding pairs giving rise to a net bond order of two. The pair of π^* orbitals is only doubly occupied, whereas there is space for four electrons. Hund's rules (which for the electronic ground state maximize the number of electrons with parallel spins) identify the lowest-energy arrangement as the one where each of the degenerate π^* components is singly occupied, the spins of the two electrons being parallel. Unpaired electrons give rise to paramagnetic behavior, and gaseous oxygen is indeed paramagnetic. [J.K.Bu.]

Molecular pathology A discipline that deals with the origins and mechanisms of diseases at their most fundamental level, that of macromolecules such as deoxyribonucleic acid (DNA) and protein, in order to provide precise diagnoses and discover possible avenues for treatment. It is interdisciplinary, including infectious disease, oncology, inherited genetic disease, and legal issues such as parentage determination or forensic identity testing. While a variety of biophysical and biochemical techniques can be applied to study the molecular basis of disease, antibodies and nucleic acid probes are two of the principal approaches. *See* ANTIBODY; NUCLEIC ACID; ONCOLOGY.

When monoclonal antibodies are either tagged to permit their detection or immobilized on a chromatographic column to purify their specific target molecule, they serve as powerful tools for analyzing pathologic processes. A monoclonal antibody conjugated to an enzyme generating a colored reaction product is the basis of the enzyme-linked immunosorbent assay (ELISA), which is widely applied in many diagnostic tests. Autoantibodies from the sera of individuals with autoimmune diseases are often used as highly specific reagents for understanding the nature of these diseases and the role that the affected molecules or organelles normally perform in the cell. These autoantibodies can be detected in tissues by using fluorescently tagged antibodies directed against human immunoglobulins. *See* AUTOIMMUNITY; MONOCLONAL ANTIBODIES.

In an analogous manner to immunohistochemistry, traditional histopathology can be enhanced by using in situ hybridization. With this technique, an infectious agent such as a virus or a specific messenger ribonucleic acid (mRNA) can be localized within a specific cell or tissue.

Diseases often result from germline or somatic mutations in the individual's DNA, such as are seen in sickle cell disease or cancer, respectively. These abnormalities can be detected by using two basic techniques of molecular genetics: the Southern blot and the polymerase chain reaction (PCR). For the Southern blot, high-molecular-weight DNA isolated from a specimen (most commonly peripheral-blood white cells) is digested by using an appropriate restriction endonuclease. The resulting fragments are then separated by gel electrophoresis and transferred to a nylon membrane, which is incubated with a solution containing a specific, labeled probe, also in single-stranded form. Probe-target hybrids formed by annealing of their complementary sequences can be detected by autoradiography or a colorimetric reaction. The Southern blot technique can detect DNA polymorphisms, mutations, or the presence of viral, bacterial, or specific sex chromosomes. In the polymerase chain reaction, short oligonucleotide primers flank the specific gene region or RNA sequence to be amplified and are combined with the target specimen and free nucleotides, which are synthesized into new DNA. An automated thermal cycler repeatedly alters the temperature to denature the target DNA, to allow the primers to reanneal to the target, and then to synthesize the product. This amplified polymerase chain reaction product is typically detectable as a band in a gel.

Understanding diseases at the genetic level has several advantages. Even when the gene's protein product is not expressed, definitive diagnoses can be made by using DNA-based techniques. Diseases that are similar clinically (phenotypically) can, in fact, be due to different mutations (genotypes) within a single gene or due to mutations in different genes, often related in an enzyme complex or as a portion of a group of structural proteins. Another advantage of molecular diagnosis is the ability to detect phenotypically normal carriers of genetic diseases in order to provide information for appropriate genetic counseling and prenatal diagnosis. *See* Human genetics; Mutation; Pathology.

[M.A.Lo.]

Molecular physics The study of the physical properties of molecules. Molecules possess a far richer variety of physical and chemical properties than do isolated atoms. This is attributable primarily to the greater complexity of molecular structure, as compared to that of the constituent atoms. Molecules also possess additional energy modes because they can vibrate; that is, the constituent nuclei oscillate about their equilibrium positions and rotate when unhindered. These modes give rise to additional spectroscopic properties, as compared to those of an atom; molecular spectroscopy in the optical, infrared, and microwave regions is one of the physical chemist's most powerful means of identifying and understanding molecular structure. Molecular spectroscopy has also given rise to the rapidly growing field of molecular astronomy.

Molecular physics is primarily concerned with the study of properties of isolated molecules, as contrasted to the more general study of molecular reactions, which is the domain of physical chemistry. Such properties, in addition to the broad field of spectroscopy, include electron affinities (for the formation of molecular negative ions); polarizabilities (the "distortability" of the molecule along its various symmetry axes by external electric fields); magnetic and electric multipole moments, attributable to the distributions of electric charge; currents and spins of the molecule; and the (nonreactive) interactions of molecules with other molecules, atoms, and ions. *See* Cosmochemistry; Infrared spectroscopy; Intermolecular forces; Microwave spectroscopy; Molecular beams; Molecular structure and spectra; Spectroscopy.

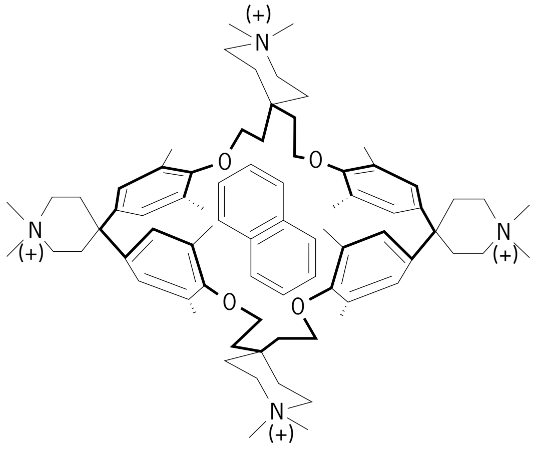
[B.B.]

Molecular recognition The ability of biological and chemical systems to distinguish between molecules and regulate behavior accordingly. How molecules fit together is fundamental in disciplines such as biochemistry, medicinal chemistry, materials science, and separation science. A good deal of effort has been expended in trying to evaluate the underlying intermolecular forces. The weak forces that act over short distances (hydrogen bonds, van der Waals interactions, and aryl stacking) provide most of the selectivity observed in biological chemistry and permit molecular recognition. The recognition event initiates behavior such as replication in nucleic acids, immune response in antibodies, signal transduction in receptors, and regulation in enzymes. Most studies of recognition in organic chemistry have been inspired by these biological phenomena. It has been the task of bioorganic chemistry to develop systems capable of such complex behavior with molecules that are comprehensible and manageable in size, that is, with model systems. *See* Antibody; Chemoreception; Enzyme; Hydrogen bond; Intermolecular forces; Nucleic acid; Synaptic transmission.

The advantage of cyclic structures lies in their ability to restrict conformation or flexibility. A rigid matrix of binding sites, that is, preorganized sites, is usually associated with high selectivity in binding. A flexible matrix tends to accept several binding partners. Although sacrificing selectivity, this has the advantage of transmitting conformational information and is relevant to biological signaling events.

Macrocyclic (crown) ethers can bind and transport ions and imitate biological processes involving macrolides. Large ring structures that are lined with oxygen present an inner surface which is complementary to the spherical outer surface of positively charged ions.

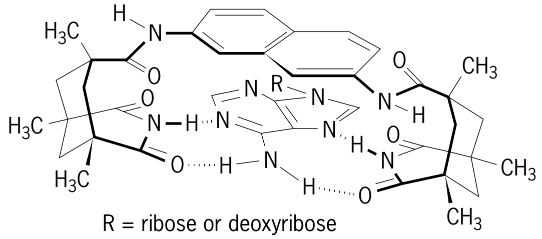
Cyclophane-type structures offer considerable rigidity because of the aromatic nuclei. Binding forces between host and guest are largely hydrophobic. A typical system is a cyclophane-naphthalene complex (**1**), in which a naphthalene guest is bound by a water-soluble cyclophane derivative. Other macrocyclic structures include the cyclodextrins and hybrid structures assembled from macrocyclic subunits. *See* Aromatic hydrocarbon; Coordination complexes; Naphthalene.



(1)

Because the encircling of larger, more complex molecules with macrocycles poses structural problems, other molecular shapes have been explored. Cleft molecules offer advantages in this regard. The principle underlying these systems involves the shape of the small organic target molecules: convex in surface and bearing functional groups that diverge from their centers. Accordingly, designing a trap for such targets requires molecules of a concave surface in which functional groups converge. This complementarity is also a feature of the immune system: the "hot spots" of an antigen tend to be convex, whereas the binding sites of the antibody are concave.

Systems featuring a cleft have been developed to bind adenine derivatives and other heterocyclic systems through chelation, as shown in (**2**). *See* Chelation.



(2)

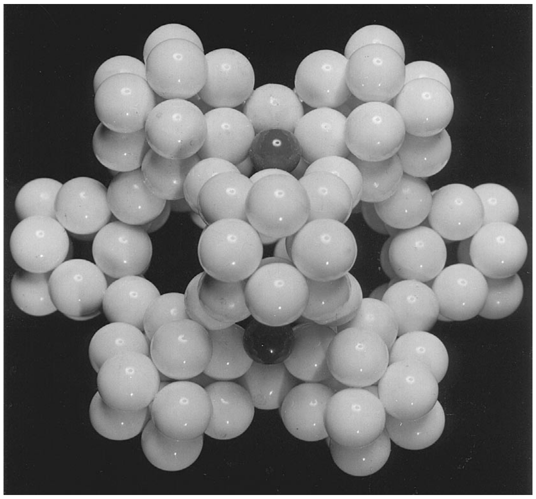
Apart from the abstract questions concerning articulation of molecules, some practical applications in the pharmaceutical industry may be envisioned. Many of the target structures are biologically active, and the use of synthetic sequestering agents for metabolic substrates can represent a novel approach to biochemical methods and drug delivery.

[J.Reb.]

Molecular sieve Any one of the crystalline metal aluminosilicates belonging to a class of minerals known as zeolites. An important characteristic of the zeolites is their ability to undergo dehydration with little or no change in crystal structure. The dehydrated crystals are honeycombed with regularly spaced cavities interlaced by channels of molecular dimensions which offer a very high surface area for the absorption of foreign molecules.

The basic formula for all crystalline zeolites can be represented as

$$M_{2/n}O:Al_2O_3:xSiO_2:yH_2O$$



Molecular sieve type-A crystal model. Dark spheres represent the included cations, and light spheres the SiO_4 or AlO_4 tetrahedrons.

where M represents a metal ion and *n* its valence. The crystal structure consists basically of a three-dimensional framework of SiO_4 and AlO_4 tetrahedrons (see illustration). The tetrahedrons are cross-linked by the sharing of oxygen atoms, so that the ratio of oxygen atoms to the total of silicon and aluminum atoms is equal to 2. The electrovalence of the tetrahedrons containing aluminum is balanced by the inclusion of cations in the crystal. One cation may be exchanged for another by the usual ion-exchange techniques. The size of the cation and its position in the lattice determine the effective diameter of the pore in a given crystal species.

The properties of molecular sieves as adsorbents which distinguish them from nonzeolitic adsorbents are (1) the relatively strong coulomb fields generated by the adsorption surface and (2) the uniform pore size; the pore size is controlled, in a given crystal species, by the associated cation.

The basic characteristics of molecular sieves are utilized commercially in several production and research applications. Their absorption properties make them useful for drying, purification, and separations of gases and liquids. Conversely, molecular sieves can be preloaded with chemical agents, which are thereby isolated from the reactive system in which they are dispersed until released from the adsorbent either thermally or by displacement by a more strongly adsorbed compound. They are also used as cation exchange media and as novel catalysts and catalyst supports. *See* ADSORPTION; GAS CHROMATOGRAPHY; ION EXCHANGE; ZEOLITE. [R.L.Ma.]

Molecular simulation A tool for predicting entirely computationally many useful functional properties of systems of interest in the chemical, pharmaceutical, materials, and related industries. Included are thermodynamic, thermochemical, spectroscopic, mechanical, and transport properties, and morphological information (such as location and shape of binding sites on a biomolecule and crystal structure).

The two main molecular simulation techniques are molecular dynamics and Monte Carlo simulation, both of which are rooted in classical statistical mechanics. Given mathematical models for the internal structure of each molecule (the intramolecular potential which describes the energy of each conformation of the molecule) and the interaction between molecules (the intermolecular potential which describes the energy associated with molecules being in a particular conformation relative to each other), classical statistical mechanics provides a formalism for predicting properties of a macroscopic collection of such molecules based on statistically averaging over the possible microscopic states of the system as it evolves under the rules of classical mechanics. Thus, the building blocks are molecules, the dynamics are described by classical mechanics, and the key concept is statistical averaging. In molecular dynamics, the microscopic states of the system are generated by solving the classical equations of motion as a function of time (typically over a period limited to tens of nanoseconds). Thus, one can observe the relaxation of a system to equilibrium (provided the time for the relaxation falls within the time accessible to molecular dynamics simulation), and so molecular dynamics permits the calculation of transport properties which at the macroscopic scale describe the relaxation of a system in response to inhomogeneities. In Monte Carlo simulation, equilibrium configurations of systems are generated stochastically according to the probabilities rigorously known from classical statistical mechanics. Thus, Monte Carlo simulation generates equilibrium states directly (which has many advantages, including bypassing configurations which are not characteristic of equilibrium but which may be difficult to escape dynamically) and so can be used to study equilibrium configurations of systems which may be expensive or impossible to access via molecular dynamics. The drawback of Monte Carlo simulation is that it cannot yield the kind of dynamical response information that leads directly to transport properties. *See* CHEMICAL DYNAMICS; COMPUTATIONAL CHEMISTRY; MONTE CARLO METHOD; SIMULATION; STOCHASTIC PROCESS.

Computational quantum chemistry and molecular simulation methods can be used to predict properties that once were only accessible experimentally, resulting in several significant applications in basic and industrial research. These applications include providing estimates of properties for systems for which little or no experimental data are available, which is especially useful in the early stages of chemical process design; yielding insight into the molecular basis for the behavior of particular systems, which is very useful in developing engineering correlations, design rules, or quantitative structure-property relations; and providing guidance for experimental studies by identifying the interesting systems or properties to be measured. [P.T.C.]

Molecular structure and spectra Until the advent of quantum theory, ideas about the structure of molecules evolved gradually from analysis and interpretation of the facts of chemistry. Chemists developed the concept of molecules as built from atoms in definite proportions, and identified and constructed (synthesized) a great variety of molecules. Later, when the structure of atoms as built from nuclei and electrons began to be understood with the help of quantum theory, a beginning was made in seeing why atoms can combine in definite ways to form molecules; also, infrared spectra began to be used to obtain information about the dimensions and the nuclear motions (vibrations) in molecules. However, a fundamental understanding of chemical bonding and molecular structure became possible only by application of the present form of quantum theory, called quantum mechanics. This theory makes it possible to obtain from the spectra of molecules a great deal of information about the nature of molecules in their normal as well as excited states, and about dissociation energies and other characteristics of molecules. *See* CHEMICAL BONDING.

Molecular sizes. The size of a molecule varies approximately in proportion to the numbers and sizes of the atoms in the molecule. Simplest are diatomic molecules. These may be thought of as built of two spherical atoms of radii r and r', flattened where they are joined. The equilibrium value R_e of the distance R between their nuclei is then smaller than the sum of the atomic radii. However, the nuclei of atoms in two different molecules cannot normally approach more closely than a distance $r + r'$; r and r' are called the van der Waals radii of the atoms.

To describe a polyatomic molecule, one must specify not merely its size but also its shape or configuration. For example, carbon dioxide (CO_2) is a linear symmetrical molecule, the

O—C—O angle being 180°. The H—O—H angle in the nonlinear water (H_2O) molecule is 105°. Many molecules which are essential for life contain thousands or even millions of atoms. Proteins are often coiled or twisted and cross-linked in ways which are important for their biological functioning.

Dipole moments. Most molecules have an electric dipole moment. In atoms, the electron cloud surrounds the nucleus so symmetrically that its electrical center coincides with the nucleus, giving zero dipole moment; in a molecule, however, these coincidences are disturbed, and a dipole moment usually results.

Thus, when the atoms of HCl come together, there is some shifting of the H-atom electron toward the Cl. A complete shift would give H^+Cl^-, which would constitute an electric dipole of magnitude eR_e, where e is the electronic charge. But in fact the dipole moment is only 0. 17 eR_e. This is because the actual electronic shift is only fractional. *See* Electronegativity.

Molecular polarizability. In the preceding consideration of dipole moments, the discussion has been in terms of atoms and molecules free from external forces. An electric field pulls the electrons of an atom or molecule toward it and pushes the nuclei away, or vice versa. This action creates a small induced dipole moment, whose magnitude per unit strength of the field is called the polarizability.

Molecular energy levels. The states of motion of nuclei and electrons in a molecule, or of electrons in an atom, are restricted by quantum mechanics to special forms with definite energies. The state of lowest energy is called the ground state; all others are excited states. In analogy to water levels, one speaks of energy levels. Excited states exist only momentarily, following an electrical or other stimulus. *See* Quantum chemistry; Quantum mechanics.

Excitation of an atom consists of a change in the state of motion of its electrons. Electronic excitation of molecules can also occur, but alternatively or additionally, molecules can be excited to discrete states of vibration and rotation.

The total energy of any molecule can be written as Eq. (1). Both the electronic energy E_{el} and vibration energy E_v can be

$$E = E_{el} + E_v + (E_r + E_{fs} + E_{hfs} + E_{ext}) \qquad (1)$$

discrete or continuous. The quantities E_r, E_{fs}, and E_{hfs} denote rotational, fine-structure, and hyperfine-structure energies. The last two appear as small or minute splittings of the rotation levels. The spacings ΔE of adjacent discrete levels of each type are usually in the order given in notation (2). The E_{ext} term in

$$\Delta E_{el} \gg \Delta E_v \gg \Delta E_r \gg \Delta E_{fs} \gg \Delta E_{hfs} \qquad (2)$$

Eq. (1) refers to additional fine structure which appears on subjecting molecules to external magnetic fields (Zeeman effect) or electric fields (Stark effect). *See* Fine structure (spectral lines); Hyperfine structure; Stark effect; Zeeman effect.

Polyatomic molecules have much more complicated patterns of vibrational and (usually) rotational energy levels than diatomic molecules.

Molecular spectra. The frequencies $c\nu$ (c = speed of light) of electromagnetic spectra obey the Einstein-Bohr equation (3),

$$hc\nu = E' - E'' \qquad (3)$$

where h is Planck's constant. Molecular emission spectra accompany jumps in energy from higher to lower levels; absorption spectra accompany jumps from lower to higher levels.

Molecular spectra can be classified as fine-structure or low-frequency spectra, rotation spectra, vibration-rotation spectra, and electronic spectra. *See* Electron paramagnetic resonance (EPR) spectroscopy; Magnetic resonance; Microwave spectroscopy; Molecular beams; Spectroscopy.

Transitions between energy levels differing only in rotational state give rise to pure rotation spectra. These typically consist of a sequence of lines spaced almost equidistantly, and lying in the far infrared or the microwave region.

Spectra involving only vibrational and rotational state changes consist of bands which lie mainly in the infrared. Each band consists of two sets of closely spaced rotational lines, one on each side of a central frequency. Vibration-rotation absorption bands of liquids and solutions are widely used in chemical analysis. Here the rotational structure is blurred out, and only an "envelope" is seen. *See* Infrared spectroscopy.

Electronic band spectra are the most general type of molecular spectra. For any one electronic transition, the spectrum consists typically of many bands. *See* Atomic structure and spectra; Intermolecular forces; Molecular weight; Raman effect; Resonance (molecular structure); Scattering experiments (atoms and molecules); Valence. [R.S.M.]

Molecular weight The sum of the atomic weights of all atoms making up a molecule. Actually, what is meant by molecular weight is molecular mass. The use of this expression is historical, however, and will be maintained. The atomic weight is the mass, in atomic mass units, of an atom. It is approximately equal to the total number of nucleons, protons and neutrons composing the nucleus. Since 1961 the official definition of the atomic mass unit (amu) has been that it is 1/12 the mass of the carbon-12 isotope, which is assigned the value 12.000 exactly. *See* Atomic mass; Atomic mass unit; Relative atomic mass; Relative molecular mass.

A mole is an amount of substance containing the Avogadro number, N_A, approximately 6.022×10^{23}, of molecules or atoms. Molecule, in this definition, is understood to be the smallest unit making up the characteristic compound. Originally, the mole was interpreted as that number of particles whose total mass in grams was numerically equivalent to the atomic or molecular weight in atomic mass units, referred to as gram-atomic or gram-molecular weight. This is how the above value for N_A was calculated. As the ability to make measurements of the absolute masses of single atoms and molecules has improved, however, modern metrology is tending to alter its approach and define the Avogadro number as an exact quantity, thereby changing slightly thebreak definition of the atomic mass unit and removing the need to define atomic weight with respect to a particular isotopic species. The latest and most accurate value forbreak the Avogadro number is $6.0221415(10) \times 10^{23}$ mol^{-1}. *See* Avogadro number; Mole (chemistry).

As the masses of all the atomic species are now well known, masses of molecules can be determined once the composition of the molecule has been ascertained. Alternatively, if the molecular weight of the molecule is known and enough additional information about composition is available, such as the basic atomic constituents, it is possible to begin to assemble structural information about the molecule. Thus, the determination of the molecular weight is one of the first steps in the analysis of an unknown species. Given the increasing emphasis on the study of biologically important molecules, particular attention has been focused on the determination of molecular weights of larger and larger units. There are a number of methods available, and the one chosen will depend on the size and physical state of the molecule. All processes are physical macroscopic measurements and determine the molecular weight directly. Connection to the absolute mass scale is straightforward by using the Avogadro number, although, for extremely large molecules, this connection is often unnecessary or impossible, as the accuracy of the measurements is not that good. The main function of molecular weight determination of large molecules is elucidation of structure.

Molecular weight determination of materials which are solid or liquid at room temperature is best achieved by taking advantage of one of the colligative properties of solutions, boiling-point elevation, freezing-point lowering, or osmotic pressure, which depend on the number of particles in solution, not on the nature of the particle. The choice of which to use will depend on a number of properties of the substance, the most important of which will be the size. All require that the molecule be small enough to dissolve in the solution but large enough not to participate in the phase change or pass through a semipermeable membrane. Freezing-point lowering is an excellent method for determining molecular weights of smaller organic molecules, and osmometry, as the osmotic pressure determination is called, for determining molecular weights of larger organic molecules, particularly polymeric species. Boiling-point elevation is used less frequently. *See* Polymer.

The basis of all the methods involving colligative properties of solutions is that the chemical potentials of all phases must be the same. (Chemical potential is the partial change in energy of a system as matter is transferred into or out of it. For two systems in contact at equilibrium, the chemical potentials for each must be equal.) *See* Chemical equilibrium; Chemical thermodynamics.

Another measurement from which molecular weights can be obtained is based on the scattering of light from the molecule. A beam of light falling on a molecule will induce in the molecule a dipole moment which in its turn will radiate. The interference between the radiated beam and the incoming beam produces an angular dependence of the scattered radiation which depends on the molecular weight of the molecule. This occurs whether the molecule is free or in solution. While the theory for this effect is complicated and varies according to the size of the molecule, the general result for molecules whose size is considerably less than that of the wavelength λ of the radiation (less than $\lambda/50$) is given by the equation below; $I(\theta)$ is the intensity of radiation at

$$\frac{I(\theta)}{I_0} = \text{constant } (1 + \cos^2\theta)\ Mc$$

angle θ, I_0 the intensity of the incoming beam, M the molecular weight, and c the concentration in grams per cubic centimeter of the molecule. If the molecules are much larger than $\lambda/50$ (about 9 nanometers for visible light), this relationship in this simple form is no longer valid, but the method is still viable with appropriate adjustments to the theory. In fact, it can be used in its extended version even for large aggregates. *See* Scattering of electromagnetic radiation. [C.D.C.]

Molecule A molecule may be thought of either as a structure built of atoms bound together by chemical forces or as a structure in which two or more nuclei are maintained in some definite geometrical configuration by attractive forces from a surrounding swarm of negative electrons. Besides chemically stable molecules, short-lived molecular fragments called free radicals can be observed under special circumstances. *See* Chemical bonding; Free radical; Molecular structure and spectra. [R.S.M.]

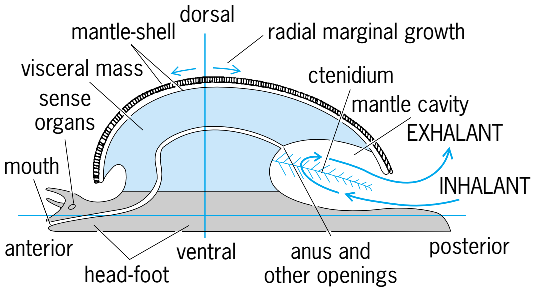
Mollusca A major phylum of the animal kingdom comprising an extreme diversity of external body forms (oysters, clams, chitons, snails, slugs, squid, and octopuses among others), all based on a remarkably uniform basic plan of structure and function. The phylum name is derived from *mollis*, meaning soft, referring to the soft body within a hard calcareous shell, which is usually diagnostic. Soft-bodied mollusks make extensive use of ciliary and mucous mechanisms in feeding, locomotion, and reproduction. Most molluscan species are readily recognizable as such.

The Mollusca constitute a successful phylum; there are probably over 110,000 living species of mollusks, a number second only to that of the phylum Arthropoda, and more than double the number of vertebrate species. More than 99% of living molluscan species belong to two classes: Gastropoda (snails) and Bivalvia. Ecologically, these two classes can make up a dominant fraction of the animal biomass in many natural communities, both marine and fresh-water.

Classification. The phylum Mollusca is divided into seven distinct extant classes, three of which (Gastropoda, Bivalvia, and Cephalopoda) are of major significance in terms both of species numbers and of ecological bioenergetics, and one extinct class. An outline of their classification follows.

- Class Monoplacophora (mainly fossil; but one living genus *Neopilina*)
- Class Aplacophora
  - Subclass Neomeniomorpha
  - Subclass Chaetodermomorpha
- Class Polyplacophora
- Class Scaphopoda
- Class Rostroconchia (fossil only)
- Class Gastropoda
  - Subclass Prosobranchia
    - Order: Archaeogastropoda
    - Mesogastropoda
    - Neogastropoda
  - Subclass Opisthobranchia
    - Order: Bullomorpha (or Cephalaspidea)
    - Aplysiomorpha (or Anaspidea)
    - Thecosomata
    - Gymnosomata
    - Pleurobranchomorpha (or Notaspidea)
    - Acochlidiacea
    - Sacoglossa
    - Nudibranchia (or Acoela)
  - Subclass Pulmonata
    - Order: Systellommatophora
    - Basommatophora
    - Stylommatophora
- Class Bivalvia (or Pelecypoda)
  - Subclass Protobranchia
  - Subclass Lamellibranchia
    - Order: Taxodonta
    - Anisomyaria
    - Heterodonta
    - Schizodonta
    - Adapedonta
    - Anomalodesmata
  - Subclass Septibranchia
- Class Cephalopoda
  - Subclass Nautiloidea
  - Subclass Ammonoidea (fossil only)
  - Subclass Coleoidea
    - Order: Belemnoidea
    - Sepioidea
    - Teuthoidea
    - Vampyromorpha
    - Octopoda

Functional morphology. The unique basic plan of the Mollusca involves the different modes of growth and of functioning of the three distinct regions of the molluscan body (see illustration). These are the head-foot with some nerve concentrations, most of the sense organs, and all the locomotory organs; the visceral mass (or hump) containing organs of digestion, reproduction, and excretion; and the mantle (or pallium) hanging from the visceral mass and enfolding it and secreting the shell. In its development and growth, the head-foot shows a bilateral symmetry with an anterioposterior axis of growth. Over and around the visceral mass, however, the mantle-shell shows a biradial symmetry, and always grows by marginal increment around a dorsoventral axis. It is of considerable functional importance that a space is left between the mantle-shell and the visceral mass forming a semi-internal cavity; this is the mantle cavity or pallial chamber within which the typical gills of the mollusk, the ctenidia, develop. This mantle cavity is almost diagnostic of the phylum; it is primarily a respiratory chamber housing the ctenidia, but with alimentary, excretory, and genital systems all discharging into it.



Generalized model of a stem mollusk (or archetype) in side view. There are three distinct regions in the molluscan body: head-foot, visceral mass, and mantle-shell. Water circulation through the mantle cavity, gills (ctenidia), and pallial complex is from ventral inhalant to dorsal exhalant. (*After W. D. Russell-Hunter, A Life of Invertebrates, Macmillan, 1979*)

In looking at any mollusk, it is important to realize that whatever the shape of the shell, it is always underlain by the mantle, a fleshy fold of tissues which has secreted it. The detailed structure of the shell and of the mantle edge (with three functionally distinct lobes) is also consistent throughout the Mollusca. The shell is made up of calcium carbonate crystals enclosed in a meshwork of tanned proteins. It is always in three layers: the outer periostracum, the prismatic layer and the innermost or nacreous layer.

Each of the eight classes of the Mollusca has a characteristic body form and shell shape. Two classes are enormous (Gastropoda and Bivalvia), one of moderate extent (Cephalopoda), the others being minor by comparison. The Gastropoda constitute a diverse group with the shell usually in one piece. This shell may be coiled as in typical snails—that is, helicoid or turbinate—or it may form a flattened spiral, or a short cone as in the limpets, or it may be secondarily absent as in the slugs. Most gastropods are marine, but many are found in fresh waters and on land; in fact, they are the only successful nonmarine mollusks.

The Bivalvia are a more uniform group, with the shell in the form of two calcareous valves united by an elastic hinge ligament. Mussels, clams, and oysters are familiar bivalves. The group is mainly marine with a few genera in estuaries and in fresh waters. There can be no land bivalves since their basic functional organization is as filter feeders. The third major group, the Cephalopoda, includes the most active and most specialized mollusks. There is a chambered, coiled shell in *Nautilus* and in many fossil forms; this becomes an internal structure in cuttlefish and squids, and is usually entirely absent in octopods.

A diversity of gill patterns have evolved in the major molluscan groups, paralleling the evolution of the mantle-shell patterns. The more advanced gastropods show reduction from a pair of aspidobranch ctenidia to a single one, and from that to a one-sided pectinibranch ctenidium (or comb gill), and subsequently to no gill at all in the pulmonate snails. The bivalves show enlargement of gill leaflets to longer filaments and their subsequent folding into the true lamellibranch condition, used in filter feeding. The gills in the cephalopods, while still structurally homologous, are modified with new skeletal elements to resist the stresses of water pumping by muscles.

Besides the gills, the other organs of the mantle cavity (termed collectively the pallial complex) again show morphological and functional consistency throughout the main groups of the Mollusca. The ctenidia form a curtain functionally dividing the mantle cavity into an inhalant part (usually ventral) containing the osphradia (pallial sense organs which sample the incoming water), and an exhalant part (usually dorsal) containing hypobranchial glands and both the anus and the openings of the kidney and genital ducts.

The cardiac structures of mollusks are also closely linked to the pallial complex. If there is a symmetrical pair of ctenidia, there will be a symmetrical pair of auricles on either side of the muscular ventricle of the heart; if one ctenidium, one auricle; if four ctenidia, four auricles. Note that body fluids in mollusks are almost all blood, just as body cavities are almost all hemocoel.

The respiratory pigment is usually hemocyanin in solution, so that neither circulatory efficiency nor blood oxygen-carrying capacity is high. However, mollusks are mostly sluggish animals with low metabolic (and hence respiratory) rates.

Uniquely molluscan is the use of cilia in “sorting surfaces,” which can segregate particles into different size categories and send them to be disposed of in different ways in several parts of the organism. In a simpler type of sorting surface, the epithelium is thrown into a series of ridges and grooves, the cilia in the grooves beating along them and the cilia on the crests of the ridges beating across them. Thus, fine particles impinging on the surface can be carried in the direction of the grooves, while larger particles are carried at right angles. Such sorting surfaces occur both externally on the feeding organs and internally in the gut of many mollusks. For example, on the labial palps of bivalves, they are used to separate the larger sand grains (which are rejected) from the smaller microorganisms which then pass to the mouth.

The range in levels of complexity of molluscan nervous systems is comparable to that found in the phylum Chordata. The four-strand nervous system with one pair of tiny ganglia found in chitons is not dissimilar to the neural plan in turbellarian flatworms. In contrast, the nervous system and sense organs of a cephalopod like an octopus are equaled and exceeded only by those of some birds and mammals. In the majority of mollusks the nervous system is in an intermediate condition. In mollusks other than cephalopods, the main effectors controlled by the nervous system are cilia and mucous glands. In fact, apart from the muscles which withdraw it into its shell, the typical mollusk is a slow-working animal with little fast nervous control or quick reflexes. In the brain of modern cephalopods, paired ganglia have been fused into a massive structure, with over 300 million neurons and extensive “association” centers providing considerable mnemic and learning capacities. *See* OCTOPUS.

In all primitive mollusks, the sexes are separate, and external fertilization follows the spawning of eggs and sperm into the sea.

In more advanced mollusks, eggs are larger (and fewer), fertilization may become internal (with complex courtship and copulatory procedures), and larval stages may be sequentially suppressed. A remarkably large number of mollusks (including many higher snails) are hermaphroditic. Although some are truly simultaneous hermaphrodites, many more show various kinds of consecutive sexuality. Most often the male phase occurs first, and these species are said to show protandric hermaphroditism.

Distributional ecology. Mollusks are largely marine. The extensive use of ciliary and mucous mechanisms in feeding, locomotion, reproduction, and other functions demands a marine environment for the majority of molluscan stocks. Apart from a small number of bivalve genera living in brackish and fresh waters, all nonmarine mollusks are gastropods.

Despite the soft, hydraulically moved bodies and relatively permeable skins typical of all mollusks, some snails are relatively successful as land animals, although they are largely limited to more humid habitats. The primary physiological requirements for life on land concern water control, conversion to air breathing, and temperature regulation.

In the sea, all classes of mollusks are found, and all habitats have mollusks. Protobranchiate bivalves are found at depths of over 30,000 ft (9000 m). Although ecologically cephalopod mollusks are limited to the sea, there are sound reasons for claiming modern cephalopods as the most highly organized invertebrate animals. The functional efficiencies of jet propulsion and of massive brains in squid, cuttlefish, and octopuses have not been paralleled in their other physiological systems.

In addition to the extreme diversity of external body form exhibited by different mollusks, they show a remarkable diversity in their ecological distribution and life styles. However, the basic molluscan plan of structure and function always remains recognizable. *See* APLACOPHORA; BIVALVIA; CEPHALOPODA; GASTROPODA; LAMELLIBRANCHIA; MONOPLACOPHORA; POLYPLACOPHORA; SCAPHOPODA; SNAIL. [W.D.R.H.]

Molting (Arthropoda) In arthropods, the shedding of the cuticle. Arthropods, such as insects and crustaceans, owe a large part of their evolutionary success to their exoskeleton. It serves as a rigid attachment site for muscles and also provides a barrier against microbial invasion from the outside and water and ion loss from within. A rigid body covering, however, is not readily expandable. Consequently, at periodic intervals a new exoskeleton is formed and the old one shed to allow increases in body size or changes in morphology. Most of this process, termed molting, is hidden since the new exoskeleton forms underneath the old one. *See* ARTHROPODA.

Molting begins with the detachment of the epidermis from the overlying cuticle, forming a space between the two structures. Cell divisions may then occur in the epidermis followed by the initiation of secretion of the new cuticle. The epicuticle is first laid down, followed by the exocuticle. Consequently, toward the end of a molt, one finds the animal with a new exoskeleton consisting of epicuticle, exocuticle, and some endocuticle, inside the partially digested old exoskeleton. The events that surround the escape from this old cuticle can be divided into three discrete phases: preparatory, ecdysis, and postecdysis.

The preparatory phase includes the behavioral and physiological changes that lead up to ecdysis. A key physiological event is the activation of the molting fluid and the resulting digestion of the inner layers of the old endocuticle, a major store of protein and chitin. The preparatory phase also involves behavior that brings the animal to an appropriate site for ecdysis.

The ecdysial movements bring about the shedding of the old exoskeleton. These are very stereotyped behaviors that are due to central motor programs whose output is modified to a greater or lesser extent by sensory feedback as the behavior progresses. Ecdysis is often accompanied by the activation of dermal glands that pour their secretion onto the surface of the new cuticle as the old one is being shed. These secretions make up an outer cement layer which further aids in waterproofing the cuticle.

The postecdysial phase is devoted to the expansion and hardening of the new exo-skeleton. Typically, the new exoskeleton is larger than the old one, so it needs to be inflated to its proper size. After its expansion, the new cuticle is tanned and acquires its new pigmentation. In crustaceans, the new cuticle is gradually mineralized through deposition of calcium into it.

In all arthropods, molting is caused by a class of steroid hormones, the ecdysteroids, the most prominent of which is 20-hydroxyecdysone. The ecdysteroid profile during a molt is characterized by initial high titers of the steroid followed by a gradual decline in levels as the molt progresses. Activation of the enzymes in the molting fluid, the digestion of the endocuticle, and molting fluid resorption all occur as the steroid titer drops. Importantly, the decline in ecdysteroids is also necessary for the release and action of the neuropeptide, eclosion hormone, that triggers ecdysis itself. Other neuropeptides are then released as a consequence of eclosion hormone action. Bursicon is the tanning hormone, and its primary target is the epidermis. Other peptides released at this time cause the circulatory changes that direct the blood into the expanding appendages. *See* ENDOCRINE SYSTEM (INVERTEBRATE); INSECT PHYSIOLOGY. [J.W.Tr.]

Molybdenite A mineral having composition MoS_2. Molybdenite is the chief ore of molybdenum. It crystallizes in the hexagonal system, but crystals are rare and when found are hexagonal plates. It is commonly in scales or foliated masses. The mineral has a greasy feel. The hardness is 1.5 (Mohs scale) and the specific gravity is 4.7. The luster is metallic and the color lead gray. Molybdenite and graphite have long been confused because of their nearly identical physical properties. They can be distinguished by the streak left on glazed paper, black for graphite and green for molybdenite. Molybdenite has been used as a lubricant.

Molybdenite occurs in various places in Norway, Sweden, Australia, England, China, and Mexico. In the United States, molybdenite is found in small amounts at many localities but the most important occurrence is at Climax, Colorado. *See* MOLYBDENUM. [C.S.Hu.]

Molybdenum A chemical element, Mo, atomic number 42, and atomic weight 95.94, in the periodic table in the triad of transition elements that includes chromium (atomic number 24) and tungsten (atomic number 74). Research has revealed it to be one of the most versatile chemical elements, finding applications not only in metallurgy but also in paints, pigments, and dyes; ceramics; electroplating; industrial catalysts; industrial lubricants; and organometallic chemistry. Molybdenum is an essential trace element in soils and in agricultural fertilizers. Molybdenum atoms have been found to perform key functions in enzymes (oxidases and reductases), with particular interest being directed toward its role in nitrogenase, which is employed by bacteria in legumes to convert inert nitrogen (N_2) of the air into biologically useful ammonia (NH_3). *See* NITROGEN FIXATION; PERIODIC TABLE.

Molybdenum is widely distributed in the Earth's crust at a concentration of 1.5 parts per million by weight in the lithosphere and about 10 parts per billion in the sea. It is found in at least 13 minerals, mainly as a sulfide [molybdenite (MoS_2)] or in the form of molybdates [for example, wulfenite ($PbMoO_4$) and magnesium molybdate ($MgMoO_4$)].

Although molybdenum is closer to chromium in atomic weight and atomic number, its chemical behavior is usually very similar to that of tungsten, which has nearly the same atomic radius. (This is due to the so-called lanthanide contraction in which atomic radii decrease for elements 57 to 71 found in the period between molybdenum and tungsten.) *See* CHROMIUM; LANTHANIDE CONTRACTION; TUNGSTEN.

Molybdenum atoms contain six valence electrons ($4d^5 5s^1$), which are employed with great versatility in forming compounds and complexes in which electronic configurations vary from d^0 (no *d* electrons in oxidation state + 6) to d^8 (8 *d* electrons in oxidation state -2). The $+6$ state is preferred, but all states from -2 to $+6$ are known. States usually exhibit a variety of coordination numbers (4 to 9), and include polynuclear complexes and metal-metal bonds in metallic clusters with two to six metal atoms in their metallic cores. Molybdenum forms a very large number of compounds with oxygen. Low-valent molybdenum [for example, $Mo(CO)_6$ and Mo_2, Mo_3, and Mo_6 clusters] has a very rich organometallic chemistry, including clusters that are being studied as models for molybdenum metal surfaces that catalyze organic reactions employed in industrial syntheses and oil refining. The ability of molybdenum atoms to vary oxidation state, coordination number, and coordination geometry and to form metal-metal bonds in clusters accounts in part for the large number of industrial catalysts and biological enzymes in which Mo atoms are found at the active site for catalysis. *See* CHEMICAL BONDING; COORDINATION CHEMISTRY; ELECTRON CONFIGURATION.

Molybdenum is a high-melting silver-gray metal, strong even at high temperatures, hard, and resistant to corrosion (see table). It also exhibits high conductivity, a high modulus of elasticity, high thermal conductivity, and a low coefficient of expansion. Its major use is in alloy steels, for example, as tool steels ($\leq$10% molybdenum), stainless steel, and armor plate. Up to 3% molybdenum is added to cast iron to increase strength. Up to 30% molybdenum may be added to iron-, cobalt-, and nickel-based alloys designed for severe heat- and corrosion-resistant applications. It may be used in filaments for light bulbs, and it has many applications in electronic circuitry. *See* ALLOY; IRON ALLOYS; STAINLESS STEEL.

Physical properties of molybdenum metal

Property	Value
Density	10.22 g/cm^3 (5.911 oz/in.^{3})
Heat of vaporization	491 kJ/mol
Heat of fusion	28 kJ/mol
Specific heat	0.267 J/g°C
Thermal conductivity	1.246 J/s/cm^2/cm°C (200°C) 0.923 J/s/cm^2/cm°C (2200°C)
Electrical conductivity	34% International Copper Standard
Electrical resistivity	5.2 microhm-cm, 20°C 78.2 microhm-cm, 2525°C
Magnetic susceptibility	0.93×10^{-6} emu, 25°C 1.11×10^{-6} emu, 1825°C
Mean linear expansion coefficient	6.65×10^{-6}/°C, 20–1600°C
Modulus of elasticity	0.324 N/m^2
Lattice parameter	0.314767 nm (body-centered cube)

Molybdenum trioxide, molybdates, sulfo-molybdates, and metallic molybdenum are found in thousands of industrial catalysts used in oil refining, ammonia synthesis, and industrial syntheses of organic chemicals. Monomeric molybdenum (IV) in aqueous solution is a powerful catalyst for the reduction of inert oxo-anions such as perchlorate (ClO_4^-) or nitrate (NO_3^-) as well as other oxidized nonmetals such as azide ion (N_3^-) and dinitrogen (N_2). The trinuclear cation $MO_3O_4^{4+}$ is inert, unreactive, and noncatalytic. *See* CATALYSIS; HOMOGENEOUS CATALYSIS.

The molybdenum enzymes comprise two major categories. The first category contains the single, highly important enzyme nitrogenase, which is responsible for biological nitrogen fixation. The second category contains all other known molybdenum enzymes, which are crucial for the metabolism of bacteria, plants, and animals, including humans. [E.I.S.]

Monazite A rare mineral that incorporates the light rare-earth elements (lanthanum, cerium, praseodymium, neodymium, promethium, samarium, europium, gadolinium) and also yttrium. Monazite has a general formula of (La,Ce, Nd)PO_4, but Pr, Sm, Eu, Gd, and Y substitute for La, Ce, and Nd in solid solution in minor amounts. The dominant rare-earth element in a particular monazite is denoted by the atomic suffix, such as monazite-(Ce) in which cerium exists in amounts greater than other rare-earth atoms. Monazite-(Ce), monazite-(La), and monazite-(Nd) are officially recognized by the International Mineralogical Association. *See* CERIUM; MINERAL; RARE-EARTH ELEMENTS; YTTRIUM.

The atomic arrangement of monazite is formed of a packing arrangement of (PO_4) tetrahedra and distorted (REO_9) polyhedra, where RE = the rare-earth elements in the particular monazite mineral. The arrangement is formed of chains of alternating phosphate tetrahedra and RE polyhedra, parallel to the *c* axis. Monazite is similar in structure and chemistry to the tetragonal mineral xenotime, Y(PO_4), that selectively incorporates the heavy rare-earth elements. *See* PHOSPHATE MINERALS.

Monazite is variably green, yellow, brown, or red-brown, and rarely occurs in crystals large enough to discern with the unaided eye. Mohs hardness is 5–5.5, and the specific gravity is 4.6–5.5, varying with substitution of different elements.

Monazite is one of the main ore minerals for the rare-earth elements that are used in the manufacture of television and computer screens, fluorescent light bulbs, and highly efficient batteries, among other industrial applications. [J.M.Hu.; J.Ra.]

Molybdenum alloys Solid solutions of molybdenum and other metals. Molybdenum is classified as a refractory metal by virtue of its high melting point (2623°C or 4750°F), and many of its applications result from its strength at high temperatures. A number of other physical and mechanical properties make it attractive for use in a wide variety of applications. Molybdenum is used extensively as electrodes in electric-boost furnaces because it erodes very slowly and does not contaminate the glass bath. Its high-temperature strength allows it to support significant structural loads imposed during operation of the furnaces. *See* MOLYBDENUM; REFRACTORY.

Four main classes of commercial molybdenum-base alloys exist. The most common of the carbide-strengthened alloys is known as TZM, containing about 0.5% titanium, 0.08% zirconium, and 0.03% carbon. Other alloys in this class include TZC (1.2% titanium, 0.3% zirconium, 0.1% carbon), MHC (1.2% hafnium, 0.05% carbon), and ZHM (1.2% hafnium, 0.4% zirconium, 0.12% carbon). The high-temperature strength imparted by these alloys is their main reason for existence. Both TZM and MHC have found application as metalworking tool materials. Their high-temperature strength and high thermal conductivity make them quite resistant to the collapse and thermal cracking that are common failure mechanisms for tooling materials.

Tungsten and rhenium are the two primary solid-solution alloys. The most common compositions are 30% tungsten (Mo-30W), 5% rhenium (Mo-5Re), 41% rhenium (Mo-41Re), and 47.5% rhenium (Mo-50Re). With the exception of the Mo-30W alloy which is available as a vacuum-arc-cast product, these alloys are normally produced by powder metallurgy. The tungsten-containing alloys find application as components in systems handling molten zinc, because of their resistance to this medium. They were developed as a lower-cost, lighter-weight alternative to pure tungsten and have served these applications well over the years. The 5% rhenium alloy is used primarily as thermocouple wire, while the 41% and 47.5% alloys are used in structural aerospace applications. *See* RHENIUM; TUNGSTEN.

The beneficial effects of solid-solution hardening and dispersion hardening found in the carbide-strengthened alloys have been combined in the HWM-25 alloy (25% tungsten, 1% hafnium, 0.07% carbon). This alloy offers high-temperature strength greater than that of carbide-strengthened molybdenum, but it has not found wide commercial application because of the added cost of tungsten and the expense of processing the material.

Dispersion-strengthened alloys rely exclusively on powder metallurgy manufacturing techniques. This allows the production of fine stable dispersions of second phases that stabilize the wrought structure against recrystallization, resulting in a material having improved high-temperature creep strength as compared to pure molybdenum. Once recrystallization occurs, the dispersoids also stabilize the interlocked recrystallized grain structure. This latter effect produces significant improvements in the ductility of the recrystallized material.

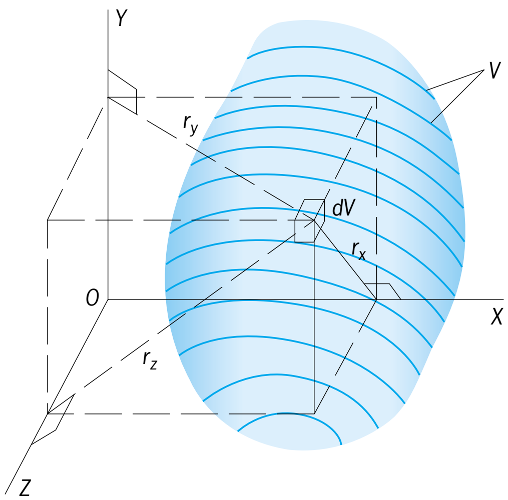
The potassium- and silicon-doped alloys such as MH (150 ppm potassium, 300 ppm silicon) and KW (200 ppm potassium, 300 ppm silicon, 100 ppm aluminum) are the oldest of this category; they are analogs to the doped tungsten alloys in common use for tungsten lamp filament. [J.A.Shi.]

Moment of inertia A relation between the area of a surface or the mass of a body to the position of a line. The analogous positive number quantities, moment of inertia of area and moment of inertia of mass, are involved in the analysis of problems of statics and dynamics respectively.

The moment of inertia of a figure (area or mass) about a line is the sum of the products formed by multiplying the magnitude of each element (of area or of mass) by the square of its distance from the line. The moment of inertia of a figure is the sum of moments of inertia of its parts.

For a body of mass distributed continuously within volume V, the movement of inertia of the mass about the X axis is given by either $I_X = \int r_x^2\, dm$ or $I_X = \int r_x^2 \rho\, dV$, where dm is the mass included in volume element dV at whose position the mass per unit volume is ρ (see illustration). Similarly $I_y = \int r_y^2 \rho\, dV$ and $I_z = \int r_z^2 \rho\, dV$.

The moments of inertia of a figure about lines which intersect at a common point are generally unequal. The moment is



Moment of inertia of a volume.

greatest about one line and least about another line perpendicular to the first one. A set of three orthogonal lines consisting of these two and a line perpendicular to both are the principal axes of inertia of the figure relative to that point. If the point is the figure's centroid, the axes are the central principal axes of inertia. The moments of inertia about principal axes are principal moments of inertia. *See* Centroids (mathematics); Product of inertia; Radius of gyration. [N.S.F.]

Momentum Linear momentum is the product of the mass and the linear velocity of a body. It is defined by Eq. (1), where m

$$\mathbf{P} = m\mathbf{v} \qquad (1)$$

is the mass and $\mathbf{v}$ is the linear velocity. Since linear momentum is the product of a scalar and a vector quantity, it is a vector and hence has both magnitude and direction.

According to the general statement of Newton's second law, for a force $\mathbf{F}$, a momentum $\mathbf{P}$, and a time t, Eq. (2) holds. Thus

$$\mathbf{F} = d\mathbf{P}/dt \qquad (2)$$

Newton's second law involves the time rate of change of momentum. Changes of momentum are important in collision processes. *See* Collision (physics).

When a group of bodies is subject only to forces that members of the group exert on one another, the total momentum of the group remains constant. *See* Angular momentum; Conservation of momentum; Impulse (mechanics). [P.W.S.]

Mongoose The name for about 39 species of carnivorous mammals which are members of the family Viverridae. This family also includes the civets and genets. Mongooses are restricted in their distribution to the warmer regions of the Old World, ranging from the Mediterranean into Africa and Southeast Asia. These are plantigrade animals about the size of a cat and have a long slender body, short legs, nonretractile claws, and scent glands. Some species are fair climbers even though the claws are nonretractile. Mongooses are predators, feeding on snakes, frogs, fishes, and crabs, and they are especially fond of bird and crocodile eggs. The mongoose cannot legally be brought into the United States because of its destructive habits. *See* Carnivora; Civet. [C.B.C.]

Monhysterida An order of nematodes in which, generally, the stoma is funnel shaped and lightly cuticularized; however, in some families the stoma is spacious and heavily cuticularized, and is armed with protrusible teeth. The amphids vary from simple spirals to circular forms. Usually the second and third circlets of cephalic sensilla are combined, but in some taxa the third circlet of four distinct setae is separate. The normal pattern of distribution is often disrupted by numerous cervical setae. The near-cyclindrical esophagus is sometimes swollen posteriorly. The cuticle may be smooth or may have annuli or ornamentation. When the annuli are distinct, the somatic setae may be long and in four to eight longitudinal rows. The female gonads are outstretched and either single or paired.

There are three monhysterid superfamilies: The Linhomoeoidea and Siphonolaimoidea are primarily marine forms; feeding habits among the groups are unknown. The Monhysteroidea are free-living nematodes found in all environments, from marine waters to fresh waters and soil; feeding habits are unknown. *See* Nemata. [A.R.M.]

Monkey An adaptive or evolutionary grade among the primates, represented by members of two of the three modern anthropoid superfamilies. The New World, platyrrhine monkeys (Ateloidea) and Old World, catarrhine forms (Cercopithecoidea) probably reached a monkey level of adaptation independently some time after their separation from a common ancestor, perhaps 40 million years ago. The term monkey is not indicative of taxonomic or phylogenetic relationship: the closest relatives of the cercopithecoids are not the ateloid monkeys but the Old World apes and humans.

The Ateloidea comprise two families, while the living Cercopithecoidea are today considered to comprise only one family, with two subfamilies. A modern classification of the Anthropoidea follows:

- Hyporder Anthropoidea
  - Infraorder Platyrrhini
    - Superfamily Ateloidea (New World or platyrrhine monkeys)
      - Family Atelidae
        - Subfamily Atelinae (howler and spider monkeys)
        - Subfamily Pitheciinae (saki, owl, and titi monkeys)
      - Family Cebidae
        - Subfamily Cebinae (capuchin and squirrel monkeys)
        - Subfamily Callitrichinae (marmosets and tamarins)
        - Subfamily Branisellinae (extinct early ateloids)
  - Infraorder Catarrhini (Old World anthropoids)
    - Parvorder Eucatarrhini (modern catarrhines)
    - Superfamily Hominoidea (gibbons, great apes, and humans)
    - Superfamily Cercopithecoidea
      - Family Cercopithecidae (Old World or catarrhine monkeys)
        - Subfamily Cercopithecinae (cheek-pouched monkeys: macaques, baboons, guenons, and mangabeys)
        - Subfamily Colobinae (leaf eaters: langurs and colobus)
        - Subfamily Victoriapithecinae (extinct early cercopithecids)
    - Parvorder Eocatarrhini (archaic catarrhines)
      - Family Pliopithecidae (later archaic catarrhines)
      - Family Propliopithecidae (early archaic catarrhines)
  - Infraorder Paracatarrhini (extinct early anthropoids)
    - Family Parapithecidae (extinct Egyptian monkeys)
    - Family Oligopithecidae (extinct archaic anthropoids)

Monkeys are hard to characterize as a group because of their great diversity, and because much of the discussion reflects a comparison with the apes. Both monkeys and apes contrast with the prosimian grade in that they are typically large, diurnal animals that live in social groups. Monkeys differ from apes in their possession of a tail, a smaller brain, quadrupedal pronograde posture, and a usually longer face. They are generally smaller than apes, but large monkeys outweigh gibbons. Like almost all primates, monkeys are pentadactyl, with nails rather than claws on the digits in most cases. They have pectoral mammary glands and well-developed vision. Monkeys are primarily vegetarian and inhabit forested tropical or subtropical regions of

Major contrasts between New and Old World monkeys and special features of each

Ateloidea (New World species)	Cercopithecoidea (Old World species)
Nose platyrrhine (nasal septum wide, nostrils open to sides)	Nose catarrhine (septum narrow, nostrills open downward)
Tail long, prehensile in atelines and *Cebus* only	Tail short to long, nonprehensile
3 premolar teeth in each quadrant	2 premolars in each quadrant
24 deciduous, 36 permanent teeth (4 fewer in Callitrichinae), I 2/2C 1/1 P 3/3 M 3/3/(M 2/2 in Callitrichinae)	20 deciduous, 32 permanent teeth, I 2/2 C 1/1 P 2/2 M 3/3
	Ischial callosities present
Jaws and teeth lightly built in Cebidae; more robust in Atelidae, with deep lower jaw	Cheek pouches in Cercopithecinae
Sacculated stomach in Colobinae	
Fingers and toes with curved nails (clawlike in Callitrichinae)	All nails tend to be flattened
Big toe opposable, thumb not fully so and sometimes reduced in Cebidae	Thumb and big toe opposable, thumb reduced in colobinae

Africa, Asia, and South America. The differences between the New and Old World monkeys are summarized in the table.

Old World species are found throughout all the warmer regions of the Eastern Hemisphere, except Australia and Madagascar. Many of the familiar monkeys are included in this family, such as the rhesus macaque, Barbary “ape,” mangabey, baboon, and mandrill.

The New World monkeys or ateloids occupy forested areas from southern Mexico to Argentina. They are divided into two main groups, or families (their major characteristics are given in the table). All are arboreal, including a few with prehensile tails; there is no living form, nor any evidence of a fossil form, that has come to the ground habitually. Familiar monkeys included in this group are marmosets, capuchins, titis, sakis and nakaris, howler monkeys, and spider and wool monkeys. *See* APES; PRIMATES. [E.D.]

Monoamine oxidase Either of two enzymes found in the outer membrane of mitochondria that degrade biogenic amines and are thus responsible for the destruction of transmitter substances at neuronal synapses. Nerve cells release neurotransmitter into the synapse in response to stimulation. The neuron must then dispose of this neurotransmitter to stop the signal or a new signal cannot get through. This is accomplished by one of three mechanisms: diffusion; reuptake into the presynaptic area; and degradation by a number of enzymes, including monoamine oxidase. *See* SYNAPTIC TRANSMISSION.

Monoamine oxidase inhibitors are drugs that block degradation of amine transmitters within the cell; however, not all of their effects can be attributed directly to monoamine oxidase inhibition, since a number of different neuronal effects have been described. The most prominent consequence of monoamine oxidase inhibition is a rapid increase in the intracellular concentrations of monoamines. In addition, the level of serotonin in the brain is raised to a greater extent than that of norepinephrine and dopamine. After these amine concentrations rise, secondary adaptive consequences occur, including a reduction in amine synthesis via an apparent feedback mechanism, which has been most clearly demonstrated for the noradrenergic system. *See* NEUROBIOLOGY; NORADRENERGIC SYSTEM; SEROTONIN.

Two types of monoamine oxidase have been identified. These are designated A and B and are distinguished by having different substrate specificity. Type A preferentially deaminates norepinephrine, cortical dopamine, and serotonin, and is selectively inhibited by clorgyline. Type B degrades phenylethylamine, dopamine, and benzylamine, and is sensitive to deprenyl or pargyline inhibition. Commonly used monoamine oxidase inhibitors are nonselective inhibitors that affect types A and B. Seventy-five percent of monoamine oxidase in the human is type B.

Monoamine oxidase inhibitors are used in medicine for controlling hypertension and for treating depression and other disorders. Other psychiatric disorders, such as obsessive-compulsive disorder, bulimia, somatoform pain disorder, panic disorder, and schizophrenia, have been reported to occasionally respond to treatment with monoamine oxidase inhibitors. There is also some evidence that patients with so-called atypical depression preferentially respond to monoamine oxidase inhibitors. *See* AFFECTIVE DISORDERS; HYPERTENSION. [M.A.Je.]

Monocleales An order of liverworts of the subclass Marchantiidae, consisting of a single genus (*Monoclea*). The gametophyte is among the largest of all liverworts; its thallus consists of homogeneous cells except for scattered oil cells. The rhizoids are smooth and both thick-walled and thin-walled. The sex organs are grouped but not elevated: the antheridia are sunken in cavities and grouped into receptacles, while the archegonia are enclosed in groups by involucres. The very long, massive seta considerably elevates the capsules which dehisce spoonlike by one slit. The lobing of spore mother cells is unique in the subclass Marchantiidae. *See* BRYOPHYTA; MARCHANTIIDAE. [H.Cr.]

Monoclonal antibodies Antibody proteins that bind to a specific target molecule (antigen) at one specific site (antigenic site). In response to either infection of immunization with a foreign agent, the immune system generates many different antibodies that bind to the foreign molecules. Individual antibodies within this polyclonal antibody pool bind to specific sites on a target molecule known as epitopes. Isolation of an individual antibody within the polyclonal antibody pool would allow biochemical and biological characterization of a highly specific molecular entity targeting only a single epitope. Realization of the therapeutic potential of such specificity launched research into the development of methods to isolate and continuously generate a supply of a single lineage of antibody, a monoclonal antibody (mAb).

In 1974, W. Köhler and C. Milstein developed a process for the generation of monoclonal antibodies. In their process, fusion of an individual B cell (or B lymphocyte), which produces an antibody with a single specificity but has a finite life span, with a myeloma (B cell tumor) cell, which can be grown indefinitely in culture, results in a hybridoma cell. This hybridoma retains desirable characteristics of both parental cells, producing an antibody of a single specificity that can grow in culture indefinitely.

Generation of monoclonal antibodies through the hybridoma process worked well with B cells from rodents but not with B cells from humans. Consequently, the majority of the first monoclonal antibodies were from mice. When administered into humans as therapeutic agents in experimental tests, the human immune system recognized the mouse monoclonal antibodies as foreign agents, causing an immune response, which was sometimes severe. Although encouraging improvements in disease were sometimes seen, this response made murine (mouse) antibodies unacceptable for use in humans with a functional immune system.

Fueled by advances in molecular biology and genetic engineering in the late 1980s, efforts to engineer new generations of monoclonal antibodies with reduced human immunogenicity have come to fruition. Today there are a number of clonal antibodies approved for human therapeutic use in the United States.

Characterization of the structure of antibodies and their genes laid the foundation for antibody engineering. In most mammals, each antibody is composed of two different polypeptides, the immunoglobulin heavy chain (IgH) and the immunoglobulin light chain (IgL). Comparison of the protein sequences of either heavy of light antibody chain reveals a portion that typically varies from one antibody to the next, the variable region, and a portion that is conserved, the constant region. A heavy and a light chain are folded together in an antibody to align their respective variable and constant regions. The unique shape of the cofolded heavy- and light-chain variable domains creates the variable domain of the antibody, which fits around the shape of the target epitope and confers the binding specificity of the antibody.

Mice genetically engineered to produce fully human antibodies allow the use of established hybridoma technology to generate fully human antibodies directly, without the need for additional engineering. These transgenic mice contain a large portion of human DNA encoding the antibody heavy and light chains. Inactivation of the mouse's own heavy- and light-chain genes forces the mouse to use the human genes to make antibodies. Current versions of these mice generate a diverse polyclonal antibody response, thereby enabling the generation and recovery of optimal monoclonal antibodies using hybridoma technology.

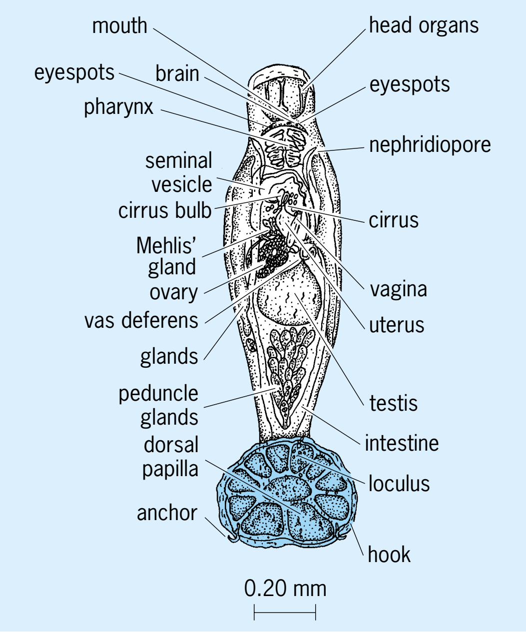
Disease areas that currently are especially amenable to antibody-based treatments include cancer, immune dysregulation, and infection. Depending upon the disease and the biology of the target, therapeutic monoclonal antibodies can have different mechanisms of action. A therapeutic monoclonal antibody may bind and neutralize the normal function of a target. For example, a monoclonal antibody that blocks the activity of the of protein needed for the survival of a cancer cell causes the cell's death. Another therapeutic monoclonal antibody may bind and activate the normal function of a target. For example, a monoclonal antibody can bind to a protein on a cell and trigger an apoptosis signal. Finally, if a monoclonal antibody binds to a target expressed only on diseased tissue, conjugation of a toxic payload (effective agent), such as a chemotherapeutic or radioactive agent, to the monoclonal antibody can create a guided missile for specific delivery of the toxic payload to the diseased tissue, reducing harm to healthy tissue. *See* ANTIBODY; ANTIGEN; GENETIC ENGINEERING; IMMUNOLOGY. [L.Gre.]

Monocotyledons This group of flowering plants (angiosperms), with one seed leaf, was previously thought to be one of the two major categories of flowering plants (the other group is dicotyledons). However, deoxyribonucleic acid (DNA) studies have revealed that, although they do constitute a group of closely related families, they are closely related to the magnoliids, with which they share a pollen type with a single aperture. The eudicots are much more distantly related. In general, monocots can also be recognized by their parallel-veined leaves and three-part flowers. Their roots have disorganized vascular bundles, and if they are treelike (yuccas, aloes, dracaenas) their wood is unusually structured. Among the important monocots are grasses (including corn, rice, and wheat), lilies, orchids, palms, and sedges. *See* DICOTYLEDONS; EUDICOTYLEDONS; FLOWER; GRASS CROPS; LILIALES; MAGNOLIOPHYTA. [M.W.C.; M.F.F.]

Monogenea A subclass of the Trematoda which are ectoparasites of the gills, skin, and orifices of fishes and, less frequently, of the esophageal tracts and bladders of amphibians and turtles. They have conspicuous anterior and posterior holdfasts, the latter usually armed. The terminal genitalia are frequently sclerotized. The group is characterized by sexual reproduction, direct development, and a single host in the life cycle.

The most widely used classification employs two orders, the Monophisthocotylea, in which the posthaptor is without discrete multiple suckers or clamps, and the Polyopisthocotylea, with suckers or clamps on the posthaptor.

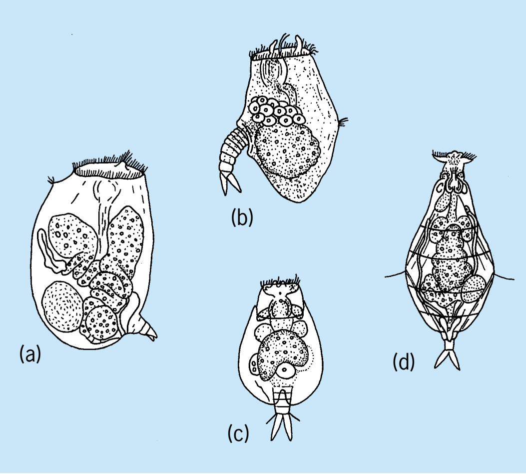
Body shapes of the various genera are distinctive, sometimes bizarre, as in *Vallisia*, which is sickle-shaped. Paired external suckers or buccal cavity suckers and adhesive glands occur anteriorly. The posterior holdfast is either solid and armed with central anchors and marginal hooks (Gyrodactyloidea), sucker-shaped with anchors and hooks (Capsaloidea; see illustration), or solid and bearing suckers or clamps (Polyopisthocotylea).



A monogeneid of the superfamily Capsaloidea, *Heterocotyle aetobatis* from the spotted eagle ray, ventral view.

Monogenea usually have direct development involving simple metamorphosis from the ciliated larval stage to the nonciliated juvenile. Juvenile anchors and hooks may be retained or replaced by adult suckers or clamps. Cross-fertilization or, perhaps less frequently, self-fertilization of hermaphroditic individuals resulting in egg capsules which hatch on the host or in its environment is most common. *See* TREMATODA. [W.J.Ha.]

Monogononta A class of the phylum Rotifera which contains the majority of species in this invertebrate class. The organisms of this order are characterized by the presence of a single gonad in both males and females. There is a striking degree of sexual dimorphism, with the males being small and degenerate. The order is made up of three suborders: Ploima, Flosculariacea, and Collothecacea.



Ploimates. (*a*) *Asplanchnopus* sp. (*b*) *Ploesoma* sp. (*c*) *Euchlanis dilata*. (*d*) *Notomata copeus*.

In suborder Ploima there is an exceptional diversity of form, varying from soft-bodied wormlike rotifers to species with variously ornamented, loricate shells (see illustration). Most of the free-swimming benthonic and pelagic rotifers belong to this suborder. Locomotion is by the ciliated corona.

The suborder Flosculariacea contains the spectacular sessile rotifers formerly known as melicertaceans of the family Flosculariidae, as well as a number of equally notable free-swimming forms included in the family Testudinellidae.

The suborder Collothecacea contains but a single family, the Collothecidae, made up of five genera. Most species of Collothecidae are sessile, and many are encased in gelatinous tubes. *See* ROTIFERA. [E.H.A.]

Monomolecular film A film one molecule thick; often referred to as a monolayer. Films that form at surfaces or interfaces are of special importance. Such films may reduce friction, wear, and rust, or may stabilize emulsions, foams, and solid dispersions. The broad field of catalysis, which is basic to petroleum refining and many chemical industries, involves chemical reactions that are accelerated in the thin films of reactants at interfaces. Moreover, thin films containing proteins, cholesterol, and related compounds constitute biological membranes, the internal interfaces that control the complex processes of life. *See* CATALYSIS; CELL MEMBRANES.

In all of these areas, a single monomolecular layer at the interface is the most important. It is held to the adsorbing surface by forces stronger than those that hold any succeeding layer. On solid surfaces, it is the only layer that can be chemisorbed. It may be the site of enhanced chemical reactivity, or the last line of defense.

Monolayers on solids, or at liquid interfaces, may be formed by adsorption from the adjacent bulk phases; the process may show high specificity for particular chemical species. Measurements of the extent of adsorption have historically provided information on the composition and structure of monolayers formed in this way. A variety of surface-sensitive instrumental techniques, such as diffraction and scattering of low-energy electrons, neutrons, and ions, and spectroscopy of adsorbed species, have been brought to bear to obtain information about the structure of the surface layer and chemical perturbations in it. *See* ADSORPTION; SPECTROSCOPY.

In addition, monolayers of a wide variety of substantially insoluble substances can be formed at a liquid-gas interface by allowing them to spread over the surface. The properties of such films at the water-air interface can be manipulated, controled, and measured in simple and elegant ways. A variety of specialized experimental techniques have been developed to study these insoluble monolayers.

In order to form spread monolayers which are sufficiently stable to study, a substance must combine low solubility and volatility with some moiety which attracts it to the liquid surface; for films on water, this generally means one or more polar functional groups. Totally nonpolar substances, such as the higher-molecular-weight paraffin hydrocarbons, will not spread on water (although they can spread on liquids of very high surface tension, such as mercury). Typical among the large group of substances which do form insoluble monolayers on water are the long-chain fatty acids and their derivatives such as glycerides, sterols, and many lipid substances of biological origin, including the fat-soluble vitamins and natural pigments such as chlorophyll. Many polar synthetic polymers, including polyvinyl acetate and polymethyl methacrylate, can be made to spread as monolayers on water; so can many proteins, because their tertiary structure unfolds at the air-water interface. *See* POLAR MOLECULE. [G.L.G.]

Mononchida An order of nematodes having a full complement of cephalic sensilla on the lips in two circlets of 6 and 10. The amphids are small and cuplike, and are located just posterior to the lateral lips; the amphidial aperture is either slit-like or ellipsoidal. The stoma is globular and heavily cuticularized, and is derived primarily from the cheilostome. The stoma bears one or more massive teeth that may be opposed by denticles in either transverse or longitudinal rows. The esophagus is cylindrical conoid, with a heavily cuticularized luminal lining. The excretory system is atrophied. Males have ventromedial supplements and paired spicules. The gubernaculum may possess lateral accessory pieces. Females have one or two ovaries. Caudal glands and a spinneret are common; however, they may be degenerate or absent.

There are three mononchid superfamilies: The Mononchoidea contain some of the most common and easily recognized free-living nonparasitic nematodes that occur in soils and fresh waters throughout the world. The closely related Bathyodontoidea are inhabitants of soil or fresh water and prey on small microorganisms. The nonparasitic Monochuloidea comprise both soil and fresh-water species, all of which are predators of microfauna. *See* NEMATA. [A.R.M.]

Monoplacophora A class of the phylum Mollusca. Although fossil monoplacophorans had been known since the end of the nineteenth century, it was the discovery of a living species in deep water off Costa Rica in the 1950s that led to universal acceptance of the class. Monoplacophorans are bilaterally symmetrical, univalved mollusks that vanish from the fossil record at the end of the Paleozoic, about 240 million years ago. The living species, such as *Neopilina galatheae*, are rare and inhabit deep water, which may explain their absence from Mesozoic and Cenozoic rocks. Living monoplacophorans have a limpet-shaped shell, a circular foot attached by pairs of retractor muscles, and several gills on each side of the body. *See* GASTROPODA; MOLLUSCA; POLYPLACOPHORA. [B.Ru.]

Monopulse radar Radar capable of estimating target position based on the return from a single pulse. In many radars, precise angular position is estimated by conically scanning a single beam around the initial coarse angle estimate; the orderly amplitude variation of echoes during such scanning provides the refinement. Such measurement is limited, however, by pulse-to-pulse fluctuations in echo strength, a property quite common in radar targets.

Monopulse radars use antennas that provide a local cluster of simultaneous beams (instead of scanning just one beam) to make the same precise angle estimate with each pulse transmitted. Since angle information is contained in each return, fluctuations in echo strength do not significantly degrade the measurement. Monopulse radars with mechanically positioned antennas address only a single target, and average the measurements over many pulses for improved accuracy. Radars using electronic beam steering in stationary phased-array antennas may make such a measurement in a single-pulse “dwell,” doing so on dozens of targets, returning to each several times a second if necessary. [R.T.H.]

Monorail A distinctive type of materials-handling machine that provides an overhead, normally horizontal, fixed path of travel in the form of a trackage system and individually propelled hand or powered trolleys which carry their loads suspended freely with an intermittent motion. Because monorails operate over fixed paths rather than over limited areas, they differ from overhead-traveling cranes, and they should not be confused with such overhead conveyors as cableways. *See* BULK-HANDLING MACHINES; MATERIALS-HANDLING EQUIPMENT. [A.M.P.]

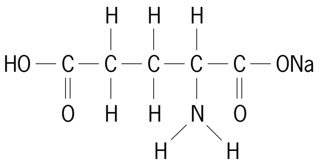
Monosaccharide A class of simple sugars containing a chain of 3–10 carbon atoms in the molecule, known as polyhydroxy aldehydes (aldoses) or ketones (ketoses). They are very soluble in water, sparingly soluble in ethanol, and insoluble in ether. The number of monosaccharides known is approximately 70, of which about 20 occur in nature. The remainder are synthetic. The existence of such a large number of compounds is due to the presence of asymmetric carbon atoms in the molecules. Aldohexoses, for example, which include the important sugar glucose, contain no less than four asymmetric atoms, each of which may be present in either D or L configuration. The number of stereoisomers rapidly increases with each additional asymmetric carbon atom.

A list of the best-known monosaccharides is given below:

Trioses:	$CH_2OH \cdot CHOH \cdot CHO$, glycerose (glyceric aldehyde)
	$CH_2OH \cdot CO \cdot CH_2OH$, dihydroxy acetone
Tetroses:	$CH_2OH \cdot (CHOH)_2 \cdot CHO$, erythrose
	$CH_2OH \cdot CHOH \cdot CO \cdot CHO$, erythrulose
Pentoses:	$CH_2OH \cdot (CHOH)_3 \cdot CHO$, xylose, arabinose, ribose
	$CH_2OH \cdot (CHOH)_2 \cdot CO \cdot CH_2OH$, xylulose, ribulose
Methyl pentoses (6-deoxyhexoses):	
	$CH_3(CHOH)_4 \cdot CHO$, rhamnose, fucose
Hexoses:	$CH_2OH \cdot (CHOH)_4 \cdot CHO$, glucose, mannose, galactose
	$CH_2OH \cdot (CHOH)_3 \cdot CO \cdot CHOH$, fructose, sorbose
Heptoses:	$CH_2OH \cdot (CHOH)_5 \cdot CHO$, glucoheptose, galamannoheptose
	$CH_2OH \cdot (CHOH)_4 \cdot CO \cdot CH_2OH$, sedoheptulose, mannoheptulose

Aldose monosaccharides having 8, 9, and 10 carbon atoms in their chains have been synthesized. *See* CARBOHYDRATE; KETONE; OPTICAL ACTIVATY; STEREOCHEMISTRY. [W.Z.H.]

Monosodium glutamate The single sodium salt of glutamic acid used in foods to accentuate flavors. It is also known as MSG. Molecular structure is represented below.



The crystal form available in commerce is the monohydrate, with structure as represented plus one molecule of water of hydration.

Originally produced from seaweed in the Orient, it is now made principally from cereal glutens, such as those of wheat, corn, and soybeans, from solutions evolved in the manufacture of beet sugar, and by microbiological fermentation of carbohydrates. The two raw materials used for the greater proportion of commercial production are wheat gluten and desugared beet-sugar molasses.

Monosodium glutamate is recognized as a standard of identity ingredient in several commercial food preparations. Its principal use is in the preparation of canned and dried soups, but it also enters into the production of some meat, vegetable, fowl, and fish products. It is the so-called secret ingredient used by many of the famous restaurant and hotel chefs. [P.D.V.M.]

Monotremata The single order of the mammalian subclass Prototheria. Two living families, the Tachyglossidae and the Ornithorhynchidae, make up this unusual order of quasi-mammals, or mammallike reptiles.

The Tachyglossidae comprise the echidnas (spiny anteaters), which have relatively large brains with convoluted cerebral hemispheres. The known genera, *Tachyglossus* and *Zaglossus*, are terrestrial, feeding on termites, ants, and other insects. They are capable diggers, both to obtain food and to escape enemies. Like hedgehogs, they can erect their spines and withdraw their limbs when predators threaten. Commonly one egg, but occasionally two or even three, is laid directly into the marsupium (pouch) of the mother where it is incubated for up to 10 days. Species of *Tachyglossus* live in rocky areas, semideserts, open forests, and scrublands. They are found in Australia, Tasmania, New Guinea, and Salawati Island. Species of *Zaglossus* are found in mountainous, forested areas.

The duck-billed platypus, constituting the Ornithorhynchidae, has a relatively small brain with smooth cerebral hemispheres. The young have calcified teeth, but in the adult these are replaced by horny plates which form around the teeth in the gums. The snout is duck-billed. The semiaquatic platypus is a capable swimmer, diver, and digger. Two eggs are usually laid by the female into a nest of damp vegetation. After incubating the eggs for about 10 days the female leaves, returning only when the eggs are hatched. The platypus is found in Australia and Tasmania in almost all aquatic habitats. *See* MAMMALIA; PROTOTHERIA. [F.S.S.]

Monsoon meteorology The study of the structure and behavior of the atmosphere in those areas of the world that have monsoon climates. In lay terminology, monsoon connotes the rains of the wet summer season that follows the dry winter. However, for mariners, the term monsoon has come to mean the seasonal wind reversals.

In true monsoon climates, both the wet summer season that follows the dry winter and the seasonal wind reversals should occur. Winds from cooler oceans blow toward heated continents in summer, bringing warm, unsettled, moisture-laden air and the season of rains, the summer monsoon. In winter, winds from the cold heartlands of the continents blow toward the oceans, bringing dry, cool, and sunny weather, the winter monsoon.

Based on these criteria, monsoon climates of the world include almost all of the Eastern Hemisphere tropics and subtropics, which is about 25% of the surface area of the Earth. The areas of maximum seasonal precipitation straddle or are adjacent to the Equator. Two of the world's areas of maximum precipitation (heavy rainfall) are within the domain of the monsoons: the central and south African region, and the larger south Asia-Australia region. The monsoon surface winds emanate from the cold continents of the winter hemisphere, cross the Equator, and flow toward and over the hot summer-hemisphere land masses.

India presents the classic example of a monsoon climate region, with an annual cycle that brings southwesterly winds and heavy rains in summer (the Indian southwest monsoon) and northeasterly winds and dry weather in winter (the northeast winter monsoon).

Like all weather systems on Earth, monsoons derive their primary source of energy from the Sun. About 30% of the Sun's energy that enters the top of the atmosphere is transmitted back to space by cloud and surface reflections. Little of the remainder is absorbed directly by the clear atmosphere; it is absorbed at the Earth's surface according to a seasonal cycle. The opposition of seasons in the Northern and Southern hemispheres leads to a slow movement of surface air across the Equator from winter hemisphere to summer hemisphere, forced by horizontal pressure gradients and vertical buoyancy forces resulting from differential seasonal heating. Such a seasonally reversing rhythm is most pronounced in the monsoon regions. *See* ALBEDO; ATMOSPHERE; HEAT BALANCE; INSOLATION; METEOROLOGY; TROPICAL METEOROLOGY. [J.S.Fe.]

Monstrilloida A small, aberrant order of the crustacean subclass Copepoda. It comprises two families whose members, as larvae, are parasitic on invertebrates, particularly polychaete worms and prosobranch mollusks. Monstrilloids are characterized by a total absence of mouthparts and gut in the free-swimming, nonfeeding adult phase. Antennae are lacking, but antennules are usually well developed. Thoracopods number four pairs, and females carry two egg sacs on a pair of ovigerous spines. *See* COPEPODA; CRUSTACEA. [P.A.McL.]

Monte Carlo method A technique for estimating the solution, x, of a numerical mathematical problem by means of an artificial sampling experiment. The estimate is usually given as the average value, in a sample, of some statistic whose mathematical expectation is equal to x. In many of the useful applications, the mathematical problem itself arises in a problem of probability in physics or other sciences, operational research, image analysis, general statistics, mathematical economics, or econometrics. The importance of the method arises primarily from the need to solve problems for which other methods are more expensive or impracticable, and from the increased importance of all numerical methods because of the development of the electronic digital computer.

The main advantage of Monte Carlo is that other methods can be more costly or impracticable. A familiar example is the estimation of the probability of winning a game of pure chance: Sometimes the only reasonably simple method of estimation is to play the game several times. There are also numerical problems that can be solved by deterministic methods but can be more simply solved approximately by the Monte Carlo method. Sometimes poor approximations are satisfactory because the aim is merely to determine the strategic variables of a problem. This is likely to be a fruitful technique in mathematical economics.

Another situation where a poor approximation is satisfactory occurs when there is available an iterative method of calculation, that is, a method of successive approximation, which converges closely to the right answer in a reasonable time provided that the first trial solution is not too far from the truth. The Monte Carlo method may then perhaps be used for obtaining a first trial solution. Modern Monte Carlo techniques are themselves usually iterative.

Sometimes the expense of a Monte Carlo method does not increase as fast as that of other methods when the dimensionality of a problem is increased. This seems to be true for multiple integration when it cannot be done analytically, and for the solution of Schrödinger's equation for several particles. *See* SCHRÖDINGER'S WAVE EQUATION.

The main disadvantage of some Monte Carlo methods is that for each extra decimal place required, it is necessary to multiply the sample size by 100. Thus, to calculate π to five decimal places by throwing a needle would require about 10^{10} throws, or 1 throw per second for about 300 years. [I.J.G.]

Month Any of several units of time based on the revolution of the Moon around Earth.

The calendar month is one of the 12 arbitrary periods into which the calendar year is divided. *See* CALENDAR.

The synodic month, the period of the lunar phases, is the average period of revolution of the Moon with respect to the Sun, the same as the average interval between successive full moons. Its duration is 29.531 days. *See* PHASE (ASTRONOMY).

The tropical month is the period required for the mean longitude of the Moon to increase 360°, or 27.322 days.

The sidereal month, 7 s longer than the tropical month, is the average period of revolution of the Moon with respect to a fixed direction in space.

The anomalistic month, 27.555 days in duration, is the average interval between closest approaches of the Moon to Earth. The variation in the Moon's distance from the Earth causes a variation in the apparent size of the Moon and thus in the duration of solar eclipses.

The nodical month, 27.212 days in duration, is the average interval between successive northward passages of the Moon across the ecliptic, points known as nodes. Since eclipses can occur only when the Sun and Moon are near such nodes, this period is also known as a draconic month, after the Chinese mythical dragon that supposedly ate the Sun to cause a solar eclipse. *See* ECLIPSE; MOON; TIME. [G.M.C.; J.M.P.]

Montmorillonite A group name for all clay minerals with an expanding structure, except vermiculite, and also a specific mineral name for the high alumina end member of the group. *See* CLAY MINERALS; VERMICULITE.

Montmorillonite clays have wide commercial use. The high colloidal, plastic, and binding properties make them especially in demand for bonding molding sands and for oil-well drilling muds. They are also widely used to decolorize oils and as a source of petroleum cracking catalysts. *See* CLAY.

Members of the montmorillonite group of clay minerals vary greatly in their modes of formation. Alkaline conditions and the presence of magnesium particularly favor the formation of these minerals. Several important modes of occurrence are in soils, in bentonites, in mineral veins, in marine shales, and as alteration products of other minerals. Recent sediments have a fairly high montmorillonite content. *See* BENTONITE; MARINE SEDIMENTS. [F.M.W.; R.E.Gr.]

Moon The Earth's natural satellite. United States and Soviet spacecraft have obtained lunar data and samples, and American astronauts have orbited, landed upon, and roved upon the Moon.

The Earth and Moon now make one revolution about their barycenter, or common center of mass (a point about 4670 km from the Earth's center), in $27^{d}\,7^{h}\,43^{m}\,11.6^{s}$. This sidereal period is slowly lengthening, and the distance (now about 60.27 earth radii) between centers of mass is increasing, because of tidal friction in the oceans of the Earth.

The Moon's present orbit is inclined about 5° to the plane of the ecliptic. As a result of differential attraction by the Sun on the Earth-Moon system, the Moon's orbital plane rotates slowly relative to the ecliptic (the line of nodes regresses in an average period of 18.60 years) and the Moon's apogee and perigee rotate slowly in the plane of the orbit (the line of apsides advances in a period of 8.850 years). Looking down on the system from the north, the Moon moves counterclockwise. It travels along its orbit at an average speed of nearly 0.6 mi/s (1 km/s) or about 1 lunar diameter per hour.

As a result of the Earth's annual motion around the Sun, the direction of solar illumination changes about 1° per day, so that lunar phases do not repeat in the sidereal period given above but in the synodic period, which averages $29^{d}\,12^{h}\,44^{m}$.

When the lunar line of nodes coincides with the direction to the Sun and the Moon happens to be near a node, eclipses can occur. *See* ECLIPSE.

The relation between the Moon's shape and its mass distribution is very important to theories of lunar origin and the history of the Earth-Moon system. By radio altimetry, Apollo confirmed that the Moon's surface on the far side is higher on the average than the near side; that is, the center of mass is offset from the center of figure. The offset is about 2 km (1.2 mi) toward the Earth. These observations suggest that the Moon's crust is thicker on the far side than on the near side. The *Clementine* mission in 1994 extended measurements to nearly the whole Moon and revealed the depth of a huge basin on the southern far side.

The Moon's small size and low mean density result in surface gravity too low to hold a permanent atmosphere, and therefore it was to be expected that lunar surface characteristics would be very different from those of Earth. However, the bulk properties of the Moon are also quite different—the density alone is evidence of that. The Moon is too small to have compressed its silicates into a metallic phase by gravity; therefore, if it has a dense core at all, the core should be of nickel-iron. Available data suggest that the Moon's iron core may have a diameter of at most a few hundred kilometers.

As can be seen from the Earth with the unaided eye, the Moon has two major types of surface: the dark, smooth maria and the lighter, rougher highlands. Photography by spacecraft shows that, for some unknown reason, the Moon's far side con-

Aristarchus-Harbinger region of the Moon, photographed from the *Apollo 15* spacecraft in lunar orbit, with the craters Aristarchus and Herodotus and Schroeter's Valley, the largest sinuous rille on the Moon. The impact crater Aristarchus, about 25 mi (40 km) in diameter and more than 2.5 mi (4 km) deep, lies at the edge of a mountainous region that shows evidence of volcanic activity. (*NASA*)

sists mainly of highlands. Both maria and highlands are covered with craters of all sizes. Numerous different types of craters can be recognized. Most prominent at full moon are the bright ray craters whose grayish ejecta appear to have traveled for hundreds of miles across the lunar surface. Observers have long recognized that some erosive process has been and may still be active on the Moon. Bombardment of the airless Moon by meteoritic matter and solar particles, and extreme temperature cycling, are now considered the most likely erosive agents, but local internal activity is also a possibility.

The lunar mountains, though very high (26,000 ft or 8000 m), are not extremely steep, and lunar explorers see rolling rather than jagged scenery. Though a widespread network of fault traces is visible, there is no evidence on the Moon of the great mountain-building processes seen on the Earth.

Basins on the Moon's near side, namely, Imbrium, Serenitatis, and Crisium, appear fully flooded. These were maria created by giant impacts, followed by subsidence of the ejecta and (probably much later) upwelling of lava from inside the Moon. Examination of small variations in Lunar Orbiter motions has revealed that each of the great circular maria is the site of a positive gravity anomaly (excess mass). The old argument about impact versus vulcanism as the primary agent in forming the lunar relief appears to be entering a new, more complicated phase with the confirmation of extensive flooding of impact craters by lava on the Moon's near side, while on the far side, where the crust is thicker, the great basins remain mostly empty.

In some of the Moon's mountainous regions bordering on the maria are found sinuous rilles (see illustration). These winding valleys were shown in Lunar Orbiter pictures to have an exquisite fineness of detail. No explanation for them yet offered has proved entirely convincing.

The Moon seems to be totally covered, to a depth of at least tens of meters, by a layer of rubble and soil with very peculiar optical and thermal properties. This layer is called the regolith. The observed optical and radio properties all point to a highly porous or underdense structure for at least the top few millimeters of the lunar surface material. A dark-gray, fine soil appears to mantle the entire Moon, softening most surface contours and covering everything except occasional fields of rocks. This soil, with a slightly cohesive character like that of damp sand and a chemical composition similar to that of some basic silicates on the Earth, is a product of the radiation, meteoroid, and thermal environment at the lunar surface. [J.D.Bu.]

Moose An even-toed ungulate (Artiodactyla) which is a member of the deer family, Cervidae. *Alces alces* is the largest member of the family and ranges in the boreal forested areas throughout North America and in northern Eurasia. The moose is known as the elk in Europe and is believed by some authorities to be a race of the American moose (*A. americana*). The legs are long, making the animal well-adapted for its feeding habits of wading for aquatic plants and browsing on trees and bushes. During the rutting season in the early fall, the male gathers a number of cows together, and mating takes place. After a gestation period of about 37 weeks, one or two calves are born. *See* ARTIODACTYLA. [C.B.C.]

Moraine An accumulation of glacial debris, usually till, with distinct surface expression related to some former ice front position. End moraine, the most common form, is an uneven ridge of till built in front of or around the terminus of a glacier margin, and reflects some degree of equilibrium between rate of ice motion, supply of rock debris at the ice front, temperature of the glacier base, and shape and resistance of underlying bedrock (*see* illustration).

End moraine in Pennsylvania (*U.S. Geological Survey*).

If an end moraine represents the farthest forward position a glacier ever moved, it is a terminal moraine. It demonstrates a steady-state condition for a period of time within the ice body where constant forward motion is balanced by frontal melting; and a continual supply of debris, as on an endless conveyor belt, is brought forward to the glacier terminus. If the ice front then melts farther back than it moves forward, till is spread unevenly over the land as ground moraine. If a retreatal position of steady-state equilibrium is maintained again, a recessional moraine may be constructed.

Drumlins, produced by glacier streamlining of ground moraine, are probably the best-known moraine forms. [S.E.Wh.]

Moraxella A genus of bacteria that are parasites of mucous membranes. Subgenus *Moraxella* is characterized by gram-negative rods that are often very short and plump, frequently resembling a coccus, and usually occurring in pairs. Subgenus *Branhamella* has gram-negative cocci occurring as single cells or in pairs with the adjacent sides flattened. They are usually harmless parasites of humans and other warm-blooded animals and are generally considered not to be highly pathogenic. Most species may be opportunistic pathogens in predisposed or debilitated hosts.

There are presently six species in the subgenus *Moraxella*: *M.* (*M.*) *lacunata* (also known as *Diplobacillus moraxaxenfeld* and *liquefaciens*), *M.* (*M.*) *bovis*, *M.* (*M.*) *nonliquefaciens* (also known as *Bacillus duplex nonliquefaciens*), *M.* (*M.*) *atlantae*, *M.* (*M.*) *phenylpyruvica*, and *M.* (*M.*) *osloensis*. The different species are recognized on the basis of phenotypic properties, including liquefaction of coagulated serum, hemolysis of human blood in blood agar media, nitrate reduction, phenylalanine deaminase activity, urease activity, and growth on mineral salts medium with ammonium ion and acetate as the sole carbon source.

The subgenus *Branhamella* presently contains four species: *M.* (*B.*) *catarrhalis*, *M.* (*B.*) *caviae*, *M.* (*B.*) *ovis*, and *M.* (*B.*) *cuniculi*. The different species are recognized on the basis of hemolysis of human blood in blood agar media, and nitrate and nitrite reduction, among other properties.

Moraxella (*M.*) *lacunata*, the type species of the subgenus *Moraxella*, was a significant causative agent of human conjunctivitis and keratitis in the past but is only rarely isolated at present. Infectious keratoconjunctivitis in cattle, called pinkeye, is caused by *M.* (*M.*) *bovis*. *Moraxella* (*M.*) *nonliquefaciens* is considered to be a well-established parasite of humans and rarely causes disease, but it has been associated with endophthalmitis and pneumonitis with pulmonary abscess. *Moraxella* (*M.*) *osloensis*, usually a harmless parasite, has been frequently associated with such human infections as osteomyelitis, endocarditis, septicemia, meningitis, stomatitis, and septic arthritis.

Moraxella (*B.*) *catarrhalis*, the type species of *Branhamella*, is the only species of this subgenus recovered from humans. The organism is considered to be a well-adapted parasite but has been judged the etiologic agent of middle-ear infection, maxillary sinus infection, bronchitis, tracheitis, conjunctivitis, pneumonia, otitis media of infants, respiratory disease in the compromised host, septicemia, meningitis, and endocarditis. The remaining *Branhamella* species (*caviae*, *ovis*, and *cuniculi*) are parasites of guinea pigs, sheep, cattle, and rabbits.

Moraxella species are susceptible to most antimicrobial agents with the exception of the lincomycins. Their usually high susceptibility to the penicillins is a feature that separates them from most other gram-negative rods. *See* Clinical microbiology. [G.G.]

Mordant A substance or combination of substances that facilitates the fixing of a dye to a fiber. A mordant enables the production of a more permanent and often deeper color. Metallic salts or hydroxides are most frequently used as mordants.

Certain mordants act directly on the fiber, making it more susceptible to the dye. Fabrics are then pretreated with the mordant before exposure to the dye. Other mordants function through the formation of a complex with the dye. The complex acts as the dyeing agent. Mordant and dye in this case are exposed simultaneously to the fabric. *See* Dye; Dyeing. [F.J.J.]

Mormonilloida The smallest of seven orders of Copepoda, containing two species in a single genus; their position in the copepod hierarchy has not been determined. Mormonilloids are free-living copepods that, in body form, closely resemble certain cyclopoids. However, they differ significantly in possessing mouthparts typical of the Calanoida. The presence of both gymnoplean and podoplean characteristics suggests a phylogenetic relationship with the Misophrioida. The lack of a heart, the small number of antennal segments, and the absence of fifth thoracic legs immediately distinguish mormonilloids from misophrioids. *See* Calanoida; Misophrioida.

Both mormonilloid species are pelagic, primarily occurring in a depth range of 1350–2300 ft (410–700 m) in the eastern North Atlantic. Males have never been observed. *See* Copepoda; Crustacea. [P.A.McL.]

Mortar A binding agent used in construction of clay brick, concrete masonry, and natural stone masonry walls and, to much less extent, landscape pavements. Modern mortars are improved versions of the lime and sand mixtures historically used in building masonry walls. *See* Brick; Masonry.

Masonry mortar is composed of one or more cementitious materials, such as masonry cement or portland cement and lime, clean sand, and sufficient water to produce a plastic, workable mixture.

Mortars are closely related to concrete but, like grout, generally do not contain coarse aggregate. Mortars function with the same calcium silicate-based chemistry as concrete and grouts, bonding with masonry units into a contiguous, weatherproof surface in the process. Masonry cement or portland cement-lime mortars can be formulated to address job-specific requirements including setting time, rate of hardening, water retentivity, and extended workability. *See* Cement; Concrete; Grout; Lime (industry). [J.Mel.]

Mosaicism The coexistence of two or more genetically distinct cell populations derived originally from a single zygote. Mosaics may arise at any stage of development, from the two-cell stage onward, or in any tissue which actively proliferates thereafter. The phenomenon is commonly observed in many species of animals and plants and may be caused by somatic mutation or chromosomal nondisjunction. An individual animal or plant may exhibit mosaicism, or it may occur in a culture of a single cell- or tissue-type obtained from an individual.

Chromosome nondisjunction is probably the principal cause of chromosomal aberration, which in turn may lead to the development of mosaicism. During cell division, the two sister chromatids usually separate completely, each chromatid going to opposite poles of the cell guided by the spindle apparatus. In some cases, one chromatid will fail to completely separate, or it may lag behind. This nondisjunction will lead to the presence of both sister chromatids in the same daughter cell instead of one in each of the daughter cells (Fig. 1). Somatic crossing-over leads to the production of a recombinant mosaic where chromosome segments, with their corresponding blocks of genes, are exchanged between homologous chromosomes during mitosis. The occurrence of this process leads to mosaicism, mostly manifested as spots (clones of variant cells) on the cuticle of insects or on leaves, petals, or stamen hairs. *See* Chromosome.

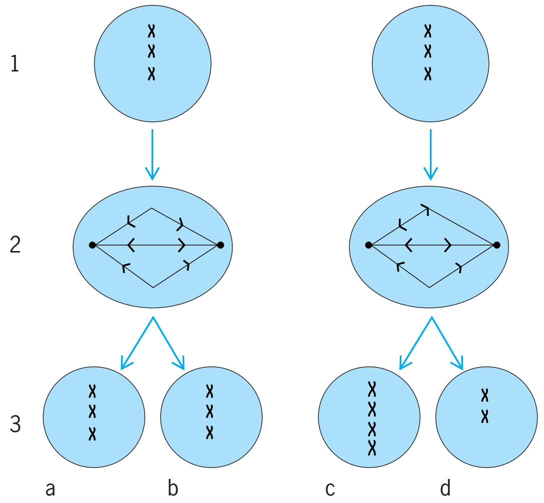


Fig. 1. Mosaicism caused by chromosome nondisjunction. (1) Two cells with an identical chromosome complement are in the process of cellular division. (2) In the cell on the left, the sister chromatids have separated normally, whereas in the other cell, one chromatid has remained in the equatorial zone. (3) Two normal daughter cells (a and b) are produced as a result of a normal mitotic division. Two aneuploid cells (c and d) result from the abnormal division. If c and d are viable, a tissue mosaicism may result with a mixture of normal cells and some aneuploid cells (c, d, or c and d).

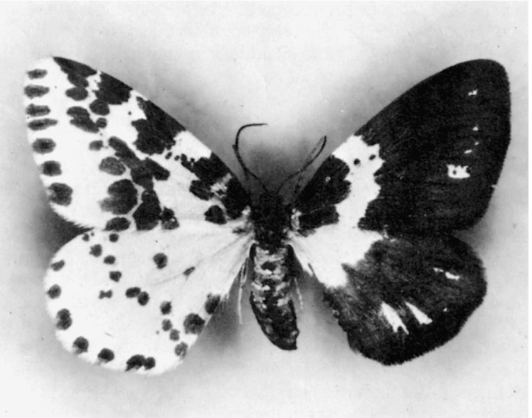

Fig. 2. Bilateral gynandromorphism in the moth *Abraxas grossulariata*. The left side shows the typical male wing patterning, whereas the right side shows a female form.

Sex chromosome mosaicism, the presence of a mixture of cell populations with different X and Y chromosome constitutions, is not uncommon and is often seen in individuals with ovarian dysgenesis. The presence of a significant proportion of chromosomally abnormal cells in any such mosaic will tend to lead to a clinically expressed syndrome. The proportion of each constituent clone may vary from tissue to tissue, but is relatively stable in each individual site throughout adult life. Sex mosaics (gynandromorphs) are particularly striking where a difference in the secondary sexual characteristics exists between the normal sexes. For example, in a butterfly with bilateral gynandromorphism, the left side may show the characteristic wing color and pattern of the male, and the light wing, typical female patterning (Fig. 2). *See* Chimera; Genetics; Sex-linked inheritance. [A.W.W.]

Mosquito Any member of the family Culicidae in the insect order Diptera. Mosquitoes are holometabolous insects and all larval stages are aquatic. Adults are recognized by their long proboscis for piercing and sucking, and characteristic scaled wing venation. This is a relatively large group of well-known flies with nearly 3000 species in 34 genera reported in the world. There are 13 genera and 167 recognized species of mosquitoes in North America north of Mexico. Almost 75% of these species belong to three genera: *Aedes* (78 species), *Culex* (29 species), and *Anopheles* (16 species).

Adult females lay their eggs on or near water. Most larvae, or wrigglers, feed on algae and organic debris that they filter from the water with their oral brushes, although certain genera may be predaceous and feed on other mosquito larvae. Larvae go through three molts and four instars before pupation. Pupae, or tumblers, are active but nonfeeding stages in which metamorphosis to the adult stage occurs. Both larvae and pupae usually breathe through air tubes at the surface of the water.

Adult male mosquitoes are relatively short-lived, and do not suck blood, but feed primarily on nectar and other plant juices. Females also feed on nectar as their primary energy source, but they require a blood meal for egg production in most species. Some mosquito species are very host-specific, blood-feeding only on humans, birds, mammals, or even reptiles and amphibians, although many species will feed on any available host.

Mosquitoes are of major importance in both human and veterinary medicine. They can cause severe annoyance and blood loss when they occur in dense populations, and they act as vectors of three important groups of disease-causing organisms: *Plasmodium*, the protozoan parasite that produces malaria; filarial worms, parasitic nematodes causing elephantiasis in humans and heartworm disease in canines; and arboviruses, which are the causative agents of yellow fever, dengue fever, LaCrosse encephalitis, St. Louis encephalitis, western equine encephalomyelitis, eastern and Venezuelan equine encephalitis, and several other viral diseases. Human malaria is transmitted exclusively by *Anopheles*, filariasis by *Culex*, *Anopheles*, and *Aedes*, and arboviruses primarily by *Culex* and *Aedes* species. *See* Arboviral encephalitides; Heartworms; Insecta; Malaria; Medical parasitology; Yellow fever. [B.M.Ch.]

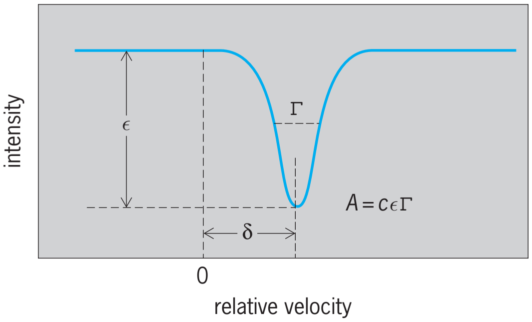
Mössbauer effect Recoil-free gamma-ray resonance absorption. The Mössbauer effect, also called nuclear gamma resonance fluorescence, has become the basis for a type of spectroscopy which has found wide application in nuclear physics, structural and inorganic chemistry, biological sciences, the study of the solid state, and many related areas of science.

The fundamental physics of this effect involves the transition (decay) of a nucleus from an excited state of energy E_e to a ground state of energy E_g with the emission of a gamma ray of energy E_γ. If the emitting nucleus is free to recoil, so as to conserve momentum, the emitted gamma ray energy is $E_\gamma = (E_e - E_g) - E_r$, where E_r is the recoil energy of the nucleus. The magnitude of E_r is given classically by the relationship $E_r = E_\gamma{}^2/2mc^2$, where m is the mass of the recoiling atom and c is the speed of light. Since E_r is a positive number, the E_γ will always be less than the difference $E_e - E_g$, and if the gamma ray is now absorbed by another nucleus, its energy is insufficient to promote the transition from E_g to E_e.

In 1957 R. L. Mössbauer discovered that if the emitting nucleus is held by strong bonding forces in the lattice of a solid, the whole lattice takes up the recoil energy, and the mass in the recoil energy equation given above becomes the mass of the whole lattice. Since this mass typically corresponds to that of 10^{10} to 10^{20} atoms, the recoil energy is reduced by a factor of 10^{-10} to 10^{-20}, with the important result that $E_r \approx 0$ so that $E_\gamma = E_e - E_g$; that is, the emitted gamma-ray energy is exactly equal to the difference between the nuclear ground-state energy and the excited-state energy. Consequently, absorption of this gamma ray by a nucleus which is also firmly bound to a solid lattice can result in the “pumping” of the absorber nucleus from the ground state to the excited state. *See* Energy level (quantum mechanics); Excited state; Gamma rays; Ground state.

In a typical Mössbauer experiment the radioactive source is mounted on a velocity transducer which imparts a smoothly varying motion (relative to the absorber, which is held stationary), up to a maximum of several centimeters per second, to the source of the gamma rays. These gamma rays are incident on the material to be examined (the absorber). Some of the gamma rays are absorbed and reemitted in all directions, while the remainder of the gamma rays traverse the absorber and are registered in an appropriate detector.

A typical display of a Mössbauer spectrum, which is the result of many repetitive scans through the velocity range of the transducer, is shown in the illustration. In certain nuclides the



Mössbauer spectrum of an absorber which gives an unsplit resonance line. The spectrum is characterized by a position δ, a line width Γ, and an area *A* related to the effect magnitude ε.

Mössbauer resonance line displays splitting that arises from the coupling of the nuclear electric quadrupole moment with the electric field gradient or of the nuclear magnetic dipole moment with the magnetic field at the nucleus, providing information on the magnitude of these interactions.

Mössbauer effect experiments have been used to elucidate problems in a very wide range of scientific disciplines. Applications include the measurement of nuclear magnetic and quadrupole moments and of excited-state lifetimes involved in the nuclear decay process; study of the chemical consequences of nuclear decay; study of the nature of magnetic interactions in iron-containing alloys and of the dependence of the magnetic field in these alloys on various parameters; study of the effects of high pressure on chemical properties of materials; investigation of the relationship between chemical composition and structure on the one hand and the superconductive transition on the other; investigation of the structure of compounds; and study of the structure and bonding properties of metal atoms in complex biological molecules. [R.H.He.]

Motion If the position of a material system as measured by a particular observer changes with respect to time, that system is said to be in motion with respect to the observer. Absolute motion, then, has no significance, and only relative motion may be defined; what one observer measures to be at rest, another observer in a different frame of reference may regard as being in motion. *See* FRAME OF REFERENCE; RELATIVE MOTION.

The time derivatives of the various coordinates used to specify the system may be used to prescribe the motion at any instant of time. How the motion develops in subsequent instants is then determined by the laws of motion. In classical dynamics it is supposed that in principle the motion and configuration of the system may be specified to an arbitrary precision, although in quantum mechanics it is recognized that the measurement of the one disturbs the other.

The most general theory of motion that has yet been developed is quantum field theory, which combines both quantum mechanics and relativity theory, as well as the experimentally observed fact that elementary particles can be created and annihilated. *See* DEGREE OF FREEDOM (MECHANICS); DYNAMICS; EULER'S EQUATION OF MOTION; HAMILTON'S EQUATIONS OF MOTION; HARMONIC MOTION; KINEMATICS; KINETICS (CLASSICAL MECHANICS); LAGRANGE'S EQUATIONS; NEWTON'S LAWS OF MOTION; OSCILLATION; PERIODIC MOTION; QUANTUM FIELD THEORY; QUANTUM MECHANICS; RECTILINEAR MOTION; RELATIVITY; ROTATIONAL MOTION. [H.C.Co./B.G.]

Motivation The intentions, desires, goals, and needs that determine human and animal behavior. An inquiry is made into a person's motives in order to explain that person's actions.

Different roles have been assigned to motivational factors in the causation of behavior. Some have defined motivation as a nonspecific energizing of all behavior. Others define it as recruiting and directing behavior, selecting which of many possible actions the organism will perform. The likely answer is that both aspects exist. More specific determinants of action may be superimposed on a dimension of activation or arousal that affects a variety of actions nonselectively. The situation determines what the animal does; arousal level affects the vigor, promptness, or persistence with which the animal does it.

Early drive theorists saw motivated behavior as adjunct to physiological mechanisms of homeostasis, that is, the mechanisms by which the body regulates internal variables such as temperature, blood sugar level, and the volume and concentration of body fluids. Thus, motivated behavior forms part of a negative-feedback loop, an arrangement characteristic of regulatory systems.

However, the homeostatic model faces difficulties. First, not all "basic biological drives" work this way. Second, motivated behavior can be influenced by external as well as internal factors. Since these external influences are not coupled with the animal's internal state, they can lead to behavior that does not promote homeostasis and may even threaten it. To add to the complexity, internal and external factors are not independent and additive; rather they interact with each other. In such cases, internal influences affect behavior by setting the animal's responsiveness to certain external signals. The interaction occurs in the opposite direction as well: external signals can affect internal state. Third, especially in humans, vigorous and persistent goal-directed behavior can occur in the absence of any physiological need. *See* HOMEOSTASIS.

Even relatively simple motives can be influenced by much more than the existing internal and external situation. They respond to potential or expected factors, as registered by cognitive apparatus. Even relatively simple motives such as hunger and thirst are responsive to cognitive factors. *See* THIRST.

To a hungry rat, food becomes a goal. The rat will make various responses, including arbitrary learned ones or operants, that lead to contact with food. A rat can be trained to do whatever else is necessary (within its capabilities) to attain its goal. It is this flexibility of goal-directed behavior that justifies the concept of motivation. If an animal will do whatever is necessary to obtain food, it must want food. Internal factors then may act by setting the goal status of environmental commodities: the effect of hunger is to make food a goal.

There is a question as to how behavior can be guided by a state or event (goal attainment) that does not yet exist. Modern approaches to this question lean heavily on cognitive concepts. Mammals, birds, and even some insects can represent to themselves a nonexistent state of affairs. They can represent what a goal object is (search images): a chimpanzee may show behavioral signs of surprise if a different food is substituted for the usual one. They can represent where it is (cognitive maps): a digger wasp remembers the location of its nest relative to arbitrary landmarks, and will fly to the wrong place if the landmarks are moved.

If this idea is generalized, motivated behavior can be thought of as guided by a feedback control system with a set point. A set point establishes a goal state which the control system seeks to bring about. Behavior is controlled, not by present external or internal stimuli alone, but by a comparison between the existing state of affairs and a desired state of affairs, that is, the set point or goal, registered or specified within the brain. The animal then acts to reduce the difference between the existing and the desired state of affairs.

This way of looking at motivation helps bridge the gap between simple motives in animals and complex ones in humans. If to be motivated is to do whatever is necessary to bring about an imagined state of affairs, then human motives can literally be as complex, and be projected as far into the future, as human imaginations permit. *See* COGNITION.

Another approach to motivation comes from ethology, which has formed links with cognitive psychology. The broken-wing display of the piping plover provides an example. If a predator approaches a nest with eggs, the parent bird may behave as if injured (hence easy prey) and thus lead the intruder away from the nest. This action pattern is characteristic of the species and unlearned in its gross topography; yet the bird monitors the intruder's behavior and modulates the display accordingly. It may approach more closely and intensify the display if the intruder is not at first diverted from its path. Thus a species-typical action pattern can be used in ways suggestive of purpose and goal direction: the bird modifies it as necessary to promote the goal of diverting the intruder. *See* ETHOLOGY.

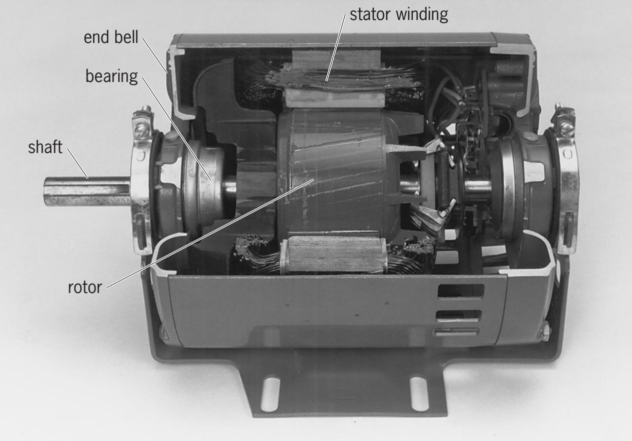
Motivation and emotion are closely related. Indeed, it has been argued that emotions are the true motivators and that other factors internal, situational, and cognitive take hold of behavior by way of the emotions they evoke. In the simplest case, pleasure and displeasure have been recognized for centuries as having motivational force. In more complex cases, the role of cognitive operations, such as how an individual feels about an event, as well as what is done about it, can depend heavily on how an individual thinks about it.

The culture in which an individual is raised has a powerful effect on how the individual behaves. It has been argued that culture teaches its members what to believe are the consequences of a specific action (cognitive), and how the individuals should feel about those consequences or about the actions themselves (emotional/motivational). [D.G.M.]

Motor A machine that converts electrical into mechanical energy. Motors that develop rotational mechanical motion are most common, but linear motors are also used. A rotary motor delivers mechanical power by means of a rotating shaft extending from one or both ends of its enclosure (see illustration). The shaft is attached internally to the rotor. Shaft bearings permit the rotor to turn freely. The rotor is mounted coaxially with the stationary part, or stator, of the motor. The small space between the rotor and stator is called the air gap, even though fluids other than air may fill this gap in certain applications.

In a motor, practically all of the electromechanical energy conversion takes place in the air gap. Commercial motors employ magnetic fields as the energy link between the electrical input and the mechanical output. The air-gap magnetic field is set up by current-carrying windings located in the rotor or the stator, or by a combination of windings and permanent magnets. The magnetic field exerts forces between the rotor and stator to produce the mechanical shaft torque; at the same time, in accord with Faraday's law, the magnetic field induces voltages in the windings. The voltage induced in the winding connected to the electrical energy source is often called a countervoltage because it is in opposition to the source voltage. By its magnitude and, in the case of alternating-current (ac) motors, its phase angle, the countervoltage controls the flow of current into the motor's electrical terminals and hence the electrical power input. The physical phenomena underlying motor operation are such that the power input is adjusted automatically to meet the requirements of the mechanical load on the shaft. *See* ELECTROMAGNETIC INDUCTION; MAGNET; WINDINGS IN ELECTRIC MACHINERY.

Both the rotor and stator have a cylindrical core of ferromagnetic material, usually steel. The parts of the core that are subjected to alternating magnetic flux are built up of thin steel laminations that are electrically insulated from each other to impede the flow of eddy currents, which would otherwise greatly reduce motor efficiency. The windings consist of coils of insulated copper or aluminum wire or, in some cases, heavy, rigid insulated conductors. The coils may be placed around pole pieces, called salient poles, projecting into the air gap from one of the cores, or they may be embedded in radial slots cut into the core surface facing the air gap. In a slotted core, the core material remaining between the slots is in the form of teeth, which should not be confused with magnetic poles. *See* EDDY CURRENT.



Cutaway view of a single-phase induction motor. (*Emerson Motor Division*)

Direct-current (dc) motors usually have salient poles on the stator and slotted rotors. Polyphase ac synchronous motors usually have salient poles on the rotor and slotted stators. Rotors and stators are both slotted in induction motors. Permanent magnets may be inserted into salient pole pieces, or they may be cemented to the core surface to form the salient poles.

The windings and permanent magnets produce magnetic poles on the rotor and stator surfaces facing each other across the air gap. If a motor is to develop torque, the number of rotor poles must equal the number of stator poles, and this number must be even because the poles on either member must alternate in polarity (north, south, north, south) circularly around the air gap. [G.McP.]

Motor-generator set A motor and one or more generators, with their shafts mechanically coupled, used to convert an available power source to another desired frequency or voltage. The motor of the set is selected to operate from the available power supply; the generators are designed to provide the desired output.

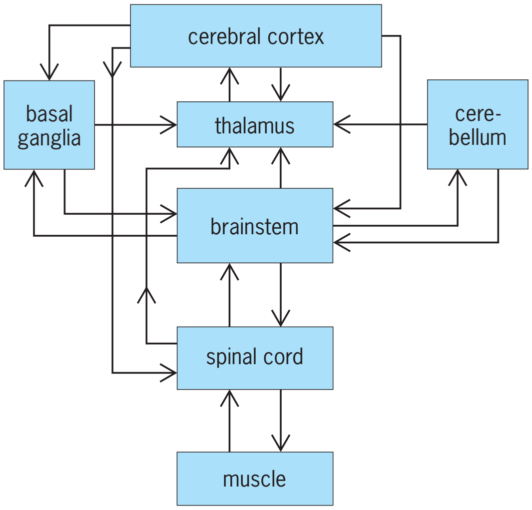
The principal advantage of a motor-generator set over other conversion systems is the flexibility offered by the use of separate machines for each function. Since a double energy conversion is involved, electrical to mechanical and back to electrical, the efficiency is lower than in most other conversion methods. *See* GENERATOR; MOTOR. [A.R.E.]

Motor systems Those portions of nervous systems that regulate and control the contractile activity of muscle and the secretory activity of glands. Muscles and glands are the two types of organ by which an organism reacts to its environment; together they constitute the machinery of behavior. Cardiac muscle and some smooth muscle and glandular structures can function independently of the nervous system but in a poorly coordinated fashion. Skeletal muscle activity, however, is entirely dependent on neural control. Destruction of the nerves supplying skeletal muscles results in paralysis, an inability to move. The somatic motor system includes those regions of the central nervous system involved in controlling the contraction of skeletal muscles in a manner appropriate to environmental conditions and internal states. *See* GLAND; MUSCLE.

Skeletal muscle. The nerve supply to skeletal muscles of the limbs and trunk is derived from large nerve cells called motoneurons, whose cell bodies are located in the ventral horn of the spinal cord. Muscles of the face and head are innervated by motoneurons in the brainstem. The axons of the motoneurons traverse the ventral spinal roots (or the appropriate cranial nerve roots) and reach the muscles via peripheral nerve trunks. In the muscle, the axon of every motoneuron divides repeatedly into many terminal branches, each of which innervates a single muscle fiber. The region of innervation, called the neuromuscular junction or motor end plate, is a secure synaptic contact between the motoneuron terminal and the muscle fiber membrane. *See* SYNAPTIC TRANSMISSION.

Since synaptic transmission at the neuromuscular junction is very secure, an action potential in the motoneuron will produce contraction of every muscle fiber that it contacts. For this reason, the motoneuron and all the fibers it innervates form a functional unit called the motor unit. The number of muscle fibers in a single motor unit may be as small as six (for intrinsic eye muscles) or over 700 (for motor units of large limb muscles). In general, muscles involved in delicate rapid movements have fewer muscle fibers per motor unit than large muscles concerned with gross movements.

Components of skeletal motor system. Motoneurons are activated by nerve impulses arriving through many different



Schematic diagram of the major components of the vertebrate motor systems. Arrows indicate the main neural connections between regions.

neural pathways. Some of their neural input originates in peripheral receptor organs located in the muscles themselves, or in receptors in skin or joints. Many muscle receptors discharge in proportion to muscle length or tension; such receptors have relatively potent connections to motoneurons, either direct monosynaptic connections or relays via one or more interneurons. Similarly, stimulation of skin and joints, particularly painful stimulation, can strongly affect motoneurons. Such simple segmental pathways constitute the basis for spinal reflexes. The other major source of input to motoneurons arises from supraspinal centers. The illustration shows the main nervous system centers involved in controlling the input to motoneurons.

Segmental circuits. At the spinal level, the motoneurons and muscles have a close reciprocal connection. Afferent connections from receptors in the muscles return sensory feedback to the same motoneurons which contract the muscle. Connections to motoneurons of synergist and antagonist muscles are sufficiently potent and appropriately arranged to subserve a variety of reflexes. In animals with all higher centers removed, these segmental circuits may function by themselves to produce simple reflex responses. Under normal conditions, however, the activity of segmental circuits is largely controlled by supraspinal centers. Descending tracts arise from two major supraspinal centers: the cerebral cortex and the brainstem.

Brainstem. The brainstem, which includes the medulla and pons, is a major and complex integrating center which combines signals descending from other higher centers, as well as afferent input arising from peripheral receptors. The descending output from brainstem neurons affects motor and sensory cells in the spinal cord. Brainstem centers considerably extend the motor capacity of an animal beyond the stereotyped reflex reactions mediated by the spinal cord. In contrast to segmental reflexes, these motor responses involve coordination of muscles over the whole body. Another major motor function of the brainstem is postural control, exerted via the vestibular nuclei of the ear.

Besides neurons controlling limb muscles, the brainstem also contains a number of important neural centers involved in regulating eye movements. These include motor neurons of the eye muscles and various types of interneurons that mediate the effects of vestibular and visual input on eye movement.

Cerebellum. Another important coordinating center in the motor system is the cerebellum, an intricately organized network of cells closely interconnected with the brainstem. The cerebellum receives a massive inflow of sensory signals from peripheral receptors in muscles, tendons, joints, and skin, as well as from visual, auditory, and vestibular receptors. Higher centers, particularly the cerebral cortex, also provide extensive input to the cerebellum via pontine brainstem relays. The integration of this massive amount of neural input in the cerebellum somehow serves to smooth out the intended movements and coordinate the activity of muscles. Without the cerebellum, voluntary movements become erratic, and the animal has difficulty accurately terminating and initiating responses. The output of the cerebellum affects primarily brainstem nuclei, but it also provides important signals to the cerebral cortex.

Basal ganglia. At another level of motor system are the basal ganglia. These massive subcortical nuclei receive descending input connections from all parts of the cerebral cortex. Their output projections send recurrent information to the cerebral cortex via the thalamus, and their other major output is to brainstem cells.

Cerebral cortex. At the highest level of the nervous system is the cerebral cortex, which exerts control over the entire motor system. The cerebral cortex performs two kinds of motor function: certain motor areas exert relatively direct control over segmental motoneurons, via a direct corticospinal pathway, the pyramidal tract, and also through extrapyramidal connections via supraspinal motor centers. The second function, performed in various cortical association areas, involves the programming of movements appropriate in the context of sensory information, and the initiation of voluntary movements on the basis of central states. Cortical language areas, for example, contain the circuitry essential to generate the intricate motor patterns of speech. Limb movements to targets in extrapersonal space appear to be programmed in parietal association cortex. Such cortical areas involved in motor programming exert their effects via corticocortical connections to the motor cortex, and by descending connections to subcortical centers, principally basal ganglia and brainstem.

As indicated in the illustration, the motor centers are all heavily interconnected, so none really functions in isolation. In fact, some of these connections are so massive that they may form functional loops, acting as subsystems within the motor system. For example, most regions of the cerebral cortex have close reciprocal interconnections with underlying thalamic nuclei, and the corticothalamic system may be considered to form a functional unit. Another example is extensive connection from cerebral cortex to pontine regions of the brainstem, controlling cells that project to the cerebellum, which in turn projects back via the thalamus to the cerebral cortex. Such functional loops are at least as important in understanding motor coordination as the individual centers themselves. *See* Brain; Nervous system (vertebrate). [E.E.F.]

Mountain A feature of the Earth's surface that rises high above its base and has generally steep slopes and a relatively small summit area. Commonly the features designated as mountains have local heights measurable in thousands of feet, lesser features of the same type being called hills, but there are many exceptions. *See* Hill and mountain terrain.

Mountains rarely occur as isolated individuals. Instead they are usually found in roughly circular groups or massifs, such as the Olympic Mountains of northwestern Washington, or in elongated ranges, like the Sierra Nevada of California. An array of linked ranges and groups, such as the Rocky Mountains, the Alps, or the Himalayas, is a mountain system. North America, South America, and Eurasia possess extensive cordilleran belts, within which the bulk of their higher mountains occur. *See* Cordilleran belt; Massif; Mountain systems.

As a rule, mountains represent portions of the Earth's crust that have been raised above their surroundings by upwarping, folding, or buckling, and have been deeply carved by streams or glaciers into their present surface form. Some individual peaks and massifs have been constructed upon the surface by outpourings of lava or eruptions of volcanic ash. *See* Orogeny. [E.H.Ha.]

Mountain meteorology The effects of mountains on the atmosphere, ranging over all scales of motion, including very small (such as turbulence), local (for instance, cloud formations over individual peaks or ridges), and global (such as the monsoons of Asia and North America).

The most readily perceived effects of a mountain, or even of a hill, are related to the blocking of air flow. When there is sufficient wind, the air either goes around the obstacle or over it, causing waves in the flow similar to those in a river washing over a boulder. Since ascending air cools by adiabatic expansion, the saturation point of water vapor may be reached in such waves as they form over an obstacle, and a cloud then forms in the ascending branch of the wave motion. Such a cloud dissipates in the descending branch where adiabatic warming takes place. The shapes and amplitudes of these lee waves (they form over and to the lee of mountains) depend not only on the thermal stability and on the vertical wind shear in the overlying atmosphere but also on the shape of the underlying terrain. *See* Cloud; Cloud physics; Wave (physics).

On a grander scale, mountain ranges, such as the Sierras of North and South America, place an obstacle in the path of the westerly winds (that is, winds from the west), which generally prevail in middle latitudes. Such a blockage tends to generate a high-pressure region upwind from the mountains (this may be viewed as air piling up as it prepares to jump the hurdle), and a low-pressure area downwind. Thus, there is a stronger push against the mountains on the high-pressure western side than on the low-pressure eastern side. The net effect is the slowing down of the atmospheric flow (mountain torque). *See* Torque.

Less subtle than mountain torque effects are the large-scale meanders that develop in the global flow patterns once they have been perturbed, mainly by the North and South American Andes and by the Plateau of Tibet and its Himalayan mountain ranges. These meanders in the large-scale flow are known as planetary waves. They appear prominently in the pressure patterns of hemispheric or global weather maps. *See* Weather map.

The major monsoon circulations interact with the global circulation, shaped in part by sea-surface temperature anomalies in the equatorial Pacific. The various aspects of mountain meteorology, therefore, have to be viewed within the larger picture. There is a continuous interaction between the weather effects on all space and time scales generated by the mountains and the weather patterns that prevail elsewhere on the Earth. *See* Meteorology. [E.R.R.]

Mountain systems Long, broad, linear to arcuate belts in the Earth's crust where extreme mechanical deformation and thermal activity have been (or are being) concentrated.

Mountain systems in the general sense occur both on continents and in ocean basins, but the geological properties of the systems in continental as opposed to oceanic settings are distinctly different. The mechanical strain in classical, continental mountain systems is expressed in the presence of major folds, faults, and intensive fracturing and cleavage. Thermal effects are in the form of vast volcanic outpourings, intruded bodies of igneous magma, and metamorphism. Uplift and deformation in young mountain systems are conspicuously displayed in the physiographic forms of topographic relief. Where mountain building is presently taking place, the dynamics are partly expressed in warping of the land surface and significant shallow or deep earthquake activity. Locations of ancient mountain systems in continental regions now beveled flat by erosion are clearly disclosed by the presence of highly deformed, intruded, and metamorphosed rocks.

Two basic classes of oceanic mountain systems exist. A world-encircling oceanic rift mountain system has been built along the extensional tectonic boundary between plates diverging at rates of 0.8–2.4 in. or 2–6 cm per year from the mid-oceanic ridges. This rift mountain system is exposed to partial view in Iceland. The second type, island arc mountain systems, occur in oceanic basins where the crust dives downward at trench sites, thus underthrusting adjacent oceanic crust. *See* Marine geology.

The classical, conspicuous mountain systems of the Earth occur at the continent/ocean interface, for this is the site where plate convergence has led to major sedimentation, subduction of oceanic crust under continents, collision of island arc mountain systems with continents, and head-on collision of continents. *See* Orogeny; Plate tectonics. [G.H.D.]

Mouse The name associated with any species of animals which are members of the families Muridae, Heteromyidae, Cricetidae, and Zapodidae in the order Rodentia. Some of the more common species are listed in the table. Many species are used for research in both biology and medicine. In addition to their use in studying the mechanisms of genetics, they are important in the study of carcinogenesis, effects of drugs, and virology. They are also important experimental animals in studying cell physiology, such as for cell and tissue culture research. The familiar white mouse is an albino form of the house mouse and is used extensively in research.

Classification MI representative species of mice

Families and subfamilies	Examples
Family: Heteromyldae	
Subfamily. Perognathinae	Pocket and kangaroo mice
Subfamfly: Heteromyinae	Spiny pocket mice
Family: Cricetidae	
Subfamily: Crtcetinae	Climbing mice, harvest mice, water mite, white-footed mice, pigmy mice
Family: Muridae	
Subfamily: Murinae	Striped mice, house mice, spiny mice, harvest mice, field mice, forest mice
Subfamily: Dendromurinae	African tree mice
Family: Zapodidae	Jumping mice

The common house mouse is one of the oldest known species of domestic rodent pests. It usually has a maximum lifespan of 4 years with four to six litters of four to eight young each per year. The gestation period is about 3 weeks. These rodents begin to breed at 3 months of age. Adults have a pointed snout, compact body, and an equally long tail. The ears are fairly large, as are the legs. While omnivorous, they have a preference for grains and other vegetable foods. Of the 44 species known, only one species occurs in the United States, and it has become wild in some parts of the country. *See* Rodentia. [C.B.C.]

Mouth The oral or buccal cavity and its related structures. The oral cavity forms in the embryo from an in-pocketing of the skin, the stomodeum; it is thus lined by ectoderm and is not, properly speaking, part of the digestive tract. Functionally, however, the mouth forms the first portion of both the digestive and respiratory systems. Various special structures are found in, or associated with, the mouths of most vertebrates. *See* Digestive system; Respiratory system.

Teeth may be present to help grasp or grind food. In most vertebrates they are relatively simple cones but in some, especially mammals, they are of diverse shapes. *See* Dentition; Tooth.

Various glands are associated with the mouth. These are of infrequent occurrence in fish but are found in most tetrapods. Humans have three pairs of salivary glands: the parotid, submaxillary, and sublingual. In forms such as some snakes salivary glands may produce a poison used to subdue prey.

Other structures also vary greatly. Most tetrapods have a mobile tongue attached to the floor of the mouth, but few fish do. The structure of the roof of the mouth, or palate, is quite different in different groups. *See* Palate; Tongue.

In mammals, including humans, the margins of the lips mark the junction between the outer skin and the inner mucous lining of the oral cavity. The mucosa of the mouth forms the lining and the gums surrounding the teeth and covers the surface of the tongue. The roof of the mammalian mouth consists of the hard palate and, behind this, the soft palate which merges into the oropharynx. The lateral walls consist of the distensible cheeks, and the floor is formed principally by the tongue and the soft tissues that lie between the two sides of the lower jaw, or mandible.

The posterior limit of the oral cavity of mammals is marked by the fauces, an aperture which leads to the pharynx. On either side of the fauces are two muscular arches covered by mucosa, the glossopalatine and pharyngopalatine arches; between them lie masses of lymphoid tissue, the tonsils. Suspended from the posterior portion of the soft palate is the soft retractable uvula. *See* MOUTH DISORDERS; TONSIL. [T.S.P.]

Moving-target indication A method of presenting pulse-radar echoes in a manner that discriminates in favor of moving targets and suppresses stationary objects. Moving-target indication (MTI) is almost a necessity when moving targets are being sought over a region from which the ground clutter echoes are very strong. The most common presentation of the output of a radar with MTI is a plan-position indicator (PPI) display. The moving targets appear as bright echoes, while ground clutter is suppressed. *See* RADAR. [J.M.C.]

Mucilage A naturally occurring, high-molecular-weight (200,000 and up), organic plant product of unknown detailed structure. The term is loosely used, often interchangeably with the term gum. Chemically, mucilage is closely allied to gums and pectins but differs in certain physical properties. Although gums swell in water to form sticky, colloidal dispersions and pectins gelatinize in water, mucilages form slippery, aqueous colloidal dispersions. Mucilages are formed in normal plant growth within the plant by mucilage-secreting hairs, sacs, and canals, but they are not found on the surface as exudates as a result of bacterial or fungal action after mechanical injury, as are gums. Mucilages occur in nearly all classes of plants in various parts of the plant, usually in relatively small percentages, and are not infrequently associated with other substances, such as tannins. The chief industrial sources of mucilages are Icelandic and Irish moss, linseed, locust bean, slippery elm bark, and quince seed. *See* ADHESIVE; GUM; PECTIN. [E.H.H.]

Muffler A device used to attenuate sound while also allowing fluid (usually gas) to flow through it; also known as silencer in British usage. Mufflers are extensively used to reduce the intake and exhaust noise from pumps, fans, compressors, and internal combustion engines. Although active noise control techniques are emerging, most mufflers continue to use passive silencing methods. Passive mufflers are categorized as reactive or dissipative based on their primary method of attenuation. Reactive mufflers reflect sound back toward the noise source, and dissipative mufflers use porous materials to absorb the sound.

Reactive mufflers reflect acoustic waves at locations where a duct expands, contracts, or branches. Often a combination of reactive elements such as expansion chambers, resonators, and flow reversals is used. Reactive mufflers can be designed to provide better low-frequency attenuation than a dissipative muffler of similar size. Also, reactive mufflers can be used in harsh environments that dissipative or active mufflers might not withstand. In most cases, reactive mufflers are best suited for low-to-moderate frequencies, where acoustic wavelengths are larger than any cross dimension of the muffler. At these frequencies, mufflers can exhibit resonance or broadband attenuation behavior. *See* RESONANCE (ACOUSTICS AND MECHANICS).

Dissipative mufflers use absorptive materials that dissipate the acoustic energy into heat. A variety of porous media can be used for absorption, with fibrous materials such as fiberglass being common. The linings and baffles can be flat, contoured, constructed from layers of different materials, or mixed and matched for a particular application. Absorptive materials may face challenges due to harsh conditions such as high temperatures and potential clogging from particulate-laden flows. Dissipative mufflers are best suited for moderate-to-high frequencies, since absorption is less effective at low frequencies. At frequencies where the absorptive materials are effective, the attenuation is broadband, and the passbands exhibited by reactive mufflers are reduced or eliminated. Compared to reactive mufflers of similar size, dissipative mufflers can have higher attenuation (except at resonances for the reactive muffler) and lower pressure drop. At higher frequencies, where the acoustic wavelength is smaller than the duct width, the attenuation of a dissipative muffler may decrease considerably. *See* SOUND ABSORPTION.

Active mufflers attenuate unwanted noise by adding sound to counteract it. The disturbances add algebraically, resulting in a cancellation of the unwanted sound. An active muffler consists of sensors (such as microphones), a controller, and actuators (such as loudspeakers). The controller unit processes the signals from the sensor, and computes an appropriate signal for the actuator. Numerous control systems and strategies exist, and are under continuous development. Active mufflers are best suited for low frequencies where the sound field is relatively simple. The effectiveness of active mufflers has been demonstrated for a number of situations, but several challenges are the topic of ongoing research. There is a need for rugged sensors and actuators that can withstand high temperatures and harsh environments. Also, high-intensity disturbances at low frequencies require large-displacement, high-power actuators. *See* ADAPTIVE SOUND CONTROL. [A.Sel.]

Mulberry A genus (*Morus*) of trees characterized by milky sap and simple, often lobed, alternate leaves. White mulberry (*M. alba*) was introduced into the United States from China during the 19th century as a source of food for silkworms. The silkworm project was unsuccessful, but the trees remained and are common in cities and on the borders of forests. Red mulberry (*M. rubra*) grows in the eastern half of the United States and in southern Ontario. The wood is used for fence posts, furniture, interior finish, agricultural implements, and barrels. [A.H.G./K.P.D.]

Mule A hybrid sired by a male ass (*Equus asinus*) out of a female horse (*E. caballus*). The opposite cross, very seldom made, produces the hinny (a hybrid between a stallion and a female ass). The mule and the hinny are usually sterile, but two authenticated cases of mules producing living progeny are known. Male mules, often called horse mules, are almost always castrated to make them more tractable as work animals. Mules are noted for their endurance, surefootedness, and ability to stand hard work in hot weather. They can safely be self-fed in lots or corrals, whereas horses cannot. Usually steady and free from nervous excitability, mules can be handled by inexperienced or careless farm labor. [J.M.K.]

Multiaccess computer A computer system in which computational and data resources are made available simultaneously to a number of users. Users access the system through terminal devices, normally on an interactive or conversational basis. A multiaccess computer system may consist of only a single central processor connected directly to a number of terminals (that is, a star configuration), or it may consist of a number of processing systems which are distributed and interconnected with each other as well as with the user terminals.

The primary purpose of multiaccess computer systems is to share resources. The resources being shared may be simply the data-processing capabilities of the central processor, or they may be the programs and the data bases they utilize. The earliest examples of the first mode of sharing are the general-purpose, time-sharing, computational services. Examples of the latter mode are airlines reservation systems in which it is essential that all ticket agents have immediate access to current information.

System components. The major hardware components of a multiaccess computer system are terminals or data entry/display devices, communication lines to interconnect the terminals to the central processors, a central processor, and on-line mass storage. Terminals may be quite simple, providing only the capabilities for entering or displaying data, or they may have an appreciable amount of "local intelligence" to support simple operations like editing of the displayed text without requiring the involvement of the central processor. The interconnecting communication lines can be provided by utilizing the common-user telephone system or by obtaining leased, private lines from the telephone company or a specialized carrier.

System operating requirements. A multiaccess system must include the following functional capabilities: (1) multiline communications capabilities that will support simultaneous conversations with a reasonably large number of remote terminals; (2) concurrent execution of a number of programs with the ability to quickly switch from executing the program of one user to executing that of another; (3) ability to quickly locate and make available data stored on the mass storage devices while at the same time protecting such data from unauthorized access.

The ability of a system to support a number of simultaneous sessions with remote users is an extension of the capability commonly known as multiprogramming. In order to provide such service, certain hardware and software features should be available in the central processor. Primary among these is the ability to quickly switch from executing one program to another while protecting all programs from interference with one another.

Memory sharing is essential to the efficient operation of a multiaccess system. A popular memory management technique is the utilization of paging. The program is broken into a number of fixed-size increments called pages. Similarly, central memory is divided into segments of the same size called page frames. (Typical sizes for pages and page frames are 512 to 4096 bytes.) Under the concept known as demand paging, only those pages that are currently required by the program are loaded into central memory.

Software capabilities. The control software component of most interest to an interactive user is the command interpreter. This routine interacts directly with users, accepting requests for service and translating them into the internal form required by the remainder of the operating system, as well as controlling all interaction with the system.

The capability to page the memory as outlined above can be utilized to provide users with the impression that each has available a memory space much larger than is actually assigned. Such a system is said to provide a virtual memory environment. Similarly, the ability of the operating system to quickly change context from one executing program to another will result in users' receiving the impression that each has an individual processor. *See* DIGITAL COMPUTER. [P.H.E.]

Multilevel control theory

An approach to the control of large-scale systems based on (1) decomposition of the complex overall control problem into simpler and more easily managed subproblems and (2) coordination of the subproblems so that overall system objectives and constraints are satisfied.

The controllers are organized in a multilevel hierarchical structure according to three basic criteria: functional, plant, and temporal decomposition. Functional and temporal decompositions are often classified as multilayer or vertical structures; plant decomposition is often classified as a multilevel or horizontal structure.

In the functional decomposition approach, the overall control problem is partitioned into a nested set of generic control functions such as the regulatory (or direct control) function, optimizing control function, the adaptive control function, and the self-organizing function.

In the plant decomposition multilevel approach, the controlled system (plant) is partitioned into subsystems along lines of weak interaction. In a two-level control hierarchy, each subsystem has its own (first-level) controller which acts to satisfy local objectives and constraints. A second-level controller (coordinator) influences the actions of the local controllers to compensate for subsystem interactions so that overall objectives and constraints are satisfied.

In the temporal decomposition approach, the control or decision-making problem is partitioned into subproblems based on the different time scales relevant to the associated action functions. These time scales reflect such factors as the response time of the plant, the bandwidth characteristics of the disturbance inputs, and trade-off considerations relating the benefit of control action to its cost. At each layer of the hierarchy, decisions and control actions determined at higher layers (corresponding to lower-frequency events) are treated as constants; disturbances and actions associated with lower layers are treated as noise to be represented by their respective mean values. The temporal hierarchy may embrace a broad spectrum of control and decision-making activities, including process control, production control, scheduling, and planning functions. Time scales may range from seconds to years. *See* ADAPTIVE CONTROL; OPTIMAL CONTROL THEORY; PROCESS CONTROL; PRODUCTION ENGINEERING.

Hierarchical control has become accepted technology in many industries. It is often implicitly embedded in the design of the system, providing the conceptual framework for integrated (or plant-wide) systems control. Motivating considerations are improved productivity, operating efficiency, product quality, or other economic-based objectives. Hierarchical control has been applied to various nonindustrial systems, such as robotics and air traffic control systems. *See* AIR-TRAFFIC CONTROL; CONTROL SYSTEMS; DISTRIBUTED SYSTEMS (CONTROL SYSTEMS). [I.L.]

Multimedia technology

Computer-based, interactive applications having multiple media elements, including text, graphics, animations, video, and sound. Multimedia technology refers to both the hardware and software used to create and run such systems.

The mode of delivery for each application depends on the amount of information that must be stored, the privacy desired, and the potential expertise of the users. Applications that require large amounts of data are usually distributed on CD-ROMs, while personal presentations might be made directly from a computer using an attached projector. Advertising and some training materials are often placed on the WWW for easy public access. Museums make use of multimedia kiosks with touch screens and earphones. *See* COMPACT DISK; INTERNET; VIDEO GAMES; WORLD WIDE WEB.

Multimedia products may be created and run on the commonly used computer environments. Multimedia system users may employ a variety of input devices in addition to the keyboard and mouse, such as joysticks and trackballs. Touch screens provide both input and display capabilities and are often the choice when potentially large numbers of novices may use the system. Other display devices include high-resolution monitors and computer projectors. Generally the abundance of graphics and video in multimedia applications requires the highest resolution and deepest color capacity possible in display devices.

Input devices for the creation of multimedia applications include graphics tablets, which are pressure-sensitive surfaces for drawing with special pens; digital cameras, which take pictures electronically; and scanners, which convert existing pictures and graphics into digital form. Other hardware devices, such as a video card and video digitizing board, are required both to create and to play digital video elements.

The hardware for incorporating sound elements into multimedia systems includes microphones, voice-recognition systems, sound chips within the computer, and speakers, which come in a wide variety of forms with varying capabilities and quality. *See* SPEECH RECOGNITION.

The future of multimedia technology is dependent upon the evolution of the hardware. As storage devices get faster and larger, multimedia systems will be able to expand, and increased use of DVD should result in improved quality. Rising network speeds will increase the possibility of delivering multimedia applications over the WWW. Currently, Virtual Reality Modeling Language (VRML) is used for some WWW applications and may drastically expand the multimedia experience. Virtual reality is becoming more realistic and will stretch the multimedia experience to envelop the user. The one certainty in multimedia technology is that it will continue to change, to be faster, better, and more realistic. *See* VIRTUAL REALITY. [P.K.C.; R.A.Ko.]

Multimeter An instrument designed to measure electrical quantities. A typical multimeter can measure alternating- and direct-current potential differences (voltages), current, and resistance, with several full-scale ranges provided for each quantity. Sometimes referred to as a volt-ohm meter (VOM), it is a logical development of the electrical meter, providing a general-purpose instrument. Many kinds of special-purpose multimeters are manufactured to meet the needs of such specialists as telephone engineers and automobile mechanics testing ignition circuits. *See* AMMETER; CURRENT MEASUREMENT; OHMMETER; RESISTANCE MEASUREMENT; VOLTAGE MEASUREMENT; VOLTMETER.

Multimeters originated when all electrical measuring instruments used analog techniques. They were generally based on a moving-coil indicator, in which a pointer moves across a graduated scale. Accuracy was typically limited to about 2%, although models achieving 0.1% were available. Analog multimeters are still preferred for some applications. For most purposes, digital instruments are now used. In these, the measured value is presented as a row of numbers in a window. Inexpensive hand-held models perform at least as well as a good analog design. High-resolution multimeters have short-term errors as low as 0.1 part per million (ppm) and drift less than 5 ppm in one year. Many digital multimeters can be commanded by, and send their indications to, computers or control equipment. [R.B.D.K.]

Multiple cropping Planting two or more species in the same field in the same year. Preserved through history to maintain biological, economic, and nutritional diversity, multiple-species systems still are used by the majority of the world's farmers, especially in developing countries. Where farm size is small and the lack of capital has made it difficult to mechanize and expand, farm families that need a low-risk source of food and income often use multiple cropping. These systems maintain a green and growing crop canopy over the soil through much of the year, the total season depending on rainfall and temperature. Systems with more than one crop frequently make better use of total sunlight, water, and available nutrients than is possible with a single crop. The family has a more diverse supply of food and more than one source of income, with both spread over much of the year.

Multiple-cropping patterns are described by the number of crops per year and the intensity of crop overlap. Double cropping or triple cropping signifies systems with two or three crops planted sequentially with no overlap in growth cycle. Intercropping indicates that two or more crops are planted at the same time, or at least planted so that significant parts of their growth cycles overlap. Relay cropping describes the planting of a second crop after the first crop has flowered; in this system there still may be some competition for water or nutrients. When a crop is harvested and allowed to regrow from the crowns or root systems, the term ratoon cropping is used. Sugarcane, alfalfa, and sudangrass are commonly produced in this way, while the potential exists for such tropical cereals as sorghum and rice. Mixed cropping, strip cropping, associated cropping, and alternative cropping represent variations of these systems. *See* AGRICULTURAL SCIENCE (PLANT); AGRICULTURAL SOIL AND CROP PRACTICES; AGRICULTURE; AGRONOMY. [C.A.F.]

Multiple proportions, law of This law states that, when two elements combine together to form more than one compound, the weights of one element that unite with a given weight of the other are in the ratio of small whole numbers. The law can be illustrated by the composition of the five oxides of nitrogen. One gram of nitrogen is combined with 2.85 g of oxygen in nitrogen pentoxide, N_2O_5; with 2.28 g in nitrogen dioxide, NO_2; with 1.71 g in nitrogen trioxide, N_2O_3; with 1.14 g in nitric oxide, NO; and with 0.57 g in nitrous oxide, N_2O. These numbers are in the simple ratio of 5:4:3:2:1. *See* DEFINITE COMPOSITION, LAW OF. [T.C.W.]

Multiple sclerosis A neuromuscular disorder that characteristically involves the destruction of myelin, the insulating material around nerve fibers. The onset of the disease is unusual in persons under 15 or over 60 years of age, and peak incidence is found in people in their 20s and 30s. Multiple sclerosis affects females more frequently than males by approximately 2:1. Distribution is worldwide, but there is an unusual relationship to latitude, with a much higher incidence at northern latitudes than near the Equator.

In multiple sclerosis, only the central nervous system is affected, but both incoming and outgoing processes may be disrupted. Common initial symptoms reflect this underlying disease mechanism. They include blindness in one eye due to disruption of the conduction of the nerve impulse through the optic nerve; weakness of one side of the body due to impairment of the downstream signals from the motor areas of the cerebral cortex through the spinal cord; difficulties with coordination related to problems with cerebellar function; and disturbances in sensation, such as tingling and numbness in an arm or a leg that is related to dysfunction of incoming sensory signals. Multiple sclerosis is a progressive disease, so that over time there is often an accumulation of new symptoms and problems.

In its classic form, the disease spreads both temporally and anatomically. Temporally, there may be a series of acute attacks, but between attacks a person may recover fully and remain well for some time. Anatomically, areas of disruption of myelin (demyelination) are scattered throughout the nervous system and spinal cord. Thus, symptoms depend upon what part of the nervous system is affected at any given time. The course of the disease is unpredictable.

The basic cause of the disease is not known. There clearly are genetic factors in that the incidence of the disease is 20 times higher in first-degree relatives than in the general population. However, other factors must be involved, including infection (presumably viral) or possibly an immunological mechanism. The prevailing hypothesis combines these two possible etiological mechanisms to suggest that some type of viral infection occurs early in life to alter the patient's immune system. Thus, the activity and progression of the disease are related to altered immune functions within the central nervous system. In keeping with this hypothesis, therapy is aimed at altering the immune status of the affected individual. *See* HUMAN GENETICS; IMMUNOGENETICS; NERVOUS SYSTEM DISORDERS. [G.M.McK.]

Multiplexing and multiple access In telecommunications, multiplexing refers to a set of techniques that enable the sharing of the usable electromagnetic spectrum of a telecommunications channel (the channel passband) among multiple users for the transfer of individual information streams. It is assumed that the user information streams join at a common access point to the channel. The term "multiple access" is usually applied to multiplexing schemes by which multiple users who are geographically dispersed gain access to the shared telecommunications facility or channel. Various methods of multiplexing and multiple access are in common use.

In frequency-division multiplexing (FDM) and frequency-division multiple access (FDMA), the passband of a channel is shared among multiple users by assigning distinct and nonoverlapping sections of the electromagnetic spectrum within the passband to individual users. The information stream from a particular user is encoded into a signal whose energy is confined to the part of the passband assigned to that user. *See* RADIO SPECTRUM ALLOCATIONS.

Time-division multiplexing (TDM) and time-division multiple access (TDMA) permit a user access to the full passband of the channel, but only for a limited time, after which the access right is assigned to another user. Normally the access rights are assigned in a cyclical order to the competing users. However, statistical time-division multiplexing assigns time on the channel on a demand basis, which typically increases the number of users who may be accommodated on the same channel, but may result in delays in accessing the channel during periods when the demand exceeds the supply.

In code-division multiple access (CDMA), all users are assigned the entire passband of the channel and are permitted to transmit their information streams simultaneously. To maintain the ability to recover the individual signals at the receiver, at the transmitter each signal has impressed on it a characteristic signature.

Space-division multiple access (SDMA) refers to the use of the same portion of the electromagnetic spectrum over two or more spatially distinct transmission paths. In most applications of space-division multiple access, the paths are formed by multibeam antennas, in which each beam is directed toward a different geographic area. *See* ANTENNA (ELECTROMAGNETISM).

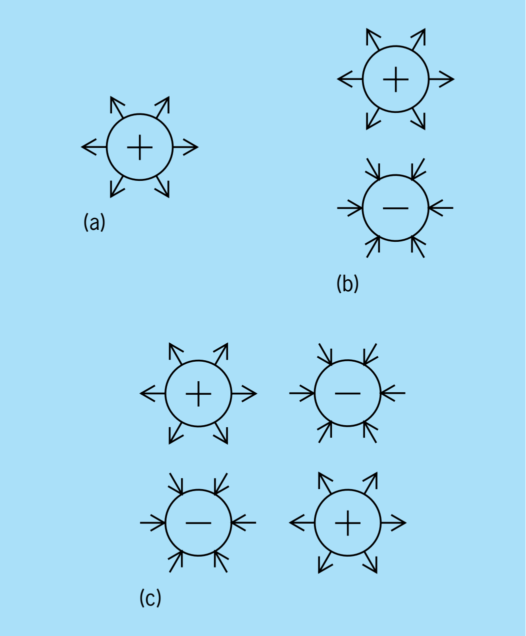
In wavelength-division multiplexing (WDM) schemes, transmission systems that employ the optical portion of the electromagnetic spectrum, such as those using fiber-optic cables as the transmission medium, share the total available passband of the medium by assigning individual information streams to signals of different wavelengths or “colors.” *See* OPTICAL COMMUNICATIONS; OPTICAL FIBERS.

Polarization refers to the direction or geometric orientation of the electric field vector of an electromagnetic field. Polarization-division multiplexing and polarization-division multiple access assign electric fields of different polarization to individual channels or users. *See* ELECTRICAL COMMUNICATIONS; POLARIZATION OF WAVES; POLARIZED LIGHT. [H.J.He.]

Multiplication One of the fundamental operations of arithmetic and algebra. The symbol × is commonly employed in arithmetic to denote multiplication. Because of its resemblance to the letter *x*, it is rarely used in algebra, where multiplication is frequently denoted by a dot (as in $a \cdot b$) or, most often, merely by juxtaposition of letters (for example, *ab*), Multiplication of numbers (real or complex) is associative, $a(bc) = (ab)c$; commutative, $ab = ba$; and distributive with respect to addition, $a(b + c) = ab + ac$; but the term has been extended to denote binary operations on many other kinds of objects, and these operations need not possess all the properties of ordinary multiplication listed above (for example, multiplication of matrices is not commutative). *See* ADDITION; ALGEBRA; DIVISION; SUBTRACTION. [L.M.Bl.]

Multipole radiation Standard patterns of radiation distribution about their source. The term radiation applies primarily to the transport of energy by acoustic, elastic, electromagnetic, or gravitational waves, and extends to the transport of atomic or subatomic particles (as represented by quantum-mechanical wave functions). *See* ELECTROMAGNETIC RADIATION; GRAVITATIONAL RADIATION; QUANTUM MECHANICS; SOUND; WAVE MOTION.

Each multipole pattern reflects the source’s geometrical shape (or the shape of a source component). These geometrical features stand out clearly for the static electric potentials generated by fixed charges as shown by the small set of monopole, dipole, and quadrupole charges (see illustration), elements of all multipoles being named (in terms of powers of 2) 2^l-poles, with l equal to any nonnegative integer. A monopole ($l = 0$) acoustic wave radiates from a perfectly spherical bubble with oscillating radius; higher multipoles would arise from bubble distortions. So-called transverse waves, elastic or electromagnetic (including light), have only $l \geq 1$ components, gravitational waves only $l \geq 2$. The angular distributions, in azimuth (φ) and colatitude (θ), of 2^l-pole waves have amplitudes distributed in directions (θ, φ) in proportion to the spherical harmonic functions $Y_l^m(\theta, \varphi)$. The index *m* is a positive or negative integer whose absolute value is equal to less than *l*. *See* COORDINATE SYSTEMS; DIPOLE; SPHERICAL HARMONICS.



Static electric potentials generated by fixed multipoles. (*a*) Monopole ($l = 0$). (*b*) Dipole ($l = 1$). (*c*) Quadrupole ($l = 2$).

The multipolarity index *l* also represents the number of angular momentum quanta $\hbar$ (Planck’s constant divided by 2π) radiated together with each energy quantum $h\nu$ (phonon, photon, graviton, and so forth). Detection and measurement of received energy quanta, together with measurement of their detection rate and mapping of their directional distribution, generally serve to diagnose the mechanics of the radiation source. Energy and momentum conservation underlie this analysis; so does the conservation of angular momentum which states that the initial angular momentum of the source equals the vector sum of the final angular momentum of the source and the angular momentum of the radiation. The quantitative implications of this vector relation are studied by the branch of quantum theory called angular momentum algebra. The balancing of parity, that is, of each variable’s sign reversal (or persistence) under reflection through the source’s center, also contributes to the analysis of experimental data. Further, more complex angular-momentum considerations play a role in the analysis of the behavior of spin-carrying particles. *See* ANGULAR MOMENTUM; CONSERVATION LAWS (PHYSICS); GRAVITON; PHONON; SELECTION RULES (PHYSICS); SPIN (QUANTUM MECHANICS). [U.F.]

Multiprocessing An organizational technique in which a number of processor units are employed in a single computer system to increase the performance of the system in its application environment above the performance of a single processor of the same kind. In order to cooperate on a single application or class of applications, the processors share a common resource. Usually this resource is primary memory, and the multiprocessor is called a primary memory multiprocessor. A system in which each processor has a private (local) main memory and shares secondary (global) memory with the others is a secondary memory multiprocessor, sometimes called a multicomputer system because of the looser coupling between processors. The more common multiprocessor systems incorporate only processors of the same type and performance and thus are called homogeneous multiprocessors; however, heterogeneous multiprocessors are also employed. A special case is the attached processor, in which a second processor module is attached to a first processor in a closely coupled fashion so that the first can perform input/output and operating system functions, enabling the attached processor to concentrate on the application workload. *See* COMPUTER STORAGE TECHNOLOGY; OPERATING SYSTEM.

Multiprocessor systems may be classified into four types: single instruction stream, single data stream (SISD); single instruction stream, multiple data stream (SIMD); multiple instruction stream, single data stream (MISD): and multiple instruction stream, multiple data stream (MIMD). Systems in the MISD category are rarely built. The other three architectures may be distinguished simply by the differences in their respective instruction cycles:

In an SISD architecture there is a single instruction cycle; operands are fetched in serial fashwion into a single processing unit before execution. Sequential processors fall into this category.

An SIMD architecture also has a single instruction cycle, but multiple sets of operands may be fetched to multiple processing units and may be operated upon simultaneously within a single instruction cycle. Multiple-functional-unit, array, vector, and pipeline processors are in this category. *See* SUPERCOMPUTER.

In an MIMD architecture, several instruction cycles may be active at any given time, each independently fetching instructions and operands into multiple processing units and operating on them in a concurrent fashion. This category includes multiple processor systems in which each processor has its own program control, rather than sharing a single control unit.

MIMD systems can be further classified into throughput-oriented systems, high-availability systems, and response-oriented systems. The goal of throughput-oriented multiprocessing is to obtain high throughput at minimal computing cost in a general-purpose computing environment by maximizing the number of independent computing jobs done in parallel. High-availability multiprocessing systems are generally interactive, often with never-fail real-time online performance requirements.

The goal of response-oriented multiprocessing (or parallel processing) is to minimize system response time for computational demands. *See* COMPUTER SYSTEMS ARCHITECTURE; CONCURRENT PROCESSING; FAULT-TOLERANT SYSTEMS; REAL-TIME SYSTEMS. [P.C.Pa.]

Multituberculata

An order in the class Mammalia, subclass Allotheria, comprising a major group of early mammals, ranging from Late Jurassic to Late Eocene (about 155 to 35 million years ago). The group is best known from North America, Mongolia, and Europe. Most multituberculates were mouselike in size, although the North American Paleocene *Taeniolabis* was larger, probably closer to the woodchuck (*Marmota monax*) in its proportions. Multituberculates appear primarily to have been terrestrial creatures, but some were probably arboreal and others fossorial. The Eocene decline and extinction of multituberculates may reflect competition from small placental mammals, especially primates and rodents. *See* ARCHAIC UNGULATE; RODENTIA.

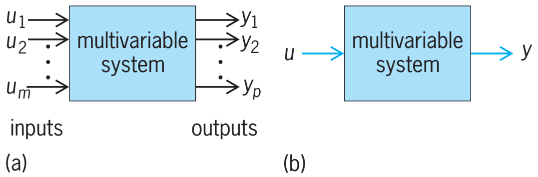
The most primitive multituberculates are traditionally classified in the suborder Plagiaulacoidea (Late Jurassic to Early Cretaceous), and the advanced multituberculates are traditionally classified in the suborders Ptilodontoidea and Taeniolabidoidea (both Late Cretaceous to Eocene).

Although clearly mammalian and often characterized as rodentlike, multituberculates are unlike rodents or other living mammals in several important features. The dentition is distinctive and, with associated jaw fragments, it is all that is known for most species. Microscopic wear patterns on multituberculate tooth enamel show that jaw motion differed radically from that in other mammals: during chewing, the mandible moved only in the vertical plane, not transversely, and was strongly retracted during the power stroke. These studies also imply that most multituberculates were probably omnivores, although species having gnawing incisors were likely specialized herbivores feeding on tough plant tissues. *See* DENTITION.

Attempts to determine multituberculate relationships to other mammals have long been inconclusive. *See* ALLOTHERIA; MAMMALIA. [R.C.Fo.]

Multivariable control

The control of systems characterized by multiple inputs, which are usually referred to as the controls; or by multiple outputs, which are often the measured variables to be controlled (see illustration); or by both multiple inputs and outputs. Automobiles, chemical processing plants, aerospace vehicles, biological systems, and the national economy are all examples of multivariable systems which require and receive some form of regulation or control, be it mathematically contrived or not. In many cases, control of such systems is implemented without a previously given design or explicit mathematical model, such as in the manual control of relatively simple motorized vehicles, or in a person's control of arm and leg movements. In more complex tasks, however, such as the manual manipulation of an inherently unstable helicopter, automatic control devices (autopilots) are employed to assist the operator.



Two multivariable system representations, (*a*) Input and output variables shown separately as u_1, U_2,..., U_m and y_1, y_2, ..., y_p, (*b*) Input and output variables shown in vector form as *u* and *y*.

The control objectives to be achieved in the multivariable case include those control objectives which are generally sought in the scalar, that is, single input/output case, and also depend on the particular application involved. In particular, stability is usually a primary concern in the design of any control system, along with various measures of the degree of stability. While controller failure in the scalar case can lead to catastrophic failure of the overall system, such need not be true in the multivariable case due to the interactions between various input/output pairs. More specifically, in certain applications it may be possible to design a multivariable controller "driven" by all *p* outputs which performs satisfactorily even when feedback information from one or more outputs is lost. The integrity of such a multivariable controller would be much better than that of its scalar counterpart.

In many control applications, a primary objective is that of tracking, or ensuring that the system output or outputs track a desired input or inputs with little or no steady-state errors. In addition, simultaneous regulation of external disturbances is also often desired; that is, ensuring that any external disturbances affect the plant outputs as little as possible. It is also obvious that simplicity of controller design is a highly desirable design objective both in the scalar and multivariable cases. One final design objective unique to the multivariable case is that of minimizing or eliminating the interaction between loops, which is often referred to as decoupling; that is, perfect decoupling would imply a controlled system where each input affects only one output or, otherwise stated, a system whose compensated transfer matrix is diagonal and nonsingular. *See* CONTROL SYSTEMS; PROCESS CONTROL. [W.Wo.]

Multivibrator A form of electronic circuit that employs positive feedback to cross-couple two devices so that two distinct states are possible, for example, one device ON and the other device OFF, and in which the states of the two devices can be interchanged either by use of external pulses or by internal capacitance coupling. When the circuit is switched between states, transition times are normally very short compared to the ON and OFF periods. Hence, the output waveforms are essentially rectangular in form.

Multivibrators may be classified as bistable, monostable, or astable. A bistable multivibrator, often referred to as a flip-flop, has two possible stable states, each with one device ON and the other OFF, and the states of the two devices can be interchanged only by the application of external pulses. A monostable multivibrator, sometimes referred to as a one-shot, also has two possible states, only one of which is stable. If it is forced to the opposite state by an externally applied trigger, it will recover to the stable state in a period of time usually controlled by a resistance-capacitance (*RC*) coupling circuit. An astable multivibrator has two possible states, neither of which is stable, and switches between the two states, usually controlled by two *RC* coupling time constants. The astable circuit is one form of relaxation oscillator, which generates recurrent waveforms at a controllable rate.

Symmetrical bistable multivibrator. In bistable multivibrators, either of the two devices in a completely symmetrical circuit may remain conducting, with the other nonconducting, until the application of an external pulse. Such a multivibrator is said to have two stable states.

The original form of bistable multivibrator made use of vacuum tubes and was known as the Eccles-Jordan circuit, after its inventors. It was also called a flip-flop or binary circuit because of the two alternating output voltage levels. The junction field-effect transistor (JFET) circuit (Fig. 1) is a solid-state version of the Eccles-Jordan circuit. Its resistance networks between positive and negative supply voltages are such that, with no current flowing to the drain of the first JFET, the voltage at the gate of the second is slightly negative, zero, or limited to, at most, a slightly positive value. The resultant current in the drain circuit of the second JFET causes a voltage drop across the drain load resistor; this drop in turn lowers the voltage at the gate of the first JFET to a sufficiently negative value to continue to reduce the drain current to zero. This condition of the first device OFF and the second ON will be maintained as long as the circuit remains undisturbed. *See* TRANSISTOR.

If a sharp negative pulse is applied to the gate of the ON transistor, its drain current decreases and its drain voltage rises. A fraction of this rise is applied to the gate of the OFF transistor, causing some drain current to flow. The resultant drop in drain voltage, transferred to the gate of the ON transistor, causes a further rise at its drain. The action is thus one of positive feedback, with nearly instantaneous transfer of conduction from one device to the other. There is one such reversal each time a pulse is applied to the gate of the ON transistor. Normally pulses are applied to both transistors simultaneously so that whichever device is ON will be turned off by the action. The capacitances between the gate of one transistor and the drain of the other play no role other than to improve the high-frequency response of the voltage divider network by compensating for the input capacitances of the transistors and thereby improving the speed of transition.

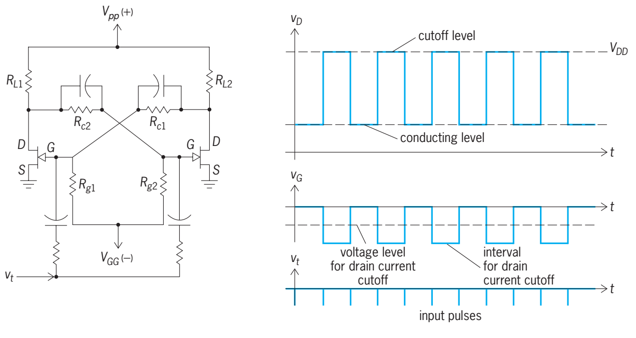


Fig. 1. Bistable multivibrator with triggering, gate, and drain waveforms shown for one transistor.

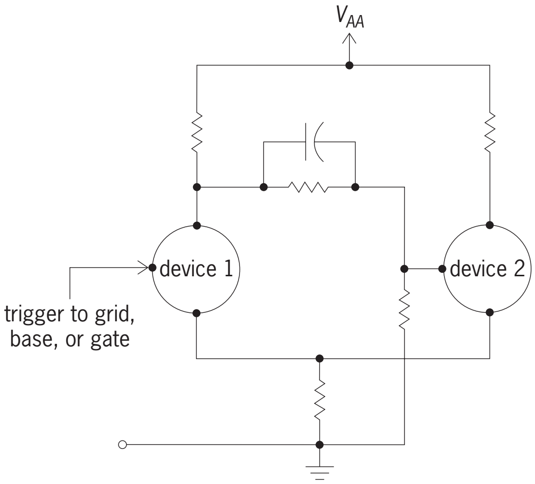

Fig. 2. Unsymmetrical bistable multivibrator.

A bipolar transistor counterpart of the JFET bistable multivibrator uses *npn* bipolar transistors. The base of the transistor corresponds to the gate, the emitter to the source, and the collector to the drain. Although waveforms are of the same polarity and the action is roughly similar to that of the JFET circuit, there are important differences. The effective resistance of the base-emitter circuit, when it is forward-biased and being used to control collector current, is much lower than the input gate resistance of the JFET when the latter resistance is used to control drain current (a few thousand ohms compared to a few megohms). This fact must be taken into account when the divider networks are designed. If *pnp* transistors are used, all voltage polarities and current directions are reversed.

Unsymmetrical bistable circuits. Bistable action can be obtained in the emitter- or source-coupled circuit with one of the set of cross-coupling elements removed (Fig. 2). In this case, regenerative feedback necessary for bistable action is obtained by the one remaining common coupling element, leaving one emitter or gate free for triggering action. Biases can be adjusted such that device 1 is ON, forcing device 2 to be OFF. In this case, a pulse can be applied to the free input in such a direction as to reverse the states. Alternatively, device 1 may initially be OFF with device 2 ON. Then an opposite polarity pulse is required to reverse states. Such an unsymmetrical bistable circuit, historically referred to as the Schmitt trigger circuit, finds widespread use in many applications.

Monostable multivibrator. A monostable or one-shot multivibrator has only one stable state. If one of the normally active devices is in the conducting state, it remains so until an external pulse is applied to make it nonconducting. The second device is thus made conducting and remains so for a duration dependent upon *RC* time constants within the circuit itself. Monostable multivibrators are available commercially in integrated chip form. *See* INTEGRATED CIRCUITS.

Astable multivibrator. The astable multivibrator has capacitance coupling between both of the active devices and therefore has no permanently stable state. Each of the two devices functions in a manner similar to that of the capacitance-coupled half of the monostable multivibrator. It will therefore generate a periodic rectangular waveform at the output with a period equal to the sum of the OFF periods of the two devices.

Astable multivibrators, although normally free-running, can be synchronized with input pulses recurrent at a rate slightly faster than the natural recurrence rate of the device itself. If the synchronizing pulses are of sufficient amplitude, they will bring the internal waveform to the conduction level at an earlier than normal time and will thereby determine the recurrence rate.

Logic gate multivibrators. Multivibrators may be formed by using two cross-coupled logic gates, with the unused input terminals used for triggering purposes. The bistable forms of such circuits are usually referred to as flip-flops. *See* LOGIC CIRCUITS. [G.M.G.]

Mumps An acute contagious viral disease, characterized chiefly by enlargement of the parotid glands (parotitis).

Besides fever, the chief signs and symptoms are the direct mechanical effect of swelling on glands or organs where the virus localizes. One or both parotids may swell rapidly, producing severe pain when the mouth is opened. In orchitis, the testicle is inflamed but is enclosed by an inelastic membrane and cannot swell; pressure necrosis produces atrophy, and if both testicles are affected, sterility may result. The ovary may enlarge, without sequelae.

An attenuated live virus vaccine can induce immunity without parotitis. It is recommended particularly for adults exposed to infected children, for students in boarding schools and colleges, and for military troops. [J.L.Me.]

Muonium An exotic atom, Mu or (μ^+e^-), formed when a positively charged muon (μ^+) and an electron are bound by their mutual electrical attraction. It is a light, unstable isotope of hydrogen, with a muon replacing the proton. Muonium has a mass 0.11 times that of a hydrogen atom due to the lighter mass of the muon, and a mean lifetime of 2.2 microseconds, determined by the spontaneous decay of the muon ($\mu^+ \to e^+\nu_e\,\overline{\nu}_\mu$). Muonium is formed when beams of μ^+ produced in particle accelerators are stopped in certain nonmetallic targets.

Since muonium is a system consisting only of leptons, it serves as a testing ground for the theory of quantum electrodynamics (QED), which describes the electromagnetic interaction between particles. Muonium chemistry and muonium spin rotation (MSR) are two developing subfields which seek to understand the chemical and physical behavior of a light hydrogen isotope in matter and to probe the structure of materials. *See* POSITRONIUM; QUANTUM ELECTRODYNAMICS. [P.O.E.]

Muscle The tissue in the body in which cellular contractility has become most apparent. Almost all forms of protoplasm exhibit some degree of contractility, but in muscle fibers specialization has led to the preeminence of this property. In vertebrates three major types of muscle are recognized: smooth, cardiac, and skeletal.

Smooth muscle. Smooth muscle, also designated visceral and sometimes involuntary, is the simplest type. These muscles consist of elongated fusiform cells which contain a central oval nucleus. The size of such fibers varies greatly, from a few micrometers up to 0.02 in. (0.5 mm) in length. These fibers contract relatively slowly and have the ability to maintain contraction for a long time. Smooth muscle forms the major contractile elements of the viscera, especially those of the respiratory and digestive tracts, and the blood vessels. Smooth muscle fibers in the skin regulate heat loss from the body. Those in the walls of various ducts and tubes in the body act to move the contents to their destinations, as in the biliary system, ureters, and reproductive tubes.

Smooth muscle is usually arranged in sheets or layers, commonly oriented in different directions. The major physiological properties of these muscles are their intrinsic ability to contract spontaneously and their dual regulation by the autonomic nerves of the sympathetic and parasympathetic systems. *See* AUTONOMIC NERVOUS SYSTEM.

Cardiac muscle. Cardiac muscle has many properties in common with smooth muscle; for example, it is innervated by the autonomic system and retains the ability to contract spontaneously. Presumably, cardiac muscle evolved as a specialized type from the general smooth muscle of the circulatory vessels. Its rhythmic contraction begins early in embryonic development and continues until death. Variations in the rate of contraction are induced by autonomic regulation and by many other local and systemic factors.

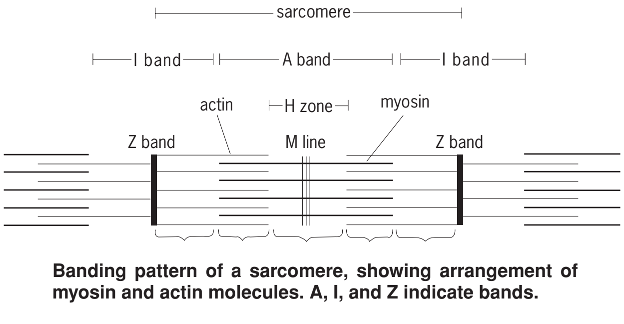
The cardiac fiber, like smooth muscle, has a central nucleus, but the cell is elongated and not symmetrical. It is a syncytium, a multinuclear cell or a multicellular structure without cell walls. Histologically, cardiac muscle has cross-striations very similar to those of skeletal muscle, and dense transverse bands, the intercalated disks, which occur at short intervals. *See* HEART (VERTEBRATE).

Skeletal muscle. Skeletal muscle is also called striated, somatic, and voluntary muscle, depending on whether the description is based on the appearance, the location, or the innervation. The individual cells or fibers are distinct from one another and vary greatly in size from over 6 in. (15 cm) in length to less than 0.04 in. (1 mm). These fibers do not ordinarily branch, and they are surrounded by a complex membrane, the sarcolemma. Within each fiber are many nuclei; thus it is actually a syncytium formed by the fusion of many precursor cells.

The transverse striations of skeletal muscle form a characteristic pattern of light and dark bands within which are narrower bands. These bands are dependent upon the arrangement of the two sets of sliding filaments and the connections between them. *See* MUSCLE PROTEINS; MUSCULAR SYSTEM. [W.J.B.]

Muscle proteins Specialized proteins in muscle cells are the building blocks of the structures constituting the moving machinery of muscle. They are disposed in myofilaments which are discernible by electron microscopy. These myofilaments are of two kinds, and their regular arrangement within the cell gives the striated pattern to skeletal muscle fibers (see illustration). It is recognized that the sliding of the two sets of filaments relative to each other is the molecular basis of muscle contraction. To understand the ultimate mechanism that causes the movement of these filaments (relative to each other), it is necessary to consider the features of the individual molecules making up these filaments. Evidence has been accumulating that practically all nonmuscle cells, although lacking the filaments of muscle, contain proteins similar to those found in muscle; these proteins are likely to be involved in cell motility and in determining properties of cell membranes.

Molecules of myosin, amounting to about 60% of the total muscle protein, are arranged in filaments occupying the central zone of each segment (sarcomere) or the fibril, the A band. Myosin is an elongated molecule made up of two intertwined heavy peptide chains (molecular weight of about 200,000) whose ends form two separate globular structures. The intertwined portion forms a rigid rod; each of the two globular portions (heads) contains a center capable of combining with, and splitting off, the terminal phosphate of adenosine triphosphate



Banding pattern of a sarcomere, showing arrangement of myosin and actin molecules. A, I, and Z indicate bands.

(ATP); ATP is the ultimate source of energy for muscle contraction. Each globular head can combine with actin.

The chief constituent of the filaments originating in the Z band of each sarcomere is actin. Actin filaments are made up of globular units in a double helix; there are 13 to 15 of these units in each strand for every complete turn of this helix.

These two proteins, or rather protein complexes, are associated with the actin filaments. Tropomyosin is an α-helical protein containing two intertwined polypeptide chains that extend over about seven globular actin units. Each tropomyosin molecule is associated with one troponin molecule, which in turn consists of three different types of subunits. In contrast to the tropomyosin molecule, the troponin complex and its subunits are thought to be essentially spherical in shape. Both tropomyosin and troponin are required to make the interaction of actin and myosin sensitive to calcium ions.

A great deal of information has come to light concerning the process by which the interaction between actin and myosin is regulated in the living cell. In higher organisms troponin and tropomyosin participate in this regulation. In the presence of these proteins the combination of actin and myosin cannot take place. However, if a small amount of ionized calcium is present, the inhibitory effect of the tropomyosin-troponin system is reversed, and the interaction with actin and myosin becomes fully effective.

This regulation involves a movement of tropomyosin molecules within the thin filaments from positions in which they block the combination of actin with the myosin moiety. Within the muscle cell the amount of calcium available is regulated by certain membranous structures, collectively the sarcoplasmic reticulum, that appear to have the ability to store calcium in the resting state. Upon excitation, the outer membrane of the muscle cell undergoes a change in permeability. This change spreads inside the muscle through the so-called transverse tubular system and causes a release of calcium within the cell. The calcium ions thus released permit the interaction of actin and myosin, leading to the liberation of chemical energy from ATP and its transformation into mechanical work. *See* MOTOR SYSTEMS; MUSCLE. [J.Ge.]

Muscovite

A mineral of the mica group with an ideal composition of $KAl_2(AlSi_3)O_{10}(OH)_2$. Sometimes it is referred to as a white mica or potash mica.

Physical properties include specific gravity 2.76–2.88, hardness on the Mohs scale 2–2.5, and luster vitreous to pearly. Thin sheets are flexible and may be colorless, with books (thick crystals) translucent, yellow, brown, reddish, or green. Muscovite occurs commonly in all the major rock types, in igneous rocks (granites, pegmatites, and hydrothermal alteration products), in metamorphic rocks (slates, phyllites, schists and gneisses), and in sedimentary rocks (sandstones and other clastic rocks). As larger flakes, muscovite is used as an electrical insulator, both for its dielectric properties and for its resistance to heat. Ground muscovite is used for fireproofing, as an additive to paint to provide a sheen and for durability, as a filler, and for many other applications. *See* MICA; SILICATE MINERALS. [S.Gu.]

Muscular dystrophy

A group of muscle diseases that are hereditary and characterized by progressive muscle weakness and wasting.

The muscular dystrophies are primary diseases of the muscle cells characterized by progressive degeneration and replacement by fibrous tissue, resulting in progressive muscle weakness. In some types of muscular dystrophies, the disease appears to be restricted to the skeletal muscles alone (facioscapulohumeral muscular dystrophy, limb-girdle muscular dystrophy), and in others skeletal-muscle involvement is a part of a more generalized process, with abnormalities in other organ systems as well (Duchenne's muscular dystrophy, myotonic dystrophy). These features as well as the differing patterns of inheritance indicate that the various muscular dystrophies are different diseases with different genetic and biochemical abnormalities underlying them.

The gene for the Duchenne and the Becker muscular dystrophy has been identified. This gene produces the muscle protein dystrophin, which is absent in Duchenne's dystrophy and qualitatively altered in Becker's dystrophy. Although the gene for myotonic dystrophy has not been identified, it has been found to be closely linked to genetic markers on chromosome 19. *See* HUMAN GENETICS; MUSCLE PROTEINS.

Duchenne's muscular dystrophy is the most rapidly progressive form of muscular dystrophy. It affects boys before the age of 4, and is characterized initially by progressive weakness of the hip muscles with difficulty in rising from the floor or chair and in climbing stairs. This is accompanied by enlargement of the calf muscles, which are infiltrated by fat and fibrous tissue (pseudohypertrophy). Weakness of the muscles of the upper arms and shoulder muscles follows.

Becker's muscular dystrophy is also characterized by calf pseudohypertrophy but is much more slowly progressive.

Myotonic dystrophy is very slowly progressive and affects the muscles of the face, neck, and hands. It usually begins in early adulthood. In addition to progressive weakness and wasting of the affected muscles, these individuals also exhibit myotonia, that is, a delayed relaxation of a muscle after forceful contraction. Mental retardation, frontal balding, cataracts, and gonadal degeneration are common.

Treatment remains largely symptomatic. *See* MUSCULAR SYSTEM DISORDERS. [S.M.Su.; T.D.B.]

Muscular system

The muscular system consists of muscular cells, the contractile elements with the specialized property of exerting tension during contraction, and associated connective tissues. The three morphologic types of muscles are voluntary muscle, involuntary muscle, and cardiac muscle. The voluntary, striated, or skeletal muscles are involved with general posture and movements of the head, body, and limbs. The involuntary, nonstriated, or smooth muscles are the muscles of the walls of hollow organs of the digestive, circulatory, respiratory, and reproductive systems, and other visceral structures. Cardiac muscle is the intrinsic muscle tissue of the heart. *See* MUSCLE.

Anatomy. Muscle groups are particularly distinct in elasmobranchs and other primitive fishes, and they are generally defined on the basis of their embryonic origin in these animals. Two major groups of skeletal muscles are recognized, somatic (parietal) muscles, which develop from the myotomes, and branchiomeric muscles, which develop in the pharyngeal wall from lateral plate mesoderm. The somatic musculature is subdivided into axial muscles, which develop directly from the myotomes and lie along the longitudinal axis of the body, and appendicular muscles, which develop within the limb bud from mesoderm derived phylogenetically as buds from the myotomes.

The vertebrate muscular system is the largest of the organ systems, making up 35–40% of the body weight in humans. The movement of vertebrates is accomplished exclusively by muscular action, and muscles play the major role in transporting materials within the body. Muscles also help to tie the bones of the skeleton together and supplement the skeleton in supporting the body against gravity. *See* SKELETAL SYSTEM.

Most of the axial musculature is located along the back and flanks of the body, and this part is referred to as trunk musculature. But anteriorly the axial musculature is modified and assigned to other subgroups. Certain of the occipital and neck myotomes form the hypobranchial muscles, and the most anterior myotomes form the extrinsic ocular muscles.

The hypaxial musculature of tetrapods can be subdivided into three groups: (1) a subvertebral (hyposkeletal) group located ventral to the transverse processes and lateral to the centra of the vertebrae, (2) the flank muscles forming the lateral part of the body wall, and (3) the ventral abdominal muscles located on each side of the midventral line. The subvertebral musculature assists the epaxial muscles in the support and movement of the vertebral column. Most of the flank musculature takes the form of broad, thin sheets of muscle that form much of the body wall and support the viscera. The midventral hypaxial musculature in all tetrapods consists of the rectus abdominis, a longitudinal muscle on each side of the midline that extends from the pelvic region to the anterior part of the trunk.

The hypobranchial musculature extends from the pectoral girdle forward along the ventral surface of the neck and pharynx to the hyoid arch, chin, and into the tongue. It is regarded as a continuation of part of the hypaxial trunk musculature.

Limb muscles are often classified as intrinsic if they lie entirely within the confines of the appendage and girdle, and extrinsic if they extend from the girdle or appendage to other parts of the body. In fishes, movements of the paired fins are not complex or powerful and the appendicular muscles in the strictest sense are morphologically simple. In terrestrial vertebrates, the limbs become the main organs for support and locomotion, and the appendicular muscles become correspondingly powerful and complex. The muscles are too numerous to describe individually, but they can be sorted into dorsal and ventral groups, because tetrapod muscles originate embryonically in piscine fashion from a dorsal and a ventral premuscular mass within the limb bud. In general, the ventral muscles, which also spread onto the anterior surface of the girdle and appendage, act to protract and adduct the limb and to flex its distal segments; the dorsal muscles, which also extend onto the posterior surface of the girdle and appendage, have the opposite effects (retraction, abduction, and extension). The limb muscles also serve as flexible ties or braces that can fix the bones at a joint and support the body.

Flight in birds has entailed a considerable modification of the musculature of the pectoral region. As one example, the ventral adductor muscles are exceedingly large and powerful, and the area from which they arise is increased by the enlargement of the sternum and the evolution of a large sternal keel. Not only does a ventral muscle, the pectoralis, play a major role in the downstroke of the humerus, but a ventral muscle, the supracoracoideus, is active in the upstroke as well.

In a number of terrestrial vertebrates, particularly amniotes, certain of the more superficial skeletal muscles of the body have spread out beneath the skin and inserted into it. These may be described as integumentary muscles. Integumentary muscles are particularly well developed in mammals and include the facial muscles (Fig. 1) and platysma, derived from the hyoid musculature, and often a large cutaneous trunci. The last is derived from the pectoralis and latissimus dorsi and fans out beneath the skin of the trunk. The twitching of the skin of an ungulate is caused by this muscle.

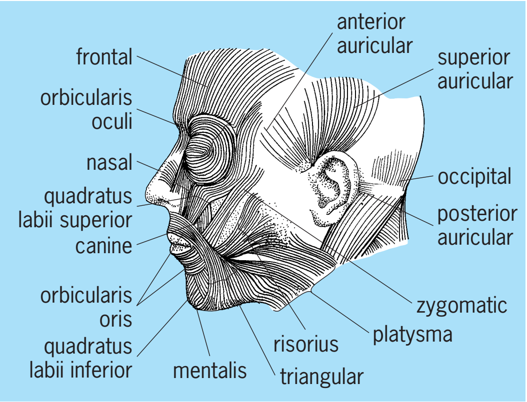


Fig. 1. Human facial muscles. (*After H. W. Rand, The Chordates, Blakiston, 1950*)

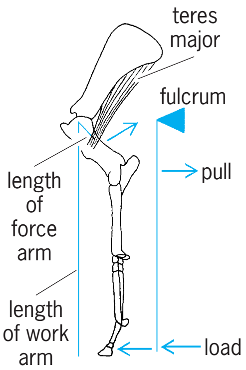

Fig. 2. A typical vertebrate lever system.

Muscle mechanics. Many of the bones serve as lever arms, and the contractions of muscles are forces acting on these arms (Fig. 2). The joint, of course, is the fulcrum and it is at one end of the lever. The length of the force arm is the perpendicular distance from the fulcrum to the line of action of the muscle; the length of the work arm is the perpendicular distance from the fulcrum to the point of application of the power generated in the lever. Compactness of the body and physiological properties of the muscle necessitates that a muscle attach close to the fulcrum; therefore, the force arm is considerably shorter than the work arm. Most muscles are at a mechanical disadvantage, for they must generate forces greater than the work to be done, but an advantage of this is that a small muscular excursion can induce a much greater movement at the end of the lever. *See* SKELETAL SYSTEM.

Slight shifts in the attachments of a muscle that bring it toward or away from the fulcrum, and changes in the length of the work arm, can alter the relationship between force and amount or speed of movement.

In general, the force of a muscle is inversely related to the amount and speed of movement that it can cause. Certain patterns of the skeleton and muscles are adapted for extensive, fast movement at the expense of force, whereas others are adapted for force at the expense of speed. In the limb of a horse, which is adapted for long strides and speed, the muscles that move the limb insert close to the fulcrum and the appendage is long. This provides a short force arm but a very long work arm to the lever system (Fig. 2). In the front leg of a mole, which is adapted for powerful digging, the distance from the fulcrum to the insertion of the muscles is relatively greater and the length of the appendage is less, with the result that the length of the force arm is increased relative to the length of the work arm. [W.F.W.]

Muscular system disorders Disorders affecting skeletal (voluntary) muscle. The normal functioning of the skeletal muscle is dependent not only on the integrity of the muscle fibers themselves, but also on that of the motor cortex, the pyramidal tract, and the extrapyramidal system (including the cerebellum). It also depends on innervation by the motoneurons of the brainstem and the spinal cord. In addition, the proper functioning of the other organ systems, such as the endocrine system, and variations in the concentration of various electrolytes may also affect muscle function.

Damage to the motor cortex or the pyramidal tract produces the type of weakness seen in humans after a stroke or spinal cord injury. Although the paralyzed limb may initially be flaccid (hypotonic), spasticity (hypertonia) eventually develops. Despite the weakness, muscle atrophy is usually not striking. When the extrapyramidal system or the cerebellum is the site of damage, instead of weakness there are uncontrolled movements, difficulty with coordination, or both. In either of these situations there is no characteristic change in the muscle, either grossly or microscopically. At most, atrophy of type 2 fibers is seen.

Motoneuron damage. With damage to the spinal motoneuron or its axon, there is flaccid weakness of the muscle with proportionate wasting. Direct involvement of the spinal motoneuron was typically seen in poliomyelitis, but is now seen more commonly in the progressive spinomuscular atrophies of infancy and childhood, and in amyotrophic lateral sclerosis (ALS) in adults. Spontaneous twitching of groups of muscle fibers (fasciculation) innervated by the same motoneuron (motor unit) is frequently seen in these disorders. *See* POLIOMYELITIS.

Progressive diseases of unknown cause may occur in infancy Werdnig-Hoffmann disease) or later in childhood (Kugelberg-Wielander disease). Both diseases result from degeneration of the motoneurons and appear to be inherited in an autosomal recessive pattern. In the infantile form, the baby is often floppy from birth with generalized weakness, a poor cry, and difficulty in sucking and breathing. Many children succumb in early childhood. In the later childhood forms, the rate of progression is slower and the outlook better. In these children weakness is more marked in the proximal muscles of the limbs.

Amyotrophic lateral sclerosis is a progressive disease of unknown cause, in which both the brainstem and spinal motoneurons, as well as the corticospinal tracts, undergo degeneration. This is a relatively rapid progressive disease, with death usually occurring within 3 years of diagnosis due to swallowing difficulty and respiratory failure. Although some cases of ALS appear to be inherited, most cases occur sporadically.

Neuromuscular junction. The most common example of disease at the neuromuscular junction is myasthenia gravis. Other, less common diseases are the myasthenic Eaton-Lambert syndrome and botulism. *See* MYASTHENIA GRAVIS.

Myopathy. Abnormalities of the muscle itself (myopathy) obviously result in muscle weakness, and muscle diseases fall into two large groups: those with a genetic basis and those which are nongenetic.

Congenital myopathies and the muscular dystrophies constitute the genetic muscle diseases. Congenital myopathies are characterized by a generalized weakness which is present at birth. The weakness is usually not progressive and often improves with time. Muscle fiber necrosis, a characteristic of the muscular dystrophies, is not seen in the congenital myopathies. *See* MUSCULAR DYSTROPHY.

Nongenetic or acquired diseases are all characterized by rapidly progressive weakness of the proximal muscles of the limbs, and so resemble the limb-girdle form of muscular dystrophy in the distribution of weakness. They are often included as inflammatory myopathies. Individuals with these disorders have difficulty arising from a recumbent or sitting position, in climbing stairs, and in lifting heavy objects onto a shelf. They also often have tender and painful muscles, may be febrile, and may have other manifestations of a systemic illness.

Metabolic diseases. A number of metabolic diseases have been associated with muscle symptoms. These include thyroid diseases and certain endocrine diseases, particularly Cushing's syndrome, which are either spontaneous or secondary to therapeutically administered adrenocorticosteroid hormones. No specific histologic changes have been described in the muscle in these disorders. Muscular symptoms are also seen with some of the glycogen storage diseases. Muscle weakness and paralysis may also be associated with alterations in the level of serum potassium.

Myotonia. A delayed relaxation of the muscle after forceful contraction (myotonic) is another symptom of muscle disease. This phenomenon is a characteristic feature of myotonic dystrophy and of congenital myotonia. Myotonia is usually present from early life and is often associated with muscle hypertrophy, but muscle weakness is not a feature of this disease. The muscle shows no definite histologic changes. *See* MUSCULAR SYSTEM.

[S.M.Su.]

Mushroom

A macroscopic fungus with a fruiting body (also known as a sporocarp). Approximately 14% (10,000) described species of fungi are considered mushrooms. Mushrooms grow aboveground or underground. They have a fleshy or nonfleshy texture. Many are edible, and only a small percentage are poisonous.

Mushrooms reproduce via microscopic spheres (spores) that are roughly comparable to the seeds of higher plants. Spores are produced in large numbers on specialized structures in or on the fruiting body. Spores that land on a suitable medium absorb moisture, germinate, and produce hyphae that grow and absorb nutrients from the substratum. If suitable mating types are present and the mycelium (the threadlike filaments or hyphae that become interwoven) develops sufficiently to allow fruiting, the life cycle will continue. In nature, completion of the life cycle is dependent on many factors, including temperature, moisture and nutritional status of the substratum, and gas exchange capacity of the medium.

Fewer than 20 species of edible mushrooms are cultivated commercially. The most common cultivated mushroom is *Agaricus bisporus*, followed by the oyster mushroom (*Pleurotus* spp.). China is the leading mushroom-producing country; Japan leads the world in number of edible species cultivated commercially.

Mushrooms may be cultivated on a wide variety of substrates. They are grown from mycelium propagated on a base of steam-sterilized cereal grain. This grain and mycelium mixture is called spawn, which is used to seed mushroom substrata.

Mushrooms contain digestible crude protein, all essential amino acids, vitamins (especially provitamin D-2), and minerals; they are high in potassium and low in sodium, saturated fats, and calories. Although they cannot totally replace meat and other high-protein food in the diet, they can be considered an important dietary supplement and a health food.

Fungi have been used for their medicinal properties for over 2000 years. Although there remains an element of folklore in the use of mushrooms in health and medicine, several important drugs have been isolated from mushroom fruiting bodies and mycelium. The best-known drugs obtained are lentinan from *L. edodes*, grifolin from *Grifola frondosa*, and krestin from *Coriolus versicolor*. These compounds are protein-bound polysaccharides or long chains of glucose, found in the cell walls, and function as antitumor immunomodulatory drugs. *See* FUNGI; MEDICAL MYCOLOGY.

[D.M.C.]

Musical acoustics

The branch of acoustics that deals with the generation of sound by musical instruments, the transmission of sound to the listener, and the perception of musical sound. A main research activity in musical acoustics is the study of the way in which musical instruments vibrate and produce sound. The most common way of classifying musical instruments is according to the nature of the primary vibrator, into string instruments, wind instruments, and percussion instruments. The vibrations of a plucked string, a struck membrane, or a blown pipe can be described in terms of normal modes of vibration. Determining the normal modes of a complex vibrator is often termed modal analysis. Much of the progress in understanding how musical instruments generate sound is due to new methods of modal analysis, such as holographic interferometry and experimental modal testing. *See* CAVITY RESONATOR; INTERFEROMETRY; MODE OF VIBRATION; VIBRATION.

In the case of most percussion, plucked string, and struck string instruments, the player delivers energy to the primary vibrator (string, membrane, bar, or plate) and thereafter has little control over the way it vibrates. In the case of wind and bowed string instruments, however, the continuing flow of energy is controlled by feedback from the vibrating system. In brass and reed woodwinds, pressure feedback opens or closes the input valve. In flutes or flue organ pipes, however, the input valve is flow-controlled. In bowed string instruments, pulses on the string control the stick-slip action of the bow on the string.

Four attributes are frequently used to describe musical sound: loudness, pitch, timbre, and duration. Each of the subjective qualities depends on one or more physical parameters that can be measured. Loudness, for example, depends mainly on sound pressure but also on the spectrum of the partials and the physical duration. Pitch depends mainly on frequency, but also shows lesser dependence on sound pressure and envelope. Timbre includes all the attributes by which sounds with the same pitch and loudness are distinguished. Relating the subjective qualities of sound to the physical parameters is a central problem in psychoacoustics, and musical acousticians are concerned with this same problem as it applies to musical sound. *See* Psychoacoustics.

Sound pressure level is measured with a sound level meter and is generally expressed on a logarithmic scale of decibels (dB) using an appropriate reference level and weighting network. From measurements of the sound pressure level at different frequencies, it is possible to calculate a subjective loudness, expressed in sones, which describes the sensation of loudness heard by an average listener. Musicians prefer to use dynamic markings ranging from *ppp* (very soft) to *fff* (very loud). *See* Decibel; Loudness; Sound; Sound pressure.

Pitch is defined as that attribute of auditory sensation in terms of which sounds may be ordered on a scale extending from low to high. Pitch is generally related to a musical scale where the octave, rather than the critical bandwidth, is the "natural" pitch interval. *See* Pitch; Scale (music).

Timbre is defined as that attribute of auditory sensation in terms of which a listener can judge two sounds similarly presented and having the same loudness and pitch as dissimilar. Timbre depends primarily on the spectrum of the sound, but it also depends upon the waveform, the sound pressure, the frequency location of the spectrum, and the temporal characteristics of the sound. It has been found impossible to construct a single subjective scale of timbre (such as the sone scale of loudness); multidimensional scales have been constructed. The term "tone color" is often used to refer to that part of timbre that is attributable to the steady-state part of the tone, but the time envelope (and especially the attack) has been found to be very important in determining timbre as well.

Another subject relating to the perception of music is combination tones. When two tones that are close together in frequency are sounded at the same time, beats generally are heard, at a rate that is equal to their frequency difference. When the frequency difference Δf exceeds 15 Hz or so, the beat sensation disappears, and a roughness appears. As Δf increases still further, a point is reached at which the "fused" tone at the average frequency gives way to two tones, still with roughness. The respective resonance regions on the basilar membrane are now separated sufficiently to give two distinct pitches, but the excitations overlap to give a sense of roughness. When the separation Δf exceeds the width of the critical band, the roughness disappears, and the two tones begin to blend. *See* Ear (vertebrate).

Pythagoras of ancient Greece is considered to have discovered that the tones produced by a string vibrating in two parts with simple ratios such as 2:1, 3:2, or 4:3 sound harmonious. These ratios define the so-called perfect intervals of music, which are considered to have the greatest consonance. Other consonant intervals in music are the major sixth ($f_2/f_1 = 5/3$), the major third ($f_2/f_1 = 5/4$), the major sixth ($f_2/f_1 = 8/5$), and the minor third ($f_2/f_1 = 6/5$). Why are some intervals more consonant than others? H. Helmholtz concluded that dissonance (the opposite of consonance) is greatest when partials of the two tones produce 30 to 40 beats per second (which are not heard as beats but produce roughness). The more the partials of one tone coincide in frequency with the partials of the other, the less chance of roughness. This explains why simple frequency ratios define the most consonant intervals. More recent research has concluded that consonance is related to the critical band. If the frequency difference between two pure tones is greater than a critical band, they sound consonant; if it is less than a critical band, they sound dissonant. The maximum dissonance occurs when Δf is approximately 1/4 of a critical band, which agrees reasonably well with Helmholtz's criterion for tones around 500 Hz. [T.D.R.]

Musical instruments Instruments for producing musical sounds have long been classified as woodwinds, brass, percussion, or strings; to these must be added electrical and electronic instruments. In a sense, all these instruments implement and extend the capability of the original musical instrument, the singing voice. The classes mentioned are useful in grouping instruments in a general way for the kinds of sounds they produce, even though woodwind instruments are not necessarily made of wood, nor are brass instruments always made of metal.

Woodwind instruments. Woodwind instruments are distinguished primarily by the fact that the effective length of the vibrating air column is shortened by opening lateral side holes in succession. Two distinctly different means of generating the sound are employed. For the flute, and its half-size version the piccolo, the player blows across the embouchure hole near one end in such away as to cause periodic puffs of air to enter the tube; after a turbulent turning these puffs excite the air column longitudinally. This method of excitation leaves the tube acoustically open in the sense that the contained air vibrates much as it does in a simple tube with both ends open to the atmosphere.

For the double-reed oboe or bassoon, the player holds between the lips a pair of thin reeds (pieces of cane appropriately thinned, shaped, and bound together) that beat against each other to change the player's breath to puffs of air. For clarinets and saxophones, a single reed attached to a mouthpiece by a ligature functions in a similar way. The portion of the mouthpiece (the lay) against which the reed beats must be appropriately curved; the character of the sound is modified somewhat by the volume of the mouthpiece as well as by the shape and material of the reed.

For both the single- and double-reed instruments, the reeds vibrate under the influence of sound waves reflected back from the distant end of the air column and allow the puffs of air to enter when the sound pressure within the instrument is large. Thus (in contrast to the flute) the air vibration at the reed end is that associated with an acoustically closed end.

Brass instruments. The typical brass instrument consists of a cup-shaped mouthpiece, a slightly tapered mouthpipe, cylindrical tubing including valves, and a roughly hyperbolic bell. Puffs of air are introduced by the player via vibrating lips stretched over the mouthpiece. The action is comparable to that of the clarinet, in that the mouthpiece end is nearly closed acoustically. The length of the air column is increased by tubing switched in by use of valves, either piston or rotary: a common arrangement is such that the first valve lowers the intonation by two semitones, the second by one semitone, and the third by three semitones. For a given length of tubing, different tones are produced by tensioning the lips to excite different modes of vibration whose frequencies are approximately in the ratios 2:3:4:5:6:8.

Percussion instruments. Instruments such as the timpani (kettledrums) and xylophone are called percussion instruments because the sound is initiated by a blow. Two kinds of sound producers are involved: a membrane under tension, associated with a cavity that can influence the frequency of vibration, as in the case of the timpani; and a rigid bar or plate vibrating transversely, whose frequency is little affected by any resonator that may be attached. Some percussion instruments give a well-defined sound that excites a sensation of definite pitch, such as does a church bell; others, such as drums, cymbals, and triangles, are useful primarily for rhythm effects.

Stringed instruments. For the guitar and harp, strings are set into vibration by plucking; for the other stringed instruments the vibration is usually initiated and maintained by bowing. The frequency of vibration is primarily established by the length, tension, and mass per unit length of the string. A string vibrates not only at the lowest (fundamental) frequency, but also at the same time at higher frequencies which tend toward integer multiples of the fundamental frequency. The sound radiated from the instrument is thus complex.

The radiation of sound from a stringed instrument is enhanced by a resonator consisting of an almost closed air cavity. Some of the energy of the vibrating string is transmitted via the bridge to the walls of the cavity. In a carefully constructed violin the resonances of the air cavity and its vibrating walls are distributed in frequency in order to afford a relatively uniform response throughout the playing range of the instrument.

Keyboard instruments. Instruments such as the celesta, pipe organ, accordion, and piano are usually put in a group called keyboard instruments, because the respective vibrating bars, pipes, reeds, and strings in these instruments are selected by use of keys in a keyboard. The celesta and piano could also be described as percussion instruments, because hammers strike the bars and strings; the pipe organ and the accordion, with its wind-driven free reeds, are wind instruments. By its multiple keyboards (and pedal board) the pipe organ puts under the control of a single player thousands of sources whose distinctive sounds can be reproduced on command. [R.W.Y.]

Electrical, electronic, and software instruments. Electrical musical instruments produce electrical tone signals for amplification (and loudspeaker listening) without using tuned mechanical vibrators or air columns. Early electrical instruments predated electronics, generating their tone signals by electromagnetic or electrostatic rotating machinery. Later, most of the instruments became electronic, producing their tone waves from vacuum-tube circuits, then transistor circuits, and now integrated electronic circuits. In the 1980s, electronic instruments transitioned from analog to digital, offering much more precise tuning (and alternative tunings) and repeatability of configuration. *See* INTEGRATED CIRCUITS.

Many different means of sound generation have been used during the evolution of electronic musical instruments. In concept at least, the most simple electronic method would be to substitute directly for each conventional mechanical (string, reed) or acoustical (resonant air column) sound source an electronic circuit source or software algorithm that generates the same complex tone wave. However, in different parts of the musical scale the waveform typically differs for the same instrument. Moreover, keyboard instruments require that a number of tones be produced at the same time. Consequently, the substitution method is less feasible economically than other methods described below. *See* WAVEFORM.

The additive synthesis method synthesizes each desired complex tone by adding together an appropriate number of simple (sine) waves at harmonically related frequencies, with the relative amplitudes of the harmonic waves adjustable to produce the desired resultant waveform. Additive synthesis has been used extensively in the field of computer music since at least the 1960s, and it has been the basis of a number of limited-production hardware devices. In current music synthesizers, however, there are typically more efficient ways than additive synthesis to achieve desired sounds, and mass-produced electronic musical instruments are generally not based on additive synthesis. However, the concept of additive synthesis remains important, and there are closely related descendents, such as sinusoidal modeling and group additive synthesis.

Subtractive synthesis is similar in principle to that of speech (and singing) sound formation within the human voice system. At each desired musical frequency an electronic circuit produces a standard basic tone waveform (such as a sawtooth wave), which already contains a very large number of harmonics at known relative amplitudes. Then a variety of electric or electronic filters is provided in the instrument wherein switch selection, individually or collectively, converts the basic tone signals into the desired musical tone waveforms. Subtractive synthesis is somewhat the opposite of additive synthesis, since it practically subtracts undesired harmonics instead of adding desired harmonics. Subtractive synthesis has been the basis for most voice synthesizers for over half a century. *See* ELECTRIC FILTER; FUNCTION GENERATOR; WAVE-SHAPING CIRCUITS.

The first all-digital synthesizer was based on frequency-modulation (FM) synthesis. Simple FM is carried out using two digital oscillators, with the output of one adding to the frequency (or phase) control of the other. In additive synthesis, two oscillators can provide only two harmonics. In FM synthesis, two oscillators can provide any number of harmonics. It is even possible for the output of a digital oscillator to modulate its own phase, giving so-called feedback FM. A major advantage of FM is the synthesis of a wide variety of complex sounds from an extremely simple digital algorithm. Disadvantages of FM are its extreme sensitivity to its control parameters, and the fact that many parameter settings sound artificial. FM synthesis remains a valuable complexity-reduction technique in the context of additive synthesis. *See* FREQUENCY MODULATION.

Sampling synthesis can refer to any synthesis method based on playing back digitally recorded and manipulated sounds. Today, ROM-based wavetable synthesizers dominate the field, from single-chip devices used in notebook computers to the most expensive synthesizers. With enough digital recordings of an instrument, it is possible to achieve any sound with sampling synthesis. However, approaching full expressive fidelity for most instruments, particularly bowed strings and solo woodwinds, requires prohibitive amounts of memory, system development, and control complexity.

A more recent approach to the synthesis of acoustic musical instruments, also made possible by digital technology, is known as physical modeling synthesis. In this approach, the algorithms are based directly on the mathematical physics of the instrument. One variant of physical modeling synthesis, which is especially effective for synthesizing string and wind instruments, is waveguide synthesis. Waveguide synthesis explicitly simulates traveling waves on a string or inside a bore or horn using digital delay lines. The theory is analogous to that of sampled (discrete-time) electric transmission lines. Filters are used in conjuction with digital waveguides to simulate losses due to bridge motion, horn radiation, air absorption, and the like. [D.W.Ma.; J.O.Sm.]

Musk-ox An even-toed ungulate, *Ovibos moschatus*, which is a member of the family Bovidae in the mammalian order Artiodactyla. This single species is the northernmost representative of the family, ranging through the tundra areas and snowfields of Canada and Alaska, as well as Greenland.

The musk-ox (*Ovibos moschatus*).

The musk-ox derives its name from the musky odor it emits. It is a stoutly built animal (see illustration) and has a coat of long dense hair that is resistant to the extreme cold of the windswept treeless tundra. They do not hibernate and are usually found in herds of 20–100 animals huddled together for warmth. As protection against its natural enemy, the wolf, the musk-ox will form a circle with the young inside. Since a cow produces a single calf every 2 years, the numbers have been so reduced that they are now protected by the Canadian government. *See* ARTIODACTYLA. [C.B.C.]

Muskeg A term derived from Chippewan Indian for "grassy bog." In North America ecologists apply diverse usage, but most include peat bogs or tussock meadows, with variable woody vegetation such as spruce or tamarack. Plant remains accumulate when trapped in the water or in media such as sphagnum moss which inhibit decay. The peat might accrue indefinitely or might approach a steady state of raised bogs, blanket bogs, or forest if input became balanced by erosion or by loss as methane and CO_2.

Organic terrain occurs on every continent. The largest expanses of it are in Russia (especially western Siberia) and Canada. Typical bog or spruce-larch muskeg develops in cool temperature and subarctic to arctic lands. In the subtropics and the tropics there is considerable organic terrain, as in Paraguay, Uruguay, and Guyana in South America. Thus, despite differences in climate or floristics, the phenomenon of peat formation persists if local aeration or biochemical conditions hinder decay. Despite climatic and biotic differences, gross peat structure categories seem comparable the world over. *See* BOG; PEAT. [N.W.R.]

Muskmelon The edible fruit of *Cucumis melo*, belonging to the gourd family, Cucurbitaceae, as do other vine crops such as cucumber, watermelons, pumpkin, and squash. The muskmelon appears to be indigenous to Africa. *See* CANTALOUPE; HONEY DEW MELON; PERSIAN MELON; VIOLALES.

The plants are annual, trailing vines, with three to five runners. The runners produce short fruiting branches, which bear the perfect flowers and later the fruits. Muskmelons maturing on the vine without becoming overripe are superior in quality to those harvested immature. The sugar content, flavor, and texture of the fresh flesh improves very rapidly as the fruit approaches maturity. When mature, the melon is sweet, averages 6 to 8% sugar, and has a slight to distinctly musky odor and flavor, depending upon cultivar and environment. The flesh is rich in potassium, in vitamin C and, when deep orange, also in vitamin A. [F.W.Z.]

Muskrat The largest member of the rodent subfamily Microtinae in the family Muridae, it is also known as the musquash. Also included in this subfamily are the lemmings and voles. *Ondatra zibethica*, the single species, is about the size of a rabbit. It is economically important for its fur, which is shiny, soft, and thick. It received its name because of its inguinal glands which produce a characteristic musky odor.

The muskrat is omnivorous, eating various types of vegetation, such as reeds and tuberous roots of aquatic plants, and animals, such as mussels, insects, and fish. These animals become active in March, when mating occurs. The female has two or three litters of 5–9 young each year, and the last litter of the season remains in the parental abode through winter. *See* LEMMING; RODENTIA. [C.B.C.]

Mustard Any one of a number of annual crucifer species of Asiatic origin belonging to the plant order Capparales. Mustards eaten as greens are *Brassica juncea*, *B. juncea* var. *crispifolia*, and *B. hirta*. Table mustard and oils are obtained from *B. nigra*. Important production centers for mustard greens are in the South, where the crop is popular. Montana and the West Coast states are important sources of mustard seed. *See* CAPPARALES. [H.J.C.]

Mutagens and carcinogens A mutagen is a substance or agent that induces heritable change in cells or organisms. A carcinogen is a substance that induces unregulated growth processes in cells or tissues of multicellular animals, leading to cancer. Although mutagen and carcinogen are not synonymous terms, the ability of a substance to induce mutations and its ability to induce cancer are strongly correlated. Mutagenesis refers to processes that result in genetic change, and carcinogenesis (the processes of tumor development) may result from mutagenic events. *See* MUTATION; RADIATION BIOLOGY.

A mutation is any change in a cell or in an organism that is transmitted to subsequent generations. Mutations can occur spontaneously or be induced by chemical or physical agents. The cause of mutations is usually some form of damage to DNA or chromosomes that results in some change that can be seen or measured. However, damage can occur in a segment of DNA that is a noncoding region and thus will not result in a mutation. Mutations may or may not be harmful, depending upon which function is affected. They may occur in either somatic or germ cells. Mutations that occur in germ cells may be transmitted to subsequent generations, whereas mutations in somatic cells are generally of consequence only to the affected individual.

Not all heritable changes result from damage to DNA. For example, in growth and differentiation of normal cells, major changes in gene expression occur and are transmitted to progeny cells through changes in the signals that control genes that are transcribed into ribonucleic acid (RNA). It is possible that chemicals and radiation alter these processes as well. When such an effect is seen in newborns, it is called teratogenic and results in birth defects that are not transmitted to the next generation. However, if the change is transmissible to progeny, it is a mutation, even though it might have arisen from an effect on the way in which the gene is expressed. Thus, chemicals can have somatic effects involving genes regulating cell growth that could lead to the development of cancer, without damaging DNA.

Cancer arises because of the loss of growth control by dearrangement of regulatory signals. Included in the phenotypic consequences of mutations are alterations in gene regulation brought about by changes either in the regulatory region or in proteins involved with coordinated cellular functions. Altered proteins may exhibit novel interactions with target substrates and thereby lose the ability to provide a regulatory function for the cell or impose altered functions on associated molecules. Through such a complex series of molecular interactions, changes occur in the growth properties of normal cells leading to cancer cells that are not responsive to normal regulatory controls and can eventually give rise to a visible neoplasm or tumor. While mutagens can give rise to neoplasms by a process similar to that described above, not all mutagens induce cancer and not all mutational events result in tumors.

The identification of certain specific types of genes, termed oncogenes, that appear to be causally involved in the neoplastic process has helped to focus mechanistic studies on carcinogenesis. Oncogenes can be classified into a few functionally different groups, and specific mutations in some of the genes have been identified and are believed to be critical in tumorigenesis. Tumor suppressor genes or antioncogenes provide a normal regulatory function; by mutation or other events, the loss of the function of these genes may release cells from normal growth-control processes, allowing them to begin the neoplastic process. *See* ONCOGENES; ONCOLOGY.

There are a number of methods and systems for identifying chemical mutagens. Mutations can be detected at a variety of genetic loci in very diverse organisms, including bacteria, insects, cultured mammalian cells, rodents, and humans. Spontaneous and induced mutations occur very infrequently, the estimated rate being less than 1 in 10,000 per gene per cell generation. This low mutation rate is probably the result of a combination of factors that include the relative inaccessibility of DNA to damaging agents and the ability of cellular processes to repair damage to DNA.

Factors that contribute to the difficulty in recognizing substances that may be carcinogenic to humans include the prevalence of cancer, the diversity of types of cancer, the generally late-life onset of most cancers, and the multifactorial nature of the disease process. Approximately 50 substances have been identified as causes of cancer in humans, but they probably account for only a small portion of the disease incidence. *See* CANCER (MEDICINE); HUMAN GENETICS; MUTATION; RADIATION BIOLOGY. [R.W.T.]

Mutation Any alteration capable of being replicated in the genetic material of an organism. When the alteration is in the nucleotide sequence of a single gene, it is referred to as gene mutation; when it involves the structures or number of the chromosomes, it is referred to as chromosome mutation, or rearrangement. Mutations may be recognizable by their effects on the phenotype of the organism (mutant).

Gene mutations. Two classes of gene mutations are recognized: point mutations and intragenic deletions. Two different types of point mutation have been described. In the first of these, one nucleic acid base is substituted for another. The second type of change results from the insertion of a base into, or its deletion from, the polynucleotide sequence. These mutations are all called sign mutations or frame-shift mutations because of their effect on the translation of the information of the gene. *See* NUCLEIC ACID.

More extensive deletions can occur within the gene which are sometimes difficult to distinguish from mutants which involve only one or two bases. In the most extreme case, all the informational material of the gene is lost.

A single-base alteration, whether a transition or a transversion, affects only the codon or triplet in which it occurs. Because of code redundancy, the altered triplet may still insert the same amino acid as before into the polypeptide chain, which in many cases is the product specified by the gene. Such DNA changes pass undetected. However, many base substitutions do lead to the insertion of a different amino acid, and the effect of this on the function of the gene product depends upon the amino acid and its importance in controlling the folding and shape of the enzyme molecule. Some substitutions have little or no effect, while others destroy the function of the molecule completely.

Single-base substitutions may sometimes lead not to a triplet which codes for a different amino acid but to the creation of a chain termination signal. Premature termination of translation at this point will lead to an incomplete and generally inactive polypeptide.

Sign mutations (adding or subtracting one or two bases to the nucleic acid base sequence of the gene) have a uniformly drastic effect on gene function. Because the bases of each triplet encode the information for each amino acid in the polypeptide product, and because they are read in sequence from one end of the gene to the other without any punctuation between triplets, insertion of an extra base or two bases will lead to translation out of register of the whole sequence distal to the insertion or deletion point. The polypeptide formed is at best drastically modified and usually fails to function at all. This sometimes is hard to distinguish from the effects of intragenic deletions. However, whereas extensive intragenic deletions cannot revert, the deletion of a single base can be compensated for by the insertion of another base at, or near, the site of the original change. *See* GENE; GENETIC CODE.

Chromosomal changes. Some chromosomal changes involve alterations in the quantity of genetic material in the cell nuclei, while others simply lead to the rearrangement of chromosomal material without altering its total amount. *See* CHROMOSOME.

Origins of mutations. Mutations can be induced by various physical and chemical agents or can occur spontaneously without any artificial treatment with known mutagenic agents.

Until the discovery of x-rays as mutagens, all the mutants studied were spontaneous in origin; that is, they were obtained without the deliberate application of any mutagen. Spontaneous mutations occur unpredictably, and among the possible factors responsible for them are tautomeric changes occurring in the DNA bases which alter their pairing characteristics, ionizing radiation from various natural sources, naturally occurring chemical mutagens, and errors in the action of the DNA-polymerizing and correcting enzymes.

Spontaneous chromosomal aberrations are also found infrequently. One way in which deficiencies and duplications may be generated is by way of the breakage-fusion-bridge cycle. During a cell division one divided chromosome suffers a break near its tip, and the sticky ends of the daughter chromatids fuse. When the centromere divides and the halves begin to move to opposite poles, a chromosome bridge is formed, and breakage may occur again along this strand. Since new broken ends are produced, this sequence of events can be repeated. Unequal crossing over is sometimes cited as a source of duplications and deficiencies, but it is probably less important than often suggested.

In the absence of mutagenic treatment, mutations are very rare. In 1927 H. J. Muller discovered that x-rays significantly increased the frequency of mutation in *Drosophila*. Subsequently, other forms of ionizing radiation, for example, gamma rays, beta particles, fast and thermal neutrons, and alpha particles, were also found to be effective. Ultraviolet light is also an effective mutagen. The wavelength most employed experimentally is 253.7 nm, which corresponds to the peak of absorption of nucleic acids.

Some of the chemicals which have been found to be effective as mutagens are the alkylating agents which attack guanine principally although not exclusively. The N7 portion appears to be a major target in the guanine molecule, although the O^6 alkylation product is probably more important mutagenically. Base analogs are incorporated into DNA in place of normal bases and produce mutations probably because there is a higher chance that they will mispair at replication. Nitrous acid, on the other hand, alters DNA bases in place. Adenine becomes hypoxanthine and cytosine becomes uracil. In both cases the deaminated base pairs differently from the parent base. A third deamination product, xanthine, produced by the deamination of guanine, appears to be lethal in its effect and not mutagenic. Chemicals which react with DNA to generate mutations produce a range of chemical reaction products not all of which have significance for mutagenesis.

Significance of mutations. Mutations are the source of genetic variability, upon which natural selection has worked to produce organisms adapted to their present environments. It is likely, therefore, that most new mutations will now be disadvantageous, reducing the degree of adaptation. Harmful mutations will be eliminated after being made homozygous or because the heterozygous effects reduce the fitness of carriers. This may take some generations, depending on the severity of their effects. Chromosome alterations may also have great significance in evolutionary advance. Duplications are, for example, believed to permit the accumulation of new mutational changes, some of which may prove useful at a later stage in an altered environment.

Rarely, mutations may occur which are beneficial: Drug yields may be enhanced in microorganisms; the characteristics of cereals can be improved. However, for the few mutations which are beneficial, many deleterious mutations must be discarded. Evidence suggests that the metabolic conditions in the treated cell and the specific activities of repair enzymes may sometimes promote the expression of some types of mutation rather than others. *See* DEOXYRIBONUCLEIC ACID (DNA). [B.J.K.]

Mutualism An interaction between two species that benefits both. Individuals that interact with mutualists experience higher sucess than those that do not. Hence, behaving mutualistically is advantageous to the individual, and it does not require any concern for the well-being of the partner. At one time, mutualisms were thought to be rare curiosities primarily of interest to natural historians. However, it is now believed that every species is involved in one or more mutualisms. Mutualisms are thought to lie at the root of phenomena as diverse as the origin of the eukaryotic cell, the diversification of flowering plants, and the pattern of elevated species diversity in tropical forests.

Mutualisms generally involve an exchange of substances or services that organisms would find difficult or impossible to obtain for themselves. For instance, *Rhizobium* bacteria found in nodules on the roots of many legume (bean) species fix atmospheric nitrogen into a form (NH_3) that can be taken up by plants. The plant provides the bacteria with carbon in the form of dicarboxylic acids. The carbon is utilized by the bacteria as energy for nitrogen fixation. Consequently, leguminous plants often thrive in nitrogen-poor environments where other plants cannot persist. Another well-known example is lichens, in which fungi take up carbon fixed during photosynthesis of their algae associates. *See* NITROGEN FIXATION.

A second benefit offered within some mutualisms is transportation. Prominent among these mutualisms is biotic pollination, in which certain animals visit flowers to obtain resources and return a benefit by transporting pollen between the flowers they visit. A final benefit is protection from one's enemies. For example, ants attack the predators and parasites of certain aphids in exchange for access to the aphids' carbohydrate-rich excretions (honeydew).

Another consideration about mutualisms is whether they are symbiotic. Two species found in intimate physical association for most or all of their lifetimes are considered to be in symbiosis. Not all symbioses are mutualistic; symbioses may benefit both, one, or neither of the partners.

Mutualisms can also be characterized as obligate or facultative (depending on whether or not the partners can survive without each other), and as specialized or generalized (depending on how many species can confer the benefit in question).

Two features are common to most mutualisms. First, mutualisms are highly variable in time and space. Second, mutualisms are susceptible to cheating. Cheaters can be individuals of the mutualist species that profit from their partners' actions without offering anything in return, or else other species that invade the mutualism for their own gain.

Mutualism has considerable practical significance. Certain mutualisms play central roles in humans' ability to feed the growing population. It has been estimated that half the food consumed is the product of biotic pollination. *See* ECOLOGY; PLANT PATHOLOGY. [J.L.Br.]

Myasthenia gravis A disease resulting from an abnormality in neuromuscular transmission, characterized by a fluctuating degree of muscle weakness. The weakness is usually aggravated by activity, and there is partial or complete restoration of strength after a period of rest or the administration of anticholinesterase medications.

It has been shown that the basic defect in myasthenia gravis is a reduction in the number of acetylcholine receptor sites in the postsynaptic membrane of the neuromuscular junction. It has also been shown that many myasthenic patients have immunoglobulins in the serum that partially block acetylcholine receptors. *See* AUTOIMMUNITY; IMMUNOGLOBULIN.

Abnormalities have been demonstrated in the thymus gland and skeletal muscle in myasthenia gravis. There is an increased incidence of thymoma in myasthenia gravis, and in those without a thymoma, hyperplasia of the germinal centers is a common finding in the thymus gland.

Although the disease affects young women more commonly, usually in the third decade, it can occur in either sex at any age. In the majority of persons, weakness affects muscles of head, neck, and limbs (generalized myasthenia), but in some the weakness is restricted to the muscles of the eyes (ocular myasthenia), in which case the disease is usually benign.

The standard treatment for myasthenia gravis has been the use of longer-acting anticholinesterase agents; thymectomy and immunosuppressive drugs are reserved for those patients with generalized myasthenia that does not respond sufficiently to these agents. [S.M.Su.]

Mycobacterial diseases Diseases caused by mycobacteria, a diffuse group of acid-fast, rod-shaped bacteria in the genus *Mycobacterium*. Some mycobacteria are saprophytes, while others can cause disease in humans. The two most important species are *M. tuberculosis* (the cause of tuberculosis) and *M. leprae* (the cause of leprosy); other species have been called by several names, particularly the atypical mycobacteria or the nontuberculous mycobacteria. *See* LEPROSY; TUBERCULOSIS.

These bacteria are classified according to their pigment formation, rate of growth, and colony morphology. The most commonly involved disease site is the lungs. Nontuberculous mycobacteria are transmitted from natural sources in the environment, rather than from person to person, and thus are not a public health hazard. Nontuberculous mycobacteria have been cultured from various environmental sources.

The diagnosis of disease caused by nontuberculous mycobacteria can be difficult, since colonization or contamination of specimens may be present rather than true infection.

Pulmonary disease resembling tuberculosis is a most important manifestation of disease caused by nontuberculous mycobacteria. The symptoms and chest x-ray findings are similar to those seen in tuberculosis. *Mycobacterium kansasii* and *M. avium intracellulare* are the most common pathogens. The disease usually occurs in middle-aged men and women with some type of chronic coexisting lung disease. The pathogenic mechanisms are obscure. Pulmonary infections due to *M. kansasii* can be treated successfully with chemotherapy. The treatment of pulmonary infections due to *M. avium intracellulare* complex is difficult.

Chronic infection involving joints and bones, bursae, synovia, and tendon sheaths can be caused by various species.

Localized abscesses due to *M. fortuitum* or *M. chelonei* can occur after trauma, after surgical incision, or at injection sites. The usual treatment is surgical incision. The most common soft tissue infection is caused by *M. marinum*, which may be introduced, following an abrasion or trauma, from handling fish or fish tanks, or around a swimming pool. Treatment is surgical. *Mycobacterium ulcerans* causes a destructive skin infection in tropical areas of the world. It is treated by wide excision and skin grafting.

Disseminated *M. avium intracellulare* is one of the opportunistic infections seen in the acquired immune deficiency syndrome (AIDS). In individuals with AIDS, the organism has been cultured from lung, brain, cerebrospinal fluid, liver, spleen, intestinal mucosa, and bone marrow. No treatment has yet been effective in this setting. *See* ACQUIRED IMMUNE DEFICIENCY SYNDROME (AIDS). [G.M.L.; L.B.R.]

Mycology The study of organisms classified under the kingdom Fungi. Common names for some of these organisms are mushrooms, boletes, bracket or shelf fungi, powdery mildew, bread molds, yeasts, puffballs, morels, stinkhorns, truffles, smuts, and rusts. Fungi are found in every ecological niche. Mycologists estimate that there are 1.5 million species of fungi, with only 70,000 species now described. Fungi typically have a filamentous-branched somatic structure surrounded by thick cell walls known as hyphae. The phyla considered to be true fungi are Chytridiomycota, Zygomycota, Ascomycota, and Basidiomycota. Other phyla that sometimes are included as true fungi are Myxomycota, Dictyosteliomycota, Acrasiomycota, and Plasmodiophoromycota. *See* FUNGAL BIOTECHNOLOGY; FUNGAL ECOLOGY; FUNGAL GENETICS; FUNGI; MEDICAL MYCOLOGY; PLANT PATHOLOGY. [S.C.Jo.]

Mycoplasmas The smallest prokaryotic microorganisms that are able to grow on cell-free artificial media. Their genome size is also among the smallest recorded in prokaryotes, about 5×10^8 to 10^9 daltons. The mycoplasmas differ from almost all other prokaryotes in lacking a rigid cell wall and in their incapability to synthesize peptidoglycan, an essential component of the bacterial cell wall.

Taxonomically, the mycoplasmas are assigned to a distinct class, the Mollicutes, containing two orders, Mycoplasmatales and Acholeplasmatales. The distinction between the orders is based primarily on differences in nutritional criteria: members of the Mycoplasmatales require cholesterol or other sterols for growth whereas those of the second order do not. The main criteria used for the subdivision of the orders into families and genera are shown:

Class: Mollicutes
Order I: Mycoplasmatales (sterol required for growth; $\mathrm{NADH_2}$ oxidase localized in cytoplasm)
Family I: Mycoplasmataceae (genome size approximately 5×10^8 daltons)
Genus I: *Mycoplasma* (70 species; do not hydrolyze urea)
Genus II: *Ureaplasma* (2 species; hydrolyze urea)
Family II: Spiroplasmataceae (helical organisms; genome size approximately 10^9 daltons)
Genus I: *Spiroplasma* (4 species)
Order II: Acholeplasmatales (sterol not required for growth; $\mathrm{NADH_2}$ oxidase localized in membrane; genome size approximately 10^9 daltons)
Family I: Acholeplasmataceae
Genus I: *Acholeplasma* (9 species)
Genus of uncertain taxonomic position
Anaeroplasma (2 species)

The term mycoplasmas is generally used as the vernacular or trivial name for all members of the class Mollicutes, irrespective of the classification in a particular genus. *See* PROKARYOTAE.

The mycoplasmas are almost ubiquitous in nature. Several species are important pathogens of humans, animals and plants, while others constitute part of the normal microbial flora of, for example, the upper respiratory and lower urogenital tracts of humans. *Mycoplasma pneumoniae* was found to be the cause of cold agglutinin-associated primary atypical pneumonia. This disease is particularly frequent in the 5–15-year age group; it is probably endemic almost all over the world and often reaches epidemic proportions at intervals of 4 to 5 years.

Mycoplasmas are generally highly resistant to benzyl penicillin and other antibiotics which act by interfering with the biosynthesis of peptidoglycan. They are usually susceptible to antibiotics that specifically inhibit protein synthesis in prokaryotes, such as tetracyclines and chloramphenicol. Susceptibility to other antibiotics, such as erythromycin and other macrolides, is variable. *See* ANTIBIOTIC; BACTERIAL PHYSIOLOGY AND METABOLISM; PLANT PATHOLOGY; PNEUMONIA. [E.A.F.]

Mycorrhizae Dual organs of absorption that are formed when symbiotic fungi inhabit healthy absorbing organs (roots, rhizomes, or thalli) of most terrestrial plants and many aquatics and epiphytes.

Mycorrhizae appear in the earliest fossil record of terrestrial plant roots. Roughly 80% of the nearly 10,000 plant species that have been examined are mycorrhizal. Present-day plants that normally lack mycorrhizae are generally evolutionarily advanced. It has been inferred that primitive plants evolved with a symbiosis between fungi and rhizoids or roots as a means to extract nutrients and water from soil. The degree of dependence varies between species or groups of plants. In absolute dependence, characteristic of perennial, terrestrial plants, the host requires mycorrhizae to survive. Some plants are facultative; they may form mycorrhizae but do not always require them. This group includes many of the world's more troublesome weeds. A minority of plant species characteristically lack mycorrhizae, so far as is known, including many aquatics, epiphytes, and annual weeds.

The three major types of mycorrhizae differ in structural details but have many functions in common. The fungus colonizes the cortex of the host root and grows its filaments (hyphae) into surrounding soil from a few centimeters to a meter or more. The hyphae absorb nutrients and water and transport them to host roots. The fungi thus tap far greater volumes of soil at a relatively lower energy cost than the roots could on their own. Moreover, many, if not all, mycorrhizal fungi produce extracellular enzymes and organic acids that release immobile elements such as phosphorus and zinc from clay particles, or phosphorus and nitrogen bound in organic matter. The fungi are far more physiologically capable in extracting or recycling nutrients in this way than the rootlets themselves.

Mycorrhizal fungi are relatively poorly competent in extracting carbon from organic matter. They derive energy from host-photosynthesized carbohydrates. Hosts also provide vitamins and other growth regulators that the fungi need.

The major types are ectomycorrhizae, vesicular-arbuscular mycorrhizae, and ericoid mycorrhizae. Ectomycorrhizae are the most readily observed type. Ectomycorrhizal hosts strongly depend on mycorrhizae to survive. Relatively few in number of species, they nonetheless dominate most forests outside the tropics. Vesicular-arbuscular mycorrhizae (sometimes simply termed arbuscular mycorrhizae) form with the great majority of terrestrial herbaceous plant species plus nearly all woody perennials that are not ectomycorrhizal. Vesicular-arbuscular mycorrhizal hosts range from strongly mycorrhiza-dependent, especially the woody perennials, to faculative, as are many grasses.

Ericoid mycorrhizae are restricted to the Ericales, the heath order. The hosts are strongly mycorrhiza-dependent. Though relatively few in number, heath species dominate large areas around the world and are common understory plants in many forests. Other mycorrhiza types include those special for the Orchidaceae (orchids) and Gentianaceae (gentians). *See* ASCOMYCOTA; ERICALES; ZYGOMYCOTINA.

The succession of plants from pioneering through seral to climax communities is governed by availability of mycorrhizal propagules. When catastrophic fire, erosion, or clearcutting reduce the availability of mycorrhizal fungi in the soil, plants dependent on those fungi will have difficulty becoming established. Each mycorrhizal fungus has its own array of physiological characteristics. Some are especially proficient at releasing nutrients bound in organic matter, some produce more effective antibiotics or growth regulators than others, and some are more active in cool, hot, wet, or dry times of year than others. Healthy plant communities or crops typically harbor diverse populations of mycorrhizal fungal species. This diversity, evolved over a great expanse of time, is a hallmark of thriving ecosystems. Factors that reduce this diversity also reduce the resilience of ecosystems.

Mycorrhizal inoculation of plants in nurseries, orchards, and fields has succeeded in many circumstances, resulting in improved survival and productivity of the inoculated plants. Inoculation with selected fungi is especially important for restoring degraded sites or introducing exotics. Because ectomycorrhizal fungi include many premier edibles such as truffles, seedlings can also be inoculated to establish orchards for production of edible fungi. *See* FOREST SOIL; FUNGI. [J.M.Tr.]

Mycotoxin Any of the mold-produced substances that may be injurious to vertebrates upon ingestion, inhalation, or skin contact. The diseases they cause, known as mycotoxicoses, need not involve the toxin-producing fungus. Diagnostic features characterizing mycotoxicoses are the following: the disease is not transmissible; drug and antibiotic treatments have little or no effect; in field outbreaks the disease is often seasonal; the outbreak is usually associated with a specific foodstuff; and examination of the suspected food or foodstuff reveals signs of fungal activity.

The earliest recognized mycotoxicoses were human diseases. Ergotism, or St. Anthony's fire, results from eating rye infected with *Claviceps purpurea*. Yellow rice disease, a complex of human toxicoses, is caused by several *Penicillium islandicum* mycotoxins. World attention was directed toward the mycotoxin problem with the discovery of the aflatoxins in England in 1961. The aflatoxins, a family of mycotoxins produced by *Aspergillus flavus* and *A. parasiticus*, can induce both acute and chronic toxicological effects in vertebrates. Aflatoxin B_1, the most potent of the group, is toxic, carcinogenic, mutagenic, and teratogenic. Major agricultural commodities that are often contaminated by aflatoxins include corn, peanuts, rice, cottonseed, and various tree nuts. *See* AFLATOXIN; ERGOT AND ERGOTISM. [A.Ci.; M.Kl.]

Myiasis The infestation of vertebrates by the larvae, or maggots, of numerous species of flies. These larvae may invade different parts of the bodies of these animals or may appear externally. The Diptera of medical and veterinary importance are largely confined to the families Oestridae, Calliphoridae, and Sarcophagidae.

In cutaneous myiasis, the larvae are found in or under the skin. There may be a migration of some species of these larvae through host tissues, resulting in a swelling with intense itching. Such a condition is known as larva migrans, or creeping eruption, and may require surgical treatment.

Intestinal myiasis in humans is usually the result of accidentally swallowing the eggs or larvae of these flies. It occurs commonly in many herbivores who ingest the eggs when feeding on contaminated herbage. The larvae settle in the stomach or intestinal tract of the animal host.

Cavity, or wound, myiasis occurs when the larvae invade natural orifices, such as the nasopharynx, vulva, and sinuses, or artificial openings such as wounds. External myiasis includes infestation by those maggots which are blood feeders. *See* DIPTERA; MEDICAL PARASITOLOGY. [C.B.C.]

Mylonite A rock that has undergone significant modification of original textures by predominantly plastic flow due to dynamic recrystallization. Mylonites form at depth beneath brittle faults in continental and oceanic crust, in rocks from quartzofeldspathic to olivine-pyroxenite composition. Mylonites were once confused with cataclasites, which form by brittle fracturing, crushing, and comminution. Microstructures that develop during mylonitization vary according to original mineralogy and modal compositions, temperature, confining pressure, strain, strain rate, applied stresses, and presence or absence of fluids.

At low to moderate metamorphic grades, mylonitization reduces the grain size of the protolith and commonly produces a very fine-grained, well-foliated rock with a pronounced linear fabric defined by elongate minerals. Lineations may be weak or absent, however, in high-strain zones that lack a significant rotational component. At high metamorphic grades, grain growth during mylonitization can produce a net increase in grain size, and the term mylonitic gneiss is used where there is a preserved or inferred undeformed protolith. *See* METAMORPHIC ROCKS. [C.Si.]

Myodocopida An order of marine organisms that forms an important part of the class Ostracoda (subphylum Crustacea) and comprises three suborders. It has a long geological history that extends back at least to the Early Silurian. However, the lightly calcified carapaces of the species in this order are a factor in their having a sparse fossil record. Indeed, of the sixteen families of myodocopids, three are known only from modern marine environments. Species of those families that have a fossil record are quite rare and discontinuous in their stratigraphical distribution. Myodocopids are only abundant as fossils from organically rich shale that was deposited in deep, anoxic environments, especially those of the Devonian seas. Such environments were devoid of benthic (bottom-dwelling) life, but the valves and carapaces of the nektonic (free-swimming) myodocopids, both immature forms (termed instars) and adults, sank into such environments and were preserved. *See* CRUSTACEA; OSTRACODA.

The myodocopids are typically much larger than other ostracodes and may be more than a centimeter long, although adults of most species are unlikely to be longer than 3 mm. As is characteristic of ostracodes, the carapace of the myodocopids comprises two valves that are joined along the animal's dorsum by a hinge and ligament. Among the myodocopids, the anterior portions of both valves are marked by a characteristic notch through which the setaceous antennae or antennules protrude. The appendages of all ostracodes are homologous with those of other crustaceans and, as is characteristic of arthropods in general, have been highly modified during their evolution. The appendages of the myodocopids are especially well adapted for swimming. Sexual dimorphism is not as pronounced among the myodocopids as it is among most smaller, more heavily calcified ostracodes.

Myodocopids are not exclusively planktonic as is often assumed. They are typically strong swimmers, but many are nektobenthic, swimming in proximity to the substrate. Others, however, live near the surface of the open ocean and are not associated with the environments of deposition that lie far beneath them on the ocean floor, where their valves and carapaces will ultimately be deposited. A fascinating characteristic of the myodocopids is the ability of many species to secrete bioluminescent material into the water. This bioluminescence functions as highly elaborate courtship displays that are species-specific and facilitate recognition of potential mates. *See* BIOLUMINESCENCE; CRUSTACEA; OSTRACODA. [R.L.Ka.]

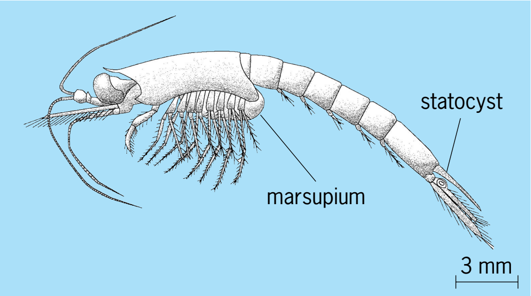
Myricales An order of flowering plants, division Magnoliophyta (Angiospermae), in the subclass Hamamelidae of the class Magnoliopsida (dicotyledons). The order consists of the single family Myricaceae, with about 50 species. Within its subclass the order is marked by its simple, resinous-dotted, aromatic leaves and unilocular ovary with two styles and a single ovule. The plants are trees or shrubs, and the flowers are much reduced and borne in catkins. The fruit is a small, waxy-coated drupe or nut. Several species of *Myrica* are occasionally cultivated as ornamentals. *See* FLOWER; HAMAMELIDAE; MAGNOLIOPSIDA. [A.Cr.]

Myrtales An order of flowering plants in the core eudicots. The order consists of 10 families and approximately 9300 species. The two largest families are Melastomataceae (approximately 4500 species) and Myrtaceae (approximately 3000 species). Thymelaeaceae are excluded in recent concepts of the order, being related instead to families of Malvales.

Myrtales are chiefly tropical, but Onagraceae and Penaeaceae are predominantly temperate. Myrtales usually have opposite, simple, entire leaves and perigynous to epigynous flowers with a compound pistil and most commonly axile placentation. The seeds have little or no endosperm. The stamens are normally numerous, and many species have tetramerous flowers. Vascular bundles characteristically have internal phloem, which is otherwise rare in the rosid dicots.

Economic crops in Myrtaceae include spice trees such as allspice (*Pimenta*) and cloves (*Syzygium*), and the timber trees *Eucalyptus*. Other important economic crops in the order include evening primrose (*Oenothera*, Onagraceae) and pomegranate (*Punica*, Lythraceae). Purple loosestrife (*Lythrum salicaria*) can be a noxious weed of North American waterways. *See* EUDICOTYLEDONS. [M.W.C.]

Mysidacea An order of free-swimming, shrimplike crustaceans belonging to the class Eumalacostraca; commonly



A member of the Mysida, showing the marsupium and the paired uropods with a statocyst in the inner one.

known as opossum shrimps. They occur in vast numbers in coastal and oceanic regions of the world.

The Mysidacea are divided into suborders Lophogastrida and the Mysida. The former contains only 38 species ascribed to six genera; they live predominantly in the deep sea and range in adult body length from 0.6 to 13 in. (17 to 350 mm), except the seven species in the genus *Paralophogaster* which are 0.2–0.8 in. (6–20 mm) in length.

The suborder Mysida contains some 800 species ascribed to four families: the primitive Petalophthalmidae and the advanced Mysidae, Lepidomysidae, and Stygiomysidae. Except for the deep-sea Petalophthalmidae and cave-dwelling Lepidomysidae (some 30 species), all species, in about 130 genera, have statocysts in the uropods (abdominal appendages; see illustration), a feature peculiar to mysids; and have adult body lengths of about 0.6 in. (15 mm) or less. Most mysidans are distributed in shallow coastal and shelf waters, a few have invaded fresh waters, and others live in the surface layers of the oceans or in the deep sea to depths as great as 23,650 ft (7210 m).

The young are carried within a marsupium formed by transparent concave plates attached to the insides of the posterior thoracic legs. These plates have short, strong setae and interlock ventrally to form a closed chamber, the marsupium. The eggs, which are fertilized during laying, are laid directly into the marsupium; develop to miniature adults; and emerge to swim freely in the sea. Mysids, like all crustaceans, increase their body size by molting.

Most species of mysids form aggregations. These are of different types and for different purposes. The functions of these aggregations, except for breeding, are not always clear, although protection of the population from predators is important. These aggregations result in many coastal mysids occurring at high densities, especially in estuarine or sandy beach habitats. Swarms of mysids in coastal waters are exploited commercially in tropical and subtropical regions of the world. *See* CRUSTACEA; EUMALACOSTRACA. [J.Mau.]

Mystacocarida A subclass of primitive Crustacea. The three species are in the genus *Derocheilocaris*. The body is wormlike and about 0.2 in. (5 mm) long. The cephalothorax bears first antennae, second antennae, mandibles, first maxillae, and second maxillae. Maxillipeds are on a separate segment, and four additional free thoracic segments bear platelike appendages. The six abdominal segments are without appendages, but large caudal rami are present, The labrum is enormous, mouthparts and nervous system are primitive, and the genital pore is on the thorax. *See* CRUSTACEA. [R.W.P.]

Myxiniformes The hagfishes, an order of eellike, jawless vertebrates (class Agnatha). They resemble the Petromyzontida in a number of respects. However, they differ from Petromyzontida in having the nasal opening at the tip of the snout and leading to the pharynx so that it can be used in respiration; in having barbels around the mouth; in having 6–15 pairs of gill pouches which open to the exterior either separately or by a common aperture; in having only one pair of semicircular canals; in having degenerate eyes lacking lens and iris and not visible externally; in having a continuous dorsal-caudal-ventral fin with fin rays only in the caudal portion; in having both male and female organs in one individual, though only one matures; and in being exclusively marine.

Hagfishes live on or near muddy bottoms in fairly deep waters, where they feed largely on dead or disabled fishes and polychaete worms, into which they bore with their rasplike tongues. They are often a considerable nuisance to commercial fishing because of their habit of damaging netted or hooked fishes. They are sometimes called slime eels because of their ability to discharge large quantities of slime from the prominent mucous pores segmentally arranged down each side.

Hagfishes are divided into three genera: *Myxine*, *Paramyxine*, and *Bdellostoma*. *See* AGNATHA; CYCLOSTOMATA (CHORDATA); PETROMYZONTIDA. [R.H.De.]

Myxomycota Organisms that are classified in the kingdom Fungi and given the class name Myxomycetes, following the rules of botanical nomenclature; or classified in the kingdom Protista at various taxonomic ranks, as class Mycetozoa, following the rules of zoological nomenclature. Evolutionary origins are controversial, but many now believe, based on DNA sequencing techniques, that the Myxomycetes diverge early on the tree of life in the region where other protists are found.

The class consists of 3 subclasses, 6 orders, approximately 57 genera, and 600 species. Subclasses Ceratiomyxomycetidae, Myxogastromycetidae, and Stemonitomycetidae are distinguished by the type of sporophore development, type of plasmodium, and method of bearing spores. The various orders, families, genera, and species are distinguished by characteristics of the fruiting bodies such as spore color, peridium, capillitium, calcium carbonate, or columella.

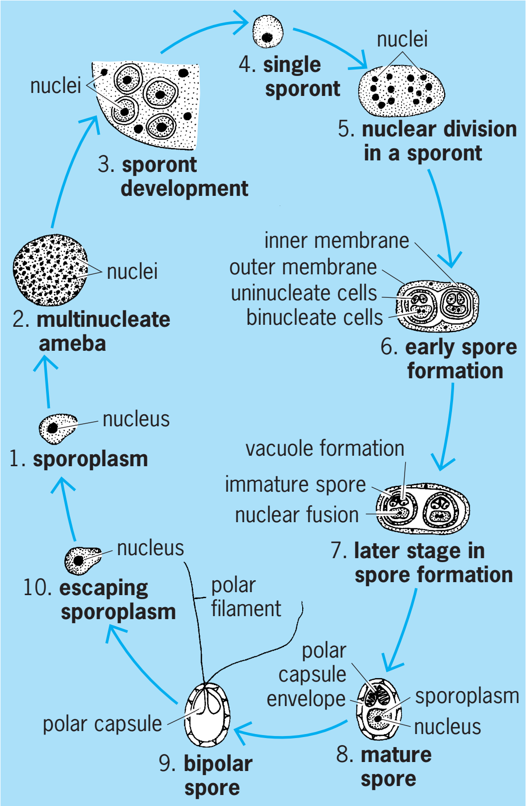
Myxomycetes begin to appear in May and fruit throughout the summer until October in the north temperate regions. Many species are universally distributed and live in moist and dark places on decaying organic matter. Some species are restricted to more specialized habitats.

Spores are released from the fruiting bodies when disturbed and fall onto the substratum where, when water is present, they germinate and release protoplasts. The protoplasts may develop into either a myxamoeba or a flagellated swarm cell, both of which are haploid and behave like gametes (sex cells). The haploid (monoploid) gametes fuse in pairs forming diploid zygotes, which then divide mitotically without subsequent cell division, resulting in the formation of a multinucleated, free-living mass of unwalled protoplasm called the plasmodium. The diploid plasmodium is representative of the slime stage, and hence the common names sometimes used for this group of organisms include plasmodial, acellular, or true slime molds. The plasmodia ingest food as particulate matter (usually bacteria) by engulfment and are capable of growing to over 70 cm in diameter.

The separate stages in their life cycle make myxomycetes ideal organisms to study basic biological problems, ranging through protoplasmic streaming, the mitotic cycle, morphogenesis, aging, and cell division in cancerous cells. *See* EUMYCOTA. [H.W.K.]

Myxosporida An order of the protozoan class Myxosporidea (subphylum Cnidospora). It is characterized by the production of spores with one or more valves and polar capsules, and by possession of a single sporoplasm with or without an iodinophilous vacuole. Myxosporidians are mainly parasites of fishes. They infect all parts of the body, including the heart and brain, and often induce considerable pathological changes in the host tissue.

Infection begins with the ingestion of the spore by a host fish. The digestive fluids cause the polar filaments to be extruded, and at the same time the sporoplasm is released from the spore



Life cycle of *Myxobolus*, a fish parasite.

(see illustration). The sporoplasm, or amebula, reaches the specific site of infection directly through the gut wall or by way of the bloodstream. The amebula becomes a trophozoite when it starts feeding on the host tissues. The trophozoite then goes through a series of nuclear divisions and, by a process of budding, gives rise to a number of cells, each of which eventually develops into a sporont. A sporont is a monosporoblast if one spore is produced and a pansporoblast if two or more spores are formed. The sporont undergoes a series of nuclear divisions, in which the number of nuclei produced will determine the number of spores and polar capsules to be formed. That is, in every spore one nucleus is involved in the formation of each valve and each polar capsule. Two nuclei become the gametic nuclei, which then fuse to form the zygotic nucleus of the sporoplasm. *See* CNIDOSPORA; MYXOSPORIDEA. [R.F.N.]

Myxosporidea A class of the protozoan subphylum Cnidospora. Members of this class, which includes the orders Myxosporida, Actinomyxida, and Helicosporida, are parasites in fish, a few amphibians, and invertebrates. The Myxosporida are divided into two suborders, the Unipolarina and Bipolarina.

Unipolarina is characterized by spores with one to six (never five) polar capsules located at the anterior end, except in some genera in which the capsules are widely separated or located in the central part of the spore but in which the polar filament is attached near the anterior end. The Unipolarina contains nine or more families.

Bipolarina, containing a single family with three genera, is characterized by the presence of one capsule at or near each end of a fusiform or ellipsoid spore. *See* ACTINOMYXIDA; CNIDOSPORA; HELICOSPORIDA; MYXOSPORIDA. [R.F.N.]

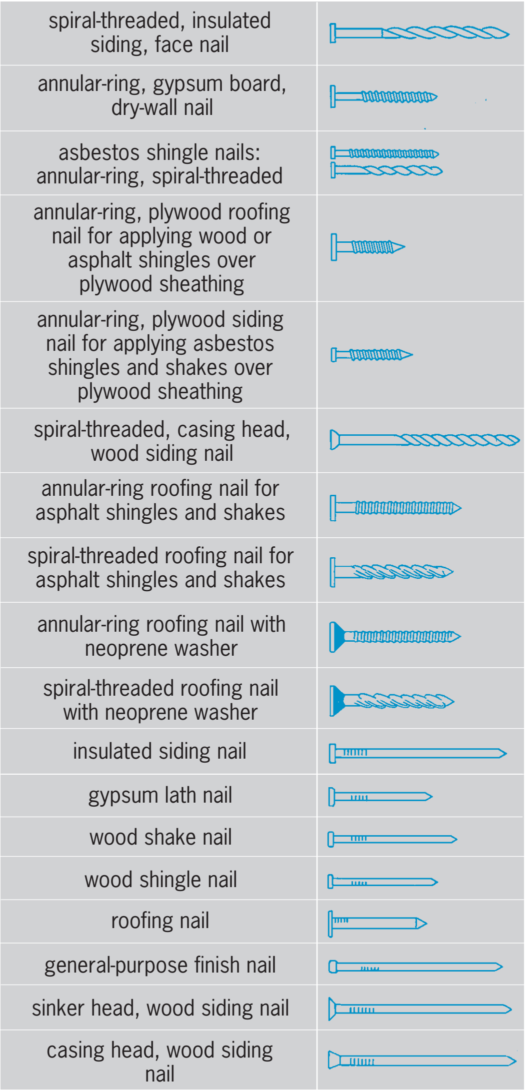
Myzostomaria An aberrant group of Polychaeta recognized for four families, each with one genus. Myzostomidae with *Myzostomum* comprise about 130 species from worldwide areas. Mesomyzostomidae with *Mesomyzostomum* has two species, from Japan and the Aru Islands. Protomyzostomidae with *Protomyzostomum* is known for three species, from Japan and the Murman Sea, and Stelechopidae with *Stelechopus* has a single species, from Crozet Island, Antarctic Ocean. All are either external or internal parasites of echinoderms, chiefly crinoids, and hence from deep water. Most are greatly depressed, broad and very small, measuring at most a few millimeters. The separation of this group of polychaetes into families and species is based on external and internal characters. *See* ANNELIDA; POLYCHAETA.

[O.H.]

N

Nailing The driving of nails in a manner that will position and hold two or more members, usually of wood, in a desired relationship to each other. The contact pressures between the surfaces of the nails and the surrounding wood fibers hold the nails in position. Some types of nails are shown in the illustration.

Factors that determine the strength and efficiency of a nailed joint are (1) the type of wood, (2) the nail used, (3) the conditions under which the nailed joint is used, and (4) the number of nails. In general, hard, dense woods hold nails better than soft woods. The better the resistance of a nail to direct withdrawal from a piece of wood, the tighter the joint will remain. To increase resistance to withdrawal or loosening, nails may be coated, etched, spirally grooved, annularly grooved, or barbed, as illustrated.



Special- and general-purpose nails.

Blunt-pointed nails are often used to prevent the wood from splitting. Using nails of a smaller diameter also tends to prevent splitting but requires a greater number of nails per joint. Beeswax is sometimes applied to nail points to make them drive more easily, but it also reduces the holding power of the nail [A.H.T.]

Najadales An order of aquatic and semiaquatic flowering plants, division Magnoliophyta (Angiospermae), in the subclass Alismatidae of the class Liliopsida (monocotyledons). The order consists of 10 families and a little more than 200 species. The Potamogetonaceae, with about 100 species, are the largest family of the order, and the name Potamogetonales is sometimes used instead of Najadales for the group. The Najadales are Alismatidae in which the perianth, when present, is not differentiated into evident sepals and petals. Usually the flowers are not individually subtended by bracts. The Zosteraceae of this order are unique among flowering plants in that they grow submersed in the ocean, albeit in shallow water near the shore. *Zostera marina*, or eelgrass, is a common member of the family. *See* ALISMATIDAE; FLOWER; LILIOPSIDA; MAGNOLIOPHYTA; PLANT KINGDOM. [A.Cr.; T.M.Ba.]

Nanochemistry The study of the synthesis and characterization of materials in the nanoscale size range (1 to 10 nanometers). These materials include large organic molecules, inorganic cluster compounds, and metallic or semiconductor particles. The synthesis of nanoscale inorganic materials is important because the small size endows these particles with unusual structural and optical properties that may find application in catalysis and electrooptical devices. Approaches to the synthesis of these materials have focused on constraining the reaction environment through the use of surface-bound organic additives, porous glasses, zeolites, clays, or polymers. The use of synthetic approaches that are inspired by the biological processes result in the deposition of inorganic materials such as bones, shells, and teeth (biomineralization). This biomimetic approach involves the use of assemblies of biological molecules that provide nanoscale reaction environments in which inorganic materials can be prepared in an organized and controlled manner. Examples of biological assemblies include phospholipid vesicles and the polypeptide micelle of the iron storage protein, ferritin. *See* MICELLE.

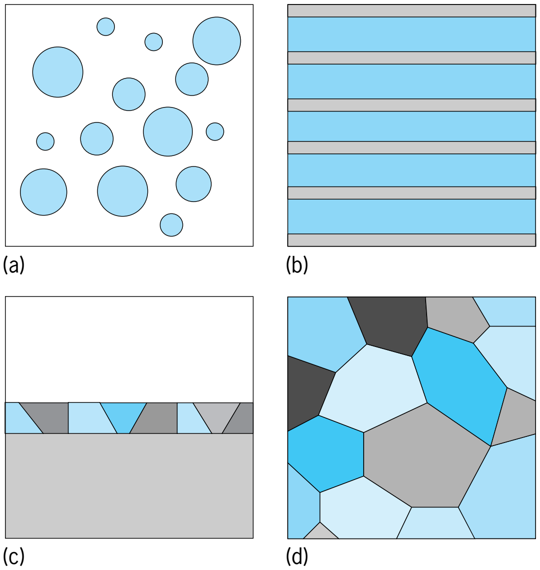
Vesicles are bounded by an organic membrane that provides a spatial limit on the size of the reaction volume. If a chemical reaction is undertaken in this confined space that leads to the formation of an inorganic material, the size of the product will also be constrained to the dimensions of the organic host structure. Provided that the chemical and physical conditions are not too severe to disrupt the organic membrane, these supramolecular assemblies may have advantages over inorganic hosts such as clays and zeolites because the chemical nature of the organic surface can be systematically modified so that controlled reactions can be accomplished. *See* SUPRAMOLECULAR CHEMISTRY.

One problem encountered with the use of phospholipid vesicles is their sensitivity to changes in temperature and ionic strength. Procedures have been developed in which the biomolecular cage of the iron storage protein, ferritin, has been used as a nanoscale reaction environment for the synthesis of inorganic materials. In the simplest approach the native iron oxide core is transformed into another material by chemical reaction within the protein shell. [S.Ma.]

Nanostructure A material structure assembled from a layer or cluster of atoms with size of the order of nanometers. Interest in the physics of condensed matter at size scales larger than that of atoms and smaller than that of bulk solids (mesoscopic physics) has grown rapidly since the 1970s, owing to the increasing realization that the properties of these mesoscopic atomic ensembles are different from those of conventional solids. As a consequence, interest in artificially assembling materials from nanometer-sized building blocks arose from discoveries that by controlling the sizes in the range of 1–100 nm and the assembly of such constituents it was possible to begin to alter and prescribe the properties of the assembled nanostructures. *See* MESOSCOPIC PHYSICS.

Nanostructured materials are modulated over nanometer length scales in zero to three dimensions. They can be assembled with modulation dimensionalities of zero (atom clusters or filaments), one (multilayers), two (ultrafine-grained overlayers or coatings or buried layers), and three (nanophase materials), or with intermediate dimensionalities (see illustration).

Multilayers and clusters. Multilayered materials have had the longest history among the various artificially synthesized nanostructures, with applications to semiconductor devices, strained-layer superlattices, and magnetic multilayers. Recognizing the technological potential of multilayered quantum heterostructure semiconductor devices helped to drive the rapid advances in the electronics and computer industries. A variety of electronic and photonic devices could be engineered by utilizing the low-dimensional quantum states in these multilayers for applications in high-speed field-effect transistors and high-efficiency lasers, for example. Subsequently, a variety of nonlinear optoelectronic devices, such as lasers and light-emitting diodes, have been created by nanostructuring multilayers. *See* ARTIFICIALLY LAYERED STRUCTURES; LIGHT-EMITTING DIODE; SEMICONDUCTOR HETEROSTRUCTURES; TRANSISTOR.



Schematic of four basic types of nanostructured materials, classified according to integral modulation dimensionality. (*a*) Dimensionality 0: clusters of any aspect ratio from 1 to infinity. (*b*) Dimensionality 1: multilayers. (*c*) Dimensionality 2: ultrafine-grained overlayers (coatings) or buried layers. (*d*) Dimensionality 3: nanophase materials. (*After R. W. Siegel, Nanostructured materials: Mind over matter, Nanostruct. Mat., 3:1–18, 1993*)

The advent of beams of atom clusters with selected sizes allowed the physics and chemistry of these confined ensembles to be critically explored, leading to increased understanding of their potential, particularly as the constituents of new materials, including metals, ceramics, and composites of these materials. A variety of carbon-based clusters (fullerenes) have also been assembled into materials of much interest. In addition to effects of confinement, interfaces play an important and sometimes dominant role in cluster-assembled nanophase materials, as well as in nanostructured multilayers. *See* ATOM CLUSTER; CERAMICS; FULLERENE.

Synthesis and properties. A number of methods exist for the synthesis of nanostructured materials. They include synthesis from atomic or molecular precursors (chemical or physical vapor deposition, gas condensation, chemical precipitation, aerosol reactions, biological templating), from processing of bulk precursors (mechanical attrition, crystallization from the amorphous state, phase separation), and from nature (biological systems). Generally, it is preferable to synthesize nanostructured materials from atomic or molecular precursors, in order to gain the most control over a variety of microscopic aspects of the condensed ensemble; however, other methodologies can often yield very useful results. *See* VAPOR DEPOSITION. [R.W.Si.]

Nanotechnology Systems for transforming matter, energy, and information, based on nanometer-scale components with precisely defined molecular features. The term nanotechnology has also been used more broadly to refer to techniques that produce or measure features less than 100 nanometers in size; this meaning embraces advanced microfabrication and metrology. Although complex systems with precise molecular features cannot be made with existing techniques, they can be designed and analyzed. Studies of nanotechnology in this sense remain theoretical, but are intended to guide the development of practical technological systems.

Nanotechnology based on molecular manufacturing requires a combination of familiar chemical and mechanical principles in unfamiliar applications. Molecular manufacturing can exploit mechanosynthesis, that is, using mechanical devices to guide the motions of reactive molecules. By applying the conventional mechanical principle of grasping and positioning to conventional chemical reactions, mechanosynthesis can provide an unconventional ability to cause molecular changes to occur at precise locations in a precise sequence. Reliable positioning is required in order for mechanosynthetic processes to construct objects with millions to billions of precisely arranged atoms.

Mechanosynthetic systems are intended to perform several basic functions. Their first task is to acquire raw materials from an externally provided source, typically a liquid solution containing a variety of useful molecular species. The second task is to process these raw materials through steps that separate molecules of different kinds, bind them reliably to specific sites, and then (often) transform them into highly active chemical species, such as radicals, carbenes, and strained alkenes and alkynes. Finally, mechanical devices can apply these bound, active species to a workpiece in a controlled position and orientation and can deposite or remove a precise number of atoms of specific kinds at specific locations.

Several technologies converge with nanotechnologies, the most important being miniaturization of semiconductor structures, driven by progress in microelectronics. More directly relevant are efforts to extend chemical synthesis to the construction of larger and more complex molecular objects. Protein engineering and supramolecular chemistry are active fields that exploit weak intermolecular forces to organize small parts into larger structures. Scanning probe microscopes are used to move individual atoms and molecules. *See* MOLECULAR RECOGNITION; MONOMOLECULAR FILM; NANOSTRUCTURE; SCANNING TUNNELING MICROSCOPE; SUPRAMOLECULAR CHEMISTRY. [E.Dr.]

Naphtha Any one of a wide variety of volatile hydrocarbon mixtures. They are sometimes obtained from coal tar but are more often derived from petroleum. Physical properties vary widely. The initial boiling point may be as low as 27°C (80°F), and end points may reach 260°C (500°F). Boiling ranges are sometimes as narrow as 11°C (20°F) or as wide as 110°C (200°F). Products sold as naphthas find their greatest use as solvents, thinners, or carriers.

There is a fairly sharp differentiation between aliphatic and aromatic naphthas. Aliphatic naphthas are relatively low in odor and toxicity and tend, also, to be low in solvent power. The aromatic naphthas are highly solvent. Their main components are toluene and xylenes; benzene is less desirable because of the extreme toxicity of its vapors. *See* PETROLEUM PRODUCTS. [J.K.R.]

Narcotic A drug which diminishes the awareness of sensory impulses, especially pain, by the brain. This action makes narcotics useful therapeutically as analgesics. While they are the most powerful pain-relieving agents available, their use is complicated by a number of undesirable side actions. *See* ANALGESIC.

All of the generally used narcotics are in some way related to opium, and the term opiate is sometimes used interchangeably with the term narcotic. Opium is a gummy exudate obtained from the unripe seed capsules of the opium poppy. Crude opium contains over a dozen alkaloids, all of which have been isolated and identified as to their structural chemistry. From this knowledge chemists have developed a number of synthetic chemical compounds, some of which have important advantages over the naturally occurring alkaloids. Therapeutically important natural alkaloids are morphine, codeine, and papaverine. Among the important synthetic narcotics are meperidine (Demerol), dihydromorphine (Dilaudid), oxymorphone (Numorphan), alphaprodine (Nisentil), anileridine (Leritine), piminodine (Alvodine), levorphanol (Levo-Dromoran), methadone (Dolophine), and phenazocine (Prinadol). *See* ALKALOID; OPIATES; POPPY.

Nalorphine (Nalline) is a narcotic antagonist and is used in the treatment of acute overdosage from narcotics; it is dangerous to drug addicts. Heroin is a highly addicting narcotic, and is so dangerous in this regard that the drug has been completely banned by both federal and state laws under all circumstances.

Pharmacology. The pharmacology of narcotics is generally similar to that of morphine, the principal narcotic used for its analgesic effects. Differences among them lie in the potency of their action and in the degree and variety of the side actions which they produce. Effects are those of analgesia, accompanied by a state of euphoria characterized by drowsiness and a change of mood from anxiety and tension to calmness and equanimity. It should be remembered that whatever narcotic is used, the effects are dose-related, and in higher doses all narcotics produce deep sleep and eventually general depression of all brain functions. Death from overdosage is due to depression of the respiratory centers with resultant failure of respiration.

The predominant pharmacological effect of morphine (and the other narcotics) is on the central nervous system. From the standpoint of its medicinal use, its most important action is relief of pain. Along with its valuable medicinal use morphine produces a great many undesirable side actions; the most frequent are depressed respiratory activity, the production of nausea and vomiting, and the inhibition of defecation and urination.

Drug dependence. All narcotics have the potential for producing dependence and addiction when used repeatedly over a period of time. Drug dependence results from compulsive, continued use of the drug, and is characterized by one or more of the following conditions: habituation, tolerance, or addiction.

Like any other habit pattern, habitual use of a drug can develop. Common examples are the use of nicotine in the form of cigarettes, or caffeine in the form of coffee or tea. Such habituation is generally regarded as innocuous.

Repeated ingestion of a drug in which the effect produced by the original dose no longer occurs results in tolerance. To produce the original effect, it is necessary to increase the dose.

When the body develops a dependence for the drug, addiction occurs. If the drug is suddenly stopped after a period of frequent use, a withdrawal syndrome develops, which is characterized by physical pain and widespread body reactions. The addict comes to dread the development of such painful and distressing reactions, and is trapped into continuing the drug.

All narcotics can produce habituation, tolerance, and addiction to a greater or less degree. Addiction to codeine is relatively rare but possible. Addiction to heroin develops rapidly, and this narcotic is therefore exceedingly dangerous. [J.M.Di.]

Native elements Those elements which occur in nature uncombined with other elements. Aside from the free gases of the atmosphere there are about 20 elements that are found as minerals in the native state. These are divided into metals, semimetals, and nonmetals. Gold, silver, copper, and platinum are the most important metals and each of these has been found abundantly enough at certain localities to be mined as an ore. Rarer native metals are others of the platinum group, lead, mercury, tantalum, tin, and zinc. Native iron is found sparingly both as terrestrial iron and meteoric iron.

The native semimetals can be divided into (1) the arsenic group, including arsenic, antimony, and bismuth; and (2) the tellurium group, including tellurium and selenium.

The native nonmetals are sulfur, and carbon in the forms of graphite and diamond. Native sulfur is the chief industrial source of that element. [C.S.Hu.]

Natrolite A fibrous or needlelike mineral belonging to the zeolite family of silicates. Most commonly it is found in radiating fibrous aggregates. The hardness is 5–$5^1/_2$ on Mohs scale, and the specific gravity is 2.25. The mineral is white or colorless with a vitreous luster that inclines to pearly in fibrous varieties. The chemical composition is $Na_2(Al_2Si_3O_{10}) \cdot 2H_2O$, but some potassium is usually present substituting for sodium.

Natrolite is a secondary mineral found lining cavities in basaltic rocks. Its outstanding locality in the United States is at Bergen Hill, New Jersey. *See* ZEOLITE. [C.Fr.; C.S.Hu.]

Natural fiber A fiber obtained from a plant, animal, or mineral. The commercially important natural fibers are those cellulosic fibers obtained from the seed hairs, stems, and leaves of plants; protein fibers obtained from the hair, fur, or cocoons of animals; and the crystalline mineral asbestos. Until the advent of the manufactured fibers near the beginning of the twentieth century, the chief fibers for apparel and home furnishings were linen and wool in the temperate climates and cotton in the tropical climates. However, with the invention of the cotton gin in 1798, cheap cotton products began to replace the more expensive linen and wool until by 1950 cotton accounted for about 70% of the world's fiber production. Despite the development of new fibers based on fossil fuels, cotton has managed to maintain its position as the fiber with the largest production volume, although its use has fallen. *See* COTTON; MANUFACTURED FIBER; WOOL.

The natural fibers may be classified by their origin as cellulosic (from plants), protein (from animals), and mineral. The plant fibers may be further ordered as seed hairs, such as cotton; bast (stem) fibers, such as linen from the flax plant; hard (leaf) fibers, such as sisal; and husk fibers, such as coconut. The animal fibers are grouped under the categories of hair, such as wool; fur, such as angora; or secretions, such as silk. The only important mineral fiber is asbestos, which because of its carcinogenic nature has been banned from consumer textiles. *See* TEXTILE. [I.Bl.]

Natural gas A combustible gas that occurs in porous rock of the Earth's crust and is found with or near accumulations of crude oil. Being in gaseous form, it may occur alone in separate reservoirs. More commonly it forms a gas cap, or mass of gas, entrapped between liquid petroleum and impervious capping rock layer in a petroleum reservoir. Under conditions of greater pressure it is intimately mixed with, or dissolved in, crude oil. *See* OIL AND GAS STORAGE.

Typical natural gas consists of hydrocarbons having a very low boiling point. Methane (CH_4) makes up approximately 85% of the typical gas. Ethane (C_2H_6) may be present in amounts up to 10%; and propane (C_3H_8) up to 3%. Butane (C_4H_{10}); pentane (C_5H_{12}); hexane; heptane; and octane may also be present.

Whereas normal hydrocarbons having 5–10 carbon atoms are liquids at ordinary temperatures, they have a definite vapor pressure and therefore may be present in the vapor form in natural gas. Carbon dioxide, nitrogen, helium, and hydrogen sulfide may also be present.

Types of natural gas vary according to composition and can be dry or lean (mostly methane) gas, wet gas (considerable amounts of so-called higher hydrocarbons), sour gas (much hydrogen sulfide), sweet gas (little hydrogen sulfide), residue gas (higher paraffins having been extracted), and casinghead gas (derived from an oil well by extraction at the surface). Natural gas has no distinct odor. Its main use is for fuel, but it is also used to make carbon black, natural gasoline, certain chemicals, and liquefied petroleum gas. Propane and butane are obtained in processing natural gas. *See* PETROLEUM PRODUCTS.

Gas occurs on every continent. Wherever oil has been found, a certain amount of natural gas is also present. Successful exploitation of these resources involves drilling, producing, gathering, processing, transporting, and metering the use of the gas. Long before supplies of natural gas run out or become expensively scarce, it is expected that some process of coal gasification will produce a gas which is completely interchangeable with natural gas and at a competitive price. This is important because coal makes up a majority of the world's known fossil fuel reserves. But when energy consumers indicated in the marketplace their preference for fluid and gaseous fuels over the solid forms, coal gasification research, already well under way, was given additional impetus. *See* COAL GASIFICATION; OIL AND GAS WELL DRILLING. [M.A.A.; M.T.H.]

Natural language processing Computer analysis and generation of natural language text. The goal is to enable natural languages, such as English, French, or Japanese, to serve either as the medium through which users interact with computer systems such as database management systems and expert systems (natural language interaction), or as the object that a system processes into some more useful form such as in automatic text translation or text summarization (natural language text processing).

In the computer analysis of natural language, the initial task is to translate from a natural language utterance, usually in context, into a formal specification that the system can process further. Further processing depends on the particular application. In natural language interaction, it may involve reasoning, factual data retrieval, and generation of an appropriate tabular, graphic, or natural language response. In text processing, analysis may be followed by generation of an appropriate translation or a summary of the original text, or the formal specification may be stored as the basis for more accurate document retrieval later. Given its wide scope, natural language processing requires techniques for dealing with many aspects of language, in particular, syntax, semantics, discourse context, and pragmatics.

The first aspect of natural language processing, and the one that has perhaps received the most attention, is syntactic processing, or parsing. Syntactic processing is important because certain aspects of meaning can be determined only from the underlying structure and not simply from the linear string of words. A second phase of natural language processing, semantic analysis, involves extracting context-independent aspects of a sentence's meaning. Given that most natural languages allow people to take advantage of discourse context, their mutual beliefs about the world, and their shared spatio-temporal context to leave things unsaid or say them with minimal effort, the purpose of a third phase of natural language processing, contextual analysis, is to elaborate the semantic representation of what has been made explicit in the utterance with what is implicit from context. A fourth phase of natural language processing, pragmatics, takes into account the speaker's goal in uttering a particular thought in a particular way—what the utterance is being used to do. [B.W.]

Nautiloidea A group of externally shelled cephalopods, represented by the single extant genus *Nautilus*. The formal designation of this group as a subclass is now generally used only for those externally shelled cephalopods that resemble *Nautilus* in having completely coiled shells (and then the subclass includes *Nautilus* itself). In living forms, the basic structural plan includes a shell consisting of a septate phragmocone, a living chamber, and a siphuncle. In fossil nautiloids, this simple pattern is modified in great variety with respect to shell form and size, structure and size of the siphuncle, and the large number of devices to counteract the buoyancy of the phragmocone. The shape of fossil nautiloids may deviate in many ways from the simple *Nautilus* model.

Fossil nautiloids are found on all continents, including Antarctica. Especially noteworthy are the rich Ordovician and Silurian faunas of North America, northern Europe, Czechoslovakia, and central and southern China. Coiled nautiloids almost certainly moved around by jet propulsion like *Nautilus* and lived close to the sea floor, at moderate to intermediate depths in many different environments. Other types may have included agile swimmers as well as slow-moving benthic adaptations. *See* CEPHALOPODA. [C.T.]

Naval architecture An engineering discipline concerned with the design of ships, boats, drill rigs, submarines, and other floating or submerged craft. The naval architect creates the initial overall concept for a new ship, integrates the work of other specialists as the ship design is developed, and is specifically responsible for the hull and superstructure shape, general arrangements, structural design, weights and centers calculations, stability analysis, hydrodynamic performance assessments, propeller and rudder design, and the arrangement and outfit of all living and working spaces, other than machinery spaces. The naval architect's ally, the marine engineer, is responsible for the design of the propulsion plant, the electric plant, and other ship machinery and mechanical systems, including the so-called distributive systems: electric cabling, piping, and ventilation system ducting. The marine engineer also is responsible for ship control systems, including propulsion and electric plant controls and the steering system. *See* FERRY; HYDROFOIL CRAFT; ICEBREAKER; MERCHANT SHIP; NAVAL SURFACE SHIP; OIL AND GAS, OFFSHORE; SUBMARINE.

In the past, naval architecture was as much an art as a science, but research, coupled with advances in computer-aided design, has greatly enhanced the scientific basis of the profession. Naval architecture is a specialized form of mechanical engineering, as is marine engineering. Thus the education of naval architects is very similar in content to that of mechanical engineers, and the same types of degree programs are offered. Some colleges and universities combine naval architecture and marine engineering education and offer a combined degree. *See* MARINE ENGINEERING; MECHANICAL ENGINEERING. [P.A.Ga.]

Naval armament A general term that covers the ordnance and control systems used by naval ships and aircraft. It includes a wide spectrum of weapons designed for use against targets in the air, on land or sea, or under the ocean surface. The spectrum of weaponry used by naval forces runs from small arms to nuclear warheads and includes weapons that are intended for

Fig. 1. Trident missile being fired from a submerged submarine. (*U.S. Navy*)

use against a particular type of target as well as general-purpose weapons.

Naval armament may be air-, surface-, or submarine-launched. It can be categorized as tactical or strategic, or by its intended primary target: surface attack, air defense, or antisubmarine. Many weapons can be used against different types of targets. Naval weaponry includes guns, guided missiles, rockets, bombs, depth charges, torpedoes, and mines.

Guided missiles. In the years since World War II, guided missiles have taken first place among families of naval weapons. Naval missiles may be adaptable to multiple launch modes: from ship, submarine, and aircraft. Modern missiles are more compact, saving critical space and weight, and their guidance systems have steadily become more sophisticated. Shipboard launchers can handle two or three different weapons, eliminating the need for separate launchers.

An *Ohio*-class missile submarine carries 24 Trident fleet ballistic missiles (Fig. 1), developed to replace the earlier Polaris and Poseidon. *See* SUBMARINE.

Standard, the Navy's principal air defense missile, replaced the first-generation Tartar, Terrier, and Talos. A supersonic solid-fuel weapon, it is produced in medium-range (MR) and extended-range (ER) versions.

Sea Sparrow is an antiaircraft adaptation of the airborne Sparrow III missile, developed as a relatively uncomplicated basic point-defense missile system (BPDMS) to protect ships without Standard missiles.

Tomahawk, a long-ranged land attack cruise missile, was used in the Gulf War and in Kosovo. Capable of attacking targets at a range up to 1000 mi (1600 km), Tomahawk has greatly increased the striking power of the surface warship, which at one time was thought to have been relegated to a subsidiary role by the aircraft carrier. It is also used by aircraft; submarines can carry them in torpedo tubes, and some submarines have been armed with vertical tube launchers.

Harpoon is a long-range antiship missile, originally designed as an air-to-surface weapon but now used in surface ships and submarines as well.

Antisubmarine weapons. ASROC (antisubmarine rocket), launched by surface warships, was originally designed to carry either a nuclear depth charge or a homing torpedo. All nuclear ASROC warheads were taken out of service by 1989. ASROC is an unguided rocket carrying a Mark 46 homing torpedo. Aimed by shipboard computers using target information obtained by sonar, the rocket is fired from a launcher and follows a ballistic trajectory to the target's predicted position. Torpedo and rocket then separate; the torpedo, slowed by a drag parachute, lands in the water and seeks the target. *See* ANTISUBMARINE WARFARE.

Rockets. Naval rockets, as distinguished from guided missiles, are unguided weapons carrying explosive warheads. Their light weight, in proportion to explosive payload, and lack of recoil allow them be used by attack planes and helicopters. *See* ROCKET PROPULSION.

Torpedoes. Torpedoes travel underwater on their own power to attack the vulnerable hulls of surface ships and submarines. Modern naval torpedoes are fast, far-ranging, and armed with a powerful explosive warhead. Torpedoes may be homing (guiding themselves acoustically to the target); nonhoming (following a preset course); or wire-guided (controlled by signals from the firing ship, transmitted through a trailing wire). They can be launched from surface ships, submarines, or aircraft. Homing torpedoes are used as payload by the ASROC system. Methods for countering the homing torpedo, like the weapons themselves, have been worked on since World War II. It remains a highly effective weapon, and will probably continue in service for a long time. *See* ACOUSTIC TORPEDO.

Guns. Though missiles are widely used by ships and aircraft, guns remain significant naval weapons. Missiles are superior for most long-range attack missions and for defense against supersonic planes and missiles at high altitudes and long ranges; the opposite, however, is often true for such missions as shore bombardment, fire support of land forces, and defense against small attack craft. Renewed attention has been given, both in the United States and in other countries, to lighter guns, with high rates of fire, and to quick-reaction control systems for close-in defense against aircraft and missiles in combination with short-range antiaircraft missiles (Fig. 2).

Bombs. These are free-falling weapons, unlike missiles, which are self-propelled. Bombs take many shapes and sizes, from small antitank and antipersonnel bomblets dispensed from a larger shell or bomb, to heavy weapons designed for blast effect. Most planes and helicopters carry arms externally to accommodate weapon-mix versatility and to keep aircraft size and weight down. High aircraft speeds led to development of

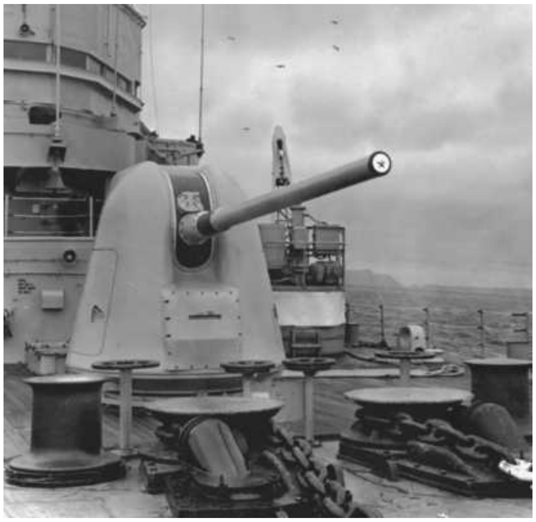


Fig. 2. Mark 45 lightweight 5-in. (127-mm) gun mount. (*U.S. Navy*)

streamlined, low-drag bombs. Bombs can be "dumb," that is, uncontrolled, or "smart." Smart bombs have guidance systems and movable control surfaces, and their trajectory can be adjusted to steer them toward a target.

Mines. A mine is a thin-cased, non-self-propelled weapon filled with high explosive and placed underwater, where it is designed to explode when struck, or closely approached, by a ship. Mines can be contact type (fired by actually striking the hull of a passing ship) or influence type (detonated by the close approach of a ship). An influence mine may be magnetic (actuated by a ship's magnetic field), acoustic (actuated by the underwater sound that a ship generates), or pressure (actuated by the change in water pressure caused by a ship's passage). It may also be fired by a combination of these influences. Influence mines are thus much harder to sweep than contact mines. Mines are planted by submarines or aircraft; some navies also use surface minelayers.

[J.C.R.]

Naval surface ship A surface ship designed primarily for use in warfare, either to operate in direct combat or to provide support to other ships engaged therein. Naval ships can therefore be categorized as either combatants or noncombatants (auxiliaries), both with unique design characteristics.

Combatant ships. This category includes battle ships, cruisers, destroyers, frigates, aircraft carriers, amphibious warfare ships, mine warfare ships, and patrol ships.

After World War II, all the surviving battleships of the U.S. Navy were disposed of except for the four most modern ships, which were retained in a decommissioned (standby or "mothball") status. In 1995 all four battleships were stricken from the naval register, but Congress later directed that two be retained as mobilization assets.

The primary purpose of modern cruisers is to provide antiair and antisubmarine protection to aircraft carriers and other friendly forces. These highly capable multimission ships can also operate independently. Equipped with antiair, antisubmarine, antiship, and land attack missiles, they are self-contained offensive units in their own right. The dominant cruisers in the world are the U.S. CG 47 *Ticonderoga* class of Aegis guided-missile cruisers (Fig. 1) designed in the 1970s.

If battleships and cruisers are the heavyweights and middleweights, then destroyers are the lightweights with a "go-anywhere, do-anything" outlook. They have tremendous firepower for their size and rely on high speed, dash, and maneuverability. Current destroyers tend either to be multipurpose or to emphasize specific warfare areas. An example of a multipurpose destroyer is the U.S. DDG 51 *Arleigh Burke* class of Aegis guided-missile destroyers. An example of a specialized destroyer is the U.S. DD 963 *Spruance* class designed primarily to detect and destroy submarines.

The smallest and most numerous surface combatants in the U.S. Navy are the *Oliver Hazard Perry* (FFG 7) class of multipurpose frigates. Designed in the 1970s, this 50-ship class was expected to protect merchant and military convoys. The speed of FFG-7 is 27–28 knots (13–14 m/s) since carrier operations were not a primary mission. By means of sonars, an embarked ASW helicopter, and shipboard torpedo tubes, it can detect and destroy submarines.

Fig. 1. Aegis guided-missile cruiser, *Ticonderoga* CG 47 class. USS *Cape St. George* is shown. (*U.S. Navy photo*)

Fig. 2. Nuclear-powered aircraft carrier, *Nimitz* CVN 68 class. USS *Theodore Roosevelt* (CVN 71) is shown. (*U.S. Navy photo*)

The largest warships in the world are aircraft carriers (Fig. 2), which through the aircraft they support can project power at great distances. An aircraft carrier is a floating mobile air station. Its flight deck provides the runways, its island is the control tower, the large hangar below the flight deck is the garage that contains maintenance and repair shops, and deep in the hull are storage tanks for aviation fuel and magazines for aviation ordnance. These ships, which can operate and maintain up to 80 aircraft, require a length of almost 1100 ft (335 m), a displacement of nearly 100,000 tons (101,600 metric tons), and a crew of 6000.

The ships used to transport, land, support, and control assault troops collectively constitute the amphibious warfare force. Despite the success of Allied amphibious operations in World War II, the need for improvement was recognized. The first major breakthrough came with the advent of the helicopter and its successful adaptation for landing assault troops (called vertical assault). The second was the development of the high-speed (40 knots; 19 m/s) landing craft, air-cushioned (LCAC). The employment of these two new vehicle types permits landing ships to remain offshore, over the horizon, during amphibious assaults. All current United States amphibious warfare ships have both flight decks for operating helicopters and well-decks for operating LCACs and other craft.

Landing craft are used to ferry tanks, vehicles, equipment, ammunition, general cargo, and personnel directly onto the beach from the landing ships offshore.

Amphibious vehicles are capable of being launched directly into the ocean from landing ships, proceeding to the beach, and then moving inland.

Minelayer ships are built in varying sizes, but can be characterized by a mine stowage system, and rails for moving the mines, and dropping them off the stern or side of the ship. Minesweepers can be broadly categorized as having either a hunter role (locate and mark mines) or a hunter/killer role (locate and destroy). Mines can be located by variable-depth sonar and later destroyed by divers or by means of a mine neutralization vehicle (MNV). The MNV is a crewless minisubmarine that lays an explosive charge near the mine, backing off before detonation. Mines can also be located by the minesweeper towing a mechanical sweep that cuts the cable between the bottom anchor and the mine. After the mine surfaces, it is destroyed by divers or gunfire. Mines can also be detonated by towing magnetic and acoustic cables that trigger them. Minesweepers are often built of wood or composite materials to reduce their magnetic signature.

Patrol ships are small ships that augment conventional surface forces in coastal areas and restricted seas. Their primary mission is coastal patrol and interdiction surveillance—an important aspect of littoral operations. These ships also provide full mission support for Navy SEALs and other special operations forces.

Noncombatant ships. Naval auxiliary ships provide services and support naval operations. Floating configurations that provide services but are not ships are called service craft. Service craft include floating dry-docks, harbor tugs, berthing barges, diving support boats, and fuel barges.

Included in the auxiliary category are the tenders for submarines, and the ships that replenish the fleet with supplies of oil, stores, ammunition, and combat support items. Also included are oceangoing salvage rescue ships, acoustic research ships, oceanographic research ships, surveying ships, hospital ships, ocean surveillance ships, cable repair ships, oceangoing tugs, marine prepositioning ships, and even experimental submarines. [B.T.]

Navier-Stokes equation A partial differential equation which describes the conservation of linear momentum for a linearly viscous (newtonian), incompressible fluid flow. In vector form, this relation is written as Eq. (1), where ρ is fluid density,

$$\rho\left[\frac{\partial \mathbf{V}}{\partial t} + (\mathbf{V}\cdot\nabla)\mathbf{V}\right] = -\nabla p + \rho\mathbf{g} + \mu\nabla^2\mathbf{V} \qquad (1)$$

$\mathbf{V}$ is fluid velocity, p is fluid pressure, $\mathbf{g}$ is the gravitational acceleration, μ is fluid viscosity, ∇ is the del or grad operator, and ∇^2 is the laplacian operator. The equation is named after its two principal developers, French engineer C. L. M. H. Navier (1823) and Irish scientist George G. Stokes (1845). When coupled with the conservation of mass relation, $\nabla \cdot \mathbf{V} = 0$, Eq. (1) can be solved for the space-time distribution of $\mathbf{V}$ and p in a given region of viscous fluid flow. Typical boundary conditions are (1) the knowledge of the velocity and pressure in the far field, and (2) the no-slip condition at solid surfaces (fluid velocity equals solid velocity). *See* CALCULUS OF VECTORS; GRADIENT OF A SCALAR; LAPLACIAN; NEWTONIAN FLUID; VISCOSITY.

Equation (1) correctly models the continuum behavior of all newtonian fluids, including the disorderly fluctuating motion known as turbulence. However, since the left-hand side is highly nonlinear, only a few score of exact solutions are known, mostly for simple geometries. The primary dimensionless parameter which governs Eq. (1) is the Reynolds number, given by Eq. (2), where L is a characteristic body dimension. For small

$$\mathrm{Re} = \frac{\rho V L}{\mu} \qquad (2)$$

$\mathrm{Re} \ll 1$, Eq. (1) can be simplified by neglecting the left-hand side, resulting in a linear approximation called Stokes flow, or creeping flow, for which many solutions are known. *See* CREEPING FLOW; LUBRICATION; REYNOLDS NUMBER.

For large $\mathrm{Re} \gg 1$, viscous effects are often confined to a thin boundary layer near solid surfaces, with the remaining flow being nearly inviscid. *See* BOUNDARY-LAYER FLOW. [F.M.Wh.; A.E.Br.]

Navigation The process of directing the movement of a craft from one place to another. Navigation involves position, direction, distance, time, and speed.

The process of keeping track of a craft's location by measuring and applying progress from a previous position is called dead reckoning. The location of a craft relative to external reference points such as landmarks or aids to navigation is called piloting. Radio navigation involves determining distances or directions to radio transmitters. Celestial navigation involves the use of celestial bodies. *See* CELESTIAL NAVIGATION; DEAD RECKONING; PILOTING.

The craft to be navigated may be a ship, small marine craft, land vehicle, aircraft, missile, spacecraft, or any moving object requiring direction or capable of being directed, even an animal or bird. The characteristics of the craft have a significant influence upon the type of navigation and the equipment used. Size, mission, weight and space limitations, and economic factors are important considerations.

Anything used in navigation, whether aboard the craft or external to it, is properly termed a navigational aid. Thus, in addition to onboard navigational equipment, the term includes such external aids as natural landmarks, prominent buildings, or other structures. Although sometimes used synonymously with "navigational aid," the expression "aid to navigation" is generally restricted to an object or device, external to the craft, established expressly to assist navigation. In this restricted sense, aids to navigation for mariners consist of buoys, beacons, lighthouses, lightships, and navigation sound and electronic transmitters. Aids to navigation for aviators consist primarily of radio ranges and beacons and radio position-fixing transmitters. *See* BUOY; ELECTRONIC NAVIGATION SYSTEMS; HYPERBOLIC NAVIGATION SYSTEM; LIGHTHOUSE; MARINE NAVIGATION. [A.B.M.]

Neanderthals A group of late archaic humans from Europe, the Near East, and central Asia that immediately preceded the first modern humans in those regions. The Neanderthals are included by some within the species *Homo sapiens*, recognizing their close affinities to modern humans; others place them in their own species, *Homo neanderthalensis*, emphasizing the differences between them and modern humans.

The first recognized Neanderthal remains were found in the Neander Valley near Düsseldorf, Germany, in 1856. Since then the remains of several hundred Neanderthals have been discovered. Since the Neanderthals were the first humans to bury their dead, a number of largely complete skeletons are preserved, providing detailed knowledge of their biology. *See* EARLY MODERN HUMANS.

In the early twentieth century, when Neanderthals were the only archaic humans known, they were reconstructed as semihuman, dull-witted, and brutish. Hence their popular image was that of the archtypical cavemen. They are now recognized as relatively recent members of the human lineage; they lived between about 125,000 and 36,000 years ago (and as late as 30,000 years ago in certain isolated regions), as compared with earlier members of the genus *Homo* who extend back more than 2 million years. The Neanderthals share many features with modern humans both anatomically and behaviorally. Yet, a number of important contrasts between them and more recent humans are recognized.

Physically, the Neanderthals were about the same height as most modern humans, on the average 5 ft 5 in. (166 cm), but they were much more heavily built. They had heavy necks, broad and muscular shoulders, and extremely muscular arms, hands, and legs. Estimates of their strength show them to have been about as strong as very athletic modern humans. Their leg bones show a marked thickening of their shafts, which is indicative of both marked strength and endurance—a necessary part of their survival.

The Neanderthals are known for their long, low braincases and their projecting faces with large brows and prominent noses. Their brains were larger than those of modern humans. The large brain size was due in part, as with early modern humans, to their large body masses. The length and lowness of their braincases was due to relatively slow brain growth during infancy. There is no evidence that they were less intelligent than modern humans, only that their behavioral system was less elaborate.

The position of the Neanderthals in modern human ancestry remains controversial. Whatever the extent to which Neanderthals can be claimed to be ancestors of modern humans, they represent the most recent phase of premodern humans, one in which people were less efficient than modern humans at hunting and gathering, and compensated for their cultural limitations with biological attributes such as tremendous strength, large front teeth, and thermal adaptations. Yet they exhibited the beginnings of many of the attributes of modern humans. They were very successful for about 100,000 years, but they were eventually replaced by humans who were better able to exploit their environments. *See* FOSSIL HUMANS. [E.T.; S.Chu.]

Nearshore processes Processes that shape the shore features of coastlines and begin the mixing, sorting, and transportation of sediments and runoff from land. In particular, the processes include those interactions among waves, winds, tides, currents, and land that relate to the waters, sediments, and organisms of the nearshore portions of the continental shelf. The nearshore extends from the landward limit of storm-wave influence, seaward to depths where wave shoaling begins. *See* COASTAL LANDFORMS.

The energy for nearshore processes comes from the sea and is produced by the force of winds blowing over the ocean by the gravitational attraction of Moon and Sun acting on the mass of the ocean, and by various impulsive disturbances at the atmospheric and terrestrial boundaries of the ocean. These forces produce waves and currents that transport energy toward the coast. The configuration of the landmass and adjacent shelves modifies and focuses the flow of energy and determines the intensity of wave and current action in coastal waters. Rivers and winds transport erosion products from the land to the coast, where they are sorted and dispersed by waves and currents.

In temperate latitudes, the dispersive mechanisms operative in the nearshore waters of oceans, bays, and lakes are all quite similar, differing only in intensity and scale, and are determined primarily by the nature of the wave action and the dimensions of the surf zone. The most important mechanisms are the orbital motion of the waves, the basic mechanism by which wave energy is expended on the shallow sea bottom, and the currents of the nearshore circulation system that produce a continuous interchange of water between the surf zone and offshore areas. The dispersion of water and sediments near the coast and the formation and erosion of sandy beaches are some of the common manifestations of nearshore processes.

Erosional and depositional nearshore processes play an important role in determining the configuration of coastlines. Whether deposition or erosion will be predominant in any particular place depends upon a number of interrelated factors: the amount of available beach sand and the location of its source; the configuration of the coastline and of the adjoining ocean floor; and the effects of wave, current, wind, and tidal action. The establishment and persistence of natural sand beaches are often the result of a delicate balance among a number of these factors, and any changes, natural or anthropogenic, tend to upset this equilibrium. *See* DEPOSITIONAL SYSTEMS AND ENVIRONMENTS; EROSION. [D.L.I.]

Nebula Originally, any fixed, extended, and usually fuzzy luminous object seen in a telescope. Nebulae are now distinguished from star clouds that can be resolved into individual stars, but earlier workers were unable to differentiate between white nebulae, which are stellar systems so remote as to show no individual stars, and gaseous or diffuse nebulae in the Milky Way Galaxy. *See* STAR CLOUDS.

Extragalactic nebulae are stellar systems comparable with the Milky Way Galaxy or the Magellanic Clouds in size and number of stars, and are more properly termed external galaxies. *See* GALAXY, EXTERNAL.

This article deals with gaseous nebulae. This class of objects includes diffuse nebulae which contain dust and gas of the interstellar medium, excited and caused to fluoresce by embedded stars. Gaseous nebulae are members of the Milky Way galactic system, and small compared with its overall dimensions. Various types of gaseous nebulae have been identified. *See* INTERSTELLAR MATTER.

Diffuse nebulae range in density from a few atoms per cubic centimeter to 10,000 or more atoms per cubic centimeter (as in the Orion Nebula). Some are compact objects less than a parsec in diameter. Both dust and gas are excited by ultraviolet radiation of stars. Some diffuse nebulae such as Orion occur at the edges of large clouds of cool dust and gas, mostly in molecular form. Those of lower density are found from the faint glow in the red hydrogen line produced as hydrogen ions recapture electrons. For this reason they are also called H II regions, indicating regions of ionized hydrogen. They are also found in external galaxies such as the Magellanic Clouds and M33. *See* MAGELLANIC CLOUDS; ORION NEBULA.

Reflection nebulae show no bright line spectra. Dust grains simply reflect the light of nearby embedded stars. Hydrogen gas is present but mostly neutral. The Pleiades nebulosity is an example of this type. *See* PLEIADES.

Nebulae associated with star formation include the so-called fan-shaped nebulae associated with T Tauri stars, certain bipolar nebulae, and Herbig-Haro Objects. Some, such as Hubble's variable nebula, associated with the variable star R Monocerotis, show brightness fluctuations. In many instances, a newly formed star excites and ionizes the gas in its immediate neighborhood, although the star itself is quite concealed by its dusty surroundings. *See* STELLAR EVOLUTION.

Planetary nebulae are so denoted because they often show small greenish disks in the telescope, not unlike the images of the planets Uranus and Neptune. The energy emitted by planetary nebulae is derived mostly from the ultraviolet emission of the central star, although in some objects an important component may be due to shock waves. *See* PLANETARY NEBULA.

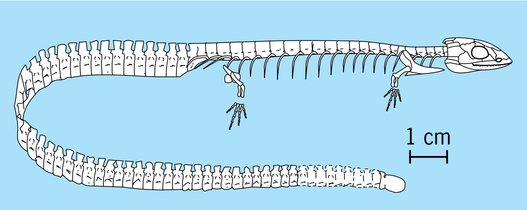
The detonation of a star in a supernova event causes the ejection of the outer layers into the surrounding interstellar medium. In early stages as in the Crab Nebula, the radiating material consists of ejecta from the star. In the later stages this rapidly moving material is slowed down as it mixes with the surrounding dust and gas of the interstellar medium. Heating by shock waves causes the material to radiate optically. Sometimes, the temperature behind the shock front can rise to more than 10^6 K, but the gas is so rarefied that the intensity of the emitted radiation is extremely low. Supernovae remnants characteristically emit nonthermal radio-frequency emission, whereby they are often detected in nearby galaxies as well as in the Milky Way system. *See* CRAB NEBULA; SUPERNOVA.

Cocoon nebulae are associated with very massive stars. At a late stage in its evolution a massive star may eject a dense shell of material that effectively hides it from view temporarily. Although the extended Carina Nebula appears to be a normal H II region, η Carinae itself is a dense, compact object which hides the central star and emits a remarkable spectrum dominated by forbidden lines of ionized iron. [L.H.Al.]

Nectarine A smooth-skinned, fuzzless form of peach, *Prunus persica*. The nectarine's lack of pubescence is a simple recessive genetic characteristic. Classically, the fruits were thought of as being somewhat smaller, softer, and richer in flavor than those of the peach. More recently developed cultivars, however, approximate fresh-market peaches in size and firmness but are not usually superior in flavor.

California is practically the sole commercial producer of nectarines. There is a considerable number of plantings in irrigated areas in south-central Washington. *See* FRUIT; FRUIT, TREE; PEACH; ROSALES. [L.F.H.; C.H.B.]

Nectridea An order of mostly aquatic lepospondyl amphibians known from Carboniferous and Permian rocks of North America, Europe, and North Africa. They were small, usually less than 20 in. (50 cm) in length, and outwardly newtlike with short



Urocordylid nectridean *Ptyonius marshii*. (*After R. L. Carroll, Vertebrate Paleontology and Evolution, W. H. Freeman, 1988*)

trunks and long tails. Limbs were small but well developed. Carpal and tarsal bones were rarely ossified. Their vertebrae exhibit the one-piece centrum characteristic of lepospondyls, but are distinct in bearing spatulate neural spines (see illustration) with crenulated dorsal edges. Three nectridean families are recognized: Urocordylidae, Keraterpetontidae and Scincosauridae. *See* Amphibia; Lepospondyli. [C.F.W.]

Negative ion An atomic or molecular system with an excess of negative charge. Negative ions, also called anions, are formed in attachment processes in which an additional electron is captured by an atom or molecule. Negative ions were first reported in the early days of mass spectrometry. It was soon learned that even a small concentration of such weakly bound, negatively charged systems had an appreciable effect on the electrical conductivity of gaseous discharges. Negative ions now play a major role in a number of areas of physics and chemistry involving weakly ionized gases and plasmas. Applications include accelerator technology, injection heating of thermonuclear plasmas, material processing, and the development of tailor-made gaseous dielectrics. In nature, negative ions are known to be present in tenuous plasmas such as those found in astrophysical and aeronomical environments. The absorption of radiation by negative hydrogen ions in the solar photosphere, for example, determines the Sun's spectral distribution. *See* Ion; Ion sources. [D.J.Pe.]

Negative-resistance circuits Electronic circuits or devices that, over some range of voltage v and current i, satisfy Eq. (1) for equivalent resistance R_{eq} (where the voltage and

$$R_{eq} = \frac{dv}{di} < 0 \qquad (1)$$

current polarities are defined in Fig. 1*a*). They are used as building blocks in designing circuits for a wide range of applications, including amplifiers, oscillators, and memory elements. *See* Amplifier; Electrical resistance; Oscillator.

An ideal negative resistor would have the voltage-current relationship (transfer characteristic) shown in Fig. 1*b*, and thus satisfy Ohm's law with a negative value for the resistance. However, the same effect can generally be obtained with any circuit (or physical device) whose voltage-current curve contains a region of negative slope. Figure 1*c*, for example, shows transfer characteristics typical of a tunnel diode and a neon bulb, which can be operated in the negative-resistance regions indicated. *See* Ohm's law; Resistor.

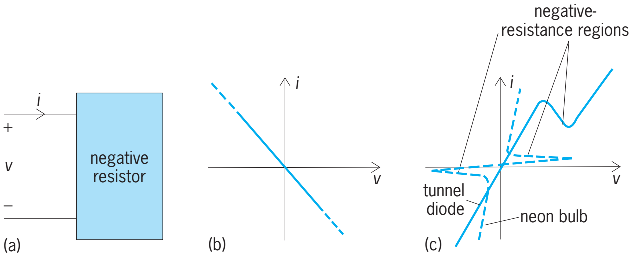


Fig. 1. Characteristics of negative resistors. (*a*) Definition of voltage (*v*) and current (*i*) polarities. (*b*) Voltage-current transfer characteristic of an ideal negative resistor. (*c*) Transfer characteristic of practical physical devices with negative-resistance regions: a tunnel diode and a neon bulb (not to the same scale).

Common generalizations of the negative-resistance idea include negative capacitors, negative inductors, and frequency-dependent negative resistors. Some of the circuits used to implement them are negative impedance converters, negative impedance inverters, and generalized immittance converters. *See* Capacitor; Electrical impedance; Immittance; Inductor.

The power dissipated in a device, given by Eq. (2), is negative

$$P_{DISS} = vi \qquad (2)$$

in the second and fourth quadrants of the v-i plane of Figs. 1*b* and *c*. Thus, the ideal negative resistor whose characteristic is shown in Fig. 1*b* generates power. Two consequences of this are that an active circuit (a circuit containing a power supply) is required to implement the ideal characteristic of Fig. 1*b* but is not necessary for the small-signal negative resistances of Fig. 1*c*; and that for any practical circuit, the characteristic curve must eventually fold over into the power-dissipating quadrants, as shown in Fig. 2*a* or *b*. If the curve did not fold but just continued forever, it would be possible to extract an infinite amount of power from the device.

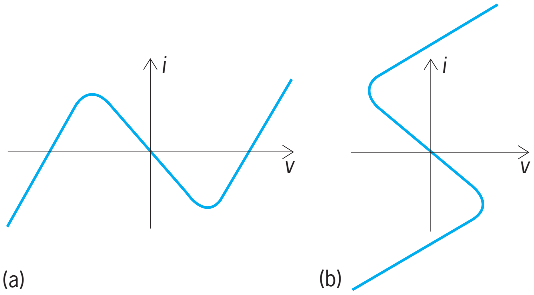

Fig. 2. Large-signal behavior of a negative resistance having a finite internal power supply. (*a*) Voltage-controlled resistance. (*b*) Current-controlled resistance.

The two types of curve of Fig. 2 correspond to an important dichotomy in types of negative resistance. The N-shaped curve of Fig. 2*a* allows current to be a single-valued function of voltage (but not vice versa), and circuits with this behavior are therefore called voltage-controlled negative resistors. Dually, the S-shaped curve of Fig. 2*b*, for which Eq. (3) is appropriate, describes a

$$v = f(i) \qquad (3)$$

current-controlled negative resistor. The tunnel-diode characteristic of Fig. 1*c* can be seen to be voltage-controlled, while the neon tube is current-controlled.

If the terminals of a current-controlled negative resistor are open-circuited, then $i = 0$ and there is a unique solution $v = f(0)$. The voltage-controlled circuit, however, can have any of three voltages in this situation (the three intersections of the N with the horizontal axis). Dually, the S-curve gives a device with multiple equilibrium states when short-circuited. When the dynamic behavior of these circuits is accounted for, it is found that some of these equilibria are stable and some are unstable. These stability considerations are essential to designing a negative-resistance circuit for a particular application.

Negative resistors can be implemented by using amplifiers in positive-feedback configurations. Figure 3*a* shows how a voltage amplifier with a gain of 2 can be used to simulate a grounded negative resistor, and Fig. 3*b* shows an operational-amplifier implementation of the same idea. *See* Operational amplifier.

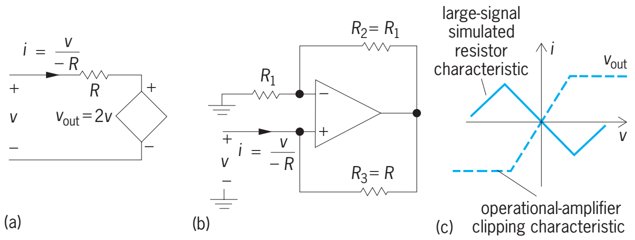

Fig. 3. Active circuits that simulate a negative resistance. (*a*) Circuit that uses an ideal voltage amplifier with a gain of 2. (*b*) Circuit that uses an operational amplifier. (*c*) The operational-amplifier clipping characteristic and resulting large-signal voltage-current characteristic of the simulated negative resistor.

In the practical case of a clipping amplifier, which has the input-output characteristics shown in Fig. 3*c*, the resulting large-signal voltage-current behavior of the simulated resistor is as shown in the figure. This is a voltage-controlled resistor.

The best-known negative-resistance device is the tunnel diode. It is very useful because the phenomenon that it exploits is a quantum-mechanical effect that happens much more rapidly than most others in electronics.

A tunnel diode consists of two very heavily doped regions of a semiconducting material with a very abrupt junction between them. These regions, like any crystalline material, can contain electrons only with energies in certain bands. One side of the junction is doped to have a generous supply of electrons in a certain band of energies, while the other side has a great many vacancies (holes) for electrons in another band. As the applied voltage increases, the bands of electrons and holes on the two sides of the junction start to slide past one another, and eventually their region of overlap starts to decrease. Since quantum tunneling can occur only from an electron in the "supply" to a vacancy at the same energy, this reduction in overlap reduces the amount of charge flowing. Thus, an increasing voltage produces decreasing current, for a negative differential resistance like that shown in Fig. 1*c*. *See* Band theory of solids; Semiconductor rectifier.

A number of other quantum electronic devices have been developed that also have negative-resistance characteristics. In particular, devices have been constructed that have two barriers (instead of the single barrier created by the tunnel-diode junction) and make use of resonant tunneling, where the spacing between the barriers creates a resonance for electrons at certain frequencies. This resonance, in turn, enhances the rate of tunneling. These devices are claimed to be useful at terahertz (10^{12} Hz) frequencies. *See* Semiconductor heterostructures; Tunnel diode; Tunneling in solids. [M.Sn.]

Negative temperature The property of a thermodynamical system which satisfies certain conditions and whose thermodynamically defined absolute temperature is negative. The essential requirements for a thermodynamical system to be capable of negative temperature are: (1) the elements of the thermodynamical system must be in thermodynamical equilibrium among themselves in order for the system to be described by a temperature at all; (2) there must be an upper limit to the possible energy of the allowed states of the system; and (3) the system must be thermally isolated from all systems which do not satisfy both requirements (1) and (2); that is, the internal thermal equilibrium time among the elements of the system must be short compared to the time during which appreciable energy is lost to or gained from other systems.

The second condition must be satisfied if negative temperatures are to be achieved with a finite energy. Most systems do not satisfy this condition; for example, there is no upper limit to the possible kinetic energy of a gas molecule. Systems of interacting nuclear spins, however, have the characteristic that under suitable circumstances they can satisfy all three of the conditions, in which case the nuclear spin system can be at negative absolute temperature. *See* Kinetic theory of matter; Statistical mechanics.

The transition between positive and negative temperatures is through infinite temperature, not absolute zero; negative absolute temperatures should therefore not be thought of as colder than absolute zero, but as hotter than infinite temperature. *See* Absolute zero; Temperature. [N.F.R.]

Nemata A phylum of unsegmented worms. A classification of nematodes follows:

- Phylum Nemata
  - Class: Adenophorea
    - Subclass: Enoplia
      - Order: Enoplida
      - Oncholaimida
      - Tripylida
      - Isolaimida
      - Mononchida
      - Dorylaimida
      - Stichosomida
    - Subclass: Chromadoria
      - Order: Araeolaimida
      - Chromadorida
      - Desmoscolecida
      - Desmodorida
      - Monhysterida
  - Class: Secernentea
    - Subclass: Rhabditia
      - Order: Rhabditida
      - Strongylida
    - Subclass: Spiruria
      - Order: Spirurida
      - Ascaridida
    - Subclass: Diplogasteria
      - Order: Diplogasterida
      - Tylenchida

Diagnosis. The Nemata are unsegmented or pseudosegmented (any superficial annulation limited to the cuticle) bilaterally symmetrical worms with a basically circular cross section. The body is covered by a noncellular cuticle. The cylindrical body is usually bluntly rounded anteriorly and tapering posteriorly. The body cannot be easily divided into head, neck, and trunk or tail, although a region posterior to the anus is generally referred to as the tail. The oral opening is terminal (rarely subterminal) and followed by the stoma, esophagus, intestine, and rectum which opens through a subterminal anus. Females have separate genital and digestive tract openings. In males the tubular reproductive system joins posteriorly with the digestive tract to form a cloaca. The sexes are separate and the gonads may be paired or unpaired. Females may be oviparous or ovoviviporous.

Adult nematodes are extremely variable in size, ranging from less than 0.012 in. (0.3 mm) to over 26 ft (8 m). Nematodes are generally colorless except for food in the intestinal tract or for those few species which have eyespots.

Life cycle. Reproduction among nematodes is either amphimictic or parthenogenetic (rarely hermaphroditic). After the completion of oogenesis the chitinous egg shell is formed and a waxy vitelline membrane forms within the egg shell; in some nematodes the uterine cells deposit an additional outermost albuminoid coating. Upon deposition or within the female body, the egg proceeds through embryonation to the eellike first- or second-stage larva, but following eclosion the larva proceeds through four molts to adulthood. This represents a direct life cycle, but among parasites more diversity occurs.

Distribution. Nemata comprise the third largest phylum of invertebrates, being exceeded only by Mollusca and Arthropoda. In sheer numbers of individuals they exceed all other metazoa. As parasites of animals they exceed all other helminths combined. Nematodes have been recovered from the deepest ocean floors to the highest mountains, from the Arctic to the Antarctic, and in soils as deep as roots can penetrate. [A.R.M.]

Nematicide A type of chemical used to kill plant-parasitic nematodes. Nematicides may be classed as soil fumigants or soil amendments, space fumigants, surface sprays, or dips. Soil treatments are commonly used because most plant-pathogenic species spend part or all of their life cycle in the soil, in or about the roots of plants. Nematicides may be liquids, gases, or solids, but on a field scale, liquids are most practical. *See* NEMATA; PESTICIDE. [D.J.R.]

Nematomorpha A phylum of worms that was formerly considered to be a class of the phylum Aschelminthes; commonly called the hairworms, and closely allied to the nematodes. The adults are free-living in aquatic habitats, while the juveniles are parasitic in arthropods. The nematomorphs are found all over the world. They are divided into two classes, the Nectonematoidea and Gordioidea, with a total of 225 species. *See* NEMATA.

The body is long and slender with a maximum length of 5 ft (1.5 m) and a diameter of 0.02–0.12 in. (0.5–3 mm). The females are longer than the males. The posterior end may be rounded with a terminal cloaca, or it may form two or three lobes in a forklike structure. The body color is yellowish, brown, or almost black. The body wall consists of three layers: an outer, rather thick fibrous cuticle; an epidermis consisting of a single layer of cells; and innermost, a muscle layer with longitudinal fibers only.

The body cavity extends the length of the body. It may be filled with tissue so that only minor spaces are left around the digestive system and the gonads.

The sexes are always separate, and the gonads are paired and stringlike extending the length of the body. During copulation the male coils itself around the female and places a drop of sperm near the cloacal opening of the female. The sperm cells actively enter the seminal receptacle. The eggs are laid in water in strings, and the adults die after egg laying. When hatched, the larvae swim to an aquatic arthropod. They penetrate the body wall of the host by means of their characteristic proboscis, which is armed with hooks and three long stylets. The gradual development in the host lasts some months without any metamorphosis. When they are mature, the worms leave the host. [B.J.Mu.]

Nematophytales An enigmatic group of fossil plants, in mid-Silurian to lower Upper Devonian rocks, composed of intertwined, branching tubes of two sizes: 10–50 micrometers in diameter, and 1–10 micrometers. Although they are referred to the algae by some authors, the occurrence of this group in inland swamps, coastal plain deposits, and marine deposits close to shore indicates that they were terrestrial organisms, unrelated to any known groups, perhaps at an intermediate level between algae and bryophytes. *See* PALEOBOTANY. [H.P.B.]

Neodymium A metallic chemical element, Nd, atomic number 60, atomic weight 144.24. Neodymium belongs to the rare-earth group of elements. The naturally occurring element includes the six isotopes. The oxide, Nd_2O_3, is a light-blue powder. It dissolves in mineral acids to give reddish-violet solutions. *See* PERIODIC TABLE; RARE-EARTH ELEMENTS.

The salts have found application in the ceramic industry for coloring glass and for glazes. The glass is particularly useful in goggles used by glass blowers, since it absorbs the intense yellow D line of sodium present in the flame. The element has found commercial application in the manufacture of lasers. [F.H.Sp.]

Neogastropoda The most highly specialized order in the subclass Prosobranchia (phylum Mollusca, class Gastropoda). Neogastropods have simplified pallial and cardiac structures involving complete separation of genital from renal organs, and a "half-gill" (that is, a one-sided comb-shaped or pectinibranch ctenidium) with its axis and major blood vessels fused to the mantle wall. The order comprises mainly marine carnivores and carrion feeders, all with a long extensible proboscis bearing a flesh-tearing radula. More efficient hydrodynamically with their simplified mantle cavity and fused ctenidial axis, neogastropods are not limited to clean waters over hard substrata (as are the archaeogastropods) but have successfully invaded all areas of the seashore and sea bottom, whether covered with sand, silt, or mud.

Neogastropods occur in all depths of the world's oceans from the tropics to polar waters, and there are at least 6000 species, mostly in four important superfamilies. The larger whelks of the superfamily Buccinacea are found from the shallow sublittoral and continental shelves down to depths of 9800 ft (3000 m). The flesh of many whelk species provides human food, and almost all species have been used in commercial longline fisheries as resilient and attractive bait. The smaller tingles, dog whelks, and oyster drills of the superfamily Muricacea are the abundant neogastropod predators in inshore and intertidal waters. A third important superfamily, Volutacea, encompasses more beautiful, much collected shells. The most specialized neogastropods are the tropical toxoglossans (superfamily Conacea) belonging to the families Conidae, or cone shells, and Terebridae, or auger shells. Both groups have been prized by shell collectors for centuries.

Despite their large number of species and diversity of habitats, the neogastropods show more anatomical uniformity (efficient mantle cavity, inhalant siphon with chemoreceptive osphradium, extensible proboscis, stenoglossan radula, and simple carnivore gut) than is found in any of the other major orders of gastropods. *See* GASTROPODA; MOLLUSCA; PROSOBRANCHIA. [W.D.R.H.]

Neognathae One of the two recognized superorders making up the subclass Neornithes of the class Aves. They are characterized as flying birds with fully developed wings and sternum with a keel, caudal vertebrae fused into a pygostyle, and absence of teeth in both jaws, or modifications of these conditions in secondary flightless birds.

This superorder includes all living birds and all known fossil birds since the Late Cretaceous; only the ancestral Jurassic *Archaeopteryx* and the specialized Cretaceous *Hesperonis* and its allies do not belong to the Neognathae. *See* ARCHAEORNITHES; AVES; ODONTOGNATHAE; RATITES. [W.J.B.]

Neognathostomata A superorder of Echinoidea, subclass Euechinoidea. These invertebrates are characterized by having a rigid, exocyclic test and a lantern or jaw apparatus developed sometime during the life history and usually persisting into the adult stage. The included orders are the Holectypoida, Clypeasteroida, and Cassiduloida. *See* ECHINODERMATA; ECHINOIDEA; EUECHINOIDEA; HOLECTYPOIDA. [H.B.F.]

Neogregarinida An order of the protozoan subclass Gregarinia, class Telosporea, subphylum Sporozoa. All gregarines are parasites of the digestive tract and body cavity of invertebrates or lower chordates; their large, mature trophozoites (vegetative stages) live outside the host's cells. The Neogregarinida are thought to be relatively advanced gregarines which live in insects. There are only about 29 species of about 12 genera, and 4 families. *See* GREGARINIA. [N.D.L.]

Neolampadoida A group of small, deep-water cassiduloid echinoids with neotenous characteristics, treated as an order by some workers; possibly polyphyletic. The presence of bourrelets and phyllodes, the elongate first ambulacral plates, the undifferentiated tuberculation, and undifferentiated posterior interambulacral plating all indicate their relationships lie with cassiduloids. The only character shared by members of this group is the lack of petals (they have simple ambulacral pores only). Other characteristics, such as apical disc plating, are varied, indicating at least two independent origins from shallow-water cassiduloids.

There are seven genera, each monospecific. Five are living today and are usually found at depths of 430–1280 ft (135–400 m). A Miocene species and an Upper Eocene species are also known. *See* ECHINODERMATA. [A.B.S.]

Neolithic The period of prehistoric culture whose basic defining attributes are the emergence of agriculture, animal domestication, and sedentary farmsteads or villages. This definition has evolved over the last century from the original characterization of this period based on the appearance of polished stone axes. By 1865, when John Lubbock published *Prehistoric Times*, two types of Stone Age had been recognized in Europe: *période de la pierre taillée* (period of chipped stone implements) and *période de la pierre polie* (period of polished stone implements). Lubbock termed the former Palaeolithic and the latter Neolithic. Subsequently, it was realized that the definition of this period based on a single artifact type was spurious, since Neolithic peoples also continued to make chipped stone tools. A more comprehensive view developed that saw the Neolithic as characterized by pottery manufacture, agriculture, livestock, and settled villages, but without the use of metals. Thus the Neolithic formed the final Stone Age precursor to the Bronze Age and the Iron Age in the classic northern European prehistoric sequence, which was soon extended throughout most of Eurasia. *See* PALEOLITHIC.

As the term Neolithic is presently used, it refers specifically to prehistoric societies in Europe, Asia, and northern Africa that derived the majority of their diet from agriculture and livestock and that lived in sedentary communities, either dispersed farmsteads or villages, but that did not yet know the use of alloyed metals. Outside of this area, the term Neolithic is rarely used, although clearly in most other parts of the world there was also a transition from hunting and gathering to agriculture at some time in prehistory. For the purposes of this article, “Neolithic” will be expanded to include a global consideration of the origins and dispersal of agriculture and sedentary life, what might be called a neolithic cultural pattern.

With the exception of the dog, which was domesticated by late Pleistocene hunter-gatherers in many parts of the world, the domestication of plants appears to have preceded that of animals. Although many parts of the world can claim to have been the location of the domestication of some food plants, the regions where the crop species which underlie the major agricultural systems of the world were domesticated are fairly well delimited. The three foci of domestication include the “Fertile Crescent” area of the Near East (wheat and barley), the Huanghe and Yangzi valleys of China (millet and rice), and Mesoamerica (maize and beans), while the broader areas of where important domestication also occurred include northern and Andean South America (potatoes and other root crops), northern sub-Saharan Africa (sorghum), and southeast Asia and many Pacific islands (various tree and root crops). Other research has added another area to this list: the indigenous domestication in eastern North America of a complex of weedy plants that include chenopod, sunflower, and marsh elder.

Just as wheat and barley were the founder crops of Near Eastern agriculture, sheep and goat can be considered the founder animals of ungulate domestication around 9000 years ago. Cattle and pigs appear to have been domesticated around 8000 years ago, with evidence pointing toward Anatolia as the likely location. The pig and the chicken were the most important domesticated animals in the Chinese Neolithic, supplemented soon after with the water buffalo.

Not only are the domestication of plants and animals and the establishment of farming settlements the hallmarks of the Neolithic, but also these provided the platform for subsequent cultural developments. The Neolithic in the Old World and its New World parallels were periods of dramatic change in human society, laying the foundation for the socially stratified societies that followed. [P.Bo.]

Neomeniomorpha A subclass of creeping, vermiform mollusks in the class Aplacophora. They are covered by a spicular integument and recognized by the presence of a ventral groove within which lies a narrow foot and by the absence of on oral shield. Neomenioids range in size from less than 0.08 to 12 in. (2 mm to 300 mm) and are found from subtidal areas to the abyss, at depths over 16,000 ft (5000 m). There are 23 families with 70 genera and 193 species worldwide.

Neomenioids creep by means of their ciliated foot along a track of sticky mucus produced from a ciliated, reversible pedal pit at the anterior end of the pedal groove. Anterior to the pedal pit, the head end is held above the substratum and freely moved.

All neomenioids are hermaphroditic. A barrel-shaped, nonfeeding larva called a pericalymma either is brooded or swims by means of a ciliated cellular test within which the animal develops; metamorphosis through loss or resorption of the test occurs within 10 days. *See* APLACOPHORA; MOLLUSCA. [A.H.S.]

Neon A gaseous chemical element, Ne, with atomic number 10 and atomic weight 20.183. Neon is a member of the family of noble gases. The only commercial source of neon is the Earth’s atmosphere, although traces of neon are found in natural gas, minerals, and meteorites. *See* INERT GASES; PERIODIC TABLE.

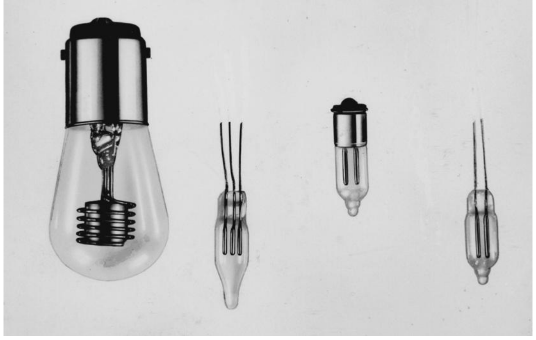
Considerable quantities of neon are used in high-energy physics research. Neon fills spark chambers used to detect the passage of nuclear particles. Liquid neon can be utilized as a refrigerant in the temperature range about 25 to 40 K (−416 to −387°F). Neon is also used in some kinds of electron tubes, in Geiger-Müller counters, in spark-plug test lamps, and in warning indicators on high-voltage electric lines. A very small wattage produces visible light in neon-filled glow lamps; such lamps are used as economical night and safety lights. *See* NEON GLOW LAMP.

Physical properties of neon

Property	Value
Atomic number	10
Atomic weight (atmospheric neon only)	20.183
Melting point, °C	−248.6
Boiling point at 1 atm pressure, °C	−246.1
Gas density at 0°C and 1 atm pressure, g/liter	0.8999
Liquid density at its boiling point, g/ml	1.207
Solubility in water at 20°C, ml neon (STP)/1000 g water at 1 atm partial pressure neon	10.5

Neon is colorless, odorless, and tasteless; it is a gas under ordinary conditions. Some of the other properties of neon are given in the table. Neon does not form any chemical compounds in the ordinary sense of the word; there is only one atom in each molecule of gaseous neon. [A.W.F.]

Neon glow lamp A low-wattage lamp often used as an indicator light or as an electronic circuit component. The neon lamp usually consists of a pair of electrodes sealed within a bulb containing neon gas at a low pressure. Some of the smaller bulbs are equipped with wire leads that are connected directly into the electrical supply circuit; others are equipped with conventional bases that vary with the size of the lamps (see illustration).



Some examples of glow lamps.

Electrodes sealed in a neon atmosphere will emit electrons if a sufficient voltage difference is impressed across them. In glow lamps the electrodes are usually treated to emit electrons freely. With a sufficiently high voltage between electrodes, the velocity of electron flow is high enough to ionize the neon nearest the negative electrode (cathode). The neon then emits a reddish-orange glow similar to the color of neon sign tubing. With direct current the glow is restricted to the immediate vicinity of the negative electrode. With alternating current, both electrodes act alternately as cathodes, and the glow appears alternately at both surfaces. At usual frequencies, the alternations occur so rapidly that both electrodes appear to glow constantly. In dc circuits, the voltage across the electrodes may be reduced significantly, once the lamp has started, without causing the lamp to go out. [A.M.]

Neornithes The subclass of Aves that contains all of the known birds other than those placed in the Archaeornithes. Comprising more than 30 orders, both fossil and living, its members are characterized by a bony, keeled sternum with fully developed powers of flapping flight (secondarily lost in a number of groups); a short tail with the caudal vertebrae fused into a single platelike pygostyle to which all tail feathers attach; a large fused pelvic girdle with a reversed pubis which is fused to a large synsacrum; and a large brain and eyes contained within a fused braincase. The jaws are specialized into a beak covered with a horny rhamphotheca; the upper jaw is kinetic, being either prokinetic or rhynchokinetic. Prokinesis refers to a bending zone at the base of the upper jaw, and rhynchokinesis to one within the upper jaw. A few fossil groups still possess teeth, but most fossil and all Recent birds have lost teeth. *See* ARCHAEORNITHES.

The Neornithes contains two superorders, the Odontognathae and the Neognathae. The Odontognathae, alternately known as the Odontornithes, may be an artificial group. Its members, which include the Cretaceous fossil orders Hesperornithiformes and Ichthyornithiformes, are united only by the presence of teeth in all species. The Neognathae contains the remaining modern birds, which have lost the teeth, and includes 26 orders. *See* AVES; NEOGNATHAE; ODONTOGNATHAE. [W.J.B.]

Neoteny A phenomenon among some salamanders, in which larvae of large size, while still retaining the gills and other larval features, become sexually mature, mate, and produce fertile eggs. In certain lakes of Mexico, only the neotenous larvae are present and are called axolotls. Neoteny occurs in certain species of the family Ambystomidae. [T.I.S.]

Nepenthales An order of flowering plants, division Magnoliophyta (Angiospermae), in the subclass Dilleniidae of the class Magnoliopsida (dicotyledons). The order (also known as Sarraceniales) consists of 3 well-marked small families: the Droseraceae, with about 90 species; the Nepenthaceae, with about 80 species; and the Sarraceniaceae, with only about 16. The plants characteristically grow in waterlogged soils which are deficient in available nitrogen. They are herbs or shrubs with alternate, simple leaves that are modified for catching insects, from which they absorb nitrogenous nutrients. The pitcher plants (*Sarracenia*), sundew (*Drosera*), and Venus' flytrap (*Dionaea muscipula*) are well-known members of the order. *See* MAGNOLIOPSIDA. [A.Cr.]

Neper A unit of attenuation used in transmission-line theory. On a uniform transmission line having waves traveling in only one direction, the magnitudes of voltage E and of current I decrease with distance x traveled, as given by Eq. (1), where

$$\frac{E}{E_0} = \frac{I}{I_0} = \epsilon^{-\alpha x} \tag{1}$$

E_0, I_0, and α are constants. The attenuation in nepers between the points where E_0, and I_0 are measured and where E and I are measured is given by Eq. (2), in which ln denotes the natural (or napierian) logarithm. One neper equals 8.686 dB, the decibel being the practical unit of attenuation. *See* DECIBEL; TRANSMISSION LINES. [E.W.K.]

$$\alpha x = \ln \frac{E_0}{E} = \ln \frac{I_0}{I} \tag{2}$$

Nepheline A mineral of variable composition: in its purest state, $NaAlSiO_4$; often nearly $Na_3K(AlSiO_4)_4$; but generally $(Na, K,\square, Ca, Mg, Fe^{2+}, Mn,Ti)_8(Al, Si, Fe^{3+})_{16}O_{32}$, where $\square$ represents vacant crystallographic sites, and Ca, Mg, Fe^{2+}, Mn, Ti, and Fe^{3+} are usually present in only minor or trace amounts. The most important variations in nepheline composition are due to crystalline solution of $KAlSiO_4$ (the mineral kalsilite), and substitution of $\square$ for K. *See* SILICATE MINERALS.

The salient physical properties of nepheline are: a Mohs scale hardness of 5.5–6.0; a specific gravity between 2.56 and 2.67; a typically dark gray, light gray, or white color, but it can also be colorless (nepheline is colorless in petrographic thin section); and a vitreous or greasy luster. Nepheline occurs as simple hexagonal prisms or, more commonly, as isolated shapeless grains or irregular polycrystalline masses.

Nepheline is the most abundant feldspathoid mineral; it occurs in a wide variety of SiO_2-deficient (quartz-free) and alkali-rich volcanic, plutonic, and metamorphic rocks. In volcanic rocks, nepheline occurs chiefly as a primary mineral in phonolites, kenytes, and melilite basalts, and it is the characteristic mineral of nephelinites.

Both "pure" (processed) nepheline and nepheline syenite are used as raw materials for the manufacture of glass, various ceramic materials, alumina, pottery, and tile. *See* FELDSPATHOID; IGNEOUS ROCKS; NEPHELINITE. [J.G.B.]

Nephelinite A dark-colored, aphanitic (very finely crystalline) rock of volcanic origin, composed essentially of nepheline (a feldspathoid) and pyroxene. *See* KALSILITE.

The texture is usually porphyritic with large crystals (phenocrysts) of augite and nepheline in a very fine-grained matrix. Augite phenocrysts may be diopsidic or titanium-rich and may be rimmed with soda-rich pyroxene (aegirine-augite). Microscopically the matrix is seen to be composed of tiny crystals or grains of nepheline, augite, aegirite, and sodalite with occasional soda-rich amphibole, biotite, and brown glass.

Nephelinite and related rocks are very rare. They occur as lava flows and small, shallow intrusives. A great variety of these feldspathoidal rocks is displayed in Kenya. *See* FELDSPATHOID; IGNEOUS ROCKS; LEUCITE. [C.A.C.]

Neptune The outermost of the four giant planets. Neptune is a near twin of Uranus in size, mass, and composition. Its discovery in 1846 within a degree from the theoretically predicted position was one of the great achievements of celestial mechanics. *See* CELESTIAL MECHANICS.

Through a small telescope, Neptune appears as a tiny greenish disk. Its linear equatorial diameter of 30,775 mi (49,528 km) is very similar to that of Uranus. The mass of Neptune is 17.20 times the mass of Earth, corresponding to a mean density of 1.62, somewhat above that of its sister planet. This suggests that the enrichment of heavy elements is somewhat greater in Neptune than in Uranus. *See* URANUS.

Most of what is known about Neptune is the result of the flyby of the planet by the *Voyager 2* spacecraft in August 1989. The cloud features included a large dark oval (about the size of Earth), reminiscent of Jupiter's Great Red Spot, as well as the white clouds of condensed methane whose brilliant contrast with the blue-green atmosphere made them visible from Earth. Unlike the Great Red Spot, Neptune's dark oval proved to have a short lifetime. By following the clouds over several weeks, scientists were able to deduce the presence of currents at different latitudes, with a tendency for the high-latitude winds to be faster than those near the equator. This circulation pattern resembles that of Uranus, despite the fact that the inclinations of the rotational axes of the two planets are very different (that of Neptune is 29.6°, while that of Uranus is 97.9°, and that of Earth is 23.5°). This active meteorology on Neptune may well be driven by the escaping internal heat, some 2.7 times the magnitude of the heat absorbed from the Sun.

The atmosphere of Neptune, like those of the other giant planets, is composed predominantly of hydrogen and helium. The relative abundance of methane is enhanced by about the same amount as on Uranus, between 20 and 30 times the value corresponding to solar abundances of the elements.

The orientation of Neptune's magnetic field is surprisingly similar to that of Uranus. It can be represented by a bar magnet inclined at an angle of 46.8° with respect to the axis of rotation and offset by 0.55 planetary radius. This field has trapped a plasma of ionized and neutral gases in the planet's magnetosphere.

Before the *Voyager* encounter, only two satellites of Neptune were known, both of them in highly irregular orbits. Triton was discovered visually by W. Lassell in 1846. It is moving in a retrograde direction around Neptune with a period of 5.9 days in a nearly circular orbit. Nereid was found almost 100 years later as a result of a photographic search by G. P. Kuiper. It has the most eccentric orbit of any known satellite. In sharp contrast to these two bodies, the six satellites discovered by the *Voyager* cameras all have very regular orbits: in the plane of the planet's equator and nearly circular. They are all close to the planet.

Triton has a tenuous atmosphere containing nitrogen, methane, and carbon monoxide. These three gases plus carbon dioxide and water are also present as frozen ices on the satellite's surface. *Voyager* revealed that this remarkable object has a diameter of only 1681 ± 4 mi (2705 ± 6 km), making it considerably smaller than the Earth's Moon (2086 mi or 3476 km). The surface temperature of Triton is -391 ± 7°F (38 ± 4 K). The size of this satellite, as well as the temperature and composition of its surface, make Triton very similar to Pluto. *See* PLUTO.

The *Voyager* cameras showed that there are three well-defined, complete rings around Neptune, accompanied by a sheet of material that itself constitutes a broad ring. The outermost discrete ring, the Adams ring, contains three concentrated clumps of material.

The confinement of these narrow rings is commonly assumed to require the presence of small shepherding satellites. Galatea and Despina orbit, respectively, just inside the outer two narrow rings, but the corresponding outer shepherds have not been found. Similarly, the persistence of the three arcs within the outer ring remains an enigma. [T.C.O.]

Neptunium A chemical element, symbol Np, atomic number 93. Neptunium is a member of the actinide or 5*f* series of elements. It was synthesized as the first transuranium element in 1940 by bombardment of uranium with neutrons to produce neptunium-239. The lighter isotope ^{237}Np, a long-lived alpha emitter with half-life 2.14×10^6 years, is particularly important chemically. *See* PERIODIC TABLE.

Neptunium metal is ductile, low-melting (637°C or 1179°F), and in its alpha form is of high density, 20.45 g/cm^3 (11.82 oz/in.^{3}). The chemistry of neptunium may be said to be intermediate between that of uranium and plutonium. Neptunium metal is reactive and forms many binary compounds, for example, with hydrogen, carbon, nitrogen, phosphorus, oxygen, sulfur, and the halogens. *See* ACTINIDE ELEMENTS; NUCLEAR CHEMISTRY; TRANSURANIUM ELEMENTS. [R.A.Pe.]

Nerve A group of nerve fibers coursing together as a bundle in the peripheral nervous system. The individual fibers are covered by Schwann cells, many of which contain large amounts of myelin, which makes the nerve appear shiny white. The nerve fibers with their Schwann cell sheaths are held together by connective tissue. In most nerves, some of the fibers are sensory (carrying information to the central nervous system) and some are motor (carrying information from the central nervous system to peripheral glands and muscles). When both sensory and motor fibers are in a nerve, it is called a mixed nerve.

In the central nervous system (brain and spinal cord) a group of nerve fibers running together is called a tract. Glial cells, not Schwann cells, form the sheaths of tract fibers, and there is no connective tissue holding the bundle together. Whereas most nerves are mixed, there is functional segregation in the central nervous system so that most tracts have only one functional type of fiber. *See* MOTOR SYSTEMS; NERVOUS SYSTEM (VERTEBRATE). [D.B.W.]

Nervous system (invertebrate) All multicellular organisms have a nervous system, which may be defined as assemblages of cells specialized by their shape and function to act as the major coordinating organ of the body. Nervous tissue underlies the ability to sense the environment, to move and react to stimuli, and to generate and control all behavior of the organism. Compared to vertebrate nervous systems, invertebrate systems are somewhat simpler and can be more easily analyzed. Invertebrate nerve cells tend to be much larger and fewer in number than those of vertebrates. They are also easily accessible and less complexly organized; and they are hardy and amenable to revealing experimental manipulations. However, the rules governing the structure, chemistry, organization, and function of nervous tissue have been strongly conserved phylogenetically. Therefore, although humans and the higher vertebrates have unique behavioral and intellectual capabilities, the underlying physical-chemical principles of nerve cell activity and the strategies for organizing higher nervous systems are already present in the lower forms. Thus neuroscientists have taken advantage of the simpler nervous systems of invertebrates to acquire further understanding of those processes by which all brains function. *See* NERVOUS SYSTEM (VERTEBRATE).

Invertebrate and vertebrate nerve cells differ more in quantity, or degree, than in qualitative features. Aside from differences in size and numbers, the most striking difference is that invertebrate neurons have a unipolar shape, whereas most vertebrate neurons are multipolar. An additional general contrast between invertebrate and vertebrate nervous systems is that invertebrates tend to have more neurons displaced to the periphery (outside the central nervous system) and to perform more integrative and processing functions in the periphery. Vertebrates perform almost all their integration within the central nervous system, using interneurons. Invertebrate nervous systems also seem to have a greater potential for regrowth, regeneration, or repair after damage than do vertebrate nerve cells. Many invertebrates continue to add new nerve cells to their ganglia with age; vertebrates, in general, do not. Only vertebrate neurons have myelin sheaths, a specialized wrapping of glial membrane around axons, increasing their conduction speed. Invertebrates tend to enhance conduction velocity by using giant axons, particularly for certain escape responses. [J.E.Bla.]

Nervous system (vertebrate) A coordinating and integrating system which functions in the adaptation of an organism to its environment. An environmental stimulus causes a response in an organism when specialized structures, receptors, are excited. Excitations are conducted by nerves to effectors which act to adapt the organism to the changed conditions of the environment.

Comparative morphology. The brain of all vertebrates, including humans, consists of three basic divisions: prosencephalon, mesencephalon, and rhombencephalon (Fig. 1). The individual divisions or patterns of the brain do not function separately to bring about a final response; rather, each pattern acts on a common set of connections in the spinal cord.

Spinal patterns are the final common patterns used by all higher brain pathways to influence all organs of the body. These reflexes are divided into two basic patterns: the monosynaptic arc and the multisynaptic arc. The monosynaptic arc, or myotatic reflex, maintains tonus and posture in vertebrates and consists of two neurons, a sensory and a motor neuron.

The multisynaptic arc, or flexor reflex, is the pattern by which an animal withdraws a part of its body from a noxious stimulus. Both sensory neurons and internuncial neurons send information to brain centers. Coordinated limb movement is based on a connective pattern of neurons at the spinal level.

The structure of the spinal cord and its connections are basically similar among all vertebrates. The major evolutionary changes in the spinal cord have been the increased segregation of cells and fibers of a common function from cells and fibers of other functions and the increase in the length of fibers which connect brain centers with spinal centers. *See* Postural equilibrium.

The rhombencephalon of the brain is subdivided into a roof, or cerebellum, and a floor, or medulla oblongata. The medulla is similar to the spinal cord and is divided into a dorsal sensory region and a ventral motor region. It is an integrating and relay area between higher brain centers and the spinal cord. In addition to these nuclei and their connections, the medulla consists of both ascending and descending pathways to and from higher brain centers. The same basic connections occur throughout vertebrates.

In mammals, the cerebellum does not initiate movement; it only times the length of muscle contractions and orders the sequence in which muscles should contract to bring about a movement. The command to initiate a movement is received from the cerebral cortex (Fig. 2). Similarly, the cerebral cortex receives information regarding limb position and state of muscular contraction to ensure that its commands can be carried out by the cerebellum.

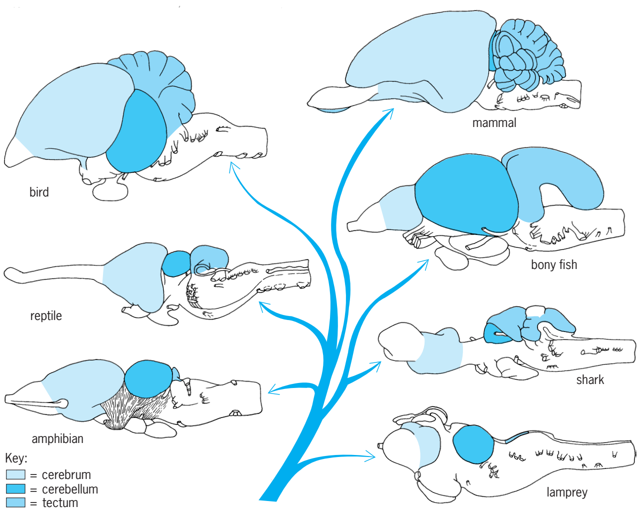


Fig. 1. Lateral views of several vertebrate brains showing evolutionary relationships.

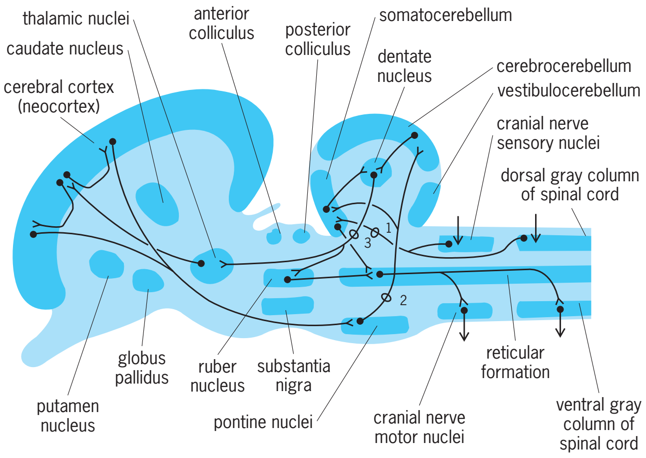

Fig. 2. Mammalian brain in sagittal section. Cerebellar patterns: tract 1, posterior cerebellar peduncle; 2, middle cerebellar peduncle; 3, anterior cerebellar peduncle.

The mesencephalon is divided into a roof or optic tectum and a floor or tegmentum. The tegmentum contains the nuclei of the oculomotor and trochlear cranial nerves and a rostral continuation of the sensory nucleus of the trigeminal cranial nerve.

In the evolution of vertebrates, the prosencephalon develops as two major divisions, the diencephalon and the telencephalon. The diencephalon retains the tubular form and serves as a relay and integrating center for information passing to and from the telencephalon and lower centers. The telencephalon is divided into a pair of cerebral hemispheres and an unpaired telencephalon medium.

There are three divisions of the diencephalon in all vertebrates: an epithalamus which forms the roof of the neural tube, a thalamus which forms the walls of the neural tube, and a hypothalamus which forms the floor of the neural tube. The epithalamus and hypothalamus are primarily concerned with autonomic functions such as homeostasis. The thalamus is subdivided into dorsal and ventral regions. The dorsal region relays and integrates sensory information, and the ventral thalamus relays and integrates motor information. *See* Homeostasis; Instinctive behavior.

The telencephalon is the most complex brain division in vertebrates. It is divided into a roof, or pallium, and a floor, or basal region. The pallium is divided into three primary divisions: a medial PI or hippocampal division, a dorsal PII or general pallial division, and a lateral PII division, often called the pyriform pallium.

The most striking change in the telencephalon of land vertebrates involves the PIIIa component. In mammals, it has proliferated with the PIIb component of the dorsal pallium to produce the mammalian neocortex. In all land vertebrates except amphibians, the PIIb and the PIIIa components, along with the corpus striatum (BI and BII), are the highest centers for the analysis of sensory information and motor coordination. The PI, PIIa, PIIb, BIII, and posterior parts of BI and BII form part of the limbic system which is concerned with behavioral regulation. [R.G.No.]

Comparative histology. The nervous system is composed of several basic cell types, including nerve cells called neurons, interstitial cells called neurolemma (cells of Schwann), satellite cells, oligodendroglia, and astroglia; and several connective-tissue cell types, including fibroblasts and microglia, blood vessels, and extracellular fluids.

Each neuron possesses three fundamental properties, involving specialized capacity to react to stimuli, to transmit the resulting excitation rapidly to other portions of the cell, and to influence other neurons, muscle, or glandular cells. Each neuron consists of a cell body (soma), one to several cytoplasmic processes called dendrites, and one process called an axon. Cell bodies vary from about 7 to more than 70 micrometers in diameter; each contains a nucleus and several cytoplasmic structures, including Nissl (chromophil) granules, mitochondria, and neurofibrils. The cell body is continuously synthesizing new cytoplasm, especially protein, which flows down the cell processes. The dendrites range from a fraction of a millimeter to a few millimeters in length. An axon may range from about a millimeter up to many feet in length. The site where two neurons come into contact with each other and where influences of one neuron are transmitted to the other neuron is called a synapse. Neurotransmitters are secreted across the presynaptic membrane into the synaptic cleft where they may excite (excitatory synapse) or inhibit (inhibitory synapse) the postsynaptic membrane. *See* Biopotentials and ionic currents; Sensation; Synaptic transmission.

There are three layers of connective tissue membranes, the meninges, covering the brain and spinal cord: the inner, pia mater; the middle layer, the arachnoid; and the outermost, the dura mater. Between the pia mater and the arachnoid is the subarachnoid space; this space and the ventricular cavities within the brain are filled with an extracellular fluid, the cerebrospinal fluid. *See* Meninges. [C.No.]

Comparative embryology. The anlage of the nervous system is formed in the outer germ layer, the ectoderm, although some later contributions are also obtained from the middle germ layer, the mesoderm. In most vertebrates a neural plate is formed, which later folds into a neural groove, then closes to form a neural tube. The formation of neural tissue within the ectoderm is due to inductive influences from underlying chordomesodermal structures. *See* Developmental biology; Embryonic induction; Neural crest.

When the neural tube is developing, a segmentation of the central nervous system occurs by the formation of transverse bulges, neuromeres. At the time of neuromeric segmentation, the brain is subdivided into the so-called brain vesicles by local widenings of its lumen. In the rostral end more or less well-developed hemispheres are formed; in the middle of the brain anlage the mesencephalic bulge develops; and behind the latter the walls of the tube thicken into cerebellar folds. In this way the brain anlage is divided into five sections: the telencephalon, diencephalon, mesencephalon, metencephalon, and myelencephalon, and its cavity is divided into the rudiments of the adult ventricles.

In spite of the extraordinary variation in adult morphology of the vertebrate brain in different species, the early phases of development are essentially similar. The spinal cord remains as a comparatively slightly differentiated tube.

The cranial or cerebral nerves are the peripheral nerves of the head that are related to the brain. Twelve pairs of cranial nerves have been distinguished in human anatomy and these nerves have been numbered rostrally to caudally as follows:

I. Olfactory nerve, fila olfactoria
II. Optic nerve, fasciculus opticus
III. Oculomotor nerve
IV. Trochlear nerve
V. Trigeminal nerve, in most vertebrates divided into three branches: ophthalmic, maxillary, and mandibular
VI. Abducens nerve
VII. Facial nerve
VIII. Statoacoustic nerve
IX. Glossopharyngeal nerve
X. Vagus nerve
XI. Accessory nerve
XII. Hypoglossal nerve

The spinal ganglia are formed from the neural crest which grows out like a continuous sheet from the dorsal margin of the neural tube and is secondarily split up into cell groups, the ganglia, by a segmentating influence from the somites. Fibers grow out from the ganglionic cells and form the sensory fibers of the spinal nerves. Motor nerve fibers emerge from cells situated in the ventral horns of the spinal cord. The ventral motor fibers and the dorsal sensory fibers fuse to form a common stem, which is again laterally divided into branches, innervating the corresponding segment of the body.

The ganglia of the sympathetic nervous system develop ventrolateral to the spinal cord as neural crest derivatives. At first a continual column of sympathetic nerve cells is formed; it later subdivides into segmental ganglia.

The parasympathetic system is made up of preganglionic fibers emanating as general visceromotor fibers from the brain and from the sacral cord segments. Cells migrate to form the peripheral ganglia along them. *See* Autonomic nervous system. [B.Kal.]

Nervous system disorders A satisfactory classification of diseases of the nervous system should include not only the type of reaction (congenital malformation, infection, trauma, neoplasm, vascular diseases, and degenerative, metabolic, toxic, or deficiency states) but also the site of involvement (meninges, peripheral nerves or gray or white matter of the spinal cord, brainstem, cerebellum, and cerebrum). To these may be added various other correlates, such as age and sex. The nerve cell may be damaged primarily, as in certain infections, but much more commonly the nerve cell is damaged secondarily as the result of metabolic or vascular diseases affecting other important organs, such as the heart, lungs, liver, and kidneys.

Malformation. The central nervous system develops as a hollow neural tube by the fusion of the crests of the neural groove, beginning in the cervical area and progressing rostrally and caudally, the last points to close being termed the anterior and posterior neuropores. If the anterior neuropore fails to close (about 24 days of fetal age), anencephaly develops. The poorly organized brain is exposed to amniotic fluid and becomes necrotic and hemorrhagic, with death usually within hours after birth. *See* Congenital anomalies.

If the posterior neuropore fails to close (about 26 days of fetal age), the lumbosacral neural groove is exposed to amniotic fluid. The nervous tissue becomes partially necrotic and incorporated in a scar. Such a meningomyelocele is readily infected unless buried surgically within a few hours after birth. In addition, in about 95% of such infants hydrocephalus occurs, which usually can be adequately treated by shunting the ventricular fluid into the venous system or peritoneal cavity.

Other developmental disorders of the nervous system may appear as hypoplasia or hyperplasia (decrease or increase in growth of cells, respectively) or as a destruction of otherwise normally developing tissues. Rapidly growing tissues such as the embryonic nervous system are generally rather easily damaged by many toxic agents. The time of onset and the extent of repair rather than the nature of the agent determine the resulting pattern of abnormal development. *See* Behavioral toxicology.

Infection. Infections of the nervous system may occur through a defect in the normal protective coverings caused by certain congenital malformations, as mentioned above, but also through other defects as the result of trauma, especially penetrating wounds or fractures opening into the paranasal sinuses or mastoid air cells. Subsequent infection of the nervous system may be the major complication of such “open head” injuries.

Infections may also spread directly from adjacent structures, as from mastoiditis, sinusitis, osteomyelitis, or subcutaneous abscesses. Such infections usually spread along venous channels producing epidural abscess, subdural empyema, leptomeningitis, and brain abscess. All of these infections are characteristically caused by pyogenic (pus-forming) bacteria. Other pyogenic bacteria may metastasize by way of the bloodstream from more distant infections, such as bacterial endocarditis, pneumonia, and enteritis.

Infections of the nervous system must be treated promptly as medical emergencies. The diagnosis is easily established by spinal puncture; the microorganisms can be visualized with special stains.

Many other microorganisms can infect the nervous system: *Mycobacterium tuberculosis* (the organism causing tuberculosis), *Treponema pallidum* (the organism causing syphilis), several fungi and rickettsiae, and many viruses.

Viral infections vary widely geographically, generally related to the necessity for intermediate hosts and vectors (animal reservoirs) by which the virus is spread. Poliomyelitis, now largely prevented by effective vaccination of most children, is primarily an intestinal infection which occasionally spreads to the nervous system, infecting and destroying motor nerve cells, thereby producing weakness of certain muscles. Herpes zoster has a similar preference for infecting sensory nerve cells and producing an acute skin eruption in the distribution of the affected sensory cells. Herpes simplex is closely related to herpes zoster, resides in the trigeminal or sacral sensory nerve cells, and intermittently produces eruptions in the distribution of these cells: "fever blisters" in and around the mouth in type I herpes, or similar blisters in the genital area in type II herpes. The latter is increasingly being recognized as a venereal disease. Rabies virus also affects certain nerve cells in the temporal lobe of the brain, as well as in the cerebellum, and is transmitted through the saliva of animals that bite other animals or humans; rabies is the single exception to the rule that immunization must precede infection to be effective, and the immunization must begin promptly after the bite. *See* ANIMAL VIRUS; HERPES; POLIOMYELITIS.

Inflammation. Certain viruses frequently produce a meningitis in humans from whose cerebrospinal fluid the virus is relatively easily grown. Other viruses, such as measles and varicella, occasionally produce meningitis or encephalomyelitis, but the cerebrospinal fluid does not contain the virus. *See* MENINGITIS.

Allergy to one's own tissue elements is an interesting possibility that has evoked many experimental approaches. Two human diseases, multiple sclerosis, a demyelinating disease affecting the central nervous system, and the Landry-Guillain-Barré syndrome, a demyelinating disease affecting the peripheral nervous system, are considered likely candidates to be related to experimental allergic encephalomyelitis and experimental allergic neuritis, respectively. *See* AUTOIMMUNITY; MULTIPLE SCLEROSIS.

Vascular disease. Vascular diseases of the nervous system are commonly called strokes, a term which emphasizes the suddenness of onset of neurological disability. Such a cataclysmic onset is characteristic of vascular diseases, since the nerve cell can function without nutrients for only a matter of seconds and will die if not renourished within several minutes. *See* VASCULAR DISORDERS.

Two main types of hemorrhage occur: hemorrhage into the subarachnoid space from rupture of an aneurysm (a focal weakening and dilatation) of a large artery; and hemorrhage into the brain from rupture of an aneurysm of a small artery or arteriole. Both types of hemorrhage occur more commonly in hypertensive adults. *See* ARTERIOSCLEROSIS; HEMORRHAGE; HYPERTENSION.

Nerve cells require oxygen and glucose for functional activity, and can withstand only brief periods of hypoxia or hypoglycemia. Even a few seconds of hypoxia can block the nerve cell's function, and more than 10 min is almost certainly fatal to most nerve cells. Transient ischemic attacks may result, with temporary impairment of blood flow to a part of the brain and consequent focal neurological dysfunction. These attacks may also be successfully treated with drugs or surgery and the disastrous major stroke prevented. Myocardial infarction, postural hypotension, and stenosis or narrowing of the carotid or vertebral arteries greater than 60% are common causes of cerebral ischemia. If the ischemia is not rapidly reversed, the neurons undergo selective necrosis; if the ischemia is more severe or prolonged, the glia and blood vessels in the gray matter also undergo necrosis; and if the ischemia is still more severe or prolonged, all the gray and white matter in the ischemic zone becomes necrotic, a condition known as cerebral infarction or encephalomalacia. One of the common ways the brain reacts to small or large hemorrhages or ischemic episodes is by swelling. Such swelling itself may be fatal within a few days to a week or so by a process known as transtentorial herniation, compressing the brainstem, where there are important neural circuits for vital functions, such as breathing and maintenance of blood pressure.

Degenerative and other diseases. Degenerative, metabolic, toxic, and deficiency states include the largest numbers of both common and rare diseases of the nervous system. Since neurons in the brain may be destroyed after birth and cannot be replaced, mental deterioration, deafness and blindness, incoordination and adventitious movements, and other neurologic signs that are so typical of these disorders are generally not reversible even if the basic metabolic defect can be corrected. Advances have been made in the early diagnosis and treatment of several diseases usually manifest in infancy with mental retardation. Three examples are phenylpyruvic oligophrenia (phenylketonuria or PKU), which is treatable with a phenylalanine-deficient diet; galactosemia, requiring a galactose-free diet also as early as possible to avoid cataracts and mental retardation; and cretinism, which requires treatment with thyroid. *See* HUNTINGTON'S DISEASE; METABOLIC DISORDERS; PARKINSON'S DISEASE; PHENYLKETONURIA.

Neoplasm. Neoplasms of the nervous system can be divided into primary and metastatic, the primary into gliomas and others, and the metastatic into bronchogenic and others. These four groups each account for about 25% of all intracranial neoplasms. *See* TUMOR. [E.C.A.; C.M.S.]

Neural crest

A strip of ectodermal material in the early vertebrate embryo inserted between the prospective neural plate and epidermis. After closure of the neural tube the crest cells migrate into the body and give rise to parts of the neural system: the main part of the visceral cranium, the mesenchyme, the chromaffin cells, and pigment cells. The true nature of the neural crest eluded recognition for many years because this primary organ has a temporary existence; its cells and derivatives are difficult to analyze when dispersed throughout the body. The fact that mesenchyme arises from this ectodermal organ was directly contrary to the doctrine of the specificity of the germ layers.

Neural crest no doubt exists, with similar qualities, in all vertebrate groups, including the cyclostomes. It has been most thoroughly studied in amphibians and the chick. *See* GERM LAYERS. [S.H.]

Neural network

An information-processing device that consists of a large number of simple nonlinear processing modules, connected by elements that have information storage and programming functions. The field of neural networks is an emerging technology in the area of machine information processing and decision making. The main thrusts are toward highly innovative machine and algorithmic architectures, radically different from those that have been employed in conventional digital computers. The information-processing elements and components of neural networks, inspired by neuroscientific studies of the structure and function of the human brain, are conceptually simple. Three broad categories of neural-network architectures have been formulated which exhibit highly complex information-processing capabilities. Several generic models have been advanced which offer distinct advantages over traditional digital-computer implementation. Neural networks have created an unusual amount of interest in the engineering and industrial communities by opening up new research directions and commercial and military applications. *See* NEUROBIOLOGY.

Automated information processing is achieved by means of modules that in general involve four functions: input/output (getting in and out of the machine), processing (executing prescribed specific information-handling tasks), memory (storing information), and connections between different modules providing for information flow and control. Neural networks contain a very large number of simple processing modules. This contrasts with traditional digital computers, which contain a small number of complex processing modules that are rather sophisticated in the sense that they are capable of executing very large sets of prescribed arithmetic and logical tasks (instructions). In conventional digital computers, the four functions listed above are carried out by separate dedicated machine units. In neural networks information storage is achieved by components which at the same time effect connections between distinct machine units. These key distinctions between the neural-network and the digital computer architectures are of a fundamental nature and have major implications in machine design and in machine utilization.

The information-processing properties of neural networks depend mainly on two factors: the network topology (the scheme used to connect elements or nodes together), and the algorithm (the rules) employed to specify the values of the weights connecting the nodes. While the ultimate configuration and parameter values are problem-specific, it is possible to classify neural networks, on the basis of how information is stored or retrieved, in four broad categories: neural networks behaving as learning machines with a teacher; neural networks behaving as learning machines without a teacher; neural networks behaving as associative memories; and neural networks that contain analog as well as digital devices and result in hybrid-machine implementations that integrate complex continuous dynamic processing and logical functions. Within these four categories, several generic models have found important applications, and still others are under intensive investigation.

Neural-network research is developing a new conceptual framework for representing and utilizing information, which will result in a significant advance in information epistemology. Communication technology is based on the notions of coding and channel capacity (bits per second), which provide the conceptual framework for information representation appropriate to machine-based communication. Neural-network systems (biological or artificial) do not store information or process it in the way that conventional digital computers do. Specifically, the basic unit of neural-network operation is not based on the notion of the instruction but on the connection. The performance of a neural network depends directly on the number of connections per second that it effects, and thus its performance is better understood in terms of its connections-per-second (CPS) capability. *See* INFORMATION THEORY. [N.DeC.]

Neurobiology Study of the development and function of the nervous system, with emphasis on how nerve cells generate and control behavior. The major goal of neurobiology is to explain at the molecular level how nerve cells differentiate and develop their specific connections and how nerve networks store and recall information. Ancillary studies on disease processes and drug effects in the nervous system also provide useful approaches for understanding the normal state by comparison with perturbed or abnormal systems. The functions of the nervous system may be studied at several levels: molecular, subcellular (organelle), cellular, simple multicellular interacting systems, complex systems, and higher functions (whole animal behavior). *See* BIOPOTENTIALS AND IONIC CURRENTS; MEMORY; MOTOR SYSTEMS; NERVOUS SYSTEM (INVERTEBRATE); NERVOUS SYSTEM (VERTEBRATE); NERVOUS SYSTEM DISORDERS; NEURON; SENSE ORGAN; SYNAPTIC TRANSMISSION. [J.R.B.; M.D.Br.]

Neurohypophysis hormone Either of two peptide hormones secreted by the neurohypophysis, or posterior lobe of the pituitary gland, in humans. These hormones, oxytocin and vasopressin, each comprise nine amino acid residues. Vasopressin is responsible for arterial vasoconstriction (pressor action) and inhibition of water excretion through the kidneys (antidiuretic action), and has a weak effect on contraction of smooth muscle including that of the uterus. The principal action of oxytocin is stimulation of smooth muscle contraction, specifically that of the uterine muscle, and milk ejection from the mammary gland.

Oxytocin and vasopressin are synthesized in neurons in the hypothalamus and subsequently packaged into neurosecretory granules, which migrate down the axon of the neuron and are stored in the posterior lobe of the pituitary gland, from where they are secreted into the systemic circulation. These hormones are also secreted directly from the hypothalamus into the third ventricle and into the hypothalamo-hypophysial portal circulation of the anterior pituitary gland. *See* NEUROSECRETION.

Major stimuli controlling the release of vasopressin include changes in osmolality of the blood, alterations in blood volume, and psychogenic stimuli such as pain, fear, and apprehension. Stimuli evoking release of oxytocin include nipple stimulation or suckling, and stretching of the cervix and vagina (Ferguson reflex).

Oxytocin probably plays an important role in the onset of labor and delivery (parturition) in primates. During lactation, significant amounts of oxytocin are released by the mother during suckling. When there is total destruction of the pituitary or the neurohypophysis, diabetes insipidus may occur. *See* DIABETES; HORMONE; PITUITARY GLAND. [M.Y.D.]

Neuroimmunology The study of basic interactions among the nervous, endocrine, and immune systems during development, homeostasis, and host defense responses to injury. In its clinical aspects, neuroimmunology focuses on diseases of the nervous system, such as myasthenia gravis and multiple sclerosis, which are caused by pathogenic autoimmune processes, and on nervous system manifestations of immunological diseases, such as primary and acquired immunodeficiencies. *See* AUTOIMMUNITY; IMMUNOLOGICAL DEFICIENCY.

Neuroimmune interactions are dependent on the expression of at least two structural components: immunocytes must display receptors for nervous system-derived mediators, and the mediators must be able to reach immune cells in concentrations sufficient to alter migration, proliferation, phenotype, or secretory or effector functions. More than 20 neuropeptide receptors have been identified on immunocompetent cells.

It has been found that stimuli derived from the nervous system could affect the course of human disease. The onset or progression of tumor growth, infections, or chronic inflammatory diseases, for example, could be associated with traumatic life events or other psychosocial variables such as personality types and coping mechanisms. More direct indications of the influence of psychosocial factors on immune function have been provided by findings that cellular immunity can be impaired in individuals who are exposed to unusually stressful situations, such as the loss of a close relative. *See* CELLULAR IMMUNOLOGY.

During responses to infection, trauma, or malignancies, cells of the immune system produce some cytokines in sufficiently high quantities to reach organs that are distant from the site of production. These cytokines are known to act on the nervous system. Fever is the classic example of changes in nervous system function induced by products of the immune system; interleukin 1, which is produced by monocytes after stimulation by certain bacterial products, binds to receptors in the hypothalamus and evokes changes via the induction of prostaglandins. Interleukin 1 also induces slow-wave sleep. Both fever and sleep may be regarded as protective behavioral changes. *See* ENDOCRINE

SYSTEM (VERTEBRATE); IMMUNOLOGY; NERVOUS SYSTEM (VERTEBRATE); NEUROSECRETION. [M.L.; W.Ku.; P.V.]

Neuron A nerve cell: the functional unit of the nervous system. Structurally, the neuron is made up of a cell body or soma and one or more long processes: a single axon and dendrites. The cell body contains the nucleus and usual cytoplasmic organelles with an exceptionally large amount of rough endoplasmic reticulum, called Nissl substance in the neuron. The longest cell process is the axon, which is capable of transmitting propagated nerve impulses. There may be none, one, or many dendrites composing part of a neuron. If there is no dendrite, it is a unipolar neuron; with one dendrite, it is a bipolar neuron; if there is more than one dendrite, it is a multipolar neuron. In most neurons only the axon propagates nerve impulses; the dendrites and somas are also irritable but do not propagate nerve impulses. *See* NERVOUS SYSTEM (VERTEBRATE). [D.B.W.]

Neuroptera An order of delicate insects having endopterygote development, chewing mouthparts, and soft bodies. Included are the insects commonly termed lacewings, ant lions, dobsonflies, and snake flies. The order consists of about 25 families and is widely distributed.

The adults have long, slender antennae and usually four similar wings, although the front pair is generally slightly larger than the hind pair. The adults of most species are strongly attracted to lights. The larvae are aggressive predators. The larvae of lacewings are especially destructive to aphids, scale insects, and mites. *See* ENDOPTERYGOTA; INSECTA. [F.M.C.]

Neurosecretion The synthesis and release of hormones by neurons. Such neurons are called neurosecretory cells, and their products are often called neurohormones. Like conventional (that is, nonglandular or ordinary) neurons, neurosecretory cells are able to receive signals from other neurons. But unlike ordinary neurons that have cell-to-cell communication over short distances at synapses, neurosecretory cells release their product into an extracellular space that may be at some distance from the target cells. In an organism with a circulatory system, the neurohormones are typically sent by the vascular route to their target, whereas in lower invertebrates that lack an organized circulatory system the neurohormones apparently simply diffuse from the release site to the target. It is now clear that the nervous and endocrine systems interact in many ways, as in the suckling reflex of mammals (where the hormone oxytocin, a neurohormone, elicits milk ejection and is reflexly released in response to nerve impulses generated by stimulation of the nipples), and neurosecretory cells form a major link between them. *See* ENDOCRINE MECHANISMS; ENDOCRINE SYSTEM (INVERTEBRATE); ENDOCRINE SYSTEM (VERTEBRATE).

It has been shown that peptides or low-molecular-weight proteins as well as amines, such as octopamine and dopamine, are released from neurosecretory cells into the circulatory systems of various animals, where they function as neurohormones. In classical neurosecretory cells, the secreted material is synthesized in the cell body by the rough-surfaced endoplasmic reticulum and subsequently packaged in the form of membrane-bounded granules by the Golgi apparatus, and is then typically transported along the axon to the axonal terminals, where it is stored until released. The release of neurohormones from axonal terminals into an extracellular space is triggered when the electrical activity (action potential) that is propagated by the axon enters the neurosecretory terminals. Calcium ions are essential for neurohormone release. *See* BIOPOTENTIALS AND IONIC CURRENTS; ENDOPLASMIC RETICULUM; GOLGI APPARATUS.

Neurohormones have a wide variety of functions. The role of the vertebrate hypothalamo-neurohypophysial system has been especially well elucidated. The pars nervosa is the site of release of vasopressin (also called the antidiuretic hormone) and oxytocin, and the median eminence is the release site for several hypothalamic neurohormones that regulate the adenohypophysis, the nonneural portion of the pituitary gland. *See* ADENOHYPOPHYSIS HORMONE; NERVOUS SYSTEM (VERTEBRATE); NEUROHYPOPHYSIS HORMONE; PITUITARY GLAND. [M.F.]

Neurotic disorders Mental disorders characterized by symptoms such as phobias, obsessive thoughts, and compulsive actions, or by losses of specific bodily functions. A neurotic disorder, termed neurosis in the psychoanalytic literature, is distinguished from more severe mental disturbances by a continued ability to recognize reality, and from more diffuse character disorders by the relatively specific nature of the symptoms. Neurosis is quite common and treatable through a range of psychological and biological methods.

The three classic neuroses were identified by S. Freud. The first is phobia (anxiety hysteria in Freud's terminology), which is characterized by unreasonable fear of common objects or situations. The second classic neurosis is conversion (conversion hysteria), in which there is loss of function in part of the body that generally does not correspond to an anatomic or physiologic disorder. The third of the original neuroses, obsessive-compulsive neurosis, is characterized by intrusive, repetitive thoughts of a disturbing nature, and a compelling need to perform ritualized, repetitive, and apparently senseless acts. *See* OBSESSIVE-COMPULSIVE DISORDER; PSYCHOSOMATIC DISORDERS.

Historically, neurosis was described and defined by Freud, and the dominant theories of its origin and treatment were psychoanalytic. There have been several generations of psychoanalytic theories, but one generally adopted by classical psychoanalysts holds that each neurotic symptom represents a conflict between an unacceptable impulse and the prohibition against that impulse. In the analytic theory, neurotic symptoms are formed when a frustration in current life prevents direct satisfaction of a wish. The recommended therapy is classical psychoanalysis, or psychoanalytic psychotherapy. This is aimed at making conscious to the patient the nature of the desire that is frustrated, as well as the prohibitions that prevent its direct satisfaction. *See* NEUROBIOLOGY; PSYCHOANALYSIS; PSYCHOTHERAPY. [M.M.]

Neurulation The process by which the vertebrate neural tube is formed. The primordium of the central nervous system is the neural plate, which arises at the close of gastrulation by inductive action of the chorda-mesoderm on the overlying ectoderm. The axial mesodermal substratum causes the neural ectoderm to thicken into a distinct plate across the dorsal midline and influences both its size and shape. Its shieldlike appearance, broader anteriorly and narrower posteriorly, presages the areas of brain and spinal cord, respectively. The lateral edges of the neural plate then rise as neural folds which meet first at the level of the future midbrain, above the dorsal midline, then fuse anteriorly and posteriorly to form the neural tube. The body ectoderm becomes confluent above the closing neural tube and separates from it. Upon closure, the cells (known as neural crest cells) which occupied the crest of the neural folds leave the roof of the tube and migrate through the mesenchyme to all parts of the embryo, forming diverse structures. The neural tube thus formed gives rise to the brain and about half of the spinal cord. The remainder of the neural tube is added by the tail bud, which proliferates a solid nerve cord that secondarily hollows into a tube. *See* NERVOUS SYSTEM (VERTEBRATE); NEURAL CREST. [H.L.H.]

Neutral currents Exchange currents which carry no electric charge and mediate certain types of electroweak interactions. The discovery of the neutral-current weak interactions and the agreement of their experimentally measured properties with the theoretical predictions were of great significance in establishing the validity of the Weinberg-Salam model of the electroweak forces.

The electroweak forces come in three subclasses: the electromagnetic interactions, the charged-current weak interactions, and the neutral-current weak interactions. The electromagnetic interaction is mediated by an exchanged photon γ. Since the photon carries no electric charge, there is no change in charge between the incoming and the outgoing particles. The charged-current weak interaction is mediated by the exchange of a charged intermediate boson, the W^{+}, and thus, for example, an incoming neutral lepton such as the ν_{μ} is changed into a charged lepton, the μ^{-}. In the neutral-current weak interactions, the exchanged intermediate boson, the Z^{0}, carries no electric charge (hence the name neutral-current interaction), and thus for example, an incident neutral lepton, such as the ν_{μ}, remains an outgoing neutral ν_{μ}. *See* Electron; Intermediate vector boson; Lepton; Neutrino; Photon.

The neutral-current interactions were experimentally discovered in 1973, and have since been extensively studied, in neutrino scattering processes. Very important information about the properties of the neutral currents have been obtained by studying the interference effects between the electromagnetic and the neutral-current weak interactions in the scattering of polarized electrons on deuterium. Parity violating effects in atomic physics processes due to the neutral weak currents have been observed, and predicted parity-violating nuclear effects have been searched for. *See* Elementary particle; Fundamental interactions; Parity (quantum mechanics); Symmetry laws (physics); Weak nuclear interactions. [C.B.]

Neutralization reaction (immunology) A procedure in which the chemical or biological activity of a reagent or a living organism is inhibited, usually by a specific neutralizing antibody. As an example, the lethal or the dermonecrotic actions of diphtheria toxin on animals may be completely neutralized by an equivalent amount of diphtheria antitoxin.

Antibodies to bacterial, snake-venom, and other enzyme preparations regularly precipitate them from solution so that the supernates are devoid of enzyme activity; however, the neutralization of activity in the precipitate may range from complete to negligible. *See* Immunology; Neutralizing antibody; Serology. [H.P.T.]

Neutralizing antibody An antibody that reduces or abolishes some biological activity of a soluble antigen or of a living microorganism. Thus, diphtheria antitoxin is a neutralizing antibody that, in adequate amounts, abolishes the pathological effects of diphtheria toxin in animals. This is only one characteristic; the other general properties of the antibody are those of the immunoglobulin family (IgG, IgA, or IgM) to which it belongs. *See* Antibody; Immunoglobulin. [H.P.T.]

Neutrino An elusive elementary particle that interacts with matter principally through the weak nuclear force. Neutrinos are electrically neutral spin-$^1/_2$ fermions with left-handed helicity. Many weak interaction processes (interactions that involve the weak force), such as radioactive nuclear beta decay and thermonuclear fusion, involve neutrinos. Present experimental knowledge is consistent with neutrinos being point particles that have no internal constituents. Neutrinos are classified as neutral leptons, where leptons are defined as elementary particles that interact with the electroweak (electromagnetic and weak nuclear) and gravitational forces but not with the strong nuclear force. *See* Elementary particle; Fundamental interactions; Helicity (quantum mechanics); Lepton; Spin (quantum mechanics); Weak nuclear interactions.

Because the role of gravitational forces is negligible in nuclear and particle interactions and because neutrinos have zero electric charge, neutrinos have the unique property that they interact almost completely via the weak nuclear force. Consequently, neutrinos can be used as sensitive probes of the weak force. As such, neutrino beams at particle accelerators have been employed to study charge-changing (charged current) and charge-preserving (neutral current) weak interactions. However, the extreme weakness (compared to the electromagnetic and strong forces) and short range (of the order of 10^{-18} m) of the weak interaction have made determination of many neutrino properties extremely difficult.

Currently, three distinct flavors (or types) of neutrinos are known to exist: the electron neutrino (ν_e), the muon neutrino (ν_{μ}), and the tau neutrino (ν_{τ}). Each neutrino flavor is associated with a corresponding charged lepton, the electron (e), muon (μ), and tau (τ) particle. The electron, muon, and tau neutrinos (or their antiparticles) have been observed in experiments. Based on present measurements, the lepton flavor families, which comprise the charged and neutral leptons and their antiparticles (e^{-}, ν_e, e^{+}, $\bar{\nu}_e$; μ^{-}, ν_{μ}, μ^{+}, $\bar{\nu}_{\mu}$; τ^{-}, ν_{τ}, τ^{+}, $\bar{\nu}_{\tau}$), obey laws of conservation of lepton number. These empirical laws state that the number of leptons minus antileptons does not change, both within a flavor family and overall. *See* Electron; Symmetry laws (physics).

The existence of neutrino oscillations (a phenomenon whereby neutrinos change their flavors during the flight from a neutrino source to a detector), seen clearly in observations of atmospheric neutrinos, shows that neutrinos have tiny finite masses which are many orders of magnitude smaller than the masses of their charged lepton counterparts, and also shows that the physical neutrinos do not have pure flavors (quantum-mechanical states) but contain mixtures of two or more neutrino states. This mixing indicates that the empirical laws of lepton number conservation are not exact and that they are violated in some physical processes. It is not known whether neutrinos have magnetic or electric dipole moments. [Y.S.]

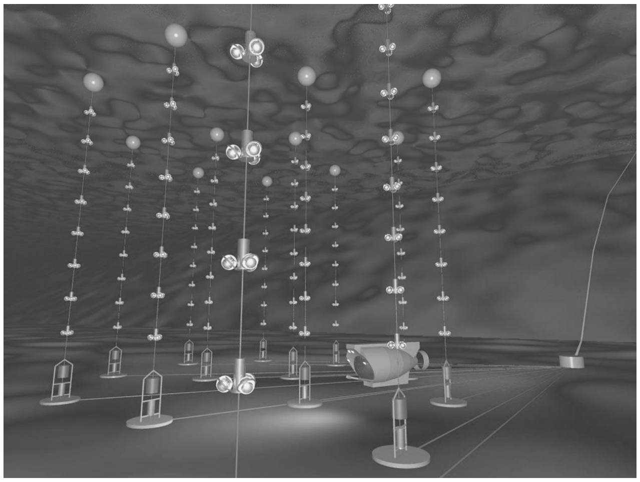
Neutrino astronomy The detection and study of neutrinos to learn about astronomical objects and the universe. These neutral, weakly interacting particles come almost without any disruption straight from their sources, traveling at very close to the speed of light. A low-energy neutrino in flight would not notice a barrier of lead 50 light-years thick. Neutrino light would provide a wondrous new view of the universe.

Neutrinos in the universe. Neutrinos were made in huge numbers at the time of the big bang. Like the cosmic background radiation, they now possess little kinetic energy as a result of the expansion of the universe. The problem with observing these relic neutrinos is that probability of a neutrino interacting within a detector decreases with the square of the neutrino's energy, for low energies. Nobody has been able to detect these lowest-energy neutrinos, and prospects are not good for doing so. *See* Big bang theory; Cosmic background radiation.

Stellar neutrinos. Neutrinos also originate in the nuclear fusion in stars. The Sun close by produces a huge flux of neutrinos, which have been detected in five experiments. However, observations of stellar neutrinos are limited to the Sun. Just as the sky is dark at night despite all the stars, the Sun far outshines all the rest of the cosmos in numbers of detectable neutrinos. *See* Solar neutrinos.

Supernovae. On February 23, 1987, two detectors in deep mines in the United States (the IMB experiment) and Japan (the Kamiokande experiment) recorded a total of 19 neutrino interactions over a span of 13 seconds. Two and a half hours later, astronomers in the Southern Hemisphere saw the first supernova to be visible with the unaided eye since 1604. Many deductions followed about the nature of neutrinos, such as limits on mass, charge, gravitational attraction, and magnetic moment.

Supernovae of the gravitational-collapse type occur when elderly massive stars run out of nuclear fusion energy and can no longer resist the force of gravity. The neutrinos carry off most of the in-fall energy. Much can be learned from the final stages of stellar evolution, not only about the process of stellar collapse to a neutron star or black hole (the latter if the progenitor is very massive) but also about properties of neutrinos. Four underground detectors have significant capability for supernova detection from the Milky Way Galaxy. From historical records and from observations of distant spiral galaxies, the rate of



View of the ANTARES Project from the ocean bottom. The optical detectors consist of modules of a cluster of photomultipliers and electronics, spaced along vertical buoy strings. Spherical floats at the top of each detector string keep the string close to vertical; anchors and releases are at the bottom. Fiber-optic cables go from each string to a junction box, which is serviced by the submarine at the far side of the array. A cable descends the slope from shore in the background. Scales are exaggerated. (*ANTARES Collaboration*)

supernovae in the Milky Way Galaxy is expected to be between one and five per century. Thus experimentalists may have to wait a long time before the next observation, and there is no way of predicting when it will occur. *See* SUPERNOVA.

High-energy cosmic neutrinos. Higher-energy neutrinos must be made in many of the most luminous and energetic objects in the universe, such as active galactic nuclei and gamma-ray bursters. Two things make prospects brighter in the near future for higher-energy neutrino astronomy than for lower energies: (1) the interaction probability for neutrinos goes up with energy, and (2) the consequences of neutrino interaction with a target (Earth or detector) become more detectable as the energy release is greater. The favored method is to detect muons produced by neutrinos. These charged particles produce Cerenkov radiation, a short flash of light detectable at tens of meters distance by photomultipliers in clear water or ice. *See* CERENKOV RADIATION; PHOTOMULTIPLIER.

High-energy neutrino telescopes. Neutrino detectors must be placed deep underground or underwater to escape the backgrounds caused by the rain of cosmic rays upon the atmosphere. The lead project, DUMAND (Deep Underwater Muon and Neutrino Detector), was canceled in 1995, but made great headway in pioneering techniques, studying backgrounds, exploring detector designs, and stimulating interest in astrophysical neutrinos.

Two projects similar to DUMAND are under way in the Mediterranean, the more developed NESTOR (Neutrino Experimental Submarine Telescope with Oceanographic Research) Project, and the ANTARES (Astronomy with a Neutrino Telescope and Abyss Environmental Research) Project (see illustration). These projects employ basically the same method of bottom-anchored cables, with photomultipliers protected in spherical glass pressure housings, as developed for DUMAND. A different type of neutrino telescope, the AMANDA (Antarctic Muon and Neutrino Detector Array) Project, is under construction in ice at the South Pole. [J.G.Le.]

Neutron An elementary particle having approximately the same mass as the proton, but lacking a net electric charge. It is indispensable in the structure of the elements, and in the free state it is an important reactant in nuclear research and the propagating agent of fission chain reactions. Neutrons, in the form of highly condensed matter, constitute the substance of neutron stars. *See* NEUTRON STAR.

Neutrons and protons are the constituents of atomic nuclei. The number of protons in the nucleus determines the chemical nature of an atom, but without neutrons it would be impossible for two or more protons to exist stably together within nuclear dimensions, which are of the order of 10^{-13} cm. The protons, being positively charged, repel one another by virtue of their electrostatic interactions. The presence of neutrons weakens the electrostatic repulsion, without weakening the nuclear forces of cohesion. In light nuclei the resulting balanced, stable configurations contain protons and neutrons in almost equal numbers, but in heavier elements the neutrons outnumber the protons; in ^{238}U, for example, 146 neutrons are joined with 92 protons. Only one nucleus, ^{1}H, contains no neutrons. For a given number of protons, neutrons in several different numbers within a restricted range often yield nuclear stability—and hence the isotopes of an element. *See* ISOTOPE; NUCLEAR STRUCTURE; PROTON.

Free neutrons have to be generated from nuclei, and since they are bound therein by cohesive forces, an amount of energy equal to the binding energy must be expended to get them out. Nuclear machines, such as cyclotrons and electrostatic generators, induce many nuclear reactions when their ion beams strike target material. Some of these reactions release neutrons, and these machines are sources of high neutron flux. Neutrons are released in the act of fission, and nuclear reactors are unexcelled as intense neutron sources. *See* NUCLEAR BINDING ENERGY; NUCLEAR FISSION.

Neutrons occur in cosmic rays, being liberated from atomic nuclei in the atmosphere by collisions of the high-energy primary or secondary charged particles. They do not themselves come from outer space. *See* DELAYED NEUTRON; COSMIC RAYS.

Having no electric charge, neutrons interact so slightly with atomic electrons in matter that energy loss by ionization and atomic excitation is essentially absent. Consequently they are vastly more penetrating than charged particles of the same energy. The main energy-loss mechanism occurs when they strike nuclei. The most efficient slowing-down occurs when the bodies that are struck in an elastic collision have the same mass as the moving bodies; hence the most efficient neutron moderator is hydrogen, followed by other light elements: deuterium, beryllium, and carbon. The great penetrating power of neutrons imposes severe shielding problems for reactors and other nuclear machines, and it is necessary to provide walls, usually of concrete, several feet in thickness to protect personnel. The currently accepted health tolerance levels for an 8-h day correspond for fast neutrons to a flux of 20 neutrons/(cm^2)(s) or 130 neutrons/(in.^{2})(s); for slow neutrons, 700/(cm^2)(s) or 4500/(in.^{2})(s). On the other hand, fast neutrons are useful in some kinds of cancer therapy. *See* RADIATION DAMAGE TO MATERIALS; RADIATION INJURY (BIOLOGY); RADIATION SHIELDING; RADIOLOGY.

Free neutrons are radioactive, each transforming spontaneously into a proton, an electron (β^- particle), and an antineutrino. This instability is a reflection of the fact that neutrons are slightly heavier than hydrogen atoms. The neutron's rest mass is 1.0086652 atomic mass units on the unified mass scale (1.67495×10^{-24} g), as compared with 1.0078252 atomic mass units for the hydrogen atom.

Neutrons are, individually, small magnets. This property permits the production of beams of polarized neutrons, that is, beams of neutrons whose magnetic dipoles are aligned predominantly parallel to one direction in space. The magnetic moment is -1.913042 nuclear magnetons. *See* MAGNETON; NUCLEAR MOMENTS; NUCLEAR ORIENTATION; SPIN (QUANTUM MECHANICS).

Despite its overall neutrality, the neutron does have an internal distribution of electric charge, as has been revealed by scattering experiments. On a still finer scale, the neutron can also be presumed to have a quark structure in analogy of that of the proton. *See* QUANTUM CHROMODYNAMICS; QUARKS.

When neutrons are completely slowed down in matter, they have a maxwellian distribution in energy that corresponds to the temperature of the moderator with which they are in equilibrium. The de Broglie wavelength of these ultracold neutrons is greater than 50 nm, which is so much larger than interatomic distances in solids that they interact with regions of a surface rather than with individual atoms, and as a result they are reflected from polished surfaces at all angles of incidence. Ultracold neutrons are important in basic physics and have applications in studies of surfaces and of the structure of inhomogeneities and magnetic domains in solids. *See* ELEMENTARY PARTICLE; NEUTRON DIFFRACTION; THERMAL NEUTRONS. [A.H.Sn.]

Neutron diffraction The phenomenon associated with the interference processes which occur when neutrons are scattered by the atoms within solids, liquids, and gases. The use of neutron diffraction as an experimental technique is relatively new compared to electron and x-ray diffraction, since successful application requires high thermal-neutron fluxes, which can be obtained only from nuclear reactors. These diffraction investigations are possible because thermal neutrons have energies with equivalent wavelengths near 0.1 nanometer and are therefore ideally suited for interatomic interference studies.

In the scattering of neutrons by atoms, there are two important interactions. One is the short-range, nuclear interaction of the neutron with the atomic nucleus. This interaction produces isotropic scattering because the atomic nucleus is essentially a point scatterer relative to the wavelengths of thermal neutrons. Strong resonances associated with the scattering process prevent any regular variation of the nuclear scattering amplitudes with atomic number. The other important process for the scattering of neutrons by atoms is the interaction of the magnetic moment of the neutron with the spin and orbital magnetic moments of the atom. *See* SCATTERING EXPERIMENTS (ATOMS AND MOLECULES); SCATTERING EXPERIMENTS (NUCLEI).

Since the nuclear scattering amplitudes for neutrons do not vary uniformly with atomic number, there are certain types of chemical structures which can be investigated more readily by neutron diffraction than by x-ray diffraction. Moreover, since neutron scattering is a nuclear process, when the scattering amplitude of an element is not favorable for a particular investigation, it is frequently possible to substitute an enriched isotope which has scattering characteristics that are markedly different. The most significant application of neutron diffraction in chemical crystallography is the structure determination of composite crystals which contain both heavy and light atoms, and the most important compounds in this general classification are the hydrogen-containing substances.

The interaction of the magnetic moment of the neutron with the orbital and spin moments in magnetic atoms makes neutron scattering a unique tool for the study of a wide variety of magnetic phenomena, because information is obtained on the magnetic properties of the individual atoms in a material. This interaction depends on the size of the atomic magnetic moment and also on the relative orientation of the neutron spin and of the atomic magnetic moment with respect to the scattering vector and with respect to each other. Consequently, detailed information can be obtained on both the magnitude and orientation of magnetic moments in any substance which displays magnetic properties.

The investigation of antiferromagnetic and ferrimagnetic substances is one of the most important applications of the neutron diffraction technique, because detailed information on the magnetic configuration in these systems cannot be obtained by other methods.

One of the most important uses of inelastic neutron scattering is the study of thermal vibrations of atoms about their equilibrium positions, because lattice vibration quanta, or phonons, can be excited or annihilated in their interactions with low-energy neutrons. The measurements provide a direct determination of the dispersion relations for the normal vibrational modes of the crystal and do not require the large corrections necessary in similar x-ray investigations. These measured dispersion relations furnish the best experimental information available on interatomic forces that exist in crystals. *See* ELECTRON DIFFRACTION; MAGNON; NEUTRON SPECTROMETRY. [M.K.W.]

Neutron optics The general class of experiments designed to emphasize the wavelike character of neutrons. Like all elementary particles, neutrons can be made to display wavelike, as well as particlelike, behavior. They can be reflected and refracted, and they can scatter, diffract, and interfere, like light or any other type of wave. Many classical optical effects, such as Fresnel diffraction, have been performed with neutrons, including even those involving the construction of Fresnel zone plates. *See* DIFFRACTION; INTERFERENCE OF WAVES; REFLECTION OF ELECTROMAGNETIC RADIATION; REFRACTION OF WAVES; SCATTERING OF ELECTROMAGNETIC RADIATION; WAVE (PHYSICS).

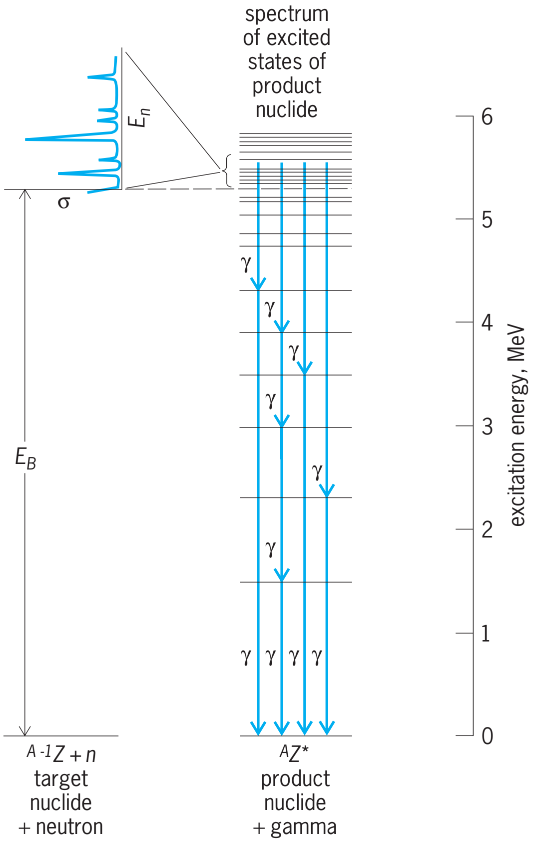
The typical energy of a neutron produced by a moderated nuclear reactor is about 0.02 eV, which is approximately equal to the kinetic energy of a particle at about room temperature (80°F or 300 K), and which corresponds to a wavelength of about 10^{-10} m. This is also the typical spacing of atoms in a crystal, so that solids form natural diffraction gratings for the scattering of neutrons, and much information about crystal structure can be obtained in this way. However, the wavelike properties of neutrons have been confirmed over a vast energy range from 10^{-7} eV to over 100 MeV. *See* NEUTRON DIFFRACTION.

Neutrons, being uncharged, can be made to interfere over large spatial distances, since they are relatively unaffected by the stray fields in the laboratory that deflect charged particles. This property has been exploited by using the neutron interferometer. This device is made possible by the ability to grow essentially perfect crystals of up to 4 in. (10 cm). The typical interferometer is made from a single perfect crystal cut so that three parallel "ears" are presented to the neutron beam. This allows the incident beam to be split and subsequently recombined coherently. *See* COHERENCE; INTERFEROMETRY; SINGLE CRYSTAL.

One of the most significant experiments performed with the interferometer involved rotating the interferometer about the incident beam so that one neutron path was higher than the other, creating a minute gravitational potential difference (of 10^{-9} eV) between the paths. This was sufficient to cause a path difference of 20 or so wavelengths between the beams. This remains the only type of experiment that has ever seen a quantum-mechanical interference effect due to gravity. It also verifies the extension of the equivalence principle to quantum theory (although in a form more subtle than its classical counterpart). *See* GRAVITATION; RELATIVITY.

Many noninterferometer experiments have also been done with neutrons. In one experiment, resonances were produced in transmitting ultracold neutrons (energy about 10^{-7} eV) through several sheets of material. This is theoretically similar to seeing the few lowest states in a square-well potential in the Schrödinger equation. *See* NEUTRON; NONRELATIVISTIC QUANTUM THEORY; QUANTUM MECHANICS. [D.M.Gre.]

Neutron spectrometry A generic term applied to experiments in which neutrons are used as the probe for measuring excited states of nuclides and for determining the properties of these states. The term neutron spectroscopy is also used. The strength of the interaction between a neutron and a target nuclide can vary rapidly as a function of the energy of the incident neutron, and it is different for every nuclide. At particular neutron energies the interaction strength for a specific nuclide can be very strong; these narrow energy regions of strong interactions are called resonances (see illustration). The strength of the interaction, expressing the probability that an interaction of a given kind will take place, can be considered as the effective cross-sectional area σ presented by a nucleus to an incident neutron.



Energy-level diagram for the product nucleus $^AZ^*$ with mass number *A* and charge number *Z*. The asterisk emphasizes that the product nucleus is in an excited state, from which it returns to ground state by emitting gamma (γ) rays. Excitation energy is the sum of the energy of the neutron E_n, and the binding energy E_B of the neutron which has been added to the target nuclide.

Neutron spectroscopy can be carried out by two different techniques (or a combination): (1) by the use of a time-pulsed neutron source which emits neutrons of many energies simultaneously, combined with the time-of-flight technique to measure the velocities of the neutrons; this time-of-flight technique can be used for neutron measurements from 10^{-3} eV to about 200 MeV; (2) by the use of a beam of nearly monoenergetic neutrons whose energy can be varied in small steps approximately equal to the energy spread of the neutron beam; however, useful "monoenergetic" neutron sources are not available from about 10 eV to about 10 keV.

Neutron spectroscopy has yielded a mass of valuable information on nuclear systematics for almost all nuclides. The distribution of the spacings between nuclear levels and the average of these spacings have provided valuable tests for various nuclear theories. The properties of these levels, that is, the probabilities that they decay by neutron or gamma-ray emission, or by fission, and the averages and distribution of these probabilities have stimulated much theoretical effort.

In addition, knowledge of neutron cross sections is fundamental for the optimum design of thermal fission power reactors and fast neutron breeder reactors, as well as fusion power reactors now in the conceptual stage. Cross sections are needed for nuclear fuel materials such as ^{235}U or ^{239}Pu, for fertile materials such as ^{238}U, for structural materials such as iron and chromium, for coolants such as sodium, for moderators such as beryllium, and for shielding materials such as concrete. *See* NUCLEAR STRUCTURE; REACTOR PHYSICS. [J.A.H.]

Neutron star A star containing about $1\frac{1}{2}$ solar masses of material compressed into a volume approximately 6 mi (10 km) in radius. (1 solar mass equals 4.4×10^{33} lbm or 2.0×10^{33} kg.) Neutron stars are one of the end points of stellar evolution and are the final states of stars that begin their lives with considerably more mass than the Sun. The density of neutron star material is 10^{14} to 10^{15} times the density of water and exceeds the density of matter in the nuclei of atoms. Neutron stars are pulsars (pulsating radio sources) if they rotate sufficiently rapidly and have strong enough magnetic fields. *See* PULSAR; STELLAR EVOLUTION.

Neutron stars play a role in astrophysics which extends beyond their status as strange, unusual types of stellar bodies. The interior of a neutron star is a cosmic laboratory in which matter is compressed to densities which are found nowhere else in the universe. Precise measurements of the rotation of neutron stars can probe the behavior of matter at such densities. Neutron stars in double-star systems can emit x-rays when matter flows toward the neutron star, swirls around it, and heats up. Neutron stars are probably formed in supernova explosions. A few pulsars are found in double-star systems, and careful timing of the pulses they emit can test Einstein's general theory of relativity. *See* BINARY STAR; GRAVITATION; RELATIVITY; SUPERNOVA.

Measured values of masses of neutron stars in double star systems range from 1.4 to 1.8 solar masses. If Einstein's theory of gravitation is the correct one, a neutron star with a mass larger than some limiting value will collapse catastrophically, because its internal pressure will be insufficient, and become a black hole. The exact value of this limiting mass is not known precisely, but lies between 3 and 5 solar masses. *See* BLACK HOLE.

Most of the interior of a neutron star consists of matter which is almost entirely composed of neutrons. In the bulk of the star, this matter is in a superfluid state, where circulation currents can flow without resistance. This material is under pressure, since it must be able to support the tremendous weight of the overlying layers at each point in the neutron star. This pressure, called degeneracy pressure, is caused by the close packing of the neutrons rather than by the motion of the particles. As a result, neutron stars can be stable no matter what the internal temperature is, because the pressure that supports the star is independent of temperature. *See* SUPERFLUIDITY. [H.L.Sh.]

New Zealand A landmass in the Southern Hemisphere, bounded by the South Pacific Ocean to the north, east, and south and the Tasman Sea to the west, with a total land area of 103,883 mi^2 (269,057 km^2). The exposed landmass represents about one-quarter of a subcontinent, with three-quarters submerged. This long, narrow, mountainous country, oriented northeast to southwest, consists of two main islands, North Island and South Island, surrounded by a much greater area of crust submerged to depths reaching 1.2 mi (2 km).

South Island lowlands are either alluvial plains as in Otago, Southland, and Nelson, or glacial outwash fans as in Westland and Canterbury. North Island lowlands such as Hawke's Bay, Wairarapa, and Manawatu are alluvial; the Waikato, Hauraki, and Bay of Plenty lowlands occupy structural basins that contain large volumes of reworked volcanic debris from the central volcanic region. The alluvial lowlands of both main islands form the most agriculturally productive areas of the country. *See* PLAINS.

The climate of New Zealand is influenced by three main factors: a location in latitudes where the prevailing airflow is westerly; an oceanic environment; and the mountain chains, which modify the weather systems as they pass eastward, causing high rainfalls on windward slopes and sheltering effects to leeward.

Weather is determined mostly by series of anticyclones and troughs of low pressure that produce alternating periods of settled and variable conditions. Westerly air masses are occasionally replaced by southerly airstreams, which bring cold conditions with snow in winter and spring to areas south of 39°S, and northerly tropical maritime air, which brings warm humid weather to the north and east coasts. *See* Meteorology.

Rainfall on land is 16–470 in. (400–12,000 mm) per year, with the highest rainfall being on the western windward slopes of the mountains, and the lowest on the eastern basins in the lee of the Southern Alps in Central Otago and south Canterbury. Annual rain days are at least 130 for most of North Island, but on South Island the totals are far more variable, with over 200 occurring in Fiordland, 180 on the west coast, and fewer than 80 in Central Otago. Summer droughts are relatively common in Northland, and in eastern regions of both islands. *See* Drought; Precipitation (meteorology).

Droughts, springtime air frosts, and hailstorms are the major common climatic hazards for the farming industry, but floods associated with prolonged intense rainstorms are the major general hazard.

The economy is heavily dependent on the natural resources soil, water, and plants. New Zealand has few exploitable minerals, but possesses a climate generally favorable for agriculture, pastoral farming, renewable forestry, and tourism. With a small population (3.4 million), much of its manufacturing is concerned with processing produce from the land and surrounding seas, and supplying the needs of those industries.

Because of its high relief and its location on an active crustal plate boundary in the zone of convergence between Antarctic air masses and tropical air masses, New Zealand is prone to high-intensity and high-frequency natural hazards—earthquakes, volcanic eruptions, large and small landslides, and floods. [M.J.Se.]

Newcastle disease

Newcastle disease A viral infection that affects the digestive, intestinal, and respiratory tracts and the neurological system of birds. The causative agent is an enveloped ribonucleic acid (RNA) virus that is classified as a paramyxovirus. *See* Paramyxovirus.

Newcastle disease occurs in five forms based on a virulence in chickens ranging from inapparent infection to severe disease and death. Viscerotropic-velogenic Newcastle disease causes a very severe infection, producing hemorrhagic lesions in the intestinal tract and high mortality. The neurotropic-velogenic type is also highly lethal and produces neurologic and respiratory signs in infected birds. The mesogenic form causes an acute respiratory or neurologic infection that may be lethal only in young birds. The lentogenic type is a mild or inapparent respiratory infection of chickens. The last group includes the viruses causing inapparent or asymptomatic infections of the digestive tract.

The wide susceptibility of avian species to infection with Newcastle disease has complicated control. Newcastle disease is spread worldwide by the international transportation of live birds disseminating the virus. Control of and protection from Newcastle disease can be achieved by the correct use of vaccines. Lentogenic and some mesogenic strains are used to produce vaccines that can be administered by aerosol, intranasal drops, or intramuscular injection, or as an additive to the drinking water. *See* Animal virus. [M.L.V.]

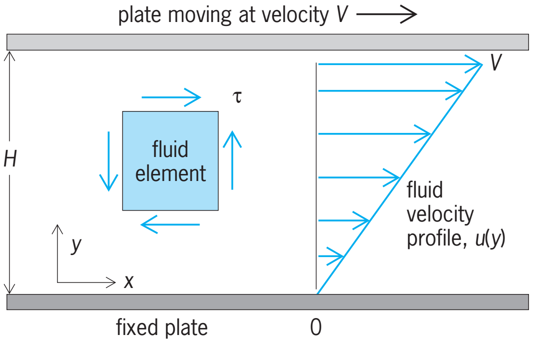
Newtonian fluid

Newtonian fluid A fluid whose stress at each point is linearly proportional to its strain rate at that point. The concept was first deduced by Isaac Newton and is directly analogous to Hooke's law for a solid. All gases are newtonian, as are most common liquids such as water, hydrocarbons, and oils. *See* Hooke's law; Stress and strain.

A simple example, often used for measuring fluid deformation properties, is the steady one-dimensional flow $u(y)$ between a fixed and a moving wall (see illustration). The no-slip condition at each wall forces the fluid into a uniform shear strain rate ϵ, given by Eq. (1), which is induced by a uniform shear stress τ.

$$\varepsilon = \frac{\partial u}{\partial y} = \frac{V}{H} \tag{1}$$

Here V is the speed of the moving wall, H is the perpendicular distance between the walls, and u is the fluid velocity at distance y from the fixed wall.



A fluid sheared between two plates. The resulting strain rate equals *V/H*.

If the fluid is newtonian, the experimental plot of τ versus ε will be a straight line. The constant of proportionality is called the viscosity μ of the fluid, as stated in Eq. (2).

$$\tau = \mu\varepsilon \tag{2}$$

The viscosity coefficients of common fluids vary by several orders of magnitude. *See* Fluid flow; Fluids; Viscosity. [F.M.Wh.]

Newton's laws of motion

Newton's laws of motion Three fundamental principles which form the basis of classical, or newtonian, mechanics. They are stated as follows:

First law: A particle not subjected to external forces remains at rest or moves with constant speed in a straight line.

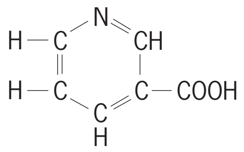
Second law: The acceleration of a particle is directly proportional to the resultant external force acting on the particle and is inversely proportional to the mass of the particle.

Third law: If two particles interact, the force exerted by the first particle on the second particle (called the action force) is equal in magnitude and opposite in direction to the force exerted by the second particle on the first particle (called the reaction force).

The newtonian laws have proved valid for all mechanical problems not involving speeds comparable with the speed of light and not involving atomic or subatomic particles. *See* Dynamics; Force; Kinetics (classical mechanics). [D.Wi.]

Niacin

Niacin A vitamin also known as nicotinic acid, a component of the vitamin B complex. It is a white water-soluble powder stable to heat, acid, and alkali, with the structure shown below.



Many animals, including humans, are capable of synthesizing niacin in varying degrees from the amino acid tryptophan. Niacin is widely distributed in foods. Yeasts, wheat germ, and meats, particularly organ meats, are rich sources of the vitamin. Some foods such as milk are relatively poor sources of niacin but contain generous quantities of tryptophan.

Niacin-deficiency disease is known as pellagra and is particularly prevalent among the poor people whose diet is largely corn. The recommended dietary allowance for niacin is 6.6 niacin equivalents per 1000 kcal. *See* Vitamin. [S.N.G.]

Nickel

Nickel A chemical element, Ni, atomic number 28, a silver-white, ductile, malleable, tough metal. The atomic mass of naturally occurring nickel is 58.71. *See* Periodic table.

Nickel consists of five natural isotopes having atomic masses of 58, 60, 61, 62, 64. Seven radioactive isotopes have also been identified, having mass numbers of 56, 57, 59, 63, 65, 66, and 67.

Most commercial nickel goes into stainless steel and other corrosion-resistant alloys. Nickel is also important in coins as a replacement for silver. Finely divided nickel is used as a hydrogenation catalyst. *See* NICKEL ALLOYS.

Nickel is a fairly plentiful element, making up about 0.008% of the Earth's crust and 0.01% of the igneous rocks. Appreciable quantities of nickel are present in some kinds of meteorite, and large quantities are thought to exist in the Earth's core. Two important ores are the iron-nickel sulfides, pentlandite and pyrrhotite $(Ni,Fe)_xS_y$; the ore garnierite, $(Ni,Mg)SiO_3 \cdot nH_2O$, is also commercially important. Nickel occurs in small quantities in plants and animals. It is present in trace amounts in sea water, petroleum, and most coal.

Nickel metal is of moderate strength and hardness (3.8 on Mohs scale). When viewed as very small particles, nickel appears black. The density of nickel is 8.90 times that of water at 20°C (68°F). Nickel melts at 1455°C (2651°F) and boils at 2840°C (5144°F). Nickel is only moderately reactive. It resists alkaline corrosion and does not burn in the massive state, although fine nickel wires can be ignited. Nickel is above hydrogen in the electrochemical series, and it dissolves slowly in dilute acids, releasing hydrogen. In metallic form nickel is a moderately strong reducing agent.

Nickel is usually dipositive in its compounds, but it can also exist in the oxidation states 0, 1+, 3+, and 4+. Besides the simple nickel compounds, or salts, nickel forms a variety of coordination compounds or complexes. Most compounds of nickel are green or blue because of hydration or other ligand bonding to the metal. The nickel ion present in water solutions of simple nickel compounds is itself a complex, $[Ni(H_2O)_6]^{2+}$. [W.E.C.]

Nickel alloys Combinations of nickel with other metals. Nickel-base alloys may be melted in open-hearth, electric-arc, or induction furnaces in air, under inert gas, or in vacuum. Casting may also be done under these same ambient conditions.

Nickel 211 and Duranickel alloy 301 are essentially binary alloys with 4.75% manganese and 4.5% aluminum, respectively. A characteristic use of nickel 211 is as wire for sparkplug electrodes. Duranickel alloy 301 is well suited to the manufacture of springs and diaphragms.

Monel alloy 400 contains about two-thirds nickel and one-third copper and is the oldest of the commercial nickel-base alloys, dating from about 1905. Nickel-chromium binary alloys are used primarily in specialty high-temperature service. Other nickel alloys contain combinations of other metals in varying quantities. *See* NICKEL. [E.N.S.; G.Sm.]

Nickel metallurgy The extraction and refining of nickel from its ores. Nickel's properties of strength, toughness, and resistance to corrosion have been used to advantage in alloys since ancient times. Although nickel ranks twenty-fourth in order of abundance of the elements, there are relatively few nickel deposits of commercial importance. Nickel ores are of two generic types, sulfides and laterites. Explorations of the ocean bottoms have revealed vast deposits of manganese oxide nodules which contain significant values of nickel, copper, and cobalt.

Selection of processes for nickel extraction is largely determined by the type of ore to be treated. Sulfide ores are amenable to concentration by such methods as flotation or magnetic separation. The state of combination of nickel in the lateritic ores usually precludes such enrichment, thus requiring treatment of the total ore.

Sulfide ores are first crushed and ground to liberate the mineral values and then subjected to froth flotation or magnetic separation to concentrate the valuable constituents and reject the gangue or rock fraction. The nickel concentrate is treated by pyrometallurgical processes. The major portion undergoes partial roasting in multihearth or fluidized-bed furnaces to eliminate about half of the sulfur and to oxidize the associated iron. The hot calcine, plus flux, is smelted in natural gas-coal-fired reverberatory furnaces operating at about 1200°C to produce a furnace matte, enriched in nickel, and a slag for discard. The furnace matte is transferred to converters and blown with air in the presence of more flux to oxidize the remaining iron and associated sulfur, yielding Bessemer matte containing nickel, copper, cobalt, small amounts of precious metals, and about 22% sulfur. The molten Bessemer matte is cast into 25-ton (22.5-metric ton) molds in which it undergoes controlled slow cooling. After crushing and grinding, the metallics are removed magnetically and treated in a refining complex for recovery of metal values.

The bulk of the nickel originating from lateritic ores is marketed as ferronickel. The process employed is basically simple and involves drying and preheating the ore usually under reducing conditions. The hot charge is then further reduced and melted in an electric-arc furnace, and the crude metal is refined and cast into ferronickel pigs. A substantial amount of nickel is produced from lateritic ores by the nickel sulfide matte technique. In this process the ore is mixed with gypsum or other sulfur-containing material such as high-sulfur fuel oil, followed by a reduction and smelting operation to form matte. The molten furnace matte is upgraded in either conventional or top-blown rotary converters to a high-grade matte, which can be further refined by roasting and reduction to a metallized product. *See* NICKEL; PYROMETALLURGY. [A.I.]

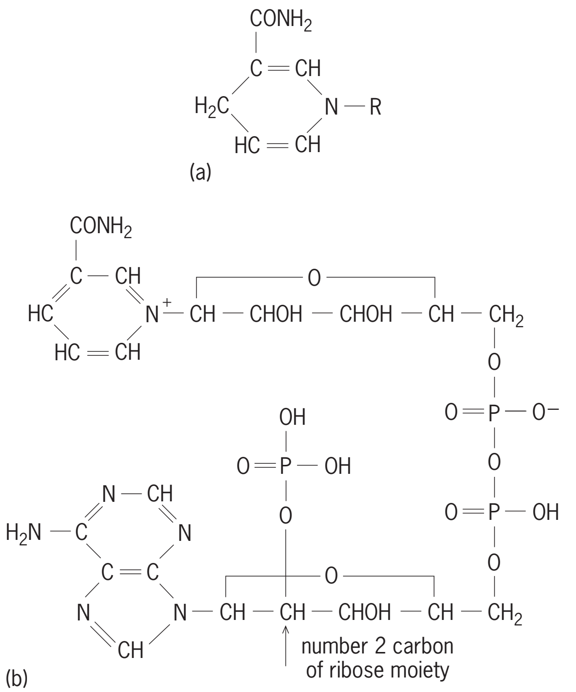
Nickeline A minor ore of nickel. Nickeline is a mineral having composition NiAs and crystallizing in the hexagonal system. Crystals are rare, and nickeline usually occurs in massive aggregates with metallic luster and pale copper-red color. Because of the color, not the composition, it is called copper nickel. The hardness is 5.5 on Mohs scale and the specific gravity is 7.78. Nickeline is frequently associated with other nickel arsenides and sulfides in massive pyrrhotite. It is also found in vein deposits with cobalt and silver minerals, as in the silver mines of Saxony, Germany, and Cobalt, Ontario, Canada. *See* HARDNESS SCALES; NICKEL; PYRRHOTITE. [C.S.Hu.]

Nicotinamide adenine dinucleotide (NAD) An organic coenzyme and one of the most important components of the enzymatic systems concerned with biological oxidation-reduction reactions. It is also known as NAD, diphosphopyridine nucleotide (DPN) coenzyme I, and codehydrogenase I. NAD is found in the tissues of all living organisms. *See* COENZYME.

The nicotinamide, or pyridine, portion of NAD can be reduced chemically or enzymatically with the formation of reduced or hydrogenated NAD (NADH). NAD functions as the immediate oxidizing agent for the oxidation, or dehydrogenation, of various organic compounds in the presence of appropriate dehydrogenases, which are specific apoenzymes, or protein portions of the enzyme. In the dehydrogenase reactions one hydrogen atom is transferred from the substrate to NAD, while another is liberated as hydrogen ion.

NAD and its reduced form, NADH, serve to couple oxidative and reductive processes and are constantly regenerated during metabolism. Hence, they serve as catalysts and NAD is referred to as a coenzyme. In some enzymatic reactions a different coenzyme, triphosphopyridine nucleotide is required. Dehydrogenases are generally quite specific with respect to the coenzyme which they can utilize. *See* ENZYME; NICOTINAMIDE ADENINE DINUCLEOTIDE PHOSPHATE (NADP). [M.D.]

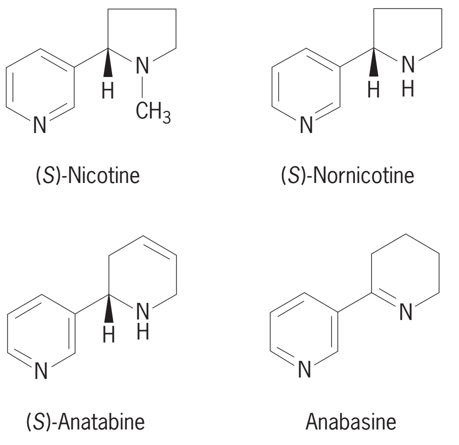
Nicotinamide adenine dinucleotide phosphate (NADP) A coenzyme and an important component of the enzymatic systems concerned with biological oxidation-reduction systems. It is also known as NAD, triphosphopyridine nucleotide (TPN), coenzyme II, and codehydrogenase II. The



Triphosphopyridine nucleotide. (*a*) Reduced form of the nicotinamide portion of TPNH. (*b*) Oxidized form of the molecule (TPN).

compound is similar in structure and function to nicotinamide adenine dinucleotide (NAD). It differs structurally from NAD in having an additional phosphoric acid group esterified at the 2′ position of the ribose moiety of the adenylic acid portion. In biological oxidation-reduction reactions the NADP molecule becomes alternately reduced to its hydrogenated form (NADPH) and reoxidized to its initial state (see illustration). *See* CARBOHYDRATE METABOLISM; COENZYME; ENZYME. [M.D.]

Nicotine alkaloids Alkaloids found in various species of the genus *Nicotiana*. The species most often used for the production of tobacco because of its high level of nicotine is *N. tabacum*, which is cultivated in many parts of the world for the preparation of cigarettes, cigars, and pipe tobacco. Nicotine is the most abundant alkaloid in *N. tabacum*, occurring to the extent of 2–8% based on the dry weight of the cured leaf. Other alkaloids that are found in this species are nornicotine, anabasine, and anatabine. The chemical structures of these alkaloids are shown in the illustration. *See* ALKALOID; TOBACCO. [E.Le.]



(*S*)-Nicotine (*S*)-Nornicotine

(*S*)-Anatabine Anabasine

Structures of nicotine and some other alkaloids found in tobacco.

Niobium A chemical element, Nb, atomic number 41 and atomic weight 92.906. In the United States this element was originally called columbium. The metallurgists and metals industry still use this older name. *See* PERIODIC TABLE.

Most niobium is used in special stainless steels, high-temperature alloys, and superconducting alloys such as Nb_3Sn. Niobium is also used in nuclear piles.

Niobium metal has a density of 8.6 g/cm^3 (5.0 oz/in.^{3}) at 20°C (68°F), a melting point of 2468°C (4474°F), and a boiling point of 4927°C (8900°F). Metallic niobium is quite inert to all acids except hydrofluoric, presumably owing to an oxide film on the surface. Niobium metal is slowly oxidized in alkaline solution. It reacts with oxygen and the halogens upon heating to form the oxidation state V oxide and halides, with nitrogen to form NbN, and with carbon to form NbC, as well as other elements such as arsenic, antimony, tellurium, and selenium.

The oxide Nb_2O_5, melting point 1520°C (2768°F), dissolves in fused alkali to yield a soluble complex niobate, $Nb_6O_{19}^{8-}$. Normal niobates such as NbO_4^{3-} are insoluble. The oxide dissolves in hydrofluoric acid to give ionic species such as $NbOF_5^{2-}$ and $NbOF_6^{3-}$, depending on the fluoride and hydrogen-ion concentration. The highest fluoro complex which can exist in solution is NbF_6^-. [E.M.L.]

Nippotaeniidea An order of tapeworms of the subclass Cestoda. The few known species are intestinal parasites of Eurasian fresh-water fishes. The head bears a single terminal sucker. The segmental anatomy shows relationships to the Pseudophyllidea and Cyclophyllidea. The life history is unknown. It is probable that this order is related to the proteocephalids. *See* CESTODA; CYCLOPHYLLIDEA; PSEUDOPHYLLIDEA. [C.P.R.]

Niter A potassium nitrate mineral with chemical composition KNO_3. Niter crystallizes in the orthorhombic system, generally in thin crusts and delicate acicular crystals; it occurs in massive, granular, or earthy forms. It is brittle; hardness is 2 on Mohs scale; specific gravity is 2.109. The luster is vitreous, and the color and streak are colorless to white. *See* NITRATE MINERALS.

Niter is commonly found, usually in small amounts, as a surface efflorescence in arid regions and in caves and other sheltered places. Niter occurs associated with soda niter in the desert regions of northern Chile, and in similar occurrences in Italy, Egypt, Russia, the western United States, and elsewhere. [G.Sw.]

Nitrate minerals These minerals are few in number and with the exception of soda niter are of rare occurrence. Normal anhydrous and hydrated nitrates occurring as minerals are soda niter, $NaNO_3$; niter, KNO_3: ammonia niter, NH_4NO_3; nitrobarite, $Ba(NO_3)_2$; nitrocalcite, $Ca(NO_3)_2 \cdot 4H_2O$; and nitromagnesite, $Mg(NO_3)_2 \cdot 6H_2O$. In addition there are three known naturally occurring nitrates containing hydroxyl or halogen, or compound nitrates. They are gerhardtite, $Cu_2(NO_3)(OH)_3$; buttgenbachite, $Cu_{19}(NO_3)_2Cl_4(OH)_{32}$ṁ $3H_2O$; and darapskite, $Na_3(NO_3)(SO_4) \cdot H_2O$. *See* NITER; SODA NITER.

The natural nitrates are for the most part readily soluble in water. For this reason they occur most abundantly in arid regions, particularly in South America along the Chilean coast. *See* FERTILIZER; NITROGEN. [G.Sw.]

Nitration A process in which a nitro group ($—NO_2$) becomes chemically attached to a carbon, oxygen, or nitrogen atom in an organic compound. A hydrogen or halogen atom is often replaced by the nitro group. Three general reactions summarize nitration chemistry:

1. C nitration, in which the nitro group attaches itself to a carbon atom [reaction (1)].

$$\rangle C—H + HNO_3 \longrightarrow \rangle C—NO_2 + H_2O \qquad (1)$$

2. O nitration (an esterification reaction), in which an O-N bond is formed to produce a nitrate [reaction (2)].

$$\rangle C—OH + HNO_3 \longrightarrow \rangle C—O + NO_2 + H_2O \qquad (2)$$

3. N nitration, in which a N-N bond is formed [reaction (3)].

$$\rangle NH + HNO_3 \longrightarrow \rangle N—NO_2 + H_2O \qquad (3)$$

Aromatics, alcohols, glycols, and amines are generally nitrated with mixed acids via an ionic reactions. The mixture includes nitric acid, a strong acid such as sulfuric acid which acts as a catalyst, and a small amount of water. With sulfuric acid, nitric acid is ionized to the nitronium ion, NO_2^+, which is the nitrating agent.

Propane is commercially nitrated in relatively large amounts using nitric acid in gas-phase free-radical reactions at temperatures of about 380–420°C. Nitric acid decomposes at these temperatures to produce nitrogen dioxide radicals (actually a mixture of $\cdot NO_2$ and $\cdot ONO$) and a hydroxy radical ($\cdot OH$). In the free-radical reaction, about 35–40% of the nitric acid reacts to form four C_1-C_3 nitroparaffins; C-C bonds are broken during the nitration. The remaining nitric acid acts mainly as an oxidizing agent to form aldehydes, alcohols, carbon monoxide, carbon dioxide, water, and small amounts of other oxidized materials. Commercially, an adiabatic reactor is used, and the heat of reaction is employed to preheat and vaporize the nitric acid feed (containing water).

The product stream from free-radical nitrations is a condensation of mixed nitroparaffins. This liquid mixture is washed to remove the aldehydes, and then is distilled to recover each of the four nitroparafins—nitromethane, nitroethane, 1-nitropropane, and 2-nitropropane. The unreacted propane is recovered, combined with the feed propane, and returned to the reactor. The oxides of nitrogen are converted back to nitric acid; carbon monoxide, carbon dioxide, and water are discarded.

In the classical Victor Meyer process, an organic halide (often a bromide) is reacted with silver nitrite to produce a nitrohydrocarbon and silver halide. In a modified process, sodium nitrite, dissolved in a suitable solvent, is substituted for the more expensive silver nitrite. The desired nitroalkanes are produced in high yields by these processes, whereas they are produced in rather low yields in free-radical nitrations.

Nitrations can also often be performed by addition reactions using unsaturated hydrocarbons with nitric acid or nitrogen dioxide. [L.F.A.]

Nitric acid A strong mineral acid having the formula HNO_3. Pure nitric acid is a colorless liquid with a specific gravity of 1.52 at 25°C (77°F); it freezes at −47°C (−53°F). Nitric acid is used in the manufacture of ammonium nitrate and phosphate fertilizers, nitro explosives, plastics, dyes, and lacquers. The principal commercial process for the manufacture of nitric acid is the Ostwald process, in which ammonia, NH_3, is catalytically oxidized with air to form nitrogen dioxide, NO_2. When the dioxide is dissolved in water, 60% nitric acid is formed. Production of 90–100% nitric acid is based on processes such as the reaction of sulfuric acid with sodium nitrate (an older method of nitric acid manufacture), dehydration of 60% acid, and oxidation of nitrogen dioxide in a solution of dilute nitric acid. *See* AMMONIA; NITROGEN. [F.J.J.]

Nitric oxide An important messenger molecule in mammals and other animals. It can be toxic or beneficial, depending on the amount and where in the body it is released. Initial research into the chemistry of nitric oxide (NO) was motivated by its production in car engines, which results in photochemical smog and acid rain. In the late 1980s, researchers in immunology, cardiovascular pharmacology, neurobiology, and toxicology discovered that nitric oxide is a crucial physiological messenger molecule. Nitric oxide is now thought to play a role in blood pressure regulation, control of blood clotting, immune defense, digestion, the senses of sight and smell, and possibly learning and memory. Nitric oxide may also participate in disease processes such as diabetes, stroke, hypertension, impotence, septic shock, and long-term depression. *See* IMMUNOLOGY; NEUROBIOLOGY.

Most cellular messengers are large, unreactive biomolecules that make specific contacts with their targets. In contrast, nitric oxide is a small molecule that contains a free radical—that is, an unpaired electron—making it very reactive. Nitric oxide can freely diffuse through aqueous solutions or membranes, reacting rapidly with metal centers in cellular proteins and with reactive groups in other cellular molecules.

Nitric oxide is produced in the body by an enzyme called nitric oxide synthase, which converts the amino acid L-arginine to nitric oxide and L-citrulline. There are three types of nitric oxide synthase: brain, endothelial, and inducible. Both brain and endothelial enzymes are constitutive, that is, they are always present in cells, while the production of inducible nitric oxide synthase can be turned on or off when a system needs nitric oxide. After nitric oxide is produced in specific areas of the body by nitric oxide synthase, it diffuses to nearby cells. Nitric oxide then reacts preferentially in the interior of these cells with the metal centers of proteins. Nitric oxide binds specifically to the iron (Fe) atom of the heme group in proteins; it can also interact with other metal sites in proteins as well as with the thiol group (SH) of the amino acid cysteine. The interaction of nitric oxide with these proteins causes a cascade of intracellular events that leads to specific physiological changes within cells. For example, nitric oxide causes the smooth muscle cells surrounding blood vessels to relax, decreasing blood pressure. Nitric oxide plays an important role in the central and peripheral nervous systems; the overproduction of nitric oxide in brain tissues has been implicated in stroke and other neurological problems.

Nitric oxide also functions as an important agent in the immune system by killing invading bacterial cells. Nitric oxide released by macrophages can inhibit important cellular processes in the bacteria, including deoxyribonucleic acid (DNA) synthesis and respiration, by binding to and destroying iron-sulfur centers in key enzymes in these pathways.

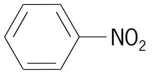
Although nitric oxide production in the immune system serves a crucial biological function, there can be adverse effects when too much nitric oxide is produced. During a massive bacterial infection, excess nitric oxide can go into the vascular system, causing a dramatic decrease in blood pressure, which may lead to possibly fatal septic shock. Thus, scientists are working on drugs that can selectively inhibit the inducible form of nitric oxide synthase in order to avoid the harmful effects produced by excess nitric oxide without interfering with useful nitric oxide pathways. [J.N.Bu.; M.F.R.]

Nitrile One of a group of organic chemical compounds of general formula RC≡N. A nitrile is named from the acid to which it can be hydrolyzed by adding the suffix -onitrile to the acid stem, for example, acetonitrile from acetic acid. An alternative system names the group attached to CN, thus CH_3CN is also named methyl cyanide. In more complex structures the CN group is named as a substituent, cyano.

Industrially, nitriles are formed by heating carboxylic acids with ammonia and a dehydration catalyst under pressure. For the preparation of acrylonitrile, which is used on a large scale in the plastics industry, a vapor-phase catalytic ammoxidation of propylene has been developed. *See* ACRYLONITRILE; AMINE. [P.E.F.]

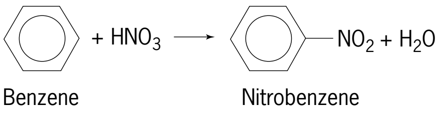
Nitro and nitroso compounds Nitro compounds are derivatives of organic hydrocarbons having one or more —NO_2 groups with nitrogen-to-carbon bonding. They differ from the oxygen-linked nitrites, which are esters. The group lacks enough electrons to form double bonds with both oxygens. However, both oxygens react alike; hence the bond is regarded as a resonance hybrid of single and double bonds.

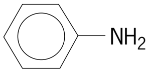
Aromatic nitro compounds have been used chiefly as dye intermediates, explosives, and Pharmaceuticals. They are formed readily by the reaction of aromatic compounds with nitric acid; H is replaced by the —NO_2 group, for example, Aliphatic nitro compounds are prepared with difficulty and have grown in importance only since the development of vapor-phase nitration of hydrocarbons with nitric acid vapors at 420°C (788°F).



Nitroso compounds contain the —NO group attached to carbon or nitrogen. Many are unstable intermediates, for example, nitrosobenzene formed during the reduction of nitrobenzene. *See* Nitration. [A.L.H.]

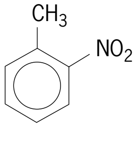
Nitroaromatic compound A member of the class of organic compounds in which the nitro group (—NO_2) is attached directly to the cyclic, aromatic nucleus. The prototypal compound is nitrobenzene. It is prepared by the reaction of benzene with nitric acid in the presence of sulfuric acid, as shown in the reactions below. The most significant use of nitrobenzene is in the manufacture of aniline (**1**). About 97% of the nitrobenzene produced in the United States is converted to aniline, which is used in the manufacture of plastics, rubber additives, dyes, drugs, and other products. *See* Benzene.



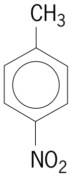


(**1**)

Second to nitrobenzene in commercial importance are the mononitrotoluenes, particularly the ortho and para isomers, (**2**) and (**3**), respectively. Reaction of toluene with a mixture of nitric and sulfuric acid at about 40°C (104°F) gives a high yield of a mixture of the isomers, which are separated by a combination of fractional distillation and crystallization. The nitrotoluenes are important intermediates in the preparation of dyes, rubber chemicals, and agricultural chemicals.

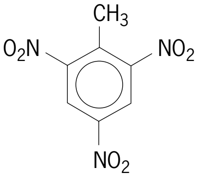


(**2**)



(**3**)

2,4,6-Trinitrotoluene (TNT; **4**) is a military explosive that is stable, nonhygroscopic, and relatively insensitive to impact, friction, shock, and electric spark. It is produced by nitration of toluene in successive stages at progressively higher temperatures and concentrations of acid.



(**4**)

Although literally thousands of other aromatic ring compounds, including the heterocyclics, have been converted to their nitro derivatives, few such compounds have achieved any significant industrial importance. *See* Aromatic hydrocarbon; Nitration. [P.E.F.]

Nitrogen A chemical element, N, atomic number 7, atomic weight 14.0067. Nitrogen, a gas under normal conditions, is the lightest element of periodic group 5 (nitrogen family). *See* Periodic table.

At standard temperature and pressure, elemental nitrogen exists as a gas with a density of 1.25046 g/liter. This value indicates that the molecular formula is N_2. Some physical properties of elemental nitrogen are listed in Table 1.

Table 1. Properties of nitrogen

Property	Value
Heat of transformation (α–β)	54.71 cal/mole
Heat of fusion	172.3 cal/mole
Heat of vaporization	1332.9 cal/mole
Critical temperature	126.26 ± 0.04 K
Critical pressure	33.54 ± 0.02 atm
Density: α form	1.0265 g/ml at −252.6°C
β form	0.8792 g/ml at −210.0°C
Liquid	$1.1607–0.0045T$ (T = abs temp)

Elemental nitrogen has a low reactivity toward most common substances at ordinary temperatures. At high temperatures, molecular nitrogen, N_2, reacts with chromium, silicon, titanium, aluminum, boron, beryllium, magnesium, barium, strontium, calcium, and lithium (but not the other alkali metals) to form nitrides; with O_2 to form NO; and at moderately high temperatures and pressures in the presence of a catalyst, with hydrogen to form ammonia. Above 1800°C (3300°F), nitrogen, carbon, and hydrogen combine to form hydrogen cyanide.

Table 2 lists the principal classes of inorganic nitrogen compounds. Thus, in addition to the typical oxidation states of the family (−3, +3, and +5), nitrogen forms compounds with a variety of additional oxidation states. *See* Amine; Ammonia; Hydrazine; Nitric acid; Nitrogen complexes; Nitrogen oxides.

Molecular nitrogen is the principal constituent of the atmosphere (78% by volume of dry air), in which its concentration is a result of the balance between the fixation of atmospheric nitrogen by bacterial, electrical (lightning), and chemical (industrial) action, and its liberation through the decomposition of organic materials by bacteria or combustion. In the combined state, nitrogen occurs in a variety of forms. It is a constituent of all proteins (both plant and animal) as well as of many other organic materials. Its chief mineral source is sodium nitrate.

The methods for the preparation of elementary nitrogen may be grouped into two classes, separation from the atmosphere and decomposition of nitrogen compounds. The industrial method

Table 2. Compounds of nitrogen

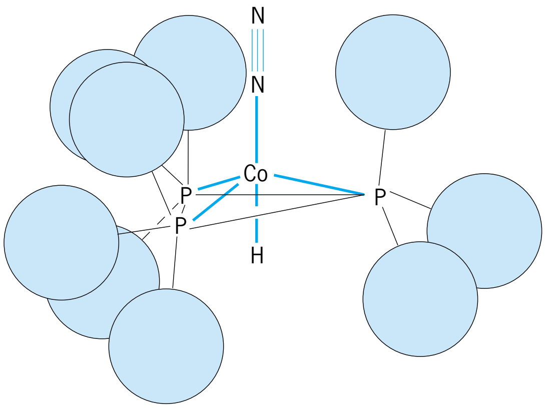
Oxidation state	Examples
+5	N_2O_5, HNO_3, nitrates, NO_2X
+4	$N_2O_4 \rightleftharpoons 2NO_2$
+3	N_2O_3, HNO_2, nitrites, NOX, NX_3
+2	NO, Na_2NO_2, nitrohydroxylamates
+1	N_2O, $H_2N_2O_2$, hyponitrites
0	N_2
−1/3	HN_3, acids
−1	NH_2OH, hydroxylammonium salts
−2	NH_2NH_2, hydrazinium salts, hydrazides
−3	NH_3, ammonium salts, amides, imides, nitrides

for the production of nitrogen is the fractional distillation of liquid air. Nitrogen containing about 1% argon and traces of other inert gases may be obtained by the chemical removal of oxygen, carbon dioxide, and water vapor from the atmosphere by appropriate chemical reagents.

Because the importance of nitrogen compounds in agriculture and chemical industry, much of the industrial interest in elementary nitrogen has been in processes for converting elemental nitrogen into nitrogen compounds. The principal methods for doing this are the Haber process for the direct synthesis of ammonia from nitrogen and hydrogen, the electric are process, which involves the direct combination of N_2 and O_2 to nitric oxide, and the cyanamide process. Nitrogen is also used for filling bulbs of incandescent lamps and, in general, wherever a relatively insert atmosphere is required. [H.H.S.]

Nitrogen complexes Compounds containing the dinitrogen molecule, N_2, bound to a metal (also called dinitrogen complexes). Outstanding in their ability to form coordination compounds with nitrogen are a number of metals which belong to the group 7 transition metal family. For each metal of this group, several nitrogen complexes have been identified. Nitrogen complexes of these metals occur in low oxidation states, such as Co(I) or Ni(O). The other ligands present in these complexes besides N_2 are usually of a type known to stabilize low oxidation states; phosphines appear to be particularly prominent bonding partners in this respect. The illustration shows the structure of a typical N_2 complex, elucidated by a crystal structure determination. The N-N bond axis in this complex is aimed, within the limits of experimental error, directly toward the position of the metal atom. The Co-N_2 bond length, 0.18 nanometer, is within the normal range of comparable metal-ligand bonds. *See* Coordination Chemistry.

Even in most favorable cases the binding of the dinitrogen molecule to the metal is fairly labile; all the compounds lose their nitrogen on mild heating. Some of the nitrogen complexes are only metastable to loss of dinitrogen even at room temperature; accordingly, they cannot be obtained by direct uptake of gaseous nitrogen. In the synthesis of these metastable complexes, hydrazine or azide compounds serve as a source of nitrogen molecules within the coordination sphere of the metal. Addition of other coordinating agents to the nitrogen complexes usually results in a displacement of N_2 from the metal. The cobalt compound in the illustration exchanges its N_2 ligand quite reversibly for other ligand molecules, such as NH_3 and $H_2C{=}CH_2$. Whereas these ligands are easily displaced again by an excess of N_2, an irreversible exchange occurs with carbon monoxide. The bulky organic groups on the phosphine ligands are likely to interfere with the approach to the metal of all but the slimmest ligands and thereby help the "thin" dinitrogen molecule to maintain or regain its position on the metal in competition with most other ligands. [H.B.]



Structure of a coordination compound with N_2 (circles represent phenyl groups).

Nitrogen cycle The collective term given to the natural biological and chemical processes through which inorganic and organic nitrogen are interconverted. It includes the process of ammonification, ammonia assimilation, nitrification, nitrate assimilation, nitrogen fixation, and denitrification.

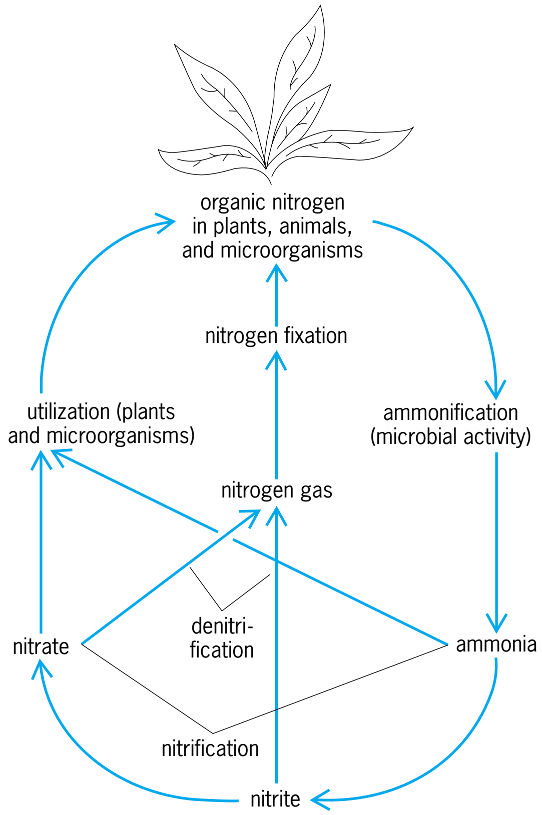


Diagram of the nitrogen cycle.

Nitrogen exists in nature in several inorganic compounds, namely N_2, N_2O, NH_3, NO_2^-, and NO_3^-, and in several organic compounds such as amino acids, nucleotides, amino sugars, and vitamins. In the biosphere, biological and chemical reactions continually occur in which these nitrogenous compounds are converted from one form to another. These interconversions are of great importance in maintaining soil fertility and in preventing pollution of soil and water.

An outline showing the general interconversions of nitrogenous compounds in the soil-water pool is presented in the illustration. There are three primary reasons why organisms metabolize nitrogen compounds: (1) to use them as a nitrogen source, which means first converting them to NH_3, (2) to use certain nitrogen compounds as an energy source such as in the oxidation of NH_3 to NO_2^- and of NO_2^- to NO_3^-, and (3) to use certain nitrogen compounds (NO_3^-) as terminal electron acceptors under conditions where oxygen is either absent or in limited supply. The reactions and products involved in these three metabolically different pathways collectively make up the nitrogen cycle.

There are two ways in which organisms obtain ammonia. One is to use nitrogen already in a form easily metabolized to ammonia. Thus, nonviable plant, animal, and microbial residues in soil are enzymatically decomposed by a series of hydrolytic and other reactions to yield biosynthetic monomers such as amino acids and other small-molecular-weight nitrogenous compounds. These amino acids, purines, and pyrimidines are decomposed further to produce NH_3 which is then used by plants and bacteria for biosynthesis, or these biosynthetic monomers can be used directly by some microorganisms. The decomposition process is called ammonification.

The second way in which inorganic nitrogen is made available to biological agents is by nitrogen fixation (this term is maintained even though N_2 is now called dinitrogen), a process in which N_2 is reduced to NH_3. Since the vast majority of nitrogen is in the form of N_2, nitrogen fixation obviously is essential to life. The N_2-fixing process is confined to prokaryotes (certain photosynthetic and nonphotosynthetic bacteria). The major nitrogen fixers (called diazotrophs) are members of the genus *Rhizobium*, bacteria that are found in root nodules of leguminous plants, and of the cyanobacteria (originally called blue-green algae). *See* Nitrogen fixation. [L.E.Mo.]

Nitrogen fixation The chemical or biological conversion of atmospheric nitrogen (N_2) into compounds which can be used by plants, and thus become available to animals and humans. In the 1990s, chemical and biological processes together contributed about 260 million tons (230 million metric tons) of fixed nitrogen per year globally. Industrial production of nitrogen fertilizer accounted for about 85 million tons (80 million metric tons) of nitrogen per year, while spontaneous chemical processes, such as lightning, ultraviolet irradiation, and combustion, leading to the synthesis of nitrogen oxides from O_2 and N_2, may have accounted for 44 million tons (40 million metric tons) per year. The remainder, roughly half of the global input of newly fixed nitrogen, arose from biological processes. World agriculture, which is very dependent on nitrogen fixation, is increasingly reliant on chemical nitrogen sources. *See* Nitrogen.

Chemical fixation. Three chemical processes for fixing atmospheric nitrogen have been developed. All require considerable thermal or electrical energy and yield different products. In arc processes, which are now rarely used, air is passed through an electric arc and about 1% nitric oxide is formed, which can be chemically converted to nitrates. In the cyanamide process, which is now obsolete, heating calcium carbide in nitrogen generates calcium cyanamide, which when moistened hydrolyzes to urea and ammonia. In the widely used Haber process, hydrogen (generated by heating natural gas) is mixed with nitrogen (from air), and burned to yield a nitrogen-hydrogen mixture. The nitrogen-hydrogen mixture is compressed (10–80 megapascals) and heated (200–700°C or 390–1300°F) in the presence of a metal oxide catalyst to give ammonia. The Haber process is the major source of ammonia used for fertilizer. *See* Ammonia; Cyanamide; Electrochemical process; Fertilizer; High-pressure processes.

Biological fixation. Only prokaryotes—bacteria, archaea, and cyanobacteria (earlier called blue-green algae)—fix nitrogen. Nitrogen-fixing microbes, called diazotrophs, fall into two main groups, free-living and symbiotic. *See* Archaebacteria; Bacteria; Cyanobacteria; Prokaryotae.

The free-living diazotrophs are subclassified. Aerobic diazotrophs, of which there are over 50 genera, including *Azotobacter*, methane-oxidizing bacteria, and cyanobacteria, require oxygen for growth and fix nitrogen when oxygen is present. *Azotobacter*, some related bacteria, and some cyanobacteria fix nitrogen in ordinary air, but most members of this group fix nitrogen only when the oxygen concentration is low. Free-living diazotrophs, which fix nitrogen only when oxygen is absent or vanishingly low, are widespread. The genera *Bacillus* and *Klebsiella* include many strains of this type, and representatives of symbiotic diazotrophs behave in this way as well. *See* Algae; Bacterial physiology and metabolism.

The best-known symbiotic bacteria belong to the genus *Rhizobium*. Species of *Rhizobium*, or related genera, such as *Bradyrhizobium* and *Sinorhizobium*, colonize the roots of leguminous plants and stimulate the formation of nodules within which they fix nitrogen microaerobically. Both plants and bacteria show specificity; for example, certain types of plants require special strains of rhizobia. Some types of rhizobium, such as *Bradyrhizobium*, can fix nitrogen in the absence of plant tissue, but require low oxygen, though most rhizobia fix nitrogen only within the nodules. *See* Soil microbiology.

The enzymes responsible for nitrogen fixation are called nitrogenases. The most common nitrogenase consists of two proteins, one large containing molybdenum, iron, and inorganic sulfur (the MoFe-protein or dinitrogenase), the other smaller containing iron and inorganic sulfur (the Fe-protein or dinitrogenase reductase). Nitrogenase reduces one molecule of N_2 to two of ammonia (NH_3), a reaction which is accompanied by the conversion of 16 molecules of adenosine triphosphate (ATP) to adenosine diphosphate (ADP) and the release of one molecule of H_2 as a by-product. Nitrogenase is irreversibly destroyed by air, so all aerobic diazotrophs have developed means of restricting access of oxygen to the active enzyme. [J.Po.]

Nitrogen oxides Chemical compounds of nitrogen and oxygen. Nitrogen and oxygen do not combine when mixed directly (as in air), but they do combine during chemical reactions of compounds containing them. A number of nitrogen oxides can be isolated which differ from one another in the numbers of nitrogen and oxygen atoms present in each molecule. The table gives data for the five nitrogen oxides which are well established.

Nitrous oxide and nitric oxide. When inhaled, nitrous oxide has anesthetic effects; in small amounts it produces mild hysteria and hence is sometimes called laughing gas. It is colorless, is the least reactive of the oxides, and dissolves in water without chemical reaction. Some nitric oxide is formed in an electric arc, as in the technical production of nitric acid.

With oxygen or air, nitric oxide is rapidly converted to nitrogen dioxide. Nitric oxide is colorless and is soluble in water without reaction. It is an important messenger molecule in animals. It is one of the few "odd" molecules which contain an odd number of electrons. As an odd molecule, it has the ability to lose or gain one electron, thus giving the electrically charged ions NO^+ and NO^-. The important nitrosyl compounds contain these ions.

Trioxide. Dinitrogen trioxide exists pure only in the solid state. It is the anhydride of nitrous acid; when the oxide is dissolved in an alkaline solution, nitrite ion is produced.

Dioxide and tetroxide. The position of the equilibrium between nitrogen dioxide and dinitrogen tetroxide depends upon temperature and physical state. Dinitrogen tetroxide reacts readily with water to give an equimolecular mixture of nitrous and nitric acids. As temperature is raised, the nitrous acid decomposes to nitric acid and nitric oxide. These reactions are important in the technical production of nitric acid by catalytic oxidation of ammonia. Dinitrogen tetroxide is an oxidizing agent comparable in strength to bromine, and is employed as such in the lead-chamber process for sulfuric acid. In organic chemistry the tetroxide finds use as a special oxidizing agent (for example, in the production of sulfoxides and phosphine oxides) and as a nitrating agent.

Pentoxide. Solid dinitrogen pentoxide readily volatilizes, and the molecular type of structure found in the gaseous state is observed also in solutions of the oxide in low dielectric solvents such as carbon tetrachloride and chloroform. Sodium metal

Oxides of nitrogen and their properties

Name	Stoichiometric formula	Melting point, °C (°F)	Boiling point, °C (°F)
Nitrous oxide (dinitrogen monoxide)	N_2O	−90.8 (−131)	−88.5 (−127.3)
Nitric oxide (nitrogen monoxide)	NO	−163.6 (−262.5)	−151.7 (241.0)
Dinitrogen trioxide	N_2O_3	−103 (−155)	3.5 (38.3)
Dinitrogen tetroxide ($\rightleftharpoons$ nitrogen dioxide)	N_2O_4 ($\rightleftharpoons NO_2$)	−11.2 (11.8)	21.2 (70.2)
Dinitrogen pentoxide	N_2O_5	41 (106)	

reacts with the liquid oxide, liberating nitrogen dioxide and forming sodium nitrate. Gaseous dinitrogen pentoxide decomposes readily, and is a strong oxidizing agent. With water it is converted to nitric acid. *See* NITRIC OXIDE; NITROGEN; OXYGEN. [C.C.A.]

Nitroparaffin Any derivative of an aliphatic hydrocarbon that contains one or more —NO_2 groups bonded via nitrogen to the carbon framework. Nitroparaffins are also known as nitroalkanes.

Low-molecular-weight nitroparaffins are prepared via the vapor-phase nitration of alkanes at >400°C (750°F). However, the process is not generally satisfactory for higher-molecular-weight nitroparaffins because of polynitration and chain cleavage. The direct nitration of propane is used commercially to prepare nitromethane (boiling point 101°C or 214°F), nitroethane (bp 114°C or 237°F), 1-nitropropane (bp 131°C or 268°F), and 2-nitropropane (bp 120°C or 248°F). Nitroparaffins are prepared in the laboratory by the reaction of nitrite salts with alkyl bromides or iodides, from the oxidation of amines or oximes by using peroxycarboxylic acids, and by the chain homologation of simple nitroparaffins. *See* NITRATION.

Nitromethane, nitroethane, and the nitropropanes are useful solvents with high dielectric constants that readily dissolve many polymers. In addition, these simple nitroparaffins are versatile intermediates for the synthesis of specialty chemicals. [A.G.M.B.]

Nobelium A chemical element, No, atomic number 102. Nobelium is a synthetic element produced in the laboratory. It decays by emitting an alpha particle, that is, a doubly charged helium ion. Only atomic quantities of the element have been produced to date. Nobelium is the tenth element heavier than uranium to be produced synthetically. It is the thirteenth member of the actinide series, a rare-earth-like series of elements. *See* ACTINIDE ELEMENTS; PERIODIC TABLE; RADIOACTIVITY; RARE-EARTH ELEMENTS; TRANSURANIUM ELEMENTS. [P.R.F.]

Noeggerathiales An incompletely known and poorly de-fined group of vascular plants whose geologic range extends from Upper Carboniferous to Triassic. Their taxonomic status and position in the plant kingdom are uncertain since morphological evidence (because of the paucity of the fossil record) does not make it possible to place the group confidently in any recognized major subdivision of the vascular plants. The Noeggerathiales have been proposed in the evolutionary scheme in two remotely related groups of vascular plants, the Pteropsida and the Sphenopsida. *See* PALEOBOTANY; PLANT KINGDOM. [E.S.B.]

Noise measurement The process of quantitatively determining one or more properties of acoustic noise. In noise assessment and control studies, knowledge of the physical properties of the undesirable sound is the initial step toward understanding the situation and what should be done to reduce or eliminate a noise problem.

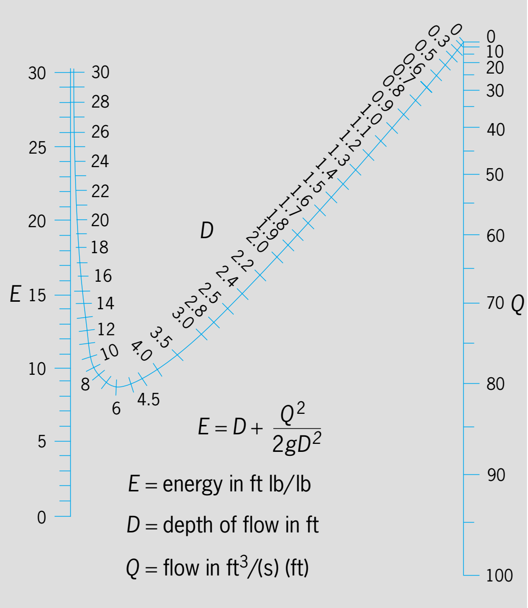
The most common measures of noise are of the magnitude and frequency content of the noise sound pressure, time-averaged or as a function of time. Of increasing interest are metrics of sound quality (that may include both physical and psychoacoustic factors), such as loudness, pitch strength, and fluctuation strength. To characterize the noise output of a source, sound power level may be determined. To locate a source or to quantify propagation paths, sound intensity level may be measured.

Essentially all noise measurements are performed using electronic equipment. An electroaoustic transducer (a microphone in air and other gases; a hydrophone in water and other liquids) transforms sound (usually the sound pressure) at the point of observation into a corresponding electrical signal. This electrical signal is then operated on by analog or digital means with devices such as signal conditioners, filters, and detectors to determine the value (or values) of interest. This value is then given on an indicating meter or digital display. *See* ELECTRIC FILTER; HYDROPHONE; MICROPHONE; TRANSDUCER.

For noise measurements in air, a sound-level meter is the most commonly used instrument. The simplest sound-level meter comprises a microphone, a frequency-weighting filter, a root-mean-square (rms) detector, and logarithmic readout of the sound pressure level in decibels relative to 20 micropascals. Standard frequency weightings, designated A and C, were originally developed to approximate human response to noise at low and high levels, respectively, but now are used as specified in standards and legislation without regard to their origin. More sophisticated sound-level meters incorporate standardized octave-band or fractional-octave-band filters, and provide additional metrics and analysis capabilities. *See* DECIBEL; LOUDNESS.

Selection of a noise metric and measurement instrument generally depends upon the application. Four classes of application are: (1) discrete source emission, (2) hearing conservation, (3) outdoor environmental noise, and (4) indoor room noise. Within these classes there are found additional subclasses, measurements for enforcement of legal limits often being done differently than those for comfort, aircraft sonic boom being measured differently than power plant noise, and so on. [J.Pop.]

Nomograph A graphical relationship between a set of variables that are related by a mathematical equation or law. The fundamental principle involved in the construction of a nomographic or alignment chart consists of representing an equation containing three variables, $f(u,v,w) = 0$, by means of three scales in such a manner that a straight line cuts the three scales in values of u, v, and w, satisfying the equation. The cutting line is called the isopleth or index line. Numbers may be quickly and easily read from the scales of such a chart even by one unfamiliar with the construction of the chart and the equation involved. The illustration shows such an example. Assume that it is desired to find the value of E when $D = 2$ and $Q = 50$. Lay a straightedge through 50 on the Q scale and through 2 on the D scale and read 11.8 at its intersection with the E scale. As another example, it might be desired to know what value or values of D should be used if E and Q are required to be 10 and 60, respectively. A straightedge through $E = 10$ and $Q = 60$ cuts the D scale in two points, $D = 2.8$ and $D = 9.4$. This is equivalent to finding two



Nomograph for energy content of a rectangular channel with uniform flow.

positive roots of the cubic equation $D^3 - 10D^2 + 56.25 = 0$. It is assumed that $g = 32$ ft/s^2 in this equation. [R.D.D.]

Nondestructive evaluation

Nondestructive evaluation (NDE) is a technique used to probe and sense material structure and properties without causing damage. It has become an extremely diverse and multidisciplinary technology, drawing on the fields of applied physics, artificial intelligence, biomedical engineering, computer science, electrical engineering, electronics, materials science and engineering, mechanical engineering, and structural engineering. Historically, NDE techniques have been used almost exclusively for detection of macroscopic defects (mostly cracks) in structures which have been manufactured or placed in service. Using NDE for this purpose is usually referred to as nondestructive testing (NDT).

A developing use of NDE methods is the nondestructive characterization (NDC) of materials properties (as opposed to revealing flaws and defects). Characterization typically sets out to establish absolute or relative values of material properties such as mechanical strength (elastic moduli), thermal conductivity or diffusivity, optical properties, magnetic parameters, residual strains, electrical resistivity, alloy composition, the state of cure in polymers, crystallographic orientation, and the degree of crystalline perfection. Nondestructive characterization can also be used for a variety of other specialized properties that are relevant to some aspect of materials processing in production, including determining how properties vary with the direction within the material, a property called anisotropy.

Much effort has been directed to developing techniques that are capable of monitoring and controlling (1) the materials production process; (2) materials stability during fabrication, transport, and storage; and (3) the amount and rate of degradation during the postfabrication in-service life for both components and structures. Real-time process monitoring for more efficient real-time process control, improved product quality, and increased reliability has become a practical reality. *See* MATERIALS SCIENCE AND ENGINEERING.

Visual inspection is the oldest and most versatile NDE tool. In visual inspection, a worker examines a material using only eyesight. The liquid (or dye) penetrant visual method uses brightly colored liquid dye to penetrate and remain in very fine surface cracks after the surface is cleaned of residual dye. The magnetic particle visual method requires that a magnetic field be generated inside a ferromagnetic test object. Flux leakage occurs where there are discontinuities on the surface. Magnetic particles (dry powder or a liquid suspension) are captured at the leakage location and can be readily seen with proper illumination.

The eddy current method uses a probe held close to the surface of a conducting test object. X-rays provide a varied and powerful insight into material, but they are somewhat limited for use in the field. The acoustic emission technique typically uses a broadband piezoelectric transducer to listen for acoustic noise. The thermography technique uses a real-time "infrared camera," much like a home camcorder, except that it forms images using infrared photons instead of visible ones. Contact ultrasonics technique is the workhorse of traditional and mature NDE technology. It uses a transducer held in contact with a test object to launch ultrasonic pulses and receive echoes. *See* EDDY CURRENT; X-RAY DIFFRACTION.

Many noncontact measurements have been developed that enhance the mature technologies. These include noncontact ultrasonic transducers that involve laser ultrasonics, electromagnetic acoustic transducers, and air- or gas-coupled transducers. Thermal wave imaging uses a main laser beam to scan the surface of the object to be examined. Electronic speckle pattern interferometry is a noncontact, full-field optical technique for high-sensitivity measurement of extremely small displacements in an object's surface. "Speckle" refers to the grainy appearance of an optically rough surface illuminated by a laser. Development of microwave techniques are under way in such diverse applications as ground-penetrating radar for land-mine detection, locating delaminations in highway bridge decks, and monitoring the curing process in polymers. *See* INTERFEROMETRY; LASER; TRANSDUCER; ULTRASONICS. [J.M.Win.]

Noneuclidean geometry

A system of geometry based upon a set of axioms different from those of the euclidean geometry based on the three-dimensional space of experience. Noneuclidean geometries, especially riemannian geometry, are useful in mathematical physics. *See* DIFFERENTIAL GEOMETRY; EUCLIDEAN GEOMETRY; PROJECTIVE GEOMETRY; RIEMANNIAN GEOMETRY. [J.D.C.]

K. F. Gauss is credited with discovering an "elliptic" noneuclidean geometry in which there are no parallels, but the other euclidean axioms are satisfied. One way to model it is to call each diameter of a sphere a "point," and call each plane through the center (intersecting the sphere in a great circle) a "line." Then each two points determine a unique line and each two lines determine one point.

Another type of noneuclidean geometry, called hyperbolic geometry, was discovered about 1830 by J. Bolyai and N. I. Lobachevski. Through a given point P not on a line l, there are many lines that do not meet l. This geometry may be modeled by defining as "lines" those circular arcs that meet a large circle C at right angles and restricting the term "points" to those within the absolute circle C. Then two points determine a unique line, but there are many lines through a point P not on a line l that do not intersect l. Since consistent geometries exist in which the parallel postulate does not hold, this postulate is independent of the others. [J.S.Fra.]

According to whether the geometry is elliptic, euclidean, or hyperbolic, the sum of the angles of a geodesic triangle is greater than π, equal to π, or less than π.

Elliptic geometry of two dimensions may be represented upon a sphere in euclidean space of three dimensions. On the other hand, hyperbolic geometry of two dimensions can be depicted on a pseudosphere in euclidean space of three dimensions. The pseudosphere is obtained by revolving the tractrix about its asymptote. [J.D.C.]

Nonlinear acoustics

The study of amplitude-dependent acoustical phenomena. The amplitude dependence is due to the nonlinear response of the medium in which the sound propagates, and not to the nonlinear behavior of the sound source. According to the linear theory of acoustics, increasing the level of a source by 10 dB results in precisely the same sound field as before, just 10 dB more intense. Linear theory also predicts that only frequency components radiated directly by the source can be present in the sound field. These principles do not hold in nonlinear acoustics. *See* AMPLITUDE (WAVE MOTION); LINEARITY; NONLINEAR PHYSICS.

The extent to which nonlinear acoustical effects are strong or even significant depends on the competing influences of energy loss, frequency dispersion, geometric spreading, and diffraction. When conditions are such that nonlinear effects are strong, acoustic signals may experience substantial waveform distortion and changes in frequency content as they propagate, and shock waves may be present. Nonlinear acoustical effects occur in gases, liquids, and solids, and they are observed over a broad range of frequencies. Shock waves present in sonic booms and thunder claps are in the audio frequency range. Principles of nonlinear acoustics form the basis for procedures at megahertz frequencies used in medical ultrasound and nondestructive evaluation of materials. Nonlinearity can also induce changes in nonfluctuating properties of the medium. These include acoustic streaming, which is the steady fluid flow produced by the absorption of sound, and radiation pressure, which results in a steady force exerted by sound on its surroundings. *See* ACOUSTIC radiation pressure; Biomedical ultrasonics; Nondestructive evaluation; Shock wave; Sonic boom; Thunder.

The principal feature that distinguishes nonlinear acoustics from nonlinear optics is that most acoustical media exhibit only weak dispersion, whereas media in which nonlinear optical effects arise exhibit strong dispersion. Dispersion is the dependence of propagation speed on frequency. In optical media, strong nonlinear wave interactions require that phase-matching conditions be satisfied, which can be accomplished only for several frequency components at one time. In contrast, all frequency components in a sound wave propagate at the same speed and are automatically phase-matched, which permits strong nonlinear interactions to occur among all components in the frequency spectrum. *See* Nonlinear optics.

Acoustic streaming is a nonlinear effect because the velocity of the flow depends quadratically on the amplitude of the sound, and the flow is not predicted by linear theory. Absorption due to viscosity and heat conduction results in a transfer of momentum from the sound field to the fluid. This momentum transfer manifests itself as steady fluid flow.

Acoustic streaming produced in sound beams is enhanced considerably when shocks develop. Shock formation generates a frequency spectrum rich in higher harmonics. Because thermoviscous absorption increases quadratically with frequency, attenuation of the wave, and therefore the streaming velocity, increases markedly following shock formation. Streaming is also generated in acoustic boundary layers formed by standing waves in contact with surfaces. Measurements of acoustic streaming have been used to determine the bulk viscosity coefficients of fluids. Thermoacoustic engines and refrigerators are adversely affected by heat transport associated with streaming. *See* Thermoacoustics.

Phase conjugation refers to wavefront reversal, also called time reversal, at a single frequency. The latter terminologies more clearly describe this procedure. A waveform is captured by a phase conjugation device and reversed in such a way that it propagates back toward the source in the same way that it propagated toward the conjugator. Sound that is radiated from a point source and propagates through an inhomogeneous medium that introduces phase distortion in the wave field is thus retransmitted by the conjugator in such a way as to compensate for the phase distortion and to focus the wave back on the point source.

Phase conjugation is used to compensate for phase distortion in applications involving imaging and retargeting of waves on sources. The most successful techniques for acoustical phase conjugation are based on modulation of acoustical properties of a material that captures the incident sound wave. The modulation is twice the frequency of the incident sound wave, and it is induced by an electric field applied to piezoelectric material, or a magnetic field applied to magnetostrictive material. Often the modulated property of interest is the sound speed in the material. When the incident wave at frequency f propagates through a medium in which the sound speed fluctuates at frequency $2f$, parametric interaction generates a wave at the difference frequency f that propagates backward as though reversed in time. *See* Magnetostriction; Optical phase conjugation; Piezoelectricity.

Phenomena associated with nonlinear acoustics have proved useful in both diagnostic and therapeutic applications of biomedical ultrasound. A very significant breakthrough in diagnostic imaging, especially for echocardiography and abdominal ultrasound imaging, is based on second-harmonic generation. Medical ultrasound imaging is performed at frequencies of several megahertz. Images constructed from the backscattered second-harmonic component have substantially reduced clutter and haze associated with the propagation of ultrasound through the outer layers of skin, which is the primary cause of phase aberrations. In another technique, microbubbles are injected into the bloodstream to enhance echoes backscattered from blood flow. The microbubbles are fabricated to make them resonant at diagnostic imaging frequencies, and they become strongly nonlinear oscillators when excited by ultrasound. Imaging is based on echoes at harmonics of the transmitted signal. Frequencies backscattered from the microbubbles differ from those in echoes coming from the surrounding tissue, which highlights the locations of the microbubbles and therefore of the blood flow itself.

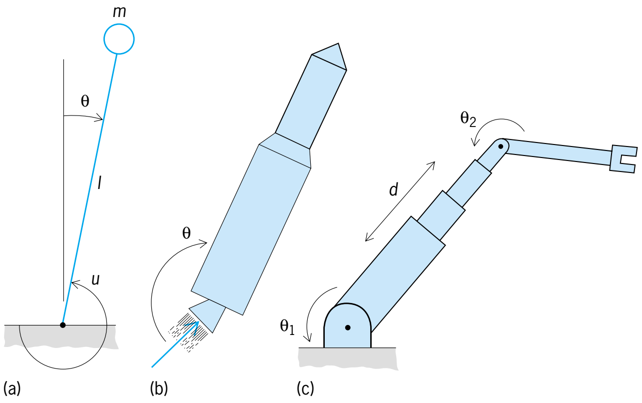
A notable therapeutic application is lithotripsy, which refers to the noninvasive disintegration of kidney stones and gallstones with focused shock waves. Nonlinear acoustical effects in lithotripsy are associated not only with propagation of the shock wave but also with the generation of cavitation activity near the stones. Radiation of shock waves due to the collapse of cavitation bubbles is believed to be the dominant cause of stone breakup. An emerging therapeutic application, high-intensity focused ultrasound (HIFU), utilizes the heat dissipated by shock waves that develop in beams of focused ultrasound. The heating is so intense and localized that the potential exists for noninvasive cauterization of internal wounds and removal of tumors and scar tissue. *See* Cavitation; Ultrasonics. [M.F.H.]

Nonlinear control theory A control system involves a plant and a controller. Plants are objects as diverse as a satellite, a distillation column, a robot arm, and a colony of bacteria. After measuring actual outputs of the plant, the controller computes signals that are applied at the inputs to the plant to achieve desired outputs. The design of controllers must be based upon mathematical models of plants, which are in most realistic situations composed of nonlinear differential and difference equations. A standard approach is to linearize the equations and use the powerful methods available for the design of linear control systems. *See* Differential equation; Linear system analysis; Optimal control (linear systems).

When the controlled outputs are allowed to have large deviations from the desired steady-state values, a linearized model will cease to describe the plant accurately, thereby causing erroneous results in the design. Linearized design models also fail in those important situations where nonlinearities are introduced into a controller to achieve a desired performance, generally at reduced cost. Typical examples of nonlinear controllers are on-off relays for temperature regulation in heating and cooling systems, switching elements in robot manipulators, and jet thrusters for the attitude control of space vehicles.

Unlike linear systems, there is no general theory for nonlinear systems. Nonlinear control theory is fragmented into areas centered around those classes of systems that are most prominent in applications.

A simple nonlinear control system is the inverted pendulum (illus. *a*), where it is required to keep the pendulum in an upright position by applying the torque $u(t)$ at its base. The pendulum can be considered as a generic model for a rocket booster



Nonlinear systems. (*a*) Inverted pendulum, which serves as a model for (*b*) a rocket booster and (*c*) a robot arm.

balanced on top of a gimbaled thruster engine (illus. *b*), and a controlled robot arm (illus. *c*). Newton's second law of motion for the pendulum is Eq. (1), where m is the mass of the bob,

$$m\dot{\theta}(t) = \frac{mg}{\ell} \sin\theta(t) + u(t) \tag{1}$$

ℓ is the length of the pendulum, and g is the acceleration due to gravity. By choosing the angular position $\theta = x_1$ and angular velocity $\dot{\theta} = x_2$ of the bob as the state of the system, Eq. (1) can be rewritten as two first-order state equations (2).

$$\begin{aligned} \dot{x}_1 &= x_2 \\ \dot{x}_2 &= \frac{g}{\ell} \sin x_1 + u \end{aligned} \tag{2}$$

See PENDULUM.

If the torque is absent ($u = 0$), the upright position of a motionless pendulum ($\dot{x}_1 = 0$, $\dot{x}_2 = 0$) is an equilibrium state: $x_1 = 0, x_2 = 0$. If the pendulum is slightly perturbed at this state, it will fall down and keep oscillating around the other equilibrium point at $x_1 = \pi$ and $x_2 = 0$, where again, $\dot{x}_1 = 0$ and $\dot{x}_2 = 0$.

To keep the pendulum in the upright position in physically realistic situations involving perturbations, the torque u is chosen to be a suitable function ϕ of the state x_1, x_2, as in Eq. (3). That

$$u = \phi(x_1, x_2) \tag{3}$$

u should be a feedback control law in terms of the state is one of the most important results of control theory. [D.D.S.]

Nonlinear optical devices Devices that use the fact that the polarization in any real medium is a nonlinear function of the optical field strength to implement various useful functions. The nonlinearities themselves can be grouped roughly into second-order and third-order. Materials that possess inversion symmetry typically exhibit only third-order nonlinearities, whereas materials without inversion symmetry can exhibit both second- and third-order nonlinearities. *See* CRYSTALLOGRAPHY; ELECTRIC SUSCEPTIBILITY; ELECTROMAGNETIC RADIATION; POLARIZATION OF DIELECTRICS.

Second-order devices. Devices based on the second-order nonlinearity involve three-photon (or three-wave) mixing. In this process, two photons are mixed together to create a third photon, subject to energy- and momentum-conservation constraints. Different names are ascribed to this mixing process, depending upon the relative magnitudes of the energies of the three photons. *See* CONSERVATION OF ENERGY; CONSERVATION OF MOMENTUM.

When the two beginning photons are of equal energy or frequency, the mixing process gives a single photon with twice the energy or frequency of the original ones. This mixing process is called second-harmonic generation. Second-harmonic generation is used often in devices where photons of visible frequency are desired but the available underlying laser system is capable of producing only infrared photons. For example, the neodymium-doped yttrium-aluminum-garnet (Nd:YAG) laser produces photons in the infrared with a wavelength of 1.06 micrometers. These photons are mixed in a crystal with a large second-order nonlinearity and proper momentum-conservation characteristics to yield green second-harmonic photons of 0.532-μm wavelength. Under different momentum-conservation constraints, a similar interaction can take place between two photon fields of different frequency, resulting in photons whose energy or frequency is the sum of those of the original photons. This process is called sum-frequency mixing. *See* LASER.

Optical parametric oscillation/amplification occurs when one of the two initial photons has the largest energy and frequency of the three. A high-energy photon and a low-energy photon mix to give a third photon with an energy equal to the difference between the two initial photons. If initially the third field amplitude is zero, it is possible to generate a third field from nothing; in this case the process is called optical parametric oscillation. If the third field exists but at a low level, it can be amplified through the optical parametric amplification process. *See* PARAMETRIC AMPLIFIER.

Third-order devices. Devices based on the third-order nonlinearity involve a process called four-photon (or four-wave) mixing. In this process, three photons are mixed together to create a fourth photon, subject to energy- and momentum-conservation constraints. The four-photon mixing nonlinearity is responsible for the existence of so-called self-action effects where the refractive index and absorption coefficient of a light field are modified by the light field's own presence, for third-harmonic generation and related processes, and for phase-conjugation processes.

In a medium with a third-order nonlinearity, the refractive index and absorption coefficient of a light field present in the medium are modified by the strength of the light intensity. Because the field effectively acts on itself, this interaction is termed a self-action effect. The momentum-conservation constraints are automatically satisfied because of the degenerate frequencies involved in the interaction. Such an interaction manifests itself by changing the total absorption experienced by the light field as well as by changing the velocity of propagation of the light field. *See* ABSORPTION OF ELECTROMAGNETIC RADIATION; REFRACTION OF WAVES.

There are many devices based on the self-action effects. A reverse saturable absorber becomes more opaque because of the nonlinear absorption (also called two-photon adsorption) that it manifests. Refractive-index changes can be used to change the transmission characteristics of resonant cavities and other structures by modifying the effective optical path length (the product of actual structure length times the effective refractive index for the structure) and shifting the cavity resonances to other frequencies. Several nonlinear optical switches have been proposed based upon this resonance-shifting phenomenon. *See* CAVITY RESONATOR; OPTICAL BISTABILITY.

In a third-harmonic generation process, three photons of like energy and frequency are mixed to yield a single photon with three times the energy and frequency of the initial photons. Applications of third-harmonic generation are typically in the areas of frequency upconversion.

Phase-conjugation devices make use of a property that third-order media possess whereby energy- and frequency-degenerate photons from two counterpropagating fields are mixed with an incoming photon to yield a photon with exactly the opposite propagation direction and conjugate phase. This phase-conjugate field will pass out of the nonlinear optical device in exactly the direction opposite to the incoming field. Such devices are used in phase-conjugate mirrors, mirrors which have the ability to cancel phase variation in a beam due to, for example, atmospheric turbulence. *See* ADAPTIVE OPTICS; OPTICAL PHASE CONJUGATION.

The suitability of available nonlinear optical materials is a critical factor in the development of nonlinear optical devices. For certain applications, silica glass fibers may be used. Because of the long propagation distances involved in intercontinental transmission systems, the small size of the optical nonlinearity in silica is not a drawback. Other key materials are semiconductors [such as gallium arsenide (GaAs), zinc selenide (ZnSe), and indium gallium arsenide phosphide (InGaAsP)], certain organic polymeric films, hybrid materials such as semiconductor-doped glasses, and liquid crystals. *See* NONLINEAR OPTICS; OPTICAL MATERIALS. [D.R.A.]

Nonlinear optics A field of study concerned with the interaction of electromagnetic radiation and matter in which the matter responds in a nonlinear manner to the incident radiation fields. The nonlinear response can result in intensity-dependent variation of the propagation characteristics of the radiation fields or in the creation of radiation fields that propagate at new frequencies or in new directions. Nonlinear effects can take place in solids, liquids, gases, and plasmas, and may involve one or more electromagnetic fields as well as internal excitations of the medium. Most of the work done in the field has made use of the high powers available from lasers. The wavelength range of interest generally extends from the far-infrared to the vacuum ultraviolet, but some nonlinear interactions have been observed at wavelengths extending from the microwave to the x-ray ranges. *See* LASER.

Nonlinear materials. Nonlinear effects of various types are observed at sufficiently high light intensities in all materials. It is convenient to characterize the response of the medium mathematically by expanding it in a power series in the electric and magnetic fields of the incident optical waves. The linear terms in such an expansion give rise to the linear index of refraction, linear absorption, and the magnetic permeability of the medium, while the higher-order terms give rise to nonlinear effects. *See* ABSORPTION OF ELECTROMAGNETIC RADIATION; REFRACTION OF WAVES.

In general, nonlinear effects associated with the electric field of the incident radiation dominate over magnetic interactions. The even-order dipole susceptibilities are zero except in media which lack a center of symmetry, such as certain classes of crystals, certain symmetric media to which external forces have been applied, or at boundaries between certain dissimilar materials. Odd-order terms can be nonzero in all materials regardless of symmetry. Generally the magnitudes of the nonlinear susceptibilities decrease rapidly as the order of the interaction increases. Second- and third-order effects have been the most extensively studied of the nonlinear interactions, although effects up to order 30 have been observed in a single process. In some situations, multiple low-order interactions occur, resulting in a very high effective order for the overall nonlinear process. For example, ionization through absorption of effectively 100 photons has been observed. In other situations, such as dielectric breakdown or saturation of absorption, effects of different order cannot be separated, and all orders must be included in the response. *See* ELECTRIC SUSCEPTIBILITY; POLARIZATION OF DIELECTRICS.

Stimulated scattering. Light can scatter inelastically from fundamental excitations in the medium, resulting in the production of radiation at a frequency that is shifted from that of the incident light by the frequency of the excitation involved. The difference in photon energy between the incident and scattered light is accounted for by excitation or deexcitation of the medium. Some examples are Brillouin scattering from acoustic vibrations; various forms of Raman scattering involving molecular rotations or vibrations, electronic states in atoms or molecules, lattice vibrations or spin waves in solids, spin flips in semiconductors, and electron plasma waves in plasmas; Rayleigh scattering involving density or entropy fluctuations; and scattering from concentration fluctuations in gases. *See* SCATTERING OF ELECTROMAGNETIC RADIATION.

At the power levels available from pulsed lasers, the scattered light experiences exponential gain, and the process is then termed stimulated, in analogy to the process of stimulated emission in lasers. In stimulated scattering, the incident light can be almost completely converted to the scattered radiation. Stimulated scattering has been observed for all of the internal excitations listed above. The most widely used of these processes are stimulated Raman scattering and stimulated Brillouin scattering.

Self-action and related effects. Nonlinear polarization components at the same frequencies as those in the incident waves can result in effects that change the index of refraction or the absorption coefficient, quantities that are constants in linear optical theory. For example, propagation through optical fibers can involve several nonlinear optical interactions. Self-phase modulation resulting from the nonlinear index can be used to spread the spectrum, and subsequent compression with diffraction gratings and prisms can be used to reduce the pulse duration. The shortest optical pulses, with durations of the order of 6 femtoseconds, have been produced in this manner. Linear dispersion in fibers causes pulses to spread in duration and is one of the major limitations on data transmission through fibers. Dispersive pulse spreading can be minimized with solitons, which are specially shaped pulses that propagate long distances without spreading. They are formed by a combined interaction of spectral broadening due to the nonlinear refractive index and anomalous dispersion found in certain parts of the spectrum. *See* SOLITON.

Coherent effects. Another class of effects involves a coherent interaction between the optical field and an atom in which the phase of the atomic wave functions is preserved during the interaction. These interactions involve the transfer of a significant fraction of the atomic population to an excited state. As a result, they cannot be described with the simple perturbation expansion used for the other nonlinear optical effects. Rather they require that the response be described by using all powers of the incident fields. These effects are generally observed only for short light pulses, of the order of several nanoseconds or less. In one interaction, termed self-induced transparency, a pulse of light of the proper shape, magnitude, and duration can propagate unattenuated in a medium which is otherwise absorbing.

Other coherent effects involve changes of the propagation speed of a light pulse or production of a coherent pulse of light, termed a photon echo, at a characteristic time after two pulses of light spaced apart by a time interval have entered the medium. Still other coherent interactions involve oscillations of the atomic polarization, giving rise to effects known as optical nutation and free induction decay. Two-photon coherent effects are also possible.

Nonlinear spectroscopy. The variation of the nonlinear susceptibility near the resonances that correspond to sum- and difference-frequency combinations of the input frequencies forms the basis for various types of nonlinear spectroscopy which allow study of energy levels that are not normally accessible with linear optical spectroscopy.

Nonlinear spectroscopy can be performed with many of the interactions discussed earlier. Multiphoton absorption spectroscopy can be performed by using two strong laser beams, or a strong laser beam and a weak broadband light source. If two counterpropagating laser beams are used, spectroscopic studies can be made of energy levels in gases with spectral resolutions much smaller than the Doppler limit. Nonlinear optical spectroscopy has been used to identify many new energy levels with principal quantum numbers as high as 150 in several elements. *See* RESONANCE IONIZATION SPECTROSCOPY; RYDBERG ATOM.

Many types of four-wave mixing interactions can also be used in nonlinear spectroscopy. The most widespread of these processes, termed coherent anti-Stokes Raman spectroscopy (CARS), offers the advantage of greatly increased signal levels over linear Raman spectroscopy for the study of certain classes of materials.

Phase conjugation. Optical phase conjugation is an interaction that generates a wave that propagates in the direction opposite to a reference, or signal, wave, and has the same spatial variations in intensity and phase as the original signal wave, but with the sense of the phase variations reversed. Several nonlinear interactions are used to produce phase conjugation.

Optical phase conjugation allows correction of optical distortions that occur because of propagation through a distorting medium. This process can be used for improvement of laser-beam quality, optical beam combining, correction of distortion because of mode dispersion in fibers, and stabilized aiming. It can also be used for neural networks that exhibit learning properties. *See* NEURAL NETWORK; OPTICAL PHASE CONJUGATION. [J.F.R.]

Photorefractive effect. The photorefractive effect occurs in many electrooptic materials. A change in the index of refraction in a photorefractive medium arises from the redistribution of charge that is induced by the presence of light. Charge carriers that are trapped in impurity sites in a photorefractive medium are excited into the material's conduction band when exposed to light. The charges migrate in the conduction band until they become retrapped at other sites. The charge redistribution produces an electric field that in turn produces a spatially varying index change through the electrooptic effect in the material. Unlike most other nonlinear effects, the index change of the photorefractive effect is retained for a time in the absence of the light and thus may be used as an optical storage mechanism. Storage times range from milliseconds to months or years, depending upon the material and the methods employed. *See* Traps in solids.

Photorefractive materials are often used for holographic storage. In this case, the index change mimics the intensity interference pattern of two beams of light. Over 500 holograms have been stored in the volume of a single crystal of iron-doped lithium niobate. *See* Holography.

Photorefractive materials are typically sensitive to very low light levels. The photorefractive effect is, however, extremely slow by the standards of optical nonlinearity. Because of their sensitivity, photorefractive materials are increasingly used for image and optical-signal processing applications. *See* Image processing; Nonlinear optical devices. [D.Z.A.]

Nonlinear physics The study of situations where, in a general sense, cause and effect are not proportional to each other; in other words, if the measure of what is considered to be the cause is doubled, the measure of its effect is not simply twice as large. Many examples have been known in physics for a long time, and they seemed well understood. Over the last few decades, however, physicists have noticed that this lack of proportionality in some of the basic laws of physics often leads to unexpected complications, if not to outright contradictions. Thus, the term nonlinear physics refers more narrowly to these developments in the understanding of physical reality.

Linearity in nonlinear systems. When a large number of particles starts out in a condition of stable equilibrium, the result of small external forces is well-coordinated vibrations of the whole collection, for example, the vibrations of a violin string, or of the electric current in an antenna. Each collective motion acts like an independent oscillator, each with its own frequency. In more complicated systems, many vibrational modes can be active simultaneously without mutual interference. A large dynamical system is, therefore, described in terms of its significant degrees of freedom, thought to be only loosely coupled. The motion of any part of the whole becomes multiperiodic; for example, a water molecule has bending and stretching vibrations with different frequencies, and both are coupled with the rotational motion of the whole molecule. *See* Antenna (electromagnetism); Degree of freedom (mechanics); Molecular structure and spectra; Vibration.

Failure of perturbation theory. H. Poincaré discovered at the end of the nineteenth century that for many problems this perturbation theory is not entirely satisfactory. He showed, in the case of the Moon's motion around the Earth, that the disturbance by the Sun is strong enough that this standard mathematical procedure fails. The main culprits are resonances, which occur when the frequencies of different degrees of freedom are combined through their nonlinear coupling. A key nonperturbative phenomenon is known to engineers as phase lock: When different frequencies arise in simple multiples of one another, the whole dynamical system falls into a dynamical trap; and for a continuous range of initial conditions, the interaction changes the frequencies of the individual degrees of freedom sufficiently to "lock" the motion into the resonance. *See* Asteroid; Phase-locked loops; Resonance (acoustics and mechanics).

KAM theorem. In the 1950s, A. N. Kolmogoroff provided a first account of how the addition of a weak coupling generates chaotic regions and islands in phase space. This problem was later worked out in detail by V. Arnold and J. Moser to yield the KAM theorem. This theorem gives detailed information about the loss of the regular structure as the strength of the coupling increases. It does not say anything, however, about the trajectories in the newly created areas of chaotic behavior. These further investigations are the main goal of such fields as chaos or complexity. The impact of Poincaré's general arguments and the KAM theorem reaches into every area of nonlinear physics. The oldest among the areas is hydrodynamics, where the phenomenon of turbulent flow has so far resisted any effective control. This is what makes weather prediction so difficult. Signal propagation along the nerves and transmission of pulses through synaptic connections are other well-known nonlinear processes. *See* Chaos; Neurobiology; Nonlinear acoustics; Nonlinear optics. [M.C.G.]

Nonlinear programming The area of applied mathematics and operations research concerned with finding the largest or smallest value of a function subject to constraints or restrictions on the variables of the function. Nonlinear programming is sometimes referred to as nonlinear optimization.

A useful example concerns a power plant that uses the water from a reservoir to cool the plant. The heated water is then piped into a lake. For efficiency, the plant should be run at the highest possible temperature consistent with safety considerations, but there are also limits on the amount of water that can be pumped through the plant, and there are ecological constraints on how much the lake temperature can be raised. The optimization problem is to maximize the temperature of the plant subject to the safety constraints, the limit on the rate at which water can be pumped into the plant, and the bound on the increase in lake temperature.

The nonlinear programming problem refers specifically to the situation in which the function to be minimized or maximized, called the objective function, and the functions that describe the constraints are nonlinear functions. Typically, the variables are continuous; this article is restricted to this case.

Researchers in nonlinear programming consider both the theoretical and practical aspects of these problems. Theoretical issues include the study of algebraic and geometric conditions that characterize a solution, as well as general notions of convexity that determine the existence and uniqueness of solutions. Among the practical questions that are addressed are the mathematical formulation of a specific problem and the development and analysis of algorithms for finding the solution of such problems.

The general nonlinear programming problem can be stated as that of minimizing a scalar-valued objective function $f(x)$ over all vectors x satisfying a set of constraints. The constraints are in the form of general nonlinear equations and inequalities. Mathematically, the nonlinear programming problem may be expressed as below, where $\mathbf{x} = (x_1, x_2, \ldots, x_n)$ are the variables of the problem,

$$\begin{aligned} &\text{minimize } f(\mathbf{x}) \text{ with respect to } \mathbf{x} \\ &\quad \text{subject to: } g_i(\mathbf{x}) \leq 0, \quad i = 1, 2, \ldots, m \\ &\qquad\qquad\quad h_j(\mathbf{x}) = 0, \quad j = 1, 2, \ldots, p \end{aligned}$$

f is the objective function, $g_i(\mathbf{x})$ are the inequality constraints, and $h_j(\mathbf{x})$ are the equality constraints. This formulation is general in that the problem of maximizing $f(\mathbf{x})$ is equivalent to minimizing $-f(\mathbf{x})$ and a constraint $g_i(\mathbf{x}) \geq 0$ is equivalent to the constraint $-g_i(\mathbf{x}) \leq 0$.

Since general nonlinear equations cannot be solved in closed form, iterative methods must be used. Such methods generate a sequence of approximations, or iterates, that will converge to a solution under specified conditions. Newton's method is one of the best-known methods and is the basis for many of the fastest methods for solving the nonlinear programming problem. [P.T.B.]

Nonmetal The elements are conveniently, but arbitrarily, divided into metals and nonmetals. The nonmetals do not conduct electricity readily, are not ductile, do not have a complex refractive index, and in general have high ionization potentials.

If the periodic table is divided diagonally from upper left to lower right, all the nonmetals are on the right-hand side of the diagonal. Examples of elements which do not fit neatly into this useful but arbitrary classification are tin, which exists in two allotropic modifications, one definitely metallic and the other with many properties of a nonmetal, and tellurium and antimony. Such elements are called metalloids. *See* METAL; METALLOID; PERIODIC TABLE. [T.C.W.]

Non-newtonian fluid A fluid that departs from the classic linear newtonian relation between stress and shear rate. In a strict sense, a fluid is any state of matter that is not a solid, and a solid is a state of matter that has a unique stress-free state. A conceptually simpler definition is that a fluid is capable of attaining the shape of its container and retaining that shape for all time in the absence of external forces. Therefore, fluids encompass a wide variety of states of matter including gases and liquids as well as many more esoteric states (for example, plasmas, liquid crystals, and foams). *See* FLUIDS; FOAM; GAS; LIQUID; LIQUID CRYSTALS; PLASMA (PHYSICS).

A newtonian fluid is one whose mechanical behavior is characterized by a single function of temperature, the viscosity, a measure of the "slipperiness" of the fluid. For the example of Fig. 1, where a fluid is sheared between a fixed plate and a moving plate, the viscosity is given by Eq. (1). Thus, as the viscosity of a fluid increases, it requires a larger force to move the top plate at a given velocity. For simple, newtonian fluids, the viscosity is a constant dependent on only temperature; but for non-newtonian fluids, the viscosity can change by many orders of magnitude as the shear rate (velocity/height in Fig. 1) changes. Typically, the viscosity (η) of these fluids is given as a function of the shear rate ($\dot{\gamma}$). A common dependence for this function is given in Fig. 2. For other non-newtonian fluids, the viscosity might increase as the shear rate increases (shear-thickening fluids). *See* NEWTONIAN FLUID; VISCOSITY.

$$\text{Viscosity} = \frac{\text{force/area}}{\text{velocity/height}} \qquad (1)$$

Many of the fluids encountered in everyday life (such as water, air, gasoline, and honey) are adequately described as being newtonian, but there are even more that are not. Common examples include mayonnaise, peanut butter, toothpaste, egg whites, liquid soaps, and multigrade engine oils. Other examples such as molten polymers and slurries are of considerable technological importance. A distinguishing feature of many non-newtonian fluids is that they have microscopic or molecular-level structures that can be rearranged substantially in flow. *See* PARTICLE FLOW; POLYMER.

Our intuitive understanding of how fluids behave and flow is built primarily from observations and experiences with newtonian fluids. However, non-newtonian fluids display a rich variety of behavior that is often in dramatic contrast to these expectations. For example, an intuitive feel for the slipperiness of fluids can be gained from rubbing them between the fingers. Furthermore, the slipperiness of water, experienced in this way, is expected to be the same as the slipperiness of automobile tires on a wet road. However, the slipperiness (viscosity) of many non-newtonian fluids changes a great deal depending on how fast they move or the forces applied to them.

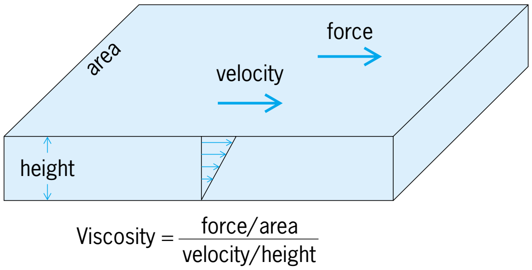


Fig. 1. Steady shear flow of a fluid between a fixed plate and a parallel plate, illustrating the concept of viscosity.

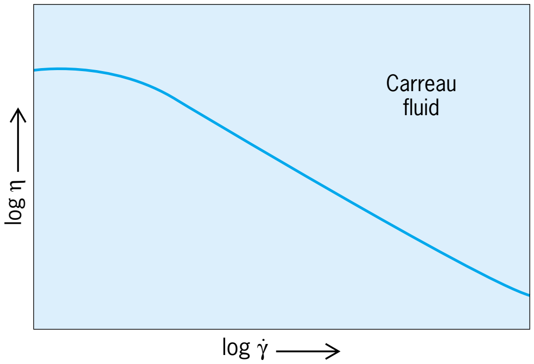

Fig. 2. Typical dependence of the viscosity (η) on shear rate ($\dot{\gamma}$) for a non-newtonian fluid (Carreau model).

Intuitive expectations for how the surface of a fluid will deform when the fluid is stirred (with the fluid bunching up at the wall of the container) are also in marked contrast to the behavior of non-newtonian fluids. When a cylindrical rod is rotated inside a container of a newtonian fluid, centrifugal forces cause the fluid to be higher at the wall. However, for non-newtonian fluids, the normal stress differences cause the fluid to climb the rod; this is called the Weissenberg effect. Intuitive understanding about the motion of material when the flow of a fluid is suddenly stopped, for example, by turning off a water tap, is also notably at odds with the behavior of non-newtonian fluids. *See* CENTRIFUGAL FORCE.

A non-newtonian fluid also displays counterintuitive behavior when it is extruded from an opening. A newtonian fluid tapers to a smaller cross section as it leaves the opening, but the cross section for a non-newtonian fluid first increases before it eventually tapers. This phenomenon is called die swell. *See* NOZZLE.

When a newtonian fluid is siphoned and the fluid level goes below the entrance to the siphon tube, the siphoning action stops. For many non-newtonian fluids, however, the siphoning action continues as the fluid climbs from the surface and continues to enter the tube. This phenomenon is called the tubeless siphon.

Perhaps the most striking behavior of non-newtonian fluids is a consequence of their viscoelasticity. Solids can be thought of as having perfect memory. If they are deformed through the action of a force, they return to their original shape when the force is removed. This happens when a rubber ball bounces; the ball is deformed as it hits a surface, but the rubber remembers its undeformed spherical shape. Recovery of the shape causes the ball to bounce back. In contrast, newtonian fluids have no memory; when a force is removed, they retain their condition at the time the force is removed (or continue moving as the result of inertia). When a newtonian fluid is dropped onto a surface, it does not bounce. Non-newtonian fluids are viscoelastic in the sense that they have fading memory. If a force is removed shortly after it is applied, the fluid will remember its undeformed shape and return toward it. However, if the force is applied on the fluid for a long time, the fluid will eventually forget its undeformed shape. If a sample of a non-newtonian fluid is dropped onto a surface, it will bounce like a ball. However, if the fluid is simply placed on the surface, it will flow smoothly. Viscoelasticity is frequently the cause of many of the secondary flows that are observed for non-newtonian fluids. These are fluid motions that are small for newtonian fluids (for example, swirling motions) but can become dominant for non-newtonian fluids. *See* ELASTICITY.

Analysis of fluid flow operations is typically performed by examining local conservation relations—conservation of mass, momentum (Newton's second law), and energy. This analysis requires material-specific information (for example, the relation between density, pressure, and temperature) that is collectively known as constitutive relations. The science devoted to obtaining suitable constitutive equations for description of the behavior of non-newtonian fluids is called rheology. The most important constitutive equation for fluid mechanics is that relating the stress in the fluid to the kinematics of the motion (that is, the velocity, the derivatives of the velocity with respect to position, and the time history of the velocity).

Although the non-newtonian behavior of many fluids has been recognized for a long time, the science of rheology is, in many respects, still in its infancy, and new phenomena are constantly being discovered and new theories proposed. Advancements in computational techniques are making possible much more detailed analyses of complex flows and more sophisticated simulations of the structural and molecular behavior that gives rise to non-newtonian behavior. Engineers, chemists, physicists, and mathematicians are actively pursuing research in rheology, particularly as more technologically important materials are found to display non-newtonian behavior. *See* FLUID FLOW; FLUID-FLOW PRINCIPLES; RHEOLOGY. [J.M.Wie.]

Nonsinusoidal waveform

The representation of a wave that does not vary in a sinusoidal manner. Electric circuits containing nonlinear elements, such as electron tubes, iron-core magnetic devices, and transistors, commonly produce nonsinusoidal currents and voltages. When these are repetitive functions of time, they are called nonsinusoidal electric waves. Oscillograms, tabulated data, and sometimes mathematical functions for segments of such waves are often used to describe the excursions throughout one cycle. A cycle corresponds to 2π electrical radians and covers the time interval T seconds in which the wave repeats itself.

These electric waves can be represented by a constant term, the average or dc component, plus a series of harmonic terms in which the frequencies of the harmonics are integral multiples of the fundamental frequency. The fundamental frequency f_1, if it does exist, has the time span $T = 1/f_1$ seconds for its cycle. The second-harmonic frequency f_2 then will have two of its cycles within T seconds, and so on.

The series of terms stated above is known as a Fourier series and can be expressed in the form of the equation below, where $y(t)$, plotted over a cycle of the fundamental, gives the shape of

$$\begin{aligned} y(t) &= B_0 + C_1 \sin(\omega t + \phi_1) + \cdots + C_n \sin(n\omega t + \phi_n) + \cdots \\ &= \sum_{n=0}^{\infty} C_n \sin(n\omega t + \phi_n) \end{aligned}$$

the nonsinusoidal wave. The radian frequency of the fundamental is $\omega = 2\pi f_1$, and n is an integer. C_1 is the amplitude of the fundamental ($n = 1$), and succeeding C_n's are the amplitudes of the respective harmonics having frequencies corresponding to $n = 2, 3, 4$, and so on, with respect to the fundamental. The phase angle of the fundamental with respect to a chosen time reference axis is ϕ_1, and the succeeding ϕ_n's are the phase angles of the respective harmonics. *See* FOURIER SERIES.

The equation for $y(t)$ shows all its separate components, which, in general, include an infinite number of terms. In practical problems the first several terms usually yield an approximate result sufficiently accurate for portrayal of the actual wave. The degree of accuracy desired in representing faithfully the actual wave determines the number of terms that must be used in any computation. [B.L.R.; W.S.P.]

Nonstoichiometric compounds

Chemical compounds in which the relative number of atoms is not expressible as the ratio of small whole numbers, hence compounds for which the subscripts in the chemical formula are not rational (for example, $Cu_{1.987}S$). Sometimes they are called berthollide compounds to distinguish them from daltonides, in which the ratio of atoms is generally simple. Nonstoichiometry is a property of the solid state and arises because a fraction of the atoms of a given kind may be (1) missing from the regular structure (for example, $Fe_{1-\delta}O$), (2) present in excess over the requirements of the structure (for example, $Zn_{1+\delta}O$), or (3) substituted by atoms of another kind (for example, $Bi_2Te_{3\pm\delta}$). The resulting materials are generally of variable composition, intensely colored, metallic or semiconducting, and different in chemical reactivity from the parent stoichiometric compounds from which they are derived.

Nonstoichiometry is best known in the binary compounds of the transition elements, particularly the hydrides, oxides, chalcogenides, pnictides, carbides, and borides. It is also well represented in the so-called insertion or intercalation compounds, in which a metallic element or neutral molecule has been inserted in a stoichiometric host. Nonstoichiometric compounds are important in some solid-state devices (such as rectifiers, thermoelectric generators, and photodetectors) and are probably formed as chemical intermediates in many reactions involving solids (for example, heterogeneous catalysis and metal corrosion).

The simplest way to classify nonstoichiometric compounds is to consider which element is in excess and how this excess is brought about. A classification scheme largely based on this distinction but which also includes some examples of ternary systems is as follows.

Binary compounds:
- I. Metal nonmetal ratio greater than stoichiometric
  - (*a*) Metal in excess, for example, $Zn_{1+\delta}O$
  - (*b*) Missing nonmetal, for example $UH_{3-\delta}$, $WO_{3-\delta}$
- II. Metal: nonmetal ratio less than stoichiometric
  - (*a*) Metal-deficient, for example, $Co_{1-\delta}O$
  - (*b*) Nonmetal in excess, for example, $UO_{2+\delta}$
- III. Deviations on both sides of stoichiometry, for example, $TiO_{1\pm\delta}$

Ternary compounds (insertion compounds):
- IV. Oxide "bronzes," for example, $M_\delta WO_3$, $M_\delta V_2O_5$
- V. Intercalation compounds, for example, $K_{1.5+\delta}MoO_3$, $LL_\delta TiS_2$

Excluded from consideration are the recognized impurity materials, such as $Na_{1-2x}Ca_xCl$, which are best considered as conventional solid solutions wherein ions of one kind and perhaps vacancies have replaced an equivalent number of ions of another kind. [M.J.Si.]

Noradrenergic system

A neuronal system that is responsible for the synthesis, storage, and release of the neurotransmitter norepinephrine. Norepinephrine, also known as noradrenalin, consists of a single amine group and a catechol nucleus (a benzene ring with two hydroxyl groups) and is therefore referred to as a monoamine or catecholamine. It exists in both the central and peripheral nervous systems. Norepinephrine is the primary neurotransmitter released by the sympathetic nervous system, which mediates the "fight or flight" reaction, preparing the body for action by affecting cardiovascular function, gastrointestinal motility and secretion, bronchiole dilation, glucose metabolism, and so on. Within the central nervous system, norepinephrine has been associated with several brain functions, including sleep, memory, learning, and emotions.

After synthesis, the majority of norepinephrine is transported into synaptic vesicles in the nerve terminals, where it remains until needed. When the nerve terminal is activated by depolarization, calcium flows into it, leading to the release of norepinephrine into the synaptic cleft. Once released into the synaptic cleft, norepinephrine is free to bind to specific receptors located on the presynaptic or postsynaptic terminal, which initiates a chain of events (the effector system) in the target cell that can be mediated by a number of different second messenger systems. The exact effect is determined by the identity of the receptor activated. *See* EPINEPHRINE; SECOND MESSENGER; SYMPATHETIC NERVOUS SYSTEM; SYNAPTIC TRANSMISSION.

Termination of norepinephrine occurs by a reuptake mechanism in the presynaptic membrane. Once transported back into the presynaptic terminal, norepinephrine can be stored in vesicles for future use or enzymatically degraded by monoamine oxidase.

Certain medications achieve their effect by altering various stages of synthesis, storage, release, and inactivation of norepinephrine. The behavioral manifestations of these alterations have led to a better understanding of norepinephrine's role in various psychiatric disorders. *See* AFFECTIVE DISORDERS; MONOAMINE OXIDASE; PSYCHOPHARMACOLOGY; SCHIZOPHRENIA; STRESS. [M.My.; D.S.C.; A.Bre.; S.So.]

Normal (mathematics) A term generically synonymous with perpendicular, which often refers specifically to a line that goes through a point P of a curve C and is perpendicular to the tangent to C at P. If curve C is not a plane curve, all normal lines of C at point P on C lie in a plane, the normal plane of C at P. *See* ANALYTIC GEOMETRY. [L.M.Bl.]

North America The third largest continent, extending from the narrow isthmus of Central America to the Arctic Archipelago. The physical environments of North America, like the rest of the world, are a reflection of specific combinations of the natural factors such as climate, vegetation, soils, and landforms. *See* CONTINENT.

Location. North America covers 9,400,000 mi^2 (24,440,000 km^2) and extends north to south for 5000 mi (8000 km) from Central America to the Arctic. It is bounded by the Pacific Ocean on the west and the Atlantic Ocean on the east. The Gulf of Mexico is a source of moist tropical air, and the frozen Arctic Ocean is a source of polar air. With the major mountain ranges stretching north-south, North America is the only continent providing for direct contact of these polar and tropical air masses, leading to frequent climatically induced natural hazards such as violent spring tornadoes, extreme droughts, subcontinental floods, and winter blizzards, which are seldom found on other continents. *See* AIR MASS; ARCTIC OCEAN; ATLANTIC OCEAN; GULF OF MEXICO; PACIFIC OCEAN.

Geologic structure. The North American continent includes (1) a continuous, broad, north-south-trending western cordilleran belt stretching along the entire Pacific coast; (2) a northeast-southwest-trending belt of low Appalachian Mountains paralleling the Atlantic coast; (3) an extensive rolling region of old eroded crystalline rocks in the north-central and northeastern part of the continent called the Canadian Shield; (4) a large, level interior lowland covered by thick sedimentary rocks and extending from the Arctic Ocean to the Gulf of Mexico; and (5) a narrow coastal plain along the Atlantic Ocean and the Gulf of Mexico. These broad structural geologic regions provide the framework for the natural regions of this continent and affect the location and nature of landform, climatic, vegetation, and soil regions.

Canadian Shield. Properly referred to as the geological core of the continent, the exposed Canadian Shield extends about 2500 mi (4000 km) from north to south and almost as much from east to west. The rest of it dips under sedimentary rocks that overlap it on the south and west. The Canadian Shield consists of ancient Precambrian rocks, over 500 million years old, predominantly granite and gneiss, with very complex structures indicating several mountain-building episodes. It has been eroded into a rolling surface of low to moderate relief with elevations generally below 2000 ft (600 m). Its surface has been warped into low domes and basins, such as the Hudson Basin, in which lower Paleozoic rocks, including Ordovician limestones, have been preserved. Since the end of the Paleozoic Era, the Shield has been dominated by erosion. Parts of the higher surface remain at about 1500–2000 ft (450–600 m) above sea level, particularly in the Labrador area. The Shield remained as land throughout the Mesozoic Era, but its western margins were covered by a Cretaceous sea and by Tertiary terrestrial sediments derived from the Western Cordillera. *See* CRETACEOUS; ORDOVICIAN; MESOZOIC; PALEOZOIC; PRECAMBRIAN; TERTIARY.

The entire exposed Shield was glaciated during the Pleistocene Epoch, and its surface was intensely eroded by ice and its meltwaters, erasing major surface irregularities and eastward-trending rivers that were there before. The surface is now covered by glacial till, outwash, moraines, eskers, and lake sediments, as well as drumlins formed by advancing ice. A deranged drainage pattern is evolving on this surface with thousands of lakes of various sizes. *See* DRUMLIN; ESKER; GLACIAL EPOCH; GLACIATED TERRAIN; MORAINE; PLEISTOCENE; TILL.

The Canadian Shield extends into the United States as Adirondack Mountains in New York State, and Superior Upland west of Lake Superior.

Southeastern Coastal Plain. The Southeastern Coastal Plain is geologically the youngest part of the continent, and it is covered by the youngest marine sedimentary rocks. This flat plain, which parallels the Atlantic and Gulf coastline, extends for over 3000 mi (4800 km) from Cape Cod, Massachusetts, to the Yucatán Peninsula in Mexico. It is very narrow in the north but increases in width southward along the Atlantic coast and includes the entire peninsula of Florida. As it continues westward along the Gulf, it widens significantly and includes the lower Mississippi River valley. It is very wide in Texas, narrows again southward in coastal Mexico, and then widens in the Yucatán Peninsula and continues as a wide submerged plain, or a continental shelf, into the sea. *See* COASTAL PLAIN.

Extending from Cape Cod, Massachusetts, to Mexico and Central America, the Coastal Plain is affected by a variety of climates and associated vegetation. While a humid, cool climate with four seasons affects its northernmost part, subtropical air masses affect the southeastern part, including Florida, and hot and arid climate dominates Texas and northern Mexico; Central America has hot, tropical climates.

Varied soils characterize the Coastal Plain, including the fertile alluvial soils of the Mississippi Valley. Broadleaf forests are present in the northeast, citrus fruits grow in Florida, grasslands dominate the dry southwest, and tropical vegetation is present on Central American coastal plains.

Eastern Seaboard Highlands. Between the Southeastern Coastal Plain and the extensive interior provinces lies a belt of mountains that, by their height and pattern, create a significant barrier between the eastern seaboard and the interior of North America. These mountains consist of the Adirondack Mountains and the New England Highlands.

The Adirondack Mountains are a domal extension of the Canadian Shield, about 100 mi (160 km) in diameter, composed of complex Precambrian rocks. The New England Highlands consist of a north-south belt of mountains east of the Hudson Valley, including the Taconic mountains in the south and the Green mountains in the north, and continuing as the Notre Dame Mountains along the St. Lawrence Valley and the Chic-Choc Mountains of the Gaspé Peninsula. The large area of New England east of these mountains is an eroded surface of old crystalline rocks culminating in the center as the White Mountains, with their highest peak of the Presidential Range, Mount Washington, reaching over 6200 ft (1880 m). This area has been intensely glaciated, and it meets the sea in a rugged shoreline. Nova Scotia and Newfoundland have a similar terrain.

New England is a hilly to mountainous region carved out of ancient rocks, eroded by glaciers, and covered by glacial moraines, eskers, kames, erratics, and drumlins, with hundreds of lakes scattered everywhere. It has a cool and moist climate with four seasons, thin and acid soils, and mixed coniferous and broadleaf forests.

Appalachian Highlands. The Appalachian Highlands are traditionally considered to consist of four parts: the Piedmont, the Blue Ridge Mountains, the Ridge and Valley Section, and the Appalachian Plateau. These subregions are all characterized by different geologic structures and rock types, as well as different geomorphologies.

The northern boundary of the entire Appalachian System is an escarpment of Paleozoic rocks trending eastward along Lake Erie, Lake Ontario, and the Mohawk Valley. The boundary then swings south along Hudson River Valley and continues southwestward along the Fall Line to Montgomery, Alabama. The western boundary trends northeastward through Cumberland Plateau in Tennessee, and up to Cleveland, Ohio, where it joins the northern boundary. Together with New England, this region forms the largest mountainous province in eastern United States.

Interior Domes and Basins Province. The southwestern part of the Appalachian Plateau, overlain mainly by the Mississippian and Pennsylvanian sedimentary rocks, has been warped into two low structural domes called the Blue Grass and Nashville Basins, and a structural basin, drained by the Green River; its southern fringe is called the Pennyroyal Region. The Interior Dome and Basin Province is contained roughly between the Tennessee River in the south and west and the Ohio River in the north.

There is no boundary on the east, because the domes are part of the same surface as the Appalachian Plateau. However, erosional escarpments, forming a belt of hills called knobs, clearly mark the topographic domes and basins. The northern dome, called the Blue Grass Basin or Lexington Plain, has been eroded to form a basin surrounded by a series of inward-facing cuesta escarpments. The westernmost cuesta reaches about 600 ft (180 m) elevation while the central part of the basin lies about 1000 ft (300 m) above sea level, which is higher than the surrounding hills. This gently rolling surface with deep and fertile soils exhibits some solutional karst topography. *See* FLUVIAL EROSION LANDFORMS.

Ozark and Ouachita Highlands. The Paleozoic rocks of the Pennyroyal Region continue Westward across southern Illinois to form another dome of predominantly Ordovician rocks, called the Ozark Plateau. This dome, located mainly in Missouri and Arkansas, has an abrupt east side, and a gently sloping west side, called the Springfield Plateau. Its surface is stream eroded into hilly and often rugged topography that is developed mainly on limestones, although shales, sandstone, and chert are present. Much residual chert, eroded out of limestone, is present on the surface. There are some karst features, such as caverns and springs. In the northeast, Precambrian igneous rocks protrude to form the St. Francois Mountains, which reach an elevation of 1700 ft (515 m).

Central Lowlands. One of the largest subdivisions of North America is the Central Lowlands province which is located between the Appalachian Plateau on the east, the Interior Domes and Basins Province and the Ozark Plateau on the south, and the Great Plains on the west. It includes the Great Lakes section and the Manitoba Lowland in Canada. This huge lowland in the heart of the continent (whose elevations vary from about 900 ft or 270 m above sea level in the east and nearly 2000 ft or 600 m in the west) is underlain by Paleozoic rocks that continue from the Appalachian Plateau and dip south under the recent coastal plain sediments; meet the Cretaceous rocks on the west; and overlap the crystalline rocks of the Canadian Shield on the northeast.

The present surface of nearly the entire Central Lowlands, roughly north of the Ohio River and east of the Missouri River, is the creation of the Pleistocene ice sheets. When the ice formed and spread over Canada, and southward to the Ohio and Missouri rivers, it eroded much of the preexisting surface. During deglaciation, it left its deposits over the Canadian Shield and the Central Lowlands.

The Central Lowlands are drained by the third longest river system in the world, the Missouri-Mississippi, which is 3740 mi (6000 km) long. This mighty river system, together with the Ohio and the Tennessee, drains not only the Central Lowlands but also parts of the Appalachian Plateau and the Great Plains, before it crosses the Coastal Plain and ends in the huge delta of the Mississippi. The river carries an enormous amount of water and alluvium and continues to extend its delta into the Gulf. In 1993 it reached a catastrophic level of a hundred-year flood, claimed an enormous extent of land and many lives, and created an unprecedented destruction of property. This flood again alerted the population to the extreme risk of occupying a river floodplain. *See* FLOODPLAIN; RIVER.

Great Plains. The Great Plains, which lie west of the Central Lowlands, extend from the Rio Grande and the Balcones Escarpment in Texas to central Alberta in Canada. On the east, they are bounded by a series of escarpments, such as the Côteau du Missouri in the Dakotas. The dry climate with less than 20 in. (50 cm) of precipitation, and steppe grass vegetation growing on calcareous soils, help to determine the eastern boundary of the Great Plains. On the west, the Great Plains meet the abrupt front of the Rocky Mountains, except where the Colorado Piedmont and the lower Pecos River Valley separate them from the mountains.

The Great Plains region shows distinct differences between its subsections from south to north. The southernmost part, called the High Plains or Llano Estacado, and Edwards Plateaus are the flattest. While Edwards Plateau, underlain by limestones of the Cretaceous age, reveals solutional karst features, the High Plains have the typical Tertiary bare cap rock surface, devoid of relief and streams.

The central part of the Great Plains has a recent depositional surface of loess and sand. The Sand Hills of Nebraska form the most extensive sand dunes area in North America, covering about 24,000 mi^2 (62,400 km^2). They are overgrown by grass and have numerous small lakes. The loess region to the south provides spectacular small canyon topography. *See* DUNE.

The northern Great Plains, stretching north of Pine Ridge and called the Missouri Plateau, have been intensly eroded by the western tributaries of the Missouri River into river breaks and interfluves. In extreme cases, badlands were formed, such as those of the White River and the Little Missouri.

The terrain of the Canadian Great Plains consists of three surfaces rising from east to west: the Manitoba, Saskatchewan, and Alberta Prairies developed on level Creteceous and Tertiary rocks. Climatic differences between the arid and warm southern part and the cold and moist northern part have resulted in regional differences. The eastern boundary of the Saskatchewan Plain is the segmented Manitoba Escarpment, which extends for 500 mi (800 km) northwestward, and in places rises 1500 ft (455 m) above the Manitoba Lowland. Côteau du Missouri marks the eastern edge of the higher Alberta Plain.

Western Cordillera. The mighty and rugged Western Cordilleras stretch along the Pacific coast from Alaska to Mexico. There are three north-south-trending belts: (1) Brooks Range, Mackenzie Mountains, and the Rocky Mountains to the north and Sierra Madre Oriental in Mexico; (2) Interior Plateaus, including the Yukon Plains, Canadian Central Plateaus and Ranges, Columbia Plateau, Colorado Plateau, and Basin and Range Province stretching into central Mexico; and (3) Coastal Mountains from Alaska Range to California, Baja California, and Sierra Madre Occidental in Mexico.

This subcontinental-size mountain belt has the highest mountains, greatest relief, roughest terrain, and most beautiful scenery of the entire continent. It has been formed by earth movements resulting from the westward shift of the North American lithospheric plate. The present movements, and the resulting devastating earthquakes along the San Andreas fault system paralleling the Pacific Ocean, are part of this process. *See* CORDILLERAN BELT; PLATE TECTONICS.

This very high, deeply eroded and rugged Rocky Mountains region comprises several distinct parts: Southern, Middle, and Northern Rockies, plus the Wyoming Basin in the United States, and the Canadian Rockies. The Southern Rockies, extending from Wyoming to New Mexico, include the Laramie Range, the

Front Range, and Spanish Peaks with radiating dikes on the east; Medicine Bow, Park, and Sangre de Cristo ranges in the center; and complex granite Sawatch Mountains and volcanic San Juan Mountains of Tertiary age on the west. Most of the ranges are elongated anticlines with exposed Precambrian granite core, and overlapping Paleozoic and younger sedimentary rocks which form spectacular hogbacks along the eastern front. There are about 50 peaks over 14,000 ft (4200 m) high, while the Front Range alone has about 300 peaks over 13,000 ft (3940 m) high. The southern Rocky Mountains, heavily glaciated into a beautiful and rugged scenery with permanent snow and small glaciers, form a major part of the Continental Divide.

The interior Plateaus and Ranges Province of the Western Cordillera lies between the Rocky Mountains and the Coastal Mountains. It is an extensive and complex region. It begins in the north with the wide Yukon Plains and Uplands; narrows into the Canadian Central Plateaus and Ranges; widens again into the Columbia Plateau, Basin and Range Province, and Colorado Plateau; and finally narrows into the Mexican Plateau and the Central American isthmus.

The coastal Lowlands and Ranges extend along the entire length of North America and include Alaskan Coast Ranges, Aleutian Islands, Alaska Range, Canadian Coast Ranges, and a double chain of the Cascade Mountains and Sierra Nevada on the east, and Coast Ranges on the west, separated by Puget Sound, Willamette Valley, and Great Valley of California. These ranges continue southward as Lower California Peninsula, Baja California, and Sierra Madre Occidental in Mexico.

The basin-and-range type of terrain of the southwest United States continues into northern Mexico and forms its largest physiographic region, the Mexican Plateau. This huge tilted block stands more than a mile above sea level—from about 4000 ft (1200 m) in the north, it rises to about 8000 ft (2400 m) in the south. The Mexican Plateau is separated from the Southern Mexican Highlands (Sierra Madre del Sur) by a low, hot and dry Balsas Lowland drained by the Balsas River. To the east of the Southern Highlands lies a lowland, the Isthmus of Tehuantepec, which is considered the divide between North and Central America. Here the Pacific and Gulf coasts are only 125 mi (200 km) apart. The lowlands of Mexico are the coastal plains. The Gulf Coastal Plain trends southward for 850 mi from the Rio Grande to the Yucatán Peninsula. It is about 100 mi (160 km) wide in the north, just a few miles wide in the center, and very wide in the Yucatan Peninsula. Barrier beaches, lagoons, and swamps occur along this coast. The Pacific Coastal Plains are much narrower and more hilly. North-south-trending ridges of granite characterize the northern part, and islands are present offshore. Toward the south, sandbars, lagoons, and deltaic deposits are common.

East of the Isthmus of Tehuantepec begins Central America with its complex physiographic and tectonic regions. This narrow, mountainous isthmus is geologically connected with the large, mountainous islands of the Greater Antilles in the Carribean. They are all characterized by east-west-trending rugged mountain ranges, with deep depressions between them. One such mountain system begins in Mexico and continues in southern Cuba, Puerto Rico, and the Virgin Islands. North of this system, called the Old Antillia, lies the Antillian Foreland, consisting of the Yucatán Peninsula and the Bahama Islands. Central American mountains are bordered on both sides by active volcanic belts. Along the Pacific, a belt of young volcanoes extends for 800 mi (1280 km) from Mexico to Costa Rica. Costa Rica and Panama are mainly a volcanic chain of mountains extending to South America. Nicaragua is dominated by a major crustal fracture trending northwest-southeast. [B.Z.B.]

North Pole That end of the Earth's axis which points toward the North Star, Polaris (Alpha Ursae Minoris). It is the geographical pole where all meridians converge, and should not be confused with the north magnetic pole, which is in the Canadian Archipelago. The North Pole's location falls near the center of the Arctic Sea. The North Pole has phenomena unlike any other place except the South Pole. For 6 months the Sun does not appear above the horizon, and for 6 months it does not go below the horizon. As there is a long period (about 7 weeks) of continuous twilight before March 21 and after September 23, the period of light is considerably longer than the period of darkness. [V.H.E.]

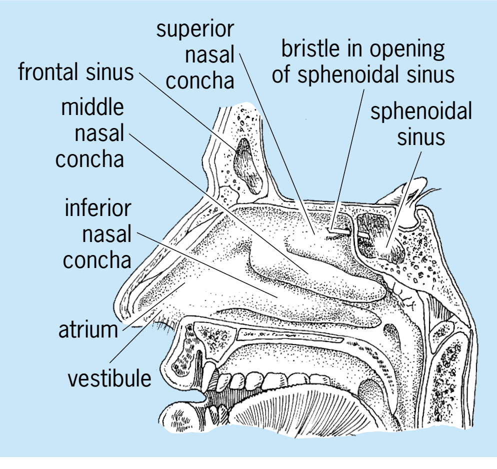
North Sea A flooded portion of the northwest continental margin of Europe occupying an area of over 200,000 mi^2 (500,000 km^2). The North Sea has extensive marine fisheries and important offshore oil and gas reserves. In the south, its depth is less than 150 ft (50 m), but north of 58° it deepens gradually to 600 ft (200 m) at the top of the continental slope. A band of deep water down to 1200 ft (400 m) extends around the south and west coast of Norway and is known as the Norwegian Trench.

The nontidal residual current circulation of the southern North Sea is mainly determined by wind velocity, but in the north, well-defined non-wind-driven currents have been identified, especially in the summer. Two of these currents bring in water from outside the North Sea; one flows through the channel between Orkney and Shetland (the Fair Isle current), and the other follows the continental slope north of Shetland and merges with the Fair Isle current southwest of Norway before entering the Skagerrak. The north-flowing Norwegian coastal current provides the exit route for North Sea waters, and is formed from the waters of these two major inflows and from other much smaller inputs such as river runoff, the English Channel, and the Baltic Sea.

There is a rich diversity of zooplankton within the North Sea. Copepods are of particular importance in the food web. There are a wide range of fish stocks in the North Sea and adjacent waters and, in terms of species exploited by commercial fisheries, they constitute the richest area in the northeast Atlantic. The commercially important stocks exploited for human consumption include cod, haddock, whiting, pollock, plaice, sole, herring, mackerel, lobster, prawn, and brown shrimp (*Crangon crangon*). A number of stocks are used for fishmeal and oil; these stocks include sand eel, Norway pout, blue whiting, and sprat. *See* COPEPODA; MARINE ECOLOGY; ZOOPLANKTON. [H.D.D.]

Nose The nasal cavities and the structures surrounding and associated with them. The nose functions primarily as the organ of smell and in most tetrapods also assumes a respiratory function, forming the anterior end of the air passage through which air is drawn in and in which it is warmed and moistened.

In humans the nasal cavities are triangular openings that pass from the external nares back to the dorsal part of the pharynx (see illustration). The lateral walls are composed principally of



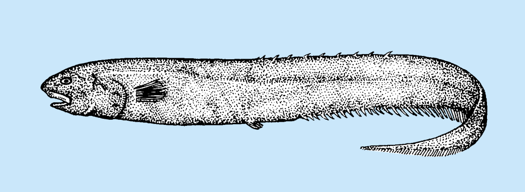
Human nose. (*After W. J. Hamilton et al., Textbook of Human Anatomy, Macmillan, 1956*) portions of the ethmoid and sphenoid bones and projections of three turbinate bones, or conchae, on each side. The floor of the nose is formed by the palate, which is also the roof of the mouth. The nasal cavities are lined with respiratory epithelium, which also lines the paranasal sinuses. The latter are cavities in the frontal, ethmoid, sphenoid, and maxillary bones which communicate with the nasal passages. The external nose consists of the two nasal bones that form the bony bridge and two pairs of lower nasal cartilages. These together with the tightly adherent skin determine the individual shape and size of the human nose. *See* OLFACTION. [T.S.P.]

Nose cone The forward portion of a spacecraft that is designed for atmospheric entry. Nose cones are utilized for intercontinental ballistic missiles and spacecraft such as Apollo and space shuttles. The nose cone is required to withstand heating encountered during atmospheric entry, maintain the structural integrity of the spacecraft, prevent overheating of the payload, and usually maintain the aerodynamic characteristics of the spacecraft.

Even for a properly designed shape, it is inevitable that some fraction of the spacecraft's initial kinetic energy will finally reach the nose cone in the form of heat. The design of the heat shield for the nose cone is a complex procedure, which is highly dependent on the heating level. There are a variety of surface-protection or cooling systems which have been used. Generally these systems consist of heat sinks of various types: the absorption of heat by virtue of a material's sensible heat capacity, latent heat capacity, or chemical heat capacity. That is, heat absorption is accomplished by a temperature rise, a phase change, or a chemical reaction. Aerodynamic lift is employed by such vehicles as reusable space shuttles to lower heating rates so that the nose cone material can radiate away much of the incident heating.

Ablation is used to provide surface protection. The designer can divert heat from the spacecraft by allowing the nose cone's outer layer of material to melt, vaporize, or sublime. While large ablation rates provide excellent thermal protection, the resulting change in profile due to surface recession can adversely change the aerodynamic characteristics of the spacecraft. The designer must account for this change. *See* SPACE SHUTTLE; SPACECRAFT STRUCTURE. [P.R.N.]

Notacanthiformes An order of actinopterygian fishes known also as the Heteromi (spiny eels or notacanths) and the Lyopomi (halosaurs). The body is elongated, tapers posteriorly, and has no caudal fin (see illustration).



Spiny eel (*Notacanthus nasus*). (*After D. S. Jordan and B. W. Evermann, The Fishes of North and Middle America, U.S. Nat. Mus. Bull. no. 47, 1900*)

This small order, which has a history extending back to the Upper Cretaceous, includes 3 families, about 8 Recent genera, and about 25 species. Spiny eels and halosaurs inhabit deep seas of all oceans; some have photophores. They are like true eels (Anguilliformes) in that they lack a firm suspension of the pectoral girdle from the skull, but some have fin spines like the perciform fishes. *See* ACTINOPTERYGII; ANGUILLIFORMES. [R.M.B.]

Nothosauria An order of extinct aquatic diapsid reptiles in the infraclass Sauropterygia, known from the Triassic System of Europe, North America, and Asia. Nothosaurs represent a primitive grade of evolution within the infraclass, which also includes the Jurassic and Cretaceous plesiosaurs.

Nothosaurs range approximately 3–13 ft (1–4 m) in length. The neck is long, with at least 15 cervical vertebrae. Like aquatic lizards and crocodiles, early nothosaurs probably swam primarily by lateral undulation of the trunk and tail, with the limbs held to the side to reduce drag. Advanced nothosaurs show modifications of the front limbs to act as paddles; the rear limbs are somewhat reduced.

Nothosaurs are distinguished from other aquatic reptiles by the closure of the openings in the palate that occur in more primitive reptiles, and by the covering of the base of the braincase. The ventral surface of the shoulder girdle is characterized by a wide gap between the base of the scapulae and the coracoids, behind a stout transverse bar formed by the interclavicle and the blades of the clavicles. As in plesiosaurs, part of the scapula is superficial to the clavicle, a reversal of the relationship of these bones in other reptiles. Primitive nothosaurs resemble primitive lepidosauromorphs in the pattern of the skull roof but have lost the lower temporal bar. *See* DIAPSIDA; PLESIOSAURIA; REPTILIA. [R.L.C.]

Notomyotina A suborder of Phanerozonida (subclass Aster-oidea) in which the upper marginals alternate in position with the lower marginals to impart a degree of flexibility to the arm, and each of the tube feet has a terminal sucking disk. Paxillae are present on the upper surface. Each arm usually contains a pair of dorsal muscles, whose contraction enables the arm to be turned upward over the disk. These are mainly deep-water forms. *See* ASTEROIDEA; ECHINODERMATA. [H.B.F.]

Notostraca An order of branchiopod crustaceans, sometimes called tadpole shrimps. Generally they range from about 20 mm (0.4 in.) to (exceptionally) about 90 mm (3.5 in.) in length. The multisegmented trunk, up to 44 segments in some species, is elongate and cylindrical. Each of the first 11 trunk segments bears a pair of limbs, while a varying number of more posterior segments bear up to six pairs of smaller limbs per segment—a very unusual situation. The trunk terminates in a telson that bears a pair of slender, segmented, caudal filaments. Notostracans feed on a variety of small organisms that are seized by the trunk limbs and passed forward to the mouthparts, but they also collect and eat detritus with the same limbs.

Some species are bisexual, but in some parts of their range some are self-fertilizing hermaphrodites. The highly resistant eggs, which can withstand desiccation if necessary, hatch as nauplii, but in some cases this stage is transient, molting almost at once to a more advanced stage. The two extant genera, *Triops* and *Lepidurus*, are essentially worldwide in distribution and occur mostly in temporary waters. *See* BRANCHIOPODA. [G.Fr.]

Notoungulata An order of dominant, hoofed herbivores of the Cenozoic of South America that are abundantly represented in Paleocene through Pleistocene nonmarine sedimentary rocks of that continent. Diverging from a primitive condylarth ancestry at an early date, they radiated into a wide diversity of forms, some of which were convergent with Northern Hemisphere ungulates.

Notoungulates were characterized by a skull with an expanded temporal region due to the presence of a large sinus in the squamosal and no postorbital bar. The feet were primitive, with five toes (three or two in some advanced forms), and the weight was borne mainly by the third digit. *See* EUTHERIA. [R.H.T.]

Nova The sudden brightening of a previously inconspicuous star. The name, short for nova stella (new star), formerly included objects now classified as supernovae and as other kinds of cataclysmic variables. Classical novae now include only those events where the energy source is hydrogen fusion (burning) on the surface of a white dwarf in a close binary system and the white dwarf is not destroyed in the process.

A handful of novae are discovered each year in the Milky Way Galaxy, and the total rate is probably 20–50 per year. A comparable number are found in other, nearby galaxies. The system consists of a normal, hydrogen-burning star in a close orbit (periods of a few days or less) around a white dwarf or degenerate star. A stream of gas flows from the normal star into a disk around the white dwarf and then accretes onto its surface. Hydrogen gradually builds up there until it is hot and dense enough for nuclear burning, normally with carbon, oxygen, neon, or magnesium from the white dwarf itself acting as a catalyst. Any nuclear fuel ignited under degenerate conditions explodes, because energy released does not cause the gas to expand, so temperature rises rapidly. *See* Binary star; White dwarf star.

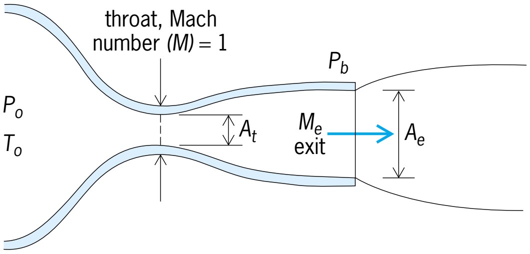
Novae brighten in a few days and fade in months to years. The peak brightness is more than 100 times the solar luminosity, and the total energy release more than 10^{45} ergs (10^{38} joules). Novae recur every 10^4–10^5 years. *See* Cataclysmic variable; Light curves; Variable star. [V.T.]

Nozzle

Nozzle A conduit with a variable cross-sectional area in which a fluid accelerates into a high-velocity stream.

The fluid must be compressed to a state of high pressure before it is sent through the nozzle. If the fluid is a gaseous medium, the temperature of the fluid also drops as the fluid accelerates. Since the velocity of sound of the fluid is directly related to the temperature of the fluid, the fluid velocity may exceed the speed of sound of the fluid, so that the fluid is in a state of supersonic flow. Under this condition, the nozzle must have a convergent-divergent geometry, since the supersonic state is realized only in the divergent portion of the nozzle (see illustration). The Mach number, which is the ratio of the velocity of the flowing fluid to the velocity of sound of the fluid, may be employed to characterize the flow. The Mach number is less than unity if the flow is subsonic, unity if the flow is sonic, and larger than unity if the flow is supersonic. If the flow at the throat is sonic, the flow is said to reach the critical state. *See* Fluid flow; Mach number; Sound.

A nozzle can be used for a variety of purposes. It is an indispensable piece of equipment in many devices employing fluid as a working medium. The reaction force that results from the fluid acceleration may be employed to propel a jet aircraft or a rocket. In fact, most military jet aircraft employ the simple convergent conical nozzle, with adjustable conical angle, as their propulsive device. If the high-velocity fluid stream is directed to turn a turbine, it may generate electric power or drive an automotive vehicle. The high-velocity stream may also be produced inside a wind tunnel so that the conditions of flight of a missile or an aircraft may be simulated inside the tunnel for research purposes. The nozzle must be carefully designed in this case to provide uniformly flowing fluid with the desired velocity, pressure, and temperature at the test section of the wind tunnel. Nozzles may also be used to disperse fuel into an atomized mist, such as that in diesel engines, for combustion purposes. *See* Atomization; Impulse turbine; Internal combustion engine; Jet propulsion; Rocket propulsion; Wind tunnel. [W.L.C.]



Typical convergent-divergent nozzle with a jet plume. P_0, T_0 = pressure and temperature upstream of the nozzle; A_t = area at the throat; P_b = backpressure; M_e, A_e = Mach number and area at exit.

Nuclear battery

Nuclear battery A battery that converts the energy of particles emitted from atomic nuclei into electric energy. Two basic types have been developed: (1) A high-voltage type, in which a beta-emitting isotope is separated from a collecting electrode by a vacuum or a solid dielectric, provides thousands of volts but the current is measured in picoamperes (pA); (2) a low-voltage type gives about 1 volt with current in microamperes (μA).

In the high-voltage type, a radioactive source is attached to one electrode, emitting charged particles. The source might be strontium-90, krypton-85, or hydrogen-3 (tritium), all of which are pure beta emitters. An adjacent electrode collects the emitted particles. A vacuum or solid dielectric separates the source and the collector electrodes. The principal use of the high-voltage battery is to maintain the voltage of a charged capacitor. The current output of the radioactive source is sufficient for this purpose.

Three different concepts have been employed in the low-voltage type of nuclear batteries: (1) a thermopile, (2) the use of an ionized gas between two dissimilar metals, and (3) the two-step conversion of beta energy into light by a phosphor and the conversion of light into electric energy by a photocell. *See* Battery. [J.D.;L.R.; K.F.]

Nuclear binding energy

Nuclear binding energy The amount by which the mass of an atom is less than the sum of the masses of its constituent protons, neutrons, and electrons expressed in units of energy. This energy difference accounts for the stability of the atom. In principle, the binding energy is the amount of energy which was released when the several atomic constituents came together to form the atom. Most of the binding energy is associated with the nuclear constituents (protons and neutrons), or nucleons, and it is customary to regard this quantity as a measure of the stability of the nucleus alone. *See* Nuclear structure.

A widely used term, the binding energy (BE) per nucleon, is defined by the equation below, where ${}_ZM^A$ represents the mass of

$$\text{BE/nucleon} = \frac{[ZH + (A - Z)n - {}_ZM^A]c^2}{A}$$

an atom of mass number A and atomic number Z, H and n are the masses of the hydrogen atom and neutron, respectively, and c is the velocity of light. The binding energies of the orbital electrons, here practically neglected, are not only small, but increase with Z in a gradual manner; thus the BE/nucleon gives an accurate picture of the variations and tends in nuclear stability.

The binding energy, when expressed in mass units, is known as the mass defect, a term sometimes incorrectly applied to quantity $M - A$, where M is the mass of the atom. *See* Mass defect.

The term binding energy is sometimes also used to describe the energy which must be supplied to a nucleus in order to remove a specified particle to infinity, for example, a neutron, proton, or alpha particle. A more appropriate term for this energy is the separation energy. This quantity varies greatly from nucleus to nucleus and from particle to particle. For example, the binding energies for a neutron, a proton, and a deuteron in ^{16}O are 15.67, 12.13, and 20.74 MeV, respectively, while the corresponding energies in ^{17}O are 4.14, 13.78, and 14.04 MeV, respectively. The usual order of neutron or proton separation energy is 7–9 MeV for most of the periodic table. [H.E.D.; D.H.W.]

Nuclear chemical engineering

Nuclear chemical engineering The branch of chemical engineering that deals with the production and use of radioisotopes, nuclear power generation, and the nuclear fuel cycle. A nuclear chemical engineer requires training in both nuclear and chemical engineering. As a nuclear engineer, he or she should be familiar with the nuclear reactions that take place in nuclear fission reactors and radioisotope production, with the properties of nuclear species important in nuclear fuels, with the properties of neutrons, gamma rays, and beta rays produced in nuclear reactors, and with the reaction, absorption, and attenuation of these radiations in the materials of reactors. *See* BETA PARTICLES; GAMMA RAYS; NEUTRON; NUCLEAR FUELS.

As a chemical engineer, he or she should know the properties of materials important in nuclear reactors and the processes used to extract and purify these materials and convert them into the chemical compounds and physical forms used in nuclear systems. *See* CHEMICAL ENGINEERING; NUCLEAR REACTOR.

Aspects of nuclear reactors of concern to nuclear chemical engineers include production and purification of the uranium dioxide fuel, production of the hafnium-free zirconium tubing used for fuel cladding, and control of corrosion and radioactive corrosion products by chemical treatment of coolant. A chemical engineering aspect of heavy-water reactor operation is control of the radioactive tritium produced by neutron activation of deuterium. Aspects of liquid-metal fast-breeder reactors of concern to nuclear chemical engineers include fabrication of the mixed uranium dioxide-plutonium dioxide fuel, purity control of sodium coolant to prevent fouling and corrosion, and reprocessing of irradiated fuel to recover plutonium and uranium for recycle. *See* NUCLEAR FUEL CYCLE; PLUTONIUM; URANIUM. [M.Be.]

Nuclear chemistry An interdisciplinary field that, in general, encompasses the application of chemical techniques to the solution of problems in nuclear physics. The discovery of the naturally occurring radioactive elements and of nuclear fission are classical examples of the work of nuclear chemists.

Although chemical techniques that are employed in nuclear chemistry are essentially the same as those in radiochemistry, these fields may be distinguished on the basis of the aims of the investigation. Thus, a nuclear chemist utilizes chemical techniques as a tool for the study of nuclear reactions and properties, whereas a radiochemist utilizes the radioactive properties of certain substances as a tool for the study of chemical reactions and properties. For the application of radioactive tracers to chemical problems *see* RADIOCHEMISTRY. For the chemical effects of radiation on various systems *see* RADIATION CHEMISTRY.

The chemical identification of radioactive nuclides and the determination of their nuclear properties has been one of the major activities of nuclear chemists. Such studies have produced an extensive array of radioisotopes, and present studies are concerned mainly with the more difficult identification of nuclides of very short half-life. Nuclear chemical investigations led to the discovery of the synthetic radioactive elements which do not have any stable isotopes and are not formed in the natural radioactive series (technetium, promethium, astatine, and the transuranium elements). Other major areas of nuclear chemistry include studies of nuclear structure and spectroscopy and of the probability and mechanisms of various nuclear reactions. *See* NUCLEAR FISSION; NUCLEAR REACTION; NUCLEAR STRUCTURE. [E.P.S.]

Nuclear engineering The branch of engineering that deals with the production and use of nuclear energy and nuclear radiation. The multidisciplinary field of nuclear engineering is studied in many universities. In some it is offered in a special nuclear engineering department; in others it is offered in other departments, such as mechanical or chemical engineering. Primarily, nuclear engineering involves the conception, development, design, construction, operation, and decommissioning of facilities in which nuclear energy or nuclear radiation is generated or used.

Examples of facilities include nuclear power plants; nuclear propulsion reactors used for the propulsion of ships and submarines; space nuclear reactors, used to power satellites, probes, and vehicles; nuclear production reactors, which produce fissile or fusile materials used in nuclear weapons; nuclear research reactors, which generate neutrons and gamma rays for scientific research and medical and industrial applications; gamma cells, which are used for sterilizing medical equipment and food and for manufacturing polymers; particle accelerators, which produce nuclear radiation for use in medical and industrial applications; and nuclear waste repositories. *See* NUCLEAR MEDICINE; NUCLEAR POWER; NUCLEAR REACTOR; PARTICLE ACCELERATOR; RADIOACTIVE WASTE MANAGEMENT; SHIP NUCLEAR PROPULSION; SPACE POWER SYSTEMS; SUBMARINE.

Many nuclear engineers are also involved in the research and development of future fusion power plants—plants that will be based on the fusion reaction for generating nuclear energy. Many challenging engineering problems are involved, including the development of technologies for heating the fusion fuel to hundreds of millions of degrees; confining this ultrahot fuel; and compressing fusion fuel to many thousand times their natural solid density. *See* NUCLEAR FUSION. [E.Gre.]

Nuclear explosion An explosion whose energy is produced by a nuclear transformation, either fission or fusion. *See* NUCLEAR FISSION; NUCLEAR FUSION.

The energy of a nuclear explosion is usually stated in terms of the mass of trinitrotoluene (TNT) which would provide the same energy. The complete fissioning of 1 kg of uranium or plutonium would be equivalent to 17,000 metric tons of TNT (17 kilotons); 2 lb would be equivalent to 17,000 short tons. The indicated yield-to-mass ratio of 1.7×10^7 cannot be realized, largely because of the ancillary equipment necessary to assemble the nuclear components into an explosive configuration in the very short time required.

Though the size of a typical nuclear explosion is appalling, the most significant feature of a nuclear device derives from its yield-to-weight ratio. The first nuclear weapons (1945) weighed about 5 tons, but with yields of 15 to 20 kT their yield-to-weight ratio was, nevertheless, close to 4000 times larger than that of previous weapons. By 1960 the United States had developed a weapon with a yield of about 1 megaton (MT) in a weight of about 1 ton for use in an intercontinental missile. With this, the yield-to-weight ratio was raised to 10^6.

Although weapons with yields of up to 15 and 60 MT were fired by the United States and Soviet Union respectively, about 1960 the main interest of the major nuclear powers focused on adapting nuclear devices for delivery by missile carriers, and this called for smaller weapons with so-called moderate yields of tens or hundreds of kilotons, up to a few megatons. *See* MISSILE.

The damage mechanism of a conventional explosion is blast—the pressure, or shock, wave transmitted in the surrounding medium. The blast wave from a nuclear explosion is similar, except for the great difference in scale. A nuclear explosion also produces several kinds of effects not experienced with ordinary explosives.

About one-third of the energy of the explosion is distributed as thermal radiation on line-of-sight trajectories. Exposure to 5–10 cal/cm^2 ($2–4 \times 10^5$ J/m^2) of thermal radiation energy in the short time (a second, or so) during which the thermal pulse is delivered will ignite many combustible materials (fabrics, paper, dry leaves, and so forth). It will cause serious flash burns on exposed skin. Such energy levels will be delivered in clear air to 0.3–0.4 mi (0.5–0.6 km) by an explosion of 1 kT. At Hiroshima, burn injuries alone would have been fatal to almost all persons in the open without protection out to a little over 1 mi (1.6 km), and burns serious enough to require treatment were experienced at distances greater than 2 mi (3.2 km).

During the few tens of seconds before the fireball rises away from the point at which the explosion occurred, it provides an intense source of gamma rays. The radiation emitted during this interval is referred to as prompt radiation. The remaining radioactivity, which is swept upward from the scene of the explosion to the altitude at which the fireball stops rising, and some of which ultimately returns to the surface, constitutes the residual radiation. *See* ALPHA PARTICLES; NEUTRON; RADIOACTIVITY.

At Hiroshima a dose equal to or greater than 450 rads (4.5 grays) extended to almost 1 mi (1.6 km). About half of the persons exposed to this dose in a short time will die within a few weeks, so that persons in this area who were not protected by heavy building walls experienced severe hazard from radiation. This is about the same distance for severe hazards from blast and thermal effects. The prompt radiation exposure falls off more rapidly with distance than the blast effect which, in turn, falls more rapidly than the intensity of thermal radiation. For an explosion much larger than 15 or 20 kT, the hazard range from thermal radiation or blast will be larger than that from prompt radiation, and prompt radiation will be a relatively unimportant effect. For much smaller yields, this order of importance will be reversed. [J.C.Ma.]

Nuclear fission

An extremely complex nuclear reaction representing a cataclysmic division of an atomic nucleus into two nuclei of comparable mass. This rearrangement or division of a heavy nucleus may take place naturally (spontaneous fission) or under bombardment with neutrons, charged particles, gamma rays, or other carriers of energy (induced fission). Although nuclei with mass number A of approximately 100 or greater are energetically unstable against division into two lighter nuclei, the fission process has a small probability of occurring, except with the very heavy elements. Even for these elements, in which the energy release is of the order of 200 megaelectronvolts, the lifetimes against spontaneous fission are reasonably long. *See* NUCLEAR REACTION.

Liquid-drop model. The stability of a nucleus against fission is most readily interpreted when the nucleus is viewed as being analogous to an incompressible and charged liquid drop with a surface tension. Long-range Coulomb forces between protons act to disrupt the nucleus, whereas short-range nuclear forces, idealized as a surface tension, act to stabilize it. The degree of stability is then the result of a delicate balance between the relatively weak electromagnetic forces and the strong nuclear forces. Although each of these forces results in potentials of several hundred megaelectronvolts, the height of a typical barrier against fission for a heavy nucleus, because they are of opposite sign but do not quite cancel, is only 5 or 6 MeV. Investigators have used this charged liquid-drop model with great success in describing the general features of nuclear fission and also in reproducing the total nuclear binding energies. *See* NUCLEAR BINDING ENERGY; NUCLEAR STRUCTURE; SURFACE TENSION.

Shell corrections. The general dependence of the potential energy on the fission coordinate representing nuclear elongation or deformation for a heavy nucleus such as ^{240}Pu is shown in Fig. 1. The expanded scale used in this figure shows the large decrease in energy of about 200 MeV as the fragments separate to infinity. It is known that ^{240}Pu is deformed in its ground state, which is represented by the lowest minimum of 7–1813 MeV near zero deformation. This energy represents the total nuclear binding energy when zero of potential energy is the energy of the individual nucleons at a separation of infinity. The second minimum to the right of zero deformation illustrates structure introduced in the fission barrier by shell corrections, that is, corrections dependent upon microscopic behavior of the individual nucleons, to the liquid-drop mass. Although shell corrections introduce small wiggles in the potential-energy surface as a function of deformation, the gross features of the surface are reproduced by the liquid-drop model. Since the typical fission barrier is only a few megaelectronvolts, the magnitude of the shell correction need only be small for irregularities to be introduced into the barrier. This structure is schematically illustrated for a heavy nucleus by the double-humped fission barrier in Fig. 2, which represents the region to the right of zero deformation in Fig. 1 on an expanded scale. The fission barrier has two maxima and a rather deep minimum in between. For comparison, the single-humped liquid-drop barrier is also schematically illustrated. The transition in the shape of the nucleus as a function of deformation is schematically represented in the upper part of the figure.

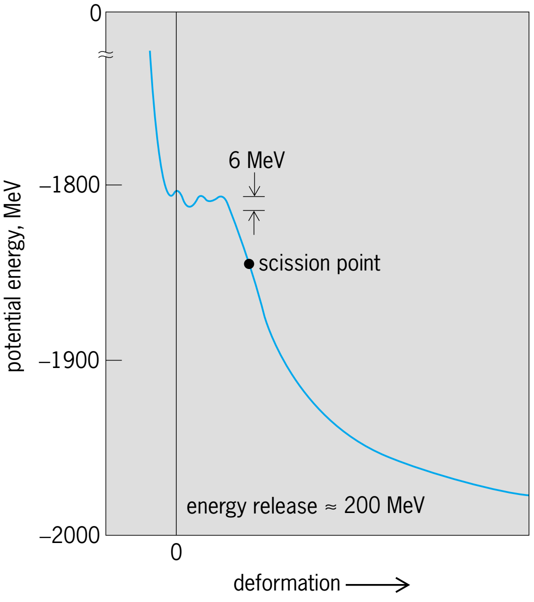


Fig. 1. Plot of the potential energy in MeV as a function of deformation for the nucleus ^{240}Pu. (*After M. Bolsteli et al., New calculations of fission barriers for heavy and superheavy nuclei, Phys. Rev., 5C:1050–1077, 1972*)

Experimental consequences. The observable consequences of the double-humped barrier have been reported in numerous experimental studies. In the actinide region more than 30 spontaneously fissionable isomers have been discovered between uranium and berkelium, with half-lives ranging from 10^{-11} to 10^{-2} s. These decay rates are faster by 20 to 30 orders of magnitude than the fission half-lives of the ground states, because of the increased barrier tunneling probability (Fig. 2). Several cases in which excited states in the second minimum decay by fission are also known. Normally these states decay within the well by

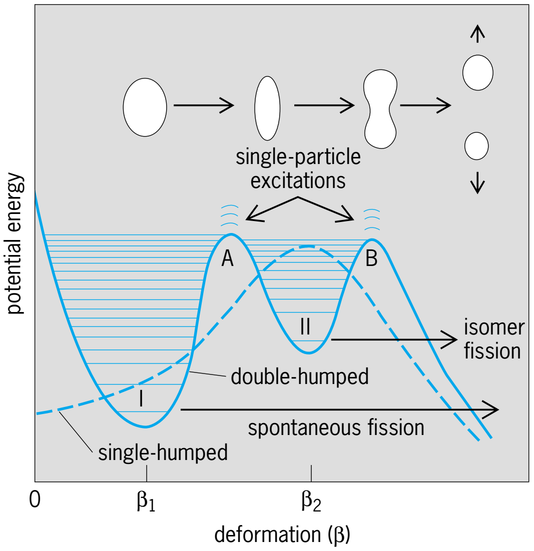

Fig. 2. Schematic plots of single-humped fission barrier of liquid-drop model and double-humped barrier Introduced by shell corrections. Humps at *A* and *B* result in minima in potential energy at deformation of β_1 and β_2. States in these wells are designated class I and class II, respectively. (*After J. R. Huizenga, Nuclear fission revisited, Science, 168:1405–1413, 1979*)

gamma decay; however, if there is a hindrance in gamma decay due to spin, the state (known as a spin isomer) may undergo fission instead.

Fission probability. The cross section for particle-induced fission $\sigma(y, f)$ represents the cross section for a projectile y to react with a nucleus and produce fission, as shown by the equation below. The quantities $\sigma_R(y)$, Γ_f and Γ_t are the total reaction

$$\sigma(y, f) = \sigma_R(y)(\Gamma_f / \Gamma_t)$$

across sections for the incident particle y, the fission width, and the total level width, respectively, where $\Gamma_t = \Gamma_f + \Gamma_n + \Gamma_y + \cdots$ is the sum of all partial-level widths. All the quantities in the above equation are energy-dependent.

When the incoming neutron has low energy, the likelihood of reaction is substantial only when the energy of the neutron is such as to form a compound nucleus in one or another of its resonance levels. The requisite sharpness of the "tuning" of the energy is specified by the total level width Γ. The nuclei ^{233}U, ^{235}U, and ^{239}Pu have a very large cross section to take up a slow neutron and undergo fission because both their absorption cross section and their probability for decay by fission are large. The probability for fission decay is high because the binding energy of the incident neutron is sufficient to raise the energy of the compound nucleus above the fission barrier. The very large, slow neutron fission cross sections of these isotopes make them important fissile materials in a chain reactor. *See* CHAIN REACTION (PHYSICS); REACTOR PHYSICS.

Postscission phenomena. After the nuclear fragments are separated, they are further accelerated as the result of the large Coulomb repulsion. The initially deformed fragments collapse to their equilibrium shapes, and the excited primary fragments lose energy by evaporating neutrons. After neutron emission, the fragments lose the remainder of their energy by gamma radiation, with a lifetime of about 10^{-11} s. The variation of neutron yield with fragment mass is directly related to the fragment excitation energy. Minimum neutron yields are observed for nuclei near closed shells because of the resistance to deformation of nuclei with closed shells. Maximum neutron yields occur for fragments that are "soft" toward nuclear deformation.

After the emission of the prompt neutrons and gamma rays, the resulting fission products are unstable against ß-decay For example, in the case of thermal neutron fission of ^{235}U, each fragment undergoes on the average about three ß-decays before it settles down to a stable nucleus. For selected fission products (for example, ^{87}Br and ^{137}I) ß-decayleaves the daughter nucleus with excitation energy exceeding its neutron binding energy. The resulting delayed neutrons amount, for thermal neutron fission of ^{235}U, to about 0.7% of all the neutrons given off in fission. Though small in number, they are quite important in stabilizing nuclear chain reactions against sudden minor fluctuations in reactivity. *See* DELAYED NEUTRON; NEUTRON; THERMAL NEUTRONS.

[J.R.Hu.]

Nuclear fuel cycle

The nuclear fuel cycle typically involves the following steps: (1) finding and mining the uranium ore; (2) refining the uranium from other elements; (3) enriching the uranium-235 content to 3–5%; (4) fabricating fuel elements; (5) interim storage and cooling of spent fuel; (6) reprocessing of spent fuel to recover uranium and plutonium (optional); (7) fabricating recycle fuel for added energy production (optional); (8) cooling of spent fuel or reprocessing waste, and its eventual transport to a repository for disposal in secure long-term storage. *See* NUCLEAR FUELS; URANIUM.

Steps 6 and 7 are used in Britain, France, India, Japan, and Russia. They are no longer used in the United States, which by federal policy has been restricted to a "once through" fuel cycle, meaning without recycle. Belgium, China, France, Germany, Japan, and Russia, with large and growing nuclear power capacities, use recycled plutonium. Disposal of highly enriched uranium from nuclear weapons is beginning to be undertaken by blending with natural or depleted uranium to make the 3–5% low-enrichment fuel. Similarly, MOX (mixed oxides) fuel capability can be used to dispose of plutonium stockpiled for nuclear weapons. This option is being planned in Europe and Russia, and is beginning to be considered in the United States. *See* PLUTONIUM.

Nuclear reactors produce energy using fuel made of uranium slightly enriched in the isotope ^{235}U. The basic raw material is natural uranium that contains 0.71% ^{235}U (the only naturally occurring isotope that can sustain a chain reaction). The other isotopes of natural uranium consist of ^{238}U, part of which converts to plutonium-239, during reactor operation. The isotope ^{239}Pu also sustains fission, typically contributing about one-third of the energy produced per fuel cycle. *See* NUCLEAR FISSION; NUCLEAR REACTOR.

Various issues revolve around the type of nuclear fuel cycle chosen. For instance, the question is still being argued whether "burning" weapons materials in recycle reactors is more or less subject to diversion (that is, falling into unauthorized hands) than storing and burying these materials. Another issue involves the composition of radioactive wastes and its impact on repository design. The nuclear fuel cycles that include reprocessing make it possible to separate out the most troublesome long-lived radioactive fission products and the minor actinide elements that continue to produce heat for centuries. The remaining waste decays to radiation levels comparable to natural ore bodies in about 1000 years. The shorter time for the resulting wastes to decay away simplifies the design, management, and costs of the repository. *See* ACTINIDE ELEMENTS. [E.L.Z.]

Nuclear fuels

Materials whose ability to release energy derives from specific properties of the atom's nucleus. In general, energy can be released by combining two light nuclei to form a heavier one, a process called nuclear fusion; by splitting a heavy nucleus into two fragments of intermediate mass, a process called nuclear fission; or by spontaneous nuclear decay processes, which are generically referred to as radioactivity. Although the fusion process may significantly contribute to the world's energy production in future centuries and although the production of limited amounts of energy by radioactive decay is a well-established technology for specific applications, the only significant industrial use of nuclear fuel so far utilizes fission. Therefore, the term nuclear fuels generally designates nuclear fission fuels only. *See* NUCLEAR BATTERY; NUCLEAR FISSION; NUCLEAR FUSION; NUCLEAR POWER; RADIOACTIVITY AND RADIATION APPLICATIONS.

Large releases of energy through a fission or a fusion reaction are possible because the stability of the nucleus is a function of its size. The binding energy per nucleon provides a measure of the nucleus stability. By selectively combining light nuclei together by a fusion reaction or by fragmenting heavy nuclei by a fission reaction, nuclei with higher binding energies per nucleon can be formed. The result of these two processes is a release of energy. The fissioning of one nucleus of uranium releases as much energy as the oxidation of approximately 5×10^7 atoms of carbon. *See* NUCLEAR BINDING ENERGY.

Many heavy elements can be made to fission by bombardment with high-energy particles. However, only neutrons can provide a self-sustaining nuclear fission reaction. Upon capture of a neutron by a heavy nucleus, the latter may become unstable and split into two fragments of intermediate mass. This fragmentation is generally accompanied by the emission of one or several neutrons, which can then induce new fissions. Only a few long-lived nuclides have been found to have a high probability of fission: ^{233}U, ^{235}U, and ^{239}Pu. Of these nuclides, only ^{235}U occurs in nature as 1 part in 140 of natural uranium, the remainder being mostly ^{238}U. The other nuclides must be produced artificially: ^{233}U from ^{232}Th, and ^{239}Pu from ^{238}U. The nuclides ^{233}U, ^{235}U, and ^{239}Pu are called fissile materials since they undergo fission with either slow or fast neutrons, while ^{232}Th and ^{238}U are called fertile materials. The latter, however, can also undergo the fission process at low yields with energetic neutrons; therefore, they are also referred to as being fissionable.

The term nuclear fuel applies not only to the fissile materials, but often to the mixtures of fissile and fertile materials as well. Using a mixture of fissile and fertile materials in a reactor allows capture of excess neutrons by the fertile nuclides to form fissile nuclides. Depending on the efficiency of production of fissile elements, the process is called conversion or breeding. Breeding is an extreme case of conversion corresponding to a production of fissile material at least equal to its consumption. *See* NUCLEAR FUEL CYCLE; NUCLEAR REACTOR. [D.Fr.; A.Mac.]

Nuclear fuels reprocessing Nuclear fuels are reprocessed for military or civilian purposes. In military applications, reprocessing is applied to extract fissile plutonium from fuels that are designed and operated to optimize production of this element. In civilian applications, reprocessing is used to recover valuable uranium and transuranic elements that remain in fuels discharged from electricity-generating nuclear power plants, for subsequent recycle in freshly constituted nuclear fuel. This military-civilian duality has made the development and application of reprocessing technology a sensitive issue worldwide and necessitates stringent international controls on reprocessing operations. It has also stimulated development of alternative processes to produce less plutonium and more uranium (or transuranic elements), so that the proliferation of nuclear weapons is held in check. *See* NUCLEAR POWER; PLUTONIUM; TRANSURANIUM ELEMENTS; URANIUM.

Nuclear fuel is removed from civilian power reactors due to chemical, physical, and nuclear changes that make it increasingly less efficient for heat generation as its cumulative residence time in the reactor core increases. The fissionable material in the fuel is not depleted; however, the buildup of fission product isotopes (with strong neutron-absorbing properties) tends to decrease the nuclear reactivity of the fuel. *See* NUCLEAR FISSION; NUCLEAR FUELS; NUCLEAR REACTOR.

A typical composition of civilian reactor spent fuel at discharge is 96% uranium, 3% fission products, and 1% transuranic elements (generally as oxides, because most commercial nuclear fuel is in the form of uranium oxide). The annual spent fuel output from a 1.2-gigawatt electric power station totals approximately 33 tons (30 metric tons) of heavy-metal content. This spent fuel can be discarded as waste or reprocessed to recover the uranium and plutonium that it contains (for recycle in fresh fuel elements). The governments of France, the United Kingdom, Russia, and China actively support reprocessing as a means for the management of highly radioactive spent fuel and as a source of fissile material for future nuclear fuel supply. The United States forbids the reprocessing of civilian reactor fuel for plutonium recovery and is the only one of the five declared nuclear weapons states with complete fuel recycling capabilities that actively opposes commercial fuel reprocessing.

Decisions to reprocess are not made on economic grounds only, making it difficult to evaluate the economic viability of reprocessing in various scenarios. In the ideal case, a number of factors must be considered, including: (1) cost of uranium/U_3O_8; (2) cost of enrichment; (3) cost of fuel fabrication; (4) cost of reprocessing; (5) waste disposal cost; and (6) fissile content of spent fuel.

The once-through fuel cycle (that is, direct disposal/no reprocessing) is favored when fuel costs and waste disposal costs are low and reprocessing costs are high. However, technological advancements and escalating waste disposal costs can swing the balance in favor of reprocessing. *See* ACTINIDE ELEMENTS; NUCLEAR FUEL CYCLE; RADIOACTIVE WASTE MANAGEMENT.

The technology of reprocessing nuclear fuel was created as a result of the Manhattan Project during World War II, with the purpose of plutonium production. Early reprocessing methods were refined over the years, leading to a solvent extraction process known as PUREX (plutonium uranium extraction). The PUREX process is an aqueous method that has been implemented by several countries and remains in operation on a commercial basis. A nonaqueous reprocessing method known as pyroprocessing was developed in the 1990s as an alternative to PUREX. It has not been deployed commercially, but promises greatly decreased costs and reduced waste volumes, with practically no secondary wastes or low-level wastes being generated. It also has the important attribute of an inability to separate pure plutonium from irradiated nuclear fuel. *See* SOLVENT EXTRACTION.

Both the PUREX process and the pyroprocess can be used in a waste management role in support of a once-through nuclear fuel cycle if the economics of this application are favorable. The PUREX process can be operated with a low decontamination factor for plutonium. The pyroprocess can place the transuranic elements in the salt waste stream that leads to a glass-ceramic waste form. Both systems are effective in placing the fission products and actinide elements present in spent nuclear fuel into more durable waste forms that can be safely disposed in a high-level waste repository. [J.J.La.]

Nuclear fusion One of the primary nuclear reactions, the name usually designating an energy-releasing rearrangement collision which can occur between various isotopes of low atomic number. *See* NUCLEAR REACTION.

Interest in the nuclear fusion reaction arises from the expectation that it may someday be used to produce useful power, from its role in energy generation in stars, and from its use in the fusion bomb. Since a primary fusion fuel, deuterium, occurs naturally and is therefore obtainable in virtually inexhaustible supply, solution of the fusion power problem would permanently solve the problem of the present rapid depletion of chemically valuable fossil fuels. As a power source, the lack of radioactive waste products from the fusion reaction is another argument in its favor as opposed to the fission of uranium. *See* HYDROGEN BOMB; NUCLEAR FISSION.

In a nuclear fusion reaction the close collision of two energy-rich nuclei results in a mutual rearrangement of their nucleons (protons and neutrons) to produce two or more reaction products, together with a release of energy. The energy usually appears in the form of kinetic energy of the reaction products, although when energetically allowed, part may be taken up as energy of an excited state of a product nucleus. In contrast to neutron-produced nuclear reactions, colliding nuclei, because they are positively charged, require a substantial initial relative kinetic energy to overcome their mutual electrostatic repulsion so that reaction can occur. This required relative energy increases with the nuclear charge Z, so that reactions between low-Z nuclei are the easiest to produce. The best known of these are the reactions between the heavy isotopes of hydrogen, deuterium, and tritium. *See* DEUTERIUM; TRITIUM.

Nuclear fusion reactions can be self-sustaining if they are carried out at a very high temperature. That is to say, if the fusion fuel exists in the form of a very hot ionized gas of stripped nuclei and free electrons termed a plasma, the agitation energy of the nuclei can overcome their mutual repulsion, causing reactions to occur. This is the mechanism of energy generation in the stars and in the fusion bomb. It is also the method envisaged for the controlled generation of fusion energy.

The cross sections (effective collisional areas) for many of the simple nuclear fusion reactions have been measured with high precision. It is found that the cross sections generally show broad maxima as a function of energy and have peak values in the general range of 0.01 barn (1 barn = 10^{-24} cm^2) to a maximum value of 5 barns, for the deuterium-tritium (D-T) reaction. The energy releases of these reactions can be readily calculated from the mass difference between the initial and final nuclei or determined by direct measurement.

Some of the important simple fusion reactions, their reaction products, and their energy releases are:

$$\begin{aligned} D + D &\rightarrow He^3 + n + 3.25\ \text{MeV} \\ D + D &\rightarrow T + p + 4.0\ \text{MeV} \\ T + D &\rightarrow He^4 + n + 17.6\ \text{MeV} \\ He^3 + D &\rightarrow He^4 + p + 18.3\ \text{MeV} \\ Li^6 + D &\rightarrow 2He^4 + 22.4\ \text{MeV} \\ Li^7 + p &\rightarrow 2He^4 + 17.3\ \text{MeV} \end{aligned}$$

If it is remembered that the energy release in the chemical reaction in which hydrogen and oxygen combine to produce a water molecule is about 1 eV per reaction, it will be seen that, gram for gram, fusion fuel releases more than 1,000,000 times as much energy as typical chemical fuels. [R.F.P.]

Nuclear isomerism The existence of excited states of atomic nuclei with unusually long lifetimes. If the lifetime of a specific excited state is unusually long, compared with the lifetimes of other excited states in the same nucleus, the state is said to be isomeric. The definition of the boundary between isomeric and normal decays is arbitrary, and the term is therefore used loosely. *See* EXCITED STATE; PARITY (QUANTUM MECHANICS); SPIN (QUANTUM MECHANICS).

The predominant decay mode of excited nuclear states is by γ-ray emission. The rate at which this process occurs is determined largely by the spins, parities, and excitation energies of the decaying state and of those to which it is decaying. In particular, the rate is extremely sensitive to the difference in the spins of initial and final states and to the difference in excitation energies. Both extremely large spin differences and extremely small energy differences can result in a slowing of the γ-ray emission by many orders of magnitude, resulting in some excited states having unusually long lifetimes and therefore being termed isomeric.

In addition to spin isomers, two other types of isomers have been identified. The first of these arises from the fact that some excited nuclear states represent a drastic change in shape of the nucleus from the shape of the ground state. In many cases this extremely deformed shape displays unusual stability, and states with this shape are therefore isomeric. A particularly important class of these shape isomers is observed in the decay of heavy nuclei by fission, and the study of such fission isomers has been the subject of intensive effort. *See* NUCLEAR FISSION.

A more esoteric form of isomer has also been observed, the so-called pairing isomer which results from differences in the microscopic motions of the constituent nucleons in the nucleus. A state of this type has a quite different character from the ground state of the nucleus, and is therefore also termed isomeric. *See* NUCLEAR STRUCTURE. [R.Bet.]

Nuclear magnetic resonance (NMR) A phenomenon exhibited when atomic nuclei in a static magnetic field absorb energy from a radio-frequency field of certain characteristic frequencies. Nuclear magnetic resonance is a powerful analytical tool for the characterization of molecular structure, quantitative analysis, and the examination of dynamic processes. It is based on quantized spectral transitions between nuclear Zeeman levels of stable isotopes, and is unrelated to radioactivity. *See* ZEEMAN EFFECT.

The format of nuclear magnetic resonance data is a spectrum that contains peaks referred to as resonances. The resonance of an isotope is distinguished by the transition frequency of the nucleus. The intensity of the resonance is directly proportional to the number of nuclei that produce the signal. Although the majority of nuclear magnetic resonance spectra are measured for samples in solution or as neat liquids, it is possible to measure nuclear magnetic resonance spectra of solid samples. Nuclear magnetic resonance is a nondestructive technique that can be used to measure spectra of cells and living organisms.

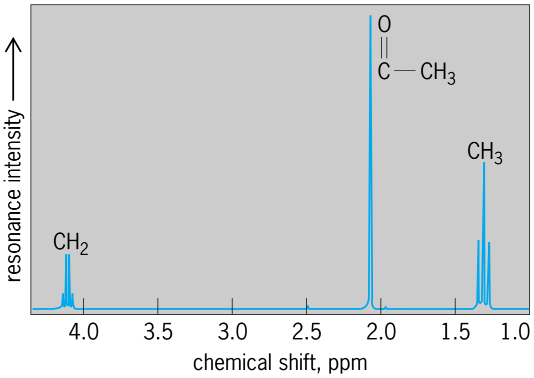
Nuclear magnetic properties. The nuclei of most atoms possess an intrinsic nuclear angular momentum. The classical picture of nuclear angular momentum is a spherical nucleus rotating about an axis in a manner analogous to the rotation of the Earth. Nuclear angular momentum, like most other atomic quantities, can be expressed as a series of quantized levels.

The transitions that give rise to the nuclear magnetic resonance spectrum are produced when the nuclei are placed in a static magnetic field. The external or applied magnetic field defines a geometric axis, denoted as the z axis. The external magnetic field orients the z components of nuclear angular momentum and the magnetic moment with respect to the z axis. The nuclear magnetic resonance spectrum is produced by spectral transitions between different spin states and is therefore dependent on the value of the nuclear spin. Nuclei for which the nuclear spin value is 0 have a magnetic spin-state value of 0. Therefore, these nuclei do not give rise to a nuclear magnetic resonance spectrum under any circumstances. Many important elements in chemistry have zero values of nuclear spin and are inherently nuclear magnetic resonance inactive, including the most abundant isotopes of carbon-12, oxygen-16, and sulfur-32. Nuclear magnetic resonance spectra are measured most often for nuclei that have nuclear spin values of $^1/_2$. Chemically important spin-$^1/_2$ nuclei include the isotopes hydrogen-1, phosphorus-31, flourine-19, carbon-13, nitrogen-15, silicon-29, iron-57, selenium-77, cadmium-113, silver-107, platinum-195, and mercury-199. Nuclear magnetic resonance spectra of nuclei that have nuclear spin values of greater than $^1/_2$, known as quadrupolar nuclei, can be measured; but the measurements are complicated by faster rates of nuclear relaxation. Nuclei that fall into this class include the isotopes hydrogen-2, lithium-6, nitrogen-14, oxygen-17, boron-11, chlorine-35, sodium-23, aluminum-27, and sulfur-33.

The transition frequency in nuclear magnetic resonance depends on the energy difference of the spin states. The intensity of the resonance is dependent on the population difference of the two spin states, which in turn depends directly on the magnitude of the energy difference. For spin-$^1/_2$ nuclei, ΔE is the difference in energy between the + and − values of the magnetic spin state. In contrast to other spectroscopic methods, the nuclear magnetic resonance frequency is variable, depending on the strength of the magnet used to measure the spectrum. Larger magnetic fields produce a greater difference in energy between the spin states. This translates into a larger difference in the population of the spin states and therefore a more intense resonance in the resulting nuclear magnetic resonance spectrum.

Individual nuclei of the same isotope in a molecule have transition frequencies that differ depending on their chemical environment. This phenomenon, called chemical shift, occurs because the effective magnetic field at a particular nucleus in a molecule is less than the applied magnetic field due to shielding by electrons.

An example of resonance chemical shift is observed in the ^1H nuclear magnetic resonance spectrum of ethyl acetate ($CH_3COOCH_2CH_3$; see illustration). Resonances at several frequencies are observed in this spectrum. The methylene (CH_2) protons are affected by the electron-withdrawing oxygen atoms of the neighboring ester group, and as a result the chemical shift of the methylene proton resonance is significantly different from the chemical shift of the resonances of the protons of the methyl (CH_3) groups of ethyl acetate. The two methyl groups are in different chemical environments and therefore give rise to resonances that have different chemical shifts. Because of the dependence of the transition frequency of a nucleus on its chemical environment, chemical shift is diagnostic of the functional group containing the nucleus of interest. Nuclear magnetic resonance spectroscopy is a frequently employed tool in chemical synthesis studies, because the nuclear magnetic resonance spectrum can confirm the chemical structure of a synthetic product.



Proton spectrum of ethyl acetate ($CH_3COOH_2CH_3$). Chemical shift is relative to the protons of tetramethylsilane. The integrated intensity of the resonances corresponds to the relative number of protons which give rise to each resonance.

In most nuclear magnetic resonance spectra, rather than frequency units, the spectra are plotted in units of chemical shift expressed as part per million (ppm). The ppm scale calculates the ratio of the resonance frequency in hertz (Hz) to the Larmor frequency of the nucleus at the magnetic field strength of the measurement. The ppm scale allows direct comparison of nuclear magnetic resonance spectra acquired by using magnets of differing field strength. This unit of nuclear magnetic resonance chemical shift should not be confused with the concentration units of ppm (mg/kg), often referred to by analytical chemists in the field of trace analysis.

The chemical shift (either in hertz or ppm) of a resonance is assigned relative to the chemical shift of a standard reference material. The nuclear magnetic resonance community has agreed to arbitrarily set the chemical shift of certain standard compounds to 0 ppm. For ^{1}H and ^{13}C nuclear magnetic resonance, the accepted standard is tetramethylsilane, which is defined to have a chemical shift of 0 ppm. However, any molecule with a resonance frequency in the appropriate chemical shift region of the spectrum that does not overlap with the resonances of the sample can be employed as a chemical shift reference. The use of a chemical shift reference compound other than the accepted standard is particularly common for nuclei that have a very large chemical shift range such as fluorine-19 or selenium-77, since it may be impossible to measure the spectrum of the accepted chemical shift reference compound and the analyte of interest simultaneously because of their very different frequencies.

In addition to the differences in chemical shift, resonances in a given spectrum, for example for ethyl acetate (see illustration), also differ in the number of signals composing the resonance detected for each group of protons. Instead of one resonance resulting from a single transition between two spin states, the methylene group (CH_2) resonance is actually a quartet composed of four lines. Similarly, although the acetate CH_3 resonance is a single resonance, the ethylene group (CH_3) resonance consists of three lines. This splitting of some resonances, called spin-spin or scalar coupling, arises from interactions between nuclei through their bonding electrons rather than through space. Scalar coupling is a short-range interaction that usually occurs for nuclei separated by one to three bonds.

The effects of spin-spin coupling can be removed from the spectrum by application of a low-strength magnetic field to one of the coupled spins. The effect of this secondary field is to equalize the population of the coupled transitions and to remove the effects of spin-spin coupling. Decoupling can be homonuclear or heteronuclear. Homonuclear decoupling is useful for assigning the resonances of coupled spin systems in the spectrum of a compound or complex mixture. For example, in ethyl acetate, decoupling at the frequency of the methylene group (CH_2) protons would remove the effects of spin-spin coupling, collapsing the ethylene group (CH_3) resonance into a singlet and confirming the resonance assignments. [C.K.L.]

Nuclear medicine A subspecialty of medicine based primarily on the use of radioactive substances in medical diagnosis, treatment, and research. In a typical examination a radioactive tracer is given, usually by injection into an arm vein, and the distribution of the radioactive substance within the body or a part of the body is portrayed in a series of nuclear images. The imaging is based on the emission of gamma rays by the tracer substance that pass out of the body and are recorded by a scintillation camera. The scintillation camera is a radiation detection device consisting of a large sodium iodide crystal (nearly 1 m in diameter in some cases) which detects the gamma rays that interact with the crystal and locates where on the detector face the interaction has occurred. These interactions are used to produce a picture or image of where the gamma rays originated within the body. The methods are related to those in routine x-ray examinations, except that gamma rays are emitted from the body to provide the diagnostic information, rather than being transmitted through the body. Nuclear images depend on specific radioactive elements or compounds labeled with radioactive elements being selectively concentrated in an organ, making it possible to obtain pictures that provide information about regional function within the organ. *See* GAMMA-RAY DETECTORS; SCINTILLATION COUNTER.

Nuclear imaging techniques make it possible to examine functions of the human body noninvasively, in ways that at times surpass the perception of pathologists at the autopsy table and surgeons at the operating table. The body can be examined as a series of physiologic processes, not simply as static structures. *See* RADIOACTIVE TRACER; RADIOISOTOPE; RADIOLOGY. [H.N.W.]

Nuclear molecule A quasistable entity of nuclear dimensions formed in nuclear collisions and comprising two or more discrete nuclei that retain their identities and are bound together by strong nuclear forces. Whereas the stable molecules of chemistry and biology consist of atoms bound through various electronic mechanisms, nuclear molecules do not form in nature except possibly in the hearts of giant stars; this simply reflects the fact that all nuclei carry positive electrical charges, and that under all natural conditions the long-range electrostatic repulsion prevents nuclear components from coming within the grasp of the short-range attractive nuclear force which could provide molecular binding. But in energetic collisions this electrostatic repulsion can be overcome. *See* NUCLEAR STRUCTURE. [D.A.B.]

Nuclear moments Intrinsic properties of atomic nuclei: electric moments result from deviations of the nuclear charge distribution from spherical symmetry; magnetic moments are a consequence of the intrinsic spin and the rotational motion of nucleons within the nucleus. The classical definitions of the magnetic and electric multipole moments are written in general in terms of multipole expansions. *See* NUCLEAR STRUCTURE; SPIN (QUANTUM MECHANICS).

In special cases nuclear moments can be measured by direct methods involving the interaction of the nucleus with an external magnetic field or with an electric field gradient produced by the scattering of high-energy charged particles. In general, however, nuclear moments manifest themselves through the hyperfine interaction between the nuclear moments and the fields or field gradients produced by either the atomic electrons' currents and spins, or the molecular or crystalline electronic and lattice structures. *See* HYPERFINE STRUCTURE. [N.Ko.]

Nuclear orientation The directional ordering of an assembly of nuclear spins I with respect to some axis in space. Under normal conditions nuclei are not oriented; that is, all directions in space are equally probable. For a system of nuclear spins with rotational symmetry about an axis, the degree of orientation is completely characterized by the relative populations a_m of the $2I + 1$ magnetic sublevels m $(= I, I - 1, \dots, -I)$.

Nuclear orientation can be achieved in various ways. The most obvious way is to modify the energies of the $2I + 1$ magnetic sublevels so as to remove their degeneracy and thereby change the populations of these sublevels. The spin degeneracy can be removed by a magnetic field interacting with the nuclear magnetic dipole moment, or by an inhomogeneous electric field interacting with the nuclear electric quadrupole moment. Significant differences in the populations of the sublevels can be established by cooling the nuclear sample to low temperatures. This means of producing nuclear orientation is called the static method. In contrast, there is the dynamic method, which is related to optical pumping in gases. There are other ways to produce oriented nuclei; for example, in a nuclear reaction such as the capture of polarized neutrons (produced by magnetic scattering) by unoriented nuclei. *See* DYNAMIC NUCLEAR POLARIZATION; OPTICAL PUMPING.

Oriented nuclei have been used to measure nuclear properties, for example, magnetic dipole and electric quadrupole moments, spins, parities, and mixing ratios of nuclear states. Oriented nuclei have been used to examine some of the fundamental properties of nuclear forces, for example, nonconservation of parity in the weak interaction. Measurement of hyperfine fields, electric-field gradients, and other properties relating to the environment of the nucleus have been made by using oriented nuclei. Nuclear orientation thermometry is one of the few sources of a primary temperature scale at low temperatures. Oriented nuclear targets used in conjunction with beams of polarized and unpolarized particles have proved very useful in examining certain aspects of the nuclear force. *See* LOW-TEMPERATURE THERMOMETRY; NUCLEAR MOMENTS; NUCLEAR STRUCTURE; PARITY (QUANTUM MECHANICS). [H.Mar.]

Nuclear physics The discipline involving the structure of atomic nuclei and their interactions with each other, with their constituent particles, and with the whole spectrum of elementary particles that is provided by very large accelerators. The nuclear domain occupies a central position between the atomic range of forces and sizes and those of elementary-particle physics, characteristically within the nucleons themselves. As the only system in which all the known natural forces can be studied simultaneously, it provides a natural laboratory for the testing and extending of many fundamental symmetries and laws of nature. Containing a reasonably large, yet manageable number of strongly interacting components, the nucleus also occupies a central position in the universal many-body problem of physics. *See* ATOMIC NUCLEUS; ATOMIC STRUCTURE AND SPECTRA; ELEMENTARY PARTICLE; SYMMETRY LAWS (PHYSICS).

Nuclear physics is unique in the extent to which it merges the most fundamental and the most applied topics. Its instrumentation has found broad applicability throughout science, technology, and medicine; nuclear engineering and nuclear medicine are two very important areas of applied specialization. *See* NUCLEAR ENGINEERING; NUCLEAR RADIATION (BIOLOGY); RADIOLOGY.

Nuclear chemistry, certain aspects of condensed matter and materials science, and nuclear physics together constitute the broad field of nuclear science; outside the United States and Canada elementary particle physics is frequently included in this more general classification. *See* ANALOG STATES; COSMIC RAYS; FUNDAMENTAL INTERACTIONS; ISOTOPE; NUCLEAR CHEMISTRY; NUCLEAR FISSION; NUCLEAR FUSION; NUCLEAR ISOMERISM; NUCLEAR MOMENTS; NUCLEAR REACTION; NUCLEAR REACTOR; NUCLEAR SPECTRA; NUCLEAR STRUCTURE; PARTICLE ACCELERATOR; PARTICLE DETECTOR; RADIOACTIVITY; SCATTERING EXPERIMENTS (NUCLEI); WEAK NUCLEAR INTERACTIONS. [D.A.B.]

Nuclear power Power derived from fission or fusion nuclear reactions. More conventionally, nuclear power is interpreted as the utilization of the fission reactions in a nuclear power reactor to produce steam for electric power production, for ship propulsion, or for process heat. Fission reactions involve the breakup of the nucleus of high-mass atoms and yield an energy release which is more than a millionfold greater than that obtained from chemical reactions involving the burning of a fuel. Successful control of the nuclear fission reactions utilizes this intensive source of energy. *See* NUCLEAR FISSION.

Fission reactions provide intensive sources of energy. For example, the fissioning of an atom of uranium yields about 200 MeV, whereas the oxidation of an atom of carbon releases only 4 eV. On a weight basis, this 50×10^6 energy ratio becomes about 2.5×10^6. Uranium consists of several isotopes, only 0.7% of which is uranium-235, the fissile fuel currently used in reactors. Even with these considerations, including the need to enrich the fuel to several percent uranium-235, the fission reactions are attractive energy sources when coupled with abundant and relatively cheap uranium ore.

Although the main process of nuclear power is the release of energy in the fission process which occurs in the reactor, there are a number of other important processes, such as mining and waste disposal, which both precede and follow fission. Together they constitute the nuclear fuel cycle. *See* NUCLEAR FUEL CYCLE.

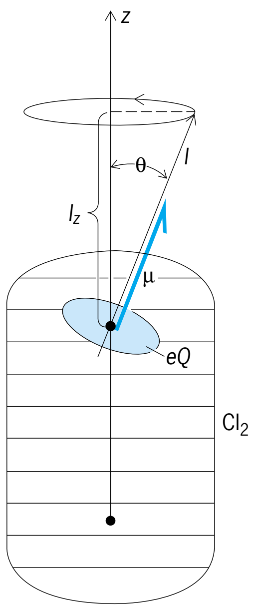
Power reactors include light-water-moderated and -cooled reactors (LWRs), including the pressurized-water reactor (PWR) and the boiling-water reactor (BWR). The high-temperature gas-cooled reactor (HTGR), and the liquid-metal-cooled fast breeder reactor (LMFBR) have reached a high level of development but are not used for commercial purposes. *See* NUCLEAR REACTOR.

Critics of nuclear power consider the radioactive wastes generated by the nuclear industry to be too great a burden for society to bear. They argue that since the high-level wastes will contain highly toxic materials with long half-lives, such as a few tenths of one percent of plutonium that was in the irradiated fuel, the safekeeping of these materials must be assured for time periods longer than social orders have existed in the past. Nuclear proponents answer that the time required for isolation is much shorter, since only 500 to 1000 years is needed before the hazard posed by nuclear waste falls below that posed by common natural ore deposits in the environment. *See* RADIOACTIVE WASTE MANAGEMENT.

Nuclear power facilities present a potential hazard rarely encounted with other facilities; that is, radiation. A major health hazard would result if, for instance, a significant fraction of the core inventory of a power reactor were released to the atmosphere. Such a release of radioactivity is clearly unacceptable, and steps are taken to assure it could never happen. These include use of engineered safety systems, various construction and design codes, regulations on reactor operation, and periodic maintenance and inspection. [F.J.Ra.]

Nuclear quadrupole resonance A selective absorption phenomenon observable in a wide variety of polycrystalline compounds containing nonspherical atomic nuclei when placed in a magnetic radio-frequency field. Nuclear quadrupole resonance (NQR) is very similar to nuclear magnetic resonance (NMR), and was originated as an inexpensive (no stable homogeneous large magnetic field is required) alternative way to study nuclear moments. It later gained a modest popularity. *See* MAGNETIC RESONANCE; NUCLEAR MAGNETIC RESONANCE (NMR).

In the simplest case, for example, ^{35}Cl in solid Cl_2, NQR is associated with the precession of the angular momentum I (and the nuclear magnetic dipole moment μ) of the nucleus, depicted in the illustration as a flat ellipsoid of rotation, around the symmetry axis (taken as the z axis) of the Cl_2 molecule fixed in the crystalline solid. The precession, with constant angle θ between the nuclear axis and symmetry axis of the molecule, is due to the torque which the inhomogeneous molecular electric field exerts



Interaction of ^{35}Cl nucleus with the electric field of a Cl_2 molecule.

on the nucleus of electric quadrupole moment *eQ*. The absorption occurs classically when the frequency of the rf field and that of the precessing motion of the angular momentum coincide.

NQR spectra have been observed in the approximate range 1–1000 MHz. Most of the NQR work has been on molecular crystals. For such crystals the coupling constants found do not differ very much from those measured for the isolated molecules in microwave spectroscopy. The most precise nuclear information which may be extracted from NQR data are quadrupole moment ratios of isotopes of the same element. If values for the axial gradient of the molecular electric field can be estimated from atomic fine structure data, then fair values of the quadrupole moment may be obtained. However, it has also proved very productive to use the quadrupole nucleus as a probe of bond character and orientation and crystalline electric fields and lattice sites, and extensive data have been accumulated in this area. *See* MICROWAVE SPECTROSCOPY. [H.De.]

Nuclear radiation All particles and radiations emanating from an atomic nucleus due to radioactive decay and nuclear reactions. Thus the criterion for nuclear radiations is that a nuclear process is involved in their production. The term was originally used to denote the ionizing radiations observed from naturally occurring radioactive materials. These radiations were alpha rays (energetic helium nuclei), beta rays (negative electrons), and gamma rays (electromagnetic radiation with wavelength much shorter than visible light). *See* ALPHA PARTICLES; BETA PARTICLES; GAMMA RAYS.

Nuclear radiations have traditionally been considered to be of three types based on the manner in which they interact with matter as they pass through it. These are the charged heavy particles with masses comparable to that of the nuclear mass (for example, protons, alpha particles, and heavier nuclei), electrons (both negatively and positively charged), and electromagnetic radiation. For all of these, the interactions with matter are considered to be primarily electromagnetic. The behavior of mesons and other particles is intermediate between that of the electron and heavy charged particles.

A striking difference in the absorption of the three types of radiations is that only heavy charged particles have a range. That is, a monoenergetic beam of heavy charged particles, in passing through a certain amount of matter, will lose energy without changing the number of particles in the beam. Ultimately, they will be stopped after crossing practically the same thickness of absorber. For electromagnetic radiation (gamma rays) and neutrons, on the other hand, the absorption is exponential. The difference in behavior reflects the fact that charged particles are not removed from the beam by individual interactions, whereas gamma radiation photons (and neutrons) are removed. Electrons exhibit a more complex behavior. *See* ELECTRON; NUCLEAR REACTION. [D.G.K.]

Nuclear radiation (biology) Nuclear radiations are used in biology because of their common property of ionizing matter. This makes their detection relatively simple, or makes possible the production of biological effects in any living cell.

Ionizing radiation is any electromagnetic or particulate radiation capable of producing ions, directly or indirectly, in its passage through matter.

All ionizing radiations produce biological changes, directly by ionization or excitation of the atoms in the molecules of biological entities, such as in chromosomes, or indirectly by the formation of active radicals or deleterious agents, through ionization and excitation, in the medium surrounding the biological entities. Ionizing radiation, having high penetrating power, can reach the most vulnerable part of a cell, an organ, or a whole organism, and is thus very effective. In terms of the energy absorbed per unit mass of a biological entity in which an effect is produced, some ionizing radiations are more effective than others. The relative biological effectiveness (RBE) depends in fact on the density of ionization (also termed the specific ionization or linear energy transfer, LET) along the path of the ionizing particle rather than on the nature of the particle itself. Relative biological effectiveness depends also on many other factors. *See* LINEAR ENERGY TRANSFER (BIOLOGY); RADIATION BIOLOGY.

The medical uses of nuclear radiations may be divided into three distinct classes:

1. The radiations, which are principally x-rays, are used to study the anatomical configuration of body organs, usually for the purpose of detecting abnormalities as an aid in diagnosis.
2. The radiations are used for therapeutic purposes to produce biological changes in such tissues as tumors.
3. The radiations are used as a simple means of tracing a suitable radioactive substance through different steps in its course through the body, in the study of some particular physiological process. *See* RADIOLOGY. [G.F.; E.H.Q.]

The radiations emitted by radioactive isotopes of the various elements are used in biological research. The most useful ones in biological research are the isotopes of the elements which are important in metabolism and in the structural materials of cells. These include carbon, hydrogen, sulfur, and phosphorus. In addition, the radioactive metals like cobalt-60, radium, and others can be used to produce radiations for external application to cells and tissues. Most of the isotopes mentioned emit beta particles when they decay, and a few emit gamma rays. Therefore, they can be easily detected by various means. These procedures are sometimes used in the study of the movement of elements or their compounds in plants and animals. They are frequently used for tracing the sequence of reactions in metabolism. *See* BETA PARTICLES; GAMMA RAYS; RADIOISOTOPE (BIOLOGY).

In addition to the radiations emitted, some of the elements change to a different element when they decay. Phosphorus-32 changes to sulfur, sulfur-35 changes to chlorine, and tritium (hydrogen-3) changes to helium when they decay by the emission of an electron, a beta particle. Therefore, in addition to the radiation produced, the transmutation of the element affects the molecule and the cell of which it is a part. In other experiments, the decay of phosphorus-32 has been used to give information on the nature and importance of the phosphorus-containing molecules to the survival or reproduction of a cell or virus particle. Nuclear radiations have also proved useful in many studies of the nature and the mechanisms of the effects of radiations on cells and cell constituents. [J.H.T.]

Nuclear reaction A process that occurs as a result of interactions between atomic nuclei when the interacting particles approach each other to within distances of the order of nuclear dimensions ($\simeq 10^{-12}$ cm). While nuclear reactions occur in nature, understanding of them and use of them as tools have taken place primarily in the controlled laboratory environment. In the usual experimental situation, nuclear reactions are initiated by bombarding one of the interacting particles, the stationary target nucleus, with nuclear projectiles of some type, and the reaction products and their behaviors are studied.

Types of nuclear interaction. As a generalized nuclear process, consider a collision in which an incident particle strikes a previously stationary particle, to produce an unspecified number of final products. If the final products are the same as the two initial particles, the process is called scattering. The scattering is said to be elastic or inelastic, depending on whether some of the kinetic energy of the incident particle is used to raise either of the particles to an excited state. If the product particles are different from the initial pair, the process is referred to as a reaction.

The most common type of nuclear reaction, and the one which has been most extensively studied, involves the production of two final products. Such reactions can be observed, for example, when deuterons with a kinetic energy of a few megaelectronvolts are allowed to strike a carbon nucleus of mass 12. Protons, neutrons, deuterons, and alpha particles are observed to be emitted, and reactions (1)–(4) are responsible. In these equations the nuclei are indicated by the usual chemical symbols; the subscripts indicate the atomic number (nuclear charge) of the nucleus, and the superscripts the mass number of the particular isotope.

$$ {}^{2}_{1}\mathrm{H} + {}^{12}_{6}\mathrm{C} \rightarrow {}^{2}_{1}\mathrm{H} + {}^{12}_{6}\mathrm{C} \qquad (1)$$

$$ {}^{2}_{1}\mathrm{H} + {}^{12}_{6}\mathrm{C} \rightarrow {}^{1}_{1}\mathrm{H} + {}^{13}_{6}\mathrm{C} \qquad (2)$$

$$ {}^{2}_{1}\mathrm{H} + {}^{12}_{6}\mathrm{C} \rightarrow {}^{0}_{1}n + {}^{13}_{7}\mathrm{N} \qquad (3)$$

$$ {}^{2}_{1}\mathrm{H} + {}^{12}_{6}\mathrm{C} \rightarrow {}^{4}_{2}\mathrm{He} + {}^{10}_{5}\mathrm{B} \qquad (4)$$

These reactions are conventionally written in the compact notation ${}^{12}\mathrm{C}(d,d){}^{12}\mathrm{C}$, ${}^{12}\mathrm{C}(d,p){}^{13}\mathrm{C}$, ${}^{12}\mathrm{C}(d,n){}^{13}\mathrm{N}$, and ${}^{12}\mathrm{C}(d,\alpha){}^{10}\mathrm{B}$, where *d* represents deuteron, *p* proton, *n* neutron, and α alpha particle. In each of these cases the reaction results in the production of an emitted light particle and a heavy residual nucleus. If the residual nucleus is formed in an excited state, it will subsequently emit this excitation energy in the form of gamma rays or, in special cases, electrons. The residual nucleus may also be a radioactive species, in which case it will undergo further transformation in accordance with its characteristic radioactive decay scheme. *See* Radioactivity.

Nuclear cross section. In general one is interested in the probability of occurrence of the various reactions as a function of the bombarding energy of the incident particle. The measure of probability for a nuclear reaction is its cross section. Consider a reaction initiated by a beam of particles incident on a region which contains N atoms per unit area (uniformly distributed), and where I particles per second striking the area result in R reactions of a particular type per second. The fraction of the area bombarded which is effective in producing the reaction products is R/I. If this is divided by the number of nuclei per unit area, the effective area or cross section $\sigma = R/IN$. This is referred to as the total cross section for the specific reaction, since it involves all the occurrences of the reaction. The dimensions are those of an area, and total cross sections are expressed in either square centimeters or barns (1 barn $= 10^{-24}$ cm^2). The differential cross section refers to the probability that a particular reaction product will be observed at a given angle with respect to the beam direction. Its dimensions are those of an area per unit solid angle (for example, barns per steradian).

Reaction mechanism. Various reaction models have been extremely successful in describing certain classes or types of nuclear reaction processes. In general, all reactions can be classified according to the time scale on which they occur, and the degree to which the kinetic energy of the incident particle is converted into internal excitation of the final products. A large fraction of the reactions observed has properties consistent with those predicted by two reaction mechanisms which represent the extremes in this general classification. These are the mechanisms of compound nucleus formation and direct interaction.

Compound nucleus formation is envisioned to take place in two distinct steps. In the first step the incident particle is captured by (or fuses with) the target nucleus, forming an intermediate or compound nucleus which lives a long time ($\simeq 10^{-16}$ s) compared to the approximately 10^{-22} s it takes the incident particle to travel past the target. During this time the kinetic energy of the incident particle is shared among all the nucleons, and all memory of the incident particle and target is lost. The compound nucleus is always formed in a highly excited unstable state, is assumed to approach themodynamic equilibrium involving all or most of the available degrees of freedom, and will decay, as the second step, into different reaction products, or through so-called exit channels. The essential feature of the compound nucleus formation or fusion reaction is that the probability for a specific reaction depends on two independent probabilities: the probability for forming the compound nucleus, and the probability for decaying into that specific exit channel.

Some reactions have properties which are in striking conflict with the predictions of the compound nucleus hypothesis. Many of these are consistent with the picture of a mechanism where no long-lived intermediate system is formed, but rather a fast mechanism where the incident particle, or some portion of it, interacts with the surface, or some nucleons on the surface, of the target nucleus. These direct reactions are assumed to involve only a very small number of the available degrees of freedom. Most direct reactions are of the transfer type, where one or more nucleons are transferred to or from the incident particle as it passes the target, leaving the two final partners either in their ground states or in one of their many excited states. Such transfer reactions are generally referred to as stripping or pickup reactions, depending on whether the incident particle has lost or acquired nucleons in the reaction.

Inelastic scattering is also a direct reaction. Whereas the states preferentially populated in transfer reactions are those of specific single-particle or shell-model structure, the states preferentially excited in inelastic scattering are collective in nature. *See* Nuclear structure; Scattering experiments (nuclei). [D.G.K.]

Nuclear reactor A system utilizing nuclear fission in a controlled and self-sustaining manner. Neutrons are used to fission the nuclear fuel, and the fission reaction produces not only energy and radiation but also additional neutrons. Thus a neutron chain reaction ensues. A nuclear reactor provides the assembly of materials to sustain and control the neutron chain reaction, to appropriately transport the heat produced from the fission reactions, and to provide the necessary safety features to cope with the radiation and radioactive materials produced by its operation. *See* Chain reaction (physics); Nuclear fission.

Nuclear reactors are used in a variety of ways as sources for energy, for nuclear irradiations, and to produce special materials by transmutation reactions. The generation of electrical energy by a nuclear power plant makes use of heat to produce steam or to heat gases to drive turbogenerators. Direct conversion of the fission energy into useful work is possible, but an efficient process has not yet been realized to accomplish this. Thus, in its operation the nuclear power plant is similar to the conventional coal-fired plant, except that the nuclear reactor is substituted for the conventional boiler as the source of heat.

The rating of a reactor is usually given in kilowatts (kW) or megawatts-thermal [MW(th)], representing the heat generation rate. The net output of electricity of a nuclear plant is about one-third of the thermal output. Significant economic gains have been achieved by building improved nuclear reactors with outputs of about 3300 MW(th) and about 1000 MW-electrical [MW(e)]. *See* ELECTRIC POWER GENERATION; NUCLEAR POWER.

Fuel and moderator. The fission neutrons are released at high energies and are called fast neutrons. The average kinetic energy is 2 MeV, with a corresponding neutron speed of 1/15 the speed of light. Neutrons slow down through collisions with nuclei of the surrounding material. This slowing-down process is made more effective by the introduction of materials of low atomic weight, called moderators, such as heavy water (deuterium oxide), ordinary (light) water, graphite, beryllium, beryllium oxide, hydrides, and organic materials (hydrocarbons). Neutrons that have slowed down to an energy state in equilibrium with the surrounding materials are called thermal neutrons, moving at 0.0006% of the speed of light. The probability that a neutron will cause the fuel material to fission is greatly enhanced at thermal energies, and thus most reactors utilize a moderator for the conversion of fast neutrons to thermal neutrons. *See* NEUTRON; THERMAL NEUTRONS.

With suitable concentrations of the fuel material, neutron chain reactions also can be sustained at higher neutron energy levels. The energy range between fast and thermal is designated as intermediate. Fast reactors do not have moderators and are relatively small.

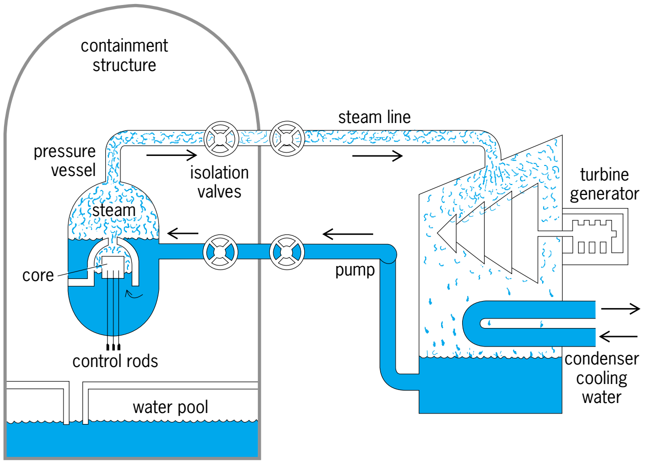
Only three isotopes—uranium-235, uranium-233, and plutonium-239—are feasible as fission fuels, but a wide selection of materials incorporating these isotopes is available.

Heat removal. The major portion of the energy released by the fissioning of the fuel is in the form of kinetic energy of the fission fragments, which in turn is converted into heat through the slowing down and stopping of the fragments. For the heterogeneous reactors this heating occurs within the fuel elements. Heating also arises through the release and absorption of the radiation from the fission process and from the radioactive materials formed. The heat generated in a reactor is removed by a primary coolant flowing through it.

Reactor coolants. Coolants are selected for specific applications on the basis of their heat-transfer capability, physical properties, and nuclear properties.

Water has many desirable characteristics. It was employed as the coolant in many of the first production reactors, and most power reactors still utilize water as the coolant. In a boiling-water reactor (BWR; see illustration), the water boils directly in the reactor core to make steam that is piped to the turbine. In a pressurized-water reactor (PWR), the coolant water is kept under increased pressure to prevent boiling. It transfers heat to a separate stream of feed water in a steam generator, changing that water to steam.

For both boiling-water and pressurized-water reactors, the water serves as the moderator as well as the coolant. Both light water and heavy water are excellent neutron moderators, although heavy water (deuterium oxide) has a neutron-absorption cross section approximately 1/500 that for light water that makes it possible to operate reactors using heavy water with natural uranium fuel. The high pressure necessary for water-cooled power reactors determines much of the plant design. *See* NUCLEAR REACTION.



Boiling-water reactor. (*Atomic Industrial Forum, Inc.*)

Gases are inherently poor heat-transfer fluids as compared with liquids because of their low density. This situation can be improved by increasing the gas pressure; however, this introduces other problems and costs. Helium is the most attractive gas (it is chemically inert and has good thermodynamic and nuclear properties) and has been selected as the coolant for the development of high-temperature gas-cooled reactor (HTGR) systems, in which the gas transfers heat from the reactor core to a steam generator. The British advanced gas reactor (AGR), however, uses carbon dioxide (CO_2). Gases are capable of operation at extremely high temperature, and they are being considered for special process applications and direct-cycle gas-turbine applications.

The alkali metals, in particular, have excellent heat-transfer properties and extremely low vapor pressures at temperatures of interest for power generation. Sodium is attractive because of its relatively low melting point (208°F or 98°C) and high heat-transfer coefficient. It is also abundant, commercially available in acceptable purity, and relatively inexpensive. It is not particularly corrosive, provided low oxygen concentration is maintained. Its nuclear properties are excellent for fast reactors. In the liquid-metal fast breeder reactor (LMFBR), sodium in the primary loop collects the heat generated in the core and transfers it to a secondary sodium loop in the heat exchanger, from which it is carried to the steam generator in which water is boiled to make steam.

Plant balance. The nuclear chain reaction in the reactor core produces energy in the form of heat, as the fission fragments slow down and dissipate their kinetic energy in the fuel. This heat must be removed efficiently and at the same rate it is being generated in order to prevent overheating of the core and to transport the energy outside the core, where it can be converted to a convenient form for further utilization. The energy transferred to the coolant, as it flows past the fuel element, is stored in it in the form of sensible heat and pressure and is called the enthalpy of the fluid. In an electric power plant, the energy stored in the fuel is further converted to kinetic energy through a device called a prime mover which, in the case of nuclear reactors, is predominantly a steam turbine. Another conversion takes place in the electric generator, where kinetic energy is converted into electric power as the final energy form to be distributed to the consumers through the power grid and distribution system. *See* ENTHALPY; GENERATOR; PRIME MOVER; STEAM TURBINE.

Fluid flow and hydrodynamics. Because heat removal must be accomplished as efficiently as possible, considerable attention must be given to fluid-flow and hydrodynamic characteristics of the system. *See* FLUID FLOW; HYDRODYNAMICS.

The heat capacity and thermal conductivity of the fluid at the temperature of operation have a fundamental effect upon the design of the reactor system. The heat capacity determines the mass flow of the coolant required. The fluid properties (thermal conductivity, viscosity, density, and specific heat) are important in determining the surface area required for the fuel—in particular, the number and arrangement of the fuel elements. These factors combine to establish the pumping characteristics of the system because the pressure drop and coolant temperature rise in the core are directly related. *See* CONDUCTION (HEAT); HEAT CAPACITY; VISCOSITY.

Thermal stress. The temperature of the reactor coolant increases as it circulates through the reactor core. Fluctuations in power level or in coolant flow rate result in variations in the temperature rise. A reactor is capable of very rapid changes in power level, particularly reduction in power level, which is a safety feature of the plant. Reactors are equipped with mechanisms (reactor scram systems) to ensure rapid shutdown of the system in the event of leaks, failure of power conversion systems, or other operational abnormalities. Therefore, reactor coolant systems must be designed to accommodate the temperature transients that may occur because of rapid power changes. In addition, they must be designed to accommodate temperature transients that might occur as a result of a coolant system malfunction, such as pump stoppage.

Coolant system components. The development of reactor systems has led to the development of special components for reactor component systems. Because of the hazard of radioactivity, leak-tight systems and components are a prerequisite to safe, reliable operation, and maintenance. Special problems are introduced by many of the fluids employed as reactor coolants.

More extensive component developments have been required for sodium, which is chemically active and is an extremely poor lubricant. Centrifugal pumps employing unique bearings and seals have been specially designed. Sodium is an excellent electrical conductor and, in some special cases, electromagnetic-type pumps have been used. These pumps are completely sealed, contain no moving parts, and derive their pumping action from electromagnetic forces imposed directly on the fluid. *See* CENTRIFUGAL PUMP; ELECTROMAGNETIC PUMP.

Core design. A typical reactor core for a power reactor consists of the fuel element rods supported by a grid-type structure inside a vessel.

Structural materials employed in reactor systems must possess suitable nuclear and physical properties and must be compatible with the reactor coolant under the conditions of operation. The most common structural materials employed in reactor systems are stainless steel and zirconium alloys. Zirconium alloys have favorable nuclear and physical properties, whereas stainless steel has favorable physical properties. Aluminum is widely used in low-temperature test and research reactors; zirconium and stainless steel are used in high-temperature power reactors. Zirconium is relatively expensive, and its use is therefore confined to applications in the reactor core where neutron absorption is important. *See* ALUMINUM; STAINLESS STEEL; ZIRCONIUM.

Reactors maintain a separation of fuel and coolant by cladding the fuel. The cladding is designed to prevent the release of radioactivity from the fuel. The cladding material must be compatible with both the fuel and the coolant.

The cladding materials must also have favorable nuclear properties. The neutron-capture cross section is most significant because the unwanted absorption of neutrons by these materials reduces the efficiency of the nuclear fission process. Aluminum is a very desirable material in this respect; however, its physical strength and corrosion resistance in water decrease very rapidly above about 300°F (149°C).

Zirconium has favorable neutron properties, and in addition is corrosion-resistant in high-temperature water. It has found extensive use in water-cooled power reactors. Stainless steel is used for the fuel cladding in fast reactors, in some light-water reactors for which neutron captures are less important.

Control. A reactor is critical when the rate of production of neutrons equals the rate of absorption in the system. The control of reactors requires the continuing measurement and adjustment of the critical condition. The neutrons are produced by the fission process and are consumed in a variety of ways, including absorption to cause fission, nonfission capture in fissionable materials, capture in fertile materials, capture in structure or coolant, and leakage from the reactor to the shielding. A reactor is subcritical (power level decreasing) if the number of neutrons produced is less than the number consumed. The reactor is supercritical (power level increasing) if the number of neutrons produced exceeds the number consumed. *See* REACTOR PHYSICS.

Reactors are controlled by adjusting the balance between neutron production and neutron consumption. Normally, neutron consumption is controlled by varying the absorption or leakage of neutrons; however, the neutron generation rate also can be controlled by varying the amount of fissionable material in the system.

The reactor control system requires the movement of neutron-absorbing rods (control rods) in the reactor under carefully controlled conditions. They must be arranged to increase reactivity (increase neutron population) slowly and under good control. They must be capable of reducing reactivity, both rapidly and slowly.

The control drives can be operated by the reactor operator or by automatic control systems. Reactor scram (rapid reactor shutdown) can be initiated automatically by a wide variety of system scram-safety signals, or it can be started by the operator depressing a scram button in the control room.

Control drives are electromechanical or hydraulic devices that impart in-and-out motion to the control rods. They are usually equipped with a relatively slow-speed reversible drive system for normal operational control. Scram is usually effected by a high-speed overriding drive accompanied by disconnecting the main drive system.

Applications. Reactor applications include mobile, stationary, and packaged power plants; production of fissionable fuels (plutonium and uranium-233) for military and commercial applications; research, testing, teaching-demonstration, and experimental facilities; space and process heat; dual-purpose design; and special applications. The potential use of reactor radiation or radioisotopes produced for sterilization of food and other products, steam for chemical processes, and gas for high-temperature applications has been recognized. *See* NUCLEAR FUEL CYCLE; NUCLEAR FUELS REPROCESSING; RADIOACTIVITY AND RADIATION APPLICATIONS; SHIP NUCLEAR PROPULSION. [F.J.Ra.]

Nuclear spectra The distribution of the intensity of particles (or radiation) emitted in a nuclear process as a function of energy. The nuclear spectrum is a unique signature of the process.

For example, when very slow neutrons (with speeds less than 0.5% of the speed of light) hit nitrogen nuclei, there is a high probability that they will be captured and that the nuclear system which is formed will emit a set of gamma rays (electromagnetic radiation) of very precise energies. The 24 gamma rays have energies ranging from 1.68 to 10.83 MeV, and their relative intensities are well known. A spectrum of these gamma rays, that is, the number of gamma rays having a particular energy, versus that energy can provide a unique signature of the presence of nitrogen. An application is the passing of a beam of slow neutrons through luggage at an airport: the presence of unusual amounts of nitrogen indicates that a plastic explosive may be present. This testing is nondestructive: relatively few neutrons are needed to produce the characteristic spectrum, and the luggage and its contents are not harmed. *See* GAMMA RAYS; NONDESTRUCTIVE EVALUATION.

Measurements. The methods used to measure nuclear spectra depend on the nature of the particles (radiation) involved. The most accurate energy measurements are those of gamma rays. Gamma-ray spectra can be measured by determining the energy deposited by the gamma rays in a crystal, often made of sodium iodide, containing thallium impurities [NaI(Tl)], or of germanium, containing lithium impurities [Ge(Li)]. In a NaI(Tl) detector, the gamma-ray energy is transferred to electrons within the crystal, and these charged particles in turn produce electromagnetic radiation with frequencies in the visible range. The crystal is surrounded by detectors (photomultipliers) that are sensitive to the visible light. The intensity of the signal in the photomultipliers is proportional to the energy of the gamma rays that entered the NaI(Tl) crystal. The signal pulse is amplified electronically, and the pulse heights (pulse sizes) are displayed in a pulse-height multichannel analyzer in a histogram. Usually the number of pulses having a certain height (strength) is plotted versus the height. What results is a plot showing the number of gamma rays having a certain energy versus the energy of the gamma rays, a spectrum. *See* GAMMA-RAY DETECTORS; PHOTOMULTIPLIER.

Neutron spectra are often determined by measuring their velocities. This is done by a time-of-flight technique in which an electronic timer measures the time interval between the emission of the neutron from a nucleus and its arrival at a detector a known distance away. This measurement uniquely determines the velocity, and thus the kinetic energy, of the neutrons. *See* NEUTRON SPECTROMETRY; TIME-OF-FLIGHT SPECTROMETERS.

Measurements of nuclear spectra involving charged particles, such as pions, protons and alpha particles, are often made by determining their momenta (mass × velocity) and then calculating the corresponding kinetic energy. Momentum measurements are made by passing the beam of charged particles through a region in which a magnetic field exists. A magnetic field that is constant in time will not cause a change in a charged particle's speed, but it will cause a charged particle to deviate in its path. *See* PARTICLE ACCELERATOR.

Modern magnetic spectrometers use sophisticated counter telescopes and multiwire proportional counters, which permit not only the registering of the particles characterized by a certain value of the radius of curvature (and therefore of momentum) but enable the particular particle (proton, alpha particle, or whatever) that caused the signal to be identified. Contemporary magnetic spectrometer systems not only utilize complex arrangements of magnetic fields, detectors, and electronics but also generally require powerful computers to monitor and analyze the results. *See* PARTICLE DETECTOR. [F.A.S.]

Nuclear structure

At the center of every atom lies a small, dense nucleus, which carries more than 99.97% of the atomic mass in less than 10^{-12} of its volume. The nucleus is a tightly bound system of protons and neutrons which is held together by strong forces that are not normally perceptible in nature because of their extremely short range. The small size, strong forces, and many particles in the nucleus result in a highly complex and unique quantal system that at present defies exact analysis. The study of the nucleus and the forces that hold it together constitute the field of nuclear structure physics. *See* ATOMIC STRUCTURE AND SPECTRA; NEUTRON; PROTON; QUANTUM MECHANICS; STRONG NUCLEAR INTERACTIONS.

The protons of the nucleus, being positively charged, generate a spherically symmetric electric field in which the atomic electrons orbit. The cloud of negatively charged atomic electrons normally balances the positive nuclear charge, making the atom electrically neutral. The atomic number of protons is usually denoted by Z and the number of neutrons, which are electrically neutral, by N. The total number of protons and neutrons (or nucleons) is the mass number $A = Z + N$. Isotopes have the same atomic number, Z, and hence are forms of the same chemical element, having the same chemical properties, but they differ in neutron number; isotones have a common number of neutrons, N, and isobars have the same mass number, A. *See* ISOBAR (NUCLEAR PHYSICS); ISOTONE; ISOTOPE.

Nuclei have masses less than the sum of the constituents, the missing mass ΔM being accounted for by the binding energy ΔMc^2 (where c is the speed of light), which holds the nuclear system together. The characteristic energy scale is in megaelectronvolts (1 MeV = 1.6×10^{-13} joule). The internuclear forces generate an attractive potential field which holds the nucleus together and in which the nucleons orbit in highly correlated patterns. The volume of nuclei increases approximately linearly with mass number A, and the radius is roughly $R = 1.2 \times 10^{-15} \cdot A^{1/3}$ m. *See* NUCLEAR BINDING ENERGY.

Size, shape, and density distributions. A variety of sophisticated techniques have been developed for precise estimates of the nuclear charge distribution, including electron scattering, the study of muonic atoms, and the laser spectroscopy of hyperfine atomic structure. An overall picture of the nuclear charge distributions emerges. The nuclear charge density saturates in the interior and has a roughly constant value in all but the lightest nuclei. The nucleus has a diffuse skin which is of nearly constant thickness.

Many nuclei are found to have nonspherical shapes. Unlike the atom, which has a spherically symmetric Coulomb field generated by the nucleus, the nuclear field is composed of a complicated superposition of short-range interactions between nucleons, and the most stable nuclear shape is the one that minimizes the energy of the system. In general, it is not spherical, and the nuclear shape is most simply described by a multipole power series, the most important term of which is the nuclear quadrupole moment. A positive quadrupole moment reflects the elongation of nuclei into a prolate or football-like shape, while a negative value reflects an oblate shape like that of Earth. *See* NUCLEAR MOMENTS.

An accurate determination of nuclear matter distributions, that is, the distribution of both protons and neutrons in nuclei, is harder to precisely ascertain.

Nuclear masses and binding energies. The variation of average binding energy with mass number is approximated by the Bethe-Weizsacker mass formula, which is noteworthy for its simplicity in reproducing the overall binding energy systematics. The formula is developed by modeling the nucleus on a liquid drop. By analogy with a drop of liquid, there is an attractive volume term, which depends on the number of particles; a repulsive surface-tension term; and a term due to the mutual Coulomb repulsion of protons, which is responsible for the decrease in binding energy for heavy nuclei. The model is spectacularly successful in reproducing the overall trends in nuclear binding energies, masses, and the energetics of nuclear fission, and in predicting the limits of stability where neutrons and protons become unbound. As in the case of predicting a mean nuclear shape, a comparison of the prediction of the Bethe-Weizsacker mass formula to measured masses shows periodic fluctuations with both N and Z, which are due to the quantum shell effects. *See* NUCLEAR FISSION.

Nuclear excited states. The small nuclear size and tightly bound nature impose very restrictive constraints on the orbits that protons and neutrons can undergo inside the system. Thus, each nucleus has a series of quantum states that particles can occupy. The Pauli principle requires that each particle have a unique set of quantum labels. Each nuclear state can then be filled with four particles: protons with internal angular momentum "up" and "down," and likewise two neutrons. *See* ANGULAR MOMENTUM; ENERGY LEVEL (QUANTUM MECHANICS); EXCLUSION PRINCIPLE; PARITY (QUANTUM MECHANICS); QUANTUM NUMBERS; QUARKS; SPIN (QUANTUM MECHANICS).

A nucleus is most stable when all of its nucleons occupy the lowest possible states without violating this occupancy rule. This is called the nuclear ground state. During nuclear collisions the protons and neutrons can be excited from their most bound states and promoted to higher-lying unoccupied states. The process is usually very short-lived and the particles deexcite to their most stable configuration on a time scale of the order of 10^{-12} s. The energy is usually released in the form of gamma rays of well-defined energy corresponding to the difference in energy of the initial and final nuclear states. Occasionally, gamma decay is not favored because of angular momentum selection rules, and long-lived nuclear isomers result. *See* GAMMA RAYS; NUCLEAR ISOMERISM; NUCLEAR SPECTRA; SELECTION RULES (PHYSICS).

Nuclear models. The detailed categorization of the excitation of protons and neutrons allows a mapping of the excited states of each nucleus and determination of its quantum numbers. These data are the essential information required for development of detailed models that can describe the motion of nucleons inside nuclei. Unlike atomic molecules, where rotational, vibrational, and single-particle degrees of freedom involve different time scales and energies, the nucleus is highly complex, with rotation, vibration, and single-particle degrees of freedom being excited at similar energies and often strongly mixed. *See* MOLECULAR STRUCTURE AND SPECTRA.

The measurement of static electric and magnetic moments of nuclear states and of dynamic transition moments has provided a great deal of information. Electric moments have revealed a variety of enhanced collective modes of excitation, including elongated, flattened, and pear-shaped nuclear shapes. Magnetic moments have provided detailed information on the differences between excitations involving neutrons (negative moments) and protons (positive moments).

For atoms, the solutions of the Schrödinger equation with a Coulomb potential lead to a reasonable prediction of the energies of quantized atomic states, as well as their spins, parities, and moments. Attempts to make the same progress for nuclei, using a variety of spherically symmetric geometric potentials of nuclear dimensions, failed to reproduce known properties until it was realized by M. G. Meyer and independently by J. H. Jensen in 1949 that an additional spin-orbit potential was required to reproduce the known sequence of nuclear states. A potential of this form binds states having the internal spin of the nucleons parallel to its orbital angular momentum more tightly than when they are antiparallel. The ensuing sequence of quantum shell gaps and subgaps was then correctly reproduced. The shell model has evolved rapidly, and its domain of applicability has widened from the limited regions of sphericity near doubly magic nuclei to encompass most light nuclei with $A < 60$ as well as enlarged regions around shell closures.

As valence particles are added to a closed core of nucleons, the mutual residual interactions can act coherently and polarize the nuclear system away from sphericity. The polarization effects are strongest when both valence protons and neutrons are involved. The deformed nuclear potential can then undergo collective rotation, which generally involves less energy than other degrees of freedom and thus dominates the spectrum of strongly deformed nuclei.

Nuclei undergo collective vibrations about both spherical and deformed shapes. The degree of softness of these vibrations is characterized by the excitation energy required to populate states. The distinguishing feature of vibrational excited states is that they are grouped in nearly degenerate angular momentum multiplets, each group being separated by a characteristic phonon energy.

It has been a goal of nuclear structure studies to develop models that incorporate all of the features described above in order to produce a unified nuclear picture. The development of generalized nuclear models has relevance to other fields of physics. There are many isotopes that will never be accessible in the laboratory but may exist in stars or may have existed earlier in cosmological time. The evolution of generalized models greatly increases the power to predict nuclear behavior and provides information that is required for cosmological calculations. *See* COSMOLOGY; NUCLEOSYNTHESIS.

Nuclei at high excitation energies. As nuclei are excited to ever higher excitation energies, it is anticipated that shell effects will be slowly replaced by statistical, or chaotic, behavior. The number of states per megaelectronvolt of excitation energy with each spin and parity rise exponentially with increasing excitation energy until the levels become sufficiently close that they overlap and mix strongly and so become a continuum of states.

Toward the top of this energy regime, new modes of nuclear collectivity become accessible. Giant resonance states can be excited that involve compression and oscillation of the nuclear medium with vibrations of the protons and neutrons in phase (isoscalar) or beating against each other (isovector). The excitation and decay of these giant resonances can provide information about shapes of nuclei at high excitation and about the compressibility of nuclear matter. Results from giant resonance studies indicate that the shell effect persists high into the region previously thought to be statistical. *See* GIANT NUCLEAR RESONANCES.

The semiclassical statistical and hydrodynamic behavior of hot nuclear matter and its experimental, theoretical, and astrophysical aspects are of great interest at the highest nuclear energies. The influence of compression and heat on the density of nuclear matter is being investigated in order to measure a nuclear equation of state in analogy with the properties of a classical fluid. It has been suggested that the nuclear matter may undergo phase changes under compression, with high-density condensates possibly providing a new metastable state. At the highest densities and temperatures, the nucleons themselves are forced to overlap and merge, leading to a plasma of quarks and gluons that are the nucleonic constituents. *See* QUARK-GLUON PLASMA; RELATIVISTIC HEAVY-ION COLLISIONS. [C.J.Li.]

Nucleation The formation within an unstable, supersaturated solution of the first particles of precipitate capable of spontaneous growth into large crystals of a more stable solid phase. These first viable particles, called nuclei, may either be formed from solid particles already present in the system (heterogeneous nucleation) or be generated spontaneously by the supersaturated solution itself (homogeneous nucleation). *See* SUPERSATURATION.

Nucleation is significant in analytical chemistry because of its influence on the physical characteristics of precipitates. Processes occurring during the nucleation period establish the rate of precipitation, and the number and size of the final crystalline particles. *See* COLLOID; PRECIPITATION (CHEMISTRY). [D.H.K.; L.Go.]

Nucleic acid An acidic, chainlike biological macromolecule consisting of multiply repeated units of phosphoric acid, sugar, and purine and pyrimidine bases. Nucleic acids as a class are involved in the preservation, replication, and expression of hereditary information in every living cell. There are two types of nucleic acid; deoxyribonucleic acid (DNA) and ribonucleic acid (RNA). *See* DEOXYRIBONUCLEIC ACID (DNA); RIBONUCLEIC ACID (RNA). [E.Jo.]

Nucleon The collective name for a proton or a neutron. These subatomic particles are the principal constituents of atomic nuclei and therefore of most matter in the universe. The proton and neutron share many characteristics. They have the same intrinsic spin, nearly the same mass, and similar interactions with other subatomic particles, and they can transform into one another by means of the weak interactions. Hence it is often useful to view them as two different states or configurations of the same particle, the nucleon. Nucleons are small compared to atomic dimensions and relatively heavy. Their characteristic size is of order 1/10,000 the size of a typical atom, and their mass is of order 2000 times the mass of the electron.

The proton and neutron differ chiefly in their electromagnetic properties. The proton has electric charge +1, the opposite of the electron, while the neutron is electrically neutral. They have significantly different intrinsic magnetic moments. Because the neutron is slightly heavier than the proton, roughly 1 part in 1000, the neutron is unstable, decaying into a proton, an electron, and an antineutrino with a characteristic lifetime of approximately 900 s. Although some unified field theories predict that the proton is unstable, no experiment has detected proton decay.

The complex forces between nucleons and the discovery during the 1950s of many similar subatomic particles led physicists to suggest that nucleons might not be fundamental particles. During the late 1960s and 1970s, inelastic electron and neutrino scattering experiments indicated that nucleons are composed of pointlike particles with spin $^1/_2$ and electric charges that are fractions of the charge on the electron. Particles with similar properties, named quarks, had been hypothesized in the early 1960s to explain other regularities among the properties of hadrons. In the early 1970s, it became clear that nucleons and other hadrons are indeed bound states of quarks. *See* HADRON; NUCLEAR STRUCTURE.

Quarks are believed to be fundamental particles without internal structure. The proton consists of two up-type quarks and one down-type quark (*uud*), while the neutron consists of *ddu*. Quarks are bound into nucleons by strong forces carried by gluons. The nucleon contains ambient gluon fields in somewhat the same way that the atom contains ambient electromagnetic fields. Because quarks and gluons are much less massive than the nucleon itself, their motion inside the nucleon is relativistic, making quark-antiquark pair creation a significant factor. Thus the nucleon contains fluctuating quark-antiquark pairs in addition to quarks and gluons. The theory of quark-gluon interactions is known as quantum chromodynamics (QCD), in analogy to the quantum theory of electrodynamics (QED). *See* ELEMENTARY PARTICLE; GLUONS; NEUTRON; PROTON; QUANTUM CHROMODYNAMICS; QUANTUM ELECTRODYNAMICS; QUARKS. [R.L.Ja.]

Nucleoprotein A generic term for any member of a large class of proteins associated with nucleic acid molecules. Nucleoprotein complexes occur in all living cells and in viruses, where they play vital roles in reproduction and protein synthesis.

Classification of the nucleoproteins depends primarily upon the type of nucleic acid involved—deoxyribonucleic acid (DNA) or ribonucleic acid (RNA)—and on the biological function of the complex. Deoxyribonucleoproteins (complexes of DNA and proteins) constitute the genetic material of all organisms and of many viruses. They function as the chemical basis of heredity and are the primary means of its expression and control. Most of the mass of chromosomes is made up of DNA and proteins whose structural and enzymatic activities are required for the proper assembly and expression of the genetic information encoded in the molecular structure of the nucleic acid. *See* DEOXYRIBONUCLEIC ACID (DNA).

Ribonucleoproteins (complexes of RNA and proteins) occur in all cells as part of the machinery for protein synthesis. This complex operation requires the participation of messenger RNAs (mRNAs), amino acyl transfer RNAs (tRNAs), and ribosomal RNAs (rRNAs), each of which interacts with specific proteins to form functional complexes called polysomes, on which the synthesis of new proteins occurs. *See* RIBONUCLEIC ACID (RNA).

In simpler life forms, such as viruses which infect animal and plant cells and bacteriophages which infect bacteria, most of the mass of the viral particle is due to its nucleoprotein content. The material responsible for the hereditary continuity of the virus may be DNA or RNA, depending on the type of virus, and it is usually enveloped by one or more proteins which protect the nucleic acid and facilitate infections. *See* BACTERIOPHAGE; CHROMOSOME; NUCLEIC ACID; VIRUS.

A typical human diploid nucleus contains 5.6×10^{-12} g of DNA. This DNA is arranged in 23 pairs of chromosomes differing in size and DNA content. The large number 1 chromosome, for example, contains 0.235×10^{-12} g of DNA, while the much smaller chromosome number 22 contains only 0.046×10^{-12} g. The DNA double-helix of chromosome 1 is actually 7.3 cm long, but this thin filamentous molecule is packaged to form a chromosome less than 10 micrometers long. The enormity of the packing problem can be appreciated from the fact that the average human contains about 100 g of DNA, and 0.5 g would reach from the Earth to the Sun! The reduction in size is largely due to interactions between the DNA and sets of small basic proteins called histones. All somatic cells of higher organisms contain five major histone classes, all of which are characterized by a high content of basic (positively charged) amino acids. [V.G.A.]

Nucleosome The fundamental histone-containing structural subunit of eukaryotic chromosomes. In most eukaryotic organisms, nuclear deoxyribonucleic acid (DNA) is complexed with an approximately equal mass of histone protein. The nucleosome is organized so that the DNA is exterior and the histones interior. The DNA makes two turns around a core of eight histone molecules, thus forming a squat cylinder 11 nanometers in diameter and 5.5 nm in height. A short length of linker or spacer DNA connects one nucleosome to the next, forming a nucleosomal chain that has been likened to a beaded string. This basic structure is found in all forms of chromatin. Nucleosomes have been found in all eukaryotic organisms examined, the only exceptions being some sperm nuclei and the dinoflagellate algae.

A chain of adjacent nucleosomes is approximately sixfold shorter than the DNA it contains. Moreover, chains of nucleosomes have the property of self-assembling into thicker fibers in which the DNA packing ratio approaches 35:1. These observations, and the lack of any obvious catalytic activity, have led to the assumption that the primary function of the nucleosome consists of organizing and packing DNA. *See* CHROMOSOME; DEOXYRIBONUCLEIC ACID (DNA); GENE. [C.L.F.W.]

Nucleosynthesis Theories of the origin of the elements involve synthesis with charged and neutral elementary particles (neutrons, protons, neutrinos, photons) and other nuclear building blocks of matter, such as alpha particles. The theory of nucleosynthesis comprises a dozen distinct processes, including big bang nucleosynthesis, cosmic-ray spallation in the interstellar medium, and static or explosive burning in various stellar environments (hydrogen-, helium-, carbon-, oxygen-, and silicon-burning, and the, *s*-, *r*-, *p*-, γ-, and ν-processes). Acceptable theories must lead to an understanding of the cosmic abundances observed in the solar system, stars, and the interstellar medium. Hydrogen and helium constitute about 98% of the total element content by number of atoms, and there is a rapid decrease with increasing nuclear mass number *A*. *See* ELEMENTS, COSMIC ABUNDANCE OF.

Observations of the expanding universe and of the 3-K background radiation indicate that the universe originated in a primordial event known as the big bang about 15×10^9 years ago. Absence of stable mass 5 and mass 8 nuclei preclude the possibility of synthesizing the major portion of the nuclei of masses greater than 4 in those first few minutes of the universe, when density and temperature were sufficiently high to support the necessary nuclear reactions to synthesize elements. *See* BIG BANG THEORY; COSMIC BACKGROUND RADIATION; COSMOLOGY.

The principal source of energy in stars is certainly nuclear reactions which release energy by fusion of lighter nuclei to form more massive nuclei. There is considerable evidence that nucleosynthesis has been going on in stars for billions of years. Observations show that the abundance ratio of iron and heavier elements to hydrogen decreases with increasing stellar age. The oldest known stars in the disk of the Milky Way Galaxy exhibit a ratio 10,000 times smaller than in the Sun. This low ratio is understood on the basis of element synthesis occurring in previous-generation stars that evolved to the point of exploding as supernovae, thus enriching the interstellar medium with the nuclei that were synthesized during their lifetimes and by the explosive synthesis that accompanies the ejection of the stellar envelope. Later-generation stars were then formed from enriched gas and dust. *See* MILKY WAY GALAXY; STELLAR EVOLUTION; STELLAR POPULATION; SUPERNOVA.

Hydrogen burning, the first process of nucleosynthesis, converts hydrogen to helium. In stars of 1.2 or less solar masses, this process occurs via the proton-proton chain. This chain was also responsible for much of the element synthesis during the big bang, producing the bulk of deuterium and helium, and some of the ^{7}Li, observed today. In more massive stars where the central temperatures exceed 2×10^7 K, hydrogen burning is accomplished through proton captures by carbon, nitrogen, and oxygen nuclei, in the carbon-nitrogen-oxygen (CNO) cycles, to form ^{4}He. The product (ash) of hydrogen burning is helium, but much of the helium produced is consumed in later stages of stellar evolution or is locked up forever in stars of lower mass that never reach the temperatures required to ignite helium burning. The observed abundances of some carbon, nitrogen, oxygen, and fluorine nuclei are attributed to hydrogen burning in the CNO cycles. *See* CARBON-NITROGEN-OXYGEN CYCLES; NUCLEAR FUSION; PROTON-PROTON CHAIN.

When the hydrogen fuel is exhausted in the central region of the star, the core contracts and its temperature and density increase. Helium, the ash of hydrogen burning, cannot be burned immediately due to the larger nuclear charge of helium ($Z = 2$) producing a much higher Coulomb barrier against fusion. When the temperature eventually exceeds about 10^8 K, helium becomes the fuel for further energy generation and nucleosynthesis. The basic reaction in this thermonuclear phase is the triple-alpha process in which three ^{4}He nuclei (three alpha particles) fuse to form ^{12}C, a carbon nucleus of mass 12 (atomic mass units). Capture of an alpha particle by ^{12}C then forms ^{16}O, symbolically written as $^{12}\mathrm{C} + {}^4\mathrm{He} \rightarrow {}^{16}\mathrm{O} + \gamma$, or simply $^{12}\mathrm{C}(\alpha,\gamma)^{16}\mathrm{O}$, where γ represents energy released in the form of electromagnetic radiation. Other reactions that are included in helium burning are $^{16}\mathrm{O}(\alpha,\gamma)^{20}\mathrm{Ne}$, $^{20}\mathrm{Ne}(\alpha,\gamma)^{24}\mathrm{Mg}$, $^{14}\mathrm{N}(\alpha,\gamma)^{18}\mathrm{F}$, and $^{18}\mathrm{O}(\alpha,\gamma)^{22}\mathrm{Ne}$. Fluorine-18, produced when ^{14}N captures an alpha particle, is unstable and decays by emitting a positron (e^+) and a neutrino (ν) to form ^{18}O [in short, $^{14}\mathrm{N}(\alpha,\gamma)^{18}\mathrm{F}(e^+,\nu)^{18}\mathrm{O}$]. Because there is likely to be ^{13}C in the stellar core if hydrogen burning proceeded by the carbon-nitrogen-oxygen cycles, the neutron-producing reaction $^{13}\mathrm{C}(\alpha,n)^{16}\mathrm{O}$ should also be included with the helium-burning reactions. Helium burning is probably responsible for much of the ^{12}C observed in the cosmic abundances, although in more massive stars the later burning stages will consume the ^{12}C produced earlier by helium burning. *See* NUCLEAR REACTION.

Upon exhaustion of the helium supply, if the star has an initial mass of at least 8 solar masses, gravitational contraction of the stellar core can lead to a temperature exceeding 5×10^8 K, where it becomes possible for two ^{12}C nuclei to overcome their high mutual Coulomb-repulsion barrier and fuse to form ^{20}Ne, ^{23}Na, and ^{24}Mg through reactions such as $^{12}\mathrm{C}(^{12}\mathrm{C},\alpha)^{20}\mathrm{Ne}$, $^{12}\mathrm{C}(^{12}\mathrm{C},p)^{23}\mathrm{Na}$, and $^{12}\mathrm{C}(^{12}\mathrm{C},\gamma)^{24}\mathrm{Mg}$. Carbon burning can produce a number of nuclei with masses less than or equal to 28 through further proton and alpha-particle captures.

Carbon burning is followed by a short-duration stage, sometimes referred to as neon burning, in which ^{20}Ne disintegrates by the reaction $^{20}\mathrm{Ne}(\gamma,\alpha)^{16}\mathrm{O}$. The eventual result is that most of the carbon from helium burning becomes oxygen, which supplements the original oxygen formed in helium burning. This stage is followed by the fusion of oxygen nuclei at much higher temperatures. (Temperatures greater than 10^9 K are required for ^{16}O nuclei to overcome their mutual Coulomb barrier.) Some relevant reactions for oxygen burning are $^{16}\mathrm{O}(^{16}\mathrm{O},\alpha)^{28}\mathrm{Si}$, $^{16}\mathrm{O}(^{16}\mathrm{O},p)^{31}\mathrm{P}$, and $^{16}\mathrm{O}(^{16}\mathrm{O},\gamma)^{32}\mathrm{S}$. Nuclei of masses up to $A = 40$ may be produced in this phase through proton, neutron, and alpha-particle captures.

Silicon burning commences when the temperature exceeds about 3×10^9 K. In this phase, photodisintegration of ^{28}Si and other intermediate-mass nuclei around $A = 28$ produces copious supplies of protons, neutrons, and alpha particles. These particles capture on the seed nuclei left from previous burning stages and thus produce new isotopes up to mass 60, resulting in the buildup of the abundance peak near $A = 56$.

Because neutrons are neutral particles, their capture is not affected by the Coulomb barrier that inhibits charged-particle reactions. If the number of neutrons per seed nucleus is small, so that time intervals between neutron captures are long compared to the beta-decay lifetimes of unstable nuclei that are formed, the *s*-process (slow process) takes place. The seed nuclei are predominantly in the iron peak, but the abundances of low-mass nuclei are also affected by neutron-capture processing. In the *s*-process, if neutron capture produces a nucleus that is unstable (due to an excess number of neutrons), the newly formed nucleus undergoes beta decay to a stable isobar by emitting an electron and an antineutrino. The resulting nucleus eventually captures another neutron, and the capture-decay step repeats. The presence of free neutrons leads to a chain of capture-decay events that drives the abundances along a unique *s*-process path that zigzags along a single line in the nuclear *Z-N* diagram near the low of beta-stable nuclei (valley of beta stability). Given enough neutrons, the *s*-process synthesizes nuclei of masses up to 209, when alpha decay becomes a deterrent to further buildup by neutron capture. *See* RADIOACTIVITY.

The *r*-process occurs when a large neutron flux allows rapid neutron capture, so that seed nuclei capture many neutrons before undergoing beta decay. The rapid neutron capture takes the nuclei far away from the valley of beta stability, into the regime of extremely neutron-rich nuclei. The time scale for the *r*-process is very short, 1–100 s, and the abundance of free neutrons is very large. These conditions are found deep inside the interiors of exploding massive stars, supernovae. The *r*-process can synthesize nuclei all the way into the transuranic elements.

The *p*-process produces heavier elements on the proton-rich side of the beta valley. The *p*-nuclei (about 35 are known) are blocked from formation by stable nuclei produced by either the *r*- or *s*-process. The major task for *p*-process theory is thus to find ways, other than beta decay, to process the more abundant *r*- and *s*-nuclei into the less abundant *p*-nuclei. Two possible mechanisms are: radiative proton capture, and gamma-induced neutron, proton, or alpha-particle removal reactions. In both cases the temperature should be in excess of $2–3 \times 10^9$ K.

The neutrino (ν) flux emitted from a cooling proto neutron star alters the yields of explosive nucleosynthesis from type II supernovae. Inelastic scattering of neutrinos (all flavors) off abundant nuclei excites states that can decay via single or multiple nucleon emission. The ν-process is probably responsible for significant contributions to the synthesis in nature of about a dozen isotopes. While the neutrino interaction cross section with matter is extremely small (about 10^{-44} cm^2), the high neutrino energies and the large number flux close to the collapsing iron core of a massive star lead to significant synthesis of nuclei, either directly or indirectly. *See* NEUTRINO.

The bulk of the light elements lithium, beryllium, and boron found in the cosmic abundance curve cannot have survived processing in stellar interiors because they are readily destroyed by proton capture. Although some ^{7}Li originated in the big bang, primordial nucleosynthesis cannot be responsible for the bulk of the ^{7}Li in existence. Spallation of more abundant nuclei such as carbon, nitrogen, and oxygen by high-energy protons and alpha particles can account for the low-abundance nuclides ^{6}Li, ^{9}Be, ^{10}B, ^{11}B, and for some ^{7}Li. The canonical process is spallation of carbon, nitrogen, and oxygen nuclei in the interstellar medium by fast light particles, such as alpha particles and protons, which are abundant in the gas between the stars. These high-energy particles are referred to as cosmic rays, leading to the term "cosmic-ray spallation (CRS) process." *See* COSMIC RAYS.

[D.H.H.]

Nucleotide A cellular constituent that is one of the building blocks of ribonucleic acids (RNA) and deoxyribonucleic acid (DNA). In biological systems, nucleotides are linked by enzymes in order to make long, chainlike polynucleotides of defined sequence. The order or sequence of the nucleotide units along a polynucleotide chain plays an important role in the storage and transfer of genetic information. Many nucleotides also perform other important functions in biological systems. Some, such as adenosine triphosphate (ATP), serve as energy sources that are used to fuel important biological reactions. Others, such as nicotinamide adenine dinucleotide (NAD) and coenzyme A (CoA), are important cofactors that are needed to complete a variety of enzymatic reactions. Cyclic nucleotides such as cyclic adenosine monophosphate (cAMP) are often used to regulate complex metabolic systems. Chemically modified nucleotides such as fluoro-deoxyridine monophosphate (Fl-dUMP) contain special chemical groups that are useful for inactivating the normal function of important enzymes. These and other such compounds are widely used as drugs and therapeutic agents to treat cancer and a variety of other serious illnesses. *See* COENZYME; CYCLIC NUCLEOTIDES; NICOTINAMIDE ADENINE DINUCLEOTIDE (NAD).

Nucleotides are generally classified as either ribonucleotides or deoxyribonucleotides. Both classes consist of a phosphorylated pentose sugar that is linked via an *N*-glycosidic bond to a purine or pyrimidine base. The combination of the pentose sugar and the purine or pyrimidine base without the phosphate moiety is called a nucleoside. *See* PURINE; PYRIMIDINE.

Ribonucleosides contain the sugar D-ribose, whereas deoxyribonucleosides contain the sugar 2-deoxyribose. The four most common ribonucleosides are adenosine, guanosine, cytidine, and uridine. The purine ribonucleosides, adenosine and guanosine, contain the nitrogenous bases adenine and guanine, respectively. The pyrimidine ribonucleosides, cytidine and uridine, contain the bases cytosine and uracil, respectively. Similarly, the most common deoxyribonucleosides include deoxyadenosine, deoxyguanosine, deoxycytidine, and thymidine, which contains the pyrimidine base thymine. Phosphorylation of the ribonucleosides or deoxyribonucleosides yields the corresponding ribonucleotide or deoxyribonucleotide. *See* DEOXYRIBONUCLEIC ACID (DNA); ENZYME; NUCLEIC ACID; RIBONUCLEIC ACID (RNA). [E.P.G.]

Nuclide A species of atom that is characterized by the constitution of its nucleus, in particular by its atomic number Z and its neutron number $A - Z$, where A is the mass number. The total number of stable nuclides is approximately 275. About a dozen radioactive nuclides are found in nature, and hundreds of others have been created artificially. [H.E.D.]

Nudibranchia An order of the gastropod subclass Opistho-branchia containing about 2500 living species of carnivorous sea slugs. They occur in all the oceans, at all depths, but reach their greatest size and diversity in warm shallow seas.

In this, the largest order of the Opisthobranchia, there is much evidence indicating polyphyletic descent from a number of long-extinct opisthobranch stocks. In all those lines which persist to the present day, the shell and operculum have been discarded in the adult form. In many of them the body has quite independently become dorsally papillate. In at least two suborders these dorsal papillae have acquired the power to nurture nematocysts derived from their coelenterate prey so as to use them for the nudibranch's own defense. In other cases such papillae (usually called cerata) have independently become penetrated by lobules of the adult digestive gland, or they may contain virulent defensive glands or prickly bundles of dagger-like calcareous spicules. *See* OPISTHOBRANCHIA. [T.E.T.]

Number theory The study of the properties and relations of the integers. There are many sets of positive integers of particular interest, such as the primes and the perfect numbers. Number theory, of ancient and continuing interest for its intrinsic beauty, also plays a crucial role in computer science, particularly in the area of cryptography.

Elementary number theory. This part of number theory does not rely on advanced mathematics, such as complex analysis and ring theory. The basic notion of elementary number theory is divisibility. An integer d is a divisor of n, written $d \mid n$, if there is an integer t such that $n = dt$. A prime number is a positive integer that has exactly two positive divisors, 1 and itself. The ten smallest primes are 2, 3, 5, 7, 11, 13, 17, 19, 23, and 29. Euclid (around 300 B.C.) proved that there are infinitely many primes by showing that if the only primes were $2, 3, 5, \ldots\ p$, a prime not in this list could be found by taking a prime factor of the number shown in Eq. (1). Primes are the building blocks

$$N = 2 \cdot 3 \cdot 5 \cdots p + 1 \qquad (1)$$

of the positive integers. The fundamental theorem of arithmetic, established by K. F. Gauss in 1801, states that every positive integer can be written as the product of prime factors in exactly one way when the order of the primes is disregarded.

A perfect number is a positive integer equal to the sum of its positive divisors other than itself. L. Euler showed that $2^{n-1}(2^n - 1)$ is perfect if and only if $2^n - 1$ is prime. If $2^n - 1$ is prime, then n itself must be prime. Primes of the form $2^p - 1$ are known as Mersenne primes after M. Mersenne, who studied them in the seventeenth century. As of 15 May 2004, there were 41 known Mersenne primes, the largest being $2^{24,036,583}-1$, a number with 7,235,733 decimal digits.

If $a - b$ is divisible by m, then a is called congruent to b modulo m, and this relation is written $a \equiv b \pmod{m}$. This relation between integers is an equivalence relation and defines equivalence classes of numbers congruent to each other, called residue classes. Congruences to the same modulus can be added, subtracted, and multiplied in the same manner as equations. However, when both sides of a congruence are divided by the same integer d, the modulus m must be divided by $\gcd(d, m)$. There are m residue classes modulo m. The number of classes containing only numbers coprime to m is denoted by $\phi(m)$, where $\phi(m)$ is called the Euler phi function.

In the third century B.C., Eratosthenes showed how all primes up to an integer n can be found when only the primes p up to n are known. It is sufficient to delete from the list of integers, starting with 2, the multiples of all primes up to n. The remaining integers are all the primes not exceeding n.

Single equations or systems of equations in more unknowns than equations, with restrictions on solutions such as that they must all be integral, are called diophantine equations, after Diophantus who studied such equations in ancient times. A wide range of diophantine equations have been studied. For example, the diophantine equation (2) has infinitely many solutions

$$x^2 + y^2 = z^2 \qquad (2)$$

in integers. These solutions are known as pythagorean triples, since they correspond to the lengths of the sides of right triangles where these sides have integral lengths. All solutions of this equation are given by $x = t(u^2 - v^2)$, $y = 2tuv$, and $z(u^2 + v^2)$, where t, u, and v are positive integers.

Perhaps the most notorious diophantine equation is Eq. (3).

$$x^n + y^n = z^n \qquad (3)$$

Fermat's last theorem states that this equation has no solutions in integers when n is an integer greater than 2 where $xyz \neq 0$. Establishing Fermat's last theorem was the quest of many mathematicians over 200 years. In the 1980s, connections were made between the solutions of this equations and points on certain elliptic curves. Using the theory of elliptic curves, A. Wiles completed a proof of Fermat's last theorem based on these connections in 1995.

Algebraic number theory. Attempts to prove Fermat's last theorem led to the development of algebraic number theory, a part of number theory based on techniques from such areas as group theory, ring theory, and field theory. Gauss extended the concepts of number theory to the ring $R[i]$ of complex numbers of the form $a + bi$, where a and b are integers. Ordinary primes $p \equiv 3 \pmod 4$ are also prime in $R[i]$, but $2 = -i(1 + i)^2$ is not prime, nor are primes $p \equiv 1 \pmod 4$ since such primes split as $p = (a + bi)(a - bi)$. More generally, an algebraic number field $R(\theta)$ of degree n is generated by the root θ of a polynomial equation $f(x) = 0$ of degree n with rational coefficients. A number α in this field is called an algebraic integer if it satisfies an algebraic equation with integer coefficients with initial coefficient 1. The algebraic integers in an algebraic number field form an integral domain. But, prime factorization may not be unique; for example, in $R[-5]$, $21 = 3 \cdot 7 = (1 + 2 - 5) \cdot (1 - 2 - 5)$ where each of the four factors in the two products is prime. To restore unique factorization, the concept of ideals is needed, as shown by E. E. Kummer and J. W. R. Dedekind. *See* RING THEORY.

Analytic number theory. There are many important results in number theory that can be established by using methods from analysis. For example, analytic methods developed by G. F. B. Riemann in 1859 were used by J. Hadamard and C. J. de la Vallée Poussin in 1896 to prove the famous prime number theorem. This theorem, first conjectured by Gauss about 1793, states that $\pi(x)$, the number of primes not exceeding x, behaves as shown in Eq. (4). These methods of Riemann are based on $\zeta(s)$, the function defined by Eq. (5), where $s = \sigma + it$ is a complex

$$\lim_{x\to\infty} \frac{\pi(x)}{(x/\log x)} = 1 \tag{4}$$

$$\zeta(s) = \sum_{n=1}^{\infty} \frac{1}{n^s} \tag{5}$$

variable; the series in this equation is convergent for $\sigma > 1$. Via an analytic continuation, this function can be defined in the whole complex plane. It is a meromorphic function with only a simple pole of residue 1 at $s = 1$. It can be shown that $\zeta(s)$ has no zeros for $\sigma = 1$; this result and the existence of a pole at $s = 1$ suffice to prove the prime number theorem. Riemann's work contains the still unproved so-called Riemann hypothesis: all zeros of $\zeta(s)$ have a real part not exceeding $^1/_2$. *See* Complex numbers and complex variables.

Diophantine approximation. A real number x is called rational if there are integers p and q such that $x = p/q$; otherwise x is called irrational. The number $b^{1/m}$ is irrational if b is an integer which is not the mth power of an integer (for example, 2 is irrational). A real number x is called algebraic if it is the root of a monic polynomial with integer coefficients; otherwise x is called transcendental. The numbers e and π are transcendental. That π is transcendental implies that it is impossible to square the circle. *See* Circle; e (mathematics).

The part of number theory called diophantine approximation is devoted to approximating numbers of a particular kind by numbers from a particular set, such as approximating irrational numbers by rational numbers with small denominators. A basic result is that, given an irrational number x, there exist infinitely many fractions h/k that satisfy the inequality (6), where c is any

$$\left| x - \frac{h}{k} \right| < \frac{1}{ck^2} \tag{6}$$

positive number not exceeding 5. However, when c is greater than 5, there are irrational numbers x for which there are only finitely many such h/k.

In 1851, J. Liouville showed that transcendental numbers exist; he did so by demonstrating that the number x given by Eq. (7) has the property that, given any positive real number m, there is a rational number h/k that satisfies Eq. (8).

$$x = \sum_{j=1}^{\infty} 10^{-j!} \tag{7}$$

$$\left| x - \frac{h}{k} \right| < \frac{1}{k^m} \tag{8}$$

See Algebra; Numbering systems; Zero. [K.H.R.]

Numbering systems A numbering system is a systematic method for representing numbers using a particular set of symbols. The most commonly used numbering system is the decimal system, based on the number 10, which is called the basis or radix of the system. The basis tells how many different individual symbols there are in the system to represent numbers. In the decimal system these symbols are the digits 0, 1, 2, 3, 4, 5, 6, 7, 8, 9. The range of these numbers varies from 0 to (10 − 1). This is a particular case of a more general rule: Given any positive basis or radix N, there are N different individual symbols that can be used to write numbers in that system. The range of these numbers varies from 0 to $N - 1$.

In the computer and telecommunication fields, three of the most frequently used numbering systems are the binary (base 2), the octal (base 8), and the hexadecimal (base 16). The binary system has only two symbols: 0 and 1. Either of these symbols can be called a binary digit or a bit. The octal system has eight symbols: 0, 1, 2, 3, 4, 5, 6, 7. The hexadecimal system has 16 symbols: 0, 1, 2, 3, 4, 5, 6, 7, 8, 9, A, B, C, D, E, F. A stands for 10, B for 11, C for 12, D for 13, E for 14, and F for 15. The reason for choosing single letters to represent numbers higher than 9 is to keep all individual symbols single characters. *See* Bit.

All the numbering systems mentioned so far are positional systems. That is, the value of any symbol depends on its position in the number. For example, the value of 2 in the decimal number 132 is that of two units, whereas its value in decimal 245 is that of two hundreds. In the decimal system, the rightmost position of a number is called the ones (10^0) place, the next position from the right is called the tens (10^1) place, the next position the hundreds (10^2) place, and so on. Observe that the powers increase from the right. The power of the rightmost digit is zero, the power of the next digit is one, the power of the next digit is two, and so on. These powers are sometimes called the weight of the digit.

Conversion to decimal numbers. In any positional system, the decimal equivalent of a digit in the representation of the number is the digit's own value, in decimal, multiplied by a power of the basis in which the number is represented. The sum of all these powers is the decimal equivalent of the number. The corresponding powers of each of the digits can be better visualized by writing superscripts beginning with 0 at the rightmost digit, and increasing the powers by 1 in moving toward the left digits of the number.

Decimal numbers to other bases. The conversion of a given decimal number to another basis r ($r > 0$) is carried out by initially dividing the given decimal number by r, and then successively dividing the resulting quotients by r until a zero quotient is obtained. The decimal equivalent is obtained by writing the remainders of the successive divisions in the opposite order in which they were obtained.

Binary to hexadecimal or octal and vice versa. The table shows the decimal numbers 1 through 15 written in binary, octal, and hexadecimal. Since each four-bit binary number corresponds to one and only one hexadecimal digit and vice versa, the hexadecimal system can be viewed as a shorthand notation of the binary system. Similar reasoning can be applied to the octal system. This one-to-one correspondence between the symbols of the binary system and the symbols of the octal and hexadecimal system provides a method for converting numbers between these bases.

To convert binary numbers to hexadecimal, the following procedure may be used: (1) Form four-bit groups beginning from the rightmost bit of the number. If the last group (at the leftmost

The first 15 integers in binary, octal, hexadecimal, and decimal notation

Binary	Octal	Hexadecimal	Decimal
0001	1	1	1

1100	14	C	12
1101	15	D	13
1110	16	E	14
1111	17	F	15

position) has fewer than four bits, add extra zeros to the left of the bits in this group to make it a four-bit group. (2) Replace each four-bit group by its hexadecimal equivalent. A process that is almost the reverse of the previous procedure can be used to convert from hexadecimal to binary. However, there is no need to add extra zeros to any group since each hexadecimal number will always convert to a group with four binary bits.

A similar process can be followed to convert a binary number to octal, except that in this case three-bit groups must be formed. Individual octal numbers will always convert to groups with three binary bits. [R.A.M.T.]

Numerical analysis

The development and analysis of computational methods (and ultimately of program packages) for the minimization and the approximation of functions, and for the approximate solution of equations, such as linear or nonlinear (systems of) equations and differential or integral equations. Originally part of every mathematician's work, the subject is now often taught in computer science departments because of the tremendous impact which computers have had on its development. Research focuses mainly on the numerical solution of (nonlinear) partial differential equations and the minimization of functions.

Numerical analysis is needed because answers provided by mathematical analysis are usually symbolic and not numeric; they are often given implicitly only, as the solution of some equation, or they are given by some limit process. A further complication is provided by the rounding error which usually contaminates every step in a calculation (because of the fixed finite number of digits carried).

Even in the absence of rounding error, few numerical answers can be obtained exactly. Among these are (1) the value of a piece-wise rational function at a point and (2) the solution of a (solvable) linear system of equations, both of which can be produced in a finite number of arithmetic steps. Approximate answers to all other problems are obtained by solving the first few in a sequence of such finitely solvable problems. A typical example is provided by Newton's method: A solution c to a nonlinear equation $f(c) = 0$ is found as the

$$\text{limit}\, c = \lim_{n \to \infty} x_n,$$

with X_{n+1} being a solution to the linear equation

$$f(x_n)\, f'(x_m)(x_{n+1} - x_n) = 0,$$

that is, $x_{n+1} = x_n - f(x_n)/f'(x_n)$, $n = 0, 1, 2, \ldots$ Of course, only the first few terms in this sequence x_0, x_1 x_2, … can ever be calculated, and thus one must consider when to break off such a solution process and how to gauge the accuracy of the current approximation.

An otherwise satisfactory computational process may become useless, because of the amplification of rounding errors. A computational process is called stable to the extent that its results are not spoiled by rounding errors. The extended calculations involving millions of arithmetic steps now possible on computers have made the stability of a computational process a prime consideration.

Interpolation and approximation. Polynomial interpolation provides a polynomial p of degree n or less which uniquely matches given function values $f(x_0), \ldots, f(x_n)$ at corresponding distinct points $x_0, \ldots, x_n$. The interpolating polynomial p is used in place of f, for example in evaluation, integration, differentiation, and zero finding. Accuracy of the interpolating polynomial depends strongly on the placement of the interpolation points, and usually degrades drastically as one moves away from the interval containing these points (that is, in case of extrapolation). *See* EXTRAPOLATION.

When many interpolation points (more than 5 or 10) are to be used, it is often much more efficient to use instead a piecewise polynomial interpolant or spline. Suppose the interpolation points above are ordered, $x_0 < x_1 < \cdots x_n$. Then the cubic spline interpolant to the above data, for example, consists of cubic polynomial pieces, with the ith piece defining the interpolant on the interval $[x_{i-1}, x_i]$ and so matched with its neighboring piece or pieces that the resulting function not only matches the given function values (hence is continuous) but also has a continuous first and second derivative.

Interpolation is but one way to determine an approximant. In full generality, approximation involves several choices: (1) a set P of possible approximants, (2) a criterion for selecting from P a particular approximant, and (3) a way to measure the approximation error, that is, the difference between the function f to be approximated and the approximant p, in order to judge the quality of approximation.

Solution of linear systems. Solving a linear system of equations is probably the most frequently confronted computational task. It is handled either by a direct method, that is, a method which obtains the exact answer in a finite number of steps, or by an iterative method, or by a judicious combination of both. Analysis of the effectiveness of possible methods has led to a workable basis for selecting the one which best fits a particular situation.

Direct methods require a number of operations which increases with the cube of the number of unknowns. Some types of problems arise wherein the matrix of coefficients is sparse, but the unknowns may number several thousand; for these, direct methods are prohibitive in computer time required. One frequent source of such problems is the finite difference treatment of partial differential equations. A significant literature of iterative methods exploiting the special properties of such equations is available. For certain restricted classes of difference equations, the error in an initial iterate can be guaranteed to be reduced by a fixed factor, using a number of computations that is proportional to $n \log n$, where n is the number of unknowns. Since direct methods require work proportional to n^3, it is not surprising that as n becomes large, iterative methods are studied rather closely as practical alternatives.

Differential equations. Classical methods yield practical results only for a moderately restricted class of ordinary differential equations, a somewhat more restricted class of systems of ordinary differential equations, and a very small number of partial differential equations. The power of numerical methods is enormous here, for in quite broad classes of practical problems relatively straightforward procedures are guaranteed to yield numerical results, whose quality is predictable. *See* DIFFERENTIAL EQUATION. [C.DeB.]

Numerical representation (computers)

Numerical data in a computer are written in basic units of storage made up of a fixed number of consecutive bits. The most commonly used units in the computer and communication industries are the byte (8 consecutive bits), the word (16 consecutive bits), and the double word (32 consecutive bits). A number is represented in each of these units by setting the bits according to the binary representation of the number. By convention the bits in a byte are numbered, from right to left, beginning with zero. Thus, the rightmost bit is bit number 0 and the leftmost bit is number 7. The rightmost bit is called the least significant bit, and the leftmost bit is called the most significant bit. Higher units are numbered also from right to left. In general, the rightmost bit is labeled 0 and the leftmost bit is labeled $(n - 1)$, where n is the number of bits available. *See* BIT.

Since each bit may have one of two values, 0 or 1, n bits can represent 2^n different unsigned numbers. The range of these nonnegative integers varies from 0 to $2^n - 1$. To represent positive or negative numbers, one of the bits is chosen as the sign bit. By convention, the leftmost bit (or most significant bit) is considered the sign bit. A value of 0 in the sign bit indicates a positive number, whereas a value of 1 indicates a negative one. A similar convention is followed for higher storage units, including words and double words. Various conventions exist for representing integers and real numbers. [R.A.M.T.]

Numerical taxonomy The grouping by numerical methods of taxonomic units based on their character states. The application of numerical methods to taxonomy, dating back to the rise of biometrics in the late nineteenth century, has received a great deal of attention with the development of the computer and computer technology. Numerical taxonomy provides methods that are objective, explicit, and repeatable, and is based on the ideas first put forward by M. Adanson in 1963. These ideas, or principles, are that the ideal taxonomy is composed of information-rich taxa based on as many features as possible, that *a priori* every character is of equal weight, that overall similarity between any two entities is a function of the similarity of the many characters on which the comparison is based, and that taxa are constructed on the basis of diverse character correlations in the groups studied. *See* TAXON.

In the early stages of development of numerical taxonomy, phylogenetic relationships were not considered. However, numerical methods have made possible exact measurement of evolutionary rates and phylogenetic analysis. Furthermore, rapid developments in the techniques of direct measurement of the homologies of deoxyribonucleic acid (DNA), and ribonucleic acid (RNA) between different organisms now provide an estimation of "hybridization" between the DNAs of different taxa and, therefore, possible evolutionary relationships. Thus, research in numerical taxonomy often includes analyses of the chemical and physical properties of the nucleic acids of the organisms the data from which are correlated with phenetic groupings established by numerical techniques. *See* PHYLOGENY; TAXONOMIC CATEGORIES. [R.R.C.]

Nummulites A genus of unicellular shelled protozoa of the order Foraminiferida (superfamily Nummulitacea, family Nummulitidae). Members are of characteristically rock-forming abundance in early Tertiary strata of the circum-Mediterranean region, and are useful as stratigraphic indicators (Paleocene to Holocene). The pyramids of Egypt were constructed of blocks of nummulitic limestone of Eocene age. *See* LIMESTONE.

The discoidal, lenticular, or globular test or shell can reach a diameter of about 5 in. (12 cm) and is composed of finely perforate calcium carbonate. It consists of planispirally enrolled whorls of many tiny undivided chambers. Reproduction may be either sexual or asexual. The alternation of these methods within a species results in successive diploid and haploid generations of marked size disparity. *See* FORAMINIFERIDA. [A.R.L.]

Nursing The application of principles from the basic sciences, social sciences, and humanities to assist healthy and sick individuals and their families or other caring persons in performing those activities that contribute to the individuals' physical and mental well-being and that they would perform unaided if able to do so. Nursing includes providing physical and emotional care, promoting comfort, serving as patient advocates, assisting in rehabilitative efforts, teaching self-care and health promotion activities, and administering treatments prescribed by a licensed physician or dentist. Patient-care activities are conceived and coordinated so as to help individuals gain independence as rapidly as possible or maintain an optimal level of function. When multiple health-care providers are involved, nursing coordinates patient-care efforts to improve the quality of care.

Nursing practice is conducted in a variety of settings, including hospitals, community facilities, private homes, nursing homes, schools, industry, physician's offices, the military, and civil service arenas. Standards for nursing practice and licensure are governed by state nurse practice acts and are directed by professional nursing organizations.

Two types of nurses are legally recognized in the United States: the registered professional nurse and the licensed practical nurse. Licensed practical or vocational nurses (LPNs or LVNs) are trained to perform uncomplicated patient-care tasks in hospitals or other health-care facilities under the aegis of registered nurses or physicians. *See* MEDICINE. [J.A.Ve.]

Nut (engineering) In mechanical structures, an internally threaded fastener. Plain square and hexagon nuts for bolts and screws are available in three degrees of finish: unfinished, semi-finished, and finished. There are two standard weights: regular and heavy. For specific applications, there are other standard forms such as jam nut, castellated nut, slotted nut, cap nut, wing nut, and knurled nut.

Wing and knurled nuts are designed for applications where a nut is to be tightened or loosened by using finger pressure only. *See* SCREW FASTENER. [W.J.L.]

Nutation (astronomy and mechanics) In mechanics, a bobbing motion that accompanies the precession of a spinning rigid body, such as a top. In simple precession, the axis of a top with a fixed point of contact sweeps out a cone, whose axis is the vertical direction. In the general motion, the angle between the axis of the top and the vertical varies with time. This motion of the top's axis, bobbing up and down as it precesses, is known as nutation. *See* RIGID-BODY DYNAMICS.

Astronomical nutation refers to irregularities in the precessional motion of the equinoxes caused by the varying torque applied to the Earth by the Sun and Moon. Astronomical nutation should not be confused with nutation as defined in mechanics; the latter is present even if the source of the torques is unvarying. *See* CELESTIAL MECHANICS; PRECESSION OF EQUINOX. [V.D.B.]

Nutmeg A delicately flavored spice obtained from the nutmeg tree (*Myristica fragrans*), a native of the Moluccas, or Spice Islands. The tree is a dark-leafed evergreen, and is a member of the nutmeg family (Myristicaceae). The golden-yellow, mature fruits resemble apricots (see illustration). They gradually lose moisture and when completely ripe, the husk (pericarp) splits open, exposing the shiny brown seed which is the nutmeg of

Mature nutmeg (*Myristica fragrans*) fruits. (*USDA*)

commerce. Nutmeg oil is used in medicine, perfumery, and dentifrices, and in the tobacco industry. [P.D.St./E.L.C]

Nutrition The science of nourishment, including the study of the nutrients that each organism must obtain from its environment to maintain life and health and to reproduce. Although each kind of organism has its distinctive needs, which can be studied separately, a far-reaching biochemical unity in nature has been discovered which gives vastly more coherence to the whole subject. Many nutrients, such as amino acids, minerals, and vitamins, needed by higher organisms may also be needed by the lowest forms of life—single-celled bacteria and protozoa. The recognition of this fact has made possible highly important developments in biochemistry.

Mammals need for their nutrition (aside from water and oxygen) a highly complex mixture of more than 40 chemical substances, including amino acids; carbohydrates; certain lipids; fibers; a great variety of minerals, including several which are required only in minute amounts, commonly referred to as trace minerals; and vitamins. *See* AMINO ACIDS; CARBOHYDRATE METABOLISM; LIPID METABOLISM; PROTEIN METABOLISM; VITAMIN.

Early workers in human nutrition focused on the minimum amounts needed to prevent or cure acute deficiency diseases, such as scurvy and beriberi. Since that time, the Recommended Dietary Allowances (RDAs) in the United States and similar recommendations in other countries include consideration of biochemical criteria of adequacy. They also include approximate adjustments for age, sex, and pregnancy and lactation, along with a rough estimate for some other sources of individual variation. However, statistical data needed to adequately assess individual variations are not yet available for any nutrient.

Interests have shifted toward what may be more nearly optimal nutritional intakes, based on the amounts needed to promote health (not merely to avoid disease or biochemical deficiency), longevity, and resistance to chronic disorders, including cardiovascular disease, cancer, hypertension, and diabetes.

For modern humans, the problems of suboptimal nutrition have increased with the advent and extensive consumption of technologically derived, refined foods. These nonwhole "foods" have lost most or all of the nutrients present in the whole foods from which they derive. Modern dietary guidelines and nutrition education focus substantially on partially replacing nonwhole foods with whole grains, legumes, low-fat meats and dairy products, fish, vegetables, fruits, and nuts that retain their natural biochemical unity.

One of the bases for interest in nutrition is the fact that individuals who have differing genetic backgrounds have differing nutritional needs; for this reason, various human ills may arise because the individuals concerned do not get all of the nutrients in amounts compatible with their own distinctive requirements.

It is clear that improper nutrition may produce or contribute to almost every conceivable type of illness. Nutritional and medical research is yielding important advances in using improved nutrition to prevent, cure, and ameliorate disease and illness. *See* DISEASE; MALNUTRITION; METABOLIC DISORDERS. [R.J.Wi.; D.R.Da.]

Nymphaeales An order of flowering plants that have previously been included in the same larger grouping as Magnoliales, the Magnoliidae. Deoxyribonucleic acid (DNA) sequence studies have demonstrated that Nymphaeales as previously defined contain two families, Ceratophyllaceae (water hornwort) and Nelumbonaceae (lotus), that are not closely related to the others. Remaining in the order is the family Nymphaeaceae, the waterlilies, from which a small group of tropical plants, Cabombaceae, are split by some scientists. Nymphaeaceae contain nearly 100 species of fresh-water aquatics that are typically found in river and lake systems throughout the world. The ovaries of these plants are filled with mucilage, which mediates pollen tube growth from the stigmas to the ovules, and they have either inappertuate or monosulcate pollen. A spectacular plant is the Amazonian water lily (*Victoria*), which has leaves up to 15 ft (5 m) in diameter. The water lily family has been shown by DNA analyses to be one of the oldest lineages of flowering plants and distantly related to all others as well. The family members are relics of the early diversification of the flowering plants. *See* EUMAGNOLIIDS; PLANT KINGDOM; POLLEN. [M.W.C.]

O

Oak A genus (*Quercus*) of trees, some of which are shrubby, with about 200 species, mainly in the Northern Hemisphere. About 50 species are native in the United States. All oaks have scaly winter buds, usually clustered at the ends of the twigs, and single at the nodes. The fruit is a nut (acorn). The leaves are simple and usually lobed.

Oaks furnish the most important hardwood lumber in the United States. Principal uses are for charcoal, barrels, building construction, flooring, railroad ties, mine timbers, boxes, crates, vehicle parts, ships, agricultural implements, caskets, woodenware, fence posts, piling, and veneer. Oak is also used for pulp and paper products. *See* Fagales. [A.H.G./K.P.D.]

Oasis An isolated fertile area, usually limited in extent and surrounded by desert. The term was initially applied to small areas in Africa and Asia typically supporting trees and cultivated crops with a water supply from springs and from seepage of water originating at some distance. However, the term has been expanded to include areas receiving moisture from intermittent streams or artificial irrigation systems. Thus the floodplains of the Nile and Colorado rivers can be considered vast oases, as can arid areas irrigated by humans. *See* Desert.

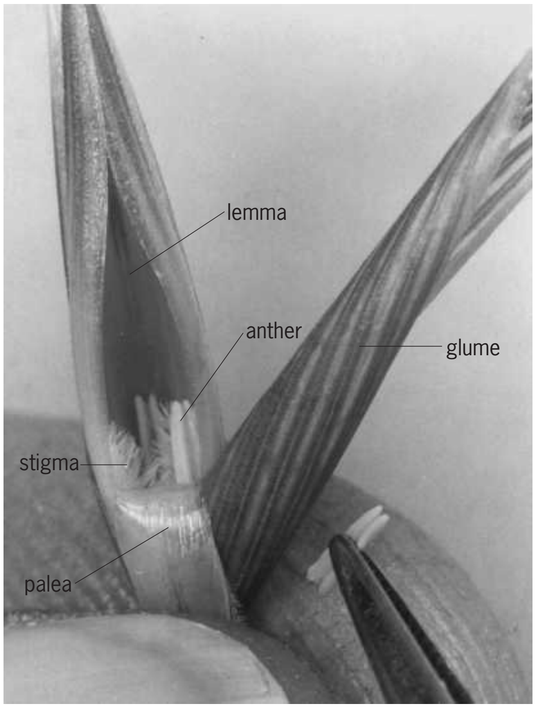
Oases are restricted to climatic regions where precipitation is insufficient to support crop production. Such regions may be classified as extremely arid (annual rainfall less than 2 in. or 50 mm), arid (annual rainfall less than 10 in. or 250 mm), and semiarid (rainfall less than 20 in. or 500 mm). Many African and Asian oases are in extremely arid areas. Most oases are found in warm climates. Oasis soils are weakly developed, high in organic matter but often saline, and have been strongly affected by human occupation. [W.G.McG.]

Oats An agricultural crop grown for its grain and straw in most countries of the temperate zones of the world. In the major oat-growing states of the midwestern United States (Iowa, North Dakota, South Dakota, Minnesota, and Wisconsin) the crop is raised for grain, whereas in the Southern states (Texas, Oklahoma, and Georgia) it is used for pasture or a combination of pasture and grain. About 90% of the annual oat grain production is used for animal feeds, and about 10% is processed into food for humans, for example, oatmeal and other cereal products. In general, oats are a cool-season crop which requires a moist climate. They grow well on both light and heavy soils if sufficient moisture and fertility nutrients are available. *See* Animal feeds; Cereal.

The fifteen species of oats in the genus *Avena* are divided into three groups on the basis of chromosome number: 14, 28, or 42. Within the 42-chromosome cultivated species there is wide variation among varieties for all plant traits. Oats belong to the Graminae (grass) family; thus the oat plant forms a crown at the soil surface from which a fibrous root system penetrates the soil. Culms usually grow 2–5 ft (0.6–1.5 m) tall, and they are terminated with inflorescences called panicles. Each panicle usually bears 10–75 spikelets on its numerous branches. A spikelet is enclosed by two papery glumes and bears two or three florets, each with an ovary, two stigmas, and three anthers enclosed in a lemma and palea (see illustration). In most varieties the lemma and palea adhere to the oat seed after threshing. A trait used to determine market grade of oats is the color of the lemma, which may be white, yellow, gray, brown, red, or black. The major trait that distinguishes wild from cultivated oats is seed shattering. In cultivated species the seed attachment is persistent, and it can be separated from the panicle only by threshing. *See* Cyperales; Flower; Grass crops; Inflorescence.

The world collection of oats, maintained by the U.S. Department of Agriculture, contains more than 14,000 lines of 42-chromosome types. These represent lines from wild species and from varieties produced at breeding stations. The collection represents a vast range of genetic types that can be used for varietal improvement. [K.J.F.]

The milling of oats is less complex than wheat milling and has many similarities to rice or barley milling operations because there is limited fractionation of the kernel. The oat grain is covered with a coarse, adhering hull which must be removed prior to production of ingredients or consumer foods. Oats as received at the mill house are termed green oats and must be cleaned to remove foreign seeds and trash. Clean, sound oats are heated slowly prior to hull removal. The green oats have active lipolytic enzymes (lipases) which will catalyze hydrolysis of triglycerides and yield free fatty acids. The heating, drying, or roasting procedures inactivate lipases, facilitate hull removal, and impart a distinctive roasted flavor to the oat product. Roasted oats are air-cooled and size-graded prior to dehulling. The products of the dehuller are primarily the whole kernel or groat and the fiber hull which are readily separated by air aspiration. The low-density oat hulls possess particularly



An oat flower; two oat grains are shown at the lower right.

high levels of fiber and pentosans which are suitable feedstock for industrial production of furfural (an important chemical nylon manufacturing) through high-temperature acid hydrolysis and dehydration. Whole, cleaned oat groats are not frequently available in the commercial food market. Selected large-sized groats are excellent for puffing into ready-to-eat cereals.

Oat cutting and flaking procedures provide more extensive utilization of groats in the form of rolled oats. Oat flour is obtained from further reduction and sieving or hammer milling of the whole groat or flaked product. This high-protein flour is frequently used in the formulations of ready-to-eat cereals and many prepared baby foods. Composite flours blended from oat flour and other cereals providing high protein content and extended shelf life have been proposed as suitable for world feeding programs. *See* FOOD MANUFACTURING. [M.A.U.]

Obesity The presence of excess body fat. The great prevalence of this condition, its severe consequences for physical and mental health, and the difficulty of treating it make the prevention of obesity a major public health priority.

Obesity is most often defined in terms of body weight relative to height, since both height and weight are easily measured. Obesity is considered to begin at a weight-for-height that is 20–30% above desirable weight, with this desirable weight taken as the midpoint of ranges of weight associated with the greatest longevity in studies of life-insured individuals. In population surveys, obesity is defined as a body weight that meets or exceeds the 85th percentile of the Body Mass Index (BMI), an index of weight-for-height that correlates well with body fat content. *See* ADIPOSE TISSUE.

The prevalence of obesity increases with age, is higher in women than men, and is highest among the poor and minority groups. Obesity increases the likelihood of high blood cholesterol, high blood pressure, and diabetes, and therefore of the diseases for which such conditions are risk factors—coronary heart disease, stroke, and kidney disease. It also increases the likelihood of gallbladder disease and cancers of the breast and uterus. Thus, obesity increases overall mortality rates, and it does so in proportion to the degree and duration of overweight. Individuals who become obese at the earliest ages are at highest risk of premature mortality. Distribution of excess fat to the upper body rather than the lower body may also increase risk.

The causes of most cases of obesity are poorly understood. At the simplest level, obesity results from an excess of energy (caloric) intake over expenditure, but this statement does not explain why some individuals can eat as much as they like without gaining weight while others remain overweight despite constant dieting. Studies of genetically obese animals and those with damage to the part of the brain called the hypothalamus suggest that individuals may balance body weight around a "setpoint" that is maintained—without conscious control—by variations in metabolic rate in response to caloric intake. Variations in the prevalence of obesity among population groups suggest a genetic basis for the condition. The complexity of body-weight regulatory mechanisms suggests that obesity is not due to a single cause but, like other chronic diseases, is multifactorial in origin. Specific inherited differences that might influence setpoints include differences in nearly every anatomic, neurologic, and biochemical factor known to affect food intake and utilization, energy metabolism, and energy expenditure. *See* ENDOCRINE MECHANISMS; ENERGY METABOLISM; METABOLIC DISORDERS.

Because the causes of obesity are incompletely understood, it is difficult to formulate effective treatment strategies. Studies suggest that programs combining diet and exercise help obese individuals lose more weight and maintain losses longer than either program does separately. *See* FOOD; NUTRITION. [M.N.]

Object-oriented programming A computer-programming methodology that focuses on data items rather than processes. Traditional software development models assume a top-down approach. A functional description of a system is produced and then refined until a running implementation is achieved. Data structures (and file structures) are proposed and evaluated based on how well they support the functional models.

The object-oriented approach focuses first on the data items (entities, objects) that are being manipulated. The emphasis is on characterizing the data items as active entities which can perform operations on and for themselves. It then describes how system behavior is implemented through the interaction of the data items.

The essence of the object-oriented approach is the use of abstract data types, polymorphism, and reuse through inheritance.

Abstract data types define the active data items described above. A traditional data type in a programming language describes only the structure of a data item. An abstract data type also describes operations that may be requested of the data item. It is the ability to associate operations with data items that makes them active. The abstract data type makes operations available without revealing the details of how the operations are implemented, preventing programmers from becoming dependent on implementation details. The definition of an operation is considered a contract between the implementor of the abstract data type and the user of the abstract data type. The implementor is free to perform the operation in any appropriate manner as long as the operation fulfills its contract. Object-oriented programming languages give abstract data types the name class.

Polymorphism in the object-oriented approach refers to the ability of a programmer to treat many different types of objects in a uniform manner by invoking the same operation on each object. Because the objects are instances of abstract data types, they may implement the operation differently as long as they fulfill the agreement in their common contract.

A new abstract data type (class) can be created in object-oriented programming simply by stating how the new type differs from some existing type. A feature that is not described as different will be shared by the two types, constituting reuse through inheritance. Inheritance is useful because it replaces the practice of copying an entire abstract data type in order to change a single feature.

In the object-oriented approach, a class is used to define an abstract data type, and the operations of the type are referred to as methods. An instance of a class is termed an object instance or simply an object. To invoke an operation on an object instance, the programmer sends a message to the object. [J.J.Sc.]

Obolellida A small extinct order of inarticulate brachiopods that ranges in age from Early to Middle Cambrian. The shell, composed of calcite, is usually elongated oval in outline and biconvex. The ventral (pedicle) valve has a well-defined flat shelf (pseudointerarea) at the posterior. The pedicle opening is unusually variable in position for an order. It can be located between the valves or at the apex of the ventral (pedicle) valve or anterior to the apex of the ventral valve. Members of this group were presumably epifaunal and sessile. *See* BRACHIOPODA; INARTICULATA. [M.W.F.]

Obsessive-compulsive disorder A type of anxiety disorder (commonly referred to as OCD) characterized by recurrent, persistent, unwanted, and unpleasant thoughts (obsessions) or repetitive, purposeful ritualistic behaviors that the person feels driven to perform (compulsions). A cardinal feature of this disorder is an awareness of the irrationality or excess of the obsessions and compulsions accompanied by an inability to control them.

Typical compulsions include an irresistible urge to wash (particularly the hands) or clean, to check doors to confirm that they are locked, to return repeatedly to appliances to make sure they are turned off, to touch, to repeat, to count, to arrange, or to save. Typical obsessions include overconcern about dirt and contamination, fear of acting on violent or aggressive impulses, feeling overly responsible for the safety of others, abhorrent religious (blasphemous) and sexual intrusions, and inordinate concern with arrangement or symmetry. Obsessions may accompany compulsions, or compulsions may occur alone.

The difference between obsessive-compulsive disorder and milder forms of obsession or compulsion seen in otherwise healthy people is that for the sufferer the obsessions or compulsions cause marked distress, are time-consuming, and significantly interfere with the person's normal routine, occupational functioning, usual social activities, and relationships with others.

Onset in adolescence occurs in about a third of cases. In another third symptoms appear in early adulthood, and in the last third they start later in life. If not treated appropriately, the disorder is often chronic, with waxing and waning of symptoms.

Obsessive-compulsive disorder is generally resistant to traditional psychotherapy, which has tried to trace the condition to conflicts of early childhood. An effective mode of psychotherapy is behavioral therapy, in which the patients are gradually exposed to their feared or triggering situation but are prevented from performing accompanying compulsions. This approach, which focuses on treating the symptoms rather than trying to understand their origin, seems to be more effective in treating the ritualistic behavior (compulsions) than the pervasive thoughts (obsessions). Obsessive-compulsive disorder is also refractory to most drugs used to treat anxiety, depression, and psychosis. However, it often eases with medications that affect the brain's serotonergic system, such as clorimipramine, fluvoxamine, and fluoxetine.

The specific response of patients with obsessive-compulsive disorder to serotonergic drugs, their hypersensitivity to activation of the serotonergic system, and the distinct functional anatomy differences found in those patients suggest a biological cause for this disorder. In this regard, obsessive-compulsive disorder represents a shift from a psychological to a neurobiological approach in the study of anxiety disorders. *See* Anxiety disorders; Neurotic disorders; Serotonin. [J.Z.]

Obsidian A volcanic glass, usually of rhyolitic composition, formed by rapid cooling of viscous lava. The color is jet-black because of abundant microscopic, embryonic crystal growths (crystallites) which make the glass opaque except on thin edges. Iron oxide dust may produce red or brown obsidian.

Obsidian usually forms the upper parts of lava flows. Well-known occurrences are Obsidian Cliffs in Yellowstone Park, Wyoming; Mount Hekla, Iceland; and the Lipari Islands off the coast of Italy. *See* Igneous rocks; Volcanic glass. [C.A.C.]

Occultation The temporary apparent disappearance from view of a celestial body as another body passes across the line of sight. Usually, it refers to stars occulted by the Moon, but it also applies to stars occulted by major or minor planets, minor planets occulting each other, Jupiter occulting its Galilean satellites, and so forth. Some occultations are called eclipses for historical reasons, for example, solar eclipses. An occultation refers strictly to a blockage in the line of sight, and not to disappearance in a shadow. *See* Eclipse.

The study of lunar occultations of stars over several centuries was used to improve the theory of the Moon's motion, and also contributed to detecting irregularities of the Earth's rotation. With that knowledge as a basis, lunar occultations are of more importance now in studying the figure of the Moon. *See* Earth rotation and orbital motion; Moon.

Occultations are used to study the size and shape of bodies whose disk cannot be seen. In such cases, if a planet is predicted to pass within its provisional radius of a star, and no occultation occurs, an upper limit is set. It was in this way that Pluto's small size was established. *See* Pluto.

Application of observational techniques has given very accurate profiles of minor planets. Successful observations are still quite rare, however. The method is also being used to seek suspected binary minor planets. *See* Asteroid.

During the occultation of a star by a planet with an atmosphere high-speed photoelectric observations of the light in several distinct wavelengths will yield information on the composition, structure, and dynamics of the atmosphere. The very thin, faint rings of Uranus were discovered accidentally in 1977 when they occulted a star during calibration observations made in preparation for observing an occultation of the star by Uranus. Now such observations are routinely made, from ground and space, both to search for more rings and to determine the fine structure of known ones. *See* Jupiter; Neptune; Solar system; Uranus. [A.D.F.]

Ocean One of the major subdivisions of the interconnected body of salt water that occupies almost three-quarters of the Earth's surface. Earth is the only planet in the solar system whose surface is covered with significant quantities of water. Of the nearly 1.4 billion cubic kilometers of water found either on the surface or in relatively accessible underground supplies, more than 97% is in the oceans. *See* Oceanography.

Oceans and the seas that connect them cover some 73% of the surface of the Earth, with a mean depth of 3729 m (12,234 ft) (table). More than 70% of the oceans have a depth between 3000 and 6000 m (10,000 and 20,000 ft). Less than 0.2% of the oceans have depths as great as 7000 m (23,000 ft).

Ocean basin characteristics

	Area, km^2	Volume, km^3	Mean depth, m
Pacific	181,344,000	714,410,000	3940
Atlantic	94,314,000	337,210,000	3575
Indian	74,118,000	284,608,000	3840
Arctic	12,257,000	13,702,000	1117
Total	362,033,000	1,349,929,000	3729

The oceans are cold and salty. Some 50% have a temperature between 0 and 2°C (32 and 36°F) and a salinity between 34.0 and 35.0. To a high degree of approximation, a salinity of 34 is the equivalent of 34 grams of salt in a kilogram of seawater. Water with a temperature above a few degrees Celsius is confined to a relatively thin surface layer of the ocean. *See* Seawater.

Ocean salinity is primarily controlled by the balance of precipitation, river runoff, and evaporation of water at the sea surface. The highest salinities are found in major evaporation basins with little rainfall or river runoff, such as the Red Sea. The lowest salinities are found near the mouths of major rivers such as the Amazon. *See* Red sea.

Nearly all elements known to humankind have been found dissolved in seawater, and those that have not are assumed to be present. However, all but a few are found in very small amounts. Sodium chloride accounts for some 85% of the dissolved salts, and an additional four ions (sulfate, magnesium, calcium, and potassium) bring the total to more than 99.3%. The ratio of ions is remarkably constant from one ocean to another and from top to bottom of each.

The oceans are continually transporting excess heat (warm water) from the tropics toward the Poles and returning colder water toward the tropics. This process of moving excess heat from lower (south of 40°) to higher (north of 40°) latitudes is shared approximately equally by the oceans and the atmosphere. A significant part of the ocean heat exchange process is carried out by the major ocean currents, the "named" currents such as the Gulf Stream, Brazil Current, California Current, and Kuroshio. These currents are primarily driven by the winds, and there is considerable similarity in their pattern from one ocean basin to another. *See* Gulf stream; Kuroshio.

The average winds over the North and South Atlantic as well as the North and South Pacific oceans come out of the west (westerlies) at the middle latitudes and from the east at the lower latitudes (trade winds). The frictional drag of these winds on the surface of the water imparts a spin or torque to the surface of the ocean, clockwise in the Northern Hemisphere and counterclockwise in the Southern Hemisphere. The major exception is the Indian Ocean north of the Equator, where the circulation is strongly influenced by the winds of the seasonal monsoon. *See* ATLANTIC OCEAN; CORIOLIS ACCELERATION; EQUATORIAL CURRENTS; INDIAN OCEAN; OCEAN CIRCULATION; PACIFIC OCEAN. [J.A.K.]

Ocean circulation The general circulation of the ocean. The term is usually understood to include large-scale, nearly steady features, such as the Gulf Stream, as well as current systems that change seasonally but are persistent from one year to the next, such as the Davidson Current, off the northwestern United States coast and the equatorial currents in the Indian Ocean. A great number of energetic motions have periods of a month or two and horizontal scales of a few hundred kilometers—a very low-frequency turbulence, collectively called eddies. Energetic motions are also concentrated near the local inertial period (24 h, at 30° latitude) and at the periods associated with tides (primarily diurnal and semidiurnal). *See* TIDE.

The greatest single driving force for currents, as for waves, is the wind. Furthermore, the ocean absorbs heat at low latitudes and loses it at high latitudes. The resultant effect on the density distribution is coupled into the large-scale wind-driven circulation. Some subsurface flows are caused by the sinking of surface waters made dense by cooling or high evaporation. *See* OCEAN WAVES.

Except in western boundary currents, and in the Antarctic Circumpolar Current, the system of strong surface currents is restricted mainly to the upper 330–660 ft (100– 200 m) of the sea. The mid-latitude anticyclonic gyres, however, are coherent in the mean well below 3300 ft (1000 m). The average speeds of the open-ocean surface currents remain mostly below 0.4 knot (20 cm/s). Exceptions to this are found in the western boundary currents, such as the Gulf Stream, and in the Equatorial Currents of the three oceans, all of which have velocities of 2–4 knots (1–2 m/s).

The deep circulation results in part from the wind stress and in part from the internal pressure forces which are maintained by the budgets of heat, salt, and water. Both groups of forces are dependent upon atmospheric influences. Apart from Coriolis and frictional forces, the topography of the sea bottom exercises a decisive influence on the course of deep circulation.

The deep circulation in marginal seas depends largely on the climate of the region, whether arid or humid. Under the influence of an arid climate, evaporation is greater than precipitation. The marginal sea is therefore filled with relatively salty water of a high density. Its surface lies at a lower level than that of the neighboring ocean. Examples of this type are the Mediterranean Sea, Red Sea, and Persian Gulf. The deep circulation of marginal seas in humid climates shows a different pattern. The level of the sea is higher than in the neighboring ocean. Therefore, the surface water with its lower density and accordingly its lower salinity flows outward, and the relatively salty ocean water of higher density flows over the sill into the marginal sea. Examples of this circulation are the Baltic Sea with the shallow Darsser and Drogden rises, the Norwegian and Greenland fiords, and the Black Sea with its entrance through the Bosporus. *See* BLACK SEA; FIORD; MEDITERRANEAN SEA.

The deep circulation in the oceans is more difficult to perceive than the circulation in the marginal seas. In addition to the internal pressure forces, determined by the distribution of density and the piling up of water by the wind, there are also the influences of Coriolis forces and large-scale turbulence. There are areas in tropical latitudes in which the surface water, as a result of strong evaporation, has a relatively high density. In thermohaline convection, the water sinks while flowing horizontally until it reaches a density corresponding to its own, and then spreads out horizontally. In this way the colder and deeper levels of the oceans take on a layered structure consisting of the so-called bottom water, deep water, and intermediate water. *See* ATLANTIC OCEAN; PACIFIC OCEAN. [W.Stu.]

Wherever oceanographers have made long-term current and temperature measurements, they have found energetic fluctuations with periods of several weeks to several months. These low-frequency fluctuations (compared to tides) are caused by oceanic mesoscale eddies which are in many respects analogous to the atmospheric mesoscale pressure systems that form weather. Like the weather, mesoscale eddies often dominate the instantaneous current, and are thought to be an integral part of the ocean's general circulation.

Eddies occur in virtually all oceans and seas, but their amplitude varies greatly from place to place. The largest amplitudes are found on the western sides of the oceans in conjunction with the strongest ocean currents (the Gulf Stream in the North Atlantic, the Kuroshio in the North Pacific) and near the Equator. Much weaker eddies are found in the ocean interior, distant from major currents. This consistent pattern of eddy amplitude suggests that instabilities of western boundary currents are an important source of eddy energy. Atmospheric forcing by variable winds can also generate eddies, and is probably most important at low latitudes where the horizontal scales of the oceanic eddies best match the scales of the atmospheric forcing. [J.F.P.]

Ocean waves The irregular moving bumps and hollows on the ocean surface. Winds blowing over the ocean, in addition to producing currents, create surface water undulations called waves or a sea. The characteristics of these waves (or the state of the sea) depend on the speed of the wind, the length of time that it has blown, the distance over which it has blown, and the depth of the water. If the wind dies down, the waves that remain are called a dead sea.

Surface waves. Ocean surface waves are propagating disturbances at the atmosphere-ocean interface. They are the most familiar ocean waves. Surface waves are also seen on other bodies of water, including lakes and rivers. *See* WAVE MOTION IN LIQUIDS.

A simple sinusoidal wave train is characterized by three attributes: wave height (H), the vertical distance from trough to crest; wavelength (L), the horizontal crest-to-crest distance; and wave period (T), the time between passage of successive crests past a fixed point. The phase velocity ($C = L/T$) is the speed of propagation of a crest. For a given ocean depth (h), wavelength increases with increasing period. The restoring force for these surface waves is predominantly gravitational. Therefore, they are known as surface gravity waves, unless their wavelength is shorter than 1.8 cm (0.7 in.), in which case surface tension provides the dominant restoring force.

Surface gravity waves may be classified according to the nature of the forces producing them. Tides are ocean waves induced by the varying gravitational influence of the Moon and Sun. They have long periods, usually 12.42 h for the strongest constituent. Storm surges are individual waves produced by the wind and dropping barometric pressure associated with storms; they characteristically last several hours. Earthquakes or other large, sudden movements of the Earth's crust can cause waves, called tsunamis, which typically have periods of less than an hour. Wakes are waves resulting from relative motion of the water and a solid body, such as the motion of a ship through the sea or the rapid flow of water around a rock. Wind-generated waves, having periods from a fraction of a second to tens of seconds, are called wind waves. Like tides, they are ubiquitous in the ocean, and continue to travel well beyond their area of generation. The ocean is never completely calm. *See* STORM SURGE; TIDE; TSUNAMI.

The growth of wind waves by the transfer of energy from the wind is not fully understood. At wind speeds less than 1.1 m/s (2.5 mi/h), a flat water surface remains unruffled by waves. Once generated, waves gain energy from the wind by wave-coupling of pressure fluctuations in the air just above the waves. For waves traveling slower than the wind, secondary, wave-induced airflows shift the wave-induced pressure disturbance downwind so the lowest pressure is ahead of the crests. This results in energy transfer from the wind to the wave, and hence growth of the wave.

If a constant wind blows over a sufficient length of ocean, called the fetch, for a sufficient length of time, a wave field develops whose statistical characteristics depend only on wind velocity.

$$S(f) = A\frac{g^2}{f^5}e^{-1.25(fm/f)^4}$$

Because of viscosity, surface waves lose energy as they propagate, short-period waves being dampened more rapidly than long-period waves. Waves with long periods (typically 10 s or more) can travel thousands of kilometers with little energy loss. Such waves, generated by distant storms, are called swell.

When waves propagate into an opposing current, they grow in height. For example, when swell from a Weddell Sea storm propagates northeastward into the southwestward-flowing Agulhas Current off South Africa, high steep waves are formed. Many large ships in this region have been severely damaged by such waves.

Because actual ocean waves consist of many components with different periods, heights, and directions, occasionally a large number of these components can, by chance, come in phase with one another, creating a freak wave with a height several times the significant wave height of the surrounding sea. According to linear theory, waves with different periods propagate with different speeds in deep water, and hence the wave components remain in phase only briefly. But nonlinear effects are bound to be significant in a large wave. In such a wave, the effects of nonlinearity can compensate for those of dispersion, allowing a solitary wave to propagate almost unchanged. Consequently, a freak wave can have a lifetime of a minute or two. *See* Soliton.

[M.Wi.]

Internal waves. Internal waves are wave motions of stably stratified fluids in which the maximum vertical motion takes place below the surface of the fluid. The restoring force is mainly due to gravity; when light fluid from upper layers is depressed into the heavy lower layers, buoyancy forces tend to return the layers to their equilibrium positions. In the oceans, internal oscillations have been observed wherever suitable measurements have been made. The observed oscillations can be analyzed into a spectrum with periods ranging from a few minutes to days. At a number of locations in the oceans, internal tides, or internal waves having the same periodicity as oceanic tides, are prominent.

Internal waves are important to the economy of the sea because they provide one of the few processes that can redistribute kinetic energy from near the surface to abyssal depths. When they break, they can cause turbulent mixing despite the normally stable density gradient in the ocean. Internal waves are known to cause time-varying refraction of acoustic waves because the sound velocity profile in the ocean is distorted by the vertical motions of internal waves. Internal waves have been found by recording fluctuating currents in middepths by moored current meters, by acoustic backscatter Doppler methods, and by studies of the fluctuations of the depths of isotherms as recorded by instruments repeatedly lowered from shipboard or by autonomous instruments floating deep in the water.

Internal waves are thought to be generated in the sea by variations of the wind pressure and stress at the sea surface, by the interaction of surface waves with each other, and by the interaction of tidal motions with the rough sea floor. [C.S.C.]

Oceanic islands Islands rising from the deep sea floor. Oceanic islands range in size from mere specks of rock or sand above the reach of tides to large masses such as Iceland (39,800 mi^2 or 103,000 km^2). Excluded are islands that have continental crust, such as the Seychelles, Norfolk, or Sardinia, even though surrounded by ocean; all oceanic islands surmount volcanic foundations. A few of these have active volcanoes, such as on Hawaii, the Galápagos islands, Iceland, and the Azores, but most islands are on extinct volcanoes. On some islands, the volcanic foundations have subsided beneath sea level, while coral reefs growing very close to sea level have kept pace with the subsidence, accumulating thicknesses of as much as 5000 ft (1500 m) of limestone deposits between the underlying volcanic rocks and the present-day coral islands. *See* Reef; Volcano.

Oceanic islands owe their existence to volcanism that began on the deep sea floor and built the volcanic edifices, flow on flow, up to sea level and above. The highest of the oceanic islands is Hawaii, where the peak of Mauna Kea volcano reaches 14,000 ft (4200 m). Most volcanic islands are probably built from scratch in less than 10^6 years, but minor recurrent volcanism may continue for millions of years after the main construction stage. *See* Volcanology.

Islands in regions of high oceanic fertility are commonly host to colonies of sea birds, and the deposits of guano have been an important source of phosphate for fertilizer. On some islands, for example, Nauru in the western equatorial Pacific, the original guano has been dissolved and phosphate minerals reprecipitated in porous host limestone rocks. The principal crop on most tropical oceanic islands is coconuts, exploited for their oil content, but some larger volcanic islands, with rich soils and abundant water supplies, are sites of plantations of sugarcane and pineapple. Atoll and barrier-reef islands have very limited water supplies, depending on small lenses of ground water, augmented by collection of rainwater. *See* Atoll; Island biogeography; Reef.

[E.L.Wi.]

Oceanographic vessels Research vessels designed to collect quantitative data from the sea's surface, its depths, the sea floor, and the overlying atmosphere. Their primary purpose is to carry scientists and increasingly sophisticated equipment to and from study sites on the ocean's surface, and in some cases below the surface. The ships must have the ability to lower and retrieve instruments by using winches and wires. The ship's equipment and instrumentation must determine precisely the location on the sea surface, and provide suitable communication, data gathering, archiving, and computational facilities for the scientific party.

The requirements list includes seakeeping (sea-kindliness, a measure of a ship's response to severe seas; and station-keeping, the ability of a ship to maintain its fixed location on the sea surface); work environment; endurance (range, days at sea); scientific complement (number of researchers accommodated); operating economy and scientific effectiveness; subdued acoustical characteristics; payload (scientific storage, weight handling); speed; and ship control. These requirements often conflict, necessitating compromise.

Ships typically can be considered in three major groups based on use: general purpose (classical biological, physical, chemical, geological, and ocean engineering research, or a combination); dedicated special purpose (hydrographic survey, mapping, geophysical, or fisheries); or unique (deep-sea drilling, crewed spar buoy, or support of submersible operations). They can be used simply as delivery and support systems for exploratory devices, such as floats and bottom landers, as well as crewless remote operating vehicles (ROVs—tethered, powered, surface-controlled robots), or autonomous underwater vehicles (AUVs—freely operating robots, using computer programmed guidances). *See* Marine engineering; Naval architecture; Oceanography. [J.J.Gr.; J.F.Ba.]

Oceanography The science of the sea; including physical oceanography, marine chemistry, marine geology, and marine biology. The need to know more about the impact of marine pollution and possible effects of the exploitation of marine resources, together with the role of the ocean in possible global warming and climate change, means that oceanography is an important scientific discipline. Improved understanding of the sea has been essential in such diverse fields as fisheries conservation, the exploitation of underwater oil and gas reserves, and coastal protection policy, as well as in national defense strategies. The scientific benefits include not only improved understanding of the oceans and their inhabitants, but important information about the evolution of the Earth and its tectonic processes, and about the global environment and climate, past and present, as well as possible future changes. *See* CLIMATE HISTORY; COASTAL ENGINEERING; MARINE MINING; MARINE SEDIMENTS; MARITIME METEOROLOGY; OIL AND GAS, OFFSHORE.

The traditional basis of modern oceanography is the hydrographic station. Hydrographic studies are still carried out at regular intervals, with the research vessel in a specific position. Seawater temperature, depth, and salinity can be measured continuously by a probe towed behind the ship. The revolution in electronics has provided not only a new generation of instruments for studying the sea but also new ways of collecting and analyzing the data they produce. Computers are employed in gathering and processing data in all fields, and are also used in the creation of mathematical models to aid in understanding. Much information can also be gained by remote sensing using satellites, which are also a valuable navigational aid. These provide data on sea surface temperature and currents, and on marine productivity. Satellite altimetry gives information on wave height and winds and even bottom topography (because this affects sea level). Deep-sea cameras and submersibles now permit visual evidence of creatures in remote depths. *See* HYDROGRAPHY; OCEANOGRAPHIC VESSELS; MARINE ECOLOGY; REMOTE SENSING; SATELLITE NAVIGATION SYSTEMS; SEAWATER.

Since the early 1900s, all recorded ocean depths have been incorporated in the General Bathymetric Chart of the Ocean. The amount of data available increased greatly with the introduction of continuous echo sounders; subsequently, side-scan sonar permitted very detailed topographical surveys to be made of the ocean floor. The features thus revealed, in particular the midocean ridges (spreading centers) and deep trenches (subduction zones), are integral to the theory of plate tectonics. An important discovery made toward the end of the twentieth century was the existence of hydrothermal vents, where hot mineral-rich water gushes from the Earth's interior. The deposition of minerals at these sites and the discovery of associated ecosystems make them of potential economic as well as great scientific interest. *See* ECHO SOUNDER; HYDROTHERMAL VENT; MARINE GEOLOGY; MID-OCEANIC RIDGE; PLATE TECTONICS; SONAR; SUBDUCTION ZONES.

[M.De.]

Octane number

Octane number A standard laboratory measure of a fuel's ability to resist knock during combustion in a spark-ignition engine, A single-cylinder four-stroke engine of standardized design is used to determine the knock resistance of a given fuel by comparing it with that of primary reference fuels composed of varying proportions of two pure hydrocarbons, one very high in knock resistance and the other very low. A highly knock-resistant isooctane (2,2,4-trimethylpentane, C_8H_{18}) is assigned a rating of 100 on the octane scale, and normal heptane (C_7H_{16}), with very poor knock resistance, represents zero on the scale. Octane number is defined as the percentage of isooctane required in a blend with normal heptane to match the knocking behavior of the gasoline being tested. *See* SPARK KNOCK; OCTANE.

For fuels with a rating higher than 100 octane, the rating is usually obtained by determining the amount of tetraethyllead compound that needs to be added to pure isooctane to match the knock resistance of the test fuel. [J.C.L.]

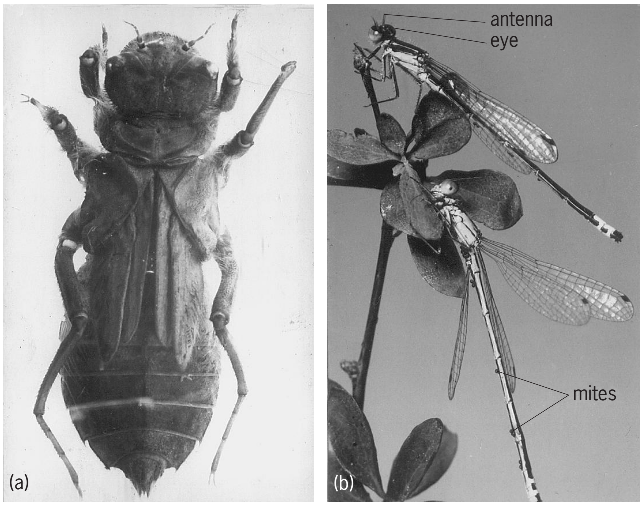
Octopoda An order of the class Cephalopoda (subclass Coleoidea), characterized by eight appendages that encircle the mouth, a saclike body, and an internal shell that is much modified or reduced from that of its ancestors. One or two rows of suckers without chitinous rings occur along the eight highly flexible contractile arms. The approximately 200 species of octopods include shallow-water forms like the common octopus, *Octopus vulgaris*; open-ocean species like the paper argonaut, *Argonauta argo*; and deep-sea forms with fins like the flapjack devilfish, *Opisthoteuthis californica*. Two suborders divide the Octopoda into those with paddle-shaped fins on the body and tendrillike cirri on the arms (Cirrata) and those without fins or cirri (Incirrata). *See* CEPHALOPODA; COLEOIDEA. [C.F.E.R.]

Oculosida An order of Radiolaria. Pores of these protozoans are restricted to certain areas in the central capsule, which may be a single or double membrane in different groups. The order is subdivided on the basis of arrangement of the pores. In the Monopylina (Nassellarina) pores lie at one pole of the single-layered capsule. In the Tripylina (Phaeodorina) the major opening (astropyle) usually contains a perforated plate. A common feature is the presence, near the astropyle, of olive-colored material (possibly it is partially digested food) sometimes known as phaeodium. *See* RADIOLARIA. [R.P.H.]

Odonata An order of the class Insecta known as dragonflies. The Odonata are a relatively small order of insects. There are probably less than 3000 species known throughout the world. The order is divided into the Anisoptera, or true dragonflies, and the Zygoptera, or damselflies (see illustration).

The young inhabit ponds, streams, and marshes; the adults fly over these localities or adjacent land. The adult structure is unique, characterized by a head with large compound eyes and wings with clear or transparent membranes traversed by networks of veins; the male has accessory genital organs possessed by no other insects.

There are three general stages in the life history: the egg, the nymph (illus. *a*), sometimes called naiad, and the adult. Development is usually slow, often requiring 3–5 years. Rarely is there more than one generation a year in the northern range. Adults may live for an extended period in summer. Eggs are laid by insertion into plant stems, either beneath the water or just above the surface. Others are dropped directly into the water and sink to the bottom, where they hatch and the nymphs develop.



Typical Odonata. (*a*) Dragonfly nymph. (*b*) Adult damselflies; note mites attached.

Enemies include birds and fishes, with frogs and insects being of lesser importance. Mites sometimes attach themselves to dragonflies (illus. *b*) but do little harm.

Dragonflies constitute one of the oldest insect orders; they can be traced back through fossil records to the Carboniferous and Permian. Surprisingly few changes have occurred since then, although the order has diversified and specialized to counter competition and to avoid enemies. [P.G.]

Odontognathae One of the two superorders making up the subclass Neornithes, or true birds. It was originally erected to include fossil birds that could fly or that were secondarily flightless but still possessed teeth; it was regarded therefore as an evolutionary step between *Archaeopteryx* and fully evolved modern birds. It is now considered to contain only a simple order, Hesperornithiformes, of which the best-known family is the Hesperornithidae containing several species from the Upper Cretaceous of North America. *See* ARCHAEORNITHES; AVES; HESPERORNITHIFORMES; NEORNITHES. [W.J.B.]

Odontostomatida An order of the Spirotrichia which represents a minor group of small, bizarre-looking protozoan species. The odontostomes are compressed laterally and possess very little ciliature. Even the adoral zone of membranelles is reduced in prominence. These ciliates are found in sewage disposal environs and other fresh- or salt-water habitats which have a very low oxygen content. *See* CILIOPHORA; SPIROTRICHIA. [J.O.C.]

Oedogoniales An order of filamentous fresh-water green algae (Chlorophyceae) with unique morphological features including (1) an elaborate method of cell division that results in the accumulation of apical caps, (2) zoospores and antherozoids with a subapical crown of flagella, and (3) a highly specialized type of oogamy. There is a single family, Oedogoniaceae, comprising three genera. *See* CHLOROPHYCEAE.

Oedogonium has the largest number of species (several hundred) and is the most common of the three genera. Its unbranched filaments are initially attached by a holdfast cell to submerged vegetation, stones, or wood, usually in permanent ponds or pools, but at maturity they may form free-floating masses. The cells are cylindrical, each containing a reticulate chloroplast with numerous pyrenoids.

Vegetative multiplication by fragmentation is common. In asexual reproduction, zoospores with a subapical crown of up to 120 flagella are formed singly within a cell. In sexual reproduction, there is a highly specialized interplay between female and male elements. The egg is a metamorphosed protoplast of an enlarged spherical cell (oogonium). Antherozoids, with a subapical crown of about 30 flagella, are produced in pairs or tetrads in very small discoid antheridia. The two types of sex organs may occur on the same filament (homothallic species), or on different filaments (heterothallic species), but in either case certain species have an indirect development of antherozoids. These species, termed nannandrous in distinction to those with direct development (macrandrous), form short cylindrical cells which initially appear like antheridia, but in which the protoplast metamorphoses into a single swarmer bearing a subapical crown of flagella. [P.C.Si.; R.L.Moe]

Oegophiurida An extinct order of Ophiuroidea comprising four families. Oegophiurids appeared in the Ordovician and became extinct in the latest Carboniferous. They were apparently the first ophiuroids in which the ambulacral ossicles fused to form the typical ophiuroid arm vertebrae. Dorsal and ventral arm plates are lacking, and the ambulacral groove remains as in their somasteroid ancestors. The gastric ceca extend into the arms, and the gonads are located there too, arranged in series. In the more advanced ophiuroids the gonads and stomach are confined to the disk, and the ambulacra are closed by a ventral plate. *See* ASTEROIDEA; ECHINODERMATA; OPHIURIDA; OPHIUROIDEA; PHRYNOPHIURIDA; STENURIDA. [A.C.C.]

Ohmmeter A portable instrument for measuring relatively low values of electrical resistance. The range of resistance measured is typically from 0.1 microhm to 1999 ohms (Ω).

The ohmmeter solves quickly and easily a variety of measurement problems, including measuring the resistance of cladding and tracks on printed circuit boards, electrical connectors, and switch and relay contacts, as well as determining the quality of ground-conductor continuity and bonding, cables, bus-bar joints, and welded connector tags. *See* RESISTANCE MEASUREMENT. [A.D.Sk.]

Ohm's law The direct current flowing in an electrical circuit is directly proportional to the voltage applied to the circuit. The constant of proportionality R, called the electrical resistance, is given by the equation below, in which V is the applied voltage

$$V = RI$$

and I is the current. Numerous deviations from this simple, linear relationship have been discovered. *See* ELECTRICAL RESISTANCE. [C.E.A.]

Oil analysis Analysis of petroleum, or crude oil, to determine its value in modern refinery operations. In addition, procedures have been developed for analysis of lubricating oil.

For refinery operations, oil analysis, or assay, must provide the refinery planner with the data needed to predict yields, qualities, and operating costs for a wide variety of refinery operating conditions and product demands. In a refinery, crude oil is distilled and separated into products according to the boiling points of the crude oil components (see table). *See* PETROLEUM; PETROLEUM PRODUCTS.

Typical products derived from crude oil

Product	Carbon atom range	Boiling point range, °F (°C)
Gas	C_1 and C_2	
Liquefied petroleum gas	C_3 and C_4	
Gasolines	C_4 to C_{10}	59–370 (15–190)
Kerosines	C_9 to C_{15}	300–540 (150–280)
Middle distillates	C_{12} to C_{20}	390–640 (200–340)
Gas oils	C_{20} to C_{45}	640–1040 (340–560)
Bottoms	Unvaporized residua	

A crude assay follows much the same procedure. The oil is distilled and separated into up to 40 narrow-boiling-range cuts. Each cut is then subjected to a variety of tests sufficient to characterize it for the products the cut could be included in. The refinery planners may then calculate yield and qualities of any product by blending the yields and qualities of the cuts that are included in the product.

Petroleum consists primarily of compounds of carbon and hydrogen containing from 1 to about 60 carbon atoms. Carbon atoms in natural petroleum occur in straight and branched chains (paraffins), in single or multiple saturated rings (cycloparaffins or naphthenes), and in cyclic structures of the aromatic type such as benzene, naphthalene, and phenanthrene. Cyclic structures may have attached to them side chains of paraffinic carbons. In lubricating oil it is usual to have naphthene rings built onto the aromatic rings and side chains attached. In products produced by cracking in the refinery, olefins or compounds with carbon-carbon double bonds not in aromatic rings are also found. The high-boiling fractions of petroleum contain increasing amounts of oxygen, nitrogen, and sulfur compounds, as well as traces of organic compounds of metals such as vanadium, nickel, and iron.

Three types of tests are used to characterize a crude oil and its narrow-boiling-range cuts: (1) tests for physical properties such as specific gravity, refractive index, freeze temperature, vapor pressure, octane number, and viscosity; (2) tests for specific chemical species such as sulfur, nitrogen, metals, and total paraffins, naphthenes, and aromatics; (3) tests for determining actual chemical composition. [J.Ree.]

Analysis of used lubricating oils is part of the maintenance program for many types of engines and industrial equipment. To analyze a lubricating oil, a representative sample of the lubricating oil flowing in the system at normal operating temperature is collected in a clear container and labeled with pertinent data. The sample is then delivered to the testing laboratory as soon as possible. Tests applied to used engine oils include viscosity, fuel dilution, water, insolubles, and spectrochemical or spectrographic analysis. Wear-metal concentrations are determined in parts per million (ppm); these metals may include silver, aluminum, chromium, copper, iron, nickel, lead, and tin, in addition to silicon. An increase in any of these concentrations may indicate abnormal engine wear. *See* ENGINE; INTERNAL COMBUSTION ENGINE; SPECTROSCOPY. [D.L.An.]

Oil and gas, offshore For many years, petroleum companies stopped at the water's edge or sought and developed oil and gas accumulations only in inland waters or shallow seas bordering onshore producing areas. Exploration deeper under the sea, and production from the continental shelves beyond territorial limits, did not begin in earnest until the world's increasing demand for petroleum energy sources, coupled with a lessening return from land drilling, provided the incentives for the huge investments needed for drilling in the open sea. *See* CONTINENTAL MARGIN; OIL AND GAS WELL DRILLING; PETROLEUM RESERVES.

Today offshore oil exploration and production is a worldwide industry. By the early 1990s, offshore sources accounted for 30% of worldwide crude oil production and 14% of worldwide natural gas. Until now, most offshore production came from reservoirs located under the continental shelf, in water depths up to 600 ft (180 m). Spurred by technology and a need to find additional secure sources of energy, exploration and production are now moving even farther from shore and into the deeper waters of the continental slopes. Exploration wells have been drilled in water deeper than 9000 ft (2750 m), and hydrocarbons are being produced from offshore fields in waters deeper than 5000 ft (1500 m).

There is a sound geologic basis for the petroleum industry turning to the continental shelves and slopes. Favorable sediments and structures exist beneath the present seas of the world in geologic settings that have proven highly productive onshore. In fact, the subsea geologic similarity, or in some cases superiority, to geologic conditions on land has been a vital factor in the expansion of the world's investment in offshore exploration and production. *See* MARINE GEOLOGY.

Significant exploration is taking place in water depths up to 10,000 ft (3050 m) in the Gulf of Mexico, offshore Brazil, offshore West Africa, and in the northern Atlantic off the coasts of Norway, Ireland, and the United Kingdom. Oil and natural gas fields in waters as deep as 5500 ft (1675 m) are already on-stream in the Gulf of Mexico and offshore Brazil. In the North Atlantic west of the Shetland Islands, where weather conditions are particularly severe, production has started from reservoirs in water depths up to 1500 ft (450 m). *See* PETROLEUM GEOLOGY.

The underwater search has been made possible only by vast improvements in offshore technology. Drillers first took to sea with land rigs mounted on barges towed to location and anchored, or with fixed platforms accompanied by a tender ship. As the search for oil and natural gas advanced worldwide and farther away from shore, types of exploration rigs evolved which could move easily between locations and operate in a wide range of water depths.

The move into the open and often hostile sea has required not only the development of drilling vessels but also a host of auxiliary equipment and techniques. An entire industrial complex has developed to serve the offshore industry, including construction of fixed platform structures from which the majority of the world's offshore oil and gas production is presently drilled and produced.

The United States Gulf coast, where a large percentage of the world's offshore drilling has taken place, is regularly hit by hurricanes that damage structures in their path, and a number of platforms were lost early on due to high wind and waves. However, improved understanding of the environment, as well as more advanced materials and structural analysis techniques, has significantly reduced failures due to environmental forces. The major causes of accident are now due to human error, process hazards, and transportation to and from offshore facilities by helicopter. *See* HURRICANE.

Improved reservoir management and further discoveries have increased production from onshore fields, where costs are less than for offshore. However, the world's increasing demand for petroleum energy continues to force the search for new reserves into even deeper waters and more remote corners of the world. [G.R.S.; J.A.T.; C.Ar.]

Oil and gas field exploitation In the petroleum industry, a field is an area underlain without substantial interruption by one or more reservoirs of commercially valuable oil or gas, or both. A single reservoir (or group of reservoirs which cannot be separately produced) is a pool. Several pools separated from one another by barren, impermeable rock may be superimposed one above another within the same field. Pools have variable areal extent. Any sufficiently deep well located within the field should produce from one or more pools. However, each well cannot produce from every pool, because different pools have different areal limits.

Development of a field includes the location, drilling, completion, and equipment of wells necessary to produce the commercially recoverable oil and gas in the field.

General considerations. Oil and gas production necessarily are intimately related, since approximately one-third of the gross gas production in the United States is produced from wells that are classified as oil wells. However, the naturally occurring hydrocarbons of petroleum are not only liquid and gaseous but may even be found in a solid state, such as asphaltite and some asphalts.

Where gas is produced without oil, the production problems are simplified because the product flows naturally throughout the life of the well and does not have to be lifted to the surface. However, there are sometimes problems of water accumulations in gas wells, and it is necessary to pump the water from the wells to maintain maximum, or economical, gas production. The line of demarcation between oil wells and gas wells is not definitely established. Most gas wells produce quantities of condensable vapors, such as propane and butane, that may be liquefied and marketed for fuel, and the more stable liquids produced with gas can be utilized as natural gasoline.

Production methods in producing wells. The common methods of producing oil wells are (1) natural flow; (2) pumping with sucker rods; (3) gas lift; (4) hydraulic subsurface pumps; (5) electrically driven centrifugal well pumps; and (6) swabbing.

However, most wells are not self-flowing and various lifting methods must be employed. Approximately 90% of the wells made to produce by some artificial lift method in the United States are equipped with sucker-rod–type pumps. In these the pump is installed at the lower end of the tubing string and is actuated by a string of sucker rods extending from the surface to the subsurface pump. The two common variations are mechanical and hydraulic long-stroke pumping. Other lifting mechanisms are the gas lift, hydraulic subsurface pumps, swabs, bailers, jet pumps, and sonic pumps. *See* OIL AND GAS WELL COMPLETION.

Production instruments. The commoner and more important instruments required in petroleum production operations are the following:

1. Gas meters, which are generally of the orifice type, are designed to record the differential pressure across the orifice, and the static pressure.
2. Recording subsurface pressure gages small enough to run down 2-in. (3-cm) ID (inside diameter) tubing are used extensively for measuring pressure gradients down the tubing of flowing wells, recording pressure buildup when the well is closed in, and measuring equilibrium bottom-hole pressures.
3. Subsurface samplers designed to sample well fluids at various levels in the tubing are used to determine physical properties.
4. Oil meters of various types are utilized to meter crude oil flowing to or from storage.
5. Dynamometers are used to measure polished-rod loads.
6. Liquid-level gages and controllers are used. They are similar to those used in other industries, but with special designs for closed lease tanks. [R.L.Ch.]

Oil and gas storage

Oil and gas storage Storage, usually in great quantities, of crude oil and natural gas after production from natural reservoirs. Large amounts of refined products are stored as well. Storage is necessary to meet seasonal and other fluctuations in demand; for efficient operation of producing equipment, pipelines, tankers, and refineries; and for emergency use.

Crude oil and refined products. Oil from producing wells is first collected in welded-steel, bolted-steel, or wooden tanks of 100 bbl (16 m^3) or greater capacity. These tanks, upright cylinders with low-pitched conical roofs, provide temporary storage while the oil is awaiting shipment. Several tanks grouped together are a tank battery. Assemblages of large steel tanks, known as tank farms, are used for more permanent storage at pipeline pump stations, points where tankers load and unload, and refineries.

For offshore producing fields a number of unique storage systems have been designed. In several instances old tankers have been adapted for storage, and barges have been constructed especially for offshore storage use.

To minimize vaporization losses, lease tanks are sometimes equipped to hold several ounces pressure. At large-capacity storage sites, special tanks are generally used. Tanks with lifter or floating roofs are used to store crude oil, motor gasoline, and less volatile natural gasoline. Motor and natural gasolines are also stored in spheroid containers. Spherical containers are used for more volatile liquids, such as butane. Horizontal cylindrical containers are used for propane and butane storage. Refrigerated insulated tank systems enabling propane to be stored at a lower pressure are also in use.

Large quantities of volatile liquid-petroleum products, including propane and butane, are stored in underground caverns dissolved in salt formations and in mined caverns, gas reservoirs, and water sands. Refrigerated propane is also being stored in excavations in frozen earth and in underground concrete tanks.

Natural gas. Natural gas is stored in low-pressure surface holders, buried high-pressure pipe batteries and bottles, depleted or partially depleted oil and gas reservoirs, water sands, and several types of containers at extremely low temperature (−258°F or −161°C) after liquefaction. Low-pressure holders, which store relatively small volumes of gas, basically use either a water or a dry seal, and variations of each type exist.

In the United States gas pipeline and utility companies store large quantities of natural gas in underground reservoirs. In most cases these reservoirs are located near market areas. Underground storage permits greatly increased pipeline utilization, resulting in lower transportation costs and reduced gas cost to the consumer. Underground storage is the only economical method of storing large enough quantities of gas to meet the seasonal fluctuations in pipeline loads.

In operating storage reservoirs only a portion of the stored gas, called working gas, is normally withdrawn. The remaining gas, called cushion gas, stays in the reservoir to provide the necessary pressure to produce the storage wells at desired rates. In aquifer storages some water returns to help maintain the reservoir pressure. In aquifer storages the original hydrostatic pressure must be exceeded in order to push the water back.

Storage of liquefied natural gas throughout the world is in connection with shipment of liquefied natural gas by tanker, and is located at the loading and unloading ends of the tanker runs as well as at peak sharing facilities operated by gas pipeline and local utility companies. Storage is in insulated metal tanks, buried concrete tanks, or frozen earth excavations. In two projects using frozen earth excavations, excessive boil-off of the liquefied gas led to replacement with insulated metal tanks. *See* LIQUEFIED NATURAL GAS (LNG); OIL AND GAS FIELD EXPLOITATION; PETROLEUM; PIPELINE. [P.G.Bu.]

Oil and gas well completion

Oil and gas well completion The operations that prepare a well bore for producing oil or gas from the reservoir. The goal of these operations is to optimize the flow of the reservoir fluids into the well bore, up through the producing string, and into the surface collection system. *See* OIL AND GAS FIELD EXPLOITATION; OIL AND GAS WELL DRILLING.

The well bore is lined (cased) with steel pipe, and the annulus between well bore and casing is filled with cement. Properly designed and cemented casing prevents collapse of the well bore and protects fresh-water aquifers above the oil and gas reservoirs from becoming contaminated with oil and gas and the oil reservoir brine. Similarly, the oil and gas reservoir is prevented from becoming invaded by extraneous water from aquifers that were penetrated above or below the productive reservoir. *See* AQUIFER.

The nature of the reservoir, evaluated from a core analysis, cuttings, or logs, or from experience with like productive formations, determines the type of completion to be used. In a barefoot completion, the casing is set just above the producing formation, and the latter is drilled out and produced with no pipe set across it. Such a completion can be used for hard rock formations which are not friable and will not slough, and when there are no opportunities for producing from another, lower reservoir. Set-through and perforated completions are also employed for relatively well-consolidated formations from which the potential for sand production is small. However, the perforated completion is used when a long producing interval must be prevented from collapse, when multiple intervals are to be completed in the one borehole, or when intervening water sands within the oil-producing interval are to be shut off and the oil-saturated intervals selectively perforated. *See* WELL LOGGING.

A string of steel tubing is lowered into the casing string and serves as the conduit for the produced fluids. The tubing may be hung from the well-head or supported by a packer set above the producing zone. The packer is used when it is desirable to isolate the casing string from the produced fluids because of the latter's pressure, temperature, or corrosivity, or when such isolation may improve production characteristics.

The tops of wells from which fluids flow as a result of the indigenous reservoir energy are equipped with a manifold known as the Christmas tree. However, only some reservoirs have sufficient pressure and sufficient gas in solution (which is released at the lower pressure existing in the well bore and therefore lowers the effective density of the fluid in the tubing) to permit natural flow to the surface. The reservoir fluids from other reservoirs and, after pressure depletion, even from those which initially flowed must be brought to the surface by one of several methods of artificial lift.

Excessive water production increases the cost of oil production since energy must be expended in lifting the water to the surface. Water production may also jeopardize the production of oil and gas by saturating the oil-productive interval with water. Such damage is more likely to occur in low-pressure formations or formations which contain water-sensitive clays that swell in an excess of water. Water exclusion may be effected by the application of cements of various types. If it is determined that water is entering from the lower portion of a producing sand in a relatively shallow, low-pressure well, a cement plug may be placed in the bottom of the hole so that it will cover the oil-water interface of the reservoir. This technique is called laying in a plug and may be accomplished by placing the cement with a dump-bottom bailer on a wire line or by pumping cement down the drill pipe or tubing. For deeper, higher-pressure, or more troublesome wells, a squeeze method is used. Squeeze cementing is the process of applying hydraulic pressure to force a cement into an exposed formation or through openings in the casing or liner. It is also used for repairing casing leaks.

Production may be impaired from a well bore as a result of drilling-mud invasion or of accumulation of clays and fine silts carried by the producing fluids to the borehole, or the lithology of the formation itself may have a naturally low permeability to reservoir fluids. Since the permeability to fluids of the formation within the first few feet of the well bore has an exponential effect on limiting the influx of fluid, the productivity of a well can frequently be increased manyfold by increasing the permeability of this element of the reservoir or removing the skin just at the face of the producing interval. This is accomplished by acidization and fracturing, and in some instances by the use of surfactants, solvents, and explosives. [T.M.D.; R.E.Wy.]

Oil and gas well drilling The drilling of holes for exploration and extraction of crude oil and natural gas. Deep holes and high pressures are characteristics of petroleum drilling not commonly associated with other types of drilling. In general, it becomes more difficult to control the direction of the drilled hole as the depth increases, and additionally, the cost per foot of hole drilled increases rapidly with the depth of the hole. Drilling-fluid pressure must be sufficiently high to prevent blowouts but not high enough to cause fracturing of the borehole. Formation-fluid pressures are commonly controlled by the use of a high-density clay-water slurry, called drilling mud. The chemicals used in drilling mud can be expensive, but the primary disadvantage in the use of drilling muds is the relatively low drilling rate which normally accompanies high bottom-hole pressure. Drilling rates can often be increased by using water to circulate the cuttings from the hole; when feasible, the use of gas as a drilling fluid can lead to drilling rates as much as 10 times those attained with mud. Drilling research has the objectives of improving the utilization of current drilling technology and the development of improved drilling techniques and tools.

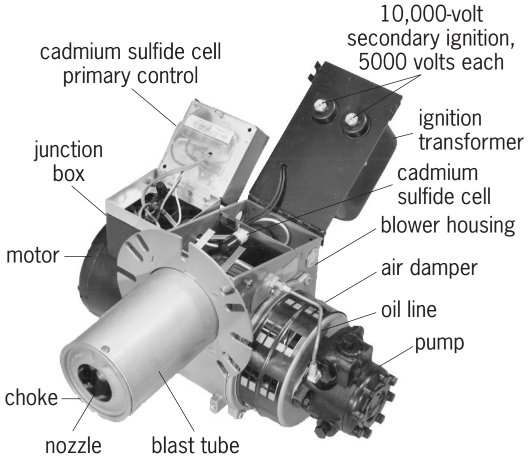
The hole direction must be controlled within permissible limits in order to reach a desired target at depths as great as 25,000 ft (7600 m). Inclined layers of rocks with different hardnesses tend to cause the direction of drilling to deviate; consequently, deep holes are rarely truly straight and vertical. The drilling rate generally increases as additional drill-collar weight is applied to the bit by adjusting the pipe tension at the surface. However, crooked-hole tendency also increases with higher weight-on-bit. A so-called packed-hole technique has been used to reduce the tendency to hole deviation. One version of this technique makes use of square drill collars that nearly fill the hole on the diagonals but permit fluid and cuttings to circulate around the sides. This procedure reduces the rate at which the hole direction can change.

In mountainous terrain, it is difficult to construct well locations over each subsurface drilling target, and from offshore drilling platforms it is necessary to drill many wells from a single surface location. For these situations, technology has been developed that permits wells to be drilled directionally from the single surface location to the desired subsurface point.

Advances in technology and the need to accomplish special objectives have led to drilling horizontal wells in deep oil or gas reservoirs. The angle of the well is successively built up in order to reach the ultimate horizontal course of the well. The program for drilling the well is developed before hand, based on the technology for actually increasing the angle and then continuing the drilling at the desired angle.

Novel drilling methods include studies of rock failure by mechanical, thermal, hydraulic, fusion and vaporization, and chemical means. Jet piercing is widely used for drilling very hard, spallable rocks, such as taconite. Other methods include the use of electric arc, laser, plasma, spark, and ultrasonic drills. *See* Oil and gas well completion; Petroleum geology; Rock mechanics; Turbodrill; Well logging. [T.M.D.]

Oil burner A device for converting fuel oil from a liquid state into a combustible mixture. A number of different types of oil burners are in use for domestic heating. These include sleeve burners, natural-draft pot burners, forced-draft pot burners, rotary wall flame burners, and air-atomizing and pressure-atomizing gun burners. The most common and modern type that handles 80% of the burners used to heat United States homes is the pressure-atomizing-gun-type burner shown in the illustration.



An oil burner of the pressure-atomizing type. (*Automatic Burner Corp.*)

The sleeve burner, commonly known as a range burner because of its use in kitchen ranges, is the simplest form of vaporizing burner. The natural-draft pot burner relies on the draft developed by the chimney to support combustion. A modification of this burner is the forced-draft pot burner which supplies its own air for combustion and does not rely totally on the chimney. The rotary wall flame burners have mechanically assisted vaporization. The gun-type burner uses a nozzle to atomize the fuel so that it becomes a vapor, and burns easily when mixed with air.

The oil burner is used for a wide assortment of heating, air conditioning, and processing applications. Oil burners heat commercial buildings such as hospitals, schools, and factories. Air conditioners using the absorption refrigeration system have been developed and fired with oil burners. Oil burners are used to produce CO_2 in greenhouses to accelerate plant growth. They also produce hot water for many commercial and industrial applications. *See* Air cooling; Comfort heating; Hot-water heating system. [R.A.K.]

Oil field waters Waters of varying mineral content which are found associated with petroleum and natural gas or have been encountered in the search for oil and gas. They are also called oil field brines, or brines. They include a variety of underground waters, usually deeply buried, and have a relatively high content of dissolved mineral matter. These waters may be (1) present in the pore space of the reservoir rock with the oil or gas, (2) separated by gravity from the oil or gas and thus lying below it, (3) at the edge of the oil or gas accumulation, or (4) in rock formations which are barren of oil and gas. Brines are commonly defined as water containing high concentrations of dissolved salts. Potable or fresh waters usually are not considered oil field waters but may be encountered, generally at shallow depths, in areas where oil and gas are produced.

Probably the most important geological use of oil field water analyses is their application to the quantitative interpretation of electrical and neutron well logs, particularly micrologs. *See* PETROLEUM GEOLOGY; WELL LOGGING. [P.McG.]

Oil furnace A combustion chamber in which oil is the heat-producing fuel. Fuel oils, having from 18,000 to 20,000 Btu/lb (42–47 megajoules/kg), which is equivalent to 140,000 to 155,000 Btu/gal (39–43 megajoules/liter), are supplied commercially. The lower flash-point grades are used primarily in domestic and other furnaces without preheating. Grades having higher flash points are fired in burners equipped with preheaters. *See* FUEL OIL.

Domestic oil furnaces with automatic thermostat control usually operate intermittently, being either off or operating at maximum capacity. *See* OIL BURNER. [F.H.R.]

Oil sand A loose to consolidated sandstone or a porous carbonate rock, impregnated with a heavy asphaltic crude oil, too viscous to be produced by conventional methods; also known as tar sand or bituminous sand.

Oil sands are distributed throughout the world but the largest proven accumulation occurs in Alberta, Canada (the Athabasca deposit). A large accumulation appears to be present in the Orinoco Basin in Venezuela, and far smaller deposits occur in Russia, the United States, Madagascar, Albania, Trinidad, and Romania. [G.R.G.]

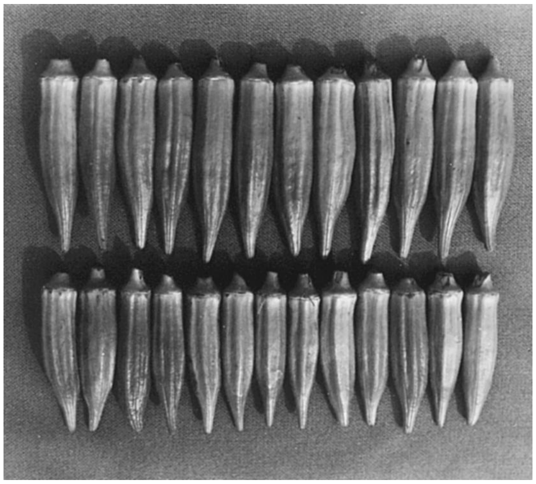
Oil shale A sedimentary rock containing solid, combustible organic matter in a mineral matrix. The organic matter, often called kerogen, is largely insoluble in petroleum solvents, but decomposes to yield oil when heated. Although "oil shale" is used as a lithologic term, it is actually an economic term referring to the rock's ability to yield oil; oil shale appears to be the cheapest source after natural petroleum for large amounts of liquid fuels. No real minimum oil yield or content of organic matter can be established to distinguish oil shale from sedimentary rocks. Additional names given to oil shales include black shale, bituminous shale, carbonaceous shale, coaly shale, cannel shale, cannel coal, lignitic shale, torbanite, tasmanite, gas shale, organic shale, kerosine shale, coorongite, maharahu, kukersite, kerogen shale, algal shale, and "the rock that burns." *See* KEROGEN.

The world's oil shale deposits represent a tremendous store of fossil energy. It has been estimated that the organic matter in sedimentary rocks contains 1.2×10^{16} tons (1.1×10^{16} metric tons) of organic carbon, nearly 1000 times that found in coals. Although part of that organic carbon has matured to produce oil and gas, most of it is still oil shale. Unfortunately, most of this tremendous resource is not well known. Oil shales occur on every continent in sediments ranging in age from Cambrian to Tertiary. Estimates for the total oil resource in shales of all grades reached 1.75×10^{15} barrels. Just 1% of that total shale oil represents more oil than the world is expected to produce as natural petroleum (2×10^{12} bbl). Oil shale represents a tremendous supply of liquid fuels.

Although the oil potential of the world's oil shales is great, commercial production of this oil has been considered uneconomic. Oil shales are lean ores, producing only limited amounts of oil which historically has been low in price. Mining and heating 1 ton of relatively rich oil shale yielding 25 gal/ton produces only 0.6 bbl of oil.

Shale oil is produced from the organic matter in oil shale when the rock is heated in the absence of oxygen (destructive distillation). This heating process is called retorting, and the equipment that is used to do the heating is known as a retort. The rate at which the oil is produced depends upon the temperature at which the shale is retorted. Most references report retorting temperatures as being about 500°C (930°F). [J.W.S.; H.B.J.]

Okra A warm-season annual, *Hibiscus esculentus*, of Ethiopian origin. Okra, also called gumbo, is grown for its immature pods (see illustration), which are generally used for preparing soups but are also eaten as a freshly cooked vegetable. It is a member of the order Malvales and is related to cotton. Georgia, Florida, and Louisiana are important producing states. *See* MALVALES. [H.J.C.]



Okra pods. (*Asgrow Seed Co., subsidiary of The Upjohn Co.*)

Olbers' paradox The riddle of cosmic darkness. The obvious explanation for the darkness of the night sky, that the Sun is on the other side of the Earth, does not account for the fact that, in space far from any star, the universe is full of darkness and not of light.

In a boundless universe of stars, with no interstellar absorption, every line of sight from the eye must eventually intercept the surface of a star. If most stars are similar to the Sun, the sky at every point should shine as bright as the Sun's disk. The sky (or celestial sphere) is 180,000 times larger than the Sun's disk, and the starlight incident on the Earth should therefore be 180,000 times more intense than sunlight, which obviously is not the case. Hermann Bondi resurrected the riddle of cosmic darkness in 1952 and attributed it to the nineteenth-century astronomer Wilhelm Olbers, although, as is now known, it had previously been discussed by Edmund Halley and other astronomers.

Edgar Allan Poe suggested in 1848 that the universe is not old enough for the light from very distant stars to have reached the Earth; this was investigated by Lord Kelvin in 1901. Modern calculations confirm Kelvin's results: light travels at approximately 186,000 mi/s (300,000 km/s) and, in a static universe $10–20 \times 10^9$ years old, stars cannot shine long enough for their light to reach the Earth from regions sufficiently distant for the visible stars to cover the entire sky. This means that stars cannot shine long enough to fill the universe with radiation in equilibrium with their surfaces. Clearly, if the sky at night is dark in a static universe of finite age, then in an expanding universe of similar age the night sky is even darker because of the redshift. *See* BIG BANG THEORY; COSMOLOGY; UNIVERSE. [E.H.]

Olfaction One of the chemical senses, specifically the sense of smell. Olfaction registers chemical information in organisms ranging from insects to humans, including marine organisms. For terrestrial animals, its stimuli comprise airborne molecules. The typical stimulus is an organic chemical with molecular weight below 300 daltons. A few inorganic chemicals can also stimulate olfaction, notably hydrogen sulfide, ozone, ammonia, and the halogens.

The anatomy of olfactory structures and the neurophysiology of olfaction differ significantly among different animal groups. For examples, insect olfactory receptors exist within sensory hairs on the antennae. The olfactory organ of fishes resides typically in tubular chambers on either side of the mouth. In terrestrial vertebrates, the olfactory receptors reside within a sac or cavity more or less similar to the human nasal cavity. The olfactory mucosa patch in the cavity characteristically contains millions of receptor cells, though in some olfactory-dominated mammals, such as the dog and rabbit, it contains tens of millions. The location of the olfactory mucosa relative to air currents in the cavity plays some role in the ongoing olfactory vigilance of the organism. In the human the mucosa sits out of the main airstream. During quiet breathing eddy currents may carry just enough stimulus to evoke a sensation, whereupon sniffing will occur. Sniffing amplifies the amount of stimulus reaching the receptors by as much as tenfold.

Reception of the chemical stimulus and transduction into a neural signal apparently occur on the olfactory receptor cilia. The ciliary membrane contains receptor protein molecules that interact with stimulating molecules through reversible binding. Vertebrate receptor cells show broad tuning, that is, they respond to many odorants.

Adjacent points in the mucosa generally project to adjacent points in the olfactory bulb of the brain (see illustration). The synapses between the incoming olfactory nerve fibers and the second-order cells, mitral cells, occur in basketlike structures called glomeruli. On average, a glomerulus receives about 1000 receptor cell fibers for each mitral cell. The location of cells within the bulb seems to play a role in encoding odor quality: each odorant stimulates a more or less unique spatial array.

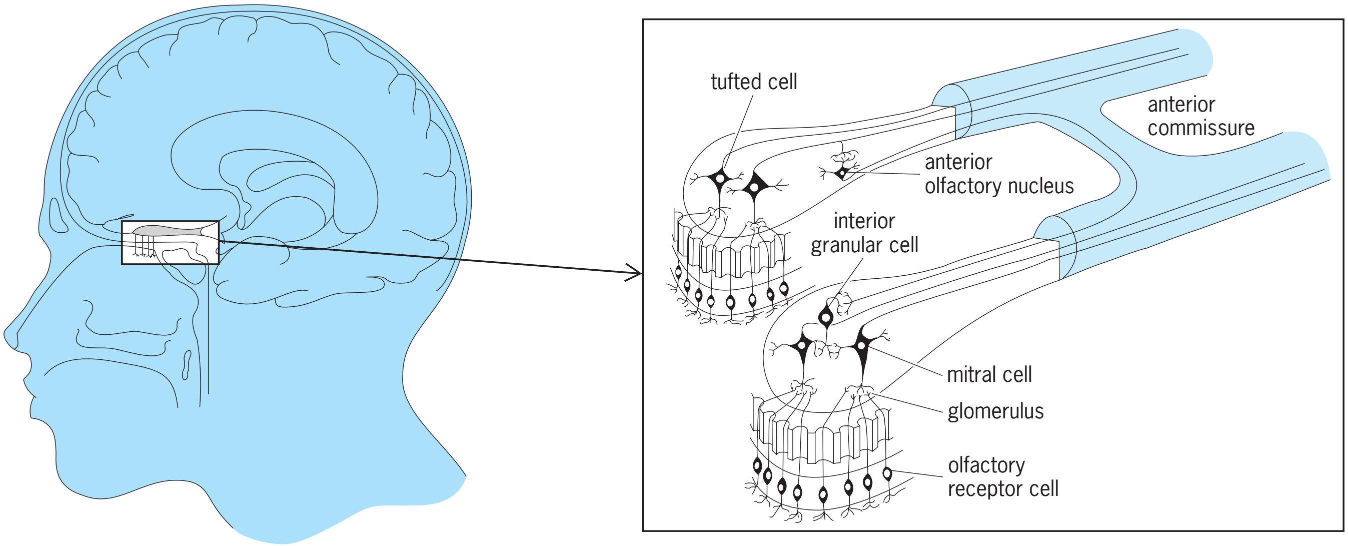
The central neural pathways of the olfactory system have a complexity unmatched among the sensory systems. One pathway carries information to the pyriform cortex (paleocortex of the temporal lobe), to a sensory relay in the thalamus (dorsomedial nucleus), and to the frontal cortex (orbitofrontal region). This pathway seems rather strictly sensory. Another pathway carries information to the pyriform cortex, the hypothalamus, and other structures of the limbic system. The latter have much to do with the control of emotions, feeding, and sex. The strong affective and motivational consequences of olfactory stimulation seem compatible with projections to the limbic system and with the role of olfaction in certain types of physiological regulation. In many vertebrate species, reception of pheromones occurs via an important accessory olfactory organ, known as the vomeronasal organ, which characteristically resides in the hard palate of the mouth or floor of the nasal cavity. *See* PHEROMONE.

Human olfactory sensitivity varies from odorant to odorant over several orders of magnitude. A common range of thresholds for materials used in fragrances and flavors is 1 to 100 parts per 10^9 parts of air. Thresholds gathered from various groups of human subjects permit certain generalities about how the state of the organism affects olfaction. For instance, persons aged 70 and above are about tenfold less sensitive than young adults. Males and females have about equal sensitivity, except perhaps in old age, where females are more sensitive. Persons with certain medical disorders, such as multiple sclerosis, Parkinson's disease, paranasal sinus disease, Kallmann's syndrome, and olfactory tumors, exhibit decreased sensitivity (hyposmia) or complete absence of sensitivity (anosmia).

Above its threshold, the perceived magnitude of an odor changes by relatively small amounts as concentration increases. A tenfold increment in concentration will cause, on average, about a twofold change in perceived magnitude. The perceived magnitude of an odor is often greatly influenced by olfactory adaptation, a process whereby during continuous short-term exposure to a stimulus its perceived magnitude falls to about one-third of its initial value.

The stimuli for olfaction are commonly complex, that is, they are mixtures. Such products as coffee, wine, cigarettes, and perfumes contain at least hundreds of odor-relevant constituents. Only rarely does the distinctive quality of a natural product, such as a vegetable, arise from only a single constituent. A chemical analysis of most products will not usually allow a simple prediction of odor intensity or quality. One general rule, however, is that the perceived intensity of the mixture falls well below the sum of the intensities of the unmixed components.

General notions about the properties that endow a molecule with its quality have spawned more than two dozen theories of olfaction, including various chemical and vibrational theories.



Location of the olfactory bulbs at the interior surface of the human brain and their connections via the anterior commissure. (*After D. Ottoson, Physiology of the Nervous System, Oxford University Press, 1983*)

Most modern theories hold that the key to quality lies in the size and shape of molecules, with some influence of chemical functionality. For molecules below about 100 daltons, functional group has obvious importance: for example, thiols smell skunky, esters fruity, amines fishy-uriny, and carboxylic acids rancid. For larger molecules, the size and shape of the molecule seem more important. Shape detection is subtle enough to enable easy discrimination of some optical isomers. Progressive changes in molecular architecture along one or another dimension often lead to large changes in odor quality. No current theory makes testable predictions about such changes. *See* CHEMICAL SENSES; CHEMORECEPTION. [W.Ca.]

Oligocene The third oldest of the seven geological epochs of the Cenozoic Era. It corresponds to an interval of geological time (and rocks deposited during that time) from the close of the Eocene Epoch to the beginning of the Miocene Epoch. The most recent geological time scales assign an age of 34 to 24 million years before present (m.y. B.P.) to the Oligocene Epoch. *See* CENOZOIC; EOCENE; MIOCENE.

An important event that characterizes the Oligocene Epoch was the development of extensive glaciation on the continent of Antarctica. Prior to that time, the world was largely ice-free through much of the Mesozoic and early Tertiary. A significant amount of ice is now known to have existed on the Antarctic continent since at least the beginning of the Oligocene, when the Earth was ushered into its most recent phase of ice-house conditions. This in turn created revolutions in the global climatic and hydrographic systems, with important repercussions for the marine and terrestrial biota. The changes include steepened latitudinal and vertical thermal gradients affecting major fluctuations in global climates, and the shift in the route of global dispersal of marine biota from an ancestral equatorial Tethys seaway, which had become severely restricted by Oligocene time, to the newly initiated circum-Antarctic circulation. *See* GLACIAL EPOCH.

Worldwide, the epoch represents an overall regressive sequence when there was a drawdown of global sea level, with relatively deeper, marine facies in the Early Oligocene and shallower-water to nonmarine facies in the late Oligocene. *See* FACIES (GEOLOGY).

Due to accentuated thermal gradients and seasonality in the Oligocene, marine biotic provinces became more fragmented. Extreme climates, with greater diurnal and seasonal temperature contrasts, are held responsible for reduced diversities in marine plankton. The Oligocene was characterized by transitional faunal features between the Paleogene and the Neogene.

Rhinocerids, tapirs, and wild boarlike hog species with strong incisors and large canines appeared. *Hyaenodon* was an Oligocene carnivore with strong canines and sharp molars, much like those of the modern cat species. The horses that had first appeared in the Eocene continued to increase in size and became three-toed, typified by *Mesohippus*. Elephants made their first appearance near the Eocene-Oligocene boundary and developed a short trunk and two pairs of tusks. An early simian, *Propliopithecus*, made its first appearance in Oligocene, and is considered ancestral to the modern family of gibbons. The general uniformity of mammalian fauna in the Oligocene suggests that the widespread regressions of the sea most likely resulted in land bridges that reconnected some of the Northern Hemispheric landmasses, which may have led to transmigrations of some families of mammals between North America, Asia, and Africa. Birds had achieved some of their modern characteristics, and at least 10 modern genera had already made their appearance by the close of Oligocene time. *See* AVES; GEOLOGIC TIME SCALE; MAMMALIA; PALEOECOLOGY; PERISSODACTYLA. [B.U.H.]

Oligochaeta A class of the phylum Annelida including worms such as the earthworms. There are 21 families with over 3000 species. These animals exhibit both external and internal segmentation. They usually possess setae which are not borne on parapodia. Oligochaetes are hermaphroditic. The gonads are few in number and situated in the anterior part of the body, the male gonads being anterior to the female gonads. The gametes are discharged through special ducts, the oviducts and sperm ducts. A clitellum is present at maturity. There is no larval stage during development.

The oligochaetes are primarily fresh-water and burrowing terrestrial animals. A few are marine and several species occur in the intertidal zone.

Oligochaetes are cylindrical, elongated animals with the anterior mouth usually overhung by a fleshy lobe, the prostomium, and the anus terminal. The body plan is that of a tube within a tube. Externally, the segments are marked by furrows. The setae or bristles are borne on most segments. Other external features are the pores of the reproductive systems opening on certain segments, the openings of the nephridia, and in many earthworms dorsal pores which open externally from the coelom. Some aquatic species have extensions of the posterior part of the body which function as gills.

The oligochaetes have been used in studies of physiology, regeneration, and metabolic gradients. Some aquatic forms are important in studies of stream pollution as indicators of organic contamination. Earthworms are important in turning over the soil and reducing vegetable material into humus. It is likely that fertile soil furnishes a suitable habitat for earthworms, rather than being a result of their activity. *See* ANNELIDA. [P.C.H.]

Oligoclase A plagioclase feldspar with composition in the range $Ab_{90}An_{10}$ to $Ab_{70}An_{30}$, where Ab represents the composition of albite, $NaAlSi_3O_8$, and An represents the composition of anorthite, $CaAl_2Si_2O_8$. The diagnostic properties are hardness on Mohs scale, 6–6.5; density, 2.65 g/cm^3; and color usually white or colorless, transparent to translucent. The presence of minute, mutually parallel inclusions of hematite (Fe_2O_3) causes a golden play of color in the variety of oligoclase called aventurine or sunstone. Oligoclase is triclinic. The mineral is common in igneous rocks and metamorphic rocks. *See* ALBITE; ANORTHITE; FELDSPAR; HARDNESS SCALE; IGNEOUS ROCKS; METAMORPHIC ROCKS. [D.T.G.]

Oligonucleotide A deoxyribonucleic acid (DNA) or ribonucleic acid (RNA) sequence composed of two or more covalently linked nucleotides. Oligonucleotides are classified as deoxyribooligonucleotides or ribooligonucleotides. Fragments containing up to 50 nucleotides are generally termed oligonucleotides, and longer fragments are called polynucleotides. *See* DEOXYRIBONUCLEIC ACID (DNA); RIBONUCLEIC ACID (RNA).

A deoxyribooligonucleotide consists of a 5-carbon sugar called deoxyribose joined covalently to phosphate at the 5′ and 3′ carbons of this sugar to form an alternating, unbranched polymer. A ribooligonucleotide consists of a similar repeating structure where the 5-carbon sugar is ribose. Chemically synthesized oligonucleotides of predetermined sequence have proven to be very useful for studying a large number of biochemical processes. In the 1960s, these compounds were used to decipher the genetic code. Later, chemically prepared deoxyoligonucleotides were joined to form genes for transfer RNAs. Gene synthesis from synthetic deoxyoligonucleotides is now routinely used to prepare genes and modified genes for proteins having potential clinical applications. Oligonucleotides have also been used to diagnose genetic disorders and bacterial or viral infections. *See* GENE; GENETIC CODE; GENETIC ENGINEERING; NUCLEIC ACID. [M.H.C.]

Oligopygoida An order of irregular echinoids in the superorder Neognathostomata resembling clypeasteroids but lacking the accessory ambulacral pores characteristic of that group. Oligopygoids have well-developed petals, and there are characteristic small demiplates present below the petals. The apical disk is monobasal and the mouth oval and usually deeply sunken. Oligopygoids have a lantern, which closely resembles that of clypeasteroids, and their lantern muscle-attachment structures are a mixture of ambulacral and interambulacral processes.

There are two genera, *Oligopygus* and *Haimea*, containing about 25 species, all from the middle and upper Eocene of the Caribbean and Gulf of Mexico regions. They were probably infaunal deposit feeders like present-day laganiids. *See* ECHINODERMATA; NEOGNATHOSTOMATA. [A.B.S.]

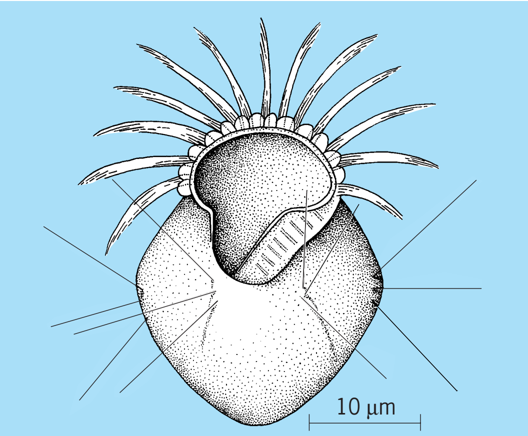
Oligosaccharide A carbohydrate molecule composed of 3–20 monosaccharides (simple sugars). Generally, free oligosaccharides do not constitute a significant proportion of naturally occurring carbohydrates. Most carbohydrates that occur in nature are in the form of monosaccharides (such as blood sugar, or glucose), disaccharides (such as table sugar, or sucrose, and milk sugar, or lactose), and polysaccharides (such as starch and glycogen, polyglucose molecules, or chitin). *See* GLUCOSE; LACTOSE; MONOSACCHARIDE; POLYSACCHARIDE.

The monosaccharides of multiple sugar units such as oligosaccharides are connected with each other through bonds called glycosidic linkages. They are linked primarily to other sugars and to other molecules through aldehyde or ketone reducing groups.

Most naturally occurring oligosaccharides are linked either to proteins (glycoproteins) or to lipids (glycolipids). Glycoconjugates are present in essentially all life forms and particularly in cell membranes and cell secretions. Many hormones are glycoproteins, and an increasing number of enzymes have been shown to have sugars attached. Antigenic properties of the human red blood cell ABO blood group system are determined by glycolipid oligosaccharides. In fact, all the major protein components of blood serum, with the exception of serum albumin, are glycoproteins. *See* BLOOD GROUPS; CELL MEMBRANES; GLYCOLIPID; GLYCOPROTEIN.

Many changes in the structures of oligosaccharides of glycoconjugates have been detected in cancer cells. Changes or differences in oligosaccharide structures are generally the result of differences in biosynthetic pathways or of degradative pathways. An understanding of glycoconjugates in normal biological systems and in certain disease states is currently of great importance. [D.M.Ca.]

Oligotrichida A minor order of the Spirotrichia. If somatic ciliature is present, it is sparse. The bodies are round in cross section, and the adoral zone of membranelles is often highly developed at the anterior, or oral, end of the organism. Species are found in fresh- and salt-water habitats, and none occurs as a parasite. *Halteria* (see illustration) has long bristles which are used in a kind of jumping movement. *See* SPIROTRICHIA. [J.O.C.]



***Halteria*, an example of an oligotrichid.**

Olive Olive fruits, which are produced by a small to medium-sized evergreen tree (*Olea europaea*), can be eaten, after processing, as table olives, or can be extracted for oil that is used on salads, for cooking, for body lotions, or for medicinal purposes. The olive tree is a historically ancient cultivated plant, having been domesticated by early civilizations in the eastern Mediterranean regions. Olive culture later spread to all the Mediterranean countries and subsequently to South America, California, South Africa, and Australia.

Olive fruits are harvested for table olives in the autumn, when the fruits change from green to straw or to a slightly red color. Raw fruits contain a bitter glucoside which makes them inedible, but treatment with an alkali such as sodium hydroxide (lye) neutralizes the bitterness. The lye must subsequently be leached out of the fruits with water. In another method most of the bitterness can be removed by leaching with salt water. A lactic acid fermentation process is widely used in the Mediterranean countries to preserve the olives.

For oil production, the fruits are harvested in midwinter when they have become black and have reached their maximum oil content—15 to 25% of the fresh weight, depending on the variety. In producing olive oil, the freshly harvested fruits including pits are ground, after which this material is placed in burlap or cloth bags and placed under high pressure. Oil and water are extracted and transferred to tanks, where the oil rises to the top and is removed. *See* FAT AND OIL (FOOD). [H.T.Ha.]

Olivine It is generally accepted that the Earth's upper mantle consists mainly of olivine, an orthorhombic silicate with the composition $(Mg_{1.8},Fe_{0.2})SiO_4$, together with some pyroxene and garnet. The natural occurrence of two high-pressure forms (polymorphs) of olivine—orthorhombic wadsleyite, and cubic ringwoodite (with a spinel structure)—was predicted from high-pressure experiments and was later confirmed by meteorite investigations. The names olivine, wadsleyite, and ringwoodite refer only to naturally occurring compositions $[(Mg,Fe)_2SiO_4]$.

Because of their abundance in the Earth's mantle, knowledge of physical and chemical properties of olivine, wadsleyite, and ringwoodite is of great geophysical importance. Until recently, many of these properties had to be inferred from theoretical considerations and from experiments on chemical analogs, which transform at lower pressures. With the development of new experimental apparatus capable of generating very high pressures and temperatures (multianvil press and diamond anvil cell), a growing number of experimental studies are being performed on phases of natural composition.

Experimentally determined thermodynamic phase equilibria data indicate that in the Earth's mantle olivine transforms to wadsleyite, then to ringwoodite, and finally to compositions of magnesiowüstite plus perovskite. Estimated transformation pressures correspond closely to the discontinuities of seismic velocities at, respectively, 246, 322, and 417 mi (410, 520, and 670 km) depth in the mantle. [L.Ke.]

Omphacite The pale to bright green monoclinic pyroxene found in eclogites and related rocks. Omphacites are essentially members of the solid solution series between jadeite $(NaAlSi_2O_6)$ and diopside $(CaMgSi_2O_6)$. The density ranges from 3.16 to 3.43 g/cm^3; hardness is 5–6.

Omphacite is stable only at the relatively high pressures of the blueschist and eclogite facies of metamorphism, where it is associated with minerals such as glaucophane and lawsonite or pyropic garnet, respectively. In such environments it also occurs in veins, either on its own or with quartz. *See* GLAUCOPHANE; PYROXENE. [T.J.B.H.]

Oncholaimida An order of nematodes comprising the single superfamily Oncholaimoidea. These nematodes are principally marine and brackish-water forms with alleged predaceous and carnivorous feeding habits. The external amphidial aperture is an oval or a widened ellipse. Generally, the stoma is armed with one dorsal tooth and two subventral teeth, and its wall may be further fortified with transverse rows of small denticles. The stoma is divisible into the cheilostome (secondary blastocoel invagination) and the esophastome (primary blastocoel invagination). In some species the stoma of the adult male is collapsed or indistinct. The cephalic sensilla are in two whorls: one is circumoral and composed of six papilliform sensilla; the second combines the ancestral two whorls of six and four into a single whorl of ten setiform sensory organs. In some forms these sensilla are papilliform. The cylindrical-to-conoid esophagus may exhibit a series of muscular bulbs posteriorly. The cuticle is generally smooth, and over the length of the body there are scattered sensory setae or papillae. *See* NEMATA. [A.R.M.]

Oncofetal antigens Antigens that are commonly present both in fetal tissue during early development of life and in adult tissue when cancer occurs. These antigens, primarily glycoprotein in nature, are the products of one or more genes that normally are expressed only during fetal development and then are repressed in adult life. Their production in adults is a result of activation of the controlled genes by a yet unknown mechanism in association with cancer. Minute but significant changes of these fetal antigens in body fluids can serve in detecting the early oncogenic process and in monitoring the efficacy of, and in developing new modalities of, cancer treatment. *See* ANTIGEN; ONCOLOGY.

Several oncofetal antigens have been investigated extensively, including alpha fetoprotein, carcinoembryonic antigen, and prostate specific antigen.

Alpha fetoprotein is a normal embryonic product during fetal development. After birth the serum alpha fetoprotein decreases to only trace amounts by 2–5 weeks, and to normal adult levels (less than 20 nanograms per milliliter) within 1 year. Alpha fetoprotein in the serum is elevated in individuals with primary hepatocellular carcinoma and with teratocarcinomas of the ovary or testes. Nonhepatic primary cancer generally exhibits an elevation of serum alpha fetoprotein only after spread to the liver.

The carcinoembryonic antigen of human digestive cancer has been the most studied oncofetal antigen. Although it is generally accepted that the carcinoembryonic antigen assay should not be used as a screening test for cancer in the general population, it does have an adjunctive role in diagnostic procedures. One of the more significant results in clinical applications of carcinoembryonic antigen is the use of radioactive-labeled antibodies for localization of carcinoembryonic antigen–producing tumors. Although carcinoembryonic antigen is not specific for malignant disease, it is found in association with a variety of epithelially derived cancers.

Prostate specific antigen is expressed exclusively by human prostate epithelial cells. An elevated level of this antigen in the blood is detected in individuals with prostate cancer, although a slightly elevated antigen also can be detected in individuals with benign prostatic hypertrophy, that is, older men with an enlarged prostate. Prostate specific antigen is the most effective parameter for monitoring the treatment response and detecting the early disease recurrence in individuals with an established diagnosis of prostate cancer. Moreover, prostate specific antigen is of clinical value as a reliable aid in the screening of the high-risk or older population for early detection of prostate cancer. *See* PROSTATE GLAND DISORDERS. [T.M.Ch.]

Oncogenes Genes that contribute to the conversion of a normal cell into a cancerous cell. Oncogenes can derive from cellular genes that undergo mutations that alter their expression or activity, or from viruses that carry oncogenes within their genome and that are transferred into the cell by infection. *See* ANIMAL VIRUS; GENE.

Most, if not all, neoplasms (cancers) arise when individual cells within the body suffer irreversible genetic damage that leads to unrestrained cell growth. Since genes consist of segments of deoxyribonucleic acid (DNA) that are linked in a specific order along each chromosome, any agent or process that breaks the DNA or alters the individual chemical subunits of the DNA can cause genetic damage.

Genetic lesions in neoplastic cells can affect two classes of genes. The first genes identified were called oncogenes, and the mutations that alter these genes occur on only one of the two similar chromosomes in a cell. The unaffected chromosome retains the normal cellular gene, while the mutant form of the gene on the affected chromosome overrides the normal gene function and promotes neoplastic growth. In contrast to the oncogenes, mutations in cancer cells can also inactivate or even delete genes whose function is required for normal cell growth. This second class of genes, called tumor suppressors, appears to restrain cell growth or prevent the accumulation of mutations, and a cell remains normal as long as at least one copy of the tumor suppressor gene is functional. *See* DEOXYRIBONUCLEIC ACID (DNA); MUTAGENS AND CARCINOGENS; MUTATION; TUMOR.

Cellular genes have highly specific functions and patterns of expression, and the mutations that convert a normal gene into an oncogene can alter either of these properties. Four major types of oncogene-forming lesions are commonly found in tumor cells: (1) Point mutations can change individual bases within the segment of the gene that encodes a protein. (2) Chromosomes can break near specific genes and rejoin (chromosomal translocations). (3) Oncogenes can be created by the localized amplification of small chromosomal domains. (4) Viruses can be inserted into the chromosome near a specific gene and alter the expression (insertional mutagenesis). *See* CHROMOSOME ABERRATION.

Some viruses contain oncogenes that are part of the viral genetic material and not derived from the cell. Although most human cancer is not associated with infectious agents such as viruses, some cancers have been shown to be caused at least in part by viruses. The most common is cervical carcinoma, where the causative agent is human papilloma virus (HPV). *See* ANIMAL VIRUS; TUMOR VIRUSES.

Normal cells divide or remain quiescent as the result of diverse extracellular signals (such as growth factors and cell-cell interactions). These signals are interpreted by receptors and cytoplasmic factors, and eventually lead to reprogramming of gene expression in the nucleus. Thus, it is logical that the majority of oncogenes encode proteins that are components of this signal transduction pathway and then they inappropriately activate the normal growth signals. Many oncogene-encoded proteins localize to the plasma membrane and are enzymes that phosphorylate other proteins, altering the activity of these substrate proteins. Other oncogenic proteins function as regulatory subunits of enzymes, and the mutations signal the enzymes to be active continuously rather than in a regulated manner. The oncogene-encoded proteins that localize to the nucleus are largely DNA-binding proteins that regulate specific sets of cellular genes involved in growth control. Finally, oncogenes can function not by promoting cell growth but by blocking cell death (apoptosis). *See* CANCER (MEDICINE); CELL SENESCENCE AND DEATH; GENE ACTION; GENETIC ENGINEERING; ONCOLOGY. [M.C.]

Oncology The study of cancer. There are five major areas of oncology: etiology, prevention, biology, diagnosis, and treatment. As a clinical discipline, it draws upon a wide variety of medical specialties; as a research discipline, oncology also involves specialists in many areas of biology and in a variety of other scientific areas. Oncology has led to major progress in the understanding not only of cancer but also of normal biology.

Cancer defies simple definition. It is a disease that develops when the orderly relationship of cell division and cell differentiation becomes disordered. In cancer, dividing cells seem to lose the capacity to differentiate, and they acquire the ability to invade through basement membranes and spread (metastasize) to many areas of the body through the bloodstream or lymphatics. Cancer is usually clonal, that is, it develops initially in a single cell. That abnormal cell then produces progeny that may behave rather heterogeneously. Some progeny continue to divide, some develop the capacity to metastasize, and some develop resistance to therapeutic agents. This single cell and its progeny, if unchecked, typically lead to the death of the host. *See* CANCER (MEDICINE).

Causes of cancer. Cancer is generally thought to result from one or more permanent genetic changes in a cell. In some cells a single mutational event can lead to neoplastic transformation, but for most tumors it appears that carcinogenesis is a multistep process. Although some rare congenital conditions lead to cancer in infancy, the vast majority of human cancers arise as a result of the complex interplay between genetic and environmental factors. Without question, there are forms of cancer clearly related to particular environmental exposures; it is equally clear, however, that these factors act on a genetic substrate that may be either susceptible or resistant to the development of cancer.

The emergence of cancer appears to involve the accumulation of genetic damage in a target tissue. Such complex genetic changes specific to tissues appear to underlie the progression to cancer. Such multistep progression is quite complicated to study in experimental systems. Much work has focused on the identification, isolation, and characterization of oncogenes, which have the ability to transform normal cells into cancer cells. More than 50 bona fide or putative oncogenes have been characterized and mapped throughout the human genome. *See* HUMAN GENETICS; ONCOGENES.

Environmental factors involved in the development of cancers can be chemical, physical, or biological carcinogenic agents. At least three stages occur in the natural history of cancer development from environmental factors. The first stage is initiation, which is a specific alteration in the deoxyribonucleic acid (DNA) of a target cell; environmental agents may act by inducing expression of oncogenes. The second phase, promotion, involves the reversible stimulation of expansion of the initiated cell or the reversible alteration of gene expression in that cell or its progeny. Because promotion is thought to be reversible, it is a target for prevention. The final phase of carcinogenesis is progression. It is characterized by the development of aneuploidy and clonal variation in the tumor; these in turn result in invasiveness and metastasis. *See* MUTAGENS AND CARCINOGENS.

Cancer prevention. An obvious starting point for cancer prevention is avoidance of environmental agents that contribute to carcinogenesis.

The role of diet in cancer prevention is controversial. Epidemologic evidence suggests a particularly strong link between a high-fat, high-calorie, low-fiber diet and an increased risk of colon cancer. But a change to a low-fat, low-calorie, high-fiber diet may not alter the risk. The addition to the diet of carotenoids, selenium, vitamins A, D, and E, and some short-chain fatty acids may prevent cancers in high-risk populations, but there is no evidence that any dietary supplement will prevent cancer. *See* NUTRITION.

There are a variety of clinical settings in which surgery may prevent cancer. For example, surgical removal of the thyroid will prevent medullary carcinoma in individuals with certain types of multiple endocrine neoplasia, breast removal can be preventive in familial breast cancer, and removal of the ovaries can prevent cancer in familial ovarian cancer.

Cancer biology. The study of cancer biology picks up where cancer etiology leaves off, namely, at the point where the tumor has developed into a clonal cluster of autonomously proliferating cells. The pathological correlate of this stage of tumor development is carcinoma in situ; a condition in which no tissue destruction is evident, but atypical-appearing cancer cells are present at their site of origin. The transition from carcinoma in situ to locally invasive cancer is accompanied by dissolution of the basement membrane, penetration of tumor cells through the membrane and into the supportive tissues, and disruption of the supportive tissues. Expansion of the primary tumor in locally invasive cancer is always accompanied by the development of blood vessels. The tumor cells can also invade regional blood vessels and lymphatics and circulate throughout the body, attaching to endothelium in a distant organ site, inducing retraction of the endothelium, and becoming attached to the endothelial basement membrane. Once attached to the basement membrane, the tumor cells are covered over by the endothelial cells and effectively separated from the flow of blood. Local dissolution of the basement membrane then occurs, allowing the tumor to completely spread into the tissue and reestablish a blood flow in the breached vessel. As it grows, more blood vessel development nourishes the enlarging tumor.

During metastasis, tumor cells must overcome host defenses. They have various mechanisms to do so. For example, they produce new cell surface receptors to facilitate basement membrane and matrix binding; make new enzymes such as collagenases, serine proteases, metalloproteinases, cysteine proteinases, and endoglycosidases to facilitate their invasiveness; and secrete motility factors to enable them to move through the holes and pathways created by their enzymes. They avoid detection by the immune system through a variety of techniques. Unlike animal tumors, most human tumors are poorly immunogenic. Tumor cells often produce factors that are immunosuppressive. *See* CELLULAR IMMUNOLOGY; TUMOR.

An unexplained feature of metastasis is the propensity of certain tumor types to spread to specific organs.

Tumor detection. There are two major strategies to detect tumors at the earliest possible stage in their history: responding to the seven warning signals of cancer and screening populations at high risk. The seven danger signals of cancer are (1) unusual bleeding or discharge, (2) a lump or thickening in the breast or elsewhere, (3) a sore that does not heal, (4) change in bowel or bladder habits, (5) persistent hoarseness or cough, (6) persistent indigestion or difficulty in swallowing, and (7) change in a wart or mole.

Diagnosis. The diagnosis of cancer depends on the careful examination of biopsy material. Cancers arising in tissues having ectodermal or endodermal origins are generally called carcinomas; those derived from glands are called adenocarcinomas. Cancers arising in tissues derived from mesoderm are called sarcomas; those of lymphohematopoietic origin are lymphomas and leukemias. The cardinal microscopic features of malignancy are anaplasia, invasion, and metastasis.

Once a diagnosis of cancer is made, it is critical to determine the extent to which the disease has spread. This is called staging. It is distinct from grading, which is an assessment of histologic atypia performed with a microscope. Staging entails performing a careful physical examination, various radiographic studies, and perhaps surgical procedures (biopsies, endoscopies) to examine those sites to which a particular tumor type is most likely to spread. For example, patients with breast cancer often undergo evaluation of the liver, brain, and bones to search for metastatic disease, whereas patients with lymphoma generally require assessment of lymph node groups, bone marrow, and liver. Often the results of such staging tests determine the nature and extent of therapy.

Treatment. There are four major approaches to cancer treatment: surgery, radiation therapy, chemotherapy, and biological therapy. These modalities are often used together with additive or synergistic effects. Surgery and radiation therapy are most effective in curing localized tumors and together result in the cure of about 40% of all newly diagnosed cases. Once the cancer has spread to regional nodes or distant sites, it is generally incurable with the use of local therapies alone. Systemic administration of a combination of chemotherapeutic agents may cure another 10–15% of all patients. *See* CHEMOTHERAPY; RADIOLOGY.

Relieving the symptoms of cancer and alleviating the side effects of agents used to treat it is another important aspect of treatment. Many agents and interventions are available for these purposes. Pharmacologic agents can control nausea and vomiting. Various strategies are available to control pain, improve appetite, and combat insomnia and mood changes. Surgical procedures and radiological techniques can palliate many of the complications of cancer that formerly were incapacitating. Even when the hope for a cure has dwindled, the oncologist can relieve much suffering. [D.L.L.]

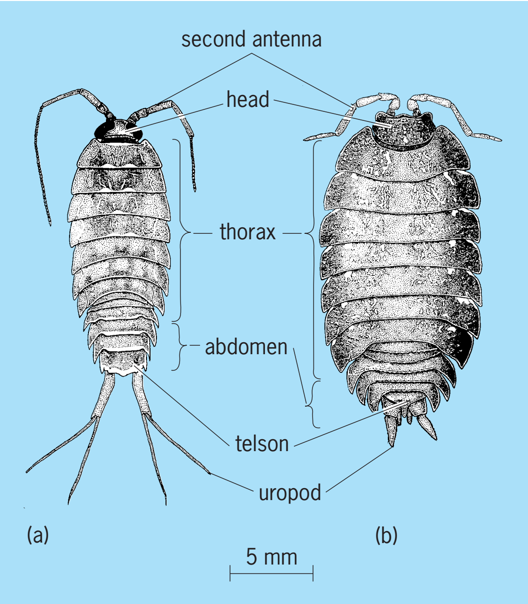
Onion A cool-season biennial, *Allium cepa*, of Asiatic origin and belonging to the plant order Liliales. The onion is grown for its edible bulbs.

Related species are leek (*A. porrum*), garlic (*A. sativum*), Welsh onion (*A. fistulosum*), shallot (*A. ascalonicum*), and chive (*A. schoenoprasum*).

Onion varieties (cultivars) are classified mainly according to pungency (mild or pungent) and use (dry bulbs or green bunching). Bulbs may be white, red, or yellow. Varieties differ markedly in their keeping quality and in their response to length of day. Hybrid varieties, with increased disease resistance, longer storage life, and improved quality, are rapidly displacing older varieties. Texas, New York, and California are important producing states. *See* Liliales. [H.J.C.]

Oniscoidea A suborder of the Isopoda which contains the terrestrial members of these crustaceans. They are popularly known as sow bugs, slaters, wood lice, or, in the case of those that roll themselves into a ball, pill bugs. Land isopods commonly occur under rocks, loose bark, leaf mold, and similar moist places. They abound in humid tropical and warm-temperate regions, particularly in the Old World. A few are practically cosmopolitan and have probably been accidentally transported by humans with plants, soil, or building materials. When abundant in gardens or greenhouses, they sometimes do considerable damage by gnawing on plants.

The body is either flattened dorsoventrally or in pill bugs is highly vaulted like an armadillo. Its three subdivisions, the head, thorax, and abdomen, are broadly joined (see illustration). The lateral margins generally form a continuous oval outline, except in types with the abdomen abruptly narrower than the thorax. The surface may be smooth or variously sculptured with tubercles, ridges, or spines. Sexual dimorphism is rare.



Genera of oniscoideans. (*a*) *Ligia*. (*b*) *Porcellio*.

Six fused segments, including the first thoracic somite, make up the head. It bears two pairs of antennae (the first being vestigial), two sessile compound eyes, and four pairs of mouthparts. The thorax has seven free segments, each bearing a pair of similar seven-jointed walking legs. The abdomen has five segments plus a terminal telson. Its appendages are biramous and include five pairs of platelike pleopods and one pair of uropods. *See* Isopoda. [M.A.M.]

Ontogeny The developmental history of an organism from its origin to maturity. It starts with fertilization and ends with the attainment of an adult state, usually expressed in terms of both maximal body size and sexual maturity. Fertilization is the joining of haploid gametes (a spermatozoon and an ovum, each bearing half the number of chromosomes typical for the species) to form a diploid zygote (with a full chromosome number), a new unicellular living being which will grow through a series of asexual reproductions. The gametes are the link between one generation and the next: the fusion of male and female gametes is the onset of a new ontogenetic cycle. Many organisms die shortly after sexual reproduction, whereas others live longer and generations are overlapped. Species are usually conceived as adults, but in most cases the majority of their representation in the environment is as intermediate ontogenetic stages. *See* Fertilization; Reproduction (animal).

In unicellular organisms, each asexual reproduction leads to the formation of new individuals, the cells deriving from a first sexually derived individual forming a clone of genetically identical individuals. In multicellular organisms, the products of the asexual reproductions starting with the first division of the zygote remain connected, and the clone they form is a single individual. Clonation of individuals occurs even in humans, when the first results of asexual reproduction of the zygote separate from each other, leading to twin formation.

The ontogeny of a multicellular organism involves segmentation (or cleavage): the zygote divides into two, four, etc., cells which continue to divide. These cells are initially similar to the zygote, although smaller in size. They soon start to differentiate from their ancestors, acquiring special features, and forming specific tissue layers and, eventually, organs. These processes lead to the formation and growth of an embryo. Embryos can develop freely, within egg shells, or within the body of one parent; they can grow directly into juveniles (as in humans) or into larvae (with an indirect development, as in insects).

Juveniles are similar to adults but are smaller in size and not sexually mature. Their ontogeny continues until they reach a maximal size and reproductive ability. Larvae have different morphology, physiology, and ecology from adults; they become juveniles through a metamorphosis (that is, an abrupt change). Usually ontogeny is interrupted at adulthood, but some organisms can grow throughout their life, so that ontogeny ends with their death. *See* Ecology. [F.V.B.]

Onychophora The only living animal phylum with true lobopods (annulate, saclike legs with internal musculature). There are about 70 known living species in two families, Peripatopsidae and Peripatidae. These terrestrial animals are frequently referred to as Peripatus. Onychophora comprise a single class or order of the same name. They were once considered a missing link between annelid worms and arthropods, but are best considered to be aligned with the arthropods.

They have a cylindrical body, 0.5–6 in. (1.4–15 cm) long, with one antennal pair, an anterior ventral mouth, and 14–43 pairs of stubby, unsegmented legs ending in walking pads and paired claws. Mandibles are present as modified tips of the first appendage pair. The body surface has a flexible chitinous cuticle. The body wall has three layers of smooth muscle, as in annelids, but the coelom is reduced to gonadal and nephridial cavities; the body cavity has an arthropodlike partitioned hemocoel; the heart is tubular with metameric ostia; and the nephridia are segmental. Gas exchange takes place by means of tracheae; spiracles are minute and numerous, located between skin folds. Slow locomotion is effected by legs and body contractions; the animals can squeeze into very tight spaces. The eyes, located at the antennal base, are the direct type with a chitinous lens and retinal layer. The sexes are separate; the testes and ovaries are paired; and the genital tracts open though the posterior ventral pore. Onychophora are oviparous, ovoviviparous, or viviparous.

The Onychophora are predatory, feeding on small invertebrates. They are largely nocturnal, occurring in humid habitats in forests. [S.B.P.]

Onychopoda A specialized order of brachiopod crustaceans formerly included in the order Cladocera. The body is up to about 12 mm (0.5 in.) in length, but much of the length of the longest species is made up by a caudal process.

The head and thorax are short, as is the abdomen in some species, but in others it is drawn out into a long caudal process. A carapace is present but is reduced to a dorsal brood pouch, leaving the body naked. A large median compound eye occupies much of the head.

Onychopods swim actively by means of their antennae—the antennules are small and sensory—and seize their food with their four pairs of grasping trunk limbs. Most are predators, but detritus is also eaten by some species. The mandibles are stoutly denticulate.

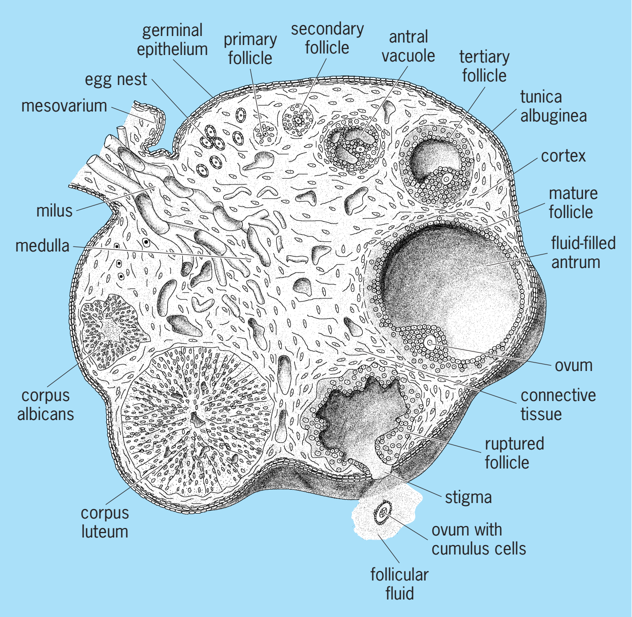
Reproduction is mostly by parthenogenesis (males are unknown in some species from the Caspian Sea); eggs and young are carried in the brood pouch. Sexual reproduction gives rise to freely shed resistant eggs that overwinter in temperate zone species. Onychopods occur in the sea and fresh water and are worldwide in distribution, but fresh-water species occur only in the Holarctic temperate zone. There is a remarkable group of endemic species in the Ponto-Caspian region. *See* BRACHIOPODA. [G.Fr.]

Onyx Banded chalcedonic quartz, in which the bands are straight and parallel, rather than curved, as in agate. Unfortunately, in the colored-stone trade, gray chalcedony dyed in various solid colors such as black, blue, and green is called onyx, with the color used as a prefix. Because the color is permanent, the fact that it is the result of dyeing is seldom mentioned.

The natural colors of true onyx are usually red or brown with white, although black is occasionally encountered as one of the colors. When the colors are red-brown with white or black, the material is known as sardonyx; this is the only kind commonly used as a gemstone. Its most familiar gem use is in cameos and intaglios. *See* CAMEO; CHALCEDONY. [R.T.L]

Oogenesis The generation of ova or eggs, the female gametes. Primordial germ cells, once they have populated the gonads, proliferate and differentiate into sperm (in the testis) or ova (in the ovary). The decision to produce either spermatocytes or oocytes is based primarily on the genotype of the embryo. In rare cases, this decision can be reversed by the hormonal environment of the embryo, so that the sexual phenotype may differ from the genotype. Formation of the ovum most often involves substantial increases in cell volume as well as the acquisition of organellar structures that adapt the egg for reception of the sperm nucleus, and support of the early embryo. In histological sections, the structure of the oocyte often appears random but as the understanding of its chemical and structural organization increases, an order begins to emerge. *See* OVUM; SPERMATOGENESIS.

Among lower vertebrates and invertebrates, mitotic divisions of the precursor cells, the oogonia, continue throughout the reproductive life of the adult; thus extremely large numbers of ova are produced. In the fetal ovary of mammals, the oogonia undergo mitotic divisions until the birth of the fetus, but a process involving the destruction of the majority of the developing ova by the seventh month of gestation reduces the number of oocytes from millions to a few hundred. Around the time of birth, the mitotic divisions cease altogether, and the infant female ovary contains its full complement of potential ova. At puberty, the pituitary hormones, follicle stimulating hormone (FSH), and luteinizing hormone (LH) stimulate the growth and differentiation of the ova and surrounding cells (see illustration). *See* MITOSIS.



Three-dimensional view of the cyclic changes in the mammalian ovary.

One important feature of oocyte differentiation is the reduction of the chromosome complement from the diploid state of the somatic cells to the haploid state of gametes. Fusion with the haploid genome of the sperm will restore the normal diploid number of chromosomes to the zygote. The meiotic divisions which reduce the chromosome content of the oocyte occur after the structural differentiation of the oocyte is complete, often only after fertilization. Unlike the formation of sperm, in which the two divisions of meiosis produce four equivalent daughter cells, the cytoplasm of the oocyte is divided unequally, so that three polar bodies with reduced cytoplasm and one oocyte are the final products. Generally, each fertilized oocyte produces a single embryo, but there are exceptions. Identical twins, for example, arise from the same fertilized egg. *See* FERTILIZATION; MEIOSIS.

The provision of nutrients for the embryo is a major function of the egg, and this is accomplished by the storage of yolk in the cytoplasm. Yolk consists of complex mixtures of proteins (vitellins), lipids, and carbohydrates in platelets, which are membrane-surrounded packets dispersed throughout the egg cytoplasm (ooplasm). The amount of yolk in an egg correlates with the nutritional needs of the embryo. Although the eggs of mammals are extremely small as compared to the fetus, the bulk of the nutrition is supplied by the placenta; yolk is required only until implantation in the uterine wall.

Egg cytoplasm also contains large stores of ribonucleic acid (RNA) in the form of ribosomal, messenger, and transfer RNA. These RNAs direct the synthesis of proteins in the early embryo, and may have a decisive influence on the course of development. The mechanism by which the RNA is supplied to the egg is the basis for a major classification of ovary types. Panoistic ovaries, in which the egg nucleus is responsible for the production of all the stored RNA in the ooplasm, are typical of vertebrates, primitive insects, and a number of invertebrates. The amounts of RNA produced during the meiotic prophase in such ovaries are much larger than those produced by a somatic cell, and thus special mechanisms seem to be involved in the synthetic process. *See* Deoxyribonucleic acid (DNA); Ribonucleic acid (RNA). [S.J.B.]

Oolite A deposit containing spheroidal grains with a mineral cortex, most commonly calcite or aragonite, accreted around a nucleus formed primarily of shell fragments or quartz grains. The term ooid is applied to grains less than 0.08 in. (2 mm) in diameter, and the term pisoid to those greater than 0.08 in. (2 mm). Accretionary layering (growth banding) is usually developed clearly. A flattened or elongate shape may occur if the nucleus shows that form. Ooids formed on nuclei of shells and shell fragments and composed of fine, radial calcite are cemented by coarse, clear calcite. Growth banding is visible in most ooids. The pisoids are composed of many thin layers of very small, tangential (lighter layers) and radial (darker layers) aragonite crystals. These pisoids are cemented with fibrous aragonite.

Ooids are primarily marine, forming in agitated shallow, warm waters. Under those conditions, the ooids are kept intermittently moving, so accretion occurs on all sides. Some ooids and most pisoids form in nonmarine environments, such as hypersaline and fresh-water lakes, hot springs, caves, caliche soils, and some rivers. *See* Aragonite; Calcite. [P.A.Sa.]

Oomycetes A class of fungi in the subdivision Mastigomycotina. They comprise a group of heterotropic, funguslike organisms that are classified with the zoosporic fungi (Mastigomycotina) but in reality are related to the heterokont algae. They are distinguished from other zoosporic fungi by the presence of biflagellate zoospores. Some taxa are nonzoosporic. Asexual reproduction involves the release of zoospores from sporangia; in some taxa the sporangium germinates with outgrowth of a germ tube. Sexual reproduction occurs when an oogonial cell is fertilized by contact with an antheridium, resulting in one or more oospores.

Oomycetes are cosmopolitan, occurring in fresh and salt water, in soil, and as terrestrial parasites of plants. Many species can be grown in pure culture on defined media. There are four orders: The Saprolegniales and Leptomitales are popularly known as water molds. Some species are destructive fish parasites. Many Lagenidiales are parasites of invertebrates and algae. The Peronosporales are primarily plant parasites attacking the root, stem, or leaf, and include some of the more destructive plant pathogens. *See* Eumycota; Fungi; Mastigomycotina. [D.J.S.B.]

Opal A natural hydrated form of silica. Opal is a relatively common mineral in its nongem form, which is known as common opal and lacks the play of color for which gem, or precious, opal is known. All opal is of relatively simple chemical composition, $SiO_2 \cdot nH_2O$. The hardness of opal on the Mohs hardness scale ranges from 5 to 6, the specific gravity from 2.25 to 1.99, and the refractive index from 1.455 to 1.435. *See* Hardness scales; Silicate minerals.

The color of common opal ranges from transparent, glassy, and colorless to white and bluish white. Common pigmenting agents, such as iron, produce yellow, brown, red, and green colors, and frequently several colors in a single specimen. Precious opal has a play of color that is the result of white light being diffracted by the relatively regular internal array of silica spheres. Because opal is a hydrous mineral, certain opals from specific geologic occurrences may crack because of water loss. Therefore, considerable care is required in the polishing and handling of opal.

Several trade terms are used to describe the appearance of precious opal based on transparency, body color, and the type of play of color. Some of these terms are black opal, which is translucent to almost opaque, with dark gray to black body color, with play of color; fire opal, which is transparent to semitransparent, with yellow, orange, red, or brown body color and with or without play of color; harlequin or mosaic opal, in which the play of color occurs in distinct, broad, angular patches; and matrix opal, which consists of thin seams of high-quality gem opal in a matrix. *See* Gem. [P.J.Da.; C.K.]

Opalescence The milky iridescent appearance of a dense transparent medium when the system (or medium) is illuminated by polychromatic radiation in the visible range, such as sunlight. Slight changes in the rainbowlike color of the system can occur, depending on the scattering angle, that is, the angle between the directions of incident radiation and of observation.

Opalescence is a general term which applies to the optical phenomenon of intense scattering in the visible range of the electromagnetic radiation by a system with strong local optical inhomogeneities. The iridescence, or rainbowlike display of interference of colors, arises because the intensity of scattered light is approximately proportional to the reciprocal fourth power of the wavelength of incident light (Rayleigh's law). *See* Scattering of electromagnetic radiation. [B.C.]

Open channel A covered or uncovered conduit in which liquid (usually water) flows with its top surface bounded by the atmosphere. Typical open channels are rivers, streams, canals, flumes, reclamation or drainage ditches, sewers, and water-supply or hydropower aqueducts.

Open-channel flow is classified according to steadiness, a condition in relation to time, and to uniformity, a condition in relation to distance. Flow is steady when the velocity at any point of observation does not change with time; if it changes from instant to instant, flow is unsteady. At every instant, if the velocity is the same at all points along the channel, flow is uniform; if it is not the same, flow is nonuniform. Nonuniform flow which is steady is called varied; nonuniform flow which is unsteady is called variable.

Flow occurs from a higher to a lower elevation by action of gravity. If the phenomenon is short, wall friction is small or negligible, and gravity shapes the flow behavior. Gravity phenomena are local; they include the hydraulic jump, flow over weirs, spillways, or sills, flow under sluices, and flow into culvert entrances.

If the phenomenon is long, friction shapes the flow behavior. Friction phenomena include flows in rivers, streams, canals, flumes, and sewers. [W.A.]

Open circuit A condition in an electric circuit in which there is no path for current between two points; examples are a broken wire and a switch in the open, or off, position. *See* Circuit (electricity).

Open-circuit voltage is the potential difference between two points in a circuit when a branch (current path) between the points is open-circuited. Open-circuit voltage is measured by a voltmeter which has a very high resistance (theoretically infinite). [C.F.G.]

Open pit mining The process of extracting beneficial minerals by surface excavations. Open pit mining is a type of surface excavation which often takes the shape of an inverted cone; the shape of the mine opening varies with the shape of the mineral deposit. Other types of surface mining are specific to the type and shape of the mineral deposit. *See* Coal mining; Placer mining; Surface mining.

The open pit mine, like any other mining operation, must extract the product minerals at a positive economic benefit. All costs of producing the product, including excavation, beneficiation, processing, reclamation, environmental, and social costs, must be paid for by the sales of the mineral product. A mineral that is in sufficient concentration to meet or exceed these economic constraints is called ore. The terms ore body and ore deposit are used to refer to the natural occurrence of an economic mineral deposit. *See* Ore and mineral deposits.

Ore bodies occur as the result of natural geologic occurrences. The geologic events that lead to the concentration of a mineral into an ore deposit are generally complex and rare. If those events placed the deposit sufficiently near the surface, open pit mining may be viable.

Material encountered during the mining process that has little or no economic value is called waste or overburden. One important economic criterion for open pit mining is the amount of overlying waste which must be removed to extract the ore. The ratio of the amount of waste to the amount of ore is referred to as the strip ratio. In general, the lower the strip ratio, the more likely an ore body is to be mined by open pit methods.

Modern open pit mining utilizes large mechanical equipment to remove the ore and waste from the open pit excavation. The amount of equipment and its type and size depend on the characteristics of the ore and waste and the required production capacity. In general, there are four basic unit operations common to most open pit mining operations. These are drilling, blasting, loading, and hauling.

Waste material that is generated during the course of mining at most mines must be discarded as economically as possible without jeopardizing future mining activities but while respecting environmental regulations. Two types of waste material are generated at most mining operations: waste rock and overburden from the mine, and tailings—the waste material from the processing plant after treatment of the ore. *See* LAND RECLAMATION.

Computer software is available to assist the mining engineer in ore reserve estimation with the application of geostatistics, mine planning and design, and production and maintenance monitoring and reporting. With the help of high-speed computers the engineering and production staff can evaluate aspects of the mining activities, which allows a more efficient and economical extraction of the mineral commodity. *See* MINING; OPERATIONS RESEARCH; OPTIMIZATION. [H.We.; J.M.M.]

Operating system The software component of a computer system that is responsible for the management and coordination of activities and the sharing of the resources of the computer. The operating system (OS) acts as a host for application programs that are run on the machine. As a host, one of the purposes of an operating system is to handle the details of the operation of the hardware. This relieves application programs from having to manage these details and makes it easier to write applications. Almost all computers, including hand-held computers, desktop computers, supercomputers, and even modern video game consoles, use an operating system of some type. *See* COMPUTER SYSTEMS ARCHITECTURE.

Operating systems offer a number of services to application programs and users. Applications access these services through application programming interfaces (APIs) or system calls. By invoking these interfaces, the application can request a service from the operating system, pass parameters, and receive the results of the operation. Users may also interact with the operating system by typing commands or using a graphical user interface (GUI, commonly pronounced “gooey”). For hand-held and desktop computers, the GUI is generally considered part of the operating system. For large multiuser systems, the GUI is generally implemented as an application program that runs outside the operating system. *See* COMPUTER PROGRAMMING; HUMAN-COMPUTER INTERACTION.

Modern operating systems provide the capability of running multiple application programs simultaneously, which is referred to as multiprogramming. Each program running is represented by a process in the operating system. The operating system provides an execution environment for each process by sharing the hardware resources so that each application does not need to be aware of the execution of other processes. The central processing unit (CPU) of the computer can be used by only one program at a time. The operating system can share the CPU among the processes by using a technique known as time slicing. In this manner, the processes take turns using the CPU. Single-user desktop personal computers (PCs) may simplify this further by granting the CPU to whichever application the user has currently selected and allowing the user to switch between applications at will.

The main memory of a computer (referred to as random access memory, or RAM) is a finite resource. The operating system is responsible for sharing the memory among the currently running processes. When a user initiates an application, the operating system decides where to place it in memory and may allocate additional memory to the application if it requests it. The operating system may use capabilities in the hardware to prevent one application from overwriting the memory of another. This provides security and prevents applications from interfering with one another. *See* COMPUTER STORAGE TECHNOLOGY.

The details of device management are left to the operating system. The operating system provides a set of APIs to the applications for accessing input/output (I/O) devices in a consistent and relatively simple manner regardless of the specifics of the underlying hardware. The operating system itself will generally use a software component called a device driver to control an I/O device. This allows the operating system to be upgraded to support new devices as they become available. In addition to a device driver for the network I/O device, the operating system includes software known as a network protocol and makes various network utilities available to the user. *See* COMPUTER PERIPHERAL DEVICES; LOCAL-AREA NETWORKS; WIDE-AREA NETWORKS.

Operating systems provide security by preventing unauthorized access to the computer's resources. Many operating systems also prevent users of a computer from accidentally or intentionally interfering with each other. The security policies that an operating system enforces range from none in the case of a video game console, to simple password protection for hand-held and desktop computers, to very elaborate schemes for use in high-security environments. *See* COMPUTER SECURITY. [C.Sch.]

Operational amplifier A voltage amplifier that amplifies the differential voltage between a pair of input nodes. For an ideal operational amplifier (also called an op amp), the amplification or gain is infinite.

Most existing operational amplifiers are produced on a single semiconductor substrate as an integrated circuit. These integrated circuits are used as building blocks in a wide variety of applications. *See* INTEGRATED CIRCUITS.

Although an operational amplifier is actually a differential-input voltage amplifier with a very high gain, it is almost never used directly as an open-loop voltage amplifier in linear applications for several reasons. First, the gain variation from one operational amplifier to another is quite high and may vary by ± 50% or more from the value specified by the manufacturer. Second, other nonidealities such as the offset voltage make it impractical to stabilize the dc operating point. Finally, performance characteristics such as linearity and bandwidth of the open-loop operational amplifier are poor. In linear applications, the operational amplifier is almost always used in a feedback mode.

A block diagram of a classical feedback circuit is shown in illus. *a*. The transfer characteristic, often termed the feedback gain A_f of this circuit, is given by Eq. (1). In the limiting case, as

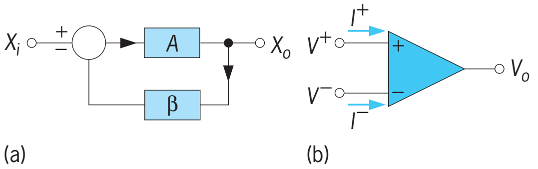
$$\frac{X_o}{X_i} = A_f = \frac{A}{1 + A\beta} \qquad (1)$$

A becomes very large, the feedback gain is approximated by Eq. (2).

$$A_f \simeq \frac{1}{\beta} \qquad (2)$$

See FEEDBACK CIRCUIT.

An operational amplifier is often used for the amplifier designated A in this block diagram. Since A_f in the limiting case is independent of A, the exact gain characteristics of the operational amplifier become unimportant provided the gain is large.



Basic circuits. (*a*) Classical feedback circuit. (*b*) Operational amplifier symbol typically used in circuit diagrams.

Although linear applications of the operational amplifier extend well beyond the simple feedback block diagram of illus. *a*, the applications invariably involve circuit structures with feedback that make the characteristics of the circuit nearly independent of the exact characteristics of the operational amplifier. Such circuits are often termed active circuits.

The commonly used operational amplifier symbol is shown in illus. *b*. In this circuit, the output voltage is related to the gain *A* of the operational amplifier by Eq. (3), where *A* is very large

$$V_0 = A(V^+ - V^-) \tag{3}$$

and the input currents I^+ and I^- are nearly zero. *See* AMPLIFIER; CIRCUIT (ELECTRONICS). [P.M.VanP.]

Operations research The application of scientific methods and techniques to decision-making problems. A decision-making problem occurs where there are two or more alternative courses of action, each of which leads to a different and sometimes unknown end result. Operations research is also used to maximize the utility of limited resources. The objective is to select the best alternative, that is, the one leading to the best result.

To put these definitions into perspective, the following analogy might be used. In mathematics, when solving a set of simultaneous linear equations, one states that if there are seven unknowns, there must be seven equations. If they are independent and consistent and if it exists, a unique solution to the problem is found. In operations research there are figuratively "seven unknowns and four equations." There may exist a solution space with many feasible solutions which satisfy the equations. Operations research is concerned with establishing the best solution. To do so, some measure of merit, some objective function, must be prescribed.

In the current lexicon there are several terms associated with the subject matter of this program: operations research, management science, systems analysis, operations analysis, and so forth. While there are subtle differences and distinctions, the terms can be considered nearly synonymous. *See* SYSTEMS ENGINEERING.

Methodology. The success of operations research, where there has been success, has been the result of the following six simply stated rules: (1) formulate the problem; (2) construct a model of the system; (3) select a solution technique; (4) obtain a solution to the problem; (5) establish controls over the system; and (6) implement the solution.

The first statement of the problem is usually vague and inaccurate. It may be a cataloging of observable effects. It is necessary to identify the decision maker, the alternatives, goals, and constraints, and the parameters of the system. A statement of the problem properly contains four basic elements that, if correctly identified and articulated, greatly eases the model formulation. These elements can be combined in the following general form: "Given (the system description), the problem is to optimize (the objective function), by choice of the (decision variable), subject to a set of (constraints and restrictions)."

In modeling the system, one usually relies on mathematics, although graphical and analog models are also useful. It is important, however, that the model suggest the solution technique, and not the other way around.

With the first solution obtained, it is often evident that the model and the problem statement must be modified, and the sequence of problem-model-technique-solution-problem may have to be repeated several times. The controls are established by performing sensitivity analysis on the parameters. This also indicates the areas in which the data-collecting effort should be made.

Implementation is perhaps of least interest to the theorists, but in reality it is the most important step. If direct action is not taken to implement the solution, the whole effort may end as a dust-collecting report on a shelf.

Mathematical programming. Probably the one technique most associated with operations research is linear programming. The basic problem that can be modeled by linear programming is the use of limited resources to meet demands for the output of these resources. This type of problem is found mainly in production systems, but is not limited to this area. *See* LINEAR PROGRAMMING.

Stochastic processes. A large class of operations research methods and applications deals with stochastic processes. These can be defined as processes in which one or more of the variables take on values according to some, perhaps unknown, probability distribution. These are referred to as random variables, and it takes only one to make the process stochastic.

In contrast to the mathematical programming methods and applications, there are not many optimization techniques. The techniques used tend to be more diagnostic than prognostic; that is, they can be used to describe the "health" of a system, but not necessarily how to "cure" it. *See* PROBABILITY; QUEUEING THEORY; STOCHASTIC PROCESS.

Scope of application. There are numerous areas where operations research has been applied. The following list is not intended to be all-inclusive, but is mainly to illustrate the scope of applications: optimal depreciation strategies; communication network design; computer network design; simulation of computer time-sharing systems; water resource project selection; demand forecasting; bidding models for offshore oil leases; production planning; classroom size mix to meet student demand; optimizing waste treatment plants; risk analysis in capital budgeting; electric utility fuel management; optimal staffing of medical facilities; feedlot optimization; minimizing waste in the steel industry; optimal design of natural-gas pipelines; economic inventory levels; optimal marketing-price strategies; project management with CPM/PERT/GERT; air-traffic-control simulations; optimal strategies in sports; optimal testing plans for reliability; optimal space trajectories. *See* DECISION THEORY; GERT; INVENTORY CONTROL; PERT. [W.G.L.]

Operator theory At one level of abstraction an operator is simply a function whose arguments and values are real- (or complex-) valued functions of one or more real variables; in more naive terms an operator is a rule for converting such real-(or complex-) valued functions into others. The following are simple examples: (i) the operator which takes each differentiable real-valued function of one variable into its derivative; (ii) the operator which takes each twice-differentiable function *f* of one variable into expression (1); (iii) the operator which takes each twice-differentiable function *f* of three variables into expression (2); and (iv) the operator which takes the continuous function *f* of one real variable into the function *g* where relation (3) holds.

$$\left(\frac{df}{dx}\right)^2 + x^2\frac{d^2f}{dx^2} \tag{1}$$

$$\frac{\partial^2 f}{\partial x^2} + \frac{\partial^2 f}{\partial y^2} + \frac{\partial^2 f}{\partial z^2} \tag{2}$$

$$g(x) \equiv \int_0^1 \sqrt{x+y}\, f(y)dy \tag{3}$$

Since an operator is a function, the usual functional notation is applicable. *L*(*f*) may be used to denote the result of operating on f with the operator L. The set of all functions f for which $L(f)$ is defined is called the domain of L, and the set of all functions g such that $L(f) = g$ for some f in the domain of L is called the range of L. It is obvious that solving a differential or integral equation is equivalent (in many ways) to solving an operator equation $L(f) = g$, where g and L are given and it is required to find f. Moreover, the operator concept can be very useful both in theory and practice, producing a great variety of illuminating insights. *See* Differential equation; Integral equation.

In large part the fruitfulness of the operator concept can be traced to two sources. One of these is the possibility of adding and multiplying operators in such a way that many, though not all, of the laws of ordinary algebra hold. The other is the fact that the ranges and domains of operators behave in many respects like ordinary space and, indeed, may be regarded as contained in infinite dimensional generalizations of the familiar three-dimensional space of solid geometry. This makes it possible to think of an operator as a geometrical transformation and to exploit one's spatial intuition. [G.W.M.]

Operator training The specialized education of an organization's employees in the general knowledge and specific skills required to do their jobs effectively. Important to the continued soundness of an enterprise, it is considered an essential function. As science advances and technology becomes more complex, competent and continuous training increases in importance.

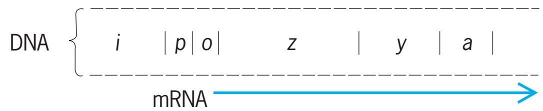
The objective of the training is to enable the operator to perform the job in a manner that is satisfactory to the employer and satisfying to the employee. It should contribute to increased output, productivity, quality, pride in quality, and morale and to decreased errors, customer complaints, rejects, rework, waste, accidents, injuries, equipment downtime, unit costs, frustration, absenteeism, and labor turnover.

An operator has been defined in the past as one who controls a machine or process but, with the advent of automated machines and processes, actual control has become less important. In the modern production environment, operators' tasks involve, in addition to controlling the machinery, monitoring the machine so that it performs its functions correctly; diagnosing any faults that may occur; understanding and predicting when problems can occur; and troubleshooting the machinery once a problem occurs. An operator can also be involved in programming the machine so it operates properly. The training should emphasize these cognitive aspects of performing the task. *See* Automation.

Operator training can be performed on several kinds of devices—actual equipment, simulators, mock-ups—and through written instructions. Ideally, operators are trained on the actual equipment; but since this is not always possible, other devices must be considered. Simulators, usually computer-controlled, offer a cost-effective alternative to training operators on the actual equipment. Mock-ups are inexpensive, but can only be used to train the worker in some aspects of the task.

Written instructions can include manuals, books, or pamphlets. These are inexpensive to reproduce. Training effectiveness is limited, however, especially when learning to control or monitor a machine. Troubleshooting procedures can be communicated through effective written instructions. [R.Eb.]

Operon A group of distinct genes that are expressed and regulated as a unit. Each operon is a deoxyribonucleic acid (DNA) sequence that contains at least two regulatory sites, the promoter and the operator, and the structural genes that code for specific proteins (see illustration). The promoter (p) site is the location at which ribonucleic acid (RNA) polymerase binds to the operon. RNA polymerase moves down the operon catalyzing the synthesis of a messenger RNA (mRNA) molecule with a sequence that is complementary to DNA. This process is called transcription. The mRNA is used as a template by ribosomes to synthesize the proteins coded for by the structural genes (in the original DNA) in a process called translation. This mRNA is referred to as polycistronic because its sequence directs the synthesis of more than one protein. The operator (o) site is located between the p site and the beginning of the coding region for the first structural gene. It is at this site that molecules called repressors can bind to the DNA and block RNA polymerase from transcribing the DNA, thus shutting off the operon. Some systems can be derepressed by the addition of small molecules called effectors, which bind to the repressor protein and cause a conformational (shape) change that makes it no longer able to bind to the DNA at the operator site. *See* Deoxyribonucleic acid (DNA); Ribonucleic acid (RNA).



The lactose (*lac*) operon from *Escherichia coli: z, y,* and *a* are structural genes; *i* is the *lac* repressor gene; *p* is the promoter site; and *o* is the operator site. The arrow indicates length and direction of mRNA synthesis.

Activation is believed to arise from the binding of a protein immediately adjacent to the promoter. The protein provides additional locations with which RNA polymerase can interact; the extra interactions result in an increased amount of polymerase binding to the promoter. Activators are more frequently involved in the regulation of genes in eukaryotes than in prokaryotes.

Once RNA polymerase begins transcribing a gene, it continues making RNA until a termination site is reached. Antiterminators are proteins that prevent termination at certain sites. In the presence of these antiterminators, RNA polymerase continues along the genome and transcribes the genes following the termination site until a different class of termination site is encountered.

Attenuation is the premature termination of the mRNA translation. Although the exact mechanism of attenuation has not been determined, it is thought that attenuation is due to the formation of a translation termination site in mRNA. *See* Gene; Gene action. [D.H.O.]

Ophioglossales An order of the class Polypodiopsida known as the adder's-tongue ferns. It is a small group with only 3 genera and about 80 species. Two genera, *Ophioglossum* and *Botrychium*, are widely distributed in tropical and temperate regions and have about the same number of species; the third genus, *Helminthostachys*, is represented by a single species confined to southeastern Asia and Polynesia. These are considered the most primitive of the present-day ferns. No fossils have been reported for this group.

The chromosome number is high in the species of *Ophioglossum*. *Ophioglossum petiolatum*, a tropical species, has a chromosome count of over 1000, the largest number observed in a naturally occurring species of vascular plants. This group is distinguished from other ferns by the arrangement of the sporogenous tissue in the characteristic fertile spike of the sporophyte. The leaves are erect or merely bent over in bud and not circinate. The gametophyte is a small, nongreen, fleshy, subterranean saprophyte, associated with an endophytic fungus. The group appears to be an evolutionary dead end. *See* Fungi; Leaf; Polypodiales; Polypodiopsida; Pteropsida. [P.A.V.]

Ophiolite A distinctive assemblage of mafic plus ultramafic rocks generally considered to be fragments of the oceanic lithosphere that have been tectonically emplaced onto continental margins and island arcs. An ophiolite is a formation made up of an association of typical rocks in a clearly defined sequence. A complete idealized ophiolite sequence from bottom to top includes (1) an ultramafic tectonite complex composed mostly of multilayered, deformed harzburgite, dunite, and minor chromitite; (2) a plutonic complex of layered mafic-ultramafic cumulates at the base, grading upward to massive gabbro, diorite, and possibly plagiogranite; (3) a mafic sheeted-dike complex; (4) an extrusive section of massive and pillow lavas, pillow breccias, and intercalated pelagic sediments; and (5) a top layer of abyssal or bathyal sediments, which may include ribbon chert, red pelagic limestone, metalliferous sediments, volcanic breccias, or pyroclastic deposits. Most ophiolites lack complete sections, and are dismembered and fragmented. Their estimated original thickness is variable, ranging from about 2 km (1.2 mi) to more than 8 km (5 mi). *See* EARTH CRUST; LITHOSPHERE.

Ophiolites typically occur in collisional mountain belts or island arcs and define a suture zone marking the boundary where two plates have welded together. The ophiolite complex is interpreted as evidence for a closed marginal ocean or back-arc basin. Throughout the world, ophiolites occur as long narrow belts, up to 10 km (6 mi) wide, that can extend more than 1000 km (600 mi) in length, in two distinct geographic settings. (1) Those in the Alpine-Mediterranean region, Tethyan ophiolite, were formed in small ocean basins that were surrounded by older, attenuated continental crust. (2) Those in western North America and the Circum-Pacific (Cordilleran) region seem to have formed in inter-arc basins. The Cordilleran ophiolites, such as the Trinity ophiolite and the Coast Range ophiolite of California, are generally incomplete, metamorphosed, or dismembered, but they commonly form the basement rocks for many North American continental margin terranes. *See* BASIN; CONTINENTAL MARGIN; STRUCTURAL GEOLOGY; GEODYNAMICS.

Ophiolites represent new oceanic crust formed in a variety of spreading environments, including oceanic ridge, back-arc basin, and island arcs above a subduction zone, and subsequently emplaced onto the continents. Their occurrence along plate sutures marks the sites of ancient tectonic interaction between oceanic and continental crust. Ophiolites provide the best opportunity for geologists to study the ocean floor on land; they also offer vertical sections in addition to horizontal distributions. Moreover, ophiolite formations record the ages of oceanic fragments that escaped, disappearing into subduction zones. [J.Li.; S.Mar.; Y.O.]

Ophiurida An order of Ophiuroidea in which the vertebrae articulate by means of ball-and-socket joints, and the arms, which do not branch, move mainly from side to side and do not coil in the vertical plane. The disk and arms are usually sheathed in regularly arranged plates. These are disposed in four series on the arms, namely, one dorsal, one ventral, and two lateral. There is a single madreporite. The order embraces most of the known genera of brittle stars and includes 13 families. *See* OPHIUROIDEA. [H.B.F.]

Ophiuroidea A subclass of the Asterozoa, known as the brittle stars, in which the arms are usually clearly demarcated from a central disk and perform whiplike locomotor movements, and the tube feet are nonsuctorial sensory tentacles. In all existing ophiuroids the ambulacral plates fuse together in pairs to form articulating joints termed vertebrae, and the ambulacral groove is converted into an internal epineural canal.

There are about 1900 extant species referred to 230 genera, arranged to form 3 orders: Oegophiurida, Phrynophiurida, and Ophiurida. There is also one Paleozoic order, the Stenurida. *See* OEGOPHIURIDA; OPHIURIDA; PHRYNOPHIURIDA; STENURIDA.

Ophiuroids are usually five-armed, with a few species being regularly six- or seven-armed. In some Euryalae the arms may branch repeatedly; these are the so-called basket fishes, Tropical species are often patterned in contrasting colors, but most ophiuroids tend to match their environment. Some species are luminescent, although not constantly so.

Ophiuroids occur in all the oceans from low-tide level downward, often in dense populations which number millions to the hectare. Six families range below a depth of 2 mi (3.2 km); the genera *Ophiura*, *Amphiophiura*, and *Ophiacantha* range below 4 mi (6.4 km). The shallow-water forms hide among algae, under stones, or within sponges or bury the disk in sand or mud, leaving only the arms protruding. Deep-water forms lie in or on the bottom material or adhere to corals or cidarids. [H.B.F.]

Opiates Drugs derived from opium, the dried juice of the oriental poppy seed. The pharmacologically active substances, which constitute approximately 25% of the extract, are the alkaloids morphine, codeine, and papaverine. The newer synthetic compounds which resemble morphine in their action are called opioids.

The principal effect of opium and opioids is to relieve pain. Even today morphine remains the best analgesic. It also assuages anxiety and causes slight drowsiness, relaxation, and a euphoric state of mind. These psychic effects are so agreeable that many troubled individuals seek solace by ingesting, smoking, or injecting opiates. *See* MORPHINE.

Codeine has an action similar to morphine, but its analgesic effects are less. Papaverine has almost no analgesic action, and is used as an antispasmodic to relieve vascular spasm and undesirable contraction of smooth muscle. *See* ANALGESIC; NARCOTIC. [R.D.A.]

Opilioacariformes The smallest and most primitive of the three orders of Acari, comprising only one suborder, the Notostigmata, and one family, the Opilioacaridae. These mites are characterized by the possession of a pretarsus, or apotele, on the pedipalp, with prominent claws, which are usually relatively unmodified and paired like those on the legs. There are two pairs of eyes on the propodosoma, above the second pair of legs. *See* ACARI. [J.H.C.]

Opiliones The harvestmen or daddy longlegs, an order of the class Arachnida; sometimes known as Phalangida. About 4500 species are known. They are common in temperate and tropical climates. Most are red, brown, or black and 5–20 mm (0.2–0.8 in.) long, although a few are only 1–2 mm (0.04–0.08 in.). Some large tropical species have bright iridescent colors and elaborate spines.

The cephalothorax (prosoma) is broadly attached to the segmented abdomen (opisthosoma). The center of the cephalothoracic shield (carapace) bears a tubercle with a simple eye on each side. Many have scent glands opening on the sides which produce repellent fluids with strong odors, possibly phenols or quinones. The six pairs of appendages include relatively small chelate chelicerae (jaws), leglike (usually) pedipalps, and four pairs of legs. The legs may be very long and slender, the distal ends being able to wrap around plant stalks.

Harvestmen are predators of small invertebrates or may scavange or eat decaying vegetation. Respiration is by means of tracheae (thin tubes), which open through spiracles on the abdomen; there may be additional spiracles on the legs.

The group is divided into three suborders: the mitelike Cyphophthalmi; the tropical Laniatores with strong pedipalps, and some species adapted for cave life; and the long-legged Palpatores, the most common opilionids in temperate areas. *See* ARACHNIDA. [H.W.L.]

Opisthobranchia A subclass in the class Gastropoda containing about 4000 living species, arranged in nine orders, including the herbivorous Aplysiomorpha (sea hares) and Sacoglossa and the carnivorous Thecosomata (sea butterflies) and Nudibranchia (sea slugs). Primitive members of many of the orders show adaptations for burrowing beneath sand or mud; more advanced members are always active surface-living or pelagic forms. This trend is accompanied by a decrease in the importance of the shell and operculum for passive defense. These are replaced by more dynamic chemical (some species secrete decinormal sulfuric acid through the skin if annoyed), physical (daggerlike calcareous epidermal spicules), or biological (redirected nematocysts derived from coelenterate prey) defensive mechanisms.

The adult shells of the primitive opisthobranchs living today are often strongly developed and sometimes colorful; a more typical opisthobranch shell is fragile, inflated, and egg-shaped. In rather more advanced forms, the external shell has a very wide gape, and in animals like *Berthella* the widely gaping shell is wholly internal, covered by the mantle. The most varied shells are found in the Sacoglossa. In the highest sacoglossans, some bullomorphs and aplysiomorphs, and in all the nudibranchs, the true shell is completely lost after larval metamorphosis. *See* GASTROPODA; MOLLUSCA; NUDIBRANCHIA; SACOGLOSSA. [T.E.T.]

Opisthocomiformes A small order of birds that contains the single family Opisthocomidae. Its one species, the hoatzin, is restricted to South America and has frequently been included in the Galliformes as a suborder. One group of scientists claims that it is simply a cuckoo, Cuculidae, and not a very aberrant one. In the absence of definite evidence of its relationship, it will be treated here as a distinct order.

The hoatzin is a unique bird, often considered rather reptilian because of the habits of the nearly unfeathered young, which leave the nest soon after birth to crawl about trees by using the clawed wings as well as the feet. The hoatzins are also adept swimmers, capable of surviving a fall into water. They are medium-sized birds of dark brown plumage streaked with white; a distinct crest of reddish-brown feathers tops the head, which is small and has a short, stout bill. The wings are long and rounded, the legs short with strong toes; the long hallux is on the same level as the anterior toes. Hoatzins are weak fliers, but they are arboreal, clambering about in trees to feed on leaves and fruit. Hoatzins are found in the forests of northern South America, especially along rivers and streams.

The hoatzins are known in the fossil record only by the Miocene *Hoazinoides* from Colombia, a typical form that reveals nothing about the evolutionary history of the order. *See* AVES. [W.J.B.]

Opossum Any member of the family Didelphidae in the order Marsupialia which includes about 65 species found in the New World. These mammals are arboreal and are mainly omnivorous.

The common opossum (*Didelphis marsupialis*) is an extremely adaptable mammal that ranges from Argentina through Central America into the United States. The uterine gestation period is quite short, about 12 days, and the young are born no larger than a bee. They then make their way through the mother's fur to the pouch (marsupium), where they remain and continue to develop for as long as 100 days. There may be two litters of 9–12 each year. The opossum is a sedentary animal and the adults, living in solitary pairs, rarely leave their territory. *See* MARSUPIALIA. [C.B.C.]

Opportunistic infections Infections that cause a disease only when the host's immune system is impaired. The classic opportunistic infection never leads to disease in the normal host. The protozoon *Pneumocystis carinii* infects nearly everyone at some point in life but never causes disease unless the immune system is severely depressed. The most common immunologic defect associated with pneumocystosis is acquired immune deficiency syndrome (AIDS). *See* ACQUIRED IMMUNE DEFICIENCY SYNDROME (AIDS).

A compromised host is an individual with an abnormality or defect in any of the host defense mechanisms that predisposes that person to an infection. The altered defense mechanisms or immunity can be either congenital, that is, occurring at birth and genetically determined, or acquired. Congenital immune deficiencies are relatively rare. Acquired immunodeficiencies are associated with a wide variety of conditions such as (1) the concomitant presence of certain underlying diseases such as cancer, diabetes, cystic fibrosis, sickle cell anemia, chronic obstructive lung disease, severe burns, and cirrhosis of the liver; (2) side effects of certain medical therapies and drugs such as corticosteroids, prolonged antibiotic usage, anticancer agents, alcohol, and nonprescribed recreational drugs; (3) infection with immunity-destroying microorganisms such as the human immunodeficiency virus that leads to AIDS; (4) age, both old and young; and (5) foreign-body exposure, such as occurs in individuals with prosthetic heart valves, intravenous catheters, and other indwelling prosthetic devices.

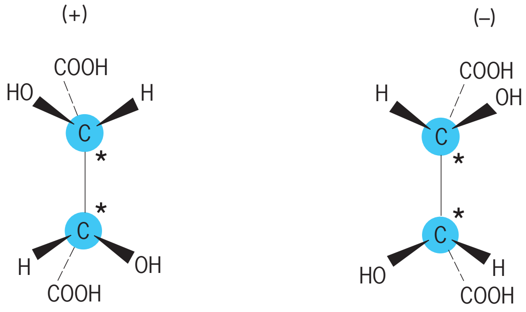
Virtually any microorganism can become an opportunist. The typical ones fall into a number of categories and may be more likely to be associated with a specific immunologic defect. Examples include (1) gram-positive bacteria: both *Staphylococcus aureus* and the coagulase-negative *S. epidermidis* have a propensity for invading the skin and as well as catheters and other foreign implanted devices; (2) gram-negative bacteria: the most common is *Escherichia coli* and the most lethal is *Pseudomonas aeruginosa*; these pathogens are more likely to occur in cases of granulocytopenia (granulocyte deficiency, as occurs in leukemia or chemotheraphy; (3) acid-fast bacteria: *Mycotuberculum tuberculosis* is more likely to reactivate in the elderly and in those individuals with underlying malignancies and AIDS; (4) protozoa: defects in cell-mediated immunity, such as AIDS, are associated with reactivated infection with *Toxoplasma gondii* and *Cryptosporidium*; (5) fungi: *Cryptococcus neoformans* is a fungus that causes meningitis in individuals with impaired cell-mediated immunity such as AIDS, cancer, and diabetes; *Candida albicans* typically causes blood and organ infection in individuals with granulocytopenia. *See* CELLULAR IMMUNOLOGY; ESCHERICHIA; MEDICAL MYCOLOGY; STAPHYLOCOCCUS; TUBERCULOSIS.

The first step in treatment of opportunistic infections involves making the correct diagnosis, which is often difficult as many of the pathogens can mistakenly be thought of as benign. The second step involves administration of appropriate antimicrobial agents. As a third step, if possible, the underlying immune defect needs to be corrected. *See* IMMUNOLOGICAL DEFICIENCY; INFECTION; MEDICAL BACTERIOLOGY. [R.Mur.]

Opsonin A term used in serology and immunology to refer to a substance that enhances the phagocytosis of bacteria by leukocytes. Opsonin is generally synonymous with the bacteriotropin of F. Neufeld and coworkers (1904–1905), a relatively thermostable antibody, increased in amount during specific immunization, that renders the corresponding bacterium more susceptible to phagocytosis. There is evidence that this action can be promoted to some extent by antibody alone, but that it is substantially increased by the further addition of the thermolabile complement system. *See* AGGLUTINATION REACTION; ANTIBODY; LYTIC REACTION; NEUTRALIZATION REACTION (IMMUNOLOGY); PHAGOCYTOSIS; PRECIPITIN; SERUM. [H.P.T.]

Optical activity The effect of asymmetric compounds on polarized light. To exhibit this effect, a molecule must be nonsuperimposable on its mirror image, that is, must be related to its mirror image as the right hand is to the left hand. An optically active compound and its mirror image are called enantiomers or optical isomers (see illustration). Enantiomers differ only in their geometric arrangements; they have identical chemical and physical properties. The right-handed and left-handed forms of a molecule can be distinguished only by their optical activity or by their interactions with other asymmetric molecules. Optical activity can be used to probe other aspects of molecular geometry, as well as to identify which enantiomer is present and its purity.

The physical basis of optical activity is the differential interaction of asymmetric substances with left versus right circularly polarized light. If solids and substances in strong magnetic fields are excluded, optical activity is an intrinsic property of the



Enantiomers of tartaric acid.

molecular structure and is one of the best methods of obtaining structural information from a sample in which the molecules are randomly oriented. The relationship between optical activity and molecular structure results from the interaction of polarized light with electrons in the molecule. Thus the molecular groups that contribute most directly to optical activity are those that have mobile electrons which can interact with light. Such groups are called chromophores, since their absorption of light is responsible for the color of objects. For example, the chlorophyll chromophore makes plants green. *See* FARADAY EFFECT; POLARIZED LIGHT; STEREOCHEMISTRY.

Optical activity is measured by two methods, optical rotation and circular dichroism. The optical rotation method depends on the different velocities of left and right circularly polarized light beams in the sample. The velocities are not measured directly, but both beams are passed through the sample simultaneously. This is equivalent to using plane-polarized light. The differing velocities of the left and right circularly polarized components yield a rotation of the plane of polarization. Circular dichroism is the difference in absorption of left and right circularly polarized light. Since this difference is about a millionth of the absorption of either polarization, special techniques are needed to determine it accurately. Circular dichroism is reported as a difference in absorption, or as an ellipticity (a measure of the elliptical polarization of the emergent beam). [V.M.]

Optical bistability

A phenomenon exhibited by certain resonant optical structures whereby it is possible to have two stable steady transmission states for the device, depending upon the history of the input. Such a bistable device may be useful for optical computing elements because of its memory characteristics. The bistability can result from the intrinsic properties of the optical device or from some external feedback such as an electrical voltage supplied by another device. This second type, extrinsic or hybrid optical bistability, is not true optical bistability.

Optical bistability is an inherently steady-state phenomenon, and typically any cycling of the device through its hysteresis cycle must be done adiabatically; that is, changes in the propagating light amplitude, envelope phase, and profile must occur sufficiently slowly that their impact on the evolution of the system may be neglected. This requirement imposes some rather severe frequency-response limitations on the use of intrinsically bistable devices in optical circuits. The two primary types of intrinsic optical bistability, each arising from a distinct physical mechanism, are absorptive bistability and refractive bistability. *See* ADIABATIC PROCESS; HYSTERESIS.

Absorptive optical bistability is based upon coupling the feedback mechanism inherent in an optical cavity with an absorbing nonlinear optical medium in which the absorption coefficient decreases with increasing light intensity (a saturable absorber). The basic theory of operation is: the saturable absorber is placed in the cavity, and the cavity is resonantly pumped. For low light intensities, the transmission coefficient for the cavity is small because of the presence of the highly absorbing medium inside the cavity. As the pump intensity is increased, the absorption of the nonlinear medium decreases. Finally, for some threshold pump intensity, the cavity switches into a high transmission state, because the absorption coefficient is reduced sufficiently that the intrinsic cavity feedback mechanism dominates. The threshold is very sharp because, when the cavity is in a highly transmittive state, the built-up intensity inside the cavity becomes very large compared to the pump intensity (due to the feedback) and effectively bleaches virtually all of the absorption in the nonlinear medium. The intense pump is then largely transmitted, although some energy is stored in the cavity to bleach the absorber. *See* ABSORPTION OF ELECTROMAGNETIC RADIATION; LASER; OPTICAL PUMPING.

This device exhibits two characteristics that constrain its usefulness in particular applications. (1) The device is based on an absorption mechanism, so the energy absorbed from the pump light must be dissipated in the bistable element or heat-sinked elsewhere. (2) It is highly frequency-sensitive because its operation is based on the switching characteristics of a resonant cavity.

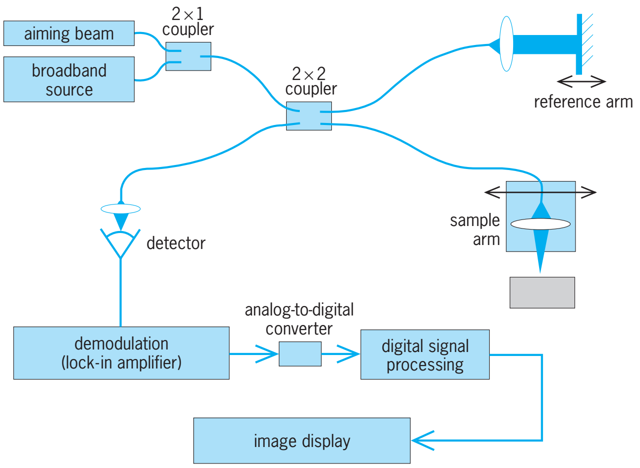
Refractive optical bistability is based on coupling the feedback mechanism inherent in an optical cavity with a nonlinear optical medium that exhibits a change in the refractive index as a function of light intensity. The nonlinear refractive medium is placed inside the optical cavity, and the cavity is pumped slightly off-resonance so that the transmission coefficient is small compared to unity. However, a small amount of light intensity does exist inside the cavity, and changes the effective optical path length inside the cavity by inducing change in the refractive index of the nonlinear medium. As the pump intensity is increased, this change in the effective path length becomes larger, until at some point the cavity switches into, and possibly past, resonance. The transmission coefficient switches abruptly to a value close to unity, and the built-up intensity inside the cavity increases abruptly. If the pump intensity is increased further, it is possible to switch the cavity through a second resonance, with an additional threshold in the transmission coefficient. *See* REFRACTION OF WAVES.

The most common implementation scheme for a bistable optical device is the nonlinear Fabry-Perot etalon. The device is typically fabricated from a semiconductor, and consists of a slab of material of approximately 1 micrometer thickness. On each surface of the semiconductor, a highly reflective coating may be deposited to increase the bandwidth of the Fabry-Perot cavity. The choice of a proper nonlinear material is based upon the operating wavelength and the temporal response time desired, and possibly other considerations. Typically for applications in the far-infrared, near-infrared, and visible wavelengths, the proper materials are indium antimonide (InSb), gallium arsenide (GaAs), and zinc selenide (ZnSe), respectively. *See* INTERFEROMETRY. [D.R.A.]

Optical coherence tomography

Optical coherence tomography (OCT) is a recently developed, noninvasive technique for imaging subsurface tissue structure with micrometer-scale resolution. The principles of time gating, optical sectioning, and optical heterodyning are combined to allow cross-sectional imaging. Depths of 1–2 mm (0.04–0.08 in.) can be imaged in turbid tissues such as skin or arteries; greater depths are possible in transparent tissues such as the eye. Optical coherence tomography complements other imaging modalities commonly used to image subsurface tissue structure, including ultrasound and confocal microscopy.

Principles of operation. In a typical optical coherence tomography system (see illustration), light from a broadband, near-infrared source and a visible aiming beam is combined and coupled into one branch of a fiber-optic Michelson interferometer. Broadband sources include superluminescent diodes, fiber amplifiers, and femtosecond pulse lasers in the wavelength range of 800–1550 nanometers. The light is split into two fibers using a 2 × 2 coupler, one leading to a reference mirror and the second focused into the tissue. Light reflects off the reference mirror and



Typical optical coherence tomography system, based on a broadband source and fiber-optic Michelson interferometer.

is recoupled into the fiber leading to the mirror. Concurrently, light is reflected from index-of-refraction mismatches in the tissue and recoupled into the fiber leading to the tissue. Reflections result from changes in the index of refraction within the structure of the tissue, for instance between intercellular fluid and collagen fibers. Light that has been back-reflected from the tissue and light from the reference arm recombine within the 2 × 2 coupler.

Because the broadband source has a short coherence length, only light which has traveled very close to the same time (or optical path length) in the reference and tissue arms will interfere constructively and destructively. By changing the length of the reference arm, reflection sites at various depths in the tissue can be sampled. The depth resolution of the optical coherence tomography system is determined by the effectiveness of this time gating and hence is inversely proportional to the bandwidth of the source. An optical detector in the final arm of the Michelson interferometer detects the interference between the reference and tissue signals. During optical coherence tomography imaging, the reference-arm mirror is scanned at a constant velocity, allowing depth scans (analogous to ultrasound A-scans) to be made. Either the tissue or the interferometer optics is mounted on a stage so that the beam can be scanned laterally across the tissue to build up two- and three-dimensional images, pixel by pixel.

Variations. Several instruments have been built based on variations of the basic optical coherence tomography system. For instance, polarization-sensitive optical coherence tomography uses polarization-altering optics in the arms of the interferometer to determine the sample birefringence from the magnitude of the back-reflected light. Optical coherence microscopy uses a system of high numerical aperture to achieve resolutions comparable to confocal microscopy but with increased depth of penetration. Color Doppler optical coherence tomography (CDOCT) is an augmentation capable of simultaneous blood flow mapping and spatially resolved imaging.

Applications. Optical coherence tomography can be used to probe the structure of any accessible tissue. Noninvasive studies of the eye and skin are being performed, and a commercial device has been developed for retinal imaging. Using optical coherence tomography, parameters such as eye length can be accurately measured, and the cross-section images of the retina give a clear and quantifiable assessment of retinal separation and macular degeneration, among other pathologies. In skin, the morphology of normal skin layers and components, and disorders such as psoriasis, can be imaged. *See* COHERENCE; COMPUTERIZED TOMOGRAPHY; CONFOCAL MICROSCOPY; DOPPLER EFFECT; FIBER-OPTICS IMAGING; HETERODYNE PRINCIPLE; INTERFEROMETRY; MEDICAL ULTRASONIC TOMOGRAPHY; ULTRASONICS. [J.K.Ba.]

Optical communications The transmission of speech, data, video, and other information by means of the visible and the infrared portion of the electromagnetic spectrum.

Optical communication is one of the newest and most advanced forms of communication by electromagnetic waves. In one sense, it differs from radio and microwave communication only in that the wavelengths employed are shorter (or equivalently, the frequencies employed are higher). However, in another very real sense it differs markedly from these older technologies because, for the first time, the wavelengths involved are much shorter than the dimensions of the devices which are used to transmit, receive, and otherwise handle the signals.

The advantages of optical communication are threefold. First, the high frequency of the optical carrier (typically of the order of 300,000 GHz) permits much more information to be transmitted over a single channel than is possible with a conventional radio or microwave system. Second, the very short wavelength of the optical carrier (typically of the order of 1 micrometer) permits the realization of very small, compact components. Third, the highest transparency for electromagnetic radiation yet achieved in any solid material is that of silica glass in the wavelength region 1–1.5 μm. This transparency is orders of magnitude higher than that of any other solid material in any other part of the spectrum. *See* ELECTROMAGNETIC RADIATION; LIGHT.

Optical communication in the modern sense of the term dates from about 1960, when the advent of lasers and light-emitting diodes (LEDs) made practical the exploitation of the wide-bandwidth capabilities of the light wave. *See* LASER; LIGHT-EMITTING DIODE; OPTICAL FIBERS.

Optical fiber communications. With the development of extremely low-loss optical fibers during the 1970s, optical fiber communication became a very important form of telecommunication almost instantaneously. For fibers to become useful as light waveguides (or light guides) for communications applications, transparency and control of signal distortion had to be improved dramatically and a method had to be found to connect separate lengths of fiber together.

The transparency objective was achieved by making glass rods almost entirely of silica. These rods could be pulled into fibers at temperatures approaching 3600°F (2000°C).

Reducing distortion over long distances required modification of the method of guidance employed in early fibers. These early fibers (called step-index fibers) consisted of two coaxial cylinders (called core and cladding) which were made of two slightly different glasses so that the core glass had a slightly higher index of refraction than the cladding glass. By reducing the core size and the index difference in a step-index fiber, it is possible to reach a point at which only axial propagation is possible. In this condition, only one mode of propagation exists. These single-mode fibers can transmit in excess of 10^{11} pulses per second over distances of several hundred miles. *See* WAVEGUIDE.

The problem of joining fibers together was solved in two ways. For permanent connections, fibers can be spliced together by carefully aligning the individual fibers and then epoxying or fusing them together. For temporary connections, or for applications in which it is not desirable to make splices, fiber connectors have been developed.

Almost every major metropolitan area in the United States has a light-wave transmission system in service connecting telephone central offices. These systems typically operate at a wavelength of either 1.3 or 1.55 μm (where silicon fibers have a minimum loss). It is anticipated that light-wave systems will gradually be installed in the telephone loop plant—that is, the portion of the telephone plant which connects the individual subscriber to the telephone central office. *See* DATA COMMUNICATIONS; FACSIMILE.

Optical transmitters. In principle, any light source could be used as an optical transmitter. In modern optical communication systems, however, only lasers and light-emitting diodes are generally considered for use. The most simple device is the light-emitting diode which emits in all directions from a fluorescent area located in the diode junction. Since optical communication systems usually require well-collimated beams of light, light-emitting diodes are relatively inefficient. On the other hand, they are less expensive than lasers and, at least until recently, have exhibited longer lifetimes.

Another device, the semiconductor laser, provides comparatively well-collimated light. In this device, two ends of the junction plane are furnished with partially reflecting mirror surfaces which form an optical resonator. As a result of cavity resonances, the light emitted through the partially reflecting mirrors is well collimated within a narrow solid angle, and a large fraction of it can be captured and transmitted by an optical fiber.

Both light-emitting diodes and laser diodes can be modulated by varying the forward diode current.

Optical receivers. Semiconductor photodiodes are used for the receivers in virtually all optical communication systems. There are two basic types of photodiodes in use. The most simple comprises a reverse-biased junction in which the received light creates electron-hole pairs. These carriers are swept out by the electric field and induce a photocurrent in the external circuit. The minimum amount of light needed for correct reconstruction of the received signal is limited by noise superimposed on the signal by the following circuits. *See* PHOTODIODE.

Avalanche photodiodes provide some increase in the level of the received signal before it reaches the external circuits. They achieve greater sensitivity by multiplying the photogenerated carriers in the diode junction. This is done by creating an internal electric field sufficiently strong to cause avalanche multiplication of the free carriers. *See* MICROWAVE SOLID-STATE DEVICES; OPTICAL DETECTORS.

Coherent communication. The transmission systems described above are all incoherent systems. That is, the signal is transmitted and detected without making use of the phase of the emitted light. Many lasers are capable of transmitting light with the phase sufficiently stable that coherent techniques such as homodyne and heterodyne detection can be used exactly as they are used for radio detection. Coherent systems offer the potential for a tremendous increase in bandwidth along with a modest increase in sensitivity. *See* HETERODYNE PRINCIPLE; RADIO RECEIVER.

Photonic interconnects. Advances in technology have opened a new application for optical communication; transmission of very large amounts of data over relatively short distances. Devices for this purpose are known as photonic interconnects. These devices are only a few centimeters in length but they are massively parallel; that is, they carry a very large number (millions or even billions) of individual channels from one chip on an integrated circuit board to another chip on the same or near-by board. *See* OPTICAL INFORMATION SYSTEMS. [W.M.Hu.]

Optical detectors

Devices that respond to incident ultraviolet, visible, or infrared electromagnetic radiation by giving rise to an output signal, usually electrical. Based upon the manner of their interaction with radiation, they fall into three categories. Photon detectors are those in which incident photons change the number of free carriers (electrons or holes) in a semiconductor (internal photoeffect) or cause the emission of free electrons from the surface of a metal or semiconductor (external photoeffect, photoemission). Thermal detectors respond to the temperature rise of the detecting material due to the absorption of radiation, by changing some property of the material such as its electrical resistance. Detectors based upon wave-interaction effects exploit the wavelike nature of electromagnetic radiation, for example by mixing the electric-field vectors of two coherent sources of radiation to generate sum and difference optical frequencies. *See* NONLINEAR OPTICAL DEVICES.

The most widely used photon effects are photoconductivity, the photovoltaic effect, and the photoemissive effect. Photoconductivity, an internal photon effect, is the decrease in electrical resistance of a semiconductor caused by the increased numbers of free carriers produced by the absorbed radiation. *See* PHOTOCONDUCTIVE CELL.

The photovoltaic effect, also an internal photoeffect, occurs at a *pn* junction in a semiconductor or at a metal-semiconductor interface (Schottky barrier). Absorbed radiation produces free hole-electron pairs which are separated by the potential barrier at the *pn* junction or Schottky barrier, thereby giving rise to a photovoltage. This is the principle employed in a solar cell. *See* PHOTODIODE; PHOTOVOLTAIC CELL; PHOTOVOLTAIC EFFECT; SEMICONDUCTOR DIODE; SOLAR CELL.

The photoemissive effect, also known as the external photoeffect, is the emission of an electron from the surface of a metal or semiconductor (cathode) into a vacuum or gas due to the absorption of a photon by the cathode. The photocurrent is collected by a positively biased anode. Internal amplification of the photoexcited electron current can be achieved by means of secondary electron emission at internal structures (dynodes). Such a vacuum tube is known as a photomultiplier. Internal amplification by means of an avalanche effect in a gas is employed in a Geiger tube. *See* GEIGER-MÜLLER COUNTER; LIGHT AMPLIFIER; PHOTOELECTRIC DEVICES; PHOTOEMISSION; PHOTOMULTIPLIER; PHOTOTUBE.

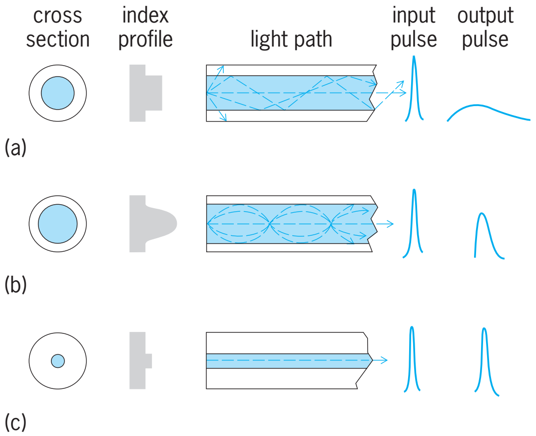
Semiconductors are key to the development of most photon detectors. These materials are characterized by a forbidden energy gap which determines the minimum energy that a photon must have to produce a free hole-electron pair in an intrinsic photoeffect. Since the energy of a photon is inversely proportional to its wavelength, the minimum energy requirement establishes a long-wavelength limit of an intrinsic photoeffect. It is also possible to produce free electrons or free holes by photoexcitation at donor or acceptor sites in the semiconductor; this is known as an extrinsic photoeffect. Here the long-wavelength limit of the photoeffect is determined by the minimum energy (ionization energy) required to photoexcite a free electron from a donor site or a free hole from an acceptor site. *See* SEMICONDUCTOR.

The choice of materials also plays a role in thermal detectors. The most widely used thermal detector is a bolometer, that is, a temperature-sensitive resistor in the form of a thin metallic or semiconductor film (although superconducting films are also used). Incident electromagnetic radiation absorbed by the film causes its temperature to rise, thereby changing its electrical resistance. The change in resistance is measured by passing a current through the film and measuring the change in voltage. Materials with a high temperature coefficient of resistance are desired for bolometers, a criterion which usually favors semiconductors over metals. *See* BOLOMETER. [P.W.K.]

Optical fibers

Flexible transparent fiber devices, sometimes called lightguides, used for either image or information transmission, in which light is propagated by total internal reflection. In simplest form, the optical fiber or lightguide consists of a core of material with a refractive index higher than the surrounding cladding. The optical fiber properties and requirements for image transfer, in which information is continuously transmitted over relatively short distances, are quite different than those for information transmission, where typically digital encoding of information into on-off pulses of light (on = 1, off = 0) is used to transmit audio, video, or data over much longer distances at high bit rates. Another application for optical fibers is in sensors, where a change in light transmission properties is used to sense or detect a change in some property, such as temperature, pressure, or magnetic field. *See* FIBER-OPTIC SENSOR; FIBER-OPTICS IMAGING; OPTICAL COMMUNICATIONS; REFLECTION OF ELECTROMAGNETIC RADIATION; REFRACTION OF WAVES.

There are three basic types of optical fibers. Propagation in these lightguides is most easily understood by ray optics, although the wave or modal description must be used for an exact description. In a multimode, stepped-refractive-index-profile fiber (illus. *a*), the number of rays or modes of light which are guided, and thus the amount of light power coupled into the



Types of optical fiber designs. (*a*) Multimode, stepped-refractive-index-profile. (*b*) Multimode, graded- index-profile. (*c*) Single-mode, stepped-index. Graded-index is possible.

lightguide, is determined by the core size and the core-cladding refractive index difference. Such fibers, used for conventional image transfer, are limited to short distances for information transmission due to pulse broadening. An initially sharp pulse made up of many modes broadens as it travels long distances in the fiber, since high-angle modes have a longer distance to travel relative to the low-angle modes. This limits the bit rate and distance because it determines how closely input pulses can be spaced without overlap at the output end.

A graded-index multimode fiber (illus. *b*), where the core refractive index varies across the core diameter, is used to minimize pulse broadening due to intermodal dispersion. Since light travels more slowly in the high-index region of the fiber relative to the low-index region, significant equalization of the transit time for the various modes can be achieved to reduce pulse broadening. This type of fiber is suitable for intermediate-distance, intermediate-bit-rate transmission systems. For both fiber types, light from a laser or light-emitting diode can be effectively coupled into the fiber. *See* LASER; LIGHT-EMITTING DIODE.

A single-mode fiber (illus. *c*) is designed with a core diameter and refractive index distribution such that only one fundamental mode is guided, thus eliminating intermodal pulse-broadening effects. Material and waveguide dispersion effects cause some pulse broadening, which increases with the spectral width of the light source. These fibers are best suited for use with a laser source in order to efficiently couple light into the small core of the lightguide and to enable information transmission over long distances at very high bit rates. *See* WAVEGUIDE.

A special class of single-mode fibers comprises polarization-preserving fibers. In an ideal, perfectly circular single-mode fiber core, the polarization state of the propagating light is preserved, but in a real fiber various imperfections can cause birefringence; that is, the two orthogonally polarized modes of the fundamental mode travel at different speeds. For applications such as sensors, where controlling the polarization is important, polarization-maintaining fibers can be designed that deliberately introduce a polarization. This is typically accomplished by using noncircular cores (shape birefringence) or by introducing asymmetric stresses (stress-induced birefringence) on the core. *See* BIREFRINGENCE; PHOTOELASTICITY; POLARIZED LIGHT.

The attenuation or loss of light intensity is an important property of the lightguide since it limits the achievable transmission distance, and is caused by light absorption and scattering. Optical fibers based on silica glass have an intrinsic transmission window at near-infrared wavelengths with extremely low losses. Glass fibers, intrinsically brittle, are coated with a protective plastic to preserve their strength. *See* OPTICAL MATERIALS. [S.R.N.]

Optical flat A disk of high-grade quartz glass approximately $^{3}/_{4}$ in. (2 cm) thick, having at least one side ground and polished with a deviation in flatness usually not exceeding 50 nanometers all over, and a surface quality of 5 microfinish or less. When two surfaces of this quality are placed lightly together so that the air is not wrung out from between them, they are separated by a film of air and actually touch at only one point. This point is the vertex of a wedge of air separating the two pieces.

If parallel beams of light pass through the flat, part will be reflected against the surface being inspected, while part will be reflected directly back through the flat. Because the distance between the surfaces is constantly increasing along the angle, the beams reflected from the flat and the beams reflected from the workpiece will alternately reinforce and interfere with each other, producing a pattern of alternate light and dark bands (see illustration). Each succeeding full band from a point of contact means the distance between surfaces is one wavelength thicker. If the light is relatively monochromatic, the wavelength is known. Red with a wavelength of 295 nm is commonly used. Thus a definite relationship is established between lineal measurement and light waves. Optical flats are used for two general purposes, determination of surface contour and comparison of lineal measurement. [R.A.B.]

Optical flat being used to determine flatness of seal ring. Interference bands on seal ring face show lines of constant depth. (*Van Keuren Co.*)

Optical guided waves Optical-frequency electromagnetic waves confined within an optical waveguide, a structure designed to carry such waves from one place to another somewhat as a pipe carries water. Optical waveguides confine light by the method of total internal reflection. (The terms optical and light are used here in the broadest sense to include visible and near-infrared electromagnetic radiation.) The demonstrations of the first semiconductor laser and the first low-loss glass optical fiber initiated a technological revolution. *See* REFLECTION OF ELECTROMAGNETIC RADIATION.

Because of the high data rates that can be achieved, the transmission of information in the form of optical guided waves confined within an optical-fiber waveguide has become the preferred method for the telecommunications industry. The optical fiber consists of two concentric glass cylinders. The inner core region is made of a glass that has a slightly higher index of refraction than the outer cladding region, as required for total internal reflection to occur. Core diameters in the range of 4–50 micrometers are used routinely to carry near-infrared optical radiation. Pulses of light with wavelengths between 0.8 and 1.55 μm are injected into the fiber on the near end. The presence or absence of a pulse is interpreted as a one or a zero by a receiver on the far end, typically many miles (kilometers) away. *See* OPTICAL COMMUNICATIONS; OPTICAL FIBERS.

Devices such as semiconductor lasers make use of optical guided waves over distances much shorter than those spanned by optical fibers. In a semiconductor laser, a planar waveguide also serves as an electrically driven amplifying medium. Gallium arsenide (GaAs), aluminum gallium arsenide (AlGaAs), or indium gallium arsenide phosphide (InGaAsP) are common examples of semiconductor laser materials. When mirrors are formed on the ends of the semiconductor waveguide, typically a few hundred micrometers apart, light travels back and forth between those mirrors just as with any laser, but in the form of optical guided waves. *See* LASER.

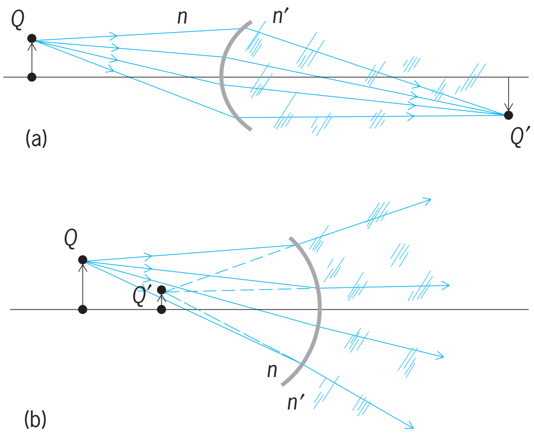
Optical waveguides are the basic constituents of an emerging technology known variously as integrated optics, integrated optoelectronics, or photonic integrated circuits. This technology integrates optical and electronic components into or on an optical waveguide. The aim is to process and manipulate light while it is trapped as optical guided waves within the confines of the optical waveguide. *See* INTEGRATED OPTICS; WAVEGUIDE. [D.G.H.]

Optical image The image formed by the light rays from a self-luminous or an illuminated object that traverse an optical system. The image is said to be real if the light rays converge to a focus on the image side and virtual if the rays seem to come from a point within the instrument (see illustration).

The optical image of an object is given by the light distribution coming from each point of the object at the image plane of an optical system. The ideal image of a point according to geometrical optics is obtained when all rays from an object point unite in a single image point. However, diffraction theory teaches that even in this case the image is not a point but a minute disk. *See* DIFFRACTION.

From the standpoint of geometrical optics, if this most desirable type of image formation cannot be achieved, the next best objective is to have the image free from all but aperture errors (spherical aberration). In this case the light distribution in the image plane is still circular, resembling the point image; there is a true coordination of object point and image, although the image may be slightly unsharp. If the aperture errors are small, or if the image is viewed from a distance, such an image formation may be very satisfactory. *See* ABERRATION (OPTICS).

Asymmetry and deformation errors may be very disturbing if not held in check, because the light distribution of the image of a point in this case has a decidedly undesirable shape. [M.J.H.]



Optical images. (*a*) Real image. Rays leaving object point *Q* and passing through the refracting surface separating media *n* and *n*′ are brought to a focus at the image point *Q*′. (*b*) Virtual image. Rays leaving *A* and refracted by the concave surface separating *n* and *n*′ appear to be coming from the virtual image point *Q*′. As the rays are diverging, they cannot be focused at any point. (*Modified from F. A. Jenkins and H. E. White, Fundamentals of Optics, 4th ed., McGraw-Hill, 1976*)

Optical information systems Systems that use light to process information. Optical information systems or processors consist of one or several light sources; one- or two-dimensional planes of data such as film transparencies, various lenses, and other optical components; and detectors. These elements can be arranged in various configurations to achieve different data-processing functions. As light passes through various data planes, the light distribution is spatially modulated proportional to the information present in each plane. This modulation occurs in parallel in one or two dimensions, and the processing is performed at the speed of light. Optical processors offer various advantages compared to other technologies: data travels at the speed of light; all data in one-dimensional and two-dimensional arrays are operated on in parallel; multiple planes of data can be processed in parallel by various multiplexing schemes; it is possible to have large numbers of interconnections with no interaction (which is not possible with electrical connections); and power dissipation is less and size and weight can be less for optical processors than for their electronic counterparts. *See* CONCURRENT PROCESSING; MULTIPLEXING AND MULTIPLE ACCESS.

In practice, the processing speed is limited by the rate at which data can be introduced into the system and the rate at which processed data (produced on output detector arrays) can be analyzed. The reusable real-time spatial light modulators used to produce new input data, filters, interconnections, and so forth, are the major components required for these optical information-processing systems to realize their full potential. Spatial light modulators convert electrical input data into a form suitable for spatially modulating input light, or react to an optical input and generate a different optical output. The manipulation of the light passing through the system is controlled by spatial light modulators, lenses, holographic optical elements, computer-generated holograms, or fiber optics. Four major application areas are image processing, signal processing, computing and interconnections, and neural networks. *See* HOLOGRAPHY; IMAGE PROCESSING; NEURAL NETWORK; OPTICAL FIBERS; OPTICAL MODULATORS. [D.Ca.]

Optical isolator A device that is interposed between two systems to prevent one of them from having undesired effects on the other, while transmitting desired signals between the systems by optical means. Optical isolators are used for both electrical systems and optical systems such as lasers.

An optical isolator for electrical systems is a very small four-terminal electronic circuit element that includes in an integral package a light emitter, a light detector, and, in some devices, solid-state electronic circuits. The emitting and detecting devices are so positioned that the majority of the emission from the emitter is optically coupled to the light-sensitive area of the detector. The device is also known as an optoisolator, optical-coupled isolator, and optocoupler. The device is housed in an integral opaque package so that the only optical emission impinging on the detector is that produced by the emitter. This configuration of components can perform as a solid-state electronic transformer or relay, since an electronic input signal causes an electronic output signal without any electrical connection between the input and the output terminals.

Optical isolators are used in electrical systems to protect humans or machines when high-voltage or high-power equipment is being controlled. In addition, optical isolators are used in electronic circuit design in situations where two circuits have large voltage differences between them and yet it is necessary to transfer small electrical signals between them without changing the basic voltage level of either. [R.D.Co.]

The need for optical isolation has broadened considerably since the advent of lasers. It is often necessary to prevent light from reentering the laser, irrespective of any electrical consideration. One example is a small laser followed by high-power laser amplifiers. If the powerful amplified light reenters the small (master oscillator) laser, it can destroy it. Another example is a frequency-stabilized laser, whose oscillation frequency is perturbed by reentering (injected signal) light.

A polarizer-plus-quarterwave-plate isolator prevents laser light from reentering the laser when the light is scattered back by specular reflectors. This device cannot ensure isolation if there is diffuse reflection or if polarization-altering (birefringent) optics are encountered. Another limitation of this isolator is that the transmitted light is circularly polarized. *See* Birefringence; Polarized light.

In contrast to the quarter-wave polarizer isolator, the Faraday isolator can provide truly one-way transmission irrespective of polarization changes from the exit side if an exit polarizer (which passes light that has undergone the Faraday rotation after passing though the entrance polarizer) is used in addition to the entrance polarizer. For example, it isolates against diffuse reflections and any light source on the exit side. *See* Faraday effect.

The isolation properties of an acoustooptic deflector are based on the fact that light deflected by it is shifted in frequency by an amount equal to the acoustic frequency. The reflected beam, passing through the deflector a second time, is again shifted in frequency by the same amount and in the same sense if the deflector is operated in the Bragg mode. Hence, the reflected light that is returned to the laser is shifted in frequency by an amount $2f$, where f is the frequency of the acoustic wave. Provided the frequency of the light returned to the laser is not close to any resonant frequency of the laser cavity, it will not perturb the laser and will simply be reflected from the output mirror. *See* Acoustooptics. [S.F.J.]

Optical materials All substances used in the construction of devices or instruments whose function is to alter or control electromagnetic radiation in the ultraviolet, visible, or infrared spectral regions. Optical materials are fabricated into optical elements such as lenses, mirrors, windows, prisms, polarizers, detectors, and modulators. These materials serve to refract, reflect, transmit, disperse, polarize, detect, and transform light. The term “light” refers here not only to visible light but also to radiation in the adjoining ultraviolet and infrared spectral regions. At the microscopic level, atoms and their electronic configurations in the material interact with the electromagnetic radiation (photons) to determine the material’s macroscopic optical properties such as transmission and refraction. These optical properties are functions of the wavelength of the incident light, the temperature of the material, the applied pressure on the material, and in certain instances the external electric and magnetic fields applied to the material. *See* Atomic structure and spectra; Dispersion (radiation); Electromagnetic radiation; Electrooptics; Infrared radiation; Lens (optics); Light; Magnetooptics; Mirror optics; Optical detectors; Optical modulators; Optical prism; Polarized light; Reflection of electromagnetic radiation; Refraction of waves; Ultraviolet radiation.

There is a wide range of substances that are useful as optical materials. Most optical elements are fabricated from glass, crystalline materials, polymers, or plastic materials. In the choice of a material, the most important properties are often the degree of transparency and the refractive index, along with each property’s spectral dependency. The uniformity of the material, the strength and hardness, temperature limits, hygroscopicity, chemical resistivity, and availability of suitable coatings may also need to be considered. *See* Hardness scales; Strength of materials.

Glass technology provided the foundation for classical optical elements, such as lenses, prisms, and filters. Glasses developed for use in the visible region have internal transmittances of over 99% throughout the wavelength range of 380–780 nanometers. However, the silicate structure in glasses limits their transmission to about 2.5 micrometers in the infrared. Chalcogenide glasses, heavy-metal fluoride glasses, and heavy-metal oxide glasses extend this transmission to 8–12 μm. *See* Color filter.

Advances in the process for manufacturing optical fibers led to the present fiber-optic communication systems that operate in the near-infrared region with windows at wavelengths of 850, 1310, 1550, and 1625 nm. An advanced fiber-optic system, LEAF (Large Effective Area Fiber), was designed to minimize nonlinearities by spreading the optical power over large areas. *See* Optical communications; Optical fibers; Vapor deposition.

The use of photolithography for printing integrated circuits has necessitated the improvement in the transmission of glasses for the ultraviolet region. Fused silica, which transmits to about 180 nm, is well suited for the lithography in the ultraviolet region. However, the crystalline material calcium fluoride, which transmits into the ultraviolet region to about 140 nm, outperforms any glass in printing microchips using fluorine excimer lasers. Deep-ultraviolet applications of fused-silica glasses include high-energy lasers, spacecraft windows, blanks for large astronomical mirrors, optical imaging, and cancer detection using ultraviolet-laser-induced autofluorescence. *See* Fluorescence; Integrated circuits; Telescope.

The need for an inexpensive, unbreakable lens that could be easily mass-produced precipitated the introduction of plastic optics in the mid-1930s. Although the variety of plastics suitable for precision optics is limited compared to glass or crystalline materials, plastics are often preferred when difficult or unusual shapes, lightweight elements, or economical mass-production techniques are required.

The softness, inhomogeneity, and susceptibility to abrasion intrinsic to plastics often restrict their application. Haze (which is the light scattering due to microscopic defects) and birefringence (resulting from stresses) are inherent to plastics. Plastics also exhibit large variations in the refractive index with changes in temperature. Shrinkage resulting during the processing must be considered. *See* Birefringence; Photoelasticity.

Organic synthetic polymers are emerging as key materials for information technologies. Polymers often have an advantage over inorganic materials because they can be designed and synthesized into compositions and architectures not possible with crystals, glasses, or plastics. They are manufactured to be durable, optically efficient, reliable, and inexpensive. Many uses of polymers in photonic and optoelectronic devices have emerged, including light-emitting diodes, liquid-crystal–polymer photodetectors, polymer-dispersed liquid-crystal devices (for projection television), optical-fiber amplifiers doped with organic dyes (rhodamine), organic thin-film optics, and electrooptic modulators. *See* Light-emitting diode; Liquid crystals.

Although most of the early improvements in optical devices were due to advancements in the production of glasses, the crystalline state has taken on increasing importance. Historically, the naturally occurring crystals such as rock salt, quartz, and fluorite plus suitable detectors permitted the first extension of visible optical techniques to harness the invisible ultraviolet and infrared rays. Synthetic crystal-growing techniques have made available single crystals such as lithium fluoride (of special value in the ultraviolet region, since it transmits at wavelengths down to about 120 nm), calcium fluoride, and potassium bromide (useful as a prism at wavelengths up to about 25 μm in the infrared). Many alkali-halide crystals are important because they transmit into the far-infrared. *See* Crystal growth; Crystal structure; Single crystal.

Following the invention of the transistor, germanium and silicon ushered in the use of semiconductors as infrared optical elements or detectors. Polycrystalline forms of these semiconductors could be fabricated into windows, prisms, lenses, and domes by casting, grinding, and polishing. Compound semiconductors such as gallium arsenide (GaAs), ternary compounds such as gallium aluminum arsenide ($Ga_{1-x}Al_xAs$), and quaternary compounds such as indium gallium arsenide phosphide (InGaAsP) now serve as lasers, light-emitting diodes, and photodetectors. *See* Semiconductor.

Single crystals are indispensable for transforming, amplifying, and modulating light. Birefringent crystals serve as retarders, or wave plates, which are used to convert the polarization state of the light. In many cases, it is desirable that the crystals not only be birefringent, but also behave nonlinearly when exposed to very large fields such as those generated by intense laser beams. A few examples of such nonlinear crystals are ammonium dihydrogen phosphate (ADP), potassium dihydrogen phosphate (KDP), beta barium borate (BBO), lithium borate (LBO), and potassium titanyl phosphate (KTP). *See* CRYSTAL OPTICS; NONLINEAR OPTICS.

Other optical materials are the liquid crystals used in displays as light valves, materials used in erasable optical disks for computers and in liquid cells (Kerr cells), laser dyes, dielectric multilayer films, filter materials, and the many metals (aluminum, gold, beryllium, and so forth) and alloys that are important as coating materials. *See* COMPUTER STORAGE TECHNOLOGY; KERR EFFECT; OPTICAL RECORDING. [J.S.Bro.]

Optical microscope

An instrument used to obtain an enlarged image of a small object. In general, a compound microscope consists of a light source, a condenser, an objective, and an ocular or eyepiece, which can be replaced by a recording device such as a photoelectric tube or a photographic plate. The optical microscope is limited by the wavelengths of the light used and by the materials available for manufacturing the lenses.

Magnifying power. The quality and design of the lens system determines the magnifying power, details of image formation, and color correcting capabilities of a light microscope. The magnifying power of a compound microscope is the product of the magnification of the objective and the magnifying power of the eyepiece. The latter is computed like that of any magnifier. The magnification of the objective is equal to the distance from the second focal point to the image formed by the objective, divided by the focal length. An objective of 18-mm (0.7-in.) focal length thus has a power of 10×. It is customary to specify objectives in terms of magnifying power instead of focal length. The distance mentioned is called the optical tube length (generally 180 mm or 7 in.), and is to be distinguished from the mechanical tube length, which is the length of the mechanical tube itself. *See* MAGNIFICATION.

Catadioptric systems. Catadioptric systems have been developed for microscopes. Their great advantage is their comparatively small chromatic aberration. Pure mirror systems have no color aberrations. In catadioptric systems, therefore, it is customary to assign all the power to the mirror or mirrors, keeping the refracting system nearly afocal (Fig. 1*a*). The chromatic errors of the entire system remain small, and the refracting part can be used to correct the remaining monochromatic errors. All microscopic work in the ultraviolet region is done with catadioptric systems (Fig. 1*b*).

Condensers. An external auxiliary lens is used to condense the light from a light source so that the object is brightly and uniformly illuminated. The usual purpose of a condenser system is to make sure that as much light as possible coming from the object goes through an optical system. Condensers are used in macroscopic projection, in which an illuminated film or slide is imaged with the help of a projection objective or magnifier. In microscope systems, they are used to direct the light from a light source so that the rays from any object point fill most of the entrance pupil. A condenser system is usually arranged to image the light source onto the entrance pupil of the optical system (Köhler illumination). The condenser is generally corrected for spherical aberration, color, and sine condition, although the requirements are slightly different than in an image-forming system. [M.Her.]

Light microscope. The mirror, condenser, oculars, and body tube of the light microscope are frequently known as the optical train. The stand, stage, and adjustments comprise the mechanical part of the microscope.

A mirror is usually attached to the substage of the microscope to reflect light along the optic axis of the microscope. When no condenser is used, the concave mirror is used because it concentrates more light on the specimen; a plane mirror is used with a condenser.

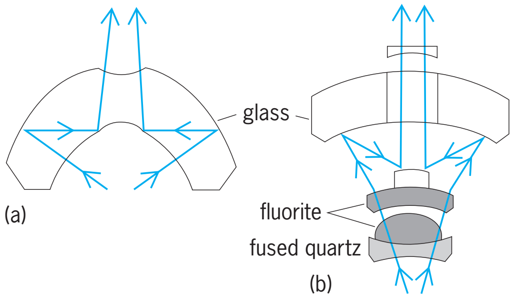


Fig. 1. **Two types of catadioptric objective. (*a*) Maksutov type. (*b*) 53X, NA 0.72, ultraviolet objective, designed by Gray. Glass elements in the latter serve purely as reflectors. (*Photographic Service Department, Kodak Research Laboratory*)**

Objectives vary from a simple doublet lens to complex corrected lens systems. Achromatic objectives are corrected for spherical aberration in one color and for chromatic aberrations in two colors. Apochromatic objectives are corrected to focus three colors together and the spherical aberration is minimized for two colors. The resolving power of an objective, the least distance at which two objects can be seen to be separate, is equal to the wavelength of light λ divided by the sum of the numerical apertures of the condenser and objective used. The larger the numerical aperture, the greater is the resolving power. Objectives are described also by the equivalent focal length. Objectives of shorter focal length have less depth of field, less working distance, and greater magnification.

Photomicrographic objectives are designed to produce a flat image with little distortion. For convenience, two to five objectives can be mounted on a revolving nosepiece to be parfocal and parcentric, so that the specimen remains almost in focus at the center of the field as the objectives are changed.

The commonly used Huygenian ocular has a fairly flat field with marked pincushion distortion. Compensating oculars complete the color correction for apochromatic objectives and have less distortion, but they do have curvature of field. *See* EYEPIECE.

The monocular body tube may be of adjustable length. American microscopes are designed for a mechanical tube length of 160 mm (6.3 in.) and a cover-glass thickness of 0.18 mm (0.007 in.). The draw tube is lengthened for thinner and shortened for thicker cover glasses to correct for the spherical aberrations from cover glasses of incorrect thickness.

Binocular bodies are designed for the use of both eyes. Most binocular bodies use prisms to reflect one-half of the light to each eye. Because each eye sees the same field, these binocular bodies do not give stereoscopic vision. The binocular is often longer than the monocular body and the proper tube length is maintained with a compensating lens.

Inverted microscope. The inverted microscope has the body of the microscope, including the objective and the ocular, below the stage and the illumination above the stage for transmitted light. The inverted microscope is especially useful for the examination of surfaces. Large and awkward specimens can be moved over the stage more readily than with the usual microscope. The inverted microscope is also useful for microdissection and the observation of hanging-drop preparations and is convenient for observing chemical reactions, melting-point determinations, and photomicrography.

Comparison microscope. The comparison microscope is an arrangement of two microscopes connected by a special viewing ocular so that the field of one microscope is seen at one side of a vertical dividing line and the field of the other microscope on the opposite side of the dividing line; or it may be a projection type of microscope in which the image is compared with a template or known pattern.

Dissecting microscope. Dissecting microscopes are of two types. The simplest is a magnifying glass mounted on a support above a glass plate, used for the dissection of materials.

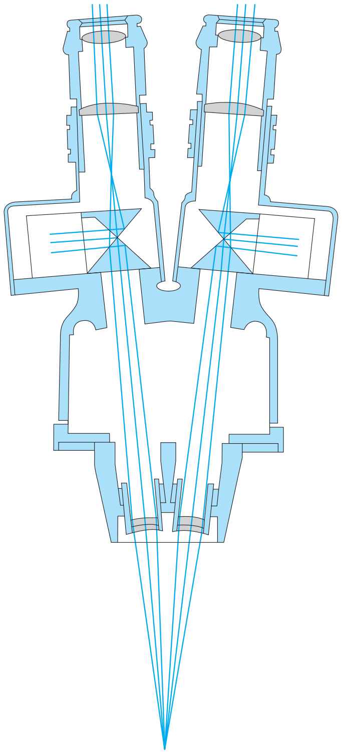

Fig. 2. Diagram of light rays as they pass through a binocular biobjective microscope.

The more usual dissecting microscope, often called a Greenough microscope, is a stereoscopic microscope composed of two separate microscopes fastened together and used as a single unit on one stand (Fig. 2). This is a truly stereoscopic instrument because the right eye sees the specimen from the right side and the left eye from the left side. Prisms are usually included in the body tube to erect the image; thus movements of the specimen are direct and are not reversed as with the monobjective microscope.

Metallurgical microscope. The metallurgical microscope is a laboratory microscope with a focusing stage and a vertical illuminator, used primarily for the examination of metal surfaces.

Near-infrared microscopy. Near-infrared microscopy is an optical method that can be used for studying a variety of materials that are opaque in transmitted visible light (400–700 nm) yet translucent in the near infrared (700–1200 nm). The method utilizes the near-infrared optical microscope, a device for the conversion of the near-infrared image to a visible image. [L.A.H.]

Near-field optical microscopy. A fundamental law of optics, the so-called diffraction limit, states that two objects can be imaged as separate entities only if their distance is larger by about one-half the wavelength of visible light, which ranges from 400 to 700 nm. As a consequence, conventional optical microscopy is restricted to a resolution of about 200 nm, and this is not enough for many important observations. The scanning near-field optical microscope (NSOM or SNOM) circumvents the diffraction limit. In contrast to nonoptical methods of surpassing this limit, such as electron microscopy, it can provide information on such qualities as color, luster, transmissivity, and birefringence, which are sensitive indicators of material composition and status. Furthermore, it operates at ambient conditions, a prerequisite for observations of living organisms. *See* MICROSCOPE. [D.W.Po.]

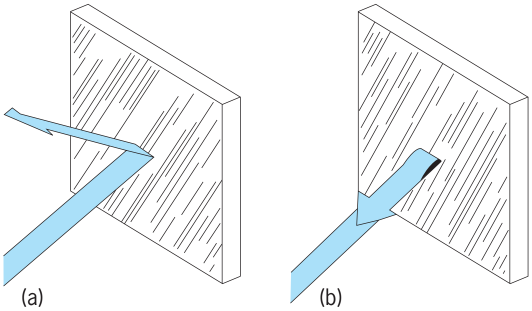
Optical modulators

Devices that serve to vary some property of a light beam. The direction of the beam may be scanned as in an optical deflector, or the phase or frequency of an optical wave may be modulated. Most often, however, the intensity of the light is modulated.

Rotating or oscillating mirrors and mechanical shutters can be used at relatively low frequencies (less than 10^5 Hz). However, these devices have too much inertia to operate at much higher frequencies. At higher frequencies it is necessary to take advantage of the motions of the low-mass electrons and atoms in liquids or solids. These motions are controlled by modulating the applied electric fields, magnetic fields, or acoustic waves in phenomena known as the electrooptic, magnetooptic, or acoustooptic effect, respectively. *See* ACOUSTOOPTICS; ELECTROOPTICS; KERR EFFECT; MAGNETOOPTICS. [I.P.K.]

Optical phase conjugation

A process that involves the use of nonlinear optical effects to precisely reverse the direction of propagation of each plane wave in an arbitrary beam of light, thereby causing the return beam to exactly retrace the path of the incident beam. The process is also known as wavefront reversal or time-reversal reflection. The unique features of this phenomenon suggest widespread application to the problems of optical beam transport through distorting or inhomogeneous media. Although closely related, the field of adaptive optics will not be discussed here. *See* ADAPTIVE OPTICS.



Comparison of reflections (*a*) from a conventional mirror and (*b*) from an optical phase conjugator. (*After V. J. Corcoran, ed., Proceedings for the International Conference on Laser '78 for Optical and Quantum Electronics, STS Press, McLean, Virginia, 1979*)

Optical phase conjugation is a process by which a light beam interacting in a nonlinear material is reflected in such a manner as to retrace its optical path. As the illustration shows, the image-transformation properties of this reflection are radically different from those of a conventional mirror. The incoming rays and those reflected by a conventional mirror (illus. *a*) are related by reversal of the component of the wave vector $\vec{k}$ which is normal to the mirror surface. Thus a light beam can be arbitrarily redirected by adjusting the orientation of a conventional mirror. In contrast, a phase-conjugate reflector (illus. *b*) inverts the vector quantity $\vec{k}$ so that, regardless of the orientation of the device, the reflected conjugate light beam exactly retraces the path of the incident beam. This retracing occurs even though an aberrator (such as a piece of broken glass) may be in the path of the incident beam. Looking into a conventional mirror, one would see one's own face, whereas looking into a phase-conjugate mirror, one would see only the pupil of the eye.

These new and remarkable image-transformation properties (even in the presence of a distorting optical element) open the door to many potential applications in areas such as laser fusion, atmospheric propagation, fiber-optic propagation, image restoration, real-time holography, optical data processing, nonlinear microscopy, laser resonator design, and high-resolution nonlinear spectroscopy. *See* HOLOGRAPHY; LASER; MIRROR OPTICS; NONLINEAR OPTICS; OPTICAL COMMUNICATIONS; OPTICAL FIBERS. [R.A.F.; B.J.F.]

Optical prism A simple component, made of a light-refracting and transparent material such as glass and bounded by two or more plane surfaces at an angle, that is used in optical devices, especially to change the direction of light travel, to accomplish image rotation or inversion, and to disperse light into its constituent colors. Once light enters a prism, it can be reflected one or more times before it exits the prism.

A variety of prisms can be classified according to their function. Some prisms, such as the dove prism, can be used to rotate an image and to change its parity. Image inversion by prisms in traditional binoculars is a typical application. Some prisms take advantage of the phenomenon of total internal reflection to deviate light, such as the right-angle prism and the pentaprism used in single lens reflex cameras. A thin prism is known as an optical wedge; it can be used to change slightly the direction of light travel, and therefore it can be used in pairs as an alignment device. Optical wedges are also use in stereoscopic instruments to allow the viewer to observe the three-dimensional effect without forcing the eyes to point in different directions. A variable wedge can be integrated into a commercial pair of binoculars to stabilize the line of sight in the presence of the user's slight hand movements. Other prisms such as corner-cubes can be used to reflect light backward, and are fabricated in arrays for car and bicycle retroreflectors. *See* Binoculars; Mirror optics; Periscope; Rangefinder (optics); Reflection of electromagnetic radiation.

An important application of a prism is to disperse light. When light enters at an angle to the face of a prism, it is refracted. Since the index of refraction depends on the wavelength, the light is refracted at different angles and therefore it is dispersed into a spectrum of colors. The blue color is refracted more than the red. When light reaches the second face of the prism, it is refracted again and the initial dispersion can be added to or canceled, depending on the prism angle. A combination of prisms in tandem can increase the amount of light dispersion. Dispersing prisms have been used in monochromators and spectroscopic instruments. With two prisms of different materials, it is possible to obtain light deviation without dispersion (an achromatic prism) or dispersion without deviation. *See* Dispersion (radiation); Refraction of waves; Spectroscopy. [J.M.Sa.]

Optical projection systems Optical projection is the process whereby a real image of a suitably illuminated object is formed by an optical system in such a manner that it can be viewed, photographed, or otherwise observed, Essential equipment in an optical projection system consists of a light source, a condenser, an object holder, a projection lens, and (usually) a screen on which the image is formed (Fig. 1). For some important applications of optical projection *see* Cinematography.

The luminance of the image in the direction of observation will depend upon (1) the average luminance of the image of the light source as seen through the projection lens from the image point under consideration, (2) the solid angle subtended by the exit pupil of the projection lens at this image point, and (3) the reflective or transmissive characteristics of the screen. Usually it is desirable to have this luminance as high as possible. Therefore, with a given screen, tens, and projection distance, the best arrangement is to have the light source imaged in the projection lens, with its image filling the exit pupil as completely and as uniformly as possible.

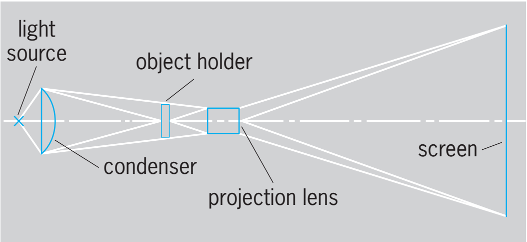


Fig. 1. A simple optical projection system.

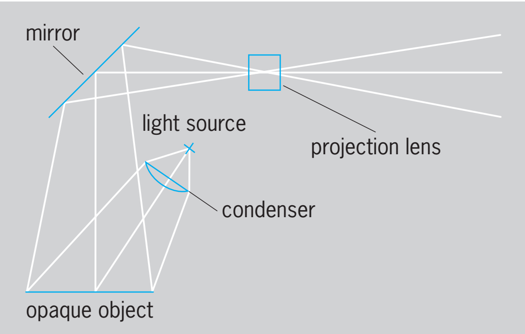

Fig. 2. An epidiascope, or system for projecting an image of an opaque object.

The object is placed between the condenser and the projection lens. If transparent, it can be inserted directly in the light beam; however, it should be positioned, and the optical system should be so designed that it does not vignette (cut off) any of the image of the light source in the projection lens. If the object is opaque, an arrangement known as an epidiascope (Fig. 2) is used. [A.J.H.]

Optical pulses Bursts of electromagnetic radiation of finite duration. Optical pulses are used to transmit information or to record the chronology of physical events. The simplest example is the photographic flash. This was probably first developed by early photographers who used flash powder that, when ignited, produced a short burst of intense light. This was followed by the flash lamp, in which a tube filled with an inert gas such as xenon is excited by a brief electrical pulse. A great advance in the creation of short optical pulses came with the invention of the laser. Lasers are now the most common and effective way of generating a variety of short optical pulses, of different durations, energies, and wavelengths. *See* Laser; Stroboscopic photography.

Pulses of millisecond (10^{-3} s) duration are very simply generated by mechanically modulating a constant light source such as a lamp or a continuous-wave laser. This can be done, for example, by placing a rotating disk with holes in it in front of the light source. Shorter laser pulses, of microsecond (10^{-6} s) or nanosecond (10^{-9} s) duration, are generated by using a technique known as Q-switching. A modulating device is incorporated inside the laser cavity that allows the buildup of the laser radiation inside the cavity and then switches it out in an instant. The modulating device is usually controlled by external electrical pulses. Semiconductor diode lasers, which are used to transmit information (voice or data) over a fiber-optic cable, are pumped by electricity and can be directly pulsed by applying to them a pulsed electrical signal. *See* Optical communications; Optical fibers.

Ultrashort laser pulses, with durations of the order of picoseconds (1 ps $= 10^{-12}$ s) or femtoseconds (1 fs $= 10^{-15}$ s), are generated by using a general principle known as mode locking, whereby several frequency modes of the laser structure are made to resonate simultaneously and with a well-orchestrated relationship so as to form a short-duration pulse at the laser output.

Pulses as short as 11 fs have been produced directly by a passively mode-locked titanium:sapphire laser. The titanium:sapphire laser has also allowed the extension of ultrashort optical pulses to other wavelength ranges, such as the near-infrared (2–10 μm). Dye lasers, based on organic dyes in solution, have achieved durations as short as 27 fs. Ultrashort diode laser pulses have been obtained by active and passive mode locking and produce pulses as short as a few hundred femtoseconds. They are more commonly operated so as to give rise to pulses in the picosecond range, appropriate for optical communication systems.

The generation of ultrashort laser pulses has been motivated by the quest for ever better resolution in the study of the temporal evolution and dynamics of physical systems, events, and processes. Such laser pulses are capable of creating snapshots in time of many events that occur on the atomic or molecular scale, a technique known as time-resolved spectroscopy. This stroboscopic aspect of ultrashort laser pulses is their most important scientific application and is used in physics, engineering, chemistry, and biology. For example, ultrashort pulses can excite and take snapshots of molecular vibrations and deformations. They can track the passage of charge carriers through a microscopic semiconductor device. This ability to understand the dynamics of the more elemental building blocks of nature can in turn make it possible to build ever faster devices for use in information processing and information transmission, in addition to providing a better understanding of the physical world. *See* LASER PHOTOCHEMISTRY; LASER SPECTROSCOPY; OPTICAL INFORMATION SYSTEMS; ULTRAFAST MOLECULAR PROCESSES. [P.C.Be.]

Optical pumping

The process of causing strong deviations from thermal equilibrium populations of selected quantized states of different energy in atomic or molecular systems by the use of optical radiation (that is, light of wavelengths in or near the visible spectrum), called the pumping radiation.

Optical pumping is vital for light amplification by stimulated emission in an important class of lasers. For example, the action of the ruby laser involves the fluorescent emission of red light by a transition from an excited level E_2 to the ground level E_1. In this case E_2 is relatively high above E_1 and the equilibrium population of E_2 is practically zero. Amplification of the red light by laser action requires that number of atoms N_2 exceed N_1 (population inversion). The inversion is accomplished by intense green and violet light from an external source which excites the chromium ion in the ruby to a band of levels, E_3 above E_2. From E_3 the ion rapidly drops without radiation to E_2, in which its lifetime is relatively long for an excited state. Sufficiently intense pumping forces more luminescent ions into E_2 by way of the E_3 levels than remain in the ground state E_1, and amplification of the red emission of the ruby by stimulated emission can then occur. *See* LASER. [W.W.]

Optical recording

The process of recording signals on a medium through the use of light, so that the signals may be reproduced at a subsequent time. Photographic film has been widely used as the medium, but in the late 1970s development of another medium, the so-called optical disk, was undertaken. The introduction of the laser as a light source greatly improves the quality of reproduced signals. The pulse-code modulation (PCM) techniques make it possible to obtain extremely high-fidelity reproduction of sound signals in optical disk recording systems.

Optical film recording. Optical film recording is also termed motion picture recording or photographic recording. A sound motion picture recording system consists basically of a modulator for producing a modulated light beam and a mechanism for moving a light-sensitive photographic film relative to the light beam and thereby recording signals on the film corresponding to the electrical signals. A sound motion picture reproducing system is basically a combination of a light source, an optical system, a photoelectric cell, and a mechanism for moving a film carrying an optical record by means of which the recorded photographic variations are converted into electrical signals of approximately similar form.

In laser-beam film recording, an optical film system utilizes a laser as a light source, a combination of an acoustooptical modulator (AOM) and an acoustooptical deflector (AOD) instead of a galvanometer. A 100-kHz pulse-width modulation (PWM) circuit converts the audio input signal into a PWM signal. The laser beam is made to continuously scan the sound track area at right angles to the direction of the film transport. This is done by means of the acoustooptical deflector, which in turn is driven by a 100-kHz sawtooth signal. Simultaneously, the laser beam is pulse-width-modulated by means of the acoustooptical modulator, which is driven by a 100-kHz PWM signal. The scanning signal and the pulse-width-modulated signal combine and generate the variable-area sound track exposure on the film. The traces of successive scans are fused into a pattern of variable-area recording. [H.D.]

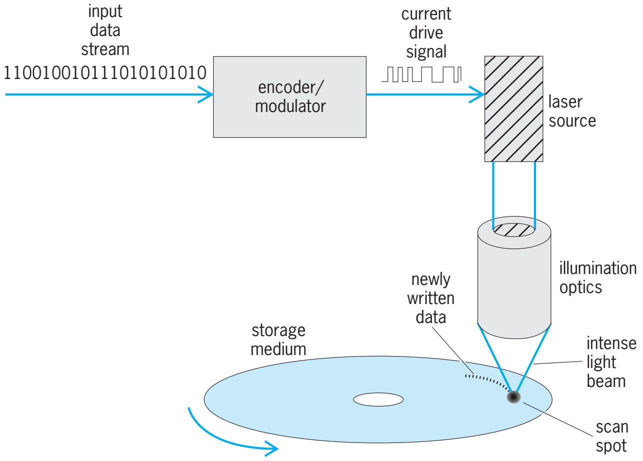

Fig. 1. Recording process for a simple optical medium. Writing data into the recording layers involves modulating an intense laser beam as the layers move under the scan spot.

Optical data storage. Optical data storage involves placing information in a medium so that, when a light beam scans the medium, the reflected light can be used to recover the information. There are many forms of storage media, and many types of systems are used to scan data.

In the recording process (Fig. 1), an input stream of digital information is converted with an encoder and modulator into a drive signal for a laser source. The laser source emits an intense light beam that is directed and focused into the storage medium with illumination optics. As the medium moves under the scanning spot, energy from the intense scan spot is absorbed, and a small localized region heats up. The storage medium, under the influence of the heat, changes its reflective properties. Since the light beam is modulated in correspondence to the input data stream, a circular track of data marks is formed as the medium

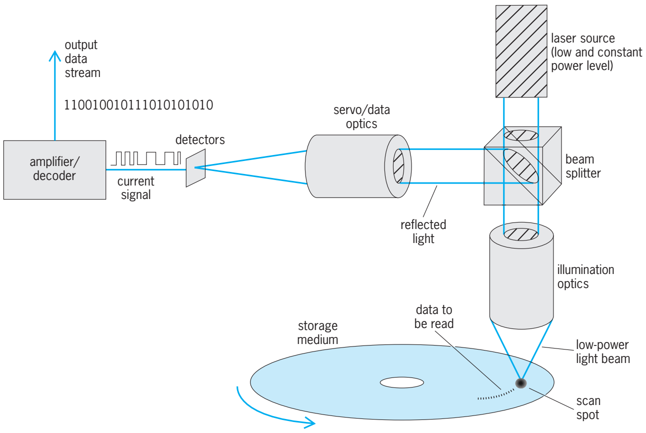

Fig. 2. Readout of an optical medium. Low-power laser beam illuminates the recording layers, and modulation of the reflected light is observed with the detectors. Beam splitter serves to direct a portion of the reflected light to detectors.

rotates. After every revolution, the path of the scan spot is changed slightly in radius to allow another track to be written.

In readout of the medium (Fig. 2), the laser is used at a constant output power level that will not heat the medium beyond its thermal writing threshold. The laser beam is directed through a beam splitter into the illumination optics, where the beam is focused into the medium. As the data to be read pass under the scan spot, the reflected light is modulated. The modulated light is collected by the illumination optics and directed by the beam splitter to the servo and data optics, which converge the light onto detectors. The detectors change the light modulation into current modulation that is amplified and decoded to produce the output data stream.

Optical media can be produced in several different configurations. The most common configuration is the single-layer disk, such as the compact disk (CD), where data are recorded in a single storage layer. A substrate provides mechanical support for the storage layer. The substrate also provides a measure of contamination protection, because light is focused through the substrate and into the recording layer. Dust particles on the surface of the substrate only partially obscure the focused beam, so enough light can penetrate for adequate signal recovery. *See* COMPACT DISK.

In order to increase data capacity of the disk, several layers can be used. Each layer is partially transmitting, which allows a portion of the light to penetrate throughout the thickness of the layers. The scan spot is adjusted by refocusing the illumination optics so that only one layer is read out at a time.

Data can also be recorded in volumetric configurations. As with the multiple-layer disk, the scan spot can be refocused throughout the volume of material to access information. Volumetric configurations offer the highest efficiency for data capacity, but they are not easily paired with simple illumination optics.

The final configuration is to place the information on a flexible surface, such as ribbon or tape. As with magnetic tape, the ribbon is pulled under the scan spot and data are recorded or retrieved. Flexible media have about the same capacity efficiency as volumetric storage. The advantage of a flexible medium over a volumetric medium is that no refocusing is necessary. The disadvantage is that a moderately complicated mechanical system must be used to move the ribbon.

There are several types of optical storage media. The most popular media are based on pit-type, magnetooptic, phase-change, and dye-polymer technologies. CD and digital versatile disc (DVD) products use pit-type technology. Erasable disks using magnetooptic (MO) technology are popular for workstation environments. Compact-disk-rewritable (CD-RW) products [also known as compact-disk-erasable (CD-E)] use phase-change technology, and compact-disk-recordable (CD-R) products use dye-polymer technology. CD and DVD products are read-only memories (ROMs); that is, they are used for software distribution and cannot be used for recording information. CD-R products can be used for recording information, but once the information is recorded, they cannot be erased and reused. Both CD-RW and MO products can be erased and reused. [T.D.M.; G.T.Si.]

Optical rotatory dispersion The change in rotation as a function of wavelength experienced by linearly polarized light as it passes through an optically active substance. *See* OPTICAL ACTIVITY.

In all materials the rotation varies with wavelength. The variation is caused by two quite different phenomena. The first accounts in most cases for the majority of the variation in rotation and should not strictly be termed rotatory dispersion. It depends on the fact that optical activity is actually circular birefringence. In other words, a substance which is optically active transmits right circularly polarized light with a different velocity from left circularly polarized light.

In addition to this pseudodispersion which depends on the material thickness, there is a true rotatory dispersion which depends on the variation with wavelength of the indices of refraction for right and left circularly polarized light. *See* POLARIZED LIGHT. [B.H.Bi.]

For wavelengths that are absorbed by the optically active sample, the two circularly polarized components will be absorbed to differing extents. This unequal absorption is known as circular dichroism. Circular dichroism causes incident linearly polarized light to become elliptically polarized. *See* ABSORPTION.

Optical rotatory dispersion and circular dichroism are closely related, just as are ordinary absorption and dispersion. If the entire optical rotatory dispersion spectrum is known, the circular dichroism spectrum can be calculated, and vice versa.

In order for a molecule (or crystal) to exhibit circular birefringence and circular dichroism, it must be distinguishable from its mirror image. An object that cannot be superimposed on its mirror image is said to be chiral, and optical rotatory dispersion and circular dichroism are known as chiroptical properties.

Most biological molecules have one or more chiral centers and undergo enzyme-catalyzed transformations that either maintain or reverse the chirality at one or more of these centers. Still other enzymes produce new chiral centers, always with a high specificity. These properties account for the fact that optical rotatory dispersion and circular dichroism are widely used in organic and inorganic chemistry and in biochemistry. *See* ENZYME; STEREOCHEMISTRY.

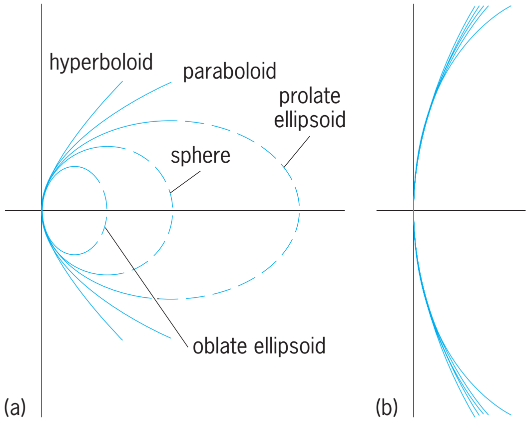
In the absence of magnetic fields, only chiral substances exhibit optical rotatory dispersion and circular dichroism. In a magnetic field, even substances that lack chirality rotate the plane of polarized light, as shown by M. Faraday. Magnetic optical rotation is known as the Faraday effect, and its wavelength dependence is known as magnetic optical rotatory dispersion. In regions of absorption, magnetic circular dichroism is observable. *See* FARADAY EFFECT. [R.W.Wo.]

Optical surfaces Interfaces between different optical media at which light is refracted or reflected. From a physical point of view, the basic elements of an optical system are such things as lenses and mirrors. However, from a conceptual point of view, the basic elements of an optical system are the refracting or reflecting surfaces of such components. Surfaces are the basic elements of an optical system because they are the elements that affect the light passing through the system. Every wavefront has its curvature changed on passing through each surface so that the final set of wavefronts in the image space may converge on the appropriate image points. Also, the aberrations of the system depend on each surface, the total aberrations of the system being the sum of the aberrations generated at the individual surfaces. *See* ABERRATION (OPTICS); REFLECTION OF ELECTROMAGNETIC RADIATION; REFRACTION OF WAVES.

Optical systems are designed by ray tracing, and refraction at an optical surface separating two media of different refractive index is the fundamental operation in the process. The transfer between two surfaces is along a straight line if, as is usually the case, the optical media are homogeneous. The refraction of the ray at a surface results in a change in the direction of the ray. This change is governed by Snell's law.

The vast majority of optical surfaces are spherical in form. This is so primarily because spherical surfaces are much easier to generate than nonspherical, or aspheric, surfaces. Moreover, lens systems seldom need aspherics because the aberrations can be controlled by changing the shape of the component lenses without changing their function in the system, apart from modifying the aberrations. Also, many lens components can be included in a lens system in order to control the aberrations. *See* LENS (OPTICS).

On the other hand, mirror systems usually require aspheric surfaces. Unlike lenses, where the shape can be changed to modify the aberrations, mirrors cannot be changed except by



Conics of revolution. (*a*) Cross sections of entire surfaces. (*b*) Cross sections of portions near the optical axis.

introducing aspheric surfaces. Mirror systems are further constrained by the fact that only a few mirrors, usually two, are used in a system because each successive mirror occludes part of the beam going to the mirror preceding it. *See* Mirror optics.

The most common form of rotationally symmetric surface is the conic of revolution. The departure of conic surfaces from spherical form is shown in the illustration. The classical virtue of the conics of revolution for mirrors is the fact that light from a point located at one focus of the conic is perfectly imaged at the other focus. If these conic foci are located on the axis of revolution, the mirror is free of spherical aberration for such conjugate points. *See* Conic section. [R.V.S.]

Optical tracking instruments A family of optical instruments used for precise time-correlated observation of distant airplanes, missiles, and artificial satellites, all of which travel at apparent velocities much greater than those of most astronomical objects. The instruments supply permanent engineering records for the determination of spatial position, missile attitude, structural behavior, and performance of specific mechanisms. These observations enable engineers to correct design, improve performance, and collect scientific data from missiles and satellites at extreme distances and altitudes.

Optical tracking instruments were used initially for photographic recording of distant engineering events and for the determination of their spatial position. Tracking telescopes were the basic engineering event-recording systems, while cinetheodolites and ballistic cameras were used for precise spatial position. Electrooptical sensors and computer developments have expanded the family of optical tracking instruments to include television and laser detection and tracking of objects out to geosynchronous orbits. The proliferation of sensors has led to the development of flexible optical tracking instruments (see illustration) capable of accommodating a variety of photographic and electrooptical sensors. These sensors have been combined with computer controllers to develop automatic tracking instruments offering both event and position functions in one instrument. The further addition of laser ranging capability permits single-station position solutions along with tracking telescope engineering event recording.

Spatial position determination can be considered the determination of the position of a moving target using dynamic adaptions of the methods of civil surveying. The classical techniques utilize a minimum of four instruments on precisely measured baselines to locate a moving target. Each instrument records the data for computing the direction of the line of sight to the target for each instant of time. This information, in the form of analog or digital elevation and azimuth angles, the times of observation, and the known location of each instrument, is used to triangulate for the location of the missile as a function of time. *See* Surveying.

Cinetheodolites. Most of the spatial position work is performed by cinetheodolites, which are surveying theodolites having 35-mm motion picture cameras with 45–120-in. focal-length (1.2–3-m) lenses substituted for the surveyor's eye and telescope. The system of cameras is synchronized up to a maximum of 30 frames per second from a master control station for simultaneous exposure as the cinetheodolites follow the moving missile. Each photograph records the elevation angle, the azimuth angle, the missile image, and the reticle lines which define the instrumental axis.

Ballistic cameras. These are fixed-axis, wide-angle, photographic-plate cameras capable of more precise spatial position determination by recording on one plate multiple exposures of the missile against a stellar background. Use of a static system and precisely cataloged star positions decreases the necessity for long-term mechanical stability and accuracy, allowing ballistic cameras to achieve 2–5 seconds' angular accuracy. Pyrotechnic flares of electronic stroboscopic lamps at the missile are used to indicate the missile positions against the night sky.

Tracking telescopes. These are long-focal-length telescopes mounted to track missiles in flight precisely while collecting missile performance data. The first systems were crude attempts to track manually with 35-mm cameras of 12–24-in. (30–60-cm) focal length. Increased focal length led to the use of geared, manually driven naval gun mounts and variable-speed, belt-driven machine gun mounts with the telescopes substituted for the armament. In all such systems, the tracking operator observes the missile through an optical sight while controlling the orientation of the telescope to ensure that the missile remains within its field. The advent of computer control and electrooptical automatic tracking systems has resulted in the adaption of direct-drive torque motor systems to replace the electrohydraulic systems.

KINETO Model 433 Tracking Mount shown with 100- and 200-in. focal-length (2.5- and 5.1-m) motion picture cameras, both with 12-in. (30-cm) aperture, and a 40–240-in. focal-length (1.0–6.1-m), 6-in.-aperture (15-cm) television camera. The fourth platform is reserved for either a laser ranger or a thermal imaging system. (*Contraves Goerz Corp.*)

Satellite optical tracking. Satellites equipped with retroflectors have been placed in orbits at altitudes which minimize gravitational and atmospheric anomalies. Satellites, such as Lageos with a 3700-mi (6000-km) orbit, are the basis of laser ranging measurements which require precise optical tracking to be effective.

The orbit of the satellite becomes the basis of measurements because of its regularity. Operation requires that the optical tracking systems must direct a 10-arc-second laser beam along the predicated laser path. Hundreds of laser ranging measurements are then made from two locations. The satellite ephemeris then becomes the yardstick for measuring the location relative to other measured points. This technique is used for geodetic and geophysical studies of polar motion, Earth rotation, gravimetric and tide models, and precise geoid determination. *See* Astronomical photography; Camera; Geodesy; Laser; Lens (optics); Satellite (spacecraft); Telescope. [G.A.E.]

Optics Narrowly, the science of light and vision; broadly, the study of the phenomena associated with the generation, transmission, and detection of electromagnetic radiation in the spectral range extending from the long-wave edge of the x-ray region to the short-wave edge of the radio region. This range, often called the optical region or the optical spectrum, extends in wavelength from about 1 nanometer to about 1 millimeter. *See* Geometrical optics; Meteorological optics; Physical optics; Vision.

The discoveries of the experimentalists of the early 17th century formed the basis of the science of optics. The statement of the law of refraction, the development of the astronomical telescope, observations of diffraction, and the principles of the propagation of light all came in this relatively short period. The publication of Isaac Newton's *Opticks* in 1704, with its comprehensive and original studies of refraction, dispersion, interference, diffraction, and polarization, established the science.

In the early nineteenth century many productive investigators established the transverse-wave nature of light. The relationship between optical and magnetic phenomena led to the crowning achievement of classical optics—the electromagnetic theory of J. C. Maxwell. Maxwell's theory, which holds that light consists of electric and magnetic fields propagated together through space as transverse waves, provided a general basis for the treatment of optical phenomena. In particular, it served as the basis for understanding the interaction of light with matter and, hence, as the basis for treatment of the phenomena of physical optics. *See* Electromagnetic radiation; Light; Maxwell's equations.

In the twentieth century optics has been in the forefront of the revolution in physical thinking caused by the theory of relativity and especially by the quantum theory.

The science of optics finds itself in a position that is satisfactory for practical purposes but less so from a theoretical standpoint. The theory of Maxwell is sufficiently valid for treating the interaction of high-intensity radiation with systems considerably larger than those of atomic dimensions. The modern quantum theory is adequate for an understanding of the spectra of atoms and molecules and for the interpretation of phenomena involving low-intensity radiation, provided one does not insist on a very detailed description of the process of emission or absorption of radiation. However, a general theory of relativistic quantum electrodynamics valid for all conditions and systems has not been worked out.

The development of the laser has been an outstanding event in the history of optics. The theory of electromagnetic radiation from its beginnings was able to comprehend and treat the properties of coherent radiation, but the controlled generation of coherent monochromatic radiation of high power was not achieved in the optical region until the work of C. H. Townes and A. L. Schawlow in 1958 pointed the way. Many achievements in optics, such as holography and interferometry over long paths, have resulted from the laser. *See* Holography; Interferometry; Laser. [R.C.L.]

Optimal control (linear systems) A branch of modern control theory that deals with designing controls for linear systems by minimizing a performance index that depends on the system variables. Under some mild assumptions, making the performance index small also guarantees that the system variables will be small, thus ensuring closed-loop stability. *See* Control system stability.

Classical control theory applies directly in the design of controls for systems that have one input and one output. Complex modern systems, however, have multiple inputs and outputs. Examples include aircraft, satellites, and robot manipulators, which, though nonlinear, can be linearized about a desired operating point. Modern control theory was developed, beginning about 1960, for these multivariable systems. It is characterized by a state-space description of systems, which involves the use of matrices and linear algebra, and by the use of optimization techniques to determine the control policies. These techniques facilitate the use of modern digital computers, which lead to an interactive approach to design of controls for complex systems. *See* Digital computer; Linear algebra; Matrix theory; Multivariable control; Optimization.

The multivariable state-variable description is of the form of Eqs. (1), where $u(t)$ is an m-dimensional control input vector and

$$x = Ax + Bu \qquad z = Hx \tag{1}$$

$z(t)$ is a performance output vector for which there are specified performance requirements. The state $x(t)$ is an internal variable of dimension n that describes the energy storage properties of the system. Matrices A and B describe the system dynamics and are determined by a physical analysis using, for example, Newton's laws of motion. They may in general be time-varying. Matrix H is chosen to select the variables of importance as the performance outputs. In the case of nonlinear systems, the description of Eq. (1) results when the system is linearized about a desired operating point. *See* Linear system analysis; Nonlinear control theory.

Traditionally, modern control-system design assumes that all the states $x(t)$ are available for feedback so that the control input is of the form of Eq. (2), where $K(t)$ is an $m \times n$ feedback gain

$$u = -Kx \tag{2}$$

matrix, generally time-varying. Substituting the control of Eq. (2) into the system of Eq. (1) yields the closed-loop system given in Eqs. (3). The control design problem is to choose the mn entries

$$\dot{x} = (A - BK)x \qquad z = Hx \tag{3}$$

of the feedback matrix K to yield a desired closed-loop behavior of the performance output $z(t)$.

To obtain satisfactory performance of the system of Eq. (1), a quadratic performance index of the form of Eq. (4) may be

$$J = {}^1/_2 x^T(T)S(T)x(T) + {}^1/_2 \int_0^T (x^T Qx + u^T Ru)\, dt \tag{4}$$

chosen, where $[0, T]$ is the time interval of interest and the symmetric weighting matrices $S(T)$, Q, and R are design parameters that are selected to obtain the required performance. They must be chosen so that $x^T(T)S(T)x(T) \geq 0$ and $x^T Qx \geq 0$ for all $x(t)$, and $u^T Ru > 0$ for all $u(t)$. That is, Q and $S(T)$ should be positive semidefinite while R should be positive definite. [F.L.L.]

Optimal control theory An extension of the calculus of variations for dynamic systems with one independent variable, usually time, in which control (input) variables are determined to maximize (or minimize) some measure of the performance (output) of a system while satisfying specified constraints. Theory is conveniently divided into two parts: optimal programming, where the control variables are determined as functions of time for a specified initial state of the system, and optimal feedback control, where the control variables are determined as functions of the current state of the system.

Examples of optimal control problems are: (1) determining paths of vehicles between two points to minimize fuel or time, and (2) determining feedback control logic for vehicles or industrial processes to keep them near a desired operating point in the presence of disturbances with acceptable control magnitudes.

Dynamic systems are conveniently divided into two categories: continuous dynamic systems, where the control and state variables are functions of a continuous independent variable, such as time or distance, and discrete dynamic systems, where the independent variable changes in discrete increments. Many discrete systems are discretized versions of continuous systems; the discretization is often made so that (1) the system can be analyzed or controlled by digital computers (or both), or (2) measurements of continuous outputs are made at discrete intervals of time (sampled-data systems) in order to share data transmission channels.

A large class of interesting optimal control problems can be described as follows: the dynamic system is described by a set of coupled first-order ordinary differential equations of the form of Eq. (1), where x (the state vector) represents the state variables

$$\dot{x} = f(x, u, t) \tag{1}$$

of the system (such as position, velocity, temperature, voltage, and so on); u (the control vector) represents the control variables of the system (such as motor torque, control-surface deflection angle, valve opening, and so on); t is time; and f represents a set of functions of x, u, and t. The performance index J, which one desires to minimize, is a scalar function of the final time t_f and the final state $x(t_f)$ plus an integral from the initial time t_0 to the final time t_f of a scalar function of the state and control vectors and time, as given in Eq. (2). Possible constraints include: (*a*)

$$J = \varphi[x(t_f), t_f] = \int_{t_0}^{t_f} L[x(t), u(t), t]\, dt \tag{2}$$

specified vector functions constraining the initial time t_0 and the initial state $x(t_0)$, as in Eq. (3); (*b*) specified vector functions con-

$$\alpha[x(t_0), t_0] = 0 \tag{3}$$

straining the final time and final state, as in Eq. (4); (*c*) specified vector functions constraining the control variables [inequality

$$\psi[x(t_f), t_f] = 0 \tag{4}$$

(5)]; (*d*) specified vector functions constraining both control and

$$C[u(t), t] \leq 0 \tag{5}$$

state variables [inequality (6)]; and (*e*) specified vector functions

$$CS[x(t), u(t), t] \leq 0 \tag{6}$$

constraining only the state variables [inequality (7)]. Constraints *a* and *b* are equality constraints, whereas constraints *c*, *d*, and *e*

$$S[x(t), t] \leq 0 \tag{7}$$

are inequality constraints. *See* Linear system analysis.

Classes of problems. There are several important classes of optimal control problems.

Bang-bang control is a type of control in which the control variables are either at their maximum or at their minimum values, never in between. This type of control is optimal, for example, in certain minimum-fuel problems where the control variables enter linearly into system equations (1), the performance index in Eq. (2), and the constraints in Eq. (5). *See* Nonlinear control theory.

Bang-zero-bang control is a type of control in which the control values are at their maximum values, zero, or their minimum values. This type of control is optimal, for example, in certain minimum-fuel problems where the control variables enter linearly into system equations (1) and the constraints in Eq. (5), and the performance index depends on the magnitude (but not the sign) of the control variables.

Linear-quadratic problems are problems in which system equations (1) are linear and the performance index in Eq. (2) is quadratic in the states x and the control u.

Neighboring optimum feedback control (NOFC) about a nominal optimal path is a viable alternative to a "complete" optimal feedback control solution. NOFC constitutes an approximation to the optimal feedback control solution in a region neighboring the nominal optimal path.

Stochastic optimal control theory. This takes into consideration, in an ensemble average sense, random disturbances on the dynamic system, random initial conditions, and random errors in measurements. A control design is sought that maximizes (or minimizes) the performance criterion on the average and satisfies the constraints within certain tolerances, also on the average. *See* Estimation theory; Stochastic control theory; Stochastic process.

Differential games. These are two-sided optimal control problems. Typically, control system A tries to minimize the performance criterion, while control system B tries to maximize it. This may lead to a minimax feedback strategy in which both systems do their best, taking into account the other controller's intelligence in seeking the opposite goal. *See* Control systems; Decision theory; Game theory. [A.E.Br.]

Optimization The design and operation of systems or processes to make them as good as possible in some defined sense. The approaches to optimizing systems are varied and depend on the type of system involved, but the goal of all optimization procedures is to obtain the best results possible (again, in some defined sense) subject to restrictions or constraints that are imposed. While a system may be optimized by treating the system itself, by adjusting various parameters of the process in an effort to obtain better results, it generally is more economical to develop a model of the process and to analyze performance changes that result from adjustments in the model. In many applications, the process to be optimized can be formulated as a mathematical model; with the advent of high-speed computers, very large and complex systems can be modeled, and optimization can yield substantially improved benefits.

Optimization is applied in virtually all areas of human endeavor, including engineering system design, optical system design, economics, power systems, water and land use, transportation systems, scheduling systems, resource allocation, personnel planning, portfolio selection, mining operations, blending of raw materials, structural design, and control systems. Optimizers or decision makers use optimization in the design of systems and processes, in the production of products, and in the operation of systems.

The first step in modern optimization is to obtain a mathematical description of the process or the system to be optimized. A mathematical model of the process or system is then formed on the basis of this description. Depending on the application, the model complexity can range from very simple to extremely complex. An example of a simple model is one that depends on only a single nonlinear algebraic function of one variable to be selected by the optimizer (the decision maker). Complex models may contain thousands of linear and nonlinear functions of many variables. As part of the procedure, the optimizer may select specific values for some of the variables, assign variables that are functions of time or other independent variables, satisfy constraints that are imposed on the variables, satisfy certain goals, and account for uncertainties or random aspects of the system.

System models used in optimization are classified in various ways, such as linear versus nonlinear, static versus dynamic, deterministic versus stochastic, or time-invariant versus time-varying. In forming a model for use with optimization, all of the important aspects of the problem should be included, so that they will be taken into account in the solution. The model can improve visualization of many interconnected aspects of the problem that cannot be grasped on the basis of the individual parts alone. A given system can have many different models that differ in detail and complexity. Certain models (for example, linear programming models) lend themselves to rapid and well-developed solution algorithms, whereas other models may not. When choosing between equally valid models, therefore, those that are cast in standard optimization forms are to be preferred. *See* MODEL THEORY.

The model of a system must account for constraints that are imposed on the system. Constraints restrict the values that can be assumed by variables of a system. Constraints often are classified as being either equality or inequality constraints. The types of constraints involved in any given problem are determined by the physical nature of the problem and by the level of complexity used in forming the mathematical model.

Constraints that must be satisfied are called rigid constraints. Physical variables often are restricted to be nonnegative; for example, the amount of a given material used in a system is required to be greater than or equal to zero. Rigid constraints also may be imposed by government regulations or by customer-mandated requirements. Such constraints may be viewed as absolute goals.

In contrast to rigid constraints, soft constraints are those constraints that are negotiable to some degree. These constraints can be viewed as goals that are associated with target values. The amount that the goal deviates from its target value could be considered in evaluating trade-offs between alternative solutions to the given problem.

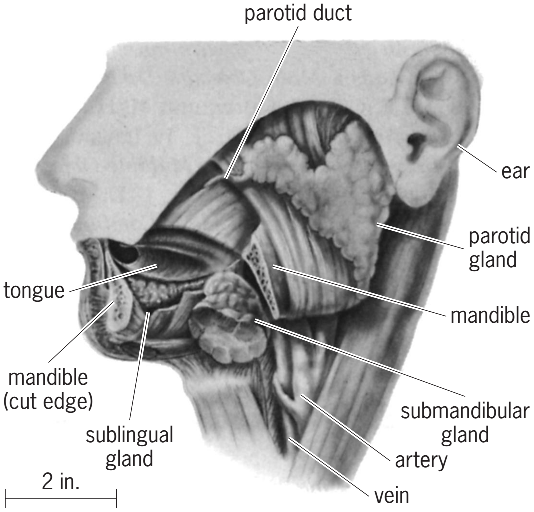
When constraints have been established, it is important to determine if there are any solutions to the problem that simultaneously satisfy all of the constraints. Any such solution is called a feasible solution, or a feasible point in the case of algebraic problems. The set of all feasible points constitutes the feasible region.

If no feasible solution exists for a given optimization problem, the decision maker may relax some of the soft constraints in an attempt to create one or more feasible solutions; a class of approaches to optimization under the general heading of goal programming may be employed to relax soft constraints in a systematic way to minimize some measure of maximum deviations from goals.

A key step in the formulation of any optimization problem is the assignment of performance measures (also called performance indices, cost functions, return functions, criterion functions, and performance objectives) that are to be optimized. The success of any optimization result is critically dependent on the selection of meaningful performance measures. In many cases, the actual computational solution approach is secondary. Ways in which multiple performance measures can be incorporated in the optimization process are varied. [D.A.Pi.]

Oral glands

Oral glands Glands located in the mouth that secrete fluids to moisten and lubricate the mouth and food and may initiate digestive activity, and that may perform other specialized functions. Fishes and aquatic amphibians have only solitary mucus-secreting cells in the epithelium of the mouth cavity. Multicellular glands first appeared in land animals to keep the mouth moist and make food easier to swallow. Some glands of terrestrial amphibians have a lubricative secretion; others serve to make the tongue sticky for use in catching insects. Some frogs secrete a serous fluid that contains ptyalin, a digestive enzyme. The oral glands of reptiles are much the same, but are more distinctly grouped. In poisonous snakes and the single poisonous lizard, the Gila monster, certain oral glands of the serous type are modified to form venom. Also many of the lizards have glands that are mixed in character, containing both mucous and serous cells. Oral glands are poorly developed in crocodilians and sea turtles. Birds bolt their food, yet graineaters have numerous glands, some of which secrete ptyalin.



The salivary glands, shown by a partial dissection of the head. (*After J. C. Brash, ed., Cunningham's Textbook of Anatomy, 9th ed., Oxford, 1951*)

All mammals except aquatic forms are well supplied with oral glands. There are numerous small glands, such as the labial glands of the lips, buccal glands of the cheeks, lingual glands of the tongue, and palatine glands of the palate. Besides these, there are larger paired sets in mammals that are quite constant from species to species and are commonly designated as salivary glands (see illustration). The parotid gland, near each ear, discharges into the vestibule. The submaxillary or submandibular gland lies along the posterior part of the lower jaw; its duct opens well forward under the tongue. The sublingual gland lies in the floor of the mouth. It is really a group of glands, each with its duct. *See* GLAND. [L.B.A.]

Orange

Orange The sweet orange (*Citrus sinensis*) is the most widely used species of citrus fruit and commercially is the most important. The sour or bitter oranges, of lesser importance, are distinct from sweet oranges and are classified as a separate species, *C. aurantium*. The United States is the largest producer of oranges, followed by Spain, Italy, and Brazil. The orange is also a major crop in several other countries.

Sweet orange fruit is consumed fresh or as frozen or canned juice. A large portion of the crop, particularly in the United States, is used as frozen concentrate. After the juice is extracted, the peel and pulp are used for cattle feed. Peel oil is used in perfumes and flavoring, and citrus molasses is used as a livestock feed.

The sweet orange tree is a moderately vigorous evergreen with a rounded, densely foliated top. The fruits are round or somewhat elongate and usually orange-colored when ripe. They can be placed in four groups: the common oranges, acid-less oranges, pigmented oranges, and navel oranges. They may also be distinguished on the basis of early midseason, and late maturity. *See* FRUIT; FRUIT, TREE. [R.K.So.]

Orbital motion

Orbital motion In astronomy the motion of a material body through space under the influence of its own inertia, a central force, and other forces. Johann Kepler found empirically that the orbital motions of the planets about the Sun are ellipses. Sir Isaac Newton, starting from his laws of motion, proved that an inverse-square gravitational field of force requires a body to move in an orbit that is a circle, ellipse, parabola, or hyperbola.

Two bodies revolving under their mutual gravitational attraction, but otherwise undisturbed, describe orbits of the same shape about a common center of mass. The less massive body has the larger orbit. In the solar system, the Sun and Jupiter have a center of mass just outside the visible disk of the Sun. For each of the other planets, the center of mass of Sun and planet lies within the Sun.

For this reason, it is convenient to consider only the relative motion of a planet of mass m about the Sun of mass M as though the planet had no mass and moved about a center of mass $M + m$. The orbit so determined is exactly the same shape as the true orbits of planet and Sun about their common center of mass, but it is enlarged in the ratio $(M + m)/M$. *See* CENTER OF MASS; PLANET.

Orbital velocity v of a planet moving in a relative orbit about the Sun may be expressed by Eq. (1) where a is the semimajor

$$v^2 = G(M+m)\left(\frac{2}{r} - \frac{1}{a}\right) \qquad (1)$$

axis, and r is the distance from the planet to the Sun. In the special case of a circular orbit, $r = a$, and the expression becomes Eq. (2). When the eccentricity of an orbit is exactly unity, the

$$v^2 = \frac{G(M+m)}{a} \qquad (2)$$

length of the major axis becomes infinite and the ellipse degenerates into a parabola. The expression for the velocity then becomes Eq. (3). This parabolic velocity is referred to as the ve-

$$v^2 = G(M+m)\left(\frac{2}{r}\right) \qquad (3)$$

locity of escape, since it is the minimum velocity required for a particle to escape from the gravitational attraction of its parent body. *See* ESCAPE VELOCITY.

Eccentricities greater than unity occur with hyperbolic orbits. Because in a hyperbola the semimajor axis a is negative, hyperbolic velocities are greater than the escape velocity.

Parabolic and hyperbolic velocities seem to be observed in the motions of some comets and meteors. Aside from the periodic ones, most comets appear to be visitors from cosmic distances, as do about two-thirds of the fainter meteors. It is possible that many of the "parabolic" comets are actually moving in elliptical orbits of extremely long period. The close approach of one of these visitors to a massive planet, such as Jupiter, could change the velocity from parabolic to elliptical if retarded, or from parabolic to hyperbolic if accelerated. It is possible that many of the periodic comets, especially those with periods under 9 years, have been captured in this way. *See* COMET; GRAVITATION; PERTURBATION (ASTRONOMY). [R.L.Du.]

Orchid Any member of the orchid family (Orchidaceae), among the largest families of plants, estimated to contain up to 35,000 species. Orchids are monocots; their flowers have inferior ovaries, three sepals, and three petals. They are distinguished by the differentiation of one petal into a labellum, and the fusion of pistil and stamens into the column. Pollen is usually contained in pollinia, that is, bundles that are removed intact by pollinators, usually insects or sometimes birds. Self-pollination and asexual reproduction without fertilization also occur. The combination of lip and column structure, flower color, fragrance, and other factors may limit the range of pollinators. Differing pollination mechanisms often provide barriers to cross-pollination between related species. Each flower can produce large quantities of seeds, with numbers in the millions in some tropical species. Seeds are minute, with undifferentiated embryo and no endosperm. Germination and establishment depends on symbiotic mycorrhizae that provide nutrients and water.

Orchids occur on all continents except Antarctica; they range from arctic tundra and temperate forest and grassland to tropical rainforest, where as epiphytes they reach their greatest abundance and diversity. Vanilla is obtained from seed pods of some species of *Vanilla*, and the beauty and mystique of many orchids make them important horticultural subjects. *See* MYCORRHIZAE; ORCHIDALES; VANILLA. [C.J.S.]

Orchidales An order of flowering plants, division Magnoliophyta (Angiospermae), in the subclass Liliidae of the class Liliopsida (monocotyledons). The order consists of four families: the Orchidaceae (see illustration), with perhaps 15,000–20,000 species; the Burmanniaceae, with about 130 species; the Cordiaceae, with 9 species; and the Geosiridaceae, with 1 species. The Orchidales are mycotrophic, sometimes nongreen Liliidae with very numerous tiny seeds that have an undifferentiated embryo and little or no endosperm. The ovary is always inferior and apparently lacks the septal nectaries found in many Liliopsida although other kinds of nectaries are present. *See* FLOWER; LILIIDAE; LILIOPSIDA; MAGNOLIOPHYTA; ORCHID. [A.Cr.; T.M.Ba.]

Ordovician The second-oldest period in the Paleozoic Era. The Ordovician is remarkable because not only did one of the most significant Phanerozoic radiations of marine life take place (early Middle Ordovician), but also one of the two or three most severe extinctions of marine life occurred (Late Ordovician). The early Middle Ordovician radiation of life included the initial colonization of land. These first terrestrial organisms were nonvascular plants. Vascular plants appeared in terrestrial settings shortly afterward. *See* GEOLOGIC TIME SCALE.

The rocks deposited during this time interval (these are termed the Ordovician System) overlie those of the Cambrian and underlie those of the Silurian. The Ordovician Period was about 7×10^7 years in duration, and it lasted from about 5.05×10^8 to about 4.35×10^8 years ago.

The Ordovician System is recognized in nearly all parts of the world, including the peak of Mount Everest, because the groups of fossils used to characterize the system are so broadly delineated. Biogeographic provinces limited the distribution of organisms in the past to patterns similar to those of modern biogeographic provinces. Three broadly defined areas of latitude—the tropics, the midlatitudes (approximately 30–60°S), and the Southern Hemisphere high latitudes—constitute the biogeographic regions. Provinces may be distinguished within these three regions based upon organismal associations unique to each province.

Early Ordovician environmental conditions in most areas were similar to those of the Late Cambrian. Accordingly, Early Ordovician life was similar to that of the latter part of the Cambrian. Trilobites were the prominent animal in most shelf sea environments. Long straight-shelled nautiloids, certain snails, a few orthoid brachiopods, sponges, small echinoderms, algae, and bacteria flourished in tropical marine environments. Linguloid brachiopods and certain bivalved mollusks inhabited cool-water, nearshore environments.

Middle Ordovician plate motions were acompanied by significant changes in life. On land, nonvascular, mosslike plants appeared in wetland habitats. Vascular plants appeared slightly later in riverine habitats. The first nonvascular plants occurred in the Middle East on Gondwanan shores. The Middle Ordovician radiation of marine invertebrates is one of the most extensive in the record of Phanerozoic marine life. Corals, bryozoans, several types of brachiopods, a number of crinozoan echniderms, conodonts, bivalved mollusks, new kinds of ostracodes, new types of trilobites, and new kinds of nautiloids suddenly developed in tropical marine environments. As upwelling conditions formed along the plate margins, oxygen minimum zones—habitats preferred by many graptolites—expanded at numerous new sites. Organic walled microfossils (chitinozoans and acritarchs) radiated in mid- to high-latitude environments. Ostracoderms (jawless, armored fish) radiated in tropical marine shallow-shelf environments. These fish were probably bottom detritus feeders. *See* PALEOECOLOGY.

The latest Ordovician stratigraphic record suggests that glacial ice melted relatively quickly, accompanied by a relatively rapid sea-level rise in many areas. Some organisms—certain conodonts, for example—did not endure significant extinctions until sea levels began to rise and shelf sea environments began to expand. *See* PALEOCEANOGRAPHY; STRATIGRAPHY. [W.B.N.B.]

Ore and mineral deposits Ore deposits are naturally occurring geologic bodies that may be worked for one or more metals. The metals may be present as native elements, or, more commonly, as oxides, sulfides, sulfates, silicates, or other compounds. The term ore is often used loosely to include such nonmetallic minerals as fluorite and gypsum. The broader term, mineral deposits, includes, in addition to metalliferous minerals, any other useful minerals or rocks. Minerals of little or no value which occur with ore minerals are called gangue. Some gangue minerals may not be worthless in that they are used as by-products; for instance, limestone for fertilizer or flux, pyrite for making sulfuric acid, and rock for road material.

Mineral deposits that are essentially as originally formed are called primary or hypogene. The term hypogene also indicates formation by upward movement of material. Deposits that have been altered by weathering or other superficial processes are secondary or supergene deposits. Mineral deposits that formed at the same time as the enclosing rock are called syngenetic, and those that were introduced into preexisting rocks are called epigenetic.

The distinction between metallic and nonmetallic deposits is at times an arbitrary one since some substances classified as nonmetals, such as lepidolite, spodumene, beryl, and rhodochrosite, are the source of metals. The principal reasons for distinguishing nonmetallic from metallic deposits are practical ones, and include such economic factors as recovery methods and uses.

Most mineral deposits are natural enrichments and concentrations of original material produced by different geologic processes. Economic considerations, such as the amount and concentration of metal, the cost of mining and refining, and the market value of the metal, determine whether the ore is of commercial grade. To be of commercial grade, for example, the following metals must be concentrated in the amounts indicated: aluminum, about 30%; copper, 0.7–10%; lead, 2–4%; zinc, 3–8%; and gold, silver, and uranium, only a small fraction of a percent of metal. *See* GEOCHEMICAL PROSPECTING; MINERAL. [A.F.H.]

Ore dressing Treatment of ores to concentrate their valuable constituents (minerals) into products (concentrate) of smaller bulk, and simultaneously to collect the worthless material (gangue) into discardable waste (tailing). The fundamental operations of ore-dressing processes are the breaking apart of the associated constituents of the ore by mechanical means (severance) and the separation of the severed components (beneficiation) into concentrate and tailing, using mechanical or physical methods which do not effect substantial chemical changes.

Comminution is a single- or multistage process whereby ore is reduced from run-of-mine size to that size needed by the beneficiation process. The process is intended to produce individual particles which are either wholly mineral or wholly gangue, that is, to produce liberation. Since the mechanical forces producing fracture are not susceptible to detailed control, a class of particles containing both mineral and gangue (middling particles) are also produced. Comminution is divided into crushing (down to 6- to 14-mesh) and grinding (down to micrometer sizes).

Screening is a method of sizing whereby graded products are produced, the individual particles in each grade being of nearly the same size. In beneficiation, screening is practiced for two reasons: as an integral part of the separation process, for example, in jigging; and to produce a feed of such size and size range as is compatible with the applicability of the separation process. *See* SCREENING.

Beneficiation consists of two fundamental operations: the determination that an individual particle is either a mineral or a gangue particle (selection); and the movement of selected particles via different paths (separation) into the concentrate and tailing products. When middling particles occur, they will either be selected according to their mineral content and then caused to report as concentrate or tailing, or be separated as a third product (middling), which is reground to achieve further liberation. *See* FLOTATION; LEACHING; MECHANICAL SEPARATION TECHNIQUES.

Separation is achieved by subjecting each particle of the mixture to a set of forces which is usually the same irrespective of the nature of the particles excepting for the force based upon the discriminating property. This force may be present for both mineral and gangue particles but differing in magnitude, or it may be present for one type of particle and absent for the other. As a result of this difference, separation is possible, and the particles are collected in the form of concentrate or tailing.

Magnetic separation utilizes the force exerted by a magnetic field upon magnetic materials to counteract partially or wholly the effect of gravity. Thus under the action of these two forces, different paths are produced for the magnetic and nonmagnetic particles. *See* MAGNETIC SEPARATION METHODS. [M.D.Ha.]

Oregano A herb, also known as wild marjoram. The dried leaves of several species of aromatic plants are known as oregano; thus oregano is a common name for a general flavor and aroma rather than the name of a specific plant.

European (*Origanum vulgare*) and Greek (*O. hervacleoticum*) oregano are both in the mint family (Lamiaceae). Mexican oregano is obtained primarily from plants of *Lippia graveolens*. These small aromatic shrubs in the verbena family grow wild in Mexico. Origanum oil used in perfumery is steam-distilled primarily from Spanish oregano, *Thymus capitatus*. *See* LAMIALES.

European oregano can be distinguished by its strong piquant character and tall growth with dark, broad leaves; it is a perennial erect herb 2–3 ft tall (0.6–1 m) with pubescent stems, ovate dark green leaves, and white or purple flowers. Native to southern Europe, southwest Asia, and the Mediterranean countries, European oregano is usually found growing in the dry, rocky, calcareous soils of the mountain regions. Greece, Italy, Spain, Turkey, and the United States are the primary sources of European oregano.

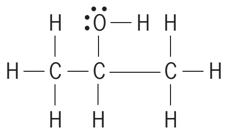
Dried oregano leaves are used as a culinary herb in meat and sausage products, salads, soups, Mexican foods, and barbeque sauces. The essential oil of oregano is used in food products, cosmetics, and liqueurs. *See* MARJORAM; SPICE AND FLAVORING.

[S.Kir.]

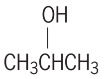
Organic chemistry The study of the structure, preparation, properties, and reactions of carbon compounds. The term organic was early applied to compounds derived from plant and animal sources. These substances from living systems were usually distillable liquids or low-melting solids and were flammable, in contrast to metals, salts, and oxides from mineral sources. Until about 1830 it was held by some that organic compounds contained some special quality, or vital force. This notion was dispelled, but the term organic remained and became broadened to include carbon compounds in general. *See* CARBON.

Structure. The structures of organic compounds are described by a molecular framework of carbon atoms on which substituents may be located at various points.

Structures can be represented in several ways, as illustrated for the three-carbon alcohol 2-propanol (**1**) and the cyclic ketone 2-methyl-3-cyclohexenone (**2**). The expanded structure of 2-propanol (***1a***) shows all bonds and electron pairs, including unshared electrons on oxygen. More compact and convenient is the condensed structure (***1b***) in which the C—C and C—H bonds are implied. In the bond-line convention (***1c***), all C—C bonds are indicated by a line, as shown for 2-propanol. Carbon atoms are not shown explicitly, but rather are implied at the ends of each line segment, together with enough hydrogen atoms to complete the tetravalency at each carbon. The bond-line convention is particularly convenient for cyclic structures such as 2-methyl-3-cyclohexenone; each vertex and the end of each line segment represents a carbon and appropriate number of hydrogens. *See* STRUCTURAL CHEMISTRY; VALENCE.

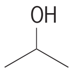


(***1a***)

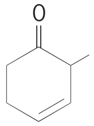


$CH_3\overset{\overset{OH}{|}}{C}HCH_3$

(***1b***)



(***1c***)



(**2**)

A functional group is an atom other than carbon or a multiple bond, such as the hydroxyl group (OH) of 2-propanol, the double bond (C═C), or the carbonyl group (C═O) of 2-methyl-3-cyclohexenone. The group defines a class of compounds and is the point at which characteristic reactions occur, for example, oxidation, reduction, or addition of an electrophilic or nucleophilic reagent. Some of the principal functional groups are shown in the table. *See* ELECTROPHILIC AND NUCLEOPHILIC REAGENTS.

The fact that there can be two or more compounds, known as isomers, with the same molecular composition was one of the key points in development of a structural theory. One type of isomerism, structural or constitutional, is illustrated by the two isomers that have the formula C_4H_{10}, butane (***3a***) and isobutane (2-methylpropane; ***3b***). The number of possible structural isomers becomes enormous in larger molecules.

$CH_3-CH_2-CH_2-CH_3$

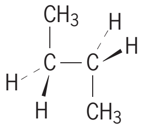
Principal organic functional groups

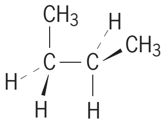
Composed class	Group	Structure
Alkene	Double bond	$>C=C<$
Alkyne	Triple bond	$-C\equiv C-$
Alcohol	Hydroxyl	$-OH$
Amine	Amino	$-NH_2(-NR_2)^*$
Aldehyde	Carbonyl	$-\overset{\overset{O}{\|}}{C}H$
Ketone	Carbonyl	$-\overset{\overset{O}{\|}}{C}R$
Acid	Carboxyl	$-\overset{\overset{O}{\|}}{C}OH$
Ester	Alkoxycarbonyl	$-\overset{\overset{O}{\|}}{C}OR$
Amide	Carbamoyl	$\overset{\overset{O}{\|}}{C}N<$
Nitrile	Cyano	$-C\equiv N$
Azide	Azido	$-N=N=N$
Nitro		$-NO_2$
Sulfide		$-S-$
Sulfoxide		$-\overset{\overset{O}{\|}}{S}-$
Sulfonic acid		$-SO_3H$

*R = any carbon group, for example, CH_3.

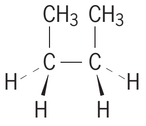
Several three-dimensional representations of butane, showing the tetrahedral geometry of the carbon atoms, are given in structures (**4**). As indicated in these structures, butane can exist in several forms, called conformations, which differ in the relative positions of the carbon atoms, and thus the overall shape of the molecule. However, the barrier to rotation around the central C—C bond is so low that these individual conformational isomers are not separable, and butane is thus a single compound. *See* CONFORMATIONAL ANALYSIS.



(***4a***)

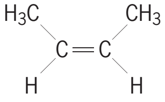


(***4b***)

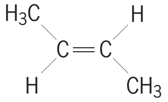


(***4c***)

In an alkene, rotation around the C═C bond does not occur, and 2-butene, for example, exists as two isomeric compounds, cis (Z) and trans (E) (***5a*** and ***5b***, respectively).

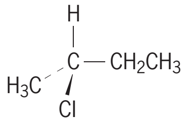


(***5a***)

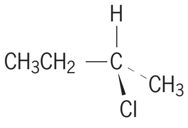


(***5b***)

Stereoisomers are compounds that have the same bond sequence but differ in the spatial array of the bonds. When a carbon atom is bonded to four unlike atoms or groups, the tetrahedral geometry of carbon causes the atom to be dissymmetric or chiral. A compound with a chiral atom can exist in two isomeric forms, known as enantiomers. The relative positions of all atoms is identical in the two enantiomers, but they differ in handedness, a characteristic of an asymmetric object and its nonsuperposable mirror image, as in structures (**6**) of 1-chlorobutane.



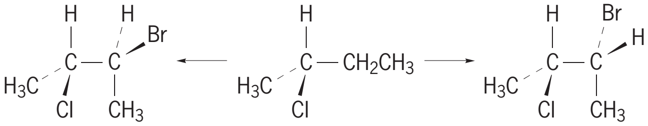
(**6*a***)



(**6*b***)

See STEREOCHEMISTRY.

When two chiral centers are present, two stereoisomers can arise from each enantiomer. Thus enantiomer (**7*a***) of chlorobutane can lead to isomeric structures (**7*b***) and (**7*c***), in which the relative positions of the atoms is not identical. In this case, the isomers are known as diastereoisomers. With *n* chiral centers, there can be 2^n stereoisomers.



(**7*b***) (**7*a***) (**7*c***)

Acyclic compounds. The simplest organic compound is methane (CH_4). It is the first member of the homologous series of alkanes, in which successive compounds differ by an additional —CH_2— group (CH_3CH_3, $CH_3CH_2CH_3$, and so forth). *See* ALKANE; METHANE.

Higher alkanes, $CH_3(CH_2)_nCH_3$ (n = 3–20), and also branched isomers and cyclic hydrocarbons are the principal components of petroleum. These compounds have no reactive functional groups.

Both acyclic and cyclic carbon frameworks can contain multiple bonds; oxygen, nitrogen, and sulfur atoms; and other functional groups listed in the table.

Carbocyclic compounds. The two large groups of compounds with rings containing only carbon are alicyclic and aromatic. The parent hydrocarbons in the former series are cycloalkanes and in the latter, benzene. The structure of benzene is a planar six-numbered ring with six electrons in a delocalized array. *See* AROMATIC HYDROCARBON; BENZENE.

Heterocyclic compounds. A nitrogen, oxygen, or sulfur atom can take the place of carbon in either alicyclic or aromatic rings. The most numerous and important hetrocyclic compounds are those with nitrogen in a five- or six-membered aromatic system.

Synthesis reactions. The preparation of compounds occupies much of the effort of organic chemistry, and is the principal business of the chemical industry. The manufacture of drugs, pigments, and polymers entails the preparation of organic compounds on a scale of thousands to billions of kilograms per year, and there is constant research to develop new products and processes. Synthesis of new substances is carried out for many purposes beyond the goal of a commercial product. A compound of a specified structure may be needed to test a mechanistic proposal or to evaluate a biochemical response such as inhibition of an enzyme. Synthesis may provide a more dependable and less expensive source of a naturally occurring compound; moreover, a synthetic approach permits variations in the structure that may lead to enhanced biological activity.

The term synthesis usually implies a planned sequence of steps leading from simple starting compounds to a desired end product. Each of these steps involves a reaction that may lead to formation of a C—C bond or to the introduction, alteration, or removal of a functional group. Progress in synthesis depends on the availability of a wide range of reactions that bring about these changes in good yield, with a minimum of interfering by-products. An integral part of synthesis is the development of new methods and reagents that are selective for a desired transformation, and, very importantly, proceed with control of the stereochemistry. *See* ASYMMETRIC SYNTHESIS; ORGANIC SYNTHESIS.

[J.A.Mo.]

Organic conductor An organic substance with low electrical resistance. Two major classes of organic conductors are charge-transfer compounds and conducting polymers.

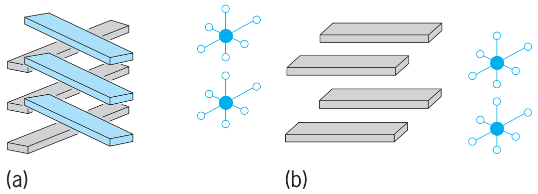
Charge-transfer compounds. The search for organic conductors in the early 1970s led to the observation of metallic-like electrical conduction in well-ordered molecular crystals and the discovery of many new phenomena such as the stabilization of charge-density waves and spin-density waves, new mechanisms for electronic transport, organic superconductivity, and new states of matter produced under strong magnetic fields. Most of these phenomena are due to the low dimensionality (one or two dimensions) of the electron gas in the charge-transfer compounds where they were observed. Among these properties, superconductivity has created much interest since the zero-resistance state is now observed at temperatures as high as 10 K (–442°F) in certain organic superconductors. *See* SUPERCONDUCTIVITY.

Charge-transfer compounds are two-component materials containing anionic and cationic species originating by charge transfer between donor and acceptor entities; these may be two organic molecules or an organic molecule with an inorganic ion. Tetrathiafulvalene-tetracyanoquinodimethane (TTF-TCNQ) is the prototype of charge-transfer organic crystals. Its crystal structure exhibits piled-up segregated columns of donor TTF and acceptor TCNQ molecules (illus. *a*). In the solid state, the amount of charge transferred from donor to acceptor is determined by the overall crystal stability.

Another class of organic conductors is exemplified by radical cation salts such as $(TMTSF)_2X$ where the organic molecule is tetramethyltetraselenafulvalene and X is an inorganic anion. In this class of materials (Bechgaard salts) the molecules display a zigzag packing along the stacking axis (illus. *b*), where one positive charge (hole) is shared between two organic molecules.

The strong overlap between electron clouds of neighboring molecules along the stacks spreads the partially filled molecular electronic states into an energy band 0.5–1 eV wide. This bandwidth is large enough to allow electron delocalization among all molecules on a given stack and to promote electrical conduction similar to that in metal crystals. *See* BAND THEORY OF SOLIDS; CONDUCTION (ELECTRICITY); DELOCALIZATION; MOLECULAR ORBITAL THEORY.

Conducting polymers. Polymeric materials are typically considered as insulators. However, research since the late 1970s has led to the discovery of polymeric materials with extremely high conductivity, approaching that of copper. The prospect of materials combining the properties of plastics and metals or semiconductors has led to a search for applications, made attractive because improved polymers no longer suffer from such drawbacks as low stability, processing difficulties, and brittleness. Most conducting polymers can be switched reversibly between conductive and nonconductive states, with the result that their conductivities can span an enormous range. This switching is accomplished through oxidation-reduction (redox) chemistry, the



Stacking of charge-transfer compounds. (*a*) Segregated stacking of TTF-TCNQ-like materials. (*b*) Typical zigzag stacking of the $(TMTSF)_2X$ series.

conductivity being sensitive to the degree of oxidation of the polymer backbone. This property distinguishes conducting polymers from metals and semiconductors and is the basis of many existing and potential applications. In addition, certain polymers become conducting upon oxidation or reduction and thus can exhibit *p*- or η-type conduction. *See* OXIDATION-REDUCTION; POLYMER.

In a conducting polymer an oxidant removes electrons from the π-electron system of the polymer, creating radical cations that, at high concentrations, dimerize to form cation pairs known as bipolarons. Charge-balancing counterions are concomitantly incorporated between polymer chains. The overall process is referred to as doping, and the counteranion (or countercation in the case of reduction) is the dopant.

Considerable progress has been made on the theory of important parameters such as oxidation potentials, band gaps, and band widths, often with good agreement with experiment. Such work is important for the design of new conductive polymers with specific properties. *See* SOLID-STATE CHEMISTRY. [G.E.W.]

Organic evolution The modification of living organisms during their descent, generation by generation, from common ancestors. Organic, or biological, evolution is to be distinguished from other phenomena to which the term evolution is often applied, such as chemical evolution, cultural evolution, or the origin of life from nonliving matter. Organic evolution includes two major processes: anagenesis, the alteration of the genetic properties of a single lineage over time; and cladogenesis, or branching, whereby a single lineage splits into two or more distinct lineages that continue to change anagenetically.

Anagenesis consists of change in the genetic basis of the features of the organisms that constitute a single species. Populations in different geographic localities are considered members of the same species if they can exchange members at some rate and hence interbreed with each other, but unless the level of interchange (gene flow) is very high, some degree of genetic difference among different populations is likely to develop. The changes that transpire in a single population may be spread to other populations of the species by gene flow. *See* SPECIES CONCEPT.

Almost every population harbors several different alleles at each of a great many of the gene loci; hence many characteristics of a species are genetically variable. All genetic variations ultimately arise by mutation of the genetic material. Broadly defined, mutations include changes in the number or structure of the chromosomes and changes in individual genes, including substitutions of individual nucleotide pairs, insertion and deletion of nucleotides, and duplication of genes. Many such mutations alter the properties of the gene products (ribonucleic acid and proteins) or the timing or tissue localization of gene action, and consequently affect various aspects of the phenotype (that is, the morphological and physiological characteristics of an organism). Whether and how a mutation is phenotypically expressed often depends on developmental (epigenetic) events. *See* GENE; GENETIC CODE; MUTATION; RIBONUCLEIC ACID (RNA).

Natural selection is a consistent difference in the average rate at which genetically different entities leave descendants to subsequent generations; such a difference arises from differences in fitness (that is, in the rate of survival, reproduction, or both). In fact, a good approximate measure of the strength of natural selection is the difference between two such entities in their rate of increase. The entities referred to are usually different alleles at a locus, or phenotypically different classes of individuals in the population that differ in genotype. Thus selection may occur at the level of the gene, as in the phenomenon of meiotic drive, whereby one allele predominates among the gametes produced by a heterozygote. Selection at the level of the individual organism, the more usual case, entails a difference in the survival and reproductive success of phenotypes that may differ at one locus or at more than one locus. As a consequence of the difference in fitness, the proportion of one or the other allele increases in subsequent generations. The relative fitness of different genotypes usually depends on environmental conditions.

Different alleles of a gene that provides an important function do not necessarily differ in their effect on survival and reproduction; such alleles are said to be neutral. The proportion of two neutral alleles in a population fluctuates randomly from generation to generation by chance, because not all individuals in the population have the same number of surviving offspring. Random fluctuations of this kind are termed random genetic drift. If different alleles do indeed differ in their effects on fitness, both genetic drift and natural selection operate simultaneously. The deterministic force of natural selection drives allele frequencies toward an equilibrium, while the stochastic (random) force of genetic drift brings them away from that equilibrium. The outcome for any given population depends on the relative strength of natural selection (the magnitude of differences in fitness) and of genetic drift (which depends on population size).

The great diversity of organisms has come about because individual lineages (species) branch into separate species, which continue to diverge. This splitting process, speciation, occurs when genetic differences develop between two populations that prevent them from interbreeding and forming a common gene pool. The genetically based characteristics that cause such reproductive isolation are usually termed isolating mechanisms. Reproductive isolation seems to develop usually as a fortuitous by-product of genetic divergence that occurs for other reasons (either by natural selection or by genetic drift). *See* SPECIATION.

A frequent consequence of natural selection is that a species comes to be dominated by individuals whose features equip them better for the environment or way of life of the species. Such features are termed adaptations. Although many features of organisms are adaptive, not all are, and it is a serious error to suppose that species are capable of attaining ideal states of adaptation. Some characteristics are likely to have developed by genetic drift rather than natural selection, and so are not adaptations; others are side effects of adaptive features, which exist because of pleiotropy or developmental correlations.

Higher taxa are those above the species level, such as genera and families. A taxon such as a genus is typically a group of species, derived from a common ancestor, that share one or more features so distinctive that they merit recognition as a separate taxon. The degree of difference necessary for such recognition, however, is entirely arbitrary: there are often no sharp limits between related genera, families, or other higher taxa, and very often the diagnostic character exists in graded steps among a group of species that may be arbitrarily divided into different higher taxa. Moreover, a character that in some groups is used to distinguish higher taxa sometimes varies among closely related species or even within species. In addition, the fossil record of many groups shows that a trait that takes on very different forms in two living taxa has developed by intermediate steps along divergent lines from their common ancestor; thus the inner ear bones of mammals may be traced to jaw elements in reptiles that in turn are homologous to gill arch elements in Paleozoic fishes.

The characteristics of a species evolve individually or in concert with certain other traits that are developmentally or functionally correlated. Because of this mosaic pattern of evolution, it is meaningful to speak of the rate of evolution of characters, but not of species or lineages as total entities. Thus in some lineages, such as the so-called living fossils, many aspects of morphology have evolved slowly since the groups first came into existence, but evolution of their deoxyribonucleic acid and amino acid sequences has proceeded at much the same rate as in other lineages. Every species, including the living fossils, is a mixture of traits that have changed little since the species' remote ancestors, and traits that have undergone some evolutionary change in the recent past. The history of life is not one of progress in any one direction, but of adaptive radiation on a grand scale: the descendants of any one lineage diverge as they adapt to different resources, habitats, or ways of life, acquiring their own specialized features as they do so. There is no evidence that evolution has any goal, nor does the mechanistic theory of evolutionary processes admit of any way in which genetic change can have a goal or be directed toward the future. However, for life taken as a whole, the only clearly discernible trend is toward ever-increasing diversity. [D.J.Fu.]

Organic geochemistry The study of the abundance and composition of naturally occurring organic substances, their origins and fate, and the processes that affect their distributions on Earth and in extraterrestrial materials. These activities share the common need for identification, measurement, and assessment of organic matter in its myriad forms.

Organic geochemistry was born from a curiosity about the organic pigments extractable from petroleum and black shales. It developed with extensive investigations of the chemical characteristics of petroleum and petroleum source rocks as clues to their occurrence and formation, and now encompasses a broad scope of activities within interdisciplinary areas of earth and environmental science. This range of studies recognizes the potential of geological records of organic matter to help characterize sedimentary depositional environments and to provide evidence of ancient life and indications of evolutionary developments through the Earth's history. Organic geochemistry includes determinations of anthropogenic contaminants amid the natural background of organic molecules and the assessment of their environmental impact and fate. Marine organic geochemistry addresses and interprets aquatic processes involving carbon species. It involves investigations of the chemical character of particulate and dissolved organic matter, evaluation of oceanic primary production including the factors (light, temperature, nutrient availability) that influence the uptake of carbon dioxide (CO_2), the composition of marine organisms, and the subsequent processing of organic constituents through the food web. Organic geochemistry extends to broader biogeochemical issues, such as the carbon cycle, and the effects of changing carbon dioxide levels, especially efforts to use geochemical data and proxies to help constrain global climate models. Examination of the organic chemistry of meteorites and lunar materials also falls within its compass, and as a critical part of the quest for remnants of life on Mars, such extraterrestrial studies are now regaining the prominence they held in the 1970s during lunar exploration. *See* COSMOCHEMISTRY; GEOCHEMISTRY.

Global inventories of carbon. Carbon naturally exists as oxidized and reduced forms in carbonate carbon and organic matter. The major reservoir of both forms of carbon on Earth is the geosphere. It contains carbonate minerals deposited as sediments and organic matter accumulated from the remains of dead organisms. Estimates of the size of the geological reservoir of carbon vary within the range of 5 to 7×10^{22} g, of which 75% is carbonate carbon and 25% is organic carbon. The amounts of carbon contained in living biota (5×10^{17} g), dissolved in the ocean (4×10^{19} g), and present in atmospheric gases (7×10^{17} g) are miniscule compared to the quantity of organic carbon buried in the rock record. The importance of buried organic matter extends beyond its sheer magnitude; it includes the fossil fuels—coal, natural gas, and petroleum—that supply 85% of the world's energy. *See* BIOGEOCHEMISTRY; CARBON; CARBON DIOXIDE; CARBONATE MINERALS; COAL; FOSSIL FUEL; NATURAL GAS; PETROLEUM; SEDIMENTARY ROCKS.

Sedimentary organic matter. The vast amounts of organic matter contained in geological materials represent the accumulated vestiges of organisms amassed over the expanse of geological time. Yet, survival of organic cellular constituents of biota into the rock record is the exception rather than the norm. Only a small portion of the carbon fixed by organisms during primary production, especially by photosynthesis, escapes degradation as it settles through the water column and eludes microbial alteration during subsequent incorporation and assimilation into sedimentary detritus. *See* BIODEGRADATION.

Sedimentary organic matter can be divided operationally into solvent-extractable bitumen and insoluble kerogen. Bitumens contain a myriad of structurally distinct molecules, especially hydrocarbons, which can be individually identified (such as by gas chromatography-mass spectrometry) although they may be present in only minute quantities (nanograms or picograms). The range of components includes many biomarkers that retain structural remnants inherited from their source organisms, which attest to their biological origins and subsequent geological fate. *See* BITUMEN; KEROGEN.

Biomarkers are individual compounds whose chemical structures carry evidence of their origins and history. Recognition of the specificity of biomarker structures initially helped confirm that petroleum was derived from organic matter produced by biological processes. Of the thousands of individual petroleum components, hundreds reflect precise biological sources of organic matter, which distinguish and differentiate their disparate origins. The diagnostic suites of components may derive from individual families of organisms, but contributions at a species level can occasionally be recognized. Biomarker abundances and distributions help to elucidate sedimentary environments, providing evidence of depositional settings and conditions. They also reflect sediment maturity, attesting to the progress of the successive, sequential transformations that convert biological precursors into geologically occurring products. Thus, specific biomarker characteristics permit assessment of the thermal history of individual rocks or entire sedimentary basins. *See* BASIN.

Carbon isotopes. Carbon naturally occurs as three isotopes: carbon-12 (^{12}C), carbon-13 (^{13}C), and radiocarbon (^{14}C). Temporal excursions in the ^{13}C values of sediment sequences can reflect perturbations of the global carbon cycle. Radiocarbon is widely employed to date archeological artifacts, but the sensitivity of its measurement also permits its use in exploration of the rates of biogeochemical cycling in the oceans. This approach permits assessment of the ages of components in sediments, demonstrating that bacterial organic matter is of greater antiquity than components derived from phytoplankton sources. *See* ISOTOPE; MARINE SEDIMENTS; PALEOCEANOGRAPHY; RADIOCARBON DATING. [S.C.B.]

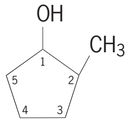
Organic nomenclature A system by which a unique and unambiguous name or other designation is assigned to a given organic molecular structure. A set of rules adopted by the International Union of Pure and Applied Chemistry (IUPAC) is the basis for a standardized name for any organic compound. Common or nonsystematic names are used for many compounds that have been known for a long time. The latter names have the advantage of being short and easily recognized, as in the examples below. However, in contrast to systematic names, common or trivial names do not convey information from which the structure can be written by reference to prescribed rules.

In the IUPAC system, a name is formed by combination of a parent alkyl chain or ring with prefixes and suffixes to denote substituents. For aliphatic compounds, the parent name is a stem that denotes the longest straight chain in the structure with the ending-ane. The first four members of the alkane series are methane, ethane, propane, and butane. From five carbons on, the names follow the Greek numerical roots, for example, pentane and hexane. Changing the ending-ane to -yl gives the name of the corresponding radical or group; for example, CH_3CH_2— is the ethyl radical or ethyl group. Branches on an alkyl chain are indicated by the name of a radical or group as a prefix. The location of a branch or other substituent is indicated by number; the chain is numbered from whichever end results in the lowest numbering. *See* ALKANE.

Double or triple bonds are indicated by the endings-ene or -yne, respectively. The configuration of the chain at a double bond is denoted by *E*- when two similar groups are on opposite sides of the plane bisecting the bond, and *Z*- when they are on the same side. *See* ALKENE; ALKYNE.

A compound containing a functional group is named by adding to the parent name a suffix characteristic of the group. If there are two or more groups, a principal group is designated by suffix and the other(s) by prefix.

The same general principles apply to cyclic compounds. For alicyclic rings, the prefix cyclo- is followed by a stem indicating the number of carbon atoms in the ring, as is illustrated in the structure below. In bicyclic compounds, the total number of carbons in the ring system is prefixed by bicyclo- and numbers in brackets which indicate the number of atoms in each connecting chain.



(1)

2-Methylcyclopentanol

The names of aromatic hydrocarbons have the ending -ene, which denotes a ring system with the maximum number of noncumulative double bonds. Each of the simpler polycyclic hydrocarbons has a different parent name. To number the positions in a polycyclic aromatic ring system, the structure must first be oriented with the maximum number of rings arranged horizontally and to the right. The system is then numbered in clockwise sequence starting with the atom in the most counterclockwise position of the upper right-hand ring, omitting atoms that are part of a ring fusion. *See* AROMATIC HYDROCARBON.

Basis of nomenclature of heterocyclic compounds

Heteroatom	Prefix	Ring size	Suffix
O	ox(a)-	4	-ete
S	thi(a)-	5	-ole
N	az(a)-	6	-ine
		7	-epine

Systematic names for rings containing a heteroatom (O, S, N) are based on a combination of a prefix denoting the heteroatom(s) and a suffix denoting the ring size, as indicated in the table. *See* CHEMICAL SYMBOLS AND FORMULAS; HETEROCYCLIC COMPOUNDS; ORGANIC CHEMISTRY. [J.A.Mo.]

Organic photochemistry

A branch of chemistry that deals with light-induced changes of organic material. Because it studies the interaction of electromagnetic radiation and matter, photochemistry is concerned with both chemistry and physics. In considering photochemical processes, therefore, it is also necessary to consider physical phenomena that do not involve strictly chemical changes, for example, absorption and emission of light, and electronic energy transfer.

Because several natural photochemical processes were known to play important roles (namely, photosynthesis in plants, process of vision, and phototropism), the study of organic photochemistry started very early in the twentieth century. However, the breakthrough occurred only after 1950 with the availability of commercial ultraviolet radiation sources and modern analytical instruments for nuclear magnetic resonance (NMR) spectroscopy and (gas) chromatography.

In general, most organic compounds consist of rapidly interconvertible, nonseparable conformers, because of the free rotation about single bonds. Each conformer has a certain energy associated with it, and its own electronic absorption spectrum. This is one cause of the broad absorption bands produced by organic compounds in solution. The equilibrium of the conformers may be influenced by the solvent and the temperature. According to the Franck-Condon principle, which states that promotion of an electron by the absorption of a photon is much faster than a single vibration, each conformer will have its own excited-state configuration. *See* CONFORMATIONAL ANALYSIS; MOLECULAR STRUCTURE AND SPECTRA.

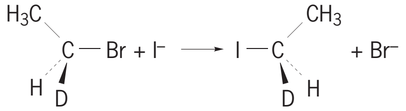
Because of the change in the pi-bond order upon excitation of the substrate and the short lifetime of the first excited state, the excited conformers are not in equilibrium and each yields its own specific photoproduct. Though different conformers may lead to the same photoproduct and one excited conformer may lead to several photoproducts, a change in solvent, temperature, or wavelength of excitation influences the photoproduct composition. This is especially true with small molecules; larger molecules with aromatic groups are less sensitive for small wavelength differences.

The influence of wavelength is also important when the primary photoproduct also absorbs light and then gives rise to another photoreaction. Excitation with selected wavelengths or monochromatic light by use of light filters or a monochromator, respectively, may then be profitable for the selective production of the primary product. Similarly, irradiation at a low temperature is helpful in detecting a primary photoproduct that is unstable when heated (thermolabile). *See* COLOR FILTER. [W.H.L.]

Organic reaction mechanism

A complete, step-by-step account of how a reaction of organic compounds takes place. A fully detailed mechanism would correlate the original structure of the reactants with the final structure of the products and account for changes in structure and energy throughout the progress of the reaction. It would also account for the formation of any intermediates and the rates of interconversions of all of the various species. Because it is not possible to detect directly all of these details, evidence for a reaction mechanism is always indirect. Experiments are designed to produce results that provide logical evidence for (but can never unequivocally prove) a mechanism. For most organic reactions, there are mechanisms that are considered to be well established based on bodies of experimental evidence. Nevertheless, new data often become available that provide further insight into new details of a mechanism or that occasionally require a complete revision of an accepted mechanism.

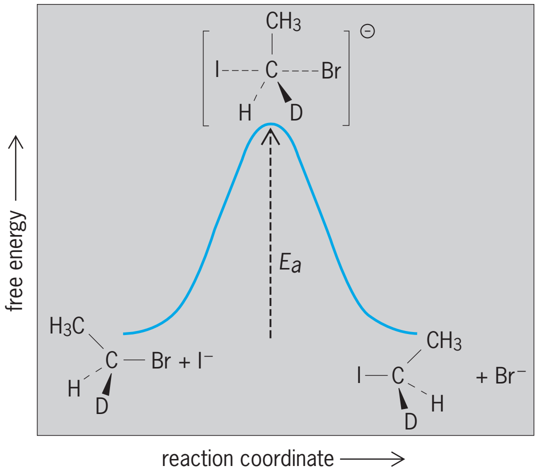
Classification of organic reactions. The description of an organic reaction mechanism typically includes designation of the overall reaction (for example, substitution, addition, elimination, oxidation, reduction, or rearrangement), the presence of any reactive intermediates (that is, carbocations, carbanions, free radicals, radical ions, carbenes, or excited states), the nature of the reagent that initiates the reaction (such as electrophilic or nucleophilic), the presence of any catalysis (such as acid or base), and any specific stereochemistry. For example, reaction (1) would be described as a concerted nucleophilic substitution of an alkyl halide that proceeds with inversion of stereochemistry. A reaction that proceeds in a single step, without intermediates, is described as concerted or synchronous. Reaction (1) is an example of the S_N2 mechanism (substitution, nucleophilic, bimolecular).



$$\mathrm{H_3C(H)(D)C{-}Br + I^- \longrightarrow I{-}C(CH_3)(D)(H) + Br^-} \qquad (1)$$

Potential energy diagrams. A common method for illustrating the progress of a reaction is the potential energy diagram, in which the free energy of the system is plotted as a function of the completion of the reaction (see illustration).

The reaction coordinate is intended to represent the progress of the reaction, and it may or may not correlate with an easily observed or measurable feature. In reaction (1), the reaction coordinate could be considered to be the increasing bond length of the carbon-bromine (C-Br) bond as it is broken, or the decreasing separation of C and iodine (I) as they come together to form a bond. In fact, a complete potential energy diagram should illustrate the variation in energy as a function of both of these

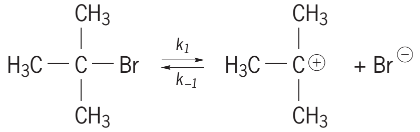


Potential energy–reaction coordinate diagram for a typical nucleophilic substitution reaction that proceeds by the S_N2 mechanism. E_a = activation energy.

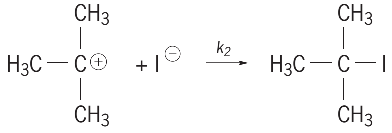
(and perhaps several other relevant structural features), but this would require a three- dimensional (or higher) plot.

Besides identifying the energy levels of the original reactants and the final products, the potential energy diagram indicates the energy level of the highest point along the reaction pathway, called the transition state. Because the transition state represents the highest energy that the molecules must attain as they proceed along the reaction pathway, the energy level of the transition state is a key indication of how easily the reaction can occur. Features that tend to make the transition state more stable (lower in energy) make the reaction more favorable. Such stabilizing features could be intramolecular, such as electron donation or withdrawal by substituents, or intermolecular, such as stabilization by solvent. *See* CHEMICAL BONDING; ENERGY.

Kinetics. Another way to illustrate the various steps involved in a reaction mechanism is as a kinetic scheme that shows all of the individual steps and their rate constants. The S_N2 mechanism is a single step, so the kinetics must represent that step; the rate is observed to depend on the concentrations of both the organic substrate and the nucleophile. However, for multistep mechanisms the kinetics can be a powerful tool for distinguishing the presence of alternative pathways. For example, when more highly substituted alkyl halides undergo nucleophilic substitution, the rate is independent of the concentration of the nucleophile. This evidence suggests a two-step mechanism, called the S_N1 mechanism, as shown in reaction scheme (2), where the *k* terms represent rate constants.



$$\mathrm{H_3C{-}\overset{CH_3}{\underset{CH_3}{C}}{-}Br} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \mathrm{H_3C{-}\overset{CH_3}{\underset{CH_3}{C}}{}^{\oplus}} + \mathrm{Br}^{\ominus} \qquad (2a)$$



$$\mathrm{H_3C{-}\overset{CH_3}{\underset{CH_3}{C}}{}^{\oplus}} + \mathrm{I}^{\ominus} \xrightarrow{k_2} \mathrm{H_3C{-}\overset{CH_3}{\underset{CH_3}{C}}{-}I} \qquad (2b)$$

The S_N1 mechanism accomplishes the same overall nucleophilic substitution of an alkyl halide, but does so by initial dissociation of the leaving group (Br^-) to form a carbocation, step (2*a*). The nucleophile then attaches to the carbocation to form the final product, step (2*b*). Alkyl halides that have bulky groups around the carbon to be substituted are less likely to be substituted by the direct S_N2 mechanism, because the nucleophile encounters difficulty in making the bond to the inaccessible site (called steric hindrance). If those alkyl groups have substituents that can support a carbocation structure, generally by electron donation, then the S_N1 mechanism becomes preferable.

A crucial feature of a multistep reaction mechanism is the identification of the rate-determining step. The overall rate of reaction can be no faster than its slowest step. In the S_N1 mechanism, the bond-breaking reaction (2*a*) is typically much slower than the bond-forming reaction (2*b*). Hence, the observed rate is the rate of the first step only. Thus, kinetics can distinguish the S_N1 and S_N2 mechanisms, as shown in Eqs. (3) and (4), where R is an

$$\text{Rate} = k\,[\text{RX}]\,[\text{Nu}] \quad \text{for an } S_N2 \text{ mechanism} \qquad (3)$$

$$\text{Rate} = k\,[\text{RX}] \quad \text{for an } S_N1 \text{ mechanism} \qquad (4)$$

alkyl group, X is a halogen or other leaving group, Nu is a nucleophile, and the terms in the brackets represent concentrations.

A more complete description of the S_N1 mechanism was recognized when it was observed that the presence of excess leaving group [for example, Br^- in reaction (2)] can affect the rate (called the common ion rate depression). This indicated that the mechanism should include a reverse step [k_{-1} in reaction step (2*a*)] in which the leaving group returns to the cation, regenerating starting material. In this case, the rate depends in a complex manner on the competition of nucleophile and leaving group for reaction with the carbocation. *See* CHEMICAL DYNAMICS; REACTIVE INTERMEDIATES; STERIC EFFECT (CHEMISTRY).

Activation parameters. The temperature dependence of the rate constant provides significant information about the transition state of the rate-determining step. The Arrhenius equation (5) expresses that dependence in terms of an exponential func-

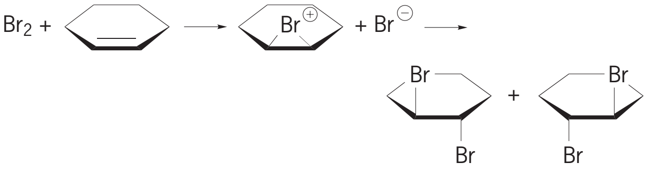
$$k = Ae^{-E_a/RT} \qquad (5)$$

tion of temperature and an activation energy, E_a; *A* is called the Arrhenius or preexponential factor, and *R* is the gas constant. *See* GAS; LOGARITHM.

The activation energy represents the energy difference between the reactants and the transition state, that is, the amount of energy that must be provided in order to proceed along the reaction pathway successfully from reactant to product.

Stereochemistry. Careful attention to the stereochemistry of a reaction often provides crucial insight into the specific orientation of the molecules as they proceed through the reaction mechanism. The complete inversion of stereochemistry observed in the S_N2 mechanism provides evidence for the backside attack of the nucleophile. Alkyl halides that undergo substitution by the S_N1 mechanism do not show specific stereochemistry, since the loss of the leaving group is completely uncorrelated with the bonding of the necleophile.

In addition reactions, possible stereochemical outcomes are addition of the new bonds to the same or opposite sides of the original pi bond, called syn and anti addition, respectively. The anti addition of bromine to double bonds provides evidence



(6)

for the intermediacy of a bridged bromonium ion, as shown in reaction (6). [C.C.W.]

Organic synthesis

The making of an organic compound fro simpler starting materials. Organic synthesis plays an important role by allowing for the creation of specific molecules for scientific and technological investigations.

The heart of organic synthesis is designing synthetic routes to a molecule. The simplest synthesis of a molecule is one in which the target molecule can be obtained by submitting a readily available starting material to a single reaction that converts it to the desired target molecule. However, in most cases the synthesis is not that straightforward; in order to convert a chosen starting material to the target molecule, numerous steps that add, change, or remove functional groups, and steps that build up the carbon atom framework of the target molecule may need to be done.

A systematic approach for designing a synthetic route to a molecule is to subject the target molecule to an intellectual exercise called a retrosynthetic analysis. This involves an assessment of each functional group in the target molecule and the overall carbon atom framework in it; a determination of what known reactions form each of those functional groups or that build up the necessary carbon framework as a product; and a determination of what starting materials for each such reaction are required. The resulting starting materials are then subjected to the same retrosynthetic analysis, thus working backward from the target molecule until starting materials are derived.

The retrosynthetic analysis of a target molecule usually results in more than one possible synthetic route. It is therefore necessary to critically assess each derived route in order to chose the single route that is most feasible and most economical. The safety of each possible synthetic route (the toxicity and reactivity hazards associated with the reactions involved) is also considered when assessing alternative synthetic routes to a molecule.

Selectivity is an important consideration in the determination of a synthetic route to a target molecule. Stereoselectivity refers to the selectivity of a reaction for forming one stereoisomer of a product in preference to another. Stereoselectivity cannot be achieved for all organic reactions; the nature of the mechanism of some reactions may not allow for the formation of one particular configuration of a chiral (stereogenic) carbon center or one particular geometry (cis versus trans) for a double bond or ring. When stereoselectivity can be achieved, it requires that the reaction proceed via a geometrically defined transition state and that one or both of the reactants possess a particular geometrical shape during the reaction. For example, if one or both of the reactants is chiral, the absolute configuration of the newly formed stereogenic carbon center can be selected for in many reactions. *See* Asymmetric synthesis; Organic reaction mechanism; Stereochemistry.

Chemoselectivity is the ability of a reagent to react selectively with one functional group in the presence of another similar functional group. An example of a chemoselective reagent is a reducing agent that can reduce an aldehyde and not a ketone. In cases where chemoselectivity cannot be achieved, the functional group that should be prevented from participating in the reaction can be protected by converting it to a derivative that is unreactive to the reagent involved. The usual strategy employed to allow for such selective differentiation of the same or similar groups is to convert each group to a masked (protected) form which is not reactive but which can be unmasked (deprotected) to yield the group when necessary.

A large variety of organic reactions that can be used in syntheses are known. They can be categorized according to whether they feature a functional group interconversion or a carbon-carbon bond formation.

TABLE 1. Examples of some functional-group interconversions

General equation for the reaction*	Net transformation (name)
 (X = Cl, Br, I, or OSO_2R; Nu = OH, OR, CN, NR_2, others)	Alkyl halide to various functional groups (alcohols, ethers, nitriles, amines, others)
	Alkyl halide to alkene (elimination)
$ROH + HX \longrightarrow RX$ (X = Cl, Br, I)	Alcohol to alkyl halide
	Alcohol to alkene (dehydration)
	Oxidation of alcohol to ketone or aldehyde
 (Y = O or N; X = OH, Cl, others)	Alcohol and carboxylic acid derivative to ester (esterification); amine and carboxylic acid derivative to amide
	Alkene to epoxide (epoxidation)
	Alkene to alkane (hydrogenation)
	Reduction of ketone or aldehyde to alcohol
$R_1COOR_2 \xrightarrow[2.\ H_2O\ workup]{1.\ LiAlH4} R_1CH_2OH + R_2OH$	Reduction of ester to two alcohols
$R_1COOR_2 \xrightarrow{H_2O,\ acid\ or\ base} R_1COOH + R_2OH$	Ester to carboxylic acid and alcohol (ester hydrolysis)
$R-CN \xrightarrow[2.\ H_2O\ workup]{1.\ LiAlH4} RCH_2NH_2$	Reduction of nitrile to amine
 (E = Br, NO_2, R, RCO, others)	Benzene to substituted benzene (electrophilic aromatic substitution)

*R = any organic group (alkyl, aryl, alkenyl) or a hydrogen atom. Nu = nucleophile.

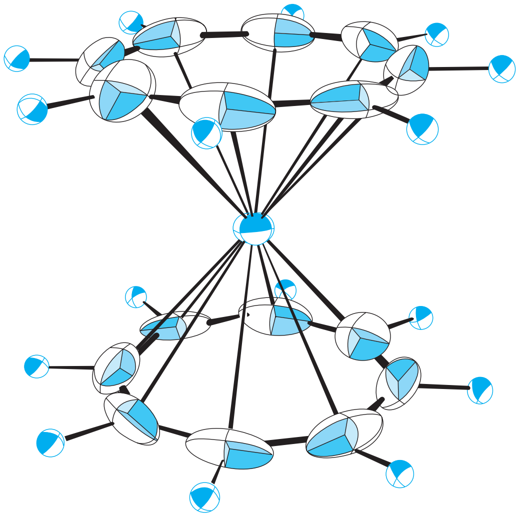
TABLE 2. Examples of some carbon-carbon bond-forming reactions

General equation for the reaction	Name of reaction
 $R_1X + Mg \longrightarrow R_1MgX \xrightarrow[2.\ H^+]{1.\ R_2COR_3} R_1-\underset{R_2}{\overset{OH}{C}}-R_3$ (X = Cl, Br, I)	Grignard
$R_1X \xrightarrow[2.\ CuI]{1.\ Li} (R_1)_2CuLi \xrightarrow{R_2X} R_1-R_2$ (X = Cl, Br, I)	Gilman
 (X = R, RO, NR_2, others)	Aldol addition
 $XCH_2CO-Y + RCHO \xrightarrow[2.\ H_2O\ workup]{1.\ Zn} \overset{OH}{RCH}-CH_2CO-Y$ (X = Cl, Br, or I; Y = R, RO, NR_2, others)	Reformatsky
 (X = R, RO, NR_2, others)	Michael addition
 (X = R, RO, NR_2, others)	Aldol condensation
	Claisen condensation
$R_1CH_2Br \xrightarrow[2.\ BuLi]{1.\ PPh_3} R_1-CH{=}PPh_3 \xrightarrow{3.\ R_2CHO} R_1CH{=}CHR_2$	Wittig
 $2RCHO \xrightarrow[2.\ H_2O\ workup]{1.\ Ti(I)} R-\overset{HO}{CH}-\overset{OH}{CH}-R$	Pinacol coupling
	Free-radical cyclization
 (Y = COOR, COR, CN, others)	Diels-Alder
	Cope rearrangement

Functional group interconversions (Table 1) are reactions that change one functional group into another functional group. A functional group is a nonhydrogen, non-all-singly-bonded carbon atom or group of atoms. Included in functional group interconversions are nucleophilic substitution reactions, electrophilic additions, oxidations, and reductions. *See* Computational chemistry; Electrophilic and nucleophilic reagents; Oxidation-reduction; Oxidizing agent; Substitution reaction.

Carbon-carbon bond-forming reactions (Table 2) feature the formation of a single bond or double bond between two carbon atoms. This is a particularly important class of reactions, as the basic strategy of synthesis—to assemble the target molecule from simpler, hence usually smaller, starting materials—implies that most complex molecules must be synthesized by a process that builds up the carbon skeleton of the target by using one or more carbon-carbon bond-forming reactions. [R.D.Wa.]

Organoactinides Organometallic compounds of the actinides—elements 90 and beyond in the periodic table. Both the large sizes of actinide ions and the presence of 5*f* valence orbitals are unique features which differ distinctly from most, if not all, other metal ions.



Molecular structure of $U(C_8H_8)_2$ determined by single-crystal x-ray diffraction. (*After K. O. Hodgson and K. N. Raymond, Inorg. Chem., 12:458, 1973*)

Organometallic compounds have been prepared for all actinides through curium (element 96), although most investigations have been conducted with readily available and more easily handled natural isotopes of thorium (Th) and uranium (U). Organic groups (ligands) which bind to actinide ions include both π- and σ-bonding functionalities. The importance of this type of compound reflects the ubiquitous character of metal-carbon two-electron sigma bonds in both synthesis and catalysis. *See* Catalysis.

The moleculaor structures of a number of organoactinides have been determined by single-crystal x-ray and neutron-diffraction techniques. In almost all cases the large size of the metal ion gives rise to unusually high (as compared to a transition-metal compound) coordination numbers. That is, a greater number of ligands or ligands with greater spatial requirements can be accommodated within the actinide coordination sphere. The sandwich complex bis(cyclooctatetraenyl)-uranium (ura-nocene), an example of this latter type, is shown in the illustration. *See* Actinide elements; Coordination chemistry; Metallocenes; Neutron diffraction; Organometallic compound; X-ray diffraction. [T.J.M.]

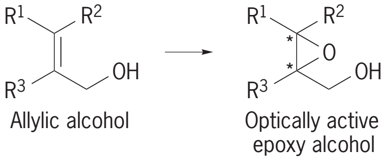
Organometallic compound A member of a broad class of compounds whose structures contain both carbon (C) and a metal (M). Although not a required characteristic of organometallic compounds, the nature of the formal carbon-metal bond can be of the covalent, ionic, or π-bound type.

The term organometallic chemistry is essentially synonymous with organotransition-metal chemistry; it is associated with a specific portion of the periodic table ranging from groups 3 through 11, and also includes the lanthanides. *See* Chemical bonding; Ligand; Periodic table; Transition elements.

From the perspective of inorganic chemistry, organometallics afford seemingly endless opportunities for structural variations due to changes in the metal coordination number, alterations in ligand-metal attachments, mixed-metal cluster formation, and so forth. From the viewpoint of organic chemistry, organometallics allow for manipulations in the functional groups that in unique ways often result in rapid and efficient elaborations of carbon frameworks for which no comparable direct pathway using non-transition organometallic compounds exists.

In moving across the periodic table, the early transition metals have seen relatively limited use in synthesis, with two exceptions: titanium (Ti) and zirconium (Zr).

Titanium has an important role in a reaction known as the Sharpless asymmetric epoxidation, where an allylic alcohol is converted into a chiral, nonracemic epoxy alcohol with excellent and predictable control of the stereochemistry [reaction (1)]. The significance of the nonracemic product is that the reaction yields a single enantiomer of high purity.

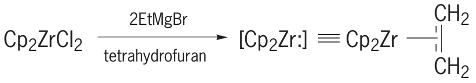


(1)

There are many applications utilizing the Sharpless asymmetric synthesis. Examples of synthetic targets that have relied on this chemistry include riboflavin (vitamin B_2) and a potent inhibitor of cellular signal transduction known as FK-506. *See* Asymmetric synthesis; Titanium.

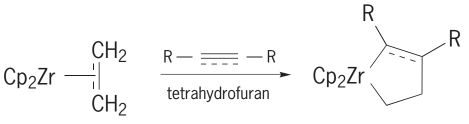
Below titanium in group 4 in the periodic table lies zirconium. Most modern organozirconium chemistry concerns zirconium's ready formation of the carbenelike complex [Cp_2Zr:], which because of its mode of preparation is more accurately thought of as a π complex (2). Also important are reactions of the zirconium chloride hydride, $Cp_2Zr(H)Cl$, commonly referred to as Schwartz's reagent, with alkenes and alkynes, and the subsequent chemistry of the intermediate zirconocenes. *See* Metallocenes.

When the complex Cp_2ZrCl_2 is exposed to two equivalents of ethyl magnesium bromide EtMgBr, the initially formed Cp_2ZrEt_2 loses a molecule of ethane (C_2H_6) to produce the complexed zirconocene [Cp_2Zr: (**1**)], as shown in reaction (2). Upon introduction of another alkene or alkyne, a zirconacyclopentane or zirconacyclopentene is formed, respectively [reaction (3)], where the structure above the arrow indicates that the chemistry applies to either alkenes (no third bond) or alkynes (with third bond)]. These are reactive species that can be converted to many useful



$$Cp_2ZrCl_2 \xrightarrow[\text{tetrahydrofuran}]{\text{2EtMgBr}} [Cp_2Zr:] \equiv Cp_2Zr - \overset{CH_2}{\underset{CH_2}{\|}} \qquad (2)$$

(**1**)

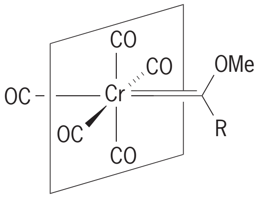


(**1**)

(3)

derivatives resulting from reactions such as insertions, halogenations, and transmetalation/quenching. When the preformed complex (**1**) is treated with a substrate containing both an alkene and alkyne, a bicyclic zirconacene results that can ultimately yield polycyclic products (for example, pentalenic acid, a likely intermediate in the biosynthesis of the antibiotic pentalenolactone). *See* Reactive intermediates.

Among the group 6–8 metals, chromium (Cr), molybdenum (Mo), and tungsten (W) have been extensively utilized in the synthesis of complex organic molecules in the form of their electrophilic Fischer carbene complexes, which are species having, formally, a double bond between carbon and a metal. They are normally generated as heteroatom-stabilized species bearing a "wall" of carbon monoxide ligands (**2**).



(**2**)

Most of the synthetic chemistry has been performed with chromium derivatives, which are highly electrophilic at the carbene center because of the strongly electron-withdrawing carbonyl (CO) ligands on the metal. Many different types of reactions are characteristic of these complexes, such as α alkylation, Diels-Alder cycloadditions of α,β-unsaturated systems, cyclopropanation with electron-deficient olefins, and photochemical extrusions/cycloadditions. The most heavily studied and applied in synthesis, however, is the Dötz reaction, which has been applied in the production of antitumor antibiotics in the anthracycline and aureolic acid families. *See* Diels-Alder reaction; Metal carbonyl.

Groups 9–11 contain transition metals that have been the most widely used not only in terms of their abilities to effect C—C bond formations but also organometallic catalysts for some of the most important industrial processes. These include cobalt (Co), rhodium (Rh), palladium (Pd), and copper (Cu). [B.H.L.]

Organophosphorus compound One of a series of derivatives of phosphorus that have at least one organic (alkyl or aryl) group attached to the phosphorus atom linked either directly to a carbon atom or indirectly by means of another element (for example, oxygen). The mono-, di-, and trialkylphosphines (and their aryl counterparts) can be regarded formally as the parent compounds of all organophosphorus compounds.

Considering the large number of organic groups that may be joined to phosphorus as well as the incorporation of other elements in these materials, the number of combinations is practically unlimited. A vast family in itself is composed of the heterocyclic phosphorus molecules, in which phosphorus is one of a group of atoms in a ring system.

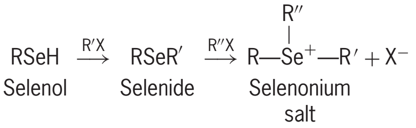
Some organophosphorus compounds have been used as polymerization catalysts, lubricant additives, flameproofing agents, plant growth regulators, and insecticides. Organophosphorus compounds were made during World War II for use as chemical warfare agents in the form of nerve gases (Sarin, Trilon 46, Soman, and Tabun). *See* Phosphorus. [S.E.Cr.]

Organoselenium compound One of a group of compounds that contain both selenium (Se) and carbon (C) and frequently other elements as well, for example, halogen, oxygen (O), sulfur (S), or nitrogen (N). Organoselenium compounds have become common in organic chemistry laboratories, where they have numerous applications, particularly in the area of organic synthesis. Organoselenium compounds formally resemble their sulfur analogs and may be classified similarly. For instance, selenols, selenides, and selenoxides are clearly related to thiols, sulfides, and sulfoxides. Despite structural similarities, however, sulfur and selenium compounds are often strikingly different with respect to their stability, properties, and ease of formation. *See* Organosulfur compound; Selenium.

Selenols have the general formula RSeH, where R represents either an aryl or alkyl group. They are prepared by the alkylation of hydrogen selenide (H_2Se) or selenide salts, as well as by the reaction of Grignard reagents or organolithium compounds with selenium, as in reactions (1).

$$\mathrm{H_2Se\ (or\ HSe^-)} \xrightarrow{\mathrm{RX}} \underset{\text{Selenol}}{\mathrm{RSeH}} \xleftarrow[\mathrm{2.\ H_3O^+}]{\mathrm{1.\ Se}} \underset{\substack{\text{Grignard}\\ \text{reagent}}}{\mathrm{RMgX}} \ \text{or}\ \underset{\substack{\text{Organolithium}\\ \text{compound}}}{\mathrm{RLi}} \qquad (1)$$

Selenols are stronger acids than thiols. They and their conjugate bases are powerful nucleophiles that react with alkyl halides (R′X; R′ = alkyl group) or similar electrophiles to produce selenides (RSeR′); further alkylation yields selenonium salts, as shown in reactions (2), where R″ represents an alkyl group that may be different from the alkyl group R′. Both acyclic and cyclic selenides are known. *See* Alkylation; Electrophilic and nucleophilic reagents; Grignard reaction; Reactive intermediates.



$$\underset{\text{Selenol}}{\mathrm{RSeH}} \xrightarrow{\mathrm{R'X}} \underset{\text{Selenide}}{\mathrm{RSeR'}} \xrightarrow{\mathrm{R''X}} \underset{\substack{\text{Selenonium}\\ \text{salt}}}{\mathrm{R{-}\overset{\displaystyle R''}{\overset{|}{Se^+}}{-}R'}} + \mathrm{X^-} \qquad (2)$$

Diselenides (RSeSeR) are usually produced by the aerial oxidation of selenols; they react in turn with chlorine or bromine, yielding selenenyl halides or selenium trihalides. Diselenides are easily oxidized to seleninic acids or anhydrides by reagents such as hydrogen peroxide or nitric acid.

Selenoxides are readily obtained from the oxidation of selenides with hydrogen peroxide (H_2O_2) or similar oxidants. Selenoxides undergo facile elimination to produce olefins and selenenic acids, a process known as syn-elimination.

Selenocarbonyl compounds tend to be considerably less stable than their thiocarbonyl or carbonyl counterparts because of the weaker double bond between the carbon and selenium atoms. Selenoamides, selenoesters and related compounds can be isolated, but selenoketones (selones) and selenoaldehydes are highly unstable. *See* Aldehyde; Amide; Ester; Ketone.

The charge-transfer complexes formed between certain Organoselenium donor molecules and appropriate acceptors such as tetracyanoquinodimethane are capable of conducting electric current. Selenium-containing polymers are also of interest as organic conductors. *See* Coordination complexes; Organic conductor.

Selenium is an essential trace element, and its complete absence in the diet is severely detrimental to human and animal health. The element is incorporated into selenoproteins such as glutathione peroxidase, which acts as a natural antioxidant. *See* Bioinorganic chemistry; Coordination chemistry; Protein. [T.G.B.]

Organosilicon compound One of a group of compounds in which silicon (Si) is bonded to an organic functional group (R) either directly or indirectly via another atom. Formally, all organosilanes can be viewed as derivatives of silane (SiH_4) by the substitution of hydrogen (H) atoms. The most common substituents are methyl (CH_3; Me) and phenyl (C_6H_5; Ph) groups. However, tremendous diversity results with cyclic structures and the introduction of heteroatoms. *See* Silicon.

Organosilicon compounds are not found in nature and must be prepared in the laboratory. The ultimate starting material is sand (silicon dioxide, SiO_2) or other inorganic silicates, which make up over 75% of the Earth's crust. The useful properties of silicone polymers were identified in the 1940s; widespread interest in Organosilicon chemistry followed.

The chemistry of organosilanes can be explained in terms of the fundamental electronic structure of silicon and the polar nature of its bonds to other elements. Silicon appears in the third row of the periodic table, immediately below carbon (C) in group IV, and has many similarities with carbon. However, it is the fundamental differences between carbon and silicon that make silicon so useful in organic synthesis and of such great theoretical interest. *See* Carbon.

In the majority of organosilicon compounds, silicon follows the octet rule and is 4-coordinate. This trend can be explained by the electronic configuration of atomic silicon ($3s^23p^23d^0$) and the formation of sp^3-hybrid orbitals for bonding. Unlike carbon ($2s^22p^2$), however, silicon is capable of expanding its octet and can form 5- and 6-coordinate species with electronegative substituents, such as the 6-coordinate octahedral dianion, $[Me_2SiF_4]^{2-}$. *See* Coordination chemistry; Electron configuration; Valence.

Silicon is a relatively electropositive element that forms polar covalent bonds ($Si^{\delta+}$—$X^{\delta-}$) with carbon and other elements, including the halogens, nitrogen, and oxygen. The strength and reactivity of silicon bonds depend on the relative electronegativities of the two elements. For example, the strongly electronegative elements fluorine (F) and oxygen (O) form bonds that have tremendous thermodynamic stabilities. *See* Chemical thermodynamics; Electronegativity.

Before 1981, multiply bonded silicon compounds were identified only as transient species both in solution and in the gas phase. However, when tetramesityldisilene ($Ar_2Si{=}SiAr_2$, where Ar = 2,4,6-trimethylphenyl) was isolated, it was found to be a crystalline, high-melting-point solid having excellent stability in the absence of oxygen and moisture.

Numerous reactive species have been generated and characterized in organosilicon chemistry. Silylenes are divalent silicon species (SiR_2, where R = alkyl, aryl, or hydrogen), analogous to carbenes in carbon chemistry. The dimerization of two silylene units gives a disilene. Silicon-based anions, cations, and radicals are important intermediates in the reactions of silicon. *See* Free radical.

The direct process for the large-scale preparation of organosilanes has provided a convenient source of raw materials for the development of the silicone industry. The process produces a mixture of chloromethylsilanes from elemental silicon and methyl chloride in the presence of a copper (Cu) catalyst, as in the reaction below.

$$\text{Me—Cl} + \text{Si} \xrightarrow{\text{Cu catalyst}} \text{Cl}_2\text{SiMe}_2 + \text{other Cl}_n\text{SiMe}_{4-n}$$

In spite of concentrated research efforts in this area, the synthetic methods available for the controlled formation of silicon-carbon bonds remain limited to only a few general reaction types. These include the reaction of organometallic reagents with silanes, catalytic hydrosilylation of multiple bonds, and reductive silylation.

The role of silicon in organic synthesis is quite extensive, and chemists exploit the unique reactivity of organosilanes to accomplish a wide variety of transformations. Silicon is usually introduced into a molecule to perform a specific function and is then removed under controlled conditions.

Polysilanes are organosilicon compounds that contain either cyclic arrays or linear chains of silicon atoms. The isolation and characterization of both cyclosilanes (with up to 35 silane units) and high-molecular-weight linear polysilanes (with up to 3000 silane units) have demonstrated that silicon is capable of extended chain formation (catenation). Polysilanes contain only silicon-silicon bonds in their backbone, which differentiates them from polysiloxanes (silicones), which contain alternating silicon and oxygen repeat units. *See* Silicone resins.

Polysilanes have found applications as photoresists in microlithography, charge carriers in electrophotography, and photoinitiators for vinyl polymerization. Polysilanes also function as preceramic polymers for the manufacture of silicon carbide fibers. [H.Y.]

Organosulfur compound

A member of a class of organic compounds with any of several dozen functional groups containing sulfur (S).

Sulfur is an element of the third row of the periodic table; it is larger and less electronegative than oxygen, which lies above it in the second row. Compounds with an expanded valence shell, that is, compounds bonding to as many as six ligands around sulfur, are therefore possible, and a broad range of compounds can be formed. Moreover, sulfur has a much greater tendency than oxygen to undergo catenation to give chains with several atoms linked together through S—S bonds. *See* Chemical bonding; Periodic table; Structural chemistry; Valence.

The structures and names of representative types of organosulfur compounds are shown in the table. Some compounds and groups are named by using the prefix thio to denote replacement of oxygen by sulfur. The prefix thia can be used to indicate that one or more —CH_2— groups have been replaced by sulfur, as in 2,7-dithianonane [$CH_3S(CH_2)_4SCH_2CH_3$].

Thiols and sulfides are sulfur counterparts of alcohols and ethers, respectively, and can be prepared by substitution reactions analogous to those used for the oxygen compounds. Sulfonium salts are obtained by further alkylation of sulfides.

Although thiols and alcohols are structurally analogous, there are significant differences in the properties of these two groups. Hydrogen bonding of the type —S–H—S— is very weak

Some types of organosulfur compounds and groups

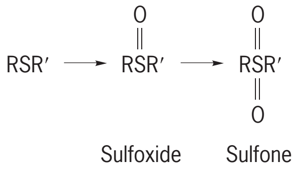
Structure	Name
RSH	Thiol (mercaptan)
RSR	Sulfide (thioether)
RSSR	Disulfide
RSSSR	Trisulfide (trisulfane)
$R\underset{\underset{R}{\mid}}{\overset{+}{S}}R\ X^-$	Sulfonium salt
$R_2C{=}S$	Thioketone
$RN{=}C{=}S$	Isothiocyanate
$R\overset{\overset{O}{\Vert}}{C}SR$	Thiolate ester (thoic acid S-ester)
$R\overset{\overset{S}{\Vert}}{C}OR$	Thionoate ester
RCS_2R	Dithioate ester
RSOH	Sulfenic acid
RSCl	Sulfenyl chloride
RSOR	Sulfoxide
$R\overset{\overset{NR}{\Vert}}{S}R$	Sulfimide
RSO_2H	Sulfinic acid
RSO_2R	Sulfinate ester
$R_2S{=}R_2$	Sulfonium ylide (sulfurane)
RSO_2R	Sulfone
RSO_3H	Sulfonic acid
RSO_2NH_2	Sulfonamide
RSO_2Cl	Sulfonyl chloride
$ROSO_3R$	Sulfate ester

compared to —O—H–O—, and thiols are thus more volatile and have lower boiling points than the corresponding alcohols; for example, methanethiol (CH_3SH) has a boiling point of 5.8°C (42.4°F) compared to 65.7°C (150.3°F) for methanol (CH_3OH).

Thiols form insoluble precipitates with heavy-metal ions such as lead or mercury. Both thiols and sulfides are extremely malodorous compounds, recalling the stench of rotten eggs (hydrogen sulfide). However, traces of these sulfur compounds are an essential component of the distinctive flavors and aromas of many vegetables, coffee, and roast meat. *See* MAILLARD REACTION; MERCAPTAN; SPICE AND FLAVORING.

Thiocarbonyl compounds contain a carbon-sulfur double bond ($C{=}S$). Thiocarbonyl compounds (thiones) are much less common than carbonyl compounds ($C{=}O$ bond). Simple thioaldehydes or thioketones have a strong tendency to form cyclic trimers, polymers, or other products.

Sulfides can be oxidized sequentially to sulfoxides and sulfones, containing the sulfinyl (—SO—) and sulfonyl (—SO_2—) groups, respectively, as in the reaction below.



$$RSR' \longrightarrow \underset{\text{Sulfoxide}}{\overset{O}{\overset{\|}{RSR'}}} \longrightarrow \underset{\text{Sulfone}}{\underset{O}{\underset{\|}{\overset{O}{\overset{\|}{RSR'}}}}}$$

Dimethyl sulfoxide (DMSO) is available in large quantities as a by-product of the Kraft sulfite paper process. It is useful as a polar solvent with a high boiling point and as a selective oxidant and reagent in organic synthesis. *See* DIMETHYL SULFOXIDE.

Compounds containing the sulfonyl group include sulfones, sulfonyl chlorides, sulfonic acids, and sulfonamides. The sulfonyl group resembles a carbonyl in the acidifying effect on an α-hydrogen. The diaryl sulfone unit is the central feature of polysulfone resins, used in some high-performance plastics. Sulfonic acids are obtained by oxidation of thiols or by sulfonation. Sulfonamides, prepared from the chlorides, were the mainstay therapeutic agents in infections until the advent of antibiotics; they are still used for some conditions. *See* POLYSULFONE RESINS; SULFONAMIDE; SULFONIC ACID.

A number of proteins and metabolic pathways in systems of living organisms depend on the amino acid cysteine and other sulfur compounds. In many proteins, for example, in the enzyme insulin, disulfide bonds formed from the —SH groups of cysteine units are an essential part of the structure. The —SH groups of cysteine also play a role in the metal-sulfur proteins that mediate electron-transport reactions in respiration and photosynthesis. *See* INSULIN; PHOTOSYNTHESIS.

The coenzyme lipoic acid is a cyclic disulfide that functions together with the coenzyme thiamine diphosphate to accept electrons and undergo reduction of the —S—S— bond in the oxidative decarboxylation of pyruvic acid. Two other major pathways in metabolism, the transfer of acetyl groups and of methyl groups, are mediated by organosulfur compounds. Acetyl transfer, a key step in lipid and carbohydrate metabolism, occurs by way of thioesters. *See* CARBOHYDRATE METABOLISM; COENZYME; LIPID METABOLISM; THIAMINE.

Sulfur is present in numerous other compounds found in natural sources. Petroleum contains variable amounts of sulfur, both as simple thiols and sulfides, and also heterocyclic compounds such as benzothiophene. Removal of these is an important step in petroleum refining. *See* PETROLEUM; PETROLEUM PROCESSING AND REFINING.

Several sulfur-containing compounds from natural sources have important pharmacological properties. Examples are the β-lactam antibiotics penicillin, cephalosporin, and thienamycin, and the platelet anticoagulating factor ajoene from garlic, produced by a series of complex enzymatic reactions from allicin. *See* ANTIBIOTIC; HETEROCYCLIC COMPOUNDS; ORGANIC CHEMISTRY; SULFUR. [J.A.Mo.]

Oriental vegetables Oriental vegetables are very important in Asian countries, but are considered as minor crops in the United States and Europe. However, in recent years there has been an increased interest in these crops because of their unusual flavors and textures and in some cases their high nutritional values. Some of the more common ones are described below.

Chinese cabbage, celery cabbage, napa, or pe-tsai (*Brassica campestris*, pekinensis group; *B. rapa*, pekinensis group; *B. pekinensis*) belongs to the mustard (Cruciferae) family, and is a biennial leafy plant but is grown as an annual. The harvested part is a head which is composed of broad crinkled leaves with a very wide, indistinct, white midrib. The outer leaves are pale green, and the inner leaves of the head are blanched. It is a good salad vegetable because of the mild flavor and crisp texture.

There are many varieties of pak choy, bok choi, Chinese mustard, or celery mustard (*Brassica campestris*, chinensis group; *B. rapa*, chinensis group; *B. chinensis*). The crop is grown as an annual. Pak choy does not form a head like most varieties of Chinese cabbage, but forms a celerylike stalk of tall, dark green leaves, with prominent white veins and long white petioles (see illustration). The base of the petiole may be expanded and spoon-shaped; the blade of the leaf is smooth, and not crinkled like that of Chinese cabbage.

The large, long, white radish (*Raphanus sativus*, longipinnatus group) is often called oriental winter radish, daikon, Chinese winter radish, lobok, and lob paak. Radish is a dicotyledonous herbaceous plant grown for its long, enlarged roots.

Edible podded peas, China peas, sugar peas, or snow peas (*Pisum sativum*, macrocarpon group) belong to the Leguminosae family. The primitive forms of pea are slightly bitter and have a tough seed coat, which allows for long dormant periods. In the garden pea the pod swells first as the seeds enlarge, but in the edible podded pea the immature seeds bulge the pod, which demarks the developing seeds. Unlike the regular garden peas which have tough fibery seed pods, the edible podded peas were selected for the tender pods and not for the seeds.

Pak choy or Chinese mustard (*Brassica campestris*). (*University of California Agricultural Experiment Station*)

Yard-long bean or asparagus bean (*Vigna sinensis*, sesquipedelis group) belongs to the Leguminosae family. It is an annual climbing plant. It is a relative of the cow pea (*V. unguiculata*).

Mung bean or green gram (*Phaseolus aureus*) sprouts have been used by the Chinese for their remarkable healing qualities for thousands of years. Only recently has the Western world recognized the value of sprouted leguminous seeds (mung, soy, and alfalfa sprouts). The unsprouted mung bean seeds contain negligible amounts of vitamin C (ascorbic acid), whereas the sprouted seeds contain 20 mg per 100 g of sprouts, which is as high as tomato juice.

Jicama (*Pachyrrizus erosus*), also called the yam bean, is indigenous to Mexico and Central America. It belongs to the pea (Leguminosae) family. The crop is grown for its enlarged turnip-shaped root, which is eaten raw or cooked, has a crisp texture, and is sweetish in taste.

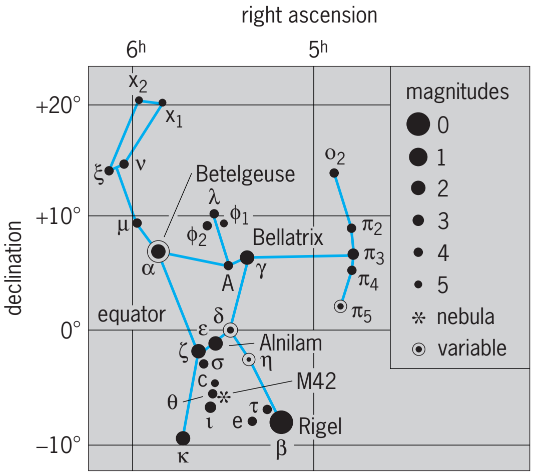
Chinese winter melon, wax gourd, winter gourd, white gourd, ash gourd, Chinese preserving melon, ash pumpkin, or tung kwa (*Benincasa hispida; B. cerifera*) is a viny annual cucurbit. The flesh of mature fruits is used in making Chinese soups. It can be eaten raw or made into sweet preserves similar to citron or watermelon rind preserves.

Balsam pear, alligator pear, bitter gourd, bitter melon, bitter cucumber, or fu kwa (*Momordica charantia*) is an annual herbaceous vine. The heart-shaped to cylindrical fruits are extremely bitter; some of the bitterness is removed before cooking by peeling and steeping in salt water. Immature fruits are less bitter than mature ones.

Chinese okra or angled loofa (*Luffa acutangula*) is called zit kwa by the Chinese; it is a close relative of *L. cylindrica*, known as loofa, sponge gourd, or dishcloth gourd. Chinese okra is an annual climbing vine grown for the immature fruits. The thoroughly mature fruits can be made into vegetable sponge.

Water spinach, water convolvulus, swamp cabbage, kang kong, or shui ung tsoi (*Ipomoea aquatica*) is a perennial semiaquatic plant grown for its long, tender shoots. It is a relative of the sweet potato (*I. batatas*), but does not produce an enlarged root. [M.Y.]

Orion The Warrior, in astronomy, and undoubtedly the finest of all constellations in the sky. Orion is a winter group near the celestial equator. Four of the most prominent stars, α, γ, β, and κ, form a huge crude rectangle (see illustration). The group is pictured as the figure of a warrior, holding a shield with his left hand and swinging a club with his raised right arm ready to strike the charging Bull. Betelgeuse (meaning armpit), one of the largest stars known, is the red star at the right shoulder, Bellatrix is at the left shoulder, and Rigel, the blue-white star, is at the left leg. Three bright stars in a straight line in the middle of the rectangle represent the warrior's belt. The center star is Alnilam. *See* CONSTELLATION; ORION NEBULA; TAURUS. [C.-S.Y.]



Line pattern of the constellation Orion. M42 designates the Orion Nebula. The grid lines represent the coordinates of the sky. The apparent brightness, or magnitude, of the stars is shown by the size of the dots, graded by appropriate numbers.

Orion Nebula The brightest emission nebula in the sky, designated M42 in Messier's catalog. The Great Nebula in Orion consists of ionized hydrogen and other trace elements (see illustration). The nebula belongs to a category of objects known as H II regions (the Roman numeral II indicates that hydrogen is in the ionized state), which mark sites of recent massive star formation. Located in Orion's Sword at a distance of 460 parsecs or 1500 light-years (8.8×10^{15} mi or 1.4×10^{16} km), the Orion Nebula consists of dense plasma, ionized by the ultraviolet radiation of a group of hot stars less than 100,000 years old known as the Trapezium cluster. The nebula covers an area slightly smaller than the full moon and is visible with the aid of binoculars or a small telescope. *See* ORION.

Visual-wavelength view of the Orion Nebula obtained by taking a time exposure on a photographic plate with the 4-m-diameter (158-in.) telescope on Kitt Peak, Arizona (*National Optical Astronomy Observatories*).

In addition to the Trapezium cluster of high-mass stars, the Orion Nebula contains about 700 low-mass stars packed into an unusually small volume of space. As the Orion Nebula evolves, the cluster is expected to expand and possibly dissolve into the smooth background of stars in the Milky Way.

Observations with the Hubble Space Telescope have shown that many low-mass stars in the Orion Nebula are surrounded by disks of dense gas and dust. These so-called proplyds (derived from the term "proto planetary disks") appear to be rapidly losing their mass as they are irradiated by intense ultraviolet radiation produced by high-mass stars in the nebula. However, the proplyds may eventually evolve into planetary systems if most of the solids in these disks have already coagulated into centimeter-sized objects which are resistant to ablation by the radiation field.

A star-forming molecular cloud core (known as OMC1 for Orion Molecular Cloud 1) is hidden behind the Orion Nebula by a shroud of dust. This cloud core is only a small part of a giant molecular cloud (the Orion A cloud), 100,000 times more massive than the Sun. *See* INTERSTELLAR MATTER; MOLECULAR CLOUD; NEBULA. [J.Ba.]

Ornithischia One of two orders of extinct reptiles popularly known as dinosaurs, the other being the Saurischia. The two orders are distinguished by various anatomical differences, but the shape of the pelvis is the primary distinction, tetraradiate or superficially "birdlike" in the Ornithischia and triradiate in the Saurischia. The ordinal names refer to these distinctive conditions: "bird-hipped" and "reptile-hipped." Like the saurischians, ornithischians probably originated from the Thecodontia in Early or Middle Triassic times. Ornithischian remains are known from rock strata ranging from Middle Triassic to latest Cretaceous in age and have been found on all continents except Antarctica. On the basis of tooth shape, all ornithischians are judged to have been herbivores. Most kinds had peculiar beaks or bills, featuring a unique predentary bone at the front of the lower jaw, for plucking vegetation. Many possessed highly specialized batteries of teeth for crushing, grinding, or slicing plant tissues. *See* SAURISCHIA.

Traditional classifications recognize four suborders: Ornithopoda, Stegosauria, Ankylosauria, and Ceratopsia. A fifth suborder, Pachycephalosauria, was suggested as a result of new discoveries in Mongolia. *See* DINOSAUR. [J.H.O.]

Orogeny The process of mountain building. As traditionally used, the term orogeny refers to the development of long, mountainous belts on the continents that are called orogenic belts or orogens. These include the Appalachian and Cordilleran orogens of North America, the Andean orogen of western South America, the Caledonian orogen of northern Europe and eastern Greenland, and the Alpine-Himalayan orogen that stretches from western Europe to eastern China. It is important to recognize that these systems represent only the most recent orogenic belts that retain the high relief characteristic of mountainous regions. In fact, the continents can be viewed as a collage of ancient orogenic belts, most of which are so deeply eroded that no trace of their original mountainous topography remains. By comparing characteristic rock assemblages from more recent orogens with their deeply eroded counterparts, geologists surmise that the processes responsible for mountain building today extended back through most (if not all) of geologic time and played a major role in the growth of the continents. *See* CONTINENTS, EVOLUTION OF.

The construction of mountain belts is best understood in the context of plate tectonics theory. Orogenic belts form at convergent boundaries, where lithosphere plates collide. *See* LITHOSPHERE; PLATE TECTONICS.

There are two basic kinds of convergent plate boundaries, leading to the development of two end-member classes of orogenic belts. Oceanic subduction boundaries are those at which oceanic lithosphere is thrust (subducted) beneath either continental or oceanic lithosphere. The process of subduction leads to partial melting near the plate boundary at depth, which is manifested by volcanic and intrusive igneous activity in the overriding plate. Where the overriding plate consists of oceanic lithosphere, the result is an intraoceanic island arc, such as the Japanese islands. Where the overriding plate is continental, a continental arc is formed. The Andes of western South America is an example. *See* MARINE GEOLOGY; OCEANIC ISLANDS; SUBDUCTION ZONES.

The second kind of convergent plate boundary forms when an ocean basin between two continental masses has been completely consumed at an oceanic subduction boundary and the continents collide. Continent collisional orogeny has resulted in some of the most dramatic mountain ranges on Earth; a good example is the Himalayan orogen, which began forming roughly 50 million years ago when India collided with the Asian continent. Because the destruction of oceanic lithosphere at subduction boundaries is a prerequisite for continental collision, continent collisional orogens contain deformational features and rock associations developed during arc formation as well as those produced by continental collision. [K.Ho.]

Orpiment A mineral having composition As_2S_3. Crystals are small, tabular, and rarely distinct; the mineral occurs more commonly in foliated or columnar masses. The hardness is 1.5–2 (Mohs scale) and the specific gravity is 3.49. The luster is resinous and pearly on the cleavage surface; the color is lemon yellow. Orpiment is found in Romania, Peru, Japan, and Russia. In the United States it occurs at Mercer, Utah; Manhattan, Nevada; and in deposits from geyser waters in Yellowstone National Park. *See* ARSENIC. [C.S.Hu.]

Orthida An order of articulate brachiopods which includes the oldest known representatives of the class. They first appeared in Early Cambrian times and became especially prolific and diverse in the Ordovician. Subsequently, the group diminished in relative abundance during Silurian and Late Paleozoic time, finally becoming extinct during the Permian. The majority of the order belong to the suborder Orthidina. Characteristically, these are biconvex, finely ribbed shells with a straight hinge line and well developed interareas on both valves. *See* BRACHIOPODA. [A.J.R.]

Orthoclase Potassium feldspar (Or = $KAlSi_3O_8$) that usually contains up to 30 mole % albite (Ab = $NaAlSi_3O_8$) in solid solution. Its hardness is 6; specific gravity, 2.57–2.5, depending on Ab content; mean refractive index, 1.52; color, white to dull pink or orange-brown. Some orthoclases may be intergrown with relatively pure albite which exsolved during cooling from a high temperature in pegmatites, granites, or granodiorites. This usually is ordered low albite, but in rare cases it may show some degree of Al,Si disorder, requiring it to be classified as analbite or high albite. If exsolution is detectable by eye, the Or-Ab composite mineral is called perthite; if microscopic examination is required to distinguish the phases, it is called microperthite; and if exsolution is detectable only by x-ray diffraction or electron optical methods, it is called cryptoperthite. Orthoclase is optically monoclinic. Its structure averaged over hundreds of nanometers may be monoclinic, but its true symmetry is triclinic. *See* ALBITE; CRYSTAL STRUCTURE; PERTHITE. [P.H.R.]

Orthogonal polynomials A special case of orthogonal functions that arise in many physical problems (often as the solutions of differential equations), in the study of distribution functions, and in certain other situations where one approximates fairly general functions by polynomials. *See* PROBABILITY.

Each set of orthogonal polynomials is defined with respect to a particular averaging procedure. The average value of a suitable function f is denoted by $E(f)$. An example is shown in Eq. (1). In general an averaging procedure has the form shown in Eq. (2),

$$E\{f\} = \frac{1}{2}\int_{-1}^{1} f(x)\,dx \qquad (1)$$

$$E\{f\} = \int_{-\infty}^{\infty} f(x)\,d\sigma(x) \qquad (2)$$

a Stieltjes integral, where σ is a distribution function, that is, an increasing function with $\sigma(-\infty) = 0$ and $\sigma(+\infty) = 1$.

Two functions f and g are said to be orthogonal with respect to a given averaging procedure if $E\{f[ba]g\} = 0$ where the bar denotes complex conjugation. By the system of orthogonal polynomials associated with the averaging procedure is meant a sequence $P_0, P_1, P_2 \dots$ of polynomials P_n haying exact degree n, which are mutually orthogonal, that is, $E\{P_m \bar{P}_n\} = 0$ for $m \neq n$. This last condition is equivalent to the statement that each P_n is orthogonal to all polynomials of degree less than n. Thus Pnn has the form $P_n(x) = a_0 + a_1x + a_2x^2 + \cdots + a_nx^n$ where $a_n \neq 0$ and is subject to the n conditions $E\{x^k P_n\} = 0$ for $k = 0, 1, \dots, n - 1$. This gives n linear equations in the $n+1$ coefficients of P_n, leaving one more condition, called a normalization, to be imposed. The method of normalization differs in different references. *See* POLYNOMIAL SYSTEMS OF EQUATIONS. [C.S.He.]

Orthonectida An order of Mesozoa. The orthonectids parasitize various marine invertebrates as multinucleate plasmodia. The plasmodia multiply by fragmentation. Eventually they give rise asexually, by polyembryony, to sexual males and females. Commonly only one sex arises from a given plasmodium.

These sexually mature forms escape as minute ciliated organisms. Structurally they are composed of a single layer of ciliated epithelial cells surrounding an inner mass of sex cells. The ciliated cells are disposed in rings around the body.

After insemination the eggs develop in the female and form ciliated larvaea. When liberated, these larvae invade new individuals of their host and then disaggregate, liberating germinal cells which give rise to new plasmodia. *See* MESOZOA. [B.H.McC.]

Orthoptera A related group of generalized insect orders (also known as Orthopteroidea). The group is characterized by gradual metamorphosis, chewing mouthparts, and two pairs of wings, the anterior pair of which is usually thickened and leathery and covers the fanwise folded second pair. Wings are reduced or absent in many species. Common representatives include cockroaches, stick insects, praying mantids, grasshoppers, locusts, and crickets. Food habits range from omnivorous to strictly carnivorous or herbivorous. Habitats are nearly all terrestrial, including arctic-alpine tundra and floating aquatic plants in the tropics. There are no parasitic orthopteroids, but a few species live as "guests" in ant nests. Although most orthopteroids are silent, many of the order Orthoptera Saltatoria (grasshoppers, crickets, and katydids) are outstandingly noisy or musical. The orthopteroids include orders of great economic importance and of considerable research potential. *See* ANIMAL COMMUNICATION.

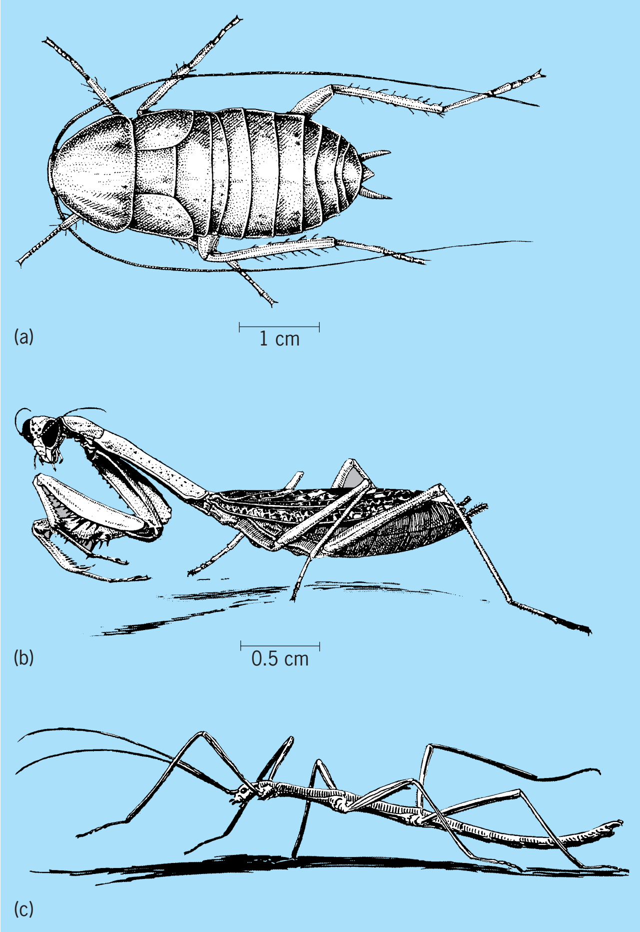
The order Blattodea includes the cockroaches, of which only a few species (illus. *a*) are important pests of stored products and homes.

Mantodea, the order of praying mantises (illus. *b*), is characterized by raptorial (grasping) forelegs on the elongated prothorax. Most are cryptically colored and some closely mimic sticks, leaves, and even flower petals, from which they ambush moving insects.

Phasmatodea, the order of stick and leaf insects (illus. *c*), are slow-moving, sometimes even mimicking the breeze-induced flutterings of their models. Most temperate species are wingless, but many tropical forms have weakly powered wings that may resemble leaves or corrugated bark. All walkingsticks are herbivorous. Many species of phasmids occur only as females.

The order Orthoptera Saltatoria has enlarged hind femora adapted for jumping. There are many families, most of which are grouped as acridoids (short-horned grasshoppers), tettigonioids (long-horned grasshoppers), or grylloids (crickets). Most are herbivorous, but omnivores and carnivores are known.

1. Acridoids. Most temperate species of short-horned grasshoppers belong to the family Acrididae. Antennae are less than half the length of the body. The ovipositor has outwardly pointing hooks. Most species are diurnal and cryptic, some mimicking stones, debris, and grass stems. The plague locusts, *Locusta migratoria*, several species of *Schistocerca*, and others migrate hundreds of miles from the outbreak center in some years to devastate thousands of acres of crops in the tropics and subtropics.



Orthoptera. (*a*) Cockroach (*Blatta orientalis*). (*b*) Praying mantis (*Stagomantis carolina*). (*c*) Walkingstick (*Diapheromera femorata*). (*From Illinois Natural History Survey*)

2. Tettigonioids. Antennae are usually longer than the body in the family Tettigoniidae. Most species are nocturnal and the males' stridulation can be very loud, especially when chorusing. The ovipositor is long and sword-shaped. Meadow grasshoppers and katydids are usually cryptically shaped and colored. A major western North American pest is the flightless Mormon cricket.

3. Grylloids. True crickets (Gryllidae) are ground-, tree-, or bush-dwelling, relatively chunky insects with antennae longer than the body and a needle-shaped ovipositor. The mole crickets (Gryllotalpidae) are serious pests of tropical crops.

Several features of the rock crawlers, order Grylloblattodea, including roachlike legs and asymmetrical male genitalia, indicate that they are a relict order of some ancient orthopteroid group (illus. *i*), but the ovipositor is katydidlike. The rock crawlers are wingless, and there is probably only a single genus, *Grylloblatta*, although the Japanese and Siberian species are sometimes given separate status. They prefer temperatures close to freezing. *See* INSECTA. [R.B.W.]

Orthorhombic pyroxene A group of minerals having the general chemical formula $XYSi_2O_6$, in which the Y site contains Fe or Mg and the X site contains Fe, Mg, Mn, or a small amount of Ca (up to about 3%). The end members of this solid solution series are enstatite ($Mg_2Si_2O_6$) and ferrosilite ($Fe_2Si_2O_6$).

Names used for intermediate members of the series are enstatite, bronzite, hypersthene, and orthoferrosilite.

Many of the physical and optical properties of orthopyroxene are strongly dependent upon composition, and especially upon the Fe-Mg ratio. In hand specimens, orthopyroxene can be distinguished from amphibole by its characteristic 88° cleavage angles, and from augite by color—augite is typically green to black, while orthopyroxene is more commonly brown, especially on slightly weathered surfaces.

Orthopyroxene is a widespread mineral in metamorphic rocks. It is characteristic of granulite facies metamorphism, in both mafic and feldspathic gneisses. Orthopyroxene occurs in many basalts and gabbros, particularly those of tholeiitic composition, and many meteorites, but is notably absent from most alkaline igneous rocks. The greatest abundance of orthopyroxene is in ultramafic rocks, especially those in large layered intrusions. *See* Pyroxene. [R.J.Tr.]

Orthotrichales An order of the true mosses (subclass Bryidae) consisting of five families and 23 genera. The plants grow in mats or tufts in relatively exposed places, on trunks of trees and on rock. They are rather freely branched and prostrate, or may be sparsely forked and erect-ascending; the habit is more or less pleurocarpous, but sporophytes may be produced at the ends of leading shoots or branches. The leaves are generally oblong and broadly pointed, with a strong midrib. The capsules are often ribbed, and the peristome, if present, has a poor development of endostome. The calyptrae are often hairy. *See* Bryidae; Bryophyta; Bryopsida. [H.Cr.]

Oscillation Any effect that varies in a back-and-forth or reciprocating manner. Examples of oscillation include the variations of pressure in a sound wave and the fluctuations in a mathematical function whose value repeatedly alternates above and below some mean value.

The term oscillation is for most purposes synonymous with vibration, although the latter sometimes implies primarily a mechanical motion. The alternating current and the associated electric and magnetic fields are referred to as electric (or electromagnetic) oscillations.

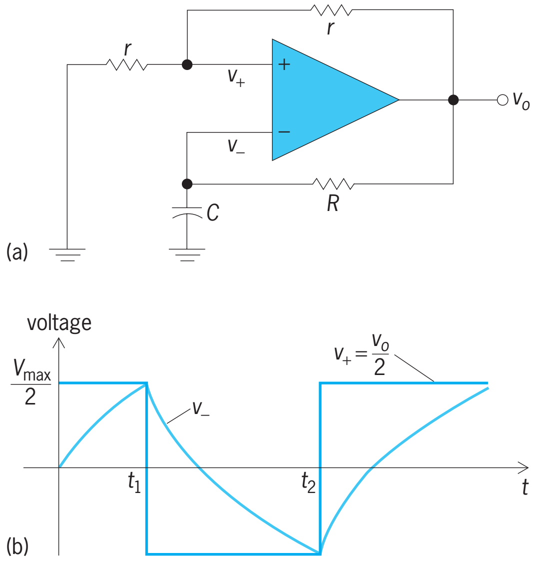
If a system is set into oscillation by some initial disturbance and then left alone, the effect is called a free oscillation. A forced oscillation is one in which the oscillation is in response to a steadily applied periodic disturbance.

Any oscillation that continually decreases in amplitude, usually because the oscillating system is sending out energy, is spoken of as a damped oscillation. An oscillation that maintains a steady amplitude, usually because of an outside source of energy, is undamped. *See* Anharmonic oscillator; Damping; Forced oscillation; Harmonic oscillator; Mechanical vibration; Oscillator; Vibration. [J.M.Ke.]

Oscillator An electronic circuit that generates a periodic output, often a sinusoid or a square wave. Oscillators have a wide range of applications in electronic circuits: they are used, for example, to produce the so-called clock signals that synchronize the internal operations of all computers; they produce and decode radio signals; they produce the scanning signals for television tubes; they keep time in electronic wristwatches; and they can be used to convert signals from transducers into a readily transmitted form.

Oscillators may be constructed in many ways, but they always contain certain types of elements. They need a power supply, a frequency-determining element or circuit, a positive-feedback circuit or device (to prevent a zero output), and a nonlinearity (to define the output-signal amplitude). Different choices for these elements give different oscillator circuits with different properties and applications.

Oscillators are broadly divided into relaxation and quasilinear classes. Relaxation oscillators use strong nonlinearities, such as switching elements, and their internal signals tend to have sharp edges and sudden changes in slope; often these signals are square waves, trapezoids, or triangle waves. The quasilinear oscillators, on the other hand, tend to contain smooth sinusoidal signals because they regulate amplitude with weak nonlinearities. The type of signal appearing internally does not always determine the application, since it is possible to convert between sine and square waves. Relaxation oscillators are often simpler to design and more flexible, while the nearly linear types dominate when precise control of frequency is important.



Simple operational-amplifier relaxation oscillator. (*a*) Circuit diagram. (*b*) Waveforms.

Relaxation oscillators. Illustration *a* shows a simple operational-amplifier based relaxation oscillator. This circuit can be understood in a number of ways (for example, as a negative-resistance circuit), but its operation can be followed by studying the signals at its nodes (illus. *b*). The two resistors, labeled *r*, provide a positive-feedback path that forces the amplifier output to saturate at the largest possible (either positive or negative) output voltage. If v_+, for example, is initially slightly greater than v_-, then the amplifier action increases v_o, which in turn further increases v_+ through the two resistors labelled *r*. This loop continues to operate, increasing v_o until the operational amplifier saturates at some value $V_{\max}$. [An operational amplifier ideally follows Eq. (1), where A_v is very large, but is restricted to output

$$v_o = A_v(v_+ - v_-) \tag{1}$$

levels $|v_o| \leq V_{\max}$.] For the purposes of analyzing the circuit, the waveforms in the illustration have been drawn with the assumption that this mechanism has already operated at time 0 and that the initial charge on the capacitor is zero. *See* Amplifier; Operational amplifier.

Capacitor *C* will now slowly change from v_o through resistor *R*, toward $V_{\max}$, according to Eq. (2).

$$v_- = V_{\max}(1 - e^{-t/RC}) \tag{2}$$

Up until time t_1, this process continues without any change in the amplifier's output because $v_+ > v_-$, and so $v_o = V_{\max}$. At t_1, however, $v_+ = v_-$ and v_o will start to decrease. This causes v_+ to drop, and the positive-feedback action now drives the amplifier output negative until $v_o = -V_{\max}$. Capacitor *C* now discharges exponentially toward the new output voltage until once again, at time t_2, $v_+ = v_-$, and the process starts again. The period of oscillation for this circuit is $2RC \ln 3$.

The basic elements of an oscillator that were mentioned above are all clearly visible in this circuit. Two direct-current power supplies are implicit in the diagram (the operational amplifier will not work without them), the *RC* circuit sets frequency, there is a resistive positive-feedback path that makes the mathematical possibility $v_o(t) = 0$ unstable, and the saturation behavior of the amplifier sets the amplitude of oscillation at the output to $\pm V_{\max}$.

Relaxation oscillators that have a low duty cycle—that is, produce output pulses whose durations are a small fraction of the overall period—are sometimes called blocking oscillators because their operation is characterized by an "on" transient that "blocks" itself, followed by a recovery period.

Inverters (digital circuits that invert a logic signal, so that a 0 at the input produces a 1 at the output, and vice versa) are essentially voltage amplifiers and can be used to make relaxation oscillators in a number of ways. A circuit related to that of the illustration uses a loop of two inverters and a capacitor *C* to provide positive feedback, with a resistor *R* in parallel with one of the inverters to provide an *RC* charging time to set frequency. This circuit is commonly given as a simple example, but there are a number of problems with using it, such as that the input voltage to the first gate sometimes exceeds the specified limits for practical gates. A more practical digital relaxation oscillator, called a ring oscillator, consists simply of a ring containing an odd number *N* (greater than 1) of inverters. *See* LOGIC CIRCUITS.

Sine-wave oscillators. Oscillators in the second major class have their oscillation frequency set by a linear circuit, and their amplitudes set by a weak nonlinearity.

A simple example of a suitable linear circuit is a two-component loop consisting of an ideal inductor [whose voltage is given by Eq. (3), where *i* is its current] and a capacitor [whose

$$v = L\frac{di}{dt} \tag{3}$$

current is given by Eq. (4)], connected in parallel. These are said

$$i = C\frac{dv}{dt} \tag{4}$$

to be linear elements because, in a sense, output is directly proportional to input, for example, doubling the voltage v across a capacitor also doubles dv/dt and therefore doubles i. The overall differential equation for a capacitor-inductor loop can be written as Eq. (5).

$$i + LC\frac{d^2i}{dt^2} = 0 \tag{5}$$

Mathematically this has solutions of the form of Eq. (6), where

$$i = A\sin(\omega t + \phi) \tag{6}$$

$\omega = 1/LC$ [which means that the circuit oscillates at a frequency $1/(2\pi LC)$] and A and ϕ are undefined. They are undefined precisely because the elements in the circuit are linear and do not vary with time: any solution (possible behavior) to the equation can be scaled arbitrarily or time-shifted arbitrarily to give another. Practically, A and ϕ are determined by weak nonlinearities in a circuit. *See* DIFFERENTIAL EQUATION; LINEARITY.

Equation (5) is a good first approximation to the equation describing a pendulum, and so has a long history as an accurate timekeeper. Its value as an oscillator comes from Galileo's original observation that the frequency of oscillation ($\omega/2\pi$) is independent of the amplitude A. This contrasts sharply with the case of the relaxation oscillator, where any drift in the amplitude (resulting from a threshold shift in a comparator, for instance) can translate directly into a change of frequency. Equation (5) also fundamentally describes the operation of the quartz crystal that has replaced the pendulum as a timekeeper; the physical resonance of the crystal occurs at a time constant defined by its spring constant and its mass. *See* HARMONIC MOTION; HARMONIC OSCILLATOR; PENDULUM.

Frequency locking. If an external signal is injected into an oscillator, the natural frequency of oscillation may be affected. If the external signal is periodic, oscillation may lock to the external frequency, a multiple of it, or a submultiple of it, or exhibit an irregular behavior known as chaos. *See* CHAOS.

This locking behavior occurs in all oscillators, sometimes corrupting intended behavior (as when an oscillator locks unintentionally to a harmonic of the power-line frequency) and sometimes by design. An important example of an oscillator that exploits this locking principle is the human heart. Small portions of heart muscle act as relaxation oscillators. They contract, incidentally producing an output voltage that is coupled to their neighbors. For a short time the muscle then recovers from the contraction. As it recovers, it begins to become sensitive to externally applied voltages that can trigger it to contract again (although it will eventually contract anyway). Each small section of heart muscle is thus an independent oscillator, electrically coupled to its neighbors, but the whole heart is synchronized by the frequency-locking mechanism. *See* CARDIAC ELECTROPHYSIOLOGY. [M.Sn.]

Oscillatory reaction

Oscillatory reaction A chemical reaction in which some composition variable of a chemical system exhibits regular periodic variations in time or space. It is a basic tenet of chemistry that a closed system moves inexorably toward an unchanging state called chemical equilibrium. That motion can be described by the monotonic increase of entropy if the system is isolated, and by the monotonic decrease of Gibbs free energy if the system is constrained to constant temperature and pressure. *See* CHEMICAL EQUILIBRIUM; ENTROPY.

The species taking part in a chemical reaction can be classified as reactants, products, or intermediates. The concentrations of reactants decrease. Intermediates are formed by some steps and destroyed by others. If there is only one intermediate, and if its concentration is always much less than the initial concentrations of reactants, this intermediate attains a stable steady state in which the rates of formation and destruction are virtually equal. Some oscillations require at least two intermediates which interact in such a way that the steady state of the total system is unstable to the minor fluctuations present in any collection of molecules. The concentrations of the intermediates may then oscillate regularly, although the oscillations must disappear before the inevitable monotonic approach to equilibrium.

The systems whose chemistries are best understood all involve an element that can exist in several different oxidation states. An example is the so-called Belousov-Zhabotinsky reaction. A strong oxidizing agent (bromate) attacks an organic substrate (such as malonic acid), and the reaction is catalyzed by a metal ion (such as cerium) that can exist in two different oxidation states.

As long as bromide ion (Br) is present, it is oxidized by bromate (BrO_3^-), as in reaction (1).

$$\mathrm{BrO_3^- + 2Br^- + 3H^+ \rightarrow 3HOBr} \tag{1}$$

When bromide ion is almost entirely consumed, the cerous ion (Ce^{3+}) is oxidized, as in reaction (2). Reaction (2) is inhibited by

$$\mathrm{BrO_3^- + 4Ce^{3+} + 5H^+ \rightarrow HOBr + 4Ce^{4+} + 2H_2O} \tag{2}$$

Br^-, but when the concentration of bromide has been reduced to a critical level, reaction (2) accelerates autocatalytically until bromate is being reduced by Ce^{3+} many times as rapidly as it is by Br^- when reaction (3) is dominant.

The hypobromous acid (HOBr) brominates the organic substrate to form bromomalonic acid (BrMA), as in reaction (3).

$$\mathrm{2Ce^{4+} + BrMA \rightarrow 2Ce^{3+} + Br^- + \text{ oxidized organic matter}} \tag{3}$$

Reaction (3) creates the bromide ion necessary to shut off fast reaction (2) and throw the system back to dominance by slow reaction (1).

As other redox oscillators become understood, they fit the same pattern of a slow reaction destroying a species that inhibits a fast reaction that can be switched on autocatalytically;

the fast reaction then generates conditions to produce the inhibitor again. *See* Oxidation-reduction. [R.M.No.]

Oscilloscope An electronic measuring instrument which produces a display showing the relationship of two or more variables. In most cases it is an orthogonal (x,y) plot with the horizontal axis being a linear function of time. The vertical axis is normally a linear function of voltage at the signal input terminal of the instrument. Because transducers of many types are available to convert almost any physical phenomenon into a corresponding voltage, the oscilloscope is a very versatile tool that is useful for many forms of physical investigation. *See* Transducer.

The oscillograph is an instrument that performs a similar function but provides a permanent record. The light-beam oscillograph used a beam of light reflected from a mirror galvanometer which was focused onto a moving light-sensitive paper. These instruments are obsolete. The mechanical version, in which the galvanometer drives a pen which writes on a moving paper chart, is still in use, particularly for process control. *See* Galvanometer; Graphic recording instruments.

Oscilloscopes are one of the most widely used electronic instruments because they provide easily understood displays of electrical waveforms and are capable of making measurements over an extremely wide range of voltage and time. Although a very large number of analog oscilloscopes are in use, digitizing oscilloscopes (also known as digital oscilloscopes or digital storage oscilloscopes) are preferred, and analog instruments are likely to be superseded. *See* Electronic display.

An analog oscilloscope, in its simplest form, uses a linear vertical amplifier and a time base to display a replica of the input signal waveform on the screen of a cathode-ray tube (CRT). The screen is typically divided into 8 vertical divisions and 10 horizontal divisions. Analog oscilloscopes may be classified into nonstorage oscilloscopes, storage oscilloscopes, and sampling oscilloscopes.

Analog nonstorage oscilloscopes are the oldest and most widely used type. Except for the cathode-ray tube, the circuit descriptions also apply to analog storage oscilloscopes. A typical oscilloscope might have a bandwidth of 150 MHz, two main vertical channels plus two auxiliary channels, two time bases (one usable for delay), and a cathode-ray-tube display area; and it might include on-screen readout of some control settings and measurement results. A typical oscilloscope is composed of five basic elements: (1) the cathode-ray tube and associated controls; (2) the vertical or signal amplifier system with input terminal and controls; (3) the time base, which includes sweep generator, triggering circuit, horizontal or x-amplifier, and unblanking circuit; (4) auxiliary facilities such as a calibrator and on-screen readout; and (5) power supplies.

Digital techniques are applied to both timing and voltage measurement in digitizing oscilloscopes. A digital clock determines sampling instants at which analog-to-digital converters obtain digital values for the input signals. The resulting data can be stored indefinitely or transferred to other equipment for analysis or plotting. *See* Voltage measurement; Waveform determination.

In its simplest form a digitizing oscilloscope comprises six basic elements: (1) analog vertical input amplifier; (2) high-speed analog-to-digital converter and digital waveform memory; (3) time base, including triggering and clock drive for the analog-to-digital converter and waveform memory; (4) waveform reconstruction and display circuits; (5) display, generally, but not restricted to, a cathode-ray tube; (6) power supplies and ancillary functions. In addition, most digitizing oscilloscopes provide facilities for further manipulation of waveforms prior to display, for direct measurements of waveform parameters, and for connection to external devices such as computers and hard-copy units.

Higher measurement accuracy is available from digitizing oscilloscopes. The first decision to be made in choosing an oscilloscope is whether this or any of the other properties exclusive to the digitizing type are essential. If not, the option of an analog design remains. The selected instrument must be appropriate for the signal under examination. It must have enough sensitivity to give an adequate deflection from the applied signal, sufficient bandwidth, adequately short rise time, and time-base facilities capable of providing a steady display of the waveform. An analog oscilloscope needs to be able to produce a visible trace at the sweep speed and repetition rate likely. A digitizing oscilloscope must have an adequate maximum digitizing rate and a sufficiently long waveform memory. [R.B.D.K.]

Osmium A chemical element, Os, atomic number 76, atomic weight 190.2. The element is a hard white metal of rare natural occurrence, usually found in nature alloyed with other platinum metals. *See* Metal; Periodic table; Platinum.

Physical properties of the element, which is found as seven naturally occurring isotopes, are given in the table. The metal is exceeded in density only by iridium. Osmium is a very hard metal and unworkable, and so it must be used in cast form or fabricated by powder metallurgy. Osmium is a third-row transition element and has the electronic configuration $[\mathrm{Xe}](4f)^{14}(5d)^{6}(6s)^{2}$; in the periodic table it lies below iron (Fe) and ruthenium (Ru). In powder form the metal may be attacked by the oxygen in air at room temperature, and finely divided osmium has a faint odor of the tetraoxide. In bulk form it does not oxidize in air below 500°C (750°F), but at higher temperatures it yields $\mathrm{OsO_4}$. It is attacked by fluorine or chlorine at 100°C (212°F). It dissolves in alkaline oxidizing fluxes to give osmates ($\mathrm{OsO_4^{2-}}$). *See* Electron configuration; Iridium; Iron; Ruthenium.

The chemistry of osmium more closely resembles that of ruthenium than that of iron. The high oxidation states VI and VIII ($\mathrm{OsO_4^{2-}}$ and $\mathrm{OsO_4}$) are much more accessible than for iron. *See* Oxidation-reduction.

Osmium forms many complexes. In water, osmium complexes with oxidation states ranging from II to VIII may be obtained. Oxo compounds, which contain $\mathrm{Os{=}O}$, are very common and occur for oxidation states IV to VIII. Although $\mathrm{OsO_4}$ is tetrahedral in the gas phase and in noncomplexing solvents such as

dichloromethane (CH_2Cl_2), it tends to be six-coordinate when appropriate ligands are available; thus, in sodium hydroxide (NaOH) solution, dark purple $OsO_4(OH)_2^{2-}$ is formed from OsO_4. Similarly, $OsO_2(OH)_4^{2-}$ is formed by addition of hydroxide to osmate anion. Analogous reactions with ligands such as halides, cyanide, and amines give osmyl derivatives like the cyanide-deduct $OsO_2(CN)_4^{2-}$, in which the trans dioxo group ($O{=}Os{=}O$) is retained.

Osmium tetraoxide, a commercially available yellow solid (melting point 40°C or 104°F), is used commercially in the important *cis*-hydroxylation of alkenes and as a stain for tissue in microscopy. It is poisonous and attacks the eyes. Osmium metal is catalytically active, but it is not commonly used for this purpose because of its high price. Osmium and its alloys are hard and resistant to corrosion and wear (particularly to rubbing wear). Alloyed with other platinum metals, osmium has been used in needles for record players, fountain-pen tips, and mechanical parts. *See* ALLOY; STAIN (MICROBIOLOGY); TRANSITION ELEMENTS. [C.Cr.]

Osmoregulatory mechanisms Physiological mechanisms for the maintenance of an optimal and constant level of osmotic activity of the fluid within and around the cells, considered to be most favorable for the initiation and maintenance of vital reactions in the cell and for maximal survival and efficient functioning of the entire organism.

The actions of osmoregulatory mechanisms are, first, to impose constraints upon the passage of water and solute between the organism and its surroundings and, second, to accelerate passage of water and solute between organism and surroundings. The first effect requires a change of architecture of membranes in that they become selectively permeable and achieve their purpose without expenditure of energy. The accelerating effect, apart from requiring a change of architecture of cell membranes, requires expenditure of energy and performance of useful osmotic work. Thus substances may be moved from a region of low to a region of higher chemical activity. Such movement can occur in opposition to the forces of diffusion of an electric field and of a pressure gradient, all of which may act across the cell membrane. It follows that there must be an energy source which is derived from the chemical reactions of cellular metabolism and that part of the free energy so generated must be stored in molecules which are driven across the membrane barrier. Active transport is the modern term for such processes. *See* CELL MEMBRANES; OSMOSIS. [W.A.B.; T.P.S.]

Osmosis The transport of solvent through a semipermeable membrane separating two solutions of different solute concentration. The solvent diffuses from the solution that is dilute in solute to the solution that is concentrated.

The flow of liquid through such a barrier may be stopped by applying pressure to the liquid on the side of higher solute concentration. The applied pressure required to prevent the flow of solvent across a perfectly semipermeable membrane is called the osmotic pressure and is a characteristic of the solution. The walls of cells in living organisms permit the passage of water and certain solutes, while preventing the passage of other solutes, usually of relatively high molecular weight. These walls act as selectively permeable membranes, and allow osmosis to occur between the interior of the cell and the surrounding media. *See* EDEMA; OSMOREGULATORY MECHANISMS; SOLUTION. [F.J.J.]

Osteichthyes The bony fishes, one of the three classes (most recently considered a subclass of the class Teleostomi) of Recent fishlike vertebrates. It includes most of the familiar fishes. The Osteichthyes are similar to the Chondrichthyes, or cartilaginous fishes, and contrast with the living Agnatha in having jaws, paired nostrils, true teeth, paired pelvic and pectoral fins and girdles (unless lost secondarily), three semicircular canals, and bony scales (unless lost or modified). Many fossil agnath fishes possess bony scales but differ from the higher fishes in the above-mentioned features. Separation of the Osteichthyes from the Paleozoic Placodermi and Acanthodii is more difficult because these three groups agree in most basic vertebrate features. The Osteichthyes contrast with the Chondrichthyes in having a bony skeleton (some Recent bony fishes possess a largely cartilaginous skeleton), a swim bladder (at least primitively), a true gill cover, and mesodermal ganoid, cycloid, or ctenoid scales (sharks possess dermal denticles, or placoid scales) which are sometimes modified or lost. Fertilization is usually external, but if it is internal, the intromittent organ is not derived from pelvic-fin claspers. Most often a modified anal fin or a fleshy tube or sheath functions in sperm transfer. *See* COPULATORY ORGAN; SCALE (ZOOLOGY); SWIM BLADDER.

The Osteichthyes evolved from some group among the primitive, bony gnathostome fishes. Plated agnaths and primitive acanthodians are known from the Silurian, but the oldest osteichthyans, or typical bony fishes, do not appear until the Lower Devonian, when lobefins and lungfishes enter the paleontological record. The class became well represented in the Middle Devonian, at which time the three subclasses (rayfin fishes, lobefin fishes, and lungfishes) were well differentiated. The ancestral stock of the Osteichthyes may be sought from among the other major groups of gnathostomes, the Placodermi, Acanthodii (spiny sharks), and Chondrichthyes, but the still fragmentary character of the early fossil record prevents clear elucidation of the origin and initial history of the group. Although the beginnings of the Osteichthyes are shrouded in uncertainty, advancements in paleontology have laid to rest the belief that the osteoichthyans evolved from that other great class of modern fishes, the Chondrichthyes. *See* ACANTHODII; CHONDRICHTHYES; PLACODERMI.

The Recent fauna of the class Osteichthyes includes 3 subclasses, 32 orders, about 357 families, roughly 3570 genera, and probably about 17,600 species. A classification of the Osteichthyes follows. Equivalent names are given in parentheses; orders known only as fossils are preceded by asterisks. For more detailed information see separate articles on each group.

- Class Osteichthyes
  - Subclass Actinopterygii
    - Infraclass Chondrostei
      - Order: *Palaeonisciformes
        - Polypteriformes (Cladistia)
      - Order: Acipenseriformes
    - Infraclass Holostei
      - Order: Semionotiformes (Protospondyli, Ginglymodi, and Lepisostei)
        - *Pycnodontiformes
        - Amiiformes (Halecomorphi)
        - *Aspidorhynchiformes
        - *Pholidophoriformes (Halecostomi)
    - Infraclass Teleostei
      - Order: *Leptolepiformes
      - Order: Elopiformes (Isospondyli in part)
        - Anguilliformes (Apodes and Saccopharyngiformes or Lyopomi)
        - Notacanthiformes (Lyopomi and Heteromi)
        - Clupeiformes
        - Osteoglossiformes (Isospondyli in part and Mormyriformes)
        - Salmoniformes (Myctophiformes, or Iniomi, and Haplomi)
      - Order: Cetomimiformes (Cetunculi)
        - Ctenothrissiformes
        - Gonorynchiformes

Cypriniformes (Heterognathi, Eventognathi, and Gymnonoti)
Siluriformes (Nematognathi)

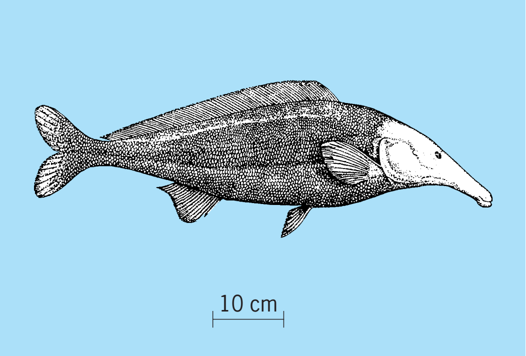
Batrachoidiformes (Haplodoci)
Gobiesociformes (Xenopterygii)
Lophiiformes (Pediculati)
Gadiformes (Anacanthini)
Atheriniformes (Beloniformes or Synentognathi, Cyprinodontiformes or Microcyprini, and Phallostethiformes)
Beryciformes (Berycomorphi)
Zeiformes (Zeomorphi)
Lampridiformes (Allotriognathi)
Gasterosteiformes (Thoracostei and Solenichthyes)
Pegasiformes (Hypostomides)
Synbranchiformes (Synbranchii)
Perciformes (Acanthopterygii or Percomorphi)
Pleuronectiformes (Heterostomata)
Tetraodontiformes (Plectognathi)
Subclass Crossopterygii
Order: *Osteolepiformes (Rhipidistia)
Coelacanthiformes (Coelacanthini)
Subclass Dipnoi [R.M.B.]

Osteoglossiformes An order of soft-rayed, actinopterygian fishes that includes the mooneyes, featherbacks, mormyrids or elephantfishes, and bonytongues.

Osteoglossiforms have the primary bite between the well-toothed tongue and the roof of the mouth, usually the strongly toothed parasphenoid but occasionally the endopterygoids. The mouth is bordered by the premaxilla, which in some forms is fused to its mate from the opposite side, and the maxilla. A unique feature is the presence of paired, usually bony rods at the base of the second gill arch.

Osteoglossiforms represent one of the basal stocks among the teleosts. The Ichthyodectidae and two related families are well represented in Cretaceous marine deposits, and *Allothrissops* and *Pachythrissops* of the Jurassic and Cretaceous probably belong here. Recent members may be classified in 2 suborders, 6 families, 22 genera, and about 135 species. All inhabit fresh water, and all are tropical except for the two species of Hiodontidae or mooneyes of North America, where they have a history to the Eocene.



African elephantnose (*Mormyrus probosctrostrls*). (*After G. A. Boulenger, Catalogue of Fresh Water Fishes of Africa In the British Museum, Natural History, vol. 1, 1909*)

Numerically the Osteoglossiformes are dominated by the Mormyridae, African river and lake fishes of varied size and form. In some the snout is very blunt and rounded, in others it is elongated (see illustration), the source of the vernacular name elephantfish. The related family Gymnarchidae consists of a single species. Scientifically, mormyrids and gymnarchids are of especial interest in that all are electrogenic. Modified muscles in the caudal peduncle generate and emit a continuous electric pulse. The discharge frequency varies, being low at rest and high when the fish is under stress. The mechanism operates like a radar device, since the fish is alerted whenever an electrical conductor enters the electromagnetic field surrounding it. *See* Actinopterygii; Electric organ (biology). [R.M.B.]

Osteoporosis A metabolic bone disease in which the amount of bone tissue is reduced sufficiently to increase the likelihood of fracture. Fractures of the vertebrae, femur (hip), and wrist are the most common osteoporotic fractures, but other bones such as the ribs, upper arm, and pelvis may also fracture.

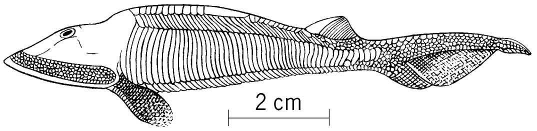
Although low bone mass is the major factor in osteoporotic fractures, there may also be qualitative and architectural changes in bone with aging that lead to increased fragility. Osteoporosis can be primary or secondary. Primary osteoporosis occurs independently of other causes. The secondary osteoporoses result from identifiable causes, such as exogenous cortisone administration, Cushing's disease, hyperparathyroidism, hyperthyroidism, hypogonadism, multiple myeloma, prolonged immobilization, alcoholism, anorexia nervosa, and various gastrointestinal disorders. Primary osteoporosis occurring in children is called juvenile osteoporosis; that occurring in premenopausal women and middle-aged or young men is known as idiopathic osteoporosis. Osteoporosis, which is found in older persons, can be classified as postmenopausal (type I) or involutional (type II) osteoporosis. *See* Alcoholism; Anorexia nervosa; Gastrointestinal tract disorders; Metabolic disorders.

Goals should include prevention of both the underlying disorder (the disease) and its effects (osteoporotic fractures). Secondary osteoporoses are managed by eliminating the underlying disorder. To prevent primary osteoporosis, good health-related behavior during childhood and young adulthood has been suggested as the most important factor. Such behavior includes avoiding cigarette smoking and excess alcohol intake, maintaining a normal body weight, and maintaining optimal dietary intake of calcium. It has been suggested that the recommended daily allowance (RDA) for calcium in the postmenopausal period and the recommended intake of vitamin D in the aged should be increased. At menopause, the possibility of estrogen replacement therapy should be considered for women who are at high risk for osteoporosis. Fracture prevention should be a lifelong effort. During childhood and the premenopausal years, a maximal peak bone mass should be developed through weight-bearing exercise. Exercise to improve coordination and flexibility and to maintain good posture is also useful. *See* Estrogen; Nutrition; Vitamin D.

The diagnosis of primary osteoporosis is made in the presence of either low bone mass or a characteristic fracture that cannot be attributed to some other cause.

The goals of treatment are rehabilitation and minimization of the risk of future fractures. Goals for rehabilitation include restoring a positive outlook on life, treating depression if it exists, increase of physical activity, restoring independence, relieving pain, restoring muscle mass, and improving posture. Various medications, including estrogen and calcitonin, can maintain bone mass. *See* Aging; Bone; Skeletal system disorders. [J.F.A.]

Osteostraci An order of extinct jawless vertebrate fishes, also called Cephalaspida, of the class Agnatha, known from the Middle Silurian to Upper Devonian of Europe, Asia, and North America. They were mostly small, about 2 in. to 2 ft (5 to 60 cm)



The ostracoderm *Hemicyclaspis*, a cephalaspid, a Lower Devonian jawless vertebrate. (*After E. H. Colbert, Evolution of the Vertebrates, Wiley, 1955*)

in length. The head and part of the body were encased in a solid armor of bone, and the posterior part of the body and the tail were covered with thick scales. Some early forms lacked paired fins, though most possessed flaplike pectoral fins. One or two dorsal fins were present. Their depressed shape and the position of the eyes on the top of the head suggest that Osteostraci were bottom dwellers (see illustration). The underside of the throat region was covered by small plates and there was a small mouth in front. [R.H.De.]

Ostracoda A major taxon of the Crustacea containing small bivalved animals 0.004–1.4 in. (0.1–33 mm) long, with most between 0.04 and 0.08 in. (1 and 2 mm). They inhabit aquatic environments in nearly all parts of the world. Semiterrestrial species have been described from moss and leaf-litter habitats in Africa, Madagascar, Australia, and New Zealand, and from vegetable debris of marine origin in the Kuril Archipelago. Of the more than 2000 species extant, none is truly parasitic and most are free-living. However, a few fresh-water and marine forms live commensally on other animals. Most ostracodes are scavengers, some are herbivorous, and a few are predacious carnivores. Exceptional biological features are known; there are myodocopine ostracodes that produce bioluminescence, and some species of podocopines form a secretion from spinning glands to enable them to climb polished surfaces.

Researchers disagree on the hierarchical classification of the Ostracoda. It is recognized as a distinct class by some and a subclass within the Maxillopoda by others. Consequently, the subdivisions within the Ostracoda may be ranked as subclasses, superorders, or orders. Six major subdivisions are currently recognized: Bradoriida, Phosphatocopida, Leperditicopida, Paleocopa, Myodocopa, and Podocopa. The first four taxa are extinct. The Myodocopa are further subdivided into the Myodocopida and Halocyprida, and the Podocopa into Platycopida and Podocopida. All fresh-water Ostracoda belong to the Podocopida. *See* Maxillopoda; Podocopa.

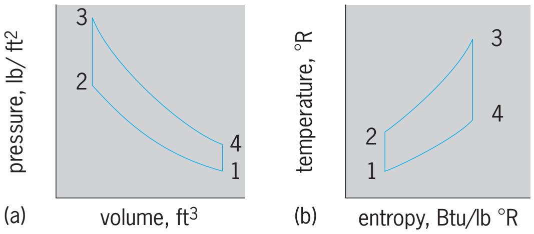
Knowledge of the morphology of the Ostracoda is based primarily on extensive study of many species. The two valves, sufficient to enclose the rest of the animal, are joined dorsally along a hinge, that may vary from a simple juncture to a complex series of teeth and sockets. From the dorsal part of the carapace, the elongate body is suspended as a pliable sac, with lateral flaps of hypodermis extending between the lamellae of the valves. It is unsegmented, but reinforced by chitinous processes for rigidity in the vicinity of the appendages. There is no true abdominal region.

Ostracodes of the Podocopida and Myodocopida possess seven pairs of segmented appendages: antennules, antennae, mandibles, maxillules, and three pairs of thoracic legs. The body terminates posteroventrally in a pair of furcae or caudal processes. The Platycopida have two pairs of thoracic legs, and the Halocyprida frequently only one pair. Appendages have muscles within them and are connected by musculature to the valves and to a centrally located chitinous structure, the endoskeleton. They are usually specialized for particular functions, such as swimming, walking, food gathering, mastication, and cleaning the interior of the carapace.

Ostracodes have separate sexes, although many species are parthenogenetic and lack males. Most ostracodes lay their eggs on the substrate or on vegetation, but some transfer them to the posterior space within the carapace, where they hatch and the young brood is retained for a time. [P.A.McL.]

Otter Members of the family Mustelidae, a large group of carnivores which also includes the martens, weasels, badgers, and skunks. Otters are more completely adapted to aquatic life than other members of the family, having a long thin body, short legs, and somewhat flattened head. The small ears possess a membrane which closes the ear canal when the animal dives. The feet have five webbed toes with nonretractile claws. The tail is broad and flattened, being used along with body movements for swimming. The short thick fur is impervious to water. Like other members of the family all have well-developed perianal scent glands. *See* Carnivora; Mammalia. [C.B.C.]

Otto cycle The basic thermodynamic cycle for the prevalent automotive type of internal combustion engine. The engine uses a volatile liquid fuel (gasoline) or a gaseous fuel to carry out the theoretic cycle shown in the illustration. The cycle consists of two isentropic (reversible adiabatic) phases interspersed between two constant-volume phases. The theoretic cycle should not be confused with the actual engine built for such service as automobiles, motor boats, aircraft, lawn mowers, and other small self-contained power plants.



Diagrams of (*a*) pressure-volume and (*b*) temperature-entropy for Otto cycle.

The thermodynamic working fluid in the cycle is subjected to isentropic compression, phase 1–2; constant-volume heat addition, phase 2–3; isentropic expansion, phase 3–4; and constant-volume heat rejection (cooling), phase 4–1.

The Otto cycle is represented in many millions of engines utilizing either the four-stroke principle or the two-stroke principle. Evidence indicates that actual Otto engines offer peak efficiencies (25±%) at compression ratios of 15±. Above this ratio, efficiency falls. The most probable explanation is that the extreme pressures associated with high compression cause increasing amounts of dissociation of the combustion products. This dissociation, near the beginning of the expansion stroke, exerts a more deleterious effect on efficiency than the corresponding gain from increasing compression ratio. *See* Brayton cycle; Carnot cycle; Diesel cycle; Internal combustion engine; Thermodynamic cycle. [T.Ba.]

Ovarian disorders A variety of neoplastic and nonneoplastic disorders that occur in the ovary. Ovarian neoplasms are of greater diversity in histologic appearance and biologic behavior than for any other organ. The nonneoplastic disorders include physiologic cysts, pregnancy luteomas, and polycystic ovarian disease (Stein-Leventhal syndrome). The ovary can also be a site of metastasis from malignant tumors originating in the genital tract, breast, and gastrointestinal tract. *See* Cancer (medicine).

As ovarian enlargement due to tumors occurs, compression of pelvic and abdominal structures produces vague symptoms such as constipation, pelvic discomfort, a feeling of heaviness, and frequent urination. Pain can be an initial symptom of both benign and malignant ovarian disorders. The symptoms of malignant ovarian disorders include abdominal pain and swelling, bloating, heartburn, nausea, and anorexia.

An examination of the pelvis is the most crucial component in the diagnosis and evaluation of ovarian disorders. This often allows the physician to differentiate between disorders of the ovary and other pelvic structures such as the uterus, rectum, and bladder.

Benign disorders. Physiologic cysts occur in response to cyclic stimulation of the ovary by hormones. Simple cysts in women of reproductive age which are greater than about 1.2 in. (3 cm) can often be treated with oral contraceptives. Persistence of the cyst for 2 months warrants surgical exploration with removal of the cyst, leaving the ovary intact.

Polycystic ovarian syndrome is caused by abnormal regulation of the hypothalamic-pituitary-ovarian axis. In this condition, the ovaries are bilaterally enlarged with multiple follicular cysts. Therapy consists of administering oral contraceptives, progesterone preparations, or clomiphene.

Endometriosis is characterized by ectopic endometrial glandular and stromal tissue that often involves the ovary as well as other pelvic structures. Ovarian endometriosis often produces a cystic mass filled with old blood termed a chocolate cyst. The two most common symptoms of endometriosis are pelvic pain and infertility. This can be treated medically with agents that suppress ovulation, or surgically by removing the ovary.

Neoplasms of the ovary can originate from epithelial, stromal, or germ cells, and produce a variety of symptoms. In a reproductive-age woman who has not completed childbearing or desires conservative therapy, removal of the cyst or one ovary is adequate treatment. In the individual who has completed childbearing or is peri- or postmenopausal, removal of both ovaries is acceptable.

Malignant disorders. As with benign tumors, malignant ovarian neoplasms can arise from epithelial, stromal, or germ cells. The primary treatment is surgery; procedures include removal of the ovaries, fallopian tubes, uterus, omentum, and other tumor masses within the abdominal cavity. *See* ONCOLOGY; OVARY; TUMOR. [D.L.Ta.]

Ovary

A part of the reproductive system of all female vertebrates. Although not vital to individual survival, the ovary is vital to perpetuation of the species. The function of the ovary is to produce the female germ cells or ova, and in some species to elaborate hormones that assist in regulating the reproductive cycle.

The ovaries develop as bilateral structures in all vertebrates, but adult asymmetry is found in certain species of all vertebrates from the elasmobranchs to the mammals.

The ovary of all vertebrates functions in essentially the same manner. However, ovarian histology of the various groups differs considerably. Even such a fundamental element as the ovum exhibits differences in various groups. *See* OVUM.

The mammalian ovary is attached to the dorsal body wall. The free surface of the ovary is covered by a modified peritoneum called the germinal epithelium. Just beneath the germinal epithelium is a layer of fibrous connective tissue. Most of the rest of the ovary is made up of a more cellular and more loosely arranged connective tissue (stroma) in which are embedded the germinal, endocrine, vascular, and nervous elements.

The most obvious ovarian structures are the follicles and the corpora lutea. The smallest, or primary, follicle consists of an oocyte surrounded by a layer of follicle (nurse) cells. Follicular growth results from an increase in oocyte size, multiplication of the follicle cells, and differentiation of the perifollicular stroma to form a fibrocellular envelope called the theca interna. Finally, a fluid-filled antrum develops in the granulosa layer, resulting in a vesicular follicle.

The cells of the theca intema hypertrophy during follicular growth and many capillaries invade the layer, thus forming the endocrine element that is thought to secrete estrogen. The other known endocrine structure is the corpus luteum, which is primarily the product of hypertrophy of the granulosa cells remaining after the follicular wall ruptures to release the ovum. Ingrowths of connective tissue from the theca interna deliver capillaries to vascularize the hypertrophied follicle cells of this new corpus luteum; progesterone is secreted here. *See* ESTROGEN; ESTRUS; MENSTRUATION; PROGESTERONE. [K.L.D.]

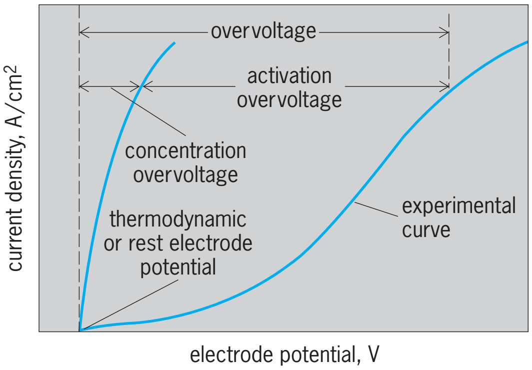
Overvoltage

The difference between the electrical potential of an electrode or cell under the passage of current and the thermodynamic value of the electrode or cell potential under identical experimental conditions in the absence of electrolysis; it is also known as overpotential. Overvoltage is expressed in volts, often in absolute value; it is a measure of the rates of the different processes associated with an electrode reaction.

An understanding of the factors that contribute to the overvoltage is important in the operation of practical electrochemical systems. In batteries, the overvoltage plays a significant role in the available voltage and power. In large-scale industrial electrolysis, overvoltage is a major factor in determining the energy efficiency of a process, and hence, the cost of electricity. *See* DECOMPOSITION POTENTIAL; ELECTROCHEMICAL PROCESS; ELECTRODE POTENTIAL; ELECTROLYSIS.

Since the overvoltage is governed by kinetic considerations, all of the experimental conditions that can affect the rate of an electrolytic reaction are of importance. These include concentration of electrolyzed substance, temperature, composition of solvent and electrolyte, nature of the electrode surface, mode of mass transfer, and the current density (current per unit area of electrode). A rapid reaction occurs with a small overvoltage (a few millivolts). A slow reaction requires a large overvoltage (a few volts).

The rates of electrode reactions are frequently determined from current density-potential curves (see illustration). Since the departure of the electrode or cell potential from the thermodynamic value upon passage of current is sometimes termed polarization, such curves are also known as polarization curves. These curves are obtained by measurements with three-electrode electrolytic cells. The current density that flows through the electrode of interest (the working electrode) is adjusted with an external direct-current power supply, and the potential of this electrode is measured with respect to a reference electrode whose potential is known and fixed. The measured potential contains a contribution, known as the ohmic drop, that results from the flow of current through the solution resistance between the working electrode and the reference electrode. This drop is minimized by placing these electrodes close together and using various experimental approaches. The thermodynamic potential is obtained from available data for the electrode reaction of interest, corrected for the concentration of the reaction species in the



Current density-potential curve.

solution under the experimental conditions. It is also sometimes given by the working electrode potential in the electrolysis cell when no current flows (the rest potential). The overvoltage can be read directly from the current-potential curve, as shown in the illustration. *See* ELECTRODE; REFERENCE ELECTRODE.

The total overvoltage can be decomposed into different components, which are assigned to different sources of rate limitations, for example, concentration overvoltage, activation overvoltage, reaction overvoltage, and crystallization overvoltage.

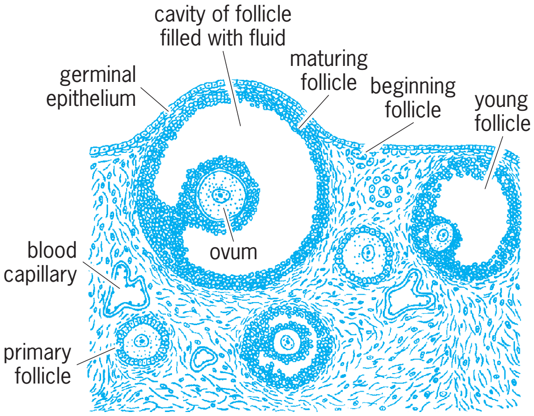
Concentration overvoltage occurs when the concentration of the reactants or products at the electrode surface are different from those in the bulk solution. These differences arise because the electroactive reactant is consumed, and products are produced by the passage of current.

Activation overvoltage arises from slowness in the rate of the electron transfer reaction at the electrode surface. To drive an electrode reaction at a given rate (current density), it is necessary to overcome an energy barrier, the energy of activation for the reaction. The additional energy (that is, beyond the thermodynamic requirements) needed to overcome this barrier is provided by the electrical energy supplied to the cell in the form of an increase in the applied potential. The magnitude of this activation overvoltage often depends upon the nature of the electrode material.

Reaction overvoltage arises when a chemical reaction is associated with the overall electrode reaction. For example, if the electroactive substance is generated from the major reactant by a chemical reaction that precedes the electron transfer, its concentration at the electrode surface will be governed by the rate of this reaction. This preceding reaction will thus affect the potential at which the electrode reaction occurs. Slow steps in the formation of nuclei and the crystal lattice, for example, in the electroplating of a metal, can lead to nucleation and crystallization overvoltages, respectively. [A.J.Ba.]

Ovum The egg or female sex cell. Strictly speaking, the term refers to this cell when it is ready for fertilization, but it is often applied to earlier or later stages. Confusion is avoided by using qualifying adjectives such as immature, ripe, mature, fertilized, or developing ova. The mature ova are generally spheroidal and large. The number of ova produced at one time varies in different animals, from millions in many marine animals that spawn into the surrounding sea water to about a dozen or less in mammals in which adaptations for internal nourishment of the developing embryo and care of the young are highly developed.

In the ovary the immature ovum is associated with follicle cells through which it receives material for growth. In mammals, as the egg matures, these cells arrange themselves into a structure known as the Graafian, or vesicular, follicle, consisting of a large fluid-filled cavity into which the ovum, surrounded by several layers of cells, projects from the layer of follicle cells that constitutes the inner wall (see illustration). The fluid contains estrogenic female sex hormone secreted by cells in an intermediate layer of the follicular wall.



Section of a mammalian ovary.

Yolk, or deutoplasm, is essentially a food reserve in the form of small spherules, present to a greater or lesser extent in all eggs. It accounts largely for the differences in size of eggs. Eggs are classified according to the distribution of yolk. In the isolecithal type there is a nearly uniform distribution through the cytoplasm, as in most small eggs. The yolk in telolecithal eggs is increasingly concentrated toward one pole, as in the large eggs of fish, amphibians, reptiles, and birds. Centrolecithal, or centrally located, yolk occurs in eggs of insects and cephalopod mollusks. *See* GAMETOGENESIS; OOGENESIS. [A.T./H.L.H.]

Oxalidales An order of flowering plants (angiosperms) in the eurosid I group of the rosid dicots. The order is previously unrecognized in classifications of the angiosperms but is indicated by numerous studies of DNA sequences. Oxalidales consist of five small families: Cephalotaceae (one species), Connaraceae (300 species of tropical trees and vines), Cunoniaceae (250 species of trees and shrubs mostly from the Southern Hemisphere), Elaeocarpaceae (350 species of trees and shrubs from the Southern Hemisphere and Asian tropics), and Oxalidaceae (350 species, mostly in *Oxalis*, mostly herbs that are found throughout the world). Oxalidales are heterogeneous in their morphological traits. Many species of the order are locally economically important, producing timbers and fruits, including zebrawood (*Connarus*, Connaraceae), star fruit (*Averrhoa*, Oxalidaceae), and lightwood (*Ceratopetalum* and *Eucryphia*, Cunoniaceae). *Oxalis* (Oxalidaceae) has some species that are grown as ornamentals and several that are noxious introduced weeds. *See* MAGNOLIOPHYTA; MAGNOLIOPSIDA; ORNAMENTAL PLANTS; PITCHER PLANT; ROSIDAE; WEEDS. [M.W.C.]

Oxidation process A process in which oxygen is caused to combine with other molecules. The oxygen may be used as elemental oxygen, as in air, or in the form of an oxygen-containing molecule which is capable of giving up all or part of its oxygen. Oxidation in its broadest sense, that is, an increase in positive valence or removal of electrons, is not considered here if oxygen itself is not involved. *See* OXIDATION-REDUCTION.

Most oxidations occur with the liberation of large amounts of energy in the form of either heat, light, or electricity. The stable ultimate products of oxidation are oxides of the elements involved. These oxidations occur in nature as corrosion, decay, and respiration and in the deliberate burning of matter such as wood, petroleum, sulfur, or phosphorus to oxides of the constituent elements.

The principal variables to be considered and controlled in any partial oxidation are temperature, pressure, reaction time (or contact time), nature of catalyst, if any, mole ratio of oxidizing agent, and whether the substance to be oxidized is to be kept in the liquid or vapor phase. Only a narrow range of conditions unique to each substance being oxidized and each product desired will give satisfactory yields. It is also essential to maintain conditions outside the range of spontaneous ignition, to avoid explosive mixtures or the accidental accumulation of unstable peroxides, and to choose materials which not only can resist the environmental conditions but also which do not have adverse catalytic effects or otherwise interfere with the desired reaction. *See* COMBUSTION. [I.E.L.]

Oxidation-reduction An important concept of chemical reactions which is useful in systematizing the chemistry of many substances. Oxidation can be represented as involving a loss of electrons by one molecule and reduction as involving an absorption of electrons by another. Both oxidation and reduction occur simultaneously and in equivalent amounts during any reaction involving either process.

Oxidation number. The oxidation state is a concept which describes some important aspects of the state of combination of the elements. An element in a given substance is characterized by a number, the oxidation number, which specifies whether the element in question is combined with elements which are more electropositive or more electronegative than it is. It further specifies the combining capacity which the element exhibits in a particular combination. A scale of oxidation numbers is defined by assigning to an oxygen atom in an ion such as SO_4^{2-} the value of 2−. That for sulfur as 6+ then follows from the requirement that the sum of the oxidation numbers of all the atoms add up to the net charge on the species. The value of 2− for oxygen is not chosen arbitrarily. It recognizes that oxygen is more electronegative than sulfur, and that when it reacts with other elements it seeks to acquire two more electrons, by sharing or outright transfer from the electropositive partner, so as to complete a stable valence shell of eight electrons.

Although oxidation number is in some respects similar to valence, the two concepts have distinct meanings. In the substance H_2, the valence of hydrogen is 1 because each H makes a single bond to another H, but the oxidation number is 0, because the hydrogen is not combined with a different element. *See* VALENCE..

When the oxidation number of an atom in a species is increased, the process is described as oxidation, no matter what reagent produces it; when a decrease in oxidation number takes place, the process is described as reduction, again without regard to the identity of the reducing agent. The term oxidation has been generalized to imply combination of an element with an element more electronegative than itself.

Reactions. In an oxidation-reduction reaction, some element decreases in oxidation state and some element increases in oxidation state. The substances containing these elements are defined as the oxidizing agents and reducing agents, and they are said to be reduced and oxidized, respectively. The processes in question can always be represented formally as involving electron absorption by the oxidizing agent and electron donation by the reducing agent. For example, reaction (1) can be regarded as the sum of the two partial processes, or half-reactions, (2) and (3). Similarly, reaction (4) consists of the two half-reactions (5) and (6), with half-reaction (5) being taken five times to balance the electron flow from reducing agent to oxidizing agent.

$$2Fe^{3+} + 2I^- \rightarrow 2Fe^{2+} + I_2 \tag{1}$$

$$2I^- \rightarrow I_2 + 2e^- \tag{2}$$

$$2Fe^{3+} + 2e^- \rightarrow 2Fe^{2+} \tag{3}$$

$$16H^+ + 2MnO_4{}^- + 10I^- \rightarrow 8H_2O + 2Mn^{2+} + 5I_2 \tag{4}$$

$$2I^- \rightarrow I_2 + 2e^- \tag{5}$$

$$16H^+ + 2MnO_4{}^- + 10e^- \rightarrow 2Mn^{2+} + 8H_2O \tag{6}$$

Each half-reaction consists of an oxidation-reduction couple; thus, in half-reaction (6) the reducing agent and oxidizing agent making up the couple are manganous ion, Mn^{2+}, and permanganate ion, $MnO_4{}^-$, respectively; in half-reaction (5) the reducing agent is I^- and the oxidizing agent is I_2. The fact that $MnO_4{}^-$ reacts with I^- to produce I_2 means that $MnO_4{}^-$ in acid solution is a stronger oxidizing agent than is I_2. Because of the reciprocal relation between the oxidizing agent and reducing agent comprising a couple, this statement is equivalent to saying that I^- is a stronger reducing agent than Mn^{2+} in acid solution. Reducing agents may be ranked in order of tendency to react, and this ranking immediately implies an opposite order of tendency to react for the oxidizing agents which complete the couples. In the list below some common oxidation-reduction couples are ranked in this fashion:

Strong reducing agent ↑		Weak oxidizing agent ↓
	$Mg = Mg^{2+} + 2e^-$	
	$Zn = Zn^{2} + 2e^-$	
	$H_2 = 2H^+ + 2e^-$	
	$Cu = Cu^{2} + 2e^-$	
Increasing reducing power	$I^- = \frac{1}{2}I_2 + e^-$	Increasing oxidizing power
	$Fe^{2+} = Fe^{3+} + e^-$	
	$Br^- = \frac{1}{2}Br_2 + e^-$	
	$Cl^- = \frac{1}{2}Cl_2 + e^-$	
	$4H_2O + Mn^{2+} = MnO_4{}^- + 8H^+ + 5e^-$	
Weak reducing agent		Strong oxidizing agent

See ELECTROCHEMICAL SERIES; ELECTRONEGATIVITY; OXIDIZING AGENT. [H.Ta.]

Oxide A binary compound of oxygen with another element. Oxides have been prepared for essentially all the elements except the noble gases. Often, several different oxides of a given element can be prepared; a number exist naturally in the Earth's crust and atmosphere: silicon dioxide (SiO_2) in quartz; aluminum oxide (Al_2O_3) in corundum; iron oxide (Fe_2O_3) in hematite; carbon dioxide (CO_2) gas; and water (H_2O).

Most elements will react with oxygen at appropriate temperature and oxygen pressure conditions, and many oxides may thus be directly prepared. Most metals in massive form react with oxygen only slowly at room temperatures because the first thin oxide coat formed protects the metal. The oxides of the alkali and alkaline-earth metals, except for beryllium and magnesium, are porous when formed on the metal surface, and they provide only limited protection to the continuation of oxidation, even at room temperatures. Gold is exceptional in its resistance to oxygen, and its oxide (Au_2O_3) must be prepared by indirect means. The other noble metals, although ordinarily resistant to oxygen, will react at high temperatures to form gaseous oxides.

Oxides may be classified as acidic or basic according to the character of the solution resulting from their reactions with water. The nonmetal oxides generally form acid solutions and the metal oxides generally form alkaline solutions. *See* ACID AND BASE; EQUIVALENT WEIGHT; OXYGEN. [R.K.E.]

Oxidizing agent A participant in a chemical reaction that absorbs electrons from another reactant. In the process a component atom of this substance undergoes a decrease in oxidation number. In this action as an oxidizing agent, the substance undergoes reduction.

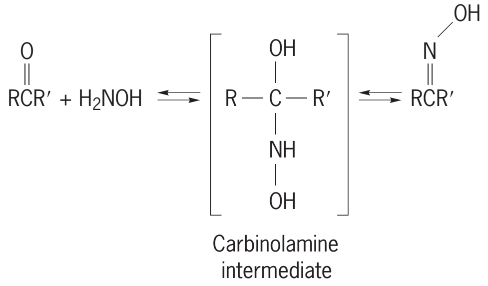
A measure of the effectiveness of a reagent as an oxidizing agent is its reduction potential. This is, in electrochemical terms, the equivalent of the free-energy change for the reduction process. The element with the highest reduction potential (and, therefore, the strongest oxidizing agent) is fluorine, F_2. The practical effectiveness of a given oxidizing (or reducing) agent will depend upon both the thermodynamics and the available kinetic pathway for the reaction process. *See* CHEMICAL THERMODYNAMICS.

Substances that are widely used as oxidizing agents in chemistry include ozone (O_3), permanganate ion ($MnO_4{}^-$), nitric acid (HNO_3), as well as oxygen itself. Organic chemists have empirically developed combinations of reagents to carry out specific oxidation steps in synthetic processes. The action of molecular oxygen as an oxidizing agent may be made more specific by photochemical excitation to an excited singlet electronic state. [F.J.J.]

Oxime One of a group of chemical substances with the general formula RR′C═N—OH, where R and R′ represent any carbon group or hydrogen. Oximes are derived from aldehydes

(RHC═NOH, aldoximes) and ketones (RR′C═NOH, where R and R′ are not hydrogen; ketoximes), and they are used to isolate and characterize these carbonyl compounds. Oximes are also useful as intermediates in organic syntheses. *See* Aldehyde; Ketone.

Hydroxylamine (H_2NOH) reacts readily with aldehydes or ketones to give oximes. The rate of the reaction of hydroxylamine with acetone is greatest at pH 4.5. Oximes are formed by nucleophilic attack of hydroxylamine at the carbonyl carbon (C═C) of an aldehyde or ketone to give an unstable carbinolamine intermediate, as in the reaction below. Since the breakdown of the carbinolamine intermediate to an oxime is acid-catalyzed, the rate of this step is enhanced at low pH. If the pH is too low, however, most of the hydroxylamine will be in the nonnucleophilic protonated form (NH_3OH^+), and the rate of the first step will decrease. Thus, in oxime formation the pH has to be such that there is sufficient free hydroxylamine for the first step and enough acid so that dehydration of the carbinolamine is facile. *See* Reactive intermediates.



One of the best-known reactions of oximes is their rearrangement to amides. This reaction, the Beckmann rearrangement, can be carried out with a variety of reagents [such as phosphorus pentachloride (PCl_5), concentrated sulfuric acid (H_2SO_4), and perchloric acid ($HClO_4$)] that induce the rearrangement by converting the oxime hydroxyl group into a group of atoms that easily departs in a displacement reaction by either protonation or formation of a derivative. The industrial synthesis of ϵ-caprolactam is carried out by a Beckmann rearrangement on cyclohexanone oxime. ϵ-Caprolactam is polymerized to the polyamide known as nylon 6, which is used in tire cords. *See* Organic synthesis. [J.E.Jo.]

Oximetry A technique that employs an oximeter, a photoelectric photometer, to measure the oxygenated fraction of the hemoglobin. This fraction is usually expressed in percent, which is referred to as the "oxygen saturation of blood."

One type of oximeter is designed to measure the oxygen saturation of blood circulating in a particular tissue of an intact animal or human. The tissue most commonly studied is the cartilaginous pinna of the ear, and the instrument used for this purpose is called an ear oximeter.

Another type of oximeter is designed to measure the oxygen saturation of blood during, or shortly after, its withdrawal from various sites in the vascular system. Such a device usually is designated a cuvette oximeter. [E.H.W.]

Oxygen A gaseous chemical element, O, atomic number 8, and atomic weight 15.9994. Oxygen is of great interest because it is the essential element both in the respiration process in most living cells and in combustion processes. It is the most abundant element in the Earth's crust. About one-fifth (by volume) of the air is oxygen. *See* Periodic table.

Oxygen is separated from air by liquefaction and fractional distillation. The chief uses of oxygen in order of their importance are (1) smelting, refining, and fabrication of steel and other metals; (2) manufacture of chemical products by controlled oxidation; (3) rocket propulsion; (4) biological life support and medicine; and (5) mining, production, and fabrication of stone and glass products.

Properties of oxygen

Property	Value
Atomic number	8
Atomic weight	15.9994
Triple point (solid, liquid, and gas in equilibrium)	−218.80°C (−139.33°F)
Boiling point at 1 atm pressure	−182.97°C (−119.4°F)
Gas density at °C and 10^5 Pa pressure, g/liter	1.4290
Liquid density at the boiling point, g/ml	1.142
Solubility in water at 20°C, oxygen (STP) per 1000 g water at 10^5 Pa partial pressure of oxygen	30

Uncombined gaseous oxygen usually exists in the form of diatomic molecules, O_2, but oxygen also exists in a unique triatomic form, O_3, called ozone. *See* Ozone.

Under ordinary conditions oxygen is a colorless, odorless, and tasteless gas. It condenses to a pale blue liquid, in contrast to nitrogen, which is colorless in the liquid state. Oxygen is one of a small group of slightly paramagnetic gases, and it is the most paramagnetic of the group. Liquid oxygen is also slightly paramagnetic. Some data on oxygen and some properties of its ordinary form, O_2, are listed in the table. *See* Paramagnetism.

Practically all chemical elements except the inert gases form compounds with oxygen. Most elements form oxides when heated in an atmosphere containing oxygen gas. Many elements form more than one oxide; for example, sulfur forms sulfur dioxide (SO_2) and sulfur trioxide (SO_3). Among the most abundant binary oxygen compounds are water, H_2O, and silica, SiO_2, the latter being the chief ingredient of sand. Among compounds containing more than two elements, the most abundant are the silicates, which constitute most of the rocks and soil. Other widely occurring compounds are calcium carbonate (limestone and marble), calcium sulfate (gypsum), aluminum oxide (bauxite), and the various oxides of iron which are mined as a source of iron. Several other metals are also mined in the form of their oxides. Hydrogen peroxide, H_2O_2, is an interesting compound used extensively for bleaching. *See* Hydrogen peroxide; Oxidation-reduction; Oxide; Peroxide; Water. [A.W.F.; L.M.Sa.]

Oxygen toxicity A toxic effect in a living organism caused by a species of oxygen. Oxygen has two aspects, one benign and the other malignant. Those organisms that avail themselves of the enormous metabolic advantages provided by dioxygen (O_2) must defend themselves against its toxicity. The complete reduction of one molecule of O_2 to two of water (H_2O) requires four electrons; therefore, intermediates must be encountered during the reduction of O_2 by the univalent pathway. The intermediates of O_2 reduction, in the order of their production, are the superoxide radical (O_2^-), hydrogen peroxide (H_2O_2), and the hydroxyl radical ($HO\cdot$). *See* Oxygen; Superoxide chemistry.

The intermediates of oxygen reduction, rather than O_2, itself, are probably the primary cause of oxygen toxicity. It follows that defensive measures must deal with these intermediates. The superoxide radical is eliminated by enzymes that catalyze the following reaction.

$$O_2^- + O_2^- + 2H^+ \rightleftharpoons H_2O_2 + O_2$$

These enzymes, known as superoxide dismutases, have been isolated from a wide variety of living things.

Hydrogen peroxide (H_2O_2) must also be eliminated, and this is achieved by two enzymatic mechanisms. The first of these is the dismutation of H_2O_2 into water and oxygen, a process catalyzed by catalases. The second is the reduction of H_2O_2 into two molecules of water at the expense of a variety of reductants, a process catalyzed by peroxidases. *See* Enzyme.

The multiplicity of superoxide dismutases, catalases, and peroxidases, and the great catalytic efficiency of these enzymes, provides a formidable defense against O_2^- and H_2O_2. If these first two intermediates of O_2 reduction are eliminated, the third (HO·) will not be produced. No defense is perfect, however, and some HO· is produced; therefore its deleterious effects must be minimized. This is achieved to a large extent by antioxidants, which prevent free-radical chain reactions from propagating. *See* ANTIOXIDANT; CHAIN REACTION (CHEMISTRY); FREE RADICAL; PEPTIDE.

The apparent comfort in which aerobic organisms live in the presence of an atmosphere that is 20% O_2 is due to a complex and effective system of defenses against this peculiar gas. Indeed, these defenses are easily overwhelmed, and overt symptoms of oxygen toxicity become apparent when organisms are exposed to 100% O_2. For example, a rat maintained in 100% O_2 will die in 2 to 3 days. [I.Fr.]

Oxymonadida An order of class Zoomastigophorea in the phylum Protozoa. These are colorless flagellate symbionts in the digestive tract of the roach *Cryptocercus* and of certain termites. They are xylophagous; that is, they ingest wood particles taken in by the host. Seven or more genera of medium or large size have been identified, the organisms varying from pyriform to ovoid in shape. At the anterior end a pliable neck-like rostrum attaches the organism to the host intestinal wall, but they are sometimes free. They can be either uni- or multinucleate. *See* ZOOMASTIGOPHOREA. [J.B.L.]

Ozone A powerfully oxidizing allotropic form of the element oxygen. The ozone molecule contains three atoms (O_3). Ozone gas is decidedly blue, and both liquid and solid ozone are an opaque blue-black color, similar to that of ink. *See* OXYGEN.

Some properties of ozone are given in the table. Ozone has a characteristic, pungent odor familiar to most persons because ozone is formed when electrical apparatus produces sparks in air. Ozone is irritating to mucous membranes and toxic to human beings and lower animals.

Some properties of ozone

Property	Value
Density of the gas at 0°C, 1 atm pressure	2.154 g/liter
Density of the liquid	
−111.9 °C	1.354 g/ml
−183°C	1.573 g/ml
Boiling point at 1 atm pressure	−111.9°C
Melting point of the solid	−192.5°C

Ozone is a more powerful oxidizing agent than oxygen, and oxidation with ozone takes place with evolution of more heat and usually starts at a lower temperature than when oxygen is used. In the presence of water, ozone is a powerful bleaching agent, acting more rapidly than hydrogen peroxide, chlorine, or sulfur dioxide. *See* OXIDIZING AGENT.

Ozone is utilized in the treatment of drinking-water supplies. Odor- and taste-producing hydrocarbons are effectively eliminated by ozone oxidation. Iron and manganese compounds which discolor water are diminished by ozone treatment. Compared to chlorine, bacterial and viral disinfection with ozone is up to 5000 times more rapid.

Ozone occurs to a variable extent in the Earth's atmosphere. Near the Earth's surface the concentration is usually 0.02–0.03 ppm in country air, and less in cities except when there is smog. At vertical elevations above 13 mi (20 km), ozone is formed by photochemical action on atmospheric oxygen. Maximum concentration of 5×10^{12} molecules/cm^3 (more than 1000 times the normal peak concentration at Earth's surface) occurs at an elevation of 19 mi (30 km). [A.W.F.]

Ozonolysis A process which uses ozone to cleave unsaturated organic bonds. Generally, ozonolysis is conducted by bubbling ozone-rich oxygen or air into a solution of the reactant. The reaction is fast at moderate temperatures. Intermediates are usually not isolated but are subjected to further oxidizing conditions to produce acids or to reducing conditions to form alcohols or aldehydes. An unsymmetrical olefin is capable of yielding two different products whose structures are related to the groups substituted on the olefin and the position of the double bond.

Before World War I, ozonolysis was applied commercially to the preparation of vanillin from isoeugenol. The only modern application of the technique in the United States is in the manufacture of azelaic and pelargonic acids from oleic acid. *See* ALKENE; OZONE. [R.K.Ba.]

P

Pacific islands A geographic designation that includes thousands of mainly small coral and volcanic islands scattered across the Pacific Ocean from Palau in the west to Easter Island in the east. Island archipelagos off the coast of the Asian mainland, such as Japan, Philippines, and Indonesia, are not included even though they are located within the Pacific Basin. The large island constituting the mainland of Papua New Guinea and Irian Jaya is also excluded, along with the continent of Australia and the islands that make up Aotearoa or New Zealand. The latter, together with the Asian Pacific archipelagos, contain much larger landmasses, with a greater diversity of resources and ecosystems, than the oceanic islands, commonly labelled Melanesia, Micronesia, and Polynesia. *See* Australia; New Zealand; Oceanic islands.

The great majority of these islands are between 4 and 4000 mi^2 (10 and 10,000 km^2) in land surface area. The three largest islands include the main island of New Caledonia (6220 mi^2 or 16,100 km^2), Viti Levu (4053 mi^2 or 10,497 km^2) in Fiji, and Hawaii (4031 mi^2 or 10,440 km^2) the big island in the Hawaiian chain. When the 80-mi (200-km) Exclusive Economic Zones are included in the calculation of surface area, some Pacific island states have very large territories. These land and sea domains, far more than the small, fragmented land areas per se, capture the essence of the island world that has meaning for Pacific peoples. *See* East Indies.

Oceanic islands are often classified on the basis of the nature of their surface lithologies. A distinction is commonly made between the larger continental islands of the western Pacific, the volcanic basalt island chains and clusters of the eastern Pacific, and the scattered coral limestone atolls and reef islands of the central and northern Pacific.

It has been suggested that a more useful distinction can be drawn between plate boundary islands and intraplate islands. The former are associated with movements along the boundaries of the great tectonic plates that make up the Earth's surface. Islands of the plate boundary type form along the convergent, divergent, or tranverse plate boundaries, and they characterize most of the larger island groups in the western Pacific. These islands are often volcanically and tectonically active and form part of the Pacific so-called Ring of Fire, which extends from Antarctica in a sweeping arc through New Zealand, Vanuatu, Bougainville, and the Philippines to Japan.

The intraplate islands comprise the linear groups and clusters of islands that are thought to be associated with volcanism, either at a fixed point or along a linear fissure. Volcanic island chains such as the Hawaii, Marquesas, and Tuamotu groups are classic examples. Others, which have their volcanic origins covered by great thickness of coral, include the atoll territories of Kiribati, Tuvalu, and the Marshall Islands. Another type of intraplate island is isolated Easter Island, possibly a detached piece of a mid-ocean ridge. The various types of small islands in the Pacific are all linked geologically to much larger structures that lie below the surface of the sea. These structures contain the answers to some puzzles about island origins and locations, especially when considered in terms of the plate tectonic theory of crustal evolution. *See* Marine geology; Mid-Oceanic Ridge; Plate tectonics; Seamount and guyot; Volcano.

The climate of most islands in the Pacific is dominated by two main forces: ocean circulation and atmospheric circulation. Oceanic island climates are fundamentally distinct from those of continents and islands close to continents, because of the small size of the island relative to the vastness of the ocean surrounding it. Because of oceanic influences, the climates of most small, tropical Pacific islands are characterized by little variation through the year compared with climates in continental areas.

The major natural hazards in the Pacific are associated either with seasonal climatic variability (especially cyclones and droughts) or with volcanic and tectonic activity. *See* Climate history. [R.D.Be.]

Pacific Ocean The Pacific Ocean has an area of 6.37×10^7 mi^2 (1.65×10^8 km^2) and a mean depth of 14,000 ft (4280 m). It covers 32% of the Earth's surface and 46% of the surface of all oceans and seas, and its area is greater than that of all land areas combined. Its mean depth is the greatest of the three oceans and its volume is 53% of the total of all oceans. Its greatest depths in the Marianas and Japan trenches are the world's deepest, more than 6 mi (10 km).

The two major wind systems driving the waters of the ocean are the westerlies which lie about 40–50° lat in both hemispheres (the "roaring forties") and the trade winds from the east which dominate in the region between 20°N and 20°S. These give momentum directly to the west wind drift (flow to the east) in high latitudes and to the equatorial currents which flow to the west. At the continents there is flow of water from one system to the other and huge circulatory systems result. *See* Ocean circulation; Southeast Asian waters.

The swiftest flow (greater than 2 knots) is found in the Kuroshio Current near Japan. It forms the northwestern part of a huge clockwise gyre whose north edge lies in the west wind drift centered at about 40°N, whose eastern part is the south-flowing California Current, and whose southern part is the North Equatorial Current.

Equatorward of 30° lat heat received from the Sun exceeds that lost by reflection and back radiation, and surface waters flowing into these latitudes from higher latitudes (California and Peru currents) increase in temperature as they flow equatorward and turn west with the Equatorial Current System. They carry heat poleward and transfer part of it to the high-latitude cyclones along the west wind drift. The temperature of the equatorward currents along the eastern boundaries of the subtropical anticyclones is thus much lower than that of the currents of their western boundaries at the same latitudes. The highest temperatures (more than 82°F or 28°C) are found at the western end of the equatorial region. Along the Equator itself somewhat lower temperatures are found. The cold Peru Current contributes to its eastern end, and there is apparent upwelling of deeper, colder water at the Equator.

Upwelling also occurs at the edge of the eastern boundary currents of the subtropical anticyclones. When the winds blow strongly equatorward (in summer) the surface waters are driven offshore, and the deeper colder waters rise to the surface and further reduce the low temperatures of these equatorward-flowing currents. *See* Upwelling.

The limiting temperature in high latitudes is that of freezing. Ice is formed at the surface at temperatures slightly less than 30°F (−1°C) depending upon the salinity; further loss of heat is retarded by its insulating effect. The ice field covers the northern and eastern parts of the Bering Sea in winter, and most of the Sea of Okhotsk, including that part adjacent to Hokkaido (the north island of Japan). Summer temperatures, however, reach as high as 43°F (6°C) in the northern Bering Sea and as high as 50°F (10°C) in the northern part of the Sea of Okhotsk. *See* BERING SEA.

Pack ice reaches to about 62°S from Antarctica in October and to about 70°S in March, with icebergs reaching as far as 50°S. *See* ICEBERG; SEA ICE.

Surface waters in high latitudes are colder and heavier than those in low latitudes. As a result, some of the high-latitude waters sink below the surface and spread equatorward, mixing mostly with water of their own density as they move, and eventually become the dominant water type in terms of salinity and temperature of that density over vast regions.

The most conspicuous water masses formed in the Pacific are the Intermediate Waters of the North and of the South Pacific, which on the vertical sections include the two huge tongues of low salinity extending equatorward beneath the surface from about 55°S and from about 45°N. The southern tongue is higher in salinity and density and lies at a greater depth. [J.L.Re.]

Packet switching A software-controlled means of directing digitally encoded information in a communication network from a source to a destination, in which information messages may be divided into smaller entities called packets. Switching and transmission are the two basic functions that effect communication on demand from one point to another in a communication network, an interconnection of nodes by transmission facilities. Each node functions as a switch in addition to having potentially other nodal functions such as storage or processing.

Switched (or demand) communication can be classified under two main categories: circuit-switched communication and store-and-forward communication. Store-and-forward communication, in turn, has two principal categories: message-switched communication (message switching) and packet-switched communication (packet switching).

In circuit switching, an end-to-end path of a fixed bandwidth (or speed) is set up for the entire duration of a communication or call. The bandwidth in circuit switching may remain unused if no information is being transmitted during a call. In store-and-forward switching, the message, either as a whole or in parts, transits through the nodes of the network one node at a time. The entire message, or a part of it, is stored at each node and then forwarded to the next.

In message switching, the switched message retains its integrity as a whole message at each node during its passage through the network. For very long messages, this requires large buffers (or storage capacity) at each node. Also, the constraint of receiving the very last bit of the entire message before forwarding its first bit to the next node may result in unacceptable delays. Packet switching breaks a large message into fixed-size, small packets and then switches these packets through the network as if they were individual messages. This approach reduces the need for large nodal buffers and "pipelines" the resources of the network so that a number of nodes can be active at the same time in switching a long message, reducing significantly the transit delay. One important characteristic of packet switching is that network resources are consumed only when data are actually sent.

All public packet networks require that terminals and computers connecting to the network use a standard access protocol. Interconnection of one public packet network to others is carried out by using another standardized protocol.

Packet-switched networks using satellite or terrestrial radio as the transmission medium are known as packet satellite or packet radio networks, respectively. Such networks are especially suited for covering large areas for mobile stations, or for applications that benefit from the availability of information at several locations simultaneously.

Asynchronous transfer mode (ATM) is a type of packet switching that uses short, fixed-size packets (called cells) to transfer information. The ATM cell is 53 bytes long, containing a 5-byte header for the address of the destination, followed by a fixed 48-byte information field. The rather short packet size of ATM, compared to conventional packet switching, represents a compromise between the needs of data communication and those of voice and video communication, where small delays and low jitter are critical for most applications.

Data communication (or computer communication) has been the primary application for packet networks. Computer communication traffic characteristics are fundamentally different from those of voice traffic. Data traffic is usually bursty, lasting from several milliseconds to several minutes or hours. The holding time for data traffic is also widely different from one application to another. These characteristics of data communication make packet switching an ideal choice for most applications. The principal motivation for ATM is to devise a unified transport mechanism for voice, still image, video, and data communication. *See* DATA COMMUNICATIONS. [P.K.V.]

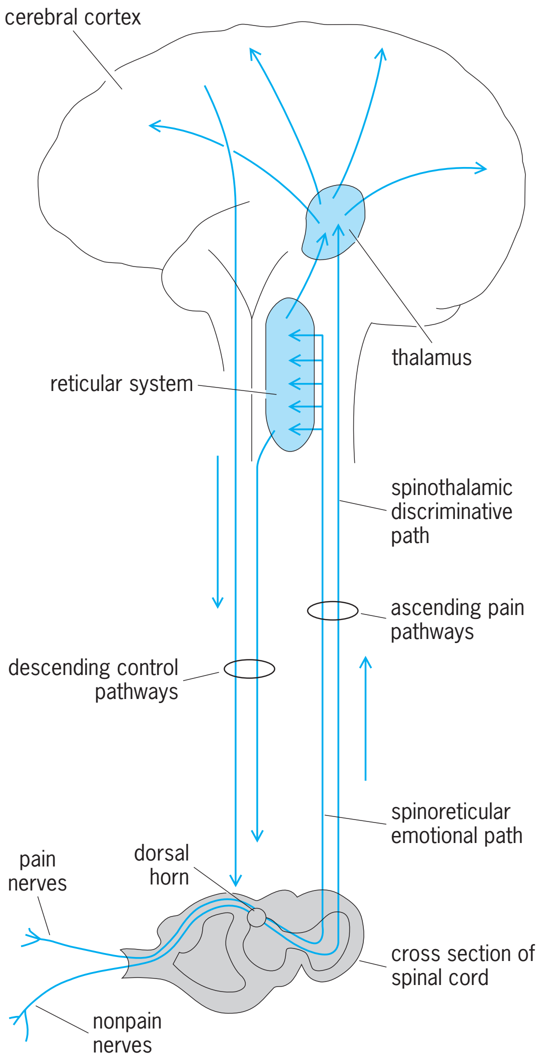
Packing A seal usually used for high pressure as in steam and hydraulic applications. The motion between parts may be infrequent as in valve stems, or continual as in pump or engine piston rods. There is no sharp dividing line between seals and packing; both are dynamic pressure resistors under motion. Diverse materials are used for packing such as impregnated fiber, rubber, cork, or asbestos compounds. In packings, it is necessary that the surface finish of the contacting metal part be smooth for long life of the material. *See* PRESSURE SEAL. [P.H.B.]

Pain Pain, especially in its acute form, is usually a reflection of a tissue-damaging or potentially tissue-damaging stimulus. There is a transmission system that conveys this information to the central nervous system. This phenomenon is called nociception. Pain is more complex than other sensory systems such as vision or hearing because it not only involves the transfer of sensory information to the nervous system, but produces suffering which then leads to aversive corrective behavior. In certain disease states, defects in the transmission system can of themselves generate false information to the nervous system, as though tissue damage were occurring in the periphery. An example of this is phantom limb pain, in which the individual often has a crushing type of pain in a foot that has been amputated.

Acute pain such as occurs with broken bones and other significant injuries is almost inevitably accounted for by the phenomenon of nociception and is probably a purely neurophysio-logical event. However, the more pain becomes a chronic phenomenon, the more such influences as psychological factors and behavior become part of the expression of pain.

Acute pain is a useful warning system. There are specific nerve paths for conducting this sensation (see illustration). Pain receptors in the skin and other tissues are nerve terminals which lack any special characteristics, and they are probably triggered by a chemical stimulus when potential tissue damage occurs. There appear to be two types of terminals: one responds to many types of painful stimuli, whereas the other specifically responds to either mechanical or thermal energy. When the terminals are stimulated, the pain (that is, nociception message) is carried along specific small sensory fibers called A-delta and C fibers. The A-delta fibers are larger and transmit the "first pain" or "fast pain" The smaller C fibers transmit a secondary dull continuous pain. These nerve fibers were traditionally believed to enter the spinal cord through the dorsal root, but it now seems that many also enter through the ventral root into the spinal cord.

Having entered the spinal cord, these fibers relay in the dorsal



Neurophysiology of incoming pain. Sensation from peripheral receptors travels along specific pain nerves, and is modulated throughout the spinal cord and brain.

horn of the spinal gray matter, an area of considerable regulation and modulation of the incoming pain stimulus which is influenced by other incoming sensory stimuli; that is, touch or pressure sensations can suppress the transmission of signals in the small pain fibers. This helps to explain why when a person is hurting, the pain can be reduced by rubbing the affected part, and this phenomenon forms the basis of some of the treatment strategies of stimulation-produced analgesia. In addition, the incoming pain signal in the spinal cord is also modulated by descending signals from the brain. At times of anxiety, these pain signals may be augmented. From these relay stations in the dorsal horn, the pain signal is carried by two nerve paths up to the brain. The classical pathway is the spinothalamic tract, on the side of the spinal cord opposite to the incoming stimulus, and this leads to the posterior part of the thalamus in the brainstem, and from there nerve paths radiate the pain sensation to many parts of the cerebral cortex, where the pain is appreciated. In addition to this direct path, there is also a diffuse ascending path known as the spinoreticular tract which relays to many of the basal ganglia in the brain, and from there to areas of the brain connected with motivational and affective behavior such as the hippocampus and the cingulate gyrus. It is possible that narcotic analgesics exert some of their action on this ascending spinoreticular tract because these drugs tend to reduce the suffering aspects of pain, but still preserve many of the discriminative qualities so that individuals can still feel the pain, but it does not bother them so much. *See* ANALGESIC; NARCOTIC.

Certain parts of the brainstem around the central canal appear to exert a strong inhibitory effect on incoming pain signals. Stimulation of these areas probably releases endorphins, which are morphinelike substances produced by the body and liberated at various sites on the incoming pain path to suppress these signals. *See* ENDORPHINS. [T.M.M.]

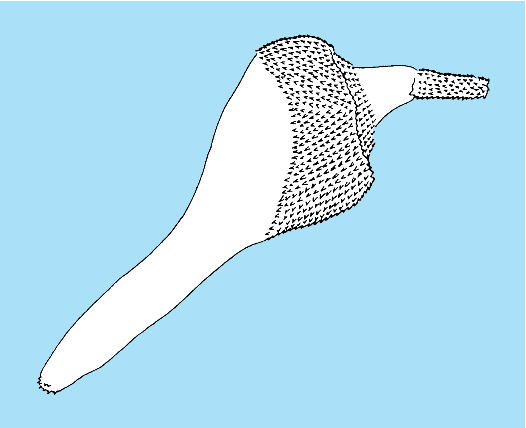
Paint A fluid, with viscosity, drying time, and flowing properties dictated by formulation, normally consisting of a vehicle or binder, a pigment, a solvent or thinner, and a drier, which may be applied in relatively thin layers and which changes to a solid in time. The change to a solid may or may not be reversible, and may occur by evaporation of the solvent, by chemical reaction, or by a combination of the two.

In modern technology, paint is classified in three major categories because of differing performance requirements: architectural paints, commercial finishes, and industrial coatings. A fourth category is artistic media.

Architectural paints are air-drying materials applied by brush or spray to architectural and structural surfaces and forms for decorative and protective purposes. Materials are classified by formulation type as solvent-thinned and water-thinned. The drying mechanism of solvent-thinned paints predominantly may be by solvent evaporation, oxidation, or a combination of the two. Solvent-thinned paints which dry essentially by solvent evaporation rely on a fairly hard resin as the vehicle. Resins include shellac, cellulose derivatives, acrylic resins, vinyl resins, and bitumens. In paints that dry by oxidation, the vehicle is usually an oil or an oil-based varnish. Water-thinned paints may be subdivided into those in which the vehicle is dissolved in water and those in which it is dispersed in emulsion form. Paints with water-soluble vehicles include the calcimines, in which the vehicle is glue, and casein paints, in which the vehicle is casein or soybean protein. Materials formed by emulsion polymerization are described as a latex, and products are called latex paints. *See* DRIER (PAINT); DRYING OIL; POLYMER.

Commercial finishes include air-drying or baking-cured materials applied by brush, spray, or magnetic agglomeration to kitchen and laundry appliances, automobiles, machinery, and furniture and used as highway marking materials. Industrial coatings are subdivided by their intended service: corrosion-resistant coatings, high-temperature coatings, and coatings for immersion service. *See* PIGMENT; SURFACE COATING. [C.R.Ma.; C.W.Si.]

Palaeacanthocephala An order of Acanthocephala, the adults of which are parasitic worms found in fishes, aquatic



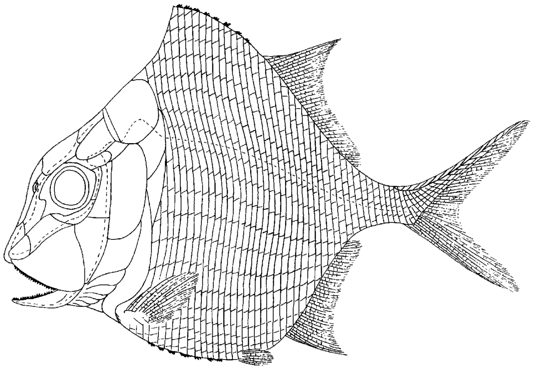
***Corynosoma reductum.* (After H. J. Van Cleave, Acanthocephala of North American Mammals, University of Illinois Press, 1953)**

birds, and mammals. They have the following characteristics. The nuclei of the hypodermis are fragmented and the chief lacunar vessels are lateral. The males have usually 2–7 cement glands. The ligament sac in the female breaks down so that the eggs develop in the body cavity. Proboscis hooks occur in long rows and spines are present on the body of some species. Species which commonly occur in vertebrates are *Leptorhynchoides thecatus* and *Corynosoma* (see illustration). *See* ACANTHOCEPHALA. [D.V.Mo.]

Palaeonemertini A rarer order of the class Anopla in the phylum Rhynchocoela, characterized by an unarmed proboscis, a thin gelatinous dermis, and either a two-layered or three-layered body musculature. Many members show primitive features, such as a peripherally located nervous system and the absence of ocelli, ciliated grooves, and intestinal diverticula. Cerebral organs, if present, are generally simple. *See* ANOPLA; RHYNCHOCOELA. [J.B.J.]

Palaeonisciformes A large order of chondrostean fish which includes the earliest known and most primitive ray-finned fishes and has a long history from the Lower Devonian, or earlier, to the Cretaceous. Many genera and species, both marine and fresh-water, have been described, but the majority are poorly understood. There are two principal Paleozoic suborders: the fusiform Palaeoniscoidei and their deep-bodied derivatives, the Platysomoidei.

Palaeoniscoids are small to medium-sized fishes with a heavily ossified exoskeleton. The body is usually covered with thick rhombic scales surfaced with enamel and articulated in oblique rows by a peg and socket mechanism. Posteriorly the body is tapered to a graceful point. This slender tapered portion is turned upward in heterocercal fashion to form the dorsal or axial lobe of the caudal fin.



***Platysomus parvulus*, an Upper Carboniferous platysomid from Britain which attained a length of 5 in. (13 cm). (*Modified from R. H. Traquair, On the structure and affinities of the Platysomidae, Trans. Roy. Soc. Edinburgh, vol. 29, 1879*)**

Typical platysomids have a laterally compressed, rhombic-shaped body with an angle at the front of the long dorsal and anal fins, small pelvic fins or none, a short lower jaw, and an upright jaw suspension. The flank scales are much deeper than long; the tail is heterocercal and forked; the facial profile is very steep (see illustration). *See* ACANTHODII; CHONDROSTEI; CROSSOPTERYGII; OSTEICHTHYES. [T.M.C.]

Palaeospondyloidea An ordinal name assigned to the single, tiny, problematic fish *Palaeospondylus*, which is known only from Middle Devonian shales of restricted extent in Caithness, Scotland. This animal seldom exceeded 2 in. (5 cm) in length. The skeleton consists of a well-calcified skull, vertebral column, caudal fin, and occasional traces of paired pelvic fins. The relationships of *Palaeospondylus* are uncertain. [R.H.De.]

Palate The roof of the mouth in those vertebrates whose mouth cavity and nasal passages are wholly or partially separate.

The palate of mammals consists of two portions. The hard palate, more anterior in position, underlies the nasal cavity, whereas the soft palate hangs like a curtain between the mouth and nasal pharynx. The hard palate has an intermediate layer of bone. The oral surface of the hard palate is a mucous membrane, covered with a stratified squamous epithelium.

The soft palate is a backward continuation from the hard palate. Its free margin connects on each side with two folds of mucous membrane, the palatine arches, enclosing a palatine tonsil. In the midline the margin extends into a fingerlike projection named the uvula. The oral side of the soft palate continues as the covering of the hard palate, and the submucosa contains pure mucous glands.

Besides separating the nasal passages from the mouth, the hard palate is a firm plate, against which the tongue crushes and manipulates food. The soft palate, at rest, is pendant. In sucking, swallowing, or vomiting it is raised to separate the oral from the nasal portion of the pharynx. The closing action also occurs in speech, except for certain consonants requiring nasal resonance. *See* SPEECH. [L.B.A.]

Paleobiochemistry The study of chemical processes used by organisms that lived in the geological past. Most information on the nature of life in the geological past comes from the study of fossils; a record of biochemical processes that occurred can be found in the organic molecules of sedimentary rocks and fossils. The organic matter in fossil fuel deposits and finely dispersed in shales and limestones represents the debris of cells which have been chemically altered to a more stable form. A comparison of the molecular structure of these preserved organic compounds with that of components of living cells enables the researcher to identify similarities and dissimilarities between past and present biochemistry.

Paleobiochemical studies have shown that a number of the common chemical processes used by living organisms today have been in use for a very great length of time. Paleobiochemical techniques are also used on materials returned from extraterrestrial sources to determine whether life exists outside of Earth. *See* PALEOECOLOGY; PALEONTOLOGY. [T.C.H.]

Paleobotany The study of fossil plants of the geologic past. A paleobotanist is a plant historian who attempts to carefully piece together the geologic history of the plant kingdom. Other organisms, including fungi and various types of microscopic plankton, are also studied by paleobotanists. Paleobotany is a branch of paleontology that requires a knowledge of both plant biology (botany) and the geological sciences. *See* BOTANY; FOSSIL; PLANT KINGDOM.

The materials used by the paleobotanist to reconstruct plants and the vegetation they represent through geologic time include fossilized remains preserved in the rock layers of the Earth. Such materials as fossil leaves, seeds, fragments of wood, fruits, and flowers are used to interpret the biology and evolution of prehistoric plants. In addition, the activities and distribution of plants are recorded in the rock record in the form of coal, resins, chemicals, and various other substances produced by plants. Some plant fossils, such as pollen grains and spores, are studied by palynologists, who work in a discipline (palynology) that has been especially important in mineral and petroleum exploration and in correlating rock layers that are widely separated geographically. *See* FOSSIL SEEDS AND FRUITS; PALYNOLOGY.

Paleobotany not only involves the collection, description, reconstruction, and naming of fossil plants but is also concerned with the evolution of major groups, relationships that exist between fossil and living forms, how ancient plants functioned and reproduced, what type of environment they lived in, how they were fossilized, and many other biological and geological questions.

Plants are preserved in a variety of ways, and various combinations of physical and chemical processes are involved at the time of preservation. To become a fossil, several unique processes must take place concomitantly to preserve the leaf of a plant. The first process involves proximity to a site where sediments are accumulating, and rapid burial of the leaf. Short-distance transport ensures that tissues of the leaf are not torn, abraded, or otherwise destroyed. Rapid burial is necessary to ensure that the biological activities of microbes do not destroy the tissues of the leaf. *See* BIODEGRADATION.

Plant parts are best preserved in very fine grained silts and shales that represent the lithified muds of ancient deposits. These sediments generally yield excellent fossils because the small grain size preserves minute details of the leaf. The location of where the fossil is deposited is critical as to whether fossil remains will ever be discovered. For example, sediments deposited in certain types of lakes, rivers, and swamps may be easily lost as the depositional system changes over time, or the sediments are eroded away as river systems cut into older fossil-bearing rocks.

Fossil plants are extensively used in two principal areas: plant biology (botany) and biostratigraphy. In botany the geological record of past floras is traced to the present. Fossil plants have provided an enormous body of knowledge about the evolution of plants from the earliest Precambrian unicellular forms to the complex multicellular flowering plants used for food and shelter. In biostratigraphy, fossils such as some plant megafossils as well as pollen grains and spores are used to date rock layers. Fossil plants can also be valuable in reconstructing climates of the past. *See* PALEOCLIMATOLOGY; PALEONTOLOGY; STRATIGRAPHY. [T.N.T.]

Paleoceanography The study of the history of the ocean with regard to circulation, chemistry, biology, and patterns of sedimentation. The source of information is largely the biogenous deep-ocean sediments, so the field may be considered a branch of sedimentology or paleontology. However, there are also strong links to geophysics, marine geochemistry, and mathematical modeling. Geophysical sciences are called upon for reconstruction of geography (position of continents, horizontal motion of the ocean floor), topography (changing depth patterns in the ocean, general subsidence of any given piece of sea floor), and dating (radioisotopes, magnetic patterns on the sea floor and in sediments). Geochemical analyses deliver information on sediment composition (stable and unstable isotopes; major and minor components such as carbonate, opal, and trace elements). Such information is useful in correlating sedimentary sequences and, when combined with geochemical arguments, yields insights about the dynamics of carbon and nutrient cycles. Mathematical modeling introduces a strong quantitative element. It draws upon the knowledge reservoir of modern oceanography and climatology. *See* CLIMATOLOGY; GEOCHEMISTRY; GEOPHYSICS; PALEONTOLOGY; SEDIMENTOLOGY.

The study of marine sediments on land is as old as geology itself. Modern paleoceanography is set apart by the study of sediments recovered from the ocean, especially the deep ocean, and by the use of concepts developed by oceanographers (controls on ocean currents and upwelling, vertical stratification, heat budget, nutrient and carbon cycles, pelagic biogeography, and water masses). Important early studies were on cores raised by the United States cable ship *Lord Kelvin* (1936) in the North Atlantic. The glacial debris zones noted in the *Kelvin* cores are now commonly referred to as Heinrich layers; they are witness to sporadic input of iceberg armadas during the last glacial epoch. *See* GLACIAL EPOCH.

Comparisons of climate-related changes between major ocean basins became possible through the systematic recovery of long cores by the circumglobal Swedish Deep Sea Expedition (1947–1949) on the research vessel *Albatross*. The expedition retrieved cores up to 15 m (45 ft) long, with records reaching back 500,000–1,000,000 years. Many fundamental paleoceanographic concepts were established by the geologists who analyzed these cores, including the role of trade winds in promoting glacial-age upwelling, the changing supply of North Atlantic Deep Water, the cyclicity of climatic change in the late Quaternary, and large-scale shifts in biogeographic boundaries. *See* CLIMATE MODELING; PALEOCLIMATOLOGY; QUATERNARY.

A quantum jump in paleoceanographic research resulted from the initiation of deep-sea drilling using the research vessel *Glomar Challenger* (1968). Enormous blank regions on the world's map suddenly became accessible for detailed exploration far back into geologic time, that is, into the Early Cretaceous. Highlights of the first decade of drilling results include the documentation of cooling steps as the planet moved into the present ice age; the reconstruction of long-term fluctuations in the carbonate compensation depth; the documentation of large-scale salt deposition in an isolated Mediterranean basin; and the discovery of temporary anoxic conditions in the Cretaceous deep sea. *See* CRETACEOUS. [W.H.B.; G.We.]

Paleocene The oldest of the seven geological epochs of the Cenozoic Era, and the oldest of the five epochs that make up the Tertiary Period. The Paleocene Epoch represents an interval of geological time (and rocks deposited during that time) from the end of the Cretaceous Period to the beginning of the Eocene Epoch. Recent revisions of the geological time scales place the Paleocene Epoch between 65 to 55 million years before present. *See* CENOZOIC; EOCENE; GEOLOGIC TIME SCALE; TERTIARY.

The close of the Cretaceous Period was characterized by the disappearance of many terrestrial and marine animals and plants. The dawn of the Cenozoic in the Paleocene Epoch saw the establishment of new fauna and flora that have evolved into modern biota.

Modern schemes of the Paleocene subdivide it into Lower and Upper series, and their formal equivalents, the Danian and Selandian stages. Some authors prefer to use a threefold subdivision of the Paleocene, adding the Thanetian at the top. The older, Danian lithofacies generally tend to be calcium carbonate-rich (pure chalk in the Danian type area), whereas the younger, Selandian and Thanetian facies have greater land-derived components and are more siliciclastic (sand, sandstone, marl). *See* CHALK; FACIES (GEOLOGY); MARL; SAND; SANDSTONE.

Several major tectonic events that began in the Mesozoic continued into the Paleocene. For example, the Laramide Orogeny that influenced deformation and uplift in the North American Rocky Mountains in the Mesozoic continued into the Paleocene. *See* OROGENY.

The establishment of deeper connections between the North and South Atlantic in the Paleocene facilitated enhanced deep-water flow from the northern to the southern basin. In the south, the Drake Passage between South America and Antarctica was still closed, although Australia had already separated from Antarctica by Paleocene time. The lack of circum-Antarctic flow precluded the geographic isolation of Antarctica and the development of cold deep water from a southern source. *See* PALEOCEANOGRAPHY; PALEOGEOGRAPHY.

Terrestrial floras and faunas corroborate the peak warming in the latest Paleocene and early Eocene and suggest that the warm tropical-temperate belt may have been twice its modern latitudinal extent. The temperate floral and faunal elements extended to 60°N, which has been used as an argument to invoke a very low angle of inclination of the Earth's rotational axis in the Paleocene-Eocene. Alternatively, the mild, equable polar climates and well-adapted physiological responses of plants and animals of those times to local conditions may be enough to explain the presence of a rich vertebrate fauna on Ellesmere Island in arctic Canada. *See* CLIMATE HISTORY; PALEOBOTANY; PALEOCLIMATOLOGY.

The Paleocene Epoch began after a meteorite struck the Earth, causing massive extinctions at the end of Cretaceous and decimating a large percentage of the terrestrial and marine biota. In the oceans, all ammonites, genuine belemnites, rudistids, most species of planktonic foraminifera and nannoplankton, and marine reptiles disappeared at the close of the Cretaceous Period. Even though some groups, such as squids, octopus, nautilus, and a few species of marine plankton, survived, the genetic pool was relatively small at the dawn of the Tertiary Period. The recovery of the marine biota was, however, fairly rapid after the mid-Paleocene due to overall transgressing seas and ameliorating climates. By the late Paleocene, the biota was well on its way to the high diversification of the Eocene. The end of the Paleocene Epoch saw marked changes in deep-water circulation of the world ocean that resulted in a massive extinction of the benthic marine species. *See* Extinction (biology).

On land the large dinosaurs, which had been on the decline for over 20 million years, died out at the close of the Cretaceous Period. However, smaller reptiles, including alligators and crocodiles, and some of the land flora escaped extinction and continued into the Paleocene. The Paleocene saw the first true radiation of mammals. The mammals of this epoch were characteristically primitive and small in size (50 cm or 20 in. or less). As the continent of Australia became more isolated geographically, its mammalian fauna, such as the marsupials, became sequestered and more specialized. *See* Dinosaur; Mammalia; Paleontology. [B.U.H.]

Paleoclimatology The study of ancient climates. Climate is the long-term expression of weather; in the modern world, climate is most noticeably expressed in vegetation and soil types and characteristics of the land surface. To study ancient climates, paleoclimatologists must be familiar with various disciplines of geology, such as sedimentology and paleontology, and with climate dynamics, which includes aspects of geography and atmospheric and oceanic physics. Understanding the history of the Earth's climate system greatly enhances the ability to predict how it might behave in the future. *See* Climatology.

Information about ancient climates comes principally from three sources: sedimentary deposits, including ancient soils; the past distribution of plants and animals; and the chemical composition of certain marine fossils. These are all known as proxy indicators of climate (as opposed to direct indicators, such as temperature, which cannot be measured in the past). In addition, paleoclimatologists use computer models of climate that have been modified for application to ancient conditions. *See* Geology; Paleontology.

Like modern climatologists, paleoclimatologists are concerned with boundary conditions, forcing, and response. Boundary conditions are the limits within which the climate system operates. The boundary conditions considered by paleoclimatologists depend on the part of Earth history that is being studied. For the recent past, that is, the last few million years, boundary conditions that can change on short time scales are considered, for example, atmospheric chemistry. For the more distant past, paleoclimatologists must also consider boundary conditions that change on long time scales. Geographic features—that is, the positions of the continents, the location and orientation of major mountain ranges, the positions of shorelines, and the presence or absence of epicontinental seaways—are important for understanding paleoclimatic patterns. Forcing is a change in boundary conditions, such as continental drift, and response is how forcing changes the climate system. Forcing and response are cause and effect in paleoclimatic change. *See* Continental drift; Continents, evolution of; Paleogeography; Plate tectonics.

Proxy indicators of paleoclimate are abundant in the geologic record. Important sedimentary indicators forming on land are coal, eolian sandstone (ancient sand dunes), evaporites (salt), tillites (ancient glacial deposits), and various types of paleosols (ancient soils), such as bauxite (aluminum ore) and laterite (some iron ores). Coals may form where conditions are favorable for growth of plants and accumulation and preservation of peat, conditions that are partly controlled by climate, especially seasonality of rainfall. *See* Bauxite; Coal; Paleosol.

Fossil indicators provide information about climate mostly by their distribution (paleobiogeography), although a few specific types of fossils may be indicative of certain climatic conditions. The latter are usually fossils from the younger part of the geologic record and are closely related to modern species that have narrow environmental tolerances. Another type of information available for documenting paleoclimatic patterns and change is stable isotope geochemistry of fossils and certain types of sedimentary rock. Many elements that are used by organisms to make shells, teeth, and stems occur naturally in several different forms, known as isotopes. The most climatically useful isotopes are those of oxygen (O). Although the effects of temperature change and ice volume change can be difficult to distinguish, the analysis of oxygen isotopes has provided a powerful quantitative tool for the study of both long-term temperature change and the history of the polar ice caps. *See* Fossil; Isotope.

A great deal of research in paleoclimatology has been devoted to understanding the causes of climatic change, and the overriding conclusion is that any given shift in the paleoclimatic history of the Earth was brought about by multiple factors operating in concert. The most important forcing factors for paleoclimatic variation are changes in paleogeography and atmospheric chemistry and variations in the Earth's orbital parameters. *See* Atmospheric chemistry; Biogeochemistry; Earth rotation and orbital motion; Precession of equinoxes. [J.T.P.; E.J.Ba.]

Paleocopa An extinct order of the crustacean class Ostracoda; also called Palaeocopida. The order is divided into nine superfamilies, one of which, Barychilinacea, is only tentatively assigned to the order. A principal feature of the species in the order is their long, straight hinge that extends along the dorsal margin of the carapace and joins the two valves together. As is true of most benthic ostracodes, the palaeocopes lack a frontal opening through which to extend their walking legs. Unlike modern ostracodes, however, they have no calcified inner lamella, and their muscle-scar patterns, which are quite useful in the taxonomy of many other groups of ostracodes, are very poorly known. *See* Ostracoda.

The carapaces of many palaeocopes are marked by ornamentation in the form of lobes and sulci. Appendages of the palaeocopes are largely unknown except for a few rather poorly preserved specimens.

One of the most remarkable morphological features of many species of palaeocope ostracodes is that their sexual dimorphism is quite pronounced and is carried far beyond the rather simple sexual dimorphism that characterizes Ostracoda. In typical instances, the males resemble the instars (immature forms), and the females have developed strongly modified morphology that is associated with reproduction—especially the development of pouches for carrying eggs and brooding the young.

The study of the ontogeny of the palaeocopes presents paleontologists with a unique opportunity to learn about the pathways and mechanisms of evolution. The palaeocopes lend themselves to this sort of study because they molt, have a predetermined number of growth stages, and have pronounced sexual dimorphism that allows one to determine the sex of individuals and the sex ratios of populations. Thus, research on the palaeocopes can reveal the pathways their evolution has followed in a way that is possible for few other kinds of fossil organisms.

As is true of other benthic ostracodes, the paleocopes do not have a planktonic larval stage. As a result, they are quite limited in their means of dispersal, and few species are biogeographically widespread. [R.L.Ka.]

Paleoecology Ecology of prehistoric times, extending from about 10,000 to about 3.5×10^9 years ago. Although the principles of paleoecology are the same as those underlying modern ecology, the two fields differ greatly. Paleoecology is a historical science that must rely on empirical data from fossils and their enclosing sedimentary rocks to make inferences about past conditions. Experimental approaches and direct measurement of environmental parameters, which are critical components of modern ecology, are generally impossible in paleoecology. Furthermore, distortion and loss of information during fossilization means that fossil assemblages and distributions are rarely congruent with living communities. Hence, the resolution of ancient ecosystems must remain relatively imprecise. The lack of precision is compensated for by the fact that paleoecology deals with processes occurring over vast spans of time that are unavailable to modern ecology. Long-term changes in communities (replacement) may be discerned and related to patterns of environmental change. More significantly, overall patterns of ecological change in the global biosphere may be documented; evolutionary paleoecology focuses on recognition and interpretation of long-term ecological trends that have been critical in shaping evolution.

Among the goals of paleoecology are the reconstruction of ancient environments (primarily depositional environments), the inference of modes of life for ancient organisms from fossils, the recognition of recurring groupings of ancient organisms that define relicts of communities (paleocommunities), the reconstruction of the interactions of organisms with their environments and with each other, and the documention of large-scale and long-term patterns of stasis or change in ecosystems. *See* ECOSYSTEM.

To reconstruct ancient marine environments, many different parameters must be inferred, such as temperature, water salinity, oxygen levels, nutrient concentrations, and water movements and depth. In this regard, paleoecology interfaces directly with the fields of sedimentology and stratigraphy, including study of modern depositional environments. *See* DEPOSITIONAL SYSTEMS AND ENVIRONMENTS; STRATIGRAPHY.

Paleoautecology, the interpretation of modes of life (broadly, niches) of ancient organisms, involves a multidisciplinary approach. Although ancient modes of life cannot be determined completely, paleoecologists can often assign fossils to generalized guilds in terms of types of feeding, substrate preference, and degree of activity. A thorough understanding of the biology of closest modern analogs is particularly important in any attempt to reconstruct paleoautecology. *See* LIVING FOSSILS.

The fossil record contains highly biased remnants of past communities or paleocommunities. Paleocommunities are generally recognized as recurring associations of fossil species. Multivariate statistical techniques such as cluster analysis and ordination analysis are commonly employed to aid in discerning the recurrent groupings of fossil species.

Communities and paleocommunities are not static entities in time, but undergo important structural changes on at least three different time scales: succession, replacement, and evolution. Because it operates on a very short time scale, from decades to centuries, ecological succession can be resolved only in a few fossil samples. Longer-term changes in community composition, encompassing thousands of years, are not truly succession. These changes are properly termed community replacement, involving wholesale migration or restructuring of communities at particular locations due to changing environments. On a scale of millions of years, communities show evolutionary changes because their component species have evolved. *See* ECOLOGICAL COMMUNITIES; ECOLOGICAL SUCCESSION.

Organisms evolve within the context of other organisms, not in a vacuum. There is substantial fossil evidence to indicate increasing complexity of organism interactions through time. This escalation in the intensity of predatory interactions, for example, may have important implications for evolutionary change.

One of the most interesting aspects of paleoecology is the possibility of long-term shifts in organism habitats. Evolutionary innovations appear to arise preferentially in shallow-water areas, but through time these new faunas may migrate offshore. Evidence from the fossil record suggests that many paleocommunities were relatively resistant to major changes over long spans of time. These periods of relative stasis in community structure may be punctuated by minor or major crises, during which communities are restructured, with new species added while others become extinct. In many cases, shoreline biotas display very little change. Similarly, deep-oceanic benthic organisms may be little changed through time. In contrast, shallow-water, shelf-dwelling, and especially pelagic organisms may be strongly affected by environmental crises such as the lowering of average temperatures. *See* ECOLOGY; PALEOCLIMATOLOGY; PALEOGEOGRAPHY; PALEONTOLOGY. [C.E.Br.]

Paleogeography The geography of the ancient past. Paleogeographers study the changing positions of the continents and the ancient extent of land, mountains, and shallow-sea and deep-ocean basins. The Earth's geography changes because its surface is in constant motion due to plate tectonics. The continents move at rates of 2–10 cm/yr (0.75–4 in./yr). Though this may seem slow, over millions of years continents can travel across the globe. As the continents move, new ocean basins form, mountains rise and erode, and sea level rises and falls. Paleogeographic maps are necessary in order to understand global climatic change, migration routes, oceanic circulation, mountain building, and the formation of many of the Earth's natural resources, including oil and gas. *See* BASIN; CONTINENTS, EVOLUTION OF; GEOGRAPHY; MID-OCEANIC RIDGE; PALEOCLIMATOLOGY; PLATE TECTONICS; SUBDUCTION ZONES.

In the late Precambrian the continents were colliding to form supercontinents, and the Earth was locked in a major ice age. About 1100 million years ago (Ma), the supercontinent of Rodinia was assembled. Rodinia split into halves approximately 750 Ma, opening the Panthalassic Ocean. By the end of the Precambrian three continents came together to form the supercontinent of Gondwana(land). This major continent-continent collision is known as the Pan-African orogeny. *See* OROGENY; PRECAMBRIAN; PROTEROZOIC; SUPERCONTINENT.

The supercontinent that formed at the end of the Precambrian Era, approximately 600 Ma, had already begun to break apart by the beginning of the Paleozoic Era. Gondwana, which was considerably larger than any of the other continents, stretched from the Equator to the south. *See* ORDOVICIAN; PALEOZOIC.

By the end of the Paleozoic Era, the continents had collided to form the supercontinent of Pangea. Centered on the Equator, Pangea stretched from the South Pole to the North Pole. Though the supercontinent that formed at the end of the Paleozoic Era is called Pangea (literally, "all land,"), this supercontinent probably did not include all the landmasses that existed at that time.

The supercontinent of Pangea did not rift apart all at once, but in three main episodes. The first episode of rifting began in the Middle Jurassic, about 180 Ma when North America rifted away from northwest Africa, opening the Central Atlantic. *See* JURASSIC.

The second phase in the breakup of Pangea began in the Early Cretaceous, about 140 Ma. Gondwana continued to fragment as South America separated from Africa, opening the South Atlantic, and India together with Madagascar rifted away from Antarctica and the western margin of Australia, opening the Eastern Indian Ocean. *See* CRETACEOUS.

The third and final phase in the breakup of Pangea took place during the early Cenozoic. North America and Greenland split away from Europe, and Antarctica released Australia. Australia, like India some 50 million years earlier, moved rapidly northward on a collision course with Southeast Asia. *See* CENOZOIC.

About 18,000 years ago, all of Antarctica and much of North America, northern Europe, and the mountainous regions of the world were covered by glaciers and great sheets of ice. These ice sheets melted approximately 10,000 years ago, giving rise to familiar geographic features such as Hudson's Bay, the Great Lakes, the English Channel, and the fiords of Norway. [C.R.Sc.]

Paleoindian The oldest archeological cultures of the New World, the ancestors of modern Native Americans, are termed Paleoindian. These colonizing populations of the Americas were

Homo sapiens sapiens who arrived during the late Pleistocene (Ice Age) from Asia, though precisely when, and whether in a single or multiple pulses of migration, are not yet known.

The presumed entryway was the Bering Straits, which emerged as dry land during glacial periods. The Bering Land Bridge (or Beringia) existed most recently between 25,000 and 11,000 years before present (B.P.), during the last major episode of the Pleistocene. The conditions that linked Siberia to Alaska may have simultaneously hindered migration south from Alaska. Groups headed in that direction had two potential routes (broadly defined): down the Pacific coast, or via the continental interior along the eastern flank of the Rocky Mountains. There is no evidence yet as to which routes might have been taken.

So far, the earliest archeologically confirmed dates put human groups in the Lena Basin and Lake Baikal region of northeast Asia at about 39,000 years B.P., in subarctic Siberia by 25,000 years B.P., but not in western Beringia (such as Kamchatka) until 14,000 years B.P. Humans were in eastern Beringia (Alaska) soon after 12,000 years B.P., and present south of the ice sheets in North America by at least 11,500 years B.P.—the latter represented by the Clovis culture. Yet, the earliest accepted archeological evidence puts human groups in South America earlier still, by at least 12,500 years B.P. at the site of Monte Verde, Chile.

There are no obvious historical or technological affinities between Clovis and the Monte Verde materials, suggesting that the two may represent populations with distinct archeological traditions and separate migratory pulses: a later one (Clovis) that came south through the ice-free corridor soon after it became viable for travel, and an earlier population that perhaps moved along the Pacific coast and reached South America without, so far at least, any traces being found in North America.

Clovis is a widespread entity that first appears on the western Plains and southwest at 11,500 years B.P. and in eastern North America at 10,600 years B.P. That Clovis and related groups apparently expanded across the continent in what may have been less than 1000 years is all the more remarkable given that they spread at a time of geologically rapid environmental and climatic change. Yet Clovis groups seemingly coped with such adaptive challenges with ease: their stylistically distinctive projectile points and tool kits—often including bifacial knives, a variety of unifacial scrapers, occasional blades and flake tools, and (more rarely) bone and ivory implements—are surprisingly similar across the continent. These were highly mobile groups who relied on high-quality stone often obtained from geological sources hundreds of kilometers from the sites where the stone was used and discarded. Their rapid radiation, broadly similar tool kits, and long-distance movement bespeak a cultural "founders effect," suggesting their access to large areas of North America was largely unrestricted. Clovis subsistence, it appears, more often involved less risky and smaller prey—and presumably plants, though remains of such are rarely preserved in the archeological record of this period.

Although the timing varies by area, by 10,500 years B.P. the Clovis tradition was replaced by regional Paleoindian variants, which generally have reduced settlement mobility (relative to Clovis), and include new technologies, prey-specific strategies for hunting and processing, increasing use of local resources, and distinctive stylistic elements and functional artifact forms.

The South American Paleoindian record, by contrast, does not evince any artifact forms that dominate the archeological landscape as Clovis does. Instead, this period is marked by more diverse unifacial and bifacial stone tool technologies, often made of stone acquired locally (and not necessarily of superior quality), and includes forms such as bolas—modified spherical stones used in slings or as hand missiles. Projectile points tend to be less common in assemblages here than in North America, and show considerable stylistic variety. South American Paleoindians utilized a wide range of animals, and early on even made occasionally heavy use of plants.

Once the founding population dispersed across South America (over an unknown length of time), subgroups became geographically isolated relatively quickly. From the earliest known site at 12,500 years B.P. (Monte Verde) until the end of the Pleistocene (10,000 years B.P.), there is a continuing diversification in tool forms and technology, evidently reflecting less mobility, increasing heterogeneity and regional mosaics in culture and adaptations, and less expansive social networks and territories. All told, it is a different trajectory from the one that unfolded in North America—testimony that the earliest colonization of the two continents, though ultimately derived from the same northeast Asian source, may have taken place at different times under very different circumstances. *See* ARCHEOLOGY; PLEISTOCENE; PREHISTORIC TECHNOLOGY. [D.J.Me.]

Paleolithic The prehistoric period when people made stone tools exclusively by chipping or flaking. John Lubbock proposed and defined the term Paleolithic, or Old Stone Age, in 1865, and also defined a subsequent Neolithic, or New Stone Age, during which some stone tools were formed by polishing or grinding. Later archeologists altered these definitions; to many today the Paleolithic is the period during which human beings lived entirely by hunting and gathering, while the Neolithic is the following interval during which plant and animal domestication was introduced. To other archeologists, the Paleolithic is simply a time interval, roughly equivalent to the Pleistocene Epoch, while the Neolithic comprises the early part of the succeeding Holocene (or Recent) Epoch.

It is impossible to devise a rigorous, global definition of the Paleolithic or any other cultural stage, because artifact technology and economic practices have changed independently at different times in different parts of the world. Hence, Paleolithic will be used here informally to refer to the time interval between the earliest appearance of stone tools, more than 2 million years before present (m.y. B.P.), and the end of the last glacial period, 12,000–10,000 years B.P. *See* GEOLOGIC TIME SCALE; NEOLITHIC; PREHISTORIC TECHNOLOGY.

The oldest artifacts found so far come from sites in Ethiopia, Kenya, and Tanzania where they are dated to between 2.5 and 1.6 m.y. B.P. They comprise crude flakes and the modified pebbles and stone chunks from which the flakes were struck. Approximately 1.6–1.5 m.y. B.P., at least some people in East Africa began to manufacture the bifacially flaked tools known to archeologists as hand axes. The flaking of the first hand axes was crude. As time passed, however, their flaking tended to become more refined. By 1 m.y. B.P. hand-ax makers had spread through most of Africa and the Near East, and by 900,000–600,000 years B.P. they had reached Europe.

The Early Stone Age/Lower Paleolithic apparently persisted until sometime between 200,000 and 130,000 years B.P., the exact time perhaps depending on the place. In sub-Saharan Africa the Early Stone Age was succeeded by the Middle Stone Age, while in North Africa and Eurasia the Lower Paleolithic was followed by the Middle Paleolithic. Most Middle Stone Age/Middle Paleolithic assemblages lack hand axes. The principal Middle Stone Age/Middle Paleolithic tools are well-made stone flakes, often modified by edge flaking ("retouch") into types called sidescrapers, knives, denticulates (serrate-edged pieces), and so forth. In Europe, Middle Paleolithic people were the Neanderthals, *H. (sapiens) neanderthalensis*. Neanderthals also lived in the Near East during the early Middle Paleolithic, but were apparently supplanted by anatomically modern people (*H. sapiens sapiens*) during the latter part (after ?70,000–60,000 years B.P.). Outside of Europe and the Near East, bones representing Middle Paleolithic/Middle Stone Age people are rare, very fragmentary, or both. *See* NEANDERTHALS.

In Europe, the Near East, and North Africa, the Middle Paleolithic was followed by the Upper Paleolithic, perhaps 50,000 years B.P. in the Near East, adjacent North Africa, and eastern Europe, and beginning around 40,000 years B.P. in western Europe. The time difference within Europe may reflect the movement of technology, people, or both from east to west. The Upper Paleolithic and Later Stone Age are difficult to characterize artifactually, because wherever they are well known, they exhibit great variability in time and space. The amount of artifactual change through time and space during the Upper Paleolithic/Later Stone Age far exceeds that in earlier periods and suggests an ability to innovate that earlier people did not exhibit. Conventionally, the Upper Paleolithic is said to end with the end of the Last Ice Age, 12,000–10,000 years B.P., although Upper Paleolithic/Later Stone Age artifact types and economic practices continued on for many millennia throughout much of Eurasia and sub-Saharan Africa.

Throughout the long Paleolithic time span, all human beings lived by hunting and gathering wild resources. Only from the very end of the Paleolithic, about 12,000–10,000 years B.P., is there evidence that some people domesticated animals, plants, or both.

The oldest reasonably secure evidence for human use of fire comes from the famous Peking man (*H. erectus*) site of Zhoukoudian in north China, tentatively dated to 500,000–240,000 years ago. More equivocal evidence for older or equally old controlled use of fire has been found in Kenya, South Africa, and Europe. Unequivocal fireplaces are found in many sites occupied by European Neanderthals and their near-modern African contemporaries after 127,000 years B.P.

Concentrations of rocks or other debris that may mark the positions of ancient structures such as wind breaks and flimsy tentlike shelters have been uncovered at several Lower Paleolithic sites in Africa and across Eurasia, but the oldest widely accepted "ruins" date from the Middle Paleolithic. However, it is not until 50,000–40,000 years ago that evidence for housing becomes compelling, with such features as fireplaces and substantial wall supports being commonplace.

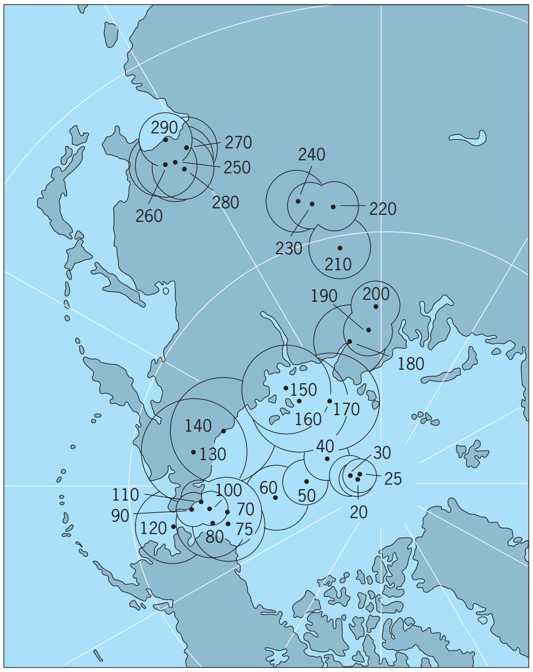
The oldest undeniable evidence for burial of the dead comes from the Middle Paleolithic of Europe and the Near East. The deceased were Neanderthals. Upper Paleolithic people also buried their dead. In addition, unlike Middle Paleolithic graves, Upper Paleolithic ones often contain special objects, such as hundreds of ivory beads, carved pendants, or other body ornaments. Upper Paleolithic graves, together with Upper Paleolithic art, provide the oldest available evidence for the intangible part of culture called ideology or religion. [R.G.K.; A.P.T.]

Paleomagnetism The study of the direction and intensity of the Earth's magnetic field through geologic time. Paleomagnetism has been, and continues to be, an important tool in unraveling the past movements of the Earth's tectonic plates. By studying the records of the ancient magnetic field left in rocks, earth scientists are able to learn how the continental and oceanic plates have moved relative to the Earth's spin axis and relative to one another. In addition, the global reference frame of the Earth's magnetic field provides a very useful basis for temporal correlation of rocks on a local or global geographic scale (magnetostratigraphy). *See* Geomagnetism; Plate tectonics.

Many rocks acquire remanent magnetizations at or about the time they are formed. These magnetizations are nearly always parallel to the direction of the Earth's magnetic field at the locality where the rock formed. *See* Rock magnetism.

In paleomagnetic studies a suite of carefully oriented samples spanning a time interval long enough to average magnetic secular variations is collected. For magnetostratigraphy, an ordered suite of samples spanning the stratigraphic section of interest are collected. The samples are taken to the laboratory, where they are cut into small upright cylinders and their magnetization is measured by using a sensitive magnetometer.

The end product of the laboratory experiments is a suite of magnetization vector directions from the collected samples. These directions are specified by the inclination *I*, the angle that the magnetization vector makes with the horizontal, and the declination *D*, the angle that the projection of the magnetization vector upon a horizontal plane makes with true north, reckoned positive clockwise from north. Provided that the sample collection represents a sufficiently long time span to average out secular variation, representative mean *D* and *I* values and an associated uncertainty in direction may be calculated by using statistical techniques. The mean declination and inclination, together with the inclination-latitude relationship mentioned earlier and some elementary spherical trigonometry, allow the calculation of a representative paleomagnetic pole from the rock unit. By connecting paleomagnetic poles of different ages in an ordered time sequence, an apparent polar wander path (APWP) may be constructed for a particular tectonic plate (see illustration). The APWP specifies the displacement history of a plate or continent with respect to the spin axis, and can be directly compared with APWPs from other plates or continents to determine whether relative movements have occurred.



Apparent polar wander path for North America for Late Carboniferous time to the present. The numbers represent time in millions of years before present. Circles encompass standard error. (*After E. Irving, Paleopoles and paleolatitudes of North America and speculations about displaced terranes, Can. J. Earth Sci., 16:669–694, 1979*)

The end product of a magnetostratigraphic study is a set of normal (N) and reversed (R) magnetizations from the stratigraphic section under investigation. The positioning and frequency of occurrence of these N-to-R and R-to-N transitions is highly diagnostic in many cases, and by using these data together with other local geologic information, such as the position of major unconformities, one stratigraphic section can be correlated with another over considerable distances. The method can also be used over intracontinental and intercontinental distances. However, because the field has only two possible states (N or R), correlation over longer distances where tectonics and sedimentation rates may vary is correspondingly less accurate. [M.O.McW.]

Paleontology The study of animal history as recorded by fossil remains. The fossil record includes a very diverse class of objects ranging from molds of microscopic bacteria in rocks more than 3×10^9 years old to unaltered bones of fossil humans in ice-age gravel beds formed only a few thousand years ago. Quality of preservation ranges from the occasional occurrence of soft parts (skin and feathers, for example) to barely decipherable impressions made by shells in soft mud that later hardened to rock. *See* FOSSIL; MICROPALEONTOLOGY.

The most common fossils are hard parts of various animal groups. Thus the fossil record is not an accurate account of the complete spectrum of ancient life but is biased in overrepresenting those forms with shells or skeletons. Fossilized worms are extremely rare, but it is not valid to make the supposition that worms were any less common in the geologic past than they are now. *See* EDIACARAN BIOTA.

The data of paleontology consist not only of the parts of organisms but also of records of their activities: tracks, trails, and burrows. Even chemical compounds formed only by organisms can, if extracted from ancient rocks, be considered as part of the fossil record. Artifacts made by people, however, are not termed fossils, for these constitute the data of the related science of archeology, the study of human civilizations. *See* ARCHEOLOGY; PALEOBIOCHEMISTRY.

Paleontology lies on the boundary between two disciplines, biology and geology. *See* BIOLOGY; GEOLOGY.

Geological aspects. A major task of any historical science, such as geology, is to arrange events in a time sequence and to describe them as fully as possible.

Fossils only tell that a rock is older or younger than another; they do not give absolute age. The decay of radioactive minerals may provide an age in years, but this method is expensive and time-consuming, and cannot always be applied since most rocks lack suitable radioactive minerals. Correlation by fossils remains the standard method for comparing ages of events in different areas. *See* INDEX FOSSIL; STRATIGRAPHY.

The physical appearance and climate of the Earth during a given period of the geologic past can be described from compilation and analysis of the data which is obtained through studies of the habitats of extant fauna, the geographic distribution of fossils, and the climatic preferences of ancient forms of life. *See* PALEOCLIMATOLOGY; PALEOECOLOGY; PALEOGEOGRAPHY.

Biological aspects. The most fundamental fact of paleontology is that organisms have changed throughout earth history and that each geological period has had its characteristic forms of life. An evolutionist has two major interests: first, to know how the process of evolution works; this is accomplished by studying the genetics and population structure of modern organisms; second, to reconstruct the events produced by this process, that is, to trace the history of life. Any modern animal group is merely a stage, frozen at one moment in time, of a dynamic, evolving lineage. Fossils give the only direct evidence of previous stages in these lineages. Horses and rhinoceroses, for example, are very different animals today, but the fossil history of both groups is traced to a single ancestral species that lived early in the Cenozoic Era. From such evidence, a tree of life can be constructed whereby the relationships among organisms can be understood. *See* ANIMAL EVOLUTION. [S.J.G.]

Paleopathology The study of ancient diseases and their origins. Paleopathology is especially important in the understanding of the origins, prevalence, and spread of infectious diseases, including how humans have contributed to the spread of disease and how they can overcome it. *See* EPIDEMIOLOGY; INFECTIOUS DISEASE; PATHOLOGY.

Hypothesis testing of populations has contributed to the field of paleopathology, as has application of macroscopic (visual) examination, routine x-ray, computerized tomography (CAT) scans, magnetic resonance imaging (MRI), electron microscopy, and immunologic, chemical, and mass spectrophotometry techniques to skeletons, soft tissue, and even scat (animal droppings). *See* COMPUTERIZED TOMOGRAPHY; MAGNETIC RESONANCE; X-RAY DIFFRACTION.

The scientific method in paleopathology is based upon comparison of archeologic or paleontologic findings with individuals documented to have the disease. To this end the following basic tenets are observed: (1) Tissue must be adequately preserved to allow recognition of disease and distinguish possible pseudopathology or postdeath artifact. (2) The manifestations of a disease must be sufficiently stable across generations to allow comparison of ancient with modern disease. (3) Analysis of entire skeletons is more accurate than analysis of isolated bones. (4) Analysis of afflicted populations (paleoepidemiology) is more accurate than analysis of isolated skeletons.

The range of diagnostic methods used in paleopathology is extensive. Skeletal remains are visually examined to identify occurrence and nature of alterations, mapping their skeletal distribution. Internal structure can then be assessed, preferably by a nondestructive technique. Even fossils are not simply casts of external surfaces, but have a visualizable internal structure.

Mummies provide an additional source of information. Rehydration of mummy tissue allows standard soft tissue histology, providing information often transcending that available through study of bones. Anthropologic study of artifacts such as daggers that sometimes accompany mummies and skeletons has also contributed to the understanding of ancient lifestyles and the diseases which impacted them. *See* HISTOLOGY.

Some of the diseases recognized in living individuals for which evidence has also been found in ancient life forms include tuberculosis, leprosy, arthritis, cancer, and various parasitic diseases. *See* ARTHRITIS; CANCER (MEDICINE); LEPROSY; PARASITOLOGY; TUBERCULOSIS. [B.M.R.]

Paleoseismology The study of geological evidence for past earthquakes. This scientific discipline has contributed greatly to modern understanding of the nature of earthquakes. The patterns of earthquakes, in both space and time, evolve over centuries and millennia and cannot be discovered by modern instruments. Knowledge of these patterns is important for understanding the physics of earthquakes and for forecasting future destructive earthquakes.

In certain natural environments, the features related to ancient earthquakes are preserved in the landforms and superficial layers of the Earth's surface. Geologists use this paleoseismological evidence to extend the short historical and instrumental record of earthquakes into ancient centuries and millennia. Such paleoseismological studies have clarified the earthquake record of many parts of the world, including the midcontinent and east coast of the United States, northern Africa, southern Europe, China, Japan, Indonesia, and New Zealand.

The geological preservation of ancient earthquakes has enabled scientists to compare modern earthquakes with those of the past. In 1983, for example, a sparsely populated region of Idaho was struck by a magnitude-7.3 earthquake. Subsequent investigations revealed a fresh, 30-km-long (18-mi) fault scarp running along the western base of the lofty Lost River Range. Inspection of the fresh escarpment revealed that it is surmounted by a more subdued, vegetated escarpment of nearly identical length and height. Excavations across this ancient fault scarp showed that it had formed about 5000 years earlier during an event very similar to the 1983 earthquake. This is one of several examples of what paleoseismologists call a characteristic earthquake: apparently, some earthquakes are nearly identical repetitions of their predecessors. *See* EARTHQUAKE; SEISMOLOGY. [K.Si.]

Paleosol A soil of the past, that is, a fossil soil. Paleosols are most easily recognized when they are buried by sediments. They also include surface profiles that are thought to have formed under very different conditions from those now prevailing, such as the deeply weathered tropical soils of Tertiary geological age that are widely exposed in desert regions of Africa and Australia. Such profiles are generally known as relict paleosols. Those that can be shown to have been buried and then uncovered by erosion are known as exhumed paleosols. The main problem in defining the term paleosol comes from defining what is meant by soil, a term that has very different meanings for agronomists, engineers, geologists, and soil scientists. Soil can be considered distinct from sediment in that it forms in place, but soil need not necessarily include traces of life. At its most general level, soil is material forming the surface of a planet or similar body and altered in place from its parent material by physical, chemical, or biological processes. *See* Soil.

Paleosols are especially abundant in volcanic, alluvial, and eolian sedimentary sequences. Along with the fossils, sedimentary structures, and volcanic rocks found in such deposits, paleosols provide an additional line of evidence for ancient environments during times between eruptions and depositional events. *See* Paleoclimatology; Sedimentology. [G.J.R.]

Paleozoic A major division of time in geologic history, extending from about 540 to 250 million years ago (Ma). It is the earliest era in which significant numbers of shelly fossils are found, and Paleozoic strata were among the first to be studied in detail for their biostratigraphic significance.

The Paleozoic Era is divided into six systems; from oldest to youngest they are Cambrian, Ordovician, Silurian, Devonian, Carboniferous, and Permian. The Carboniferous is subdivided into two subsystems, the Mississippian and the Pennsylvanian which, in North America, are considered systems by many geologists. The Silurian and Devonian systems are closer to international standardization than others; all the series and stage names and lower boundaries have been agreed upon, and most have been accepted. *See* Cambrian; Carboniferous; Devonian; Ordovician; Permian; Silurian.

Because Alpine and Appalachian mountain chains were among the first studied in detail, orogenies were first named there. In eastern North America, mountain-building effects during the early Paleozoic were ascribed to the Taconic orogeny (Middle and Late Ordovician); middle Paleozoic events were assigned to the Acadian orogeny (Middle and Late Devonian); and late Paleozoic movements were called Appalachian (more accurately Alleghenian) for Permian and, perhaps, Triassic events. *See* Dating methods; Isotope; Orogeny; Plate tectonics; Unconformity.

The major changes in lithofacies during the Paleozoic were also effected by biotic evolution through the era. Limestone facies became more abundant and more diversified in the shallow warm seas as calcium-fixing organisms became more diverse and more widespread. Sediment input from the land was modified as plants moved from the seas to the low coastal plains and, eventually, to the higher ground during the Devonian. Primitive vertebrates evolved during the Cambro-Ordovician, but true fishes and sharks did not flourish until the Devonian. Amphibians invaded the land during the Late Devonian and early Carboniferous at about the same time that major forests began to populate the terrestrial realm. These changes produced an entirely new suite of nonmarine facies related to coal formation, and the Carboniferous was a time of formation of major coal basins on all continental plates.

Major cycles of cold and warm climates were overlaid on depositional and evolutionary patterns, producing periods of continental glaciation when large amounts of the Earth's water were tied up in ice during the Late Ordovician, the Late Devonian, and the late Permian. During the earliest and latest of these periods, icesheets were concentrated in the Southern Hemisphere on a single large Paleozoic continental mass—Gondwana. *See* Depositional systems and environments; Facies (geology); Paleoclimatology.

The Paleozoic featured a single southern landmass (Gondwana) for most of the era. This megaplate moved relatively sedately northward during this entire time interval (540–250 Ma) and always contained the magnetic and geographic south poles. Consequently, many of the facies and biologic provinces in the Gondwanan region were influenced by the cooler marine realms and continental and mountain glaciers in nearly every Paleozoic period. Most of the tectonic action that produced major periods of collision, mountain building, carbonate platform building, back-arc fringing troughs with their distinctive faunas and lithofaces, and formation of coal basins and evaporites took place in the Northern Hemisphere. These pulsations produced combinations of Laurentian (North American), Euro-Baltic, Uralian, Siberian, and Chinese plates a various times during the Paleozoic; and these combined units, in turn, moved slowly across the latitudes, producing climatic change; lithofacies changed in response to both the climate and the plate tectonics. *See* Paleogeography.

There were fewer and simpler life forms in the Cambrian—often termed the Age of Trilobites. All groups of invertebrates and plants became more numerous through geologic time. For example, 7 major invertebrate animal groups at the beginning of the Cambrian doubled to 14 by the end of the period, 20 by the end of the Ordovician, 23 at the end of the Devonian, and 25 at the end of the Paleozoic. The pattern for plant diversification, although starting later, is similar. Three simple plant groups became 5 by the end of the Silurian, 7 at the end of the Devonian, and 13 at the end of the Paleozoic. The vertebrates also diversified very slowly. From one or two groups in the Cambro-Ordovician (conodonts are now considered primitive vertebrates), the number of major kinds rose to 6 at the end of the Devonian and 8 at the end of the Paleozoic. *See* Biogeography; Geologic time scale; Index fossil; Paleoecology; Stratigraphy; Trilobita. [J.T.D.]

Palladium A chemical element, Pd, atomic number 46, and atomic weight 106.4. A transition metal, palladium occurs in combination with platinum (Pt) and is the second most abundant platinum-group metal, accounting for 38% of the reserves of these metals. *See* Periodic table; Platinum.

Palladium is soft and ductile and can be fabricated into wire and sheet. The metal forms ductile alloys with a broad range of elements. Palladium is not tarnished by dry or moist air at ordinary temperatures. At temperatures from 350 to 790°C (660 to 1450°F) a thin protective oxide forms in air, but at temperatures from 790°C (1450°F) this film decomposes by oxygen loss, leaving the bright metal. In the presence of industrial sulfur-containing gases a slight brownish tarnish develops; however, alloying palladium with small amounts of iridium or rhodium prevents this action. Important physical properties of palladium are given in the table. *See* Alloy; Metal.

At room temperature, palladium is resistant to nonoxidizing acids such as sulfuric acid, hydrochloric acid, hydrofluoric acid, and acetic acid. The metal is attacked by nitric acid, and a mixture of nitric acid and hydrochloric acid is a solvent for the metal.

Physical properties of palladium

Property	Value
Atomic weight	106.4
Naturally occurring isotopes (percent abundance)	102 (0.96)
	104 (10.97)
	105 (22.23)
	106 (27.33)
	108 (26.71)
	110 (11.81)
Crystal structure	Face-centered cubic
Thermal neutron capture cross section, barns	8.0
Density at 25°C (77°F), g/cm^3	12.01
Melting point, °C (°F)	1554 (2829)
Boiling point, °C (°F)	2900 (5300)
Specific heat at 0°C (32°F), cal/g	0.0584
Thermal conductivity,(cal·cm)(cm^2·s·°C)	0.18
Linear coefficient of thermal expansion, (μin./in./)/°C	11.6
Electrical resistivity at 0°C (32°F), $\mu\Omega$-cm	9.93
Young's modulus, lb/in.^{2}, static, at 20°C (68°F)	16.7×10^6
Atomic radius in metal, nm	0.1375
Ionization potential, eV	8.33
Binding energy, eV	3.91
Pauling electronegativity	2.2
Oxidation potential, V	−0.92

Palladium is also attacked by moist chlorine (Cl) and bromine (Br). *See* ELECTROPLATING OF METALS; NONSTOICHIOMETRIC COMPOUNDS.

The major applications of palladium are in the electronics industry, where it is used as an alloy with silver for electrical contacts or in pastes in miniature solid-state devices and in integrated circuits. Palladium is widely used in dentistry as a substitute for gold. Other consumer applications are in automobile exhaust catalysts and jewelry. *See* INTEGRATED CIRCUITS.

Palladium supported on carbon or alumina is used as a catalyst for hydrogenation and dehydrogenation in both liquid- and gas-phase reactions. Palladium finds widespread use in catalysis because it is frequently very active under ambient conditions, and it can yield very high selectivities. Palladium catalyzes the reaction of hydrogen with oxygen to give water. Palladium also catalyzes isomerization and fragmentation reactions. *See* CATALYSIS.

Halides of divalent palladium can be used as homogeneous catalysts for the oxidation of olefins (Wacker process). This requires water for the oxygen transfer step, and a copper salt to reoxidize the palladium back to its divalent state to complete the catalytic cycle. *See* HOMOGENEOUS CATALYSIS; TRANSITION ELEMENTS. [D.M.Ro.]

Palpigradi

An order of rare arachnids comprising 21 known species from tropical and warm temperate regions. American species occur in Texas and California. All are minute, whitish, eyeless animals, varying from 0.027 to 0.112 in. (0.68 to 2.8 mm) in length, that live under stones, in caves, and in other moist, dark places. The elongate body terminates in a slender, multisegmented flagellum set with setae. In a curious reversal of function, the pedipalps, the second pair of head appendages, serve as walking legs. The first pair of true legs, longer than the others and set with sensory setae, has been converted to tactile appendages which are vibrated constantly to test the substratum. *See* ARACHNIDA. [W.J.Ger.]

Palynology

The study of pollen grains and spores, both extant and extinct, as well as other organic microfossils. Although the origin of the discipline dates back to the seventeenth century, when modern pollen was first examined microscopically, the term palynology was not coined until 1944.

Palynologists study microscopic bodies generally known as palynomorphs. These include an array of organic entities, each consisting of a highly resistant wall component. Examples include acritarchs and chitinozoans (microfossils with unknown affinities), foraminiferans (protists), scolecodonts (tooth and mouth parts of marine annelid worms), fungal spores, dinoflagellates, algal spores, and spores and pollen grains of land plants. Spores and pollen grains are reproductive propagules and play a paramount role in the life history of land plants. *See* MICROPALEONTOLOGY; POLLEN; REPRODUCTION (PLANT).

Palynology can be classified into two broad fields, paleopalynology and neopalynology. Although a range of methodologies and instruments are employed in both subdisciplines, the utilization of contemporary microscopy is fundamental.

The subdisciplines of neopalynology include taxonomy, genetics, and evolution; development, functional morphology, and pollination; aeropalynology; and melissopalynology. Aeropalynology is the study of pollen grains and spores that are dispersed into the atmosphere. Melissopalynologists analyze bee pollen loads and the pollen component within honeys. *See* PLANT EVOLUTION; PLANT TAXONOMY; POLLINATION.

The main fields of study within paleopalynology are paleobotany, past vegetation and climate reconstruction, geochronology and biostratigraphy, and petroleum and natural gas exploration. *See* FOSSIL; PALEOBOTANY; PALEOGEOGRAPHY; POSTGLACIAL VEGETATION AND CLIMATE; STRATIGRAPHY. [J.M.Os.]

Pancreas

A composite gland in most vertebrates, containing both exocrine cells—which produce and secrete enzymes involved in digestion—and endocrine cells, arranged in separate islets which elaborate at least two distinct hormones, insulin and glucagon, both of which play a role in the regulation of metabolism, and particularly of carbohydrate metabolism. *See* CARBOHYDRATE METABOLISM.

Anatomy. The pancreas of mammals shows large variations. The extremes are the unique, massive pancreas of humans, and the richly branched organ of the rabbit. Usually, the main duct, the duct of Wirsung, opens into the duodenum very close to the hepatic duct. In humans, the pancreas weighs about 2.5 oz (70 g). It can be divided into head, body, and tail. Accessory pancreases are frequently found anywhere along the small intestine, in the wall of the stomach, and in Meckel's diverticulum.

The exocrine portion of the pancreas shows tubuloalveolar glands. Each terminal alveolus is called an acinus. The various acini have central cavities, which open into intralobular ducts through narrow intercalated tubes. The interlobular ducts anastomose and ultimately form the main duct of Wirsung. The activity of the acini is stimulated by secretin as well as by pilocarpine.

The endocrine portion shows cellular masses called islands or islets of Langerhans, in which the cellular cords or masses are more or less isolated by irregular spaces filled with connective tissue and blood capillaries. The two main types of cells are the alpha and the beta cells.

Between the grapelike exocrine portion with its ducts and the islands of Langerhans, it is possible to observe connective tissue septa, numerous blood vessels, and nerves.

Physiology. The pancreatic juice carried to the duodenum is a slightly alkaline liquid containing trypsinogen, which, when activated, causes the hydrolysis of the proteins into amino acids, amylase, and maltase, which act on the glucides, and lipase, which causes the hydrolysis of fatty substances. The intense stimulation of the pancreatic secretion after ingestion of food is considered to be the result of a nervous reflex originating in the mouth, and also of direct introduction of acids and fats into the duodenum, causing the liberation of a hormone called secretin into the bloodstream to stimulate the exocrine secretion.

F. Banting and C. Best (1922) prepared pancreatic extracts which were able to prevent the lethal effects of pancreatectomy. The same effect was obtained with extracts from pancreas in which, after ligature of the duct of Wirsung, the exocrine portion of the gland had disappeared. *See* DIABETES.

The alpha cells and beta cells in the islets are the sources of two hormones, insulin from the beta, and glucagon, also known as the hyperglycemic factor, from the alpha. The former is a hormone which influences carbohydrate metabolism, enabling the organism to utilize sugar. The latter accelerates the conversion of liver glycogen into glucose. Glucagon elevates the blood sugar level, and its effects are the opposite of those of insulin, so that the two hormones together maintain the sugar metabolism of the body in balance. When the level of sugar in the blood becomes too low, the secretion of glucagon is stimulated. *See* GLUCAGON; INSULIN. [E.L.V.C.]

Pancreas disorders

The pancreas is affected by a variety of congenital and acquired diseases. Because of the dual functional role, the diseases of the exocrine portion of the pancreas will be separated from the endocrine lesions in this discussion.

The most frequent congenital lesion of the pancreas is more appropriately designated as a developmental abnormality—ectopic or aberrant pancreas. Ectopic pancreas can be found anywhere within the gastrointestinal tract, but is more frequent in the stomach and duodenum.

Cystic fibrosis (mucoviscidosis) is a systemic disease in which mucus secretion is altered so that a viscid mucus is produced. The disease is inherited as a mendelian recessive. Cystic fibrosis affects all exocrine glands, including the acinar portion of the pancreas. Production of altered mucus leads to dilation of the exocrine ducts (cystic), destruction of acinar tissue, and replacement of the destroyed tissue by fibrous connective tissue (fibrosis). The islets are not affected by this disease. Elevation in secretion of sodium and chloride in sweat is also common.

Acute hemorrhagic pancreatitis is a serious disease of unknown etiology which causes sudden liberation of activated pancreatic enzymes that digest the pancreatic parenchyma. The digestive process leads to dissolution of fat and production of calcium soaps. In addition, rupture of pancreatic vessels occurs with resultant hemorrhage and shock. This disease is associated with biliary tract disease, especially gallstones (cholelithiasis), alcoholism, hyperlipidemia, and hypercalcemia. *See* ALCOHOLISM; GALLBLADDER DISORDERS.

Chronic pancreatitis, perhaps better designated chronic relapsing pancreatitis, is a condition in which recurrent episodes of pancreatitis occur without the production of symptoms or with the production of mild symptoms. Destruction of the pancreatic tissue, with repair by fibrosis, calcification, and cyst formation, is frequent.

Diabetes mellitus is the principal disease associated with the endocrine portion of the pancreas. Two clinical forms of the disease are recognized—insulin-dependent diabetes mellitus and non-insulin-dependent diabetes mellitus. While many factors are involved in the causation of this disease, basically the disease is a result of the failure of the beta cells of the pancreas to produce appropriate kinds and amounts of insulin to meet metabolic needs. *See* DIABETES.

Tumors of the pancreas can be either benign or malignant. They affect both the endocrine and exocrine portions of the pancreas. Benign tumors of the exocrine pancreas are extremely rare. Malignant tumors of the exocrine pancreas arise most frequently from the pancreatic ducts. Acinar carcinomas also exist but are very rare. Exocrine pancreatic carcinomas are very malignant tumors. Islet cell lesions are quite rare but may be associated with increased hormone production. The tumors can be single or multiple, benign or malignant, and they can form anywhere in the pancreas. Hyperfunction of the islets of Langerhans can result in three distinct clinical syndromes: hyperinsulinism and hypoglycemia, the Zollinger-Ellison syndrome (gastrinoma), and multiple endocrine neoplasia. *See* ONCOLOGY; PANCREAS. [H.T.N.]

Panda The name for two species of carnivores in the raccoon family, Procyonidae, both of which are found in Asia. The red panda (*Ailurus fulgens*) inhabits the forested regions of the Himalayas and western China. It has thick fur which gives it a heavy stocky appearance. Actually, it weighs an average of 10–12 lb (4.5–5.5 kg). The fur is black on the lower parts and red on the back. The face is white with a dark stripe from each eye to the corner of the mouth. The red panda is primarily a vegetarian, feeding on lichens, roots, and bamboo shoots. It is arboreal, nesting in a hollow tree or in the fork of a tree. The giant panda (*Ailuropoda melanoleuca*) superficially resembles a bear and may be a true member of the Ursidae. Little is known about the natural history of this animal; its diet of bamboo restricts it to the bamboo forests located in cold, damp mountainous areas of central China. The adults weigh 200–300 lb (90–135 kg) and are somewhat smaller than the brown bear. *See* CARNIVORA. [C.B.C.]

Pandanales An order of monocotyledons, the composition of which only recently has been revealed by deoxyribonucleic acid (DNA) sequence studies of four genes. Included are four families. Pandanaceae (800 species; the screw pine family), Cyclanthaceae (230 species; the Panama hat family), Stemonaceae (35 species), and Velloziaceae (200 species). Pandanaceae are often lianas or large herbs from the Old World; Cyclanthaceae are herbs or lianas from the New World tropics; Stemonaceae are herbs or lianas of the Old World (but with one species in the southeastern United States); and Velloziaceae are herbs or small shrubs of Africa and particularly South America (with one genus in southwest China). Cyclanthaceae, Pandanaceae, and Stemonaceae have flower parts in twos or fours, which is unusual among monocotyledons, in which threes are most common.

Several species in Pandanales are economically important. The leaves of Pandanaceae are fibrous and used for making rope and roofing, and the fruits are eaten in many areas. Cyclanthaceae leaves are fibrous and have similar uses, including the manufacture of Panama hats. *See* ARECIDAE; LILIOPSIDA; MAGNOLIOPHYTA; PLANT KINGDOM. [M.W.C.]

Panel heating and cooling A system in which the heat-emitting and heat-absorbing means is the surface of the ceiling, floor, or wall panels of the space which is to be environmentally conditioned. The heating or cooling medium may be air, water, or other fluid circulated in air spaces, conduits, or pipes within or attached to the panel structure. For heating only, electric current may flow through resistors in or on the panels. *See* ELECTRIC HEATING.

Heat energy is transmitted from a warmer to a cooler mass by conduction, convection, and radiation. The output from heating surfaces comprises both radiation and convection components in varying proportions. In panel heating systems, especially the ceiling type, the radiation component predominates. *See* RADIANT HEATING.

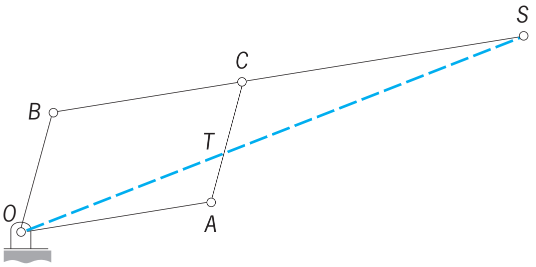
When a panel system is used for cooling, the dew-point temperature of the ambient air must remain below the surface temperature of the heat-absorbing panels to avoid condensation of moisture on the panels. Panel cooling effectively prevents the disagreeable feeling of cold air blown against the body and minimizes the occurrence of summer colds. *See* COMFORT HEATING; HOT-WATER HEATING SYSTEM. [E.L.W./R.Ko.]

Pantodonta An extinct order of relatively large placental mammals represented by Paleocene-Eocene fossils from western Europe, North America, and eastern Asia. Pantodonts were an early evolutionary experiment in large-bodied herbivory by primitive placental mammals. They first appeared in Asia during the early Paleocene and disappeared during the middle Eocene, leaving no descendants. With the possible exception of the most primitive pantodonts, all were herbivores, and pantodonts were either the largest or among the largest mammals of their time. The adaptive radiation of pantodonts was diverse and encompassed mammals as different as small [1 kg (2 lb) or less in body mass], arboreal herbivores, and large [650 kg (1430 lb)], ground-sloth–like, terrestrial herbivores. *See* EOCENE; PALEOCENE.

Pantodonts are unique among placental mammals in having upper third and fourth premolar tooth crowns in which there are V-shaped crests. All pantodonts were obligate quadrupeds, with four nearly equal-sized limbs. Most pantodonts had large tusks and long, heavy tails. When compared to living mammals, many pantodonts would have looked somewhat like bears, pigs, or small hippos. *See* DENTITION; MAMMALIA.

The most primitive pantodonts are assigned to the family Bemalambdidae. All other pantodonts belong to the suborder Eupantodonta, which diverged early into the superfamilies Pantolambdodontoidea and Pantolambdoidea. The pantolambdodontoids include the Asian family Pantolambdodontidae, the North American family Titanoideidae, and the South American genus *Alcidedorbigniya*. The pantolambdoids include the North American families Pantolambdidae and Barylambdidae and the more cosmopolitan (known from North America and Eurasia) family Coryphodontidae. [S.G.L.]

Pantograph A four-bar parallel linkage, with no links fixed, used as a copying device for generating geometrically similar figures, larger or smaller in size, within the limits of the mechanism. In the illustration the curve traced by point *T* will be similar to that generated by point *S*. This similarity results because points



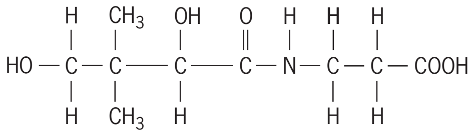
Similar triangles of a pantograph.

T and *S* will always lie on the straight line $\overline{OTS}$; triangles $\overline{OBS}$ and $\overline{TCS}$ are always similar because lengths $\overline{OB}$, $\overline{BS}$, $\overline{CT}$, and $\overline{CS}$ are constant and $\overline{OB}$ is always parallel to $\overline{CT}$. Distance $\overline{OT}$ always maintains a constant proportion to distance $\overline{OS}$ because of the similarity of the above triangles. Numerous modifications of the pantograph as a copying device have been made. *See* FOUR-BAR LINKAGE.

A second use of the pantograph geometry is seen in the collapsible parallel linkage used on electric locomotives and rail cars to keep a current-collector bar or wheel in contact with an overhead wire. Two such congruent linkages in planes parallel to the train's motion are affixed securely on the top of the locomotive with joining horizontal members perpendicular to each other. The uppermost member collects the current, and powerful springs thrust the configuration upward with sufficient pressure normally to make low-resistance contact from wire to collector. [D.P.Ad.]

Pantothenic acid

A member of the B vitamin group with the structural formula



$$\mathrm{HO-\underset{H}{\overset{H}{C}}-\underset{CH_3}{\overset{CH_3}{C}}-\underset{H}{\overset{OH}{C}}-\overset{O}{\overset{\|}{C}}-\overset{H}{N}-\underset{H}{\overset{H}{C}}-\underset{H}{\overset{H}{C}}-COOH}$$

It is a light-yellow, viscous oil which is readily soluble in H_2O. Pantothenic acid is widely distributed, and liver, kidneys, fresh green vegetables, and egg yolks are among its best sources. Losses of the vitamin during cooking are minimal, as it is present in stable conjugated form in food.

No definite pathologic lesions due to a specific pantothenic acid deficiency have been reported in humans. The factors affecting the requirement for pantothenic acid are probably similar to those altering the needs for the other B vitamins. Pantothenic acid has been reported to improve the reactions of young men to stress. The widespread occurrence of pantothenic acid assures protection against the deficiency state under most conditions. Most Americans eat 10 mg of pantothenic acid per 2500 cal of good diet. The daily requirement is probably about 3–5 mg. *See* VITAMIN. [S.N.G.]

Papaverales

An order of flowering plants, division Magnoliophyta (Angiospermae), subclass Magnoliidae of the class Magnoliposida (dicotyledons). The order consists of only two families: Papaveraceae with some 200 species, and Fumariaceae with about 400 species. Within its subclass, the order is marked by its syncarpous gynoecium, parietal placentation, and only two (seldom three) sepals. Most of the species are herbaceous, and many of them contain isoquinoline alkaloids similar to those in the order Ranunculales. The Papaveraceae, with regular flowers, numerous stamens, and a well-developed latex system, include the poppies (*Papaver* and related genera; see illustration), bloodroot (*Sanguinaria*), and celandine (*Chelidonium*). *Papaver somniferum* is the source of opium. The Fumariaceae, with four or six stamens, irregular flowers that usually have some of the petals spurred or saccate, and no latex system, include the bleeding heart (*Dicentra spectabilis*) and some other common ornamentals. *See* MAGNOLIIDAE; MAGNOLIOPHYTA; MAGNOLIOPSIDA; POPPY; RANUNCULALES. [A.Cr.; T.M.Ba.]

Oriental poppy (*Papaver orientale*) of the family Papaveraceae and the order Papaverales. (*John H. Gerard, National Audubon Society*)

Paper

A flexible web or mat of fibers isolated from wood or other plants materials by the operation of pulping. Nonwovens are webs or mats made from synthetic polymers, such as high-strength polyethylene fibers, that substitute for paper in large envelopes and tote bags.

Paper is made with additives to control the process and modify the properties of the final product. The fibers may be whitened by bleaching, and the fibers are prepared for papermaking by the process of refining. Stock preparation involves removal of dirt from the fiber slurry and mixing of various additives to the pulp prior to papermaking. Papermaking is accomplished by applying a dilute slurry of fibers in water to a continuous wire or screen; the rest of the machine removes water from the fiber mat. The steps can be demonstrated by laboratory handsheet making, which is used for process control.

Although paper has numerous specialized uses in products as diverse as cigarettes, capacitors, and counter tops (resin-impregnated laminates), it is principally used in packaging (~50%), printing (~40%), and sanitary (~7%) applications.

Material of basis weight greater than 200 g/m^2 is classified as paperboard, while lighter material is called paper. Production by weight is about equal for these two classes. Paperboard is used in corrugated boxes; corrugated material consists of top and bottom layers of paperboard called linerboard, separated by fluted corrugating paper. Paperboard also includes chipboard (a solid material used in many cold-cereal boxes, shoe boxes, and the backs of paper tablets) and food containers.

Mechanical pulp is used in newsprint, catalog, and other short-lived papers; they are only moderately white, and yellow quickly with age because the lignin is not removed. A mild bleaching treatment (called brightening) with hydrogen peroxide or sodium dithionite (or both) masks some of the color of the lignin without lignin removal. Paper made with mechanical pulp and coated with clay to improve brightness and gloss is used in 70% of magazines and catalogs, and in some enamel grades. Bleached chemical pulps are used in higher grades of printing papers used for xerography, typing paper, tablets, and envelopes; these papers are termed uncoated wood-free (meaning free of mechanical pulp). Coated wood-free papers are of high to very high grade and are used in applications such as high-quality magazines and annual reports; they are coated with calcium carbonate, clay, or titanium dioxide.

Like wood, paper is a hygroscopic material; that is, it absorbs water from, and also releases water into, the air. It has an equilibrium moisture content of about 7–9% at room temperature and 50% relative humidity. In low humidities, paper is brittle; in high humidities, it has poor strength properties.

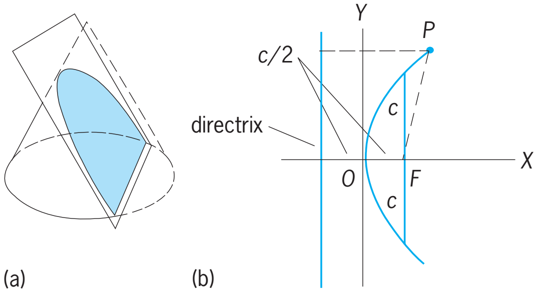
The heaviest grades of papers, such as chipboard, are made on multiformer (cylinder) machines that form three to eight layers of fiber mats. These fiber mats are combined prior to pressing and drying. The lightest grades of paper, tissues, cannot withstand numerous felt transfers and are dried on very large Yankee dryers.

Paper may be smoothed against a series of rolls made from metal or rubbery material to impart smoothness or gloss. Paper may also be coated with a paintlike material to give it high brightness and gloss. In addition, numerous other converting operations may be performed on paper. [C.J.Bi.]

Paprika A type of pepper, *Capsicum annuum* (order Polemoniales), with nonpungent flesh, grown for its long red fruit. It is of American origin, but is most popular in Hungary and adjacent countries. Seeds are removed from the mature fruit, and the flesh is dried and ground to prepare the dry condiment commonly referred to as paprika. California is the only important producing state in the United States. *See* Pepper; Solanales. [H.J.C.]

Parablastoidea A small class of primitive blastozoan echinoderms containing three genera found in the early Middle Ordovician in eastern Canada; northeastern, eastern, southcentral, and western United States; and near Leningrad, Russia. Parablastoids have a bud-shaped theca or body with well-developed pentameral symmetry. A stem with one-piece columnals attached the theca to the sea floor, suggesting that parablastoids were attached, medium- to high-level suspension feeders. Although they converged on blastoids in thecal design and way of life, parablastoids had differences in their plating, ambulacra, and respiratory structures to indicate a separate origin and history. That is the justification for assigning parablastoids and blastoids to different classes. *See* Crinozoa; Echinodermata. [J.Sp.]

Parabola A member of the class of curves that are intersections of a plane with a cone of revolution. It is obtained (see illustration) when the cutting plane is parallel to an element of the cone. *See* Conic section.



Parabola as (*a*) conic section and (*b*) locus of points.

In analytic geometry the parabola is defined at the locus of points (in a plane) equally distant from the fixed point *F* (focus) and a fixed line (directrix) not through the point. It is symmetric about the line through *F* perpendicular to the directrix.

The curve has numerous other properties of interest in both pure and applied mathematics. For example, the trajectory of an artillery shell, assumed to be acted upon only by the force of gravity, is a parabola.

Archimedes found the area bounded by an arc of a parabola and its chord; for example, the area bounded by the parabola $y^2 ;= 2cx$ and its latus rectum (the chord through F perpendicular to the axis) is ${}^2/_3\, c^2$. [L.M.Bl.]

Parachute A flexible, lightweight structure, generally intended to retard the passage of an object within or through atmosphere by materially increasing the resistive surface. A parachute is a decelerator or air-braking device in the general form of an oblate hemisphere. The parachute is the only suitably demonstrated device for emergency descent from aircraft. It comprises a canopy and cords, which form the suspension and attachment between canopy and object. A parachute canopy is a membrane which relies upon pressure differential across it to maintain its inflated shape. The differential is created by entrapment of an air mass on the inside and movement of the air on the outside. [S.E.W.]

Paraffin A term used variously to describe either a waxlike substance or a group of compounds. The former use pertains to the high-boiling residue obtained from certain petroleum crudes. It is recovered by freezing out on a cold drum and is purified by crystallization from methyl ethyl ketone. Paraffin wax is a mixture of 26- to 30-carbon alkane hydrocarbons; it melts at 52–57°C (126–135°F). Microcrystalline wax contains compounds of higher molecular weight and has a melting point as high as 90°C (190°F). The name paraffin was formerly used to designate a group of hydrocarbons—now known as alkanes. *See* Alkane. [A.L.H.]

Parainfluenza virus A member of the genus *Paramyxovirus* of the family Paramyxoviridae which is associated with a variety of respiratory illnesses. The virus particles range in size from 90 to 200 nanometers, agglutinate red blood cells, and (like the influenza viruses) contain a receptor-destroying enzyme. They differ from the influenza viruses in their large size, their possession of the larger ribonucleoprotein helix characteristic of the paramyxoviruses, their tendency to lyse as well as agglutinate erythrocytes, and their generally poor growth in eggs. *See* Complement-fixation test; Embryonated egg culture; Paramyxovirus; Tissue culture.

Four subgroups are known, designated parainfluenza 1, 2, 3, and 4. Types 1, 2, and 3 are distributed throughout the world, but thus far type 4 has been found only in the United States. Parainfluenza 1 and 3 are ubiquitous endemic agents producing infections all through the year. Types 2 and 4 occur more sporadically. With all of the parainfluenza viruses, most primary infections take place early in life. About half of the first infections with parainfluenza 1, about two-thirds of those with parainfluenza 2, and three-fourths of those with parainfluenza 3 produce febrile illnesses. The target organ of type 3 is the lower respiratory tract, with first infections frequently resulting in bronchial pneumonia, bronchiolitis, or bronchitis. Type 1 is the chief cause of croup, but the other types have also been incriminated, to the extent that one-half of all cases of croup can be shown to be caused by parainfluenza viruses. *See* Animal virus; Influenza; Virus classification. [J.L.Me.; M.E.Re.]

Parainsecta A class of hexapod (six-legged) arthropods consisting of the orders Collembola and Protura. Class Parainsecta (also known as Ellipura) is one of several classifications of those hexapods, which, while similar to insects, are sufficiently different that most researchers believe they deserve separate class status.

Collembola and Protura have frequently been lumped with the Diplura (Entotrophi) into one class (Entognatha) on the basis of their mouthparts, which are inside the head capsule rather than exposed as in the Insecta. However, some recent morphological and paleontological studies support a closer link between insects and Diplura. In addition, there are a number of features found in Protura and Collembola that are not found in Diplura. These include the developmental process: Both Collembola and Protura have epimorphic development (that is, development of the young is completed in the egg). Two unique features of the Parainsecta are the presence of a ventral midline or groove and coxal vesicles (fluid-filled sacs, generally associated with leg bases) that are limited to the first abdominal segment.

In the Collembola these vesicles are fused into a single ventral tube. The digestive tract lacks anterior or posterior enlargements, which are often present in Diplura and primitive insects. Other distinguishing features of the Parainsecta are the absence of styli and unpaired pretarsal claws.

Both Collembola and Protura contain very small animals, generally less than 4 mm long. Protura are exclusively, and Collembola primarily, soil and litter inhabitants. Genetic evidence concerning relationships is at present confusing. In addition, differences of interpretation concerning the phylogenetic importance of various morphological features leave the status of the Parainsecta ambiguous. *See* ARTHROPODA; DIPLURA; INSECT PHYSIOLOGY; INSECTA; PROTURA. [K.C.]

Parallax (astronomy) The apparent angular displacement of a celestial object due to a change in the position of the observer. With a baseline of known length between two observations, the distance to the object can be determined directly.

The rotation of the Earth or the linear separation of two points on its surface can be used to establish distances within the solar system. The parallax determined is scaled to the equatorial radius of the Earth, which is equal to 6378 km (3963 mi). At the mean distance of the Moon, this baseline subtends an angle of $57'02.61''$, and at the mean distance to the Sun it amounts to $8.794148''$. This latter distance is defined as the astronomical unit and serves as a measure of distances within the solar system. One astronomical unit is $149{,}597{,}870.66 \pm 0.02$ km ($92{,}955{,}807.25 \pm 0.01$ mi) in length, and its high precision results from tracking interplanetary space probes. *See* ASTRONOMICAL UNIT; EARTH ROTATION AND ORBITAL MOTION.

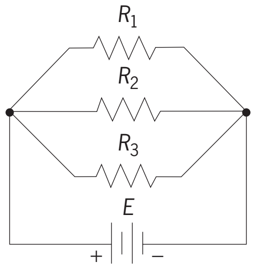
The astronomical unit is the baseline for the measure of stellar parallaxes or distances and ultimately every other distance in the universe outside the solar system. Observations made from the Earth in its orbit on opposite sides of the Sun are scaled to the astronomical unit. The stellar parallax is given in units of arc-seconds and is by definition the reciprocal of the distance in parsecs. One parsec is the distance at which one astronomical unit subtends an angle of one second of arc and equals 206,264.8 astronomical units or 3.2616 light-years. *See* LIGHT-YEAR; PARSEC.

In 1989 the European Space Agency launched the first space satellite entirely devoted to astrometry, named *HIPPARCOS* (from *High Precision Parallax Collecting Satellite*, and also honoring the ancient astronomer Hipparchus). In 1993 it completed its mission by obtaining positions, parallaxes, and proper motions for 118,322 stars listed in its final catalog. Its precision averages about $\pm 0.0015''$ for stars brighter than its completeness limit of about the 8th magnitude, and rises to perhaps twice that amount at its ultimate limiting magnitude of 12. This precision is about equal to that of the best of current ground-based work for the brighter stars and less for faint stars. The advantage of *HIPPARCOS* lies in the much greater numbers of stars, including all the bright ones, with quality parallaxes. The contributions to stellar knowledge from this satellite are enormous. *See* BINARY STAR; HERTZSPRUNG-RUSSELL DIAGRAM; SATELLITE (ASTRONOMY).

Distance estimates are possible based on the assumption that the apparent mean space motion of a large number of stars with similar characteristics is a reflection of the peculiar motion of the Sun, derived from previous observations. Two related methods apply; the first equates the mean drift of the stars to the Sun's motion vector. The second requires measurements of radial velocities as well as proper motions, and assumes that the radial velocity distribution at the solar apex and antapex (the directions toward and away from which the Sun is moving, respectively) matches that in the transverse velocities along the direction normal to that of the assumed solar motion. These methods are referred to as secular and statistical parallax, respectively, although the terms are sometimes confused.

Several methods for the establishment of distance are frequently and incorrectly labeled parallax. These methods, such as spectroscopic or photometric parallax, involve a comparison of an object to another of known distance and like luminosity, and scaling the distance as necessary. *See* ASTROMETRY. [A.R.U.]

Parallel circuit An electric circuit in which the elements, branches (elements in series), or components are connected between two points with one of the two ends of each component connected to each point. The illustration shows a simple parallel circuit. In more complicated electric networks one or more branches of the network may be made up of various combinations of series or series-parallel elements. *See* CIRCUIT (ELECTRICITY).



Schematic of a parallel circuit. *E* is a battery; R_1, R_2, and R_3 are resistors.

In a parallel circuit the potential difference (voltage) across each component is the same. However, the current through each branch of the parallel circuit may be different. For example, the lights and outlets in a house are connected in parallel so that each load will have the same voltage (120 volts) but each load may draw a different current (0.5 ampere in a 60-watt lamp and 10 amperes in a toaster). [C.F.G.]

Paramagnetism A property exhibited by substances which, when placed in a magnetic field, are magnetized parallel to the field to an extent proportional to the field (except at very low temperatures or in extremely large magnetic fields). Paramagnetic materials always have permeabilities greater than 1, but the values are in general not nearly so great as those of ferromagnetic materials. Paramagnetism is of two types, electronic and nuclear.

The following types of substances are paramagnetic:

1. All atoms and molecules which have an odd number of electrons. According to quantum mechanics, such a system cannot have a total spin equal to zero; therefore, each atom or molecule has a net magnetic moment which arises from the electron spin angular momentum. Examples are organic free radicals and gaseous nitric oxide.

2. All free atoms and ions with unfilled inner electron shells and many of these ions when in solids or in solution. Examples are transition, rare-earth, and actinide elements and many of their salts. This includes ferromagnetic and antiferromagnetic materials above their transition temperatures. For a discussion of these materials *See* ANTIFERROMAGNETISM; FERRIMAGNETISM; FERROMAGNETISM.

3. Several miscellaneous compounds including molecular oxygen and organic biradicals.

4. Metals. In this case, the paramagnetism arises from the magnetic moments associated with the spins of the conduction electrons and is called Pauli paramagnetism.

Relatively few substances are paramagnetic. Aside from the Pauli paramagnetism found in metals, the most important paramagnetic effects are found in the compounds of the transition and rare-earth elements which have partially filled $3d$ and $4f$ electron shells respectively.

Electronic paramagnetism arises in a substance if its atoms or molecules possess a net electronic magnetic moment. The magnetization arises because of the tendency of a magnetic field to orient the electronic magnetic moments parallel to itself.

Nuclear paramagnetism arises when there is a net magnetic moment due to the magnetic moments of the nuclei in a substance. Nuclear magnetic moments are about 10^3 times smaller than electron magnetic moments. As a result, nuclear paramagnetism produces effects 10^6 times smaller than electron paramagnetic or diamagnetic effects. *See* DIAMAGNETISM; MAGNETIC RESONANCE; NUCLEAR MOMENTS. [E.Ad.; F.Ke.]

Parameter An auxiliary variable, functions of which give the coordinates of a curve or surface. The coordinates of a curve are functions of one parameter. A curve in 3-space has parametric equations (1).

$$x = f(t) \quad y = g(t) \quad z = h(t) \tag{1}$$

The coordinates of a surface are functions of two parameters, shown in Eqs. (2).

$$x = f(u, v) \quad y = g(u, v) \quad z = h(u, v) \tag{2}$$

An arbitrary constant in an equation is also called a parameter. Variations in the values of the parameter generate a system of equations which may represent a family of curves or surfaces. Such families are called one-parameter, two-parameter, and so on, according to the number of independent parameters. *See* PARAMETRIC EQUATION. [L.Br.]

Parametric amplifier A highly sensitive low-noise amplifier for ultrahigh-frequency and microwave radio signals, utilizing as the active element an inductor or capacitor whose reactance is varied periodically at another microwave or ultra-high frequency. A varactor diode is most commonly used as the variable reactor. Amplification of weak signal waves occurs through a nonlinear modulation or signal-mixing process which produces additional signal waves at other frequencies. This process may provide negative-resistance amplification for the applied signal wave and increased power in one or more of the new frequencies which are generated. *See* VARACTOR.

There are several possible circuit arrangements for obtaining useful parametric amplification. The two most common are the up-converter and the negative-resistance amplifier. In both types, the pump frequency is normally much higher than the input-signal frequency. In the up-converter, a new signal wave is generated at a higher power than the input wave. In the negative-resistance device, negative resistance is obtained for the input-signal frequency, causing an enhancement of signal power at the same frequency. *See* NEGATIVE-RESISTANCE CIRCUITS.

The most important advantage of the parametric amplifier is its low level of noise generation. The parametric amplifier finds its greatest use as the first stage at the input of microwave receivers where the utmost sensitivity is required. Its noise performance has been exceeded only by the maser. Maser amplifiers are normally operated under extreme refrigeration using liquid helium at about 4 K above absolute zero (−452°F). The parametric amplifier does not require such refrigeration but in some cases cooling to very low temperatures has been used to give improved noise performance that is only slightly poorer than the maser. *See* AMPLIFIER; MASER. [M.E.Hi.]

Parametric arrays Arrays of sources (or receivers) of sound formed by variation of appropriate parameters of the propagation medium. Normally, these parameters are the local sound speed and the particle velocity which vary because of the presence of large-amplitude pump, or primary, sound waves.

The usual parametric source configuration simply consists of a directional transducer (often a plane piston or planar array) driven at two frequencies near the transducer resonance, forming a dual-frequency sound beam called the primary beam. Because sound-wave propagation is not a completely linear process, signals at new frequencies are formed effectively through the interaction of sound with sound as the beam progresses and are generated along the length of the primary beam. The lowest of these new frequencies is the difference of the two primary frequencies, and so the primary beam acts as an end-fire array of sources at the difference frequency. The effective length of the array will be determined by the attenuation of the primary beam, which occurs either as a result of small-signal absorption or, for sufficiently high primary amplitudes, as a result of nonlinear losses due to the generation of harmonics of the primary frequencies and other intermodulation components, such as the sum-frequency component.

Most applications of parametric sources have been to underwater acoustics, but their use in air, as well as in other media, may be expected. Because the effective length of a parametric source can be made quite long in practice, it is possible to generate highly directional difference-frequency beams, and because the primary amplitude is shaded very gradually along the length of the array, these beams can be made practically side-lobe-free, in contrast to the beams from conventional acoustic sources. As a result, echoes from a parametric source exhibit practically no reverberation, whereas conventional echoes may be obscured by reverberation from reflection of the side lobes. Thus, the parametric source may be expected to be useful in reverberation-limited situations where one desires a narrow beam from a small projector. Such applications include precision fathometry, subbottom profiling, echo ranging, communications, and Doppler navigation logs. In order to obtain the advantages of a parametric source, however, one must be willing to tolerate low efficiency and low search rate. *See* DIRECTIVITY; ECHO SOUNDER; SONAR; SOUND; UNDERWATER SOUND. [M.B.M.]

Parametric equation A type of mathematical equation used, typically, to represent curves in a plane or in space of three dimensions, In principle, however, there is no limitation to any particular number of dimensions. A parameter is actually an independent variable. In elementary analytic geometry a curve in the xy plane is often studied, in the first instance, as the locus of an equation $y = F(x)$ or $G(x,y) = 0$. The form $y = F(x)$ is not adequate for the complete representation of certain curves, whereas the form $G(x,y) = 0$ may be adequate. The circle $x^2 + y^2 - 16 = 0$ affords an example. But the form $G(x,y) = 0$ is not always convenient. The parametric form $x = f(t)$, $y = g(t)$ is often the most convenient; moreover, it is often the naturally occurring form of representation of the curve. For the circle $x^2 + y^2 - 16 = 0$, one possible parametric representation is $x = 4 \cos t$ and $y = 4 \sin t$.

A pair of equations $x = f(t)$, $y = g(t)$, where f and g are continuous functions defined for some interval of values of t, for example, $a \leq t \leq b$, is said to define a parametric curve. If one thinks of t as time, the equations define the motion of the point (x, y) as t increases from a to b. Clearly the path can cross itself, double back on itself, or the point may even remain motionless.

A parametric surface in space of three dimensions is defined by $x = f(u,v)$, $y = g(u,v)$, $z = h\,(u,v)$, where f, g, h are continuous functions of the two parameters, u,v. *See* ANALYTIC GEOMETRY; CALCULUS; PARTIAL DIFFERENTIATION. [A.E.Ta.]

Paramo A biological community, essentially a grassland, covering extensive high areas in equatorial mountains of the Western Hemisphere. Geographically, paramos are limited to the Northern Andes and adjacent mountains. Paramos occur in alpine regions above timberline and are controlled by a complex of climatic and soil factors peculiar to mountains near the Equator. The richly diverse flora and the fauna of the paramos are adapted to severely cold, mostly wet conditions. Humans have found some paramos suitable for living and use. [H.G.B.]

Paramyxovirus A subgroup of myxoviruses that includes the viruses of mumps, measles, parainfluenza, respiratory syncytial (RS) disease, and Newcastle disease. Like influenza viruses, the paramyxoviruses are ribonucleic acid (RNA)-containing viruses and possess an ether-sensitive lipoprotein envelope. *See* ANIMAL VIRUS; MEASLES; MUMPS; NEWCASTLE DISEASE; PARAINFLUENZA VIRUS. [J.L.Me.]

Paranoia A mode of thought, feeling, and behavior characterized centrally by false persecutory beliefs, more specifically referred to as paranoidness. Commonly associated with these core persecutory beliefs are properties of suspiciousness, fearfulness, hostility, hypersensitivity, rigidity of conviction, and an exaggerated sense of self-reference. These properties are evident with varying degrees of intensity and duration.

The paranoid mode can be triggered at either biological or psychological levels. Common precipitating biological causes are brain trauma or tumor, thyroid disorder, cerebral arteriosclerosis, and intoxication with certain drugs, including alcohol, amphetamines, cocaine, other psychostimulants, and hallucinogens such as mescaline or lysergic acid diethylamide (LSD). They can produce disordered activity of central dopaminergic and noradrenergic pathways. At the psychological level, triggering causes include false arrest, birth of a deformed child, social isolation, deafness, and intensely humiliating experiences. *See* NORADRENERGIC SYSTEM.

The paranoid mode is resistant to modification by psychotherapeutic or pharmacological methods. Acute psychotic states of paranoidness accompanied by high levels of anxiety are usually responsive to neuroleptic medication. *See* PSYCHOPHARMACOLOGY. [K.M.C.]

Parasitology The scientific study of parasites and of parasitism. Parasitism is a subdivision of symbiosis and is defined as an intimate association between an organism (parasite) and another, larger species of organism (host) upon which the parasite is metabolically dependent. Implicit in this definition is the concept that the host is harmed, while the parasite benefits from the association. Although technically parasites, pathogenic bacteria and viruses and nematode, fungal, and insect parasites of plants are traditionally outside the field of parasitology.

Parasites often cause important diseases of humans and animals. For this reason, parasitology is an active field of study; advances in biotechnology have raised expectations for the development of new drugs, vaccines, and other control measures. However, these expectations are dampened by the inherent complexity of parasites and host-parasite relationships, the entrenchment of parasites and vectors in their environments, and the vast socioeconomic problems in the geographical areas where parasites are most prevalent.

The ecological and physiological relationships between parasites and their hosts constitute some of the most impressive examples of biological adaptation known. Much of classical parasitology has been devoted to the elucidation of one of the most important aspects of host-parasite ecological relationships, namely, the dispersion and the transmission of parasites to new hosts.

Parasite life cycles range from simple to highly complex. Simple life cycles (transmission from animal to animal) are direct and horizontal with adaptations that include high reproduction rates, and the production of relatively inactive stages (cysts or eggs) that are resistant to environmental factors such as desiccation, ultraviolet radiation, and extreme temperatures. The infective stages are passively consumed when food or water is contaminated with feces that contain cysts. The cysts are then activated in the gut by cues such as acidity to continue their development. Other direct-transmission parasites, such as hookworms, actively invade new hosts by penetrating the skin. Physiologically more complicated are those life cycles that are direct and vertical, with transmission being from mother to offspring. The main adaptation of the parasite for this type of life cycle is the ability to gain access to the fetus or young animal through the ovaries, placenta, or mammary glands of the mother.

Many parasites have taken advantage of the food chain of free-living animals for transmission to new hosts. During their life cycle, these parasites have intermediate hosts that are the normal prey of their final hosts. Parasites may ascend the food chain by utilizing a succession of progressively larger hosts, a process called paratenesis. *See* FOOD WEB.

Vectors are intermediate hosts that are not eaten by the final host, but rather serve as factories for the production of more parasites and may even carry them to new hosts or to new environments frequented by potential hosts. Blood-sucking athropods such as mosquitoes and tsetse flies are well-known examples. After acquiring the parasite from an infected host, they move to another host, which they bite and infect. Snails are important vectors for two-host trematodes (flukes), which increase their numbers greatly in the snail by asexual reproduction. The stages that leave the snail may either infect second intermediate hosts that are eaten by carnivorous final hosts, may encyst on vegetation that is eaten by herbivorous hosts, or in the case of the blood flukes (schistosomes) may swim to and directly penetrate the final host.

Metabolic dependency is the key to parasitism, and parasites employ many ways to feed off their hosts. The simplest is exhibited by the common intestinal roundworm, *Ascaris*, which consumes the host's intestinal contents. Parasites require from their hosts not only energy-yielding molecules but also basic monomers for macromolecular synthesis and essential cofactors for these synthetic processes. Many examples of the specific absence of key parts of energy-yielding or biosynthetic pathways in parasites are known, and these missing enzymes, cofactors, or intermediates are supplied by the host. Tapeworms are more complex than *Ascaris* in nutritional requirements from the host. They lack a gut, but their surface actively takes up, by facilitated diffusion or active transport, small molecules such as amino acids and simple sugars.

Parasites, by coevolving with their hosts, have the ability to evade the immune response. The best-known evasive tactic is antigenic variation, as found in African trypanosomes, which have a complicated genetic mechanism for producing alternative forms of a glycoprotein that virtually cover the entire parasite. By going through a genetically programmed sequence of variant surface glycoproteins, the trypanosome population in a host stays one step ahead of immunity and is not eliminated. Other possible immune escape mechanisms in parasites have been discovered and probably cooperate to prolong parasite survival.

Parasites are not altogether exempt from the effects of immunity. Rather than completely eliminating parasites, the immune system more often functions to control their populations in the host. Thus a balance is achieved between hosts and parasites that have lived in long evolutionary association, with both surviving through compromise. Enhancing these particular antiparasite mechanisms and neutralizing the parasite's evasion mechanisms would tip the balance in favor of the host. *See* MEDICAL PARASITOLOGY; POPULATION ECOLOGY. [R.T.D.]

Parasympathetic nervous system A portion of the autonomic system. It consists of two neuron chains, but differs from the sympathetic nervous system in that the first neuron has a long axon and synapses with the second neuron near or in the organ innervated. In general, its action is in opposition to that of the sympathetic nervous system, which is the other part of the autonomic system. It cannot be said that one system, the sympathetic, always has a excitatory role and the other, the parasympathetic, an inhibitory role; the situation depends on the organ in question. However, it may be said that the sympathetic system, by altering the level at which various organs function, enables the body to rise to emergency demands encountered in flight, combat, pursuit, and pain. The parasympathetic system appears to be in control during such pleasant periods as digestion and rest. The alkaloid pilocarpine excites parasympathetic activity while atropine inhibits it. *See* AUTONOMIC NERVOUS SYSTEM; SYMPATHETIC NERVOUS SYSTEM. [D.B.W.]

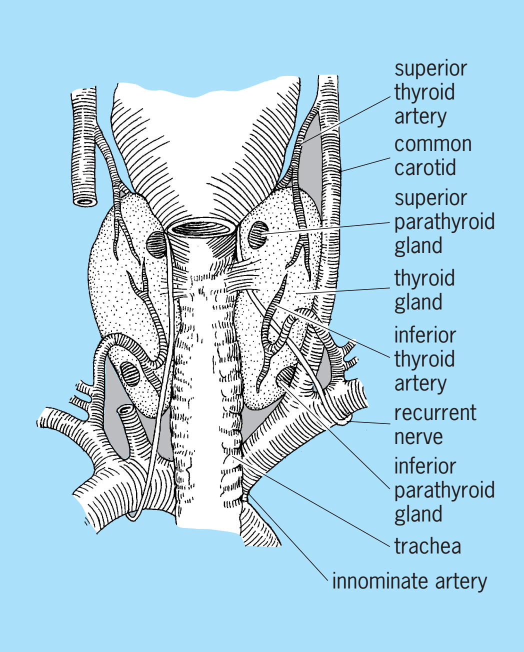
Parathyroid gland An endocrine organ usually associated with the thyroid gland and possessed by all vertebrates except the fishes. In response to lowered serum calcium concentration, a hormone is produced which promotes bone destruction and inhibits the phosphorus-conserving activity of the kidneys. *See* THYROID GLAND.

In humans, there are typically four glands situated as shown in the illustration; however, the number varies between three and six, with four appearing about 80% of the time. Variations in the positioning of the glands along the craniocaudal axis occur but, excepting parathyroid III which may occasionally be found upon the anterior surface of the trachea, the relation to the posterior surface of the thyroid is rarely lost. [W.E.D.]

The parathyroid glands are essential for the regulation of calcium and phosphate concentrations in the extracellular fluids of amphibians and higher vertebrates. Parathyroid hormone has two major target organs, bone and kidney. It acts on bone in several ways. Short-term changes include a rapid uptake of bone fluid calcium into osteoblast cells, which in turn pump the calcium into the extracellular fluids. Long-term effects include increased activity and number of osteoclasts, bone cells which act to break down bone matrix and release calcium from bone. All of these effects result in increased blood calcium values. *See* BONE; CALCIUM METABOLISM.

Parathyroid hormone inhibits the renal reabsorption of phosphate, thus increasing the urinary output of phosphate. Phosphate reabsorption across the renal tubule is dependent upon sodium transport, and parathyroid hormone interferes with this sodium-dependent phosphate transport in the proximal tubule. Another important effect of parathyroid hormone on the kidney is to increase the renal reabsorption of calcium, thus reducing the loss of calcium in the urine and conserving calcium in the body. *See* KIDNEY.

Finally, there are reports that parathyroid hormone indirectly stimulates calcium uptake into the body across the intestine. Parathyroid hormone stimulates the production of the most active metabolite of vitamin D, 1,25-dihydroxycholecalciferol, during vitamin D synthesis. This metabolite of vitamin D directly stimulates the intestinal absorption of calcium. *See* ENDOCRINE SYSTEM (VERTEBRATE); PARATHYROID HORMONE; VITAMIN D. [N.B.C.]



Common positions of human parathyroid glands on the posterior aspect of the thyroid. (*After W. H. Hollinshead, Anatomy of the endocrine glands, Surg. Clln, N. Amer., 21(4):1115–1140, 1952*)

Parathyroid gland disorders Disorders involving excessive or deficient blood levels of parathyroid hormone caused by abnormal functioning of the parathyroid gland. Parathyroid hormone is responsible for keeping the concentration of calcium in blood within a narrow normal range. If the blood calcium concentration falls, the parathyroid glands respond by secreting hormone which tends to increase the concentration of calcium. Parathyroid hormone acts directly on bone and kidney, and indirectly on the intestine, to increase the concentration of calcium in blood. It also acts on the kidney to increase excretion of phosphate in the urine, causing a lowering of the concentration of phosphorus in blood. *See* PARATHYROID GLAND.

Hyperparathyroidism is a group of disorders characterized by excessive parathyroid hormone secretion. Primary hyperparathyroidism is defined as increased parathyroid hormone secretion despite elevated blood calcium. Symptoms and signs range from overt loss of calcium from bone and formation of calcium stones in the kidney to nonspecific manifestations such as weakness and fatigue. The disorder occurs most frequently in women after menopause. There are also inherited forms of the disease. Treatment of primary hyperparathyroidism involves surgical removal of the abnormal gland(s). Secondary hyperparathyroidism is defined as excessive secretion of parathyroid hormone in response to reduction in blood calcium caused by kidney or intestinal disorders or vitamin D deficiency. Treatment is directed at the underlying disorder (for example, kidney transplantation for kidney failure). *See* CALCIUM METABOLISM; VITAMIN D.

Hypoparathyroidism is a group of disorders that involves a deficiency in parathyroid hormone secretion or metabolism. Manifestations include involuntary muscle contractions, or generalized seizures in the most extreme cases. In most forms of hypoparathyroidism, parathyroid hormone is low or undetectable in blood despite reduced blood calcium because the parathyroid glands are unable to respond appropriately by secreting parathyroid hormone. Hypoparathyroidism can be caused by parathyroid gland destruction, for example, by inadvertent surgical removal. Certain rare forms of hypoparathyroidism are due to resistance to parathyroid hormone action rather than hormone deficiency, and are termed pseudohypoparathyroidism. Treatment of all forms of hypoparathyroidism involves administration of calcium and large amounts of vitamin D to restore a normal blood calcium and phosphorus. [A.M.Sp.]

Parathyroid hormone The secretory product of the parathyroid glands. Parathyroid hormone (PTH) is a single-chain polypeptide composed of 84 amino acids. The sequences of human, bovine, and porcine parathyroid hormone are known, and the gene for human parathyroid hormone has been cloned and sequenced.

The major regulator of parathyroid hormone secretion is the serum concentration of calcium ions, to which the parathyroid cells are exquisitely sensitive. Only a limited amount of parathyroid hormone is stored in secretory granules, so that a hypocalcemic stimulus must ultimately influence biosynthesis as well as secretion of the hormone. Parathyroid secretory protein is a large, acidic glycoprotein which is stored and cosecreted with parathyroid hormone in roughly equimolar amounts; the biological function of parathyroid secretory protein is unknown.

Parathyroid hormone is responsible for the fine regulation of serum calcium concentration on a minute-to-minute basis. This is achieved by the acute effects of the hormone on calcium resorption in bone and calcium reabsorption in the kidney. The phosphate mobilized from bone is excreted into the urine by means of the hormone's influence on renal phosphate handling. Parathyroid hormone also stimulates calcium absorption in the intestine, this being mediated indirectly by 1,25-dihydroxyvitamin D. Thus, a hypocalcemic stimulus of parathyroid hormone secretion results in an increased influx of calcium from three sources (bone, kidney, and intestine), resulting in a normalization of the serum calcium concentration without change in the serum phosphate concentration. *See* CALCIUM METABOLISM; PARATHYROID GLAND; PARATHYROID GLAND DISORDERS; THYROCALCITONIN; VITAMIN D. [A.E.Bro.]

Parazoa A name proposed for a subkingdom of animals which includes the sponges. Erection of a separate subkingdom for the sponges implies that they originated from protozoan ancestors independently of all other Metazoa. This theory is supported by the uniqueness of the sponge body plan and by peculiarities of fertilization and development. Much importance is given to the fact that during the development of sponges with parenchymella larvae, the flagellated external cells of the larva take up an internal position as choanocytes after metamorphosis, whereas the epidermal and mesenchymal cells arise from what was an internal mass of cells in the larva. These facts suggest that either the germ layers of sponges are reversed in comparison with those of other Metazoa or the choanocytes cannot be homologized with the endoderm of other animals. Either interpretation supports the wide separation of sponges from all other Metazoa to form the subkingdom Parazoa or Enantiozoa. On the other hand, there are cogent arguments in favor of the basic similarity of the development of sponges and other Metazoa. *See* CALCAREA; DEMOSPONGIAE; METAZOA; PORIFERA. [W.D.H.]

Parenchyma A ground tissue chiefly concerned with the manufacture and storage of food. The primary functions of plants, such as photosynthesis, assimilation, respiration, storage, secretion, and excretion—those associated with living protoplasm—proceed mainly in parenchymal cells. Parenchyma is frequently found as a homogeneous tissue in stems, roots, leaves, and flower parts. Other tissues, such as sclerenchyma, xylem, and phloem, seem to be embedded in a matrix of parenchyma; hence the use of the term ground tissue with regard to parenchyma is derived. The parenchymal cell is one of the most frequently occurring cell types in the plant kingdom. *See* PLANT ANATOMY; PLANT PHYSIOLOGY.

Typical parenchyma occurs in pith and cortex of roots and stems as a relatively undifferentiated tissue composed of polyhedral cells that may be more or less compactly arranged and show little variation in size or shape. The mesophyll, that is, the tissue located between the upper and lower epidermis of leaves, is a specially differentiated parenchyma called chlorenchyma because its cells contain chlorophyll in distinct chloroplastids.

This chlorenchymatous tissue is the major locus of photosynthetic activity and consequently is one of the more important variants of parenchyma. Specialized secretory parenchymal cells are found lining resin ducts and other secretory structures. *See* PHOTOSYNTHESIS; SECRETORY STRUCTURES (PLANT). [R.L.Hu.]

Pareto's law A law (sometimes called the 20–80 rule) describing the frequency distribution of an empirical relationship fitting the skewed concentration of the variate-values pattern. The phenomenon wherein a small percentage of a population accounts for a large percentage of a particular characteristic of that population is an example of Pareto's law. When the data are plotted graphically, the result is called a maldistribution curve. To take a specific case, an analysis of a manufacturer's inventory might reveal that less than 15% of the component part items account for over 90% of the total annual usage value.

The mathematics required to calculate and graph the curve of Pareto's law is simple arithmetic. It should be noted, however, that the calculations need not be done in all cases. It may suffice to merely make a rough approximation of a situation in order to determine whether or not Pareto's law is present and whether benefits may subsequently accrue. [V.M.A.]

Parity (quantum mechanics) A physical property of a wave function which specifies its behavior under simultaneous reflection of all spatial coordinates through the origin, that is, when x is replaced by $-x$, y by $-y$, and z by $-z$. If the single-particle wave function ψ satisfies Eq. (1), it is said to have even parity. If, on the other hand, Eq. (2) holds, the wave function is said to have odd parity. These two expressions can be combined in Eq. (3), where $P = \pm 1$ is a quantum number, parity, having

$$\psi(x,y,z) = \psi(-x,-y,-z) \tag{1}$$

$$\psi(x,y,z) = -\psi(-x,-y,-z) \tag{2}$$

$$\psi(x,y,z) = P\psi(-x,-y,-z) \tag{3}$$

only the two values $+1$ (designated as even parity) and -1 (odd parity). More precisely, parity is defined as the eigenvalue of the operation of space inversion. Parity is a concept that has meaning only for fields or waves and therefore has meaning only in classical field theory or in quantum mechanics. *See* QUANTUM MECHANICS.

The conservation of parity follows from the inversion symmetry of space, that is, the invariance of the Schrödinger equation $H\psi = E\psi$ (the wave equation satisfied by the wave function ψ) to the inversion of space coordinates, $\mathbf{r} \rightarrow -\mathbf{r}$. The parity (or inversion) operator, which changes $\mathbf{r}$ to $-\mathbf{r}$, has the alternative interpretation that the coordinate values remain unchanged but the coordinate axes are inverted; that is, the positive x axis of the new frame points along the old negative x axis, and similarly for y and z. If the original frame was right-handed, then the new frame is left-handed. [A cartesian coordinate system (frame, for short) is called right-handed if it is possible to place the right hand at the origin and point the thumb and first and second fingers along the positive x, y, and z axes, respectively.] Thus, parity would be conserved if the statement of physical laws were independent of the handedness of the coordinate system that was being used. Of course, the fact that most people are right-handed is not a physical law but an accident of evolution; there is nothing in the relevant laws of physics which favors a right-handed over a left-handed human. The same holds for optically active organic compounds, such as the amino acids. However, the statement that the neutrino is left-handed is a physical law. *See* NEUTRINO.

All the strong interactions between hadrons (for example, nuclear forces) and the electromagnetic interactions are symmetrical to inversion, so that parity is conserved by these interactions. As far as is known, only the weak interactions fail to conserve parity. Thus parity is not conserved in the weak decays of elementary particles (including beta decay of nuclei); in all other processes the weak interactions play a small role, and parity is very nearly conserved. Likewise, in energy eigenstates, weak interactions can be neglected to a very good approximation, and parity is very nearly a good quantum number, so that each atomic, nuclear, or hadronic state is characterized by a definite value of parity, and its conservation in reactions is an important principle. *See* FUNDAMENTAL INTERACTIONS; WEAK NUCLEAR INTERACTIONS.

One of the selection rules which follows from parity conservation is the following: A spin zero boson cannot decay sometimes into two π mesons and sometimes into three π mesons, because these final states have different parities, even and odd respectively. But the positive K meson is observed to have both these decay modes, originally called the θ and the τ mesons, respectively, but later shown by the identity of masses and lifetimes to be decay modes of the same particle. This τ-θ puzzle was the first observation of parity nonconservation. In 1956, T. D. Lee and C. N. Yang made the bold hypothesis that parity also is not conserved in beta decay. They reasoned that the magnitude of the beta-decay coupling is about the same as the coupling which leads to decay of the K meson, and so these decay processes may be manifestations of a single kind of coupling. Also, there is a very natural way to introduce parity nonconservation in beta decay, namely, by assuming a restriction on the possible states of the neutrino (two-component theory). They pointed out that no beta-decay experiment had ever looked for the spin-momentum correlations that would indicate parity nonconservation; they urged that these correlations be sought.

In the first experiment to show parity nonconservation in beta decay, the spins of the beta-active nuclei cobalt-60 were polarized with a magnetic field at low temperature; the decay electrons were observed to be emitted preferentially in directions opposite to the direction of the ^{60}Co spin. The magnitude of this correlation shows that the parity-nonconserving and parity-conserving parts of the beta interaction are of equal size, substantiating the two-component neutrino theory.

It was at first somewhat disconcerting to find parity not conserved, for that seemed to imply a handedness of space. But this is not really the situation; the saving thing is that anti-^{60}Co decays in the opposite direction. Thus, after all, there is nothing intrinsically left-handed about the world, just as there is nothing intrinsically positively charged about nuclei. What really exists here is a correlation between handedness and sign of charge. [C.J.G.]

Parkinson's disease

A progressive disorder of the nervous system that mainly affects elderly people, with peak onset in the 60s and 70s. Males and females are equally affected. The basic mechanism of the disease is not known. The disease usually occurs sporadically. However, 10–15% of the time it runs in families.

Parkinson's disease is characterized by abnormalities of motor function, several of which predominate, but all do not necessarily occur in all individuals. Slowness of movement and an inability to start a movement are hallmarks of the disease. The motor disturbance also results in diminished facial expression and a decreased rate of blinking. The second important manifestation is stiffness and rigidity so that the person encounters increased resistance when attempting to move a limb and a joint. The third manifestation, in some individuals, is a tremor that may be quite asymmetrical, occurring in just one hand, or may involve both hands and the trunk.

As the disease progresses, problems with balance become quite limiting, and falls may occur frequently. Alternatively, with disease progression, episodes of "freezing" may occur, during which voluntary movement becomes impossible. Finally, some individuals have an associated dementia, which appears to be an integral part of the Parkinson's disease process, although in others it may be a manifestation of Alzheimer's disease. *See* ALZHEIMER'S DISEASE.

The basic pathologic change is degeneration of a group of nerve cells deep within the center of the brain in an area called the substantia nigra. These cells use dopamine as their neurotransmitter to signal other nerve cells. As these cells degenerate and stop functioning, dopamine fails to reach the areas of the brain that affect motor functions. The possible role of toxins in the disease process has aroused considerable interest. *See* DOPAMINE.

Therapy for Parkinson's disease is aimed at replacing dopamine. Since the blood-brain barrier prevents dopamine from entering the brain from the bloodstream, a precursor of dopamine (L-dopa) that will enter the brain is given. L-Dopa is usually administered as part of a compound that inhibits the enzymes that break down L-dopa in the liver, thus making a greater part of it available to the brain. *See* MOTOR SYSTEMS; NERVOUS SYSTEM (VERTEBRATE); SENSATION. [G.M.McK.]

Parsec

A unit of measure of astronomical distances. One parsec is equivalent to 3.084×10^{13} kilometers, or 1.916×10^{13} miles. There are 3.26 light-years in 1 parsec. The parsec is defined as the distance at which the semimajor axis of Earth's orbit around the Sun (1 astronomical unit) subtends 1 second of arc. Thus, because the angle is small, the equation below holds.

$$\frac{1\ \text{astronomical unit}}{1\ \text{parsec}} = 1\ \text{second} = \frac{1}{206{,}265}$$

A parsec is then 206,265 astronomical units. At a distance of 1 parsec, the parallax is 1 second of arc. The nearest star is about 1.3 parsecs distant; the farthest known galaxy is several billion parsecs. *See* PARALLAX (ASTRONOMY). [J.L.Gr.]

Parsley

A biennial, *Petroselinum crispum*, of European origin belonging to the plant order Umbellales. Parsley is grown for its foliage and is used to garnish and flavor foods. It contains large quantities of vitamins A and C. Two types, plain-leafed and curled, are grown for their foliage; Hamburg parsley (*P. crispum* var. *tuberosum*), also called turnip-rooted parsley, is grown for its edible parsniplike root. *See* APIALES. [H.J.C.]

Parsnip

A hardy biennial, *Pastinaca sativa*, of Mediterranean origin belonging to the plant order Umbellales. The parsnip is grown for its thickened taproot and is used primarily as a cooked vegetable. Exposure of mature roots to low temperatures, not necessarily freezing, improves the quality of the root by favoring the conversion of starch to sugar. *See* APIALES. [H.J.C.]

Partial differentiation

A mathematical operation performed on functions of more than one variable. In this article only two or three variables are considered; however, the principles apply to functions of n variables, for any positive integer $n > 1$. If $z = f(x,y)$, the partial derivative $\partial z/\partial x$ is defined as the derivative of $f(x,y)$ with respect to x, y being regarded as fixed; that is,

$$\frac{\partial z}{\partial x} = \lim_{h\to 0} \frac{f(x+h,\, y) - f(x,\, y)}{h}$$

Another notation for $\partial z/\partial x$ is $f_1(x,y)$. The other first partial derivative is $\partial z/\partial y$, also written $f_2(x,y)$. For values at particular points the notation is

$$\left(\frac{\partial z}{\partial x}\right)_{(a,b)} = f_1(a,\, b)$$

In the case of a function of three variables, $f(x,y,z)$, the expression is

$$\frac{\partial f}{\partial z} = f_3(x,\, y,\, z)$$

The second derivatives of $f(x,y)$ are given by

$$f_{11}(x,\, y) = \frac{\partial}{\partial x}\left(\frac{\partial f}{\partial x}\right) \qquad f_{12}(x,\, y) = \frac{\partial}{\partial y}\left(\frac{\partial f}{\partial x}\right)$$

$$f_{21}(x,\, y) = \frac{\partial}{\partial y}\left(\frac{\partial f}{\partial y}\right) \qquad f_{22}(x,\, y) = \frac{\partial}{\partial y}\left(\frac{\partial f}{\partial y}\right)$$

It can happen that $f_{12}(x,\ y) \neq f_{21}(x,y)$, but this will not happen in common practice, especially with elementary functions. If f_1, f_2, f_{12}, f_{21} are defined in neighborhood of (a,b), and if f_{12}, f_{21} are continuous at $(a,\ b)$, then $f_{12}(a,b) = f_{21}(a,b)$. In addition, there are more delicate theorems relating to this matter.

The notion of the differentiability of a function is fundamental in the theory of partial differentiation. The requirement that $f(x,y)$ be differentiable is not the same as the requirement that $f_1,(x,y)$ and $f_2(x,\ y)$ both exist; it is a more inclusive requirement. The geometric meaning of f being differentiable at (a,b) is that the surface defined by $z = f(x,y)$ has a tangent plane not parallel to the z axis when $x = a$, $y = b$. In analytic terms the condition is that if

$$\epsilon = f(a+h,\, b+k) - f(a,b) - f_1(a,b)h - f_2(a,b)k$$

then

$$\lim_{(h,k)\to(0,0)} \frac{\epsilon}{|h|+|k|} = 0$$

A sufficient condition that f be differentiable at (a,b) is that the partial derivatives f_1, f_2 be defined at all points near (a,b), and continuous at (a,b).

The prime importance of the differentiability concept is that the differentiability property is needed in proving the chain rule for functions of several variables. This rule asserts that a differentiable function of a differentiable function is differentiable, and the rule tells how to compute partial derivatives of the composite function. For example, if $x = f(s,t)$, $y = g(s,t)$, where f and g are differentiable, and if $z = F(x,y)$, where F is differentiable, then the composite function is $G(s,t) = F[f(s,t),g(s,t)]$. Then $z = G(s,t)$ is differentiable as a function of s and t, and

$$\frac{\partial G}{\partial s} = \frac{\partial F}{\partial x}\frac{\partial f}{\partial s} + \frac{\partial F}{\partial y}\frac{\partial g}{\partial s}$$

$$\frac{\partial G}{\partial t} = \frac{\partial F}{\partial x}\frac{\partial f}{\partial t} + \frac{\partial F}{\partial y}\frac{\partial g}{\partial t}$$

These equations, expressing the formal part of the chain rule, are often written in the form

$$\frac{\partial z}{\partial s} = \frac{\partial z}{\partial x}\frac{\partial x}{\partial s} + \frac{\partial z}{\partial y}\frac{\partial y}{\partial s}$$

$$\frac{\partial z}{\partial t} = \frac{\partial z}{\partial x}\frac{\partial x}{\partial t} + \frac{\partial z}{\partial y}\frac{\partial y}{\partial t}$$

See CALCULUS; DIFFERENTIATION; PARAMETRIC EQUATION. [A.E.Ta.]

Particle accelerator An electrical device which accelerates charged atomic or subatomic particles to high energies. The particles may be charged either positively or negatively. If subatomic, the particles are usually electrons or protons and, if atomic, they are charged ions of various elements and their isotopes throughout the entire periodic table of the elements.

Accelerators that produce various subatomic particles at high intensity have many practical applications in industry and medicine as well as in basic research. Electrostatic generators, pulse transformer sets, cyclotrons, and electron linear accelerators are used to produce high levels of various kinds of radiation that in turn can be used to polymerize plastics, provide bacterial sterilization without heating, and manufacture radioisotopes which are utilized in industry and medicine for direct treatment of some illnesses as well as research. They can also be used to provide high-intensity beams of protons, neutrons, heavy ions, pi mesons, or x-rays that are used for cancer therapy and research. The x-rays used in industry are usually produced by arranging for accelerated electrons to strike a solid target. However, with the advent of electron synchrotron storage rings that produce x-rays in the form of synchrotron radiation, many new industrial applications of these x-rays have been realized, especially in the field of solid-state microchip fabrication and medical diagnostics. *See* ISOTOPIC IRRADIATION; RADIATION BIOLOGY; RADIATION CHEMISTRY; RADIOACTIVITY AND RADIATION APPLICATIONS; RADIOGRAPHY; RADIOISOTOPE; RADIOLOGY; SYNCHROTRON RADIATION.

Particle accelerators fall into two general classes—electrostatic accelerators that provide a steady dc potential, and varieties of accelerators that employ various combinations of time-varying electric and magnetic fields.

Electrostatic accelerators. Electrostatic accelerators in the simplest form accelerate the charged particle either from the source of high voltage to ground potential or from ground potential to the source of high voltage. All particle accelerations are carried out inside an evacuated tube so that the accelerated particles do not collide with air molecules or atoms and may follow trajectories characterized specifically by the electric fields utilized for the acceleration. The maximum energy available from this kind of accelerator is limited by the ability of the evacuated tube to withstand some maximum high voltage.

Time-varying field accelerators. In contrast to the high-voltage-type accelerator which accelerates particles in a continuous stream through a continuously maintained increasing potential, the time-varying accelerators must necessarily accelerate particles in small discrete groups or bunches.

An accelerator that varies only in electric field and does not use any magnetic guide or turning field is customarily referred to as a linear accelerator or linac. In the simplest version of this kind of accelerator, the electrodes that are used to attract and accelerate the particles are connected to a radio-frequency (rf) power supply or oscillator so that alternate electrodes are of opposite polarity. In this way, each successive gap between adjacent electrodes is alternately accelerating and decelerating. If these acceleration gaps are appropriately spaced to accommodate the increasing velocity of the accelerated particle, the frequency can be adjusted so that the particle bunches are always experiencing an accelerating electric field as they cross each successive gap. In this way, modest voltages can be used to accelerate bunches of particles indefinitely, limited only by the physical length of the accelerator construction.

All conventional (but not superconducting) research linacs usually are operated in a pulsed mode because of the extremely high rf power necessary for their operation. The pulsed operation can then be adjusted so that the duty cycle or amount of time actually on at full power averages to a value that is reasonable in cost and practical for cooling. This necessarily limited duty cycle in turn limits the kinds of research that are possible with linacs; however, they are extremely useful (and universally used) as pulsed high-current injectors for all electron and proton synchrotron ring accelerators. Superconducting linear accelerators have been constructed that are used to accelerate electrons and also to boost the energy of heavy ions injected from electrostatic machines. These linacs can easily operate in the continuous-wave (cw) rather than pulsed mode, because the rf power losses are only a few watts.

The Continuous Electron Beam Accelerator Facility (CEBAF) uses two 400-MeV superconducting linacs to repeatedly accelerate electrons around a racetrack-like arrangement where the two linacs are on the opposite straight sides of the racetrack and the circular ends are a series of recirculation bending magnets, a different set for each of five passes through the two linacs in succession. The continuous electron beam then receives a 400-MeV acceleration on each straight side or 0.8 GeV per turn, and is accelerated to a final energy of 4 GeV in five turns and extracted for use in experiments. The superconducting linacs allow for continuous acceleration and hence a continuous beam rather than a pulsed beam. This makes possible many fundamental nuclear and quark structure measurements that are impossible with the pulsed electron beams from conventional electron linacs. *See* SUPERCONDUCTING DEVICES.

As accelerators are carried to higher energy, a linac eventually reaches some practical construction limit because of length. This problem of extreme length can be circumvented conveniently by accelerating the particles in a circular path maintained by either static or time-varying magnetic fields. Accelerators utilizing steady magnetic fields as guide paths are usually referred to as cyclotrons or synchrocyclotrons, and are arranged to provide a steady magnetic field over relatively large areas that allow the particles to travel in an increasing spiral orbit of gradually increasing size as they increase in energy.

Practical limitations of magnet construction and cost have kept the size of circular proton accelerators with static magnetic fields to the vicinity of 100 to 1000 MeV. For even higher energies, up to 400 GeV per nucleon in the largest conventional (not superconducting) proton synchrotron in operation, it is necessary to vary the magnetic field as well as the electric field in time. In this way the magnetic field can be of a minimal practical size, which is still quite extensive for a 980-GeV accelerator (6500 ft or

2000 m in diameter). This circular magnetic containment region, or "racetrack," is injected with relatively low-energy particles that can coast around the magnetic ring when it is at minimum field strength. The magnetic field is then gradually increased to stay in step with the higher magnetic rigidity of the particles as they are gradually accelerated with a time-varying electric field.

Superconducting magnets. The study of the fundamental structure of nature and all associated basic research require an ever increasing energy in order to allow finer and finer measurements on the basic structure of matter. Since the voltage-varying and magnetic-field-varying accelerators also have limits to their maximum size in terms of cost and practical construction problems, the only way to increase particle energies even further is to provide higher-varying magnetic fields through superconducting magnet technology, which can extend electromagnetic capability by a factor of 4 to 5. Large superconducting cyclotrons and superconducting synchrotrons are in operation. *See* MAGNET.

Storage rings. Beyond the limit just described, the only other possibility is to accelerate particles in opposite directions and arrange for them to collide at certain selected intersection regions around the accelerator. The main technical problem is to provide adequate numbers of particles in the two colliding beams so that the probability of a collision is moderately high. Such storage ring facilities are in operation for both electrons and protons. Besides storing the particles in circular orbits, the rings can operate initially as synchrotrons and accelerate lower-energy injected particles to much higher energies and then store them for interaction studies at the beam interaction points.

Large proton synchrotrons have been used as storage-ring colliders by accelerating and storing protons in one direction around the ring while accelerating and storing antiprotons (negative charge) in the opposite direction. The proton and antiproton beams are carefully programmed to be in different orbits as they circulate in opposite directions and to collide only when their orbits cross at selected points around the ring where experiments are located. The antiprotons are produced by high-energy proton collisions with a target, collected, stored, cooled, and eventually injected back into the synchrotron as an antiproton beam.

Electron-positron synchrotron accelerator storage rings have been in operation for many years in the basic study of particle physics, with energies ranging from 2 GeV + 2 GeV to 104 GeV + 104 GeV. The by-product synchrotron radiation from many of these machines is used in numerous applications. However, the synchrotron radiation loss forces the machine design to larger and larger diameters, characterized by the Large Electron Positron Storage Ring (LEP) at CERN, near Geneva, Switzerland (closed down in 2000), which was 17 mi (27 km) in circumference. Conventional rf cavities enable electron-positron acceleration only up to 50–70 GeV (limited by synchrotron radiation loss) while higher energies of 100–150 GeV require superconducting cavities. *See* SYNCHROTRON RADIATION.

Advanced linacs. Although circular machines with varying magnetic fields have been developed because linacs of comparable performance would be too long (many miles), developments in linac design and utilization of powerful laser properties may result in a return to linacs that will outperform present ring machines at much lower cost. As a first example, the 20-GeV electron linac at Stanford University, Palo Alto, California, has been modified to provide simultaneous acceleration of positrons and electrons to energies as high as 50 GeV, while operating in what is called the SLED mode. After acceleration the electrons and positrons are separated by a magnet, and the two beams are magnetically directed around the opposite sides of a circle so that they collide at one intersection point approximately along a diameter extending from the end of the linac across the circle. This collider arrangement is much less expensive than the 17-mi (27-km) ring at CERN and provides electron-positron collisions of comparable energies but at lower intensities. [H.E.W.]

Particle detector A device used to detect and measure radiation characteristically emitted in nuclear processes, including gamma rays or x-rays, lightweight charged particles (electrons or positrons), nuclear constituents (neutrons, protons, and heavier ions), and subnuclear constituents such as mesons. The device is also known as a radiation detector. Since human senses do not respond to these types of radiation, detectors are essential tools for the discovery of radioactive minerals, for all studies of the structure of matter at the atomic, nuclear, and subnuclear levels, and for protection from the effects of radiation. They have also become important practical tools in the analysis of materials using the techniques of neutron activation and x-ray fluorescence analysis. *See* ACTIVATION ANALYSIS; ELEMENTARY PARTICLE; NUCLEAR REACTION; NUCLEAR SPECTRA; PARTICLE ACCELERATOR; PROSPECTING; RADIOACTIVITY; X-RAY FLUORESCENCE ANALYSIS.

A convenient way to classify radiation detectors is according to their mode of use: (1) For detailed observation of individual photons or particles, a pulse detector is used to convert each such event (that is, photon or particle) into an electrical signal. (2) To measure the average rate of events, a mean-current detector, such as an ion chamber, is often used. Radiation monitoring and neutron flux measurements in reactors generally fall in this category. Sometimes, when the total number of events in a known time is to be determined, an integrating version of this detector is used. (3) Position-sensitive detectors are used to provide information on the location of particles or photons in the plane of the detector. (4) Track-imaging detectors image the whole three-dimensional structure of a particle's track. The output may be recorded by immediate electrical readout or by photographing tracks as in the bubble chamber. (5) The time when a particle passes through a detector or a photon interacts in it is measured by a timing detector. Such information is used to determine the velocity of particles and when observing the time relationship between events in more than one detector. *See* TIME-OF-FLIGHT SPECTROMETERS.

The ionization produced by a charged particle is the effect commonly employed in a particle detector. In the basic type of gas ionization detector, an electric field applied between two electrodes separates and collects the electrons and positive ions produced in the gas by the radiation to be measured. Multiwire proportional chambers and spark chambers are position-sensitive adaptations of gas detectors. The signal division or time delay that occurs between the ends of an electrode made of resistive material is sometimes used to provide position sensitivity in gas and semiconductor detectors. Track-imaging detectors rely on a secondary effect of the ionization along a particle's track to reveal its structure. *See* IONIZATION CHAMBER.

In a semiconductor detector, a solid replaces the gas. The "insulating" region (depletion layer) of a reverse-biased *pn* junction in a semiconductor is employed. Since solids are approximately 1000 times denser than gases, absorption of radiation can be accomplished in relatively small volumes. A less obvious but fundamental advantage of semiconductor detectors is the fact that much less energy is required (~3 eV) to produce a hole-electron pair than that required (~30 eV) to produce an ion electron pair in gases. *See* CRYSTAL COUNTER; JUNCTION DETECTOR.

In addition to producing free electrons and ions, the passage of a charged particle through matter temporarily raises electrons in the material into excited states. When these electrons fall back into their normal state, light may be emitted and detected as in the scintillation detector. *See* SCINTILLATION COUNTER.

Neutral particles, such as neutrons, cannot be detected directly by ionization. Consequently, they must be converted into charged particles by a suitable process and then observed by detecting the ionization caused by these particles.

Although ionization detectors dominate the field, a number of detector types based on other radiation-induced effects are used. Examples are (1) transition radiation detectors, which depend on the x-rays and light emitted when a particle passes through the interface between two media of different refractive indices;

(2) track detectors, in which the damage caused by charged particles in plastic films and in minerals is revealed by etching procedures; (3) thermoluminescent and radiophotoluminescent detectors, which rely on the latent effects of radiation in creating traps in a material or in creating trapped charge; and (4) Cerenkov detectors, which depend on measurement of the light produced by passage of a particle whose velocity is greater than the velocity of light in the detector medium. *See* CERENKOV RADIATION; PARTICLE TRACK ETCHING; TRANSITION RADIATION DETECTORS.

The very large detector systems used in relativistic heavy-ion experiments and in the detection of the products of collisions of charged particles at very high energies, typically at the intersection region of storage rings, deserve special consideration. These detectors are frequently composites of several of the basic types of detectors discussed above and are designed to provide a detailed picture of the multiple products of collisions at high energies. The complete detector system may occupy a space tens of feet in extent and involve tens or hundreds of thousands of individual signal processing channels, together with large computer recording and analysis facilities. [F.S.G.]

Particle flow Particle flow is important to many industrial processes, including the pneumatic conveying of solids, transport of solids in liquids (slurries), removal of particulates from gas streams for pollution control, combustion of pulverized coal, and drying of particulates in the food and pharmaceutical industries. The vast majority of flow problems in industrial design involve the flow of gas or liquids with suspended solids. *See* DRYING; FLUIDIZED-BED COMBUSTION; PIPELINE.

A key parameter in fluid-particle flows is the Stokes number, which is the ratio of the response time of a particle to a time characteristic of a flow system. Particle response time is the time that a particle takes to respond to a change in carrier flow velocity. If the Stokes number is small (say, less than 0.1), the particles have sufficient time to respond to the change in fluid velocity, so the particle velocity approaches the fluid velocity. However, if the Stokes number is large (say, greater than 10), the particles have little time to respond to the varying fluid velocity and the particle velocity shows little change.

The relative concentration of the particles in the fluid is referred to as loading. The loading may be defined in several ways, such as the ratio of particle mass flow to fluid mass flow. Many industrial applications involve highly loaded particle flows.

If the particle loading is small, the fluid will affect the particle properties (velocity, temperature, and so forth), but the particles will not influence the fluid properties. This is referred to as one-way coupling. If the conditions are such that there is a mutual interaction between the particles and fluid, the flow is two-way-coupled. Two-way coupling effects are reduced with increasing Stokes number because the particles undergo less acceleration.

If the particle motion is controlled by the action of the fluid on the particle, the flow is termed dilute. But if the particle concentration is sufficiently high, the particles will collide with each other and their motion will be dependent on particle-particle collisions; the flow is then regarded as dense. *See* FLUID FLOW; PARTICULATES. [C.T.Cr.]

Particle track etching A technique of selective chemical etching to reveal tracks of heavy nuclear particles in a wide variety of solid substances. Developed in order to see fossil particle tracks in extraterrestrial materials, the technique finds application in many fields of science and technology.

An etchable track is produced if the charged particle has a sufficiently high radiation-damage rate and if the damaged region in the solid is permanently localized. Thus only highly ionizing particles are detectable; only nonconductors record tracks; and radiation-sensitive plastics can detect lighter particles than can radiation-insensitive minerals and glasses. The conical shape of the etched track depends on the ratio of the rate of etching along the track to the bulk etching rate of the solid.

The lunar surface, meteorites, and other objects exposed in space have been irradiated by charged particles from a variety of sources in the Sun and the Galaxy. Comparison of fossil particle tracks in lunar rocks and meteorites with spacecraft measurements of present-day radiations has established that solar flares and galactic cosmic rays have not changed over the last 2×10^7 years—the typical time a lunar rock exists before being shattered by impacting interplanetary debris.

Studies of tracks in a piece of glass from the *Surveyor 3* spacecraft after a 2.6-year exposure on the lunar surface, and of tracks in plastic detectors exposed briefly above the Earth's atmosphere in rockets, have led to the surprising discovery that the Sun preferentially ejects heavy elements in its flares rather than an unbiased sample of its atmosphere. The existence of galactic cosmic rays with atomic number greater than 30 was discovered in 1966 when fossil particle tracks were first studied in meteorites. Several particles heavier than uranium have been detected, indicating that cosmic rays originate in sources where synthesis has proceeded explosively beyond uranium. *See* COSMIC RAYS.

Unique advantages of etched-track detectors in nuclear and elementary particle physics are their ability to distinguish heavy-particle events in a large background of lightly ionizing radiation and their ability to detect individual rare events by a specialized technique such as electric-spark scanning or ammonia penetration through etched holes. These advantages have permitted such advances as the measurement of very long fission half-lives and the discovery of ternary fission. *See* NUCLEAR FISSION; TRANSURANIUM ELEMENTS.

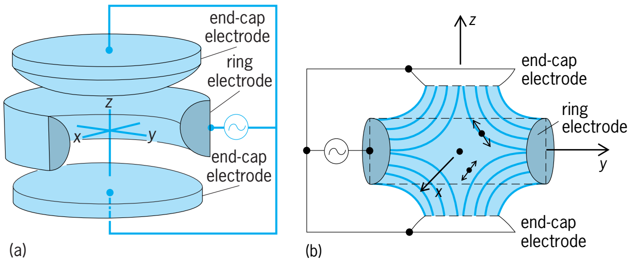
The spontaneous fission of ^{238}U, present as a trace-element purity, gives tracks that can be used to date terrestrial samples ranging from rocks to human artifacts. Because fission tracks are erased in a particular mineral at a well-defined temperature, one can use the apparent fission-track ages as a function of distance from the heat source to measure the thermal (tectonic) history of regions. *See* FISSION TRACK DATING.

Filters are produced by irradiating thin plastic sheets with fission fragments and then etching holes to the desired size. Uses include biological research, wine filtration, and virus sizing. A uranium exploration method relies on a survey of radon emanation, as measured by alpha-particle tracks in plastic detectors, to locate promising locations in which to drill. Plastic detectors are also used in conjunction with a beam of high-energy heavy ions to take radiographs of cancer patients that reveal details not detectable in x-rays. [P.B.P.]

Particle trap A device used to confine charged or neutral particles where their interaction with the wall of a container must be avoided. Electrons or protons accelerated to energies as high as 1 teraelectronvolt (10^{12} electronvolts) are trapped in magnetic storage rings in high-energy collision studies. Other forms of magnetic bottles are designed to hold dense hot plasmas of hydrogen isotopes for nuclear fusion. At the other end of the energy spectrum, ion and atom traps can store isolated atomic systems at temperatures below 1 millikelvin. Other applications of particle traps include the storage of antimatter such as antiprotons and positrons (antielectrons) for high-energy collision studies or low-energy experiments. *See* ANTIMATTER; NUCLEAR FUSION; PARTICLE ACCELERATOR; PLASMA (PHYSICS); POSITRON.

Charged-particle traps. Charged particles can be trapped in a variety of ways. An electrostatic (Kingdon) trap is formed from a thin charged wire. The ion is attracted to the wire, but its angular momentum causes it to spiral around the wire in a path with a low probability of hitting the wire.

A magnetostatic trap (magnetic bottle) is based on the fact that a charged particle with velocity perpendicular to the magnetic field lines travels in a circle, whereas a particle moving parallel to the field is unaffected by it. In general, the particle has velocity components both parallel and perpendicular to the field lines and moves in a helical spiral. In high-energy physics, accelerators and storage rings also use magnetic forces to guide and confine



Radio-frequency Paul trap consisting of two end caps and a ring electrode. (*a*) Cutaway view (*after G. Kamas, ed., Time and Frequency Users's Manual, National Bureau of Standards Technical Note 695, 1977*). (*b*) Cross section, showing the amplitude of the instantaneous oscillations for several locations in the trap.

charged particles. A tokamak has magnetic field lines configured in the shape of a torus, confining particles in spiral orbits. This type of bottle is used to contain hot plasmas in nuclear fusion studies. Another type of bottle uses a magnetic mirror.

The radio-frequency Paul trap uses inhomogeneous radio-frequency electric fields to confine particles, forcing them to oscillate rapidly in the alternating field (see illustration). If the amplitude of oscillation (micromotion) is small compared to the trap dimensions, the trap may be thought of as increasing the (kinetic) energy of the particle in a manner that is a function of the particle position. The particle moves to the position of minimal energy and is therefore attracted to the center of the trap where the oscillating electric fields are weakest. At the center of the trap, the fields are exactly zero, and a single, cold ion or electron trapped there is essentially at rest with almost no micromotion.

The Penning trap, with the same electrode configuration as the Paul trap, uses a combination of static electric and magnetic fields instead of oscillating electric fields.

Neutral-particle traps. Uncharged particles such as neutrons or atoms are manipulated by higher-order moments of the charge distribution such as the magnetic or electric dipole moments.

Magnetic traps of neutral particles use the fact that atoms usually have a magnetic dipole moment on which the gradient of a magnetic field exerts a force. The atom can be in a state whose magnetic energy increases or decreases with the field strength, depending on whether the moment is antiparallel or parallel to the field. A magnetic field cannot be constructed with a local maximum in a current-free region, but a local minimum is possible, allowing particles seeking a weak field to be trapped.

Laser traps use the strong electric fields of the laser beam to induce an electric dipole moment on the atom. A laser field tuned below the atomic resonance polarizes the atom in phase with the driving field; the instantaneous dipole moment points in the same direction as the field. Thus the energy of the atom is lowered if it is in a region of high laser intensity. The high-intensity trapping region is formed simply by focusing the beam of a laser. *See* Laser.

Magnetooptic hybrid traps use, instead of the dipole forces induced by the laser field, the scattering force that arises when an atom absorbs photons. An inhomogeneous magnetic field separates the magnetic substates of an atom in a position-dependent manner. These states interact differently with circularly polarized light. It is possible to arrange a combination of laser beams with proper polarizations to create net scattering forces that drive the atom into the region of zero magnetic field. Such a trap requires much lower laser intensities and weaker magnetic fields. *See* Laser cooling. [S.Ch.]

Particulates Solids or liquids in a subdivided state. Because of this subdivision, particulates exhibit special characteristics which are negligible in the bulk material. Normally, particulates will exist only in the presence of another continuous phase, which may influence the properties of the particulates. A particulate may comprise several phases. The table categorizes particulate systems and relates them to commonly recognized designations. *See* Alloy; Emulsion; Foam; Gel.

Fine-particle technology deals with particulate systems in which the particulate phase is subject to change or motion, and is concerned with those particles which are tangible to human senses, yet small compared to the human environment—particles that are larger than molecules but smaller than gravel. Fine particles are in abundance in nature (as in rain, soil, sand, minerals, dust, pollen, bacteria, and viruses) and in industry (as in paint pigments, insecticides, powdered milk, soap, powder, cosmetics, and inks). Particulates are involved in such undesirable forms as fumes, fly ash, dust, and smog and in military strategy in the form of signal flares, biological and chemical warfare, explosives, and rocket fuels.

Many of the characteristics of particulates are influenced to a major extent by the particle size. For this reason, particle size has been accepted as a primary basis for characterizing particulates. However, with anything but homogeneous spherical particles, the measured "particle size" is not necessarily a unique property of the particulate but may be influenced by the technique used. Consequently, it is important that the techniques used for size analysis be closely allied to the utilization phenomenon for which the analysis is desired.

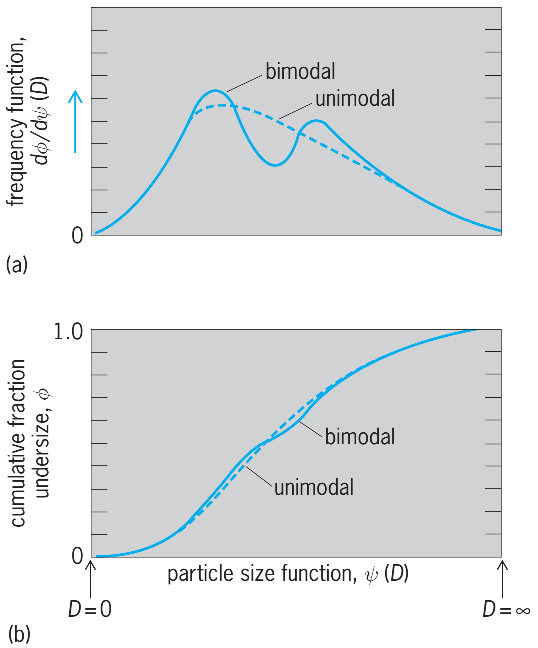
Size is generally expressed in terms of some representative, average, or effective dimension of the particle. The most widely used unit of particle size is the micrometer (μm). Another common method is to designate the screen mesh that has an aperture corresponding to the particle size. The screen mesh normally refers to the number of screen openings per unit length or area; several screen standards are in general use.

Particulate systems are often complex. Primary particulates may exist as loosely adhering (as by van der Waals forces) particles called floes or as strongly adhering (as by chemical bonds) particulates called agglomerates. Primary particles are those whose size can only be reduced by the forceful shearing of crystalline or molecular bonds. *See* Chemical bonding; Intermolecular forces.

Mechanical dispersoids are formed by comminution, decrepitation, or disintegration of larger masses of material, as by grinding of solids or spraying of liquids, and usually involve a wide distribution of particle sizes. Condensed dispersoids are formed by condensation of the vapor phase (or crystallization of a solution) or as the product of a liquid- or vapor-phase reaction; these

Types of particulate systems

System			Hydrosol	Aerosol	Powder
Continuous phase		Solid	Liquid	Gas	None (or gas)
Dispersed or particulate phase	Gas	Sponge	Foam	—	—
	Liquid	Gel	Emulsion	Mist Spray Fog Rain	—
	Solid	Alloy	Slurry Suspension	Fume Dust Snow Hail	Single phase
					Multi-phase (ores, flour)



Methods for representing size distribution. (*a*) Frequency distribution. (*b*) Cumulative distribution.

are usually very fine and often relatively uniform in size. Condensed dispersoids and very fine mechanical dispersoids generally tend to flocculate or agglomerate to form loose clusters of larger particle size.

Most real systems are composed of a range of particle sizes. The two common general methods for representing size distribution graphically are shown in the illustration. The frequency distribution (illus. *a*) gives the fraction of particles $d\phi$ (on whatever basis desired) that lie in a given narrow size range dD as a function of the average size of the range (or of some function of the average size). A cumulative distribution (illus. *b*) is the integral of the frequency curve. It gives the fraction ϕ of the particles that are smaller or larger than a given size D. *See* INTEGRATION; STATISTICS.

If a particle suspended in a fluid is acted upon by a force, it will accelerate to a terminal velocity at which the resisting force due to fluid friction just balances the applied force. If a particle falls under the action of gravity, this velocity is known as the terminal gravitational settling velocity.

Particles suspended in a fluid partake of the molecular motion of the suspending fluid and hence acquire diffusional characteristics analogous to those of the fluid molecules. This random zigzag motion of the particles, commonly known as brownian motion, is obvious under the microscope for particles smaller than 1 μm. *See* BROWNIAN MOVEMENT. [C.E.La.]

Pascal's law A law of physics which states that a confined fluid transmits externally applied pressure uniformly in all directions. More exactly, in a static fluid, force is transmitted at the velocity of sound throughout the fluid. The force acts normal to any surface. This natural phenomenon is the basis of the pneumatic fire, balloon, hydraulic jack, and related devices. *See* HYDROSTATICS. [K.Arn.; R.S.R.]

Paschen-Back effect An effect on spectral lines obtained when the light source is placed in a very strong magnetic field, first explained by F. Paschen and E. Back in 1921. In such a field the anomalous Zeeman effect, which is obtained with weaker fields, changes over to what is, in a first approximation, the normal Zeeman effect. The term "very strong field" is a relative one, since the field strength required depends on the particular lines being investigated. It must be strong enough to produce a magnetic splitting that is large compared to the separation of the components of the spin-orbit multiplet. *See* ATOMIC STRUCTURE AND SPECTRA; ZEEMAN EFFECT. [F.A.J./W.W.W.]

Passeriformes The largest and most diverse order of birds, which is found worldwide, including most oceanic islands but excluding Antarctica, in all terrestrial habitats. The most closely related species may be other land birds such as the Coraciiformes and the Piciformes. The Passeriformes is divided into the suborders: Eurylaimi, Furnarii, Tyranni, and Oscines. The affinities of most families within those suborders is still much disputed. *See* CORACIIFORMES; PICIFORMES.

The perching birds are small to medium-sized birds, ravens (*Corvus corax*) being the largest. The wings are short to medium in length and vary from rounded to pointed. A few species, including lyrebirds, scrubbirds, and New Zealand wrens, are almost flightless. The tail varies from nearly absent to long. The bill is widely variable in shape. Passeriforms have legs of short to medium length that are usually strong. The four toes show the usual avian arrangement, three in front and a well-developed hallux behind. Most forms can walk or climb well, or both. Plumage varies widely, from all black to mostly white and from bright colors and bold patterns to cryptic coloration.

Feeding habits and food choices show wide variation. Most species eat insects or small animals. Song is important to most perching birds for species recognition and courtship. The pair bond is usually strong, with both sexes incubating and caring for the young, which remain in the nest until they are able to fly. Many arctic and cold temperature passerine species migrate to warmer areas for the cold months. Some of the migratory flights measure several thousand miles. *See* AVES. [W.J.B.]

Passive radar A receive-only radar used for search, tracking, surveillance, identification, guidance, and mapping. The operation of passive radars depends upon the detection of microwave or infrared radiation from warm bodies. *See* INFRARED RADIATION; MICROWAVE; RADIOMETRY.

Many potential military targets radiate high noise power, such as ships at sea, exhaust from trucks, tanks, missiles, and airplanes, and factory chimneys. Unlike an active radar, a passive radar cannot determine the range to a target. However, using the high antenna directivity obtainable at microwave and infrared wavelengths, a passive radar can locate a source of radiation accurately in direction and discriminate between nearby targets.

A passive radar can track a target closely and be used to direct weapon fire toward it. A passive radar, mounted on a missile, can be used to home the missile in on a target by using just the pointing information provided by the radar. The power required to operate such a radar is quite small because there is no transmitter. Ground surveillance and mapping can be accomplished with an airborne ground scanner. This type of radar provides an infrared picture of the terrain and any targets which may be present. Radars of this type can often see through visual camouflage.

The absence of transmitted power makes the location, and even the existence, of a passive radar difficult to determine. Even if the position of a passive radar is known, its frequency cannot be determined; for this reason and because of the high angular resolution, it is difficult to jam. *See* RADAR. [C.L.Ru.]

Pasteurella A genus of gram-negative, nonmotile, nonsporulating, facultatively anaerobic coccobacillary to rod-shaped bacteria which are parasitic and often pathogens in many species of mammals, birds, and reptiles. It was named to honor Louis Pasteur in 1887. Genetic studies have shown that *Pasteurella*, together with *Haemophilus* and *Actinobacillus*, constitute a family, Pasteurellaceae.

The genus contains at least 10 species. *Pasteurella multocida* causes hemorrhagic septicemia in various mammals and fowl cholera, and is occasionally transmitted to humans, mainly in rural areas. Human pasteurellosis may include inflammation in bite and scratch lesions, infections of the lower respiratory tract and of the small intestine, and generalized infections with septicemia and meningitis. *Pasteurella canis* and *P. stomatis* may cause similar, though generally less severe, infections in humans after contact with domestic or wild animals. Although drug-resistant *Pasteurella* strains have been encountered, human *Pasteurella* infections are as a rule readily sensitive to the penicillins and a variety of other chemotherapeutic agents. *See* ANTIBIOTIC; DRUG RESISTANCE. [W.Ma.]

Pasteurellosis A variety of infectious diseases caused by the coccobacilli *Pasteurella multocida* and *P. haemolytica*; the term also applies to diseases caused by any *Pasteurella* species. All *Pasteurella* species occur as commensals in the upper respiratory and alimentary tracts of their various hosts. Although varieties of some species cause primary disease, many of the infections are secondary to other infections or result from various environmental stresses. *Pasteurella* species are generally extracellular parasites that elicit mainly a humoral immune response. Several virulence factors have been identified. *See* VIRULENCE.

Pasteurella multocida is the most prevalent species of the genus causing a wide variety of infections in many domestic and wild animals, and humans. It is a primary or, more frequently, a secondary pathogen of cattle, swine, sheep, goats, and other animals. As a secondary invader, it is often involved in pneumonic pasteurellosis of cattle (shipping fever) and in enzootic or mycoplasmal pneumonia of swine. It is responsible for a variety of sporadic infections in many animals, including abortion, encephalitis, and meningitis. It produces severe mastitis in cattle and sheep, and toxin-producing strains are involved in atrophic rhinitis, an economically important disease of swine. Hemorrhagic septicemia, caused by capsular type B strains, has been reported in elk and deer in the United States.

All strains of *P. haemolytica* produce a soluble cytotoxin (leukotoxin) that kills various leukocytes of ruminants, thus lowering the primary pulmonary defense. It is the principal cause of the widespread pneumonic pasteurellosis of cattle. Other important diseases caused by certain serotypes of *P. haemolytica* are mastitis of ewes and septicemia of lambs.

All of the *Pasteurella* species can be isolated by culturing appropriate clinical specimens on blood agar. Multiple drug resistance is frequently encountered. Treatment is effective if initiated early. Among the drugs used are penicillin and streptomycin, tetracyclines, chloramphenicol, sulphonamides, and some cephalosporins. Sound sanitary practices and segregation of affected animals may help limit the spread of the major pasteurelloses. Live vaccines and bacterins (killed bacteria) are used for the prevention of some. *See* PASTEURELLA. [G.R.Ca.]

Pasteurization The treatment of foods or beverages with mild heat, irradiation, or chemical agents to improve keeping quality or to inactivate disease-causing microorganisms. Originally, Louis Pasteur observed that spoilage of wine and beer could be prevented by heating them a few minutes at 122–140°F (50–60°C). Today pasteurization as a thermal treatment is applied to many foods. In foods consumed directly, destruction of pathogens to protect consumer health is paramount, while in products without public health hazards, control of spoilage microorganisms is primary. In fermentation processes, the raw material may be pasteurized to eliminate microorganisms that produce abnormal end products, or the final product may be heated to stop the fermentation at the desired level.

Milk and dairy products probably represent the most widespread use of pasteurization. Several time-temperature combinations have been approved as equivalent: 145°F (63°C) for 30 min; 161°F (72°C) for 15 s; 191°F (89°C) for 1 s; 194°F (90°C) for 0.5 s; 201°F (94°C) for 0.1 s; 204°F (96°C) for 0.05 s; or 212°F (100°C) for 0.01 s. These precise heat treatments are based on the destruction of the rickettsia *Coxiella burnetii*, which is considered the most heat-resistant nonsporeforming pathogen found in milk. Absolute control of the thermal treatment is essential for safety. Pasteurization of milk has successfully eliminated the spread of diseases such as diphtheria, tuberculosis, and brucellosis through contaminated milk. *See* DAIRY MACHINERY; FOOD MANUFACTURING; MALT BEVERAGE; MILK; WINE. [F.F.B.]

Patent Common designation for letters patent, which is a certificate of grant by a government of an exclusive right with respect to an invention for a limited period of time. A United States patent confers the right to exclude others from making, using, or selling the patented subject matter in the United States and its territories. Portions of those rights deriving naturally from it may be licensed separately, as the rights to use, to make, to have made, and to lease. Any violation of this right is an infringement.

An essential substantive condition which must be satisfied before a patent will be granted is the presence of patentable invention or discovery. To be patentable, an invention or discovery must relate to a prescribed category of contribution, such as process, machine, manufacture, composition of matter, plant, or design. In the United States there are different classes of patents for different members of these categories. [D.W.B.]

Paterinida A small extinct order of inarticulate brachiopods that ranges in age from Early Cambrian to Middle Ordovician. The shell is chitinophosphatic in composition, and its outline is circular or elliptical. The ventral (pedicle) valve is more convex than the dorsal (brachial) valve. The pedicle was absent or emerged between the valves. The muscle scars are unusual compared to other inarticulates, and form narrow triangular tracks radiating from the posterior extremity of each valve. Except for their shell composition and lack of articulation, the Paterinida resemble articulate brachiopods. Members were presumably epifaunal and sessile. *See* BRACHIOPODA; INARTICULATA. [M.W.F.]

Pathogen Any agent capable of causing disease. The term pathogen is usually restricted to living agents, which include viruses, rickettsia, bacteria, fungi, yeasts, protozoa, helminths, and certain insect larval stages. *See* DISEASE.

Pathogenicity is the ability of an organism to enter a host and cause disease. The degree of pathogenicity, that is, the comparative ability to cause disease, is known as virulence. The terms pathogenic and nonpathogenic refer to the relative virulence of the organism or its ability to cause disease under certain conditions. This ability depends not only upon the properties of the organism but also upon the ability of the host to defend itself (its immunity) and prevent injury. The concept of pathogenicity and virulence has no meaning without reference to a specific host. For example, gonococcus is capable of causing gonorrhea in humans but not in lower animals. *See* MEDICAL MYCOLOGY; MEDICAL PARASITOLOGY; PLANT PATHOLOGY; PLANT VIRUSES AND VIROIDS; VIRULENCE. [D.N.La.]

Pathology The study of the etiologies, mechanisms, and manifestations of disease. Techniques and knowledge gained from other disciplines, including anatomy, physiology, microbiology, biochemistry, and histology, are utilized. The information obtained from the study of pathology is necessary prior to developing methods with which to control and prevent disease.

With the light microscope it became possible to correlate the observed signs and symptoms in an individual with cellular changes. In its early stages pathology was very descriptive. Diseases were understood and categorized in part, by how gross and microscopic anatomy was altered. In the last half of the 19th century, by using this approach to pathology, coupled with microbiological techniques, it was learned that the major causes of human death were biotic agents: protozoans, bacteria, viruses, and fungi. Infectious diseases took a heavy toll in human lives. Better sanitation and public health measures were instrumental in controlling these diseases, and the production of antibiotics and immunization procedures further reduced their importance. It is now apparent that all diseases reflect changes at the molecular level. Scientists are beginning to understand what these biochemical alterations are in some diseases.

There are many branches of pathology. Divisions are made depending upon focus of interest. Clinical pathology is concerned with diagnosis of disease. As medicine has expanded, subspecialties such as surgical pathology and neuropathology have developed. Experimental pathology attempts to study disease mechanisms under controlled conditions. General pathology covers all areas, but in less detail, and serves in medical education.

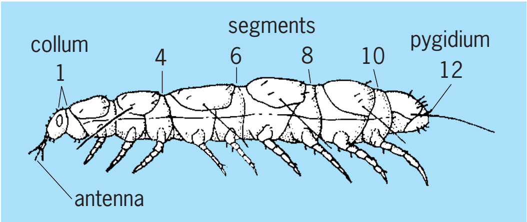
A relatively new area of pathology is environmental pathology, which deals with disease processes resulting from physical and chemical agents. At present, the leading causes of death have environmental agents as the known or suspected major etiologic factors; these diseases include heart disease, atherosclerosis, and cancer. It is believed that with understanding, many such diseases, like those produced in response to biotic agents, can be brought under control. *See* Disease. [N.K.M.; C.Qu.]

Pathotoxin A chemical of biological origin, other than an enzyme, that plays an important causal role in a plant disease. Most pathotoxins are produced by plant pathogenic fungi or bacteria, but some are produced by higher plants, and one has been reported to be the product of an interaction between a plant and a bacterial pathogen. Some pathogen-produced pathotoxins are highly selective in that they cause severe damage and typical disease symptoms only on plants susceptible to the pathogens that produce them. Others are nonselective and are equally toxic to plants susceptible or resistant to the pathogen involved. A few pathotoxins are species-selective, and are damaging to many but not all plant species. In these instances, some plants resistant to the pathogen are sensitive to its toxic product. *See* Plant pathology. [H.Wh.]

Pattern formation (biology) The mechanisms that ensure that particular cell types differentiate in the correct location within the embryo and that the layers of cells bend and grow in the correct relative positions. Pattern formation is one of four processes that underlie development, the others being growth, cell diversification, and morphogenesis. *See* Animal growth; Animal morphogenesis; Cell differentiation; Plant growth.

Pattern formation is the creation of a predictable arrangement of cell types in space during embryonic development. The types of patterns of cell types found in animals and plants can be conveniently described as simple or complex. Simple patterns involve the spatial arrangement of identical or equivalent structures such as bristles on the leg of a fly, hairs on a person's head, or leaves on a plant. Such equivalent patterns are thought to be produced by mechanisms that are the same or very similar in the fly and the plant. Complex patterns are those that are made up of parts that are not equivalent to one another. In the vertebrate limb, for example, the structure of the arm is different at each level, with one bone (humerus) in the upper arm, two bones (radius and ulna) in the lower arm, and a complex set of bones making up the wrist and the hand. How are such nonequivalent parts patterned during development? The theoretical framework that allows a basis for understanding how such patterns arise is called positional information. Two stages exist in the positional information framework. First, a cell must become aware of its position within a developing group, or field, of cells. This specification of cellular position requires a mechanism by which each cell within a field can obtain a unique value or address. The second component is the interpretation of the positional address by a cell to manifest a particular cell type by the expression of a particular set of genes. *See* Developmental biology; Embryonic differentiation. [N.Ho.]

Pauropoda A class, and perhaps the most obscure group, of the Myriapoda. They are pale creatures, no more than 0.04–0.08 in. (1–2 mm) in length, inhabiting damp situations in leaf litter, under bark, stones and debris, and in humus and similar detritus. Apparently very widely distributed as a class, they have been undiscovered only in deserts and in the arctic and antarctic regions.



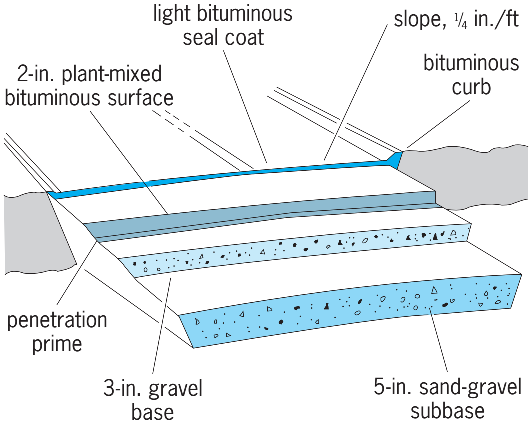
***Pauropus silvaticus*. (*After R. E. Snodgrass, A Textbook of Arthropod Anatomy, Cornell University Press, 1952*)**

Like millipedes, they are progoneate and have one pair of maxillae, and their trunk segments display a certain degree of amalgamation. Their peculiar bifurcate antennae and adult complement of 12 trunk segments with 9 pairs of functional legs are distinctive within the myriapod complex (see illustration). All pauropods lack eyes, spiracles, tracheae, and a circulatory system.

The class currently consists of 2 families with less than 10 genera; there are probably fewer than 60 species known. [R.E.Cr.]

Pavement An artificial surface laid over the ground to facilitate travel. A pavement's ability to support loads depends primarily upon the magnitude of the load, how often it is applied, the supporting power of the soil underneath, and the type and thickness of the pavement structure. Before the necessary thickness of a pavement can be calculated, the volume, type, and weight of the traffic (the traffic load) and the physical characteristics of the underlying soil must be determined.

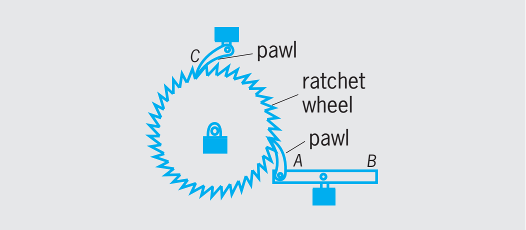
Once the grading operation has been completed and the subgrade compacted, construction of the pavement can begin. Pavements are either flexible or rigid. Flexible pavements, which are composed of aggregate (sand, gravel, or crushed stone) and



Flexible pavement design for a city collector street with maximum traffic load of 5 tons (4.5 metric tons) per axle. Right-of-way is 60 ft (18 m) wide and the pavement width is 38 ft (11.6 m). Berms or boulevards at the sides are sloped in order to drain toward the street. 1 in. = 2.5 cm.

bituminous material (see illustration), have less resistance to bending than do rigid pavements, which are made of concrete. Both types can be designed to withstand heavy traffic. Selection of the type of pavement depends, among other things, upon (1) estimated construction costs; (2) experience of the highway agency doing the work with each of the two types; (3) availability of contractors experienced in building each type; (4) anticipated yearly maintenance costs; and (5) experience of the owner in maintenance of each type. *See* Concrete; Highway engineering. [A.N.C.]

Pawl The driving link or holding link of a ratchet mechanism, also called a click or detent. In the illustration the driving pawl at *A*, forced upward by lever *B*, engages the teeth of the ratchet wheel and rotates it counterclockwise. Holding pawl *C* prevents clockwise rotation of the wheel when the pawl at *A* is making its return stroke, Pawl and ratchet are an open, upper pair.



Holding and driving pawls with a ratchet wheel.

Driving and holding pawls likewise engage rack teeth on the plunger of a ratchet lifting jack, such as those supplied with automobiles. A ratchet wheel with a holding pawl only, acting as a safety brake, is fastened to the drum of a capstan, winch, or other powered hoisting device.

A double pawl can drive in either direction or be easily reversed in holding. A cam pawl prevents the wheel from turning clockwise by a wedging action while permitting free counterclockwise rotation. This technique is used in the automobile hill-holder to prevent the vehicle's rolling backward. *See* Escapement. [D.P.Ad.]

Paxillosida An order of sea stars and members of the class Asteroidea. The name is derived from the club-shaped plates, or paxillae, that form the sea star's upper skeletal surface and that have tiny spinelets or granules covering their tips. Paxillosida encompasses six families, the largest being the Astropectinidae, Luidiidae, and Porcellanasteridae. The Ctenodiscidae, Goniopectinidae, and Radiasteridae are represented by comparatively few members. Astropectinids and luidiids are primarily predators of mollusks and other echinoderms. The former are found over a wide range of depths, whereas the latter live in relatively shallow water. Porcellanasterids are deep-water asteroids that swallow sediment in bulk as they bury themselves to a level just below the surface.

In addition to the presence of paxillae, paxillosidans are characterized by a number of unusual features that have been thought to indicate a primitive phylogenetic position among living asteroids. Although the tube feet of most asteroids have suckered disks, those of most paxillosidans are pointed. The digestive system of most asteroids is relatively complex and complete, terminating in an anus, whereas that of the paxillosidans is simple, saclike, and lacking an anus in some members. Most asteroids can extrude their stomach during feeding, but that ability is limited in paxillosidans. A brachiolarian larval stage has been recognized in the development of most asteroids, yet that stage is thought to be absent from paxillosidans. *See* Asteroidea; Echinodermata. [D.B.B.]

Pea The pea is one of the oldest cultivated crops. It is a native to western Asia from the Mediterranean Sea to the Himalaya Mountains. It appears to have been carried to Europe as early as the time of the lake dwellers of prehistoric times. Peas were introduced into China from Persia about A.D. 400; they were introduced into the United States in very early Colonial days.

Garden peas (*Pisum sativum*) have wrinkled seed coats at maturity when dry; field peas (*P. arvense*) have a smooth seed coat. Both types are annual leafy plants. Each leaf bears three pairs of leaflets and ends in a slender tendril. Five to nine round seeds are enclosed in a pod about 3 in. (7.5 cm) long. Seed color varies from white to cream, green, yellow, or brown. Smooth-seeded varieties may be harvested fresh for freezing or canning, or harvested dry as edible peas. Dry peas may be split or ground and prepared in various ways, such as for split-pea soup.

Wisconsin, Washington, Minnesota, Oregon, Illinois, New York, Pennsylvania, Utah, and Idaho lead in the production of peas harvested green. [K.J.M.]

Peach A deciduous fruit tree species (*Prunus persica*) that originated and was first cultivated in western China. It is adapted to relatively moderate climates in the temperate zone. Although most peach cultivars require a substantial amount of winter chilling (temperatures between 32 and 45°F, or 0–7°C) to ensure adequate breaking of winter dormancy and uniform budbreak, peach wood is susceptible to winter injury at temperatures below −15°F (−25°C) and dormant fruit buds are injured by temperatures below 0°F (−18°C). Consequently, commercial cultivation is limited to lower latitudes in the temperate zone or to higher latitudes where large bodies of water have a moderating influence on climate. The principal peach-growing regions in North America, ranked in order of commercial production, are central California, Georgia and the Carolinas, the mid-Atlantic region, the Great Lakes region, and the Pacific northwestern region. Other important peach-growing regions in the world include Italy, southern France, Spain, Japan, China, Argentina, southern Brazil, Chile, South Africa, and southeastern Australia. *See* Fruit; Fruit, tree; Rosales.

Peach cultivars can vary greatly and are usually distinguished by their fruit types. Peach fruits are covered with short epidermal trichomes called fuzz (smooth-skinned peaches are called nectarines) and at maturity are usually yellow or white with a red blush. The internal flesh is also yellow or white. Clingstone cultivars have a relatively firm flesh that adheres to the pit at maturity, and are primarily used for canning. Freestones usually have a softer flesh that separates from the pit at fruit maturity, and are primarily used for the fresh market, freezing, and drying. [T.M.DeJ.]

Peanut A self-pollinated, one- to six-seeded legume which is cultivated throughout the tropical and temperate climates of the world. The oil, expressed from the seed, is of high quality, and a large percentage of the annual world production is used for this purpose. In the United States some 65% goes into the cleaned and shelled trade, the end products of which are roasted or salted peanuts, peanut butter, and confections. *See* Rosales.

Botanically, peanuts may be divided into three main types, Virginia, Spanish, and Valencia, based on branching order and pattern and the number of seeds per pod. The USDA Marketing Standards includes an additional type, Runner, which refers to the small-seeded Virginia type produced in Georgia and Alabama. *See* Seed.

The peanut's most distinguishing characteristic is the yellow flower, which resembles a butterfly (papilionaceous) and is borne above ground. The pod, a one-loculed legume, splits under pressure along a longitudinal ventral suture. Pod size varies, and seed weight varies from 0.08 to 0.2 oz (0.2 to 5 g). The number of seeds per pod usually is two in the Virginia type, two or three in the Spanish, and three to six in the Valencia. *See* Legume. [A.Pe.]

Pear Any of approximately 20 species of deciduous tree fruits in the genus *Pyrus*. About half of the species are native to Europe, North Africa, and the Middle East around the Mediterranean Sea; the others are native to Asia. Pear culture is documented to have started as early as 1100 B.C. Pears are best adapted to temperate climates with warm, dry summers and cold winters. They require winter cold to break the dormant period but are injured by temperatures below −10 to −15°F (−23 to −26°C). Commercial pear production in the United States is concentrated in the interior valleys of California, Oregon, and Washington.

Nearly all United States pear production is of the European pear, *P. communis*. The Bartlett variety comprises over 75% of the United States pear crop. Other European pear varieties include d'Anjou, Bosc, Comice, Seckel, and Winter Nelis. The European pear is noted for its soft, juicy flesh. The skin color is medium green to yellow, depending on fruit maturity and the variety. Skin texture can be smooth or rough. Fruit shape ranges from the classic pear shape (round base with narrow neck) to a rounded oblong shape with no clearly defined neck area.

The crisp-fleshed Asian pear, *P. pyrifolia*, is the second most popular type of pear grown worldwide. The Asian pear is characterized by a crisp, juicy flesh that has a gritty texture, and has been referred to as the sand pear. The fruit shape is round, the skin color is generally yellow to amber at maturity, and the skin texture is smooth or corky. *Pyrus communis* and *P. pyrifolia* hybrids, such as Kieffer and Leconte, have been developed for limited commercial use in the southeastern United States. *Pyrus ussuriensis* has also been selected for Asian pear varieties. The snow pear, *P. nivalis*, is produced in Europe for cider and perry (a fermented liquor). *See* Fruit; Fruit, tree. [K.M.W.]

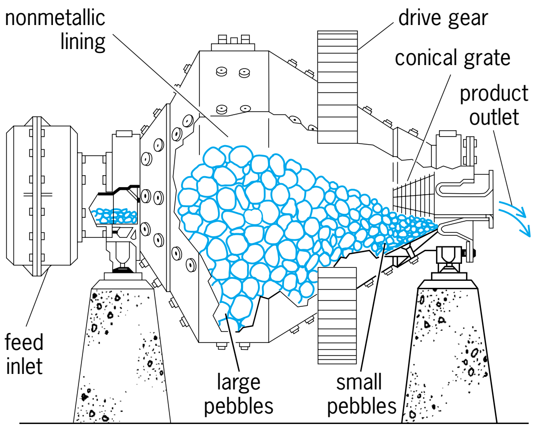
Pearl Any mollusk-formed calcareous concretion that displays an orient and is lustrous. There are two major groups of bivalved mollusks in which gem pearls may form: the saltwater pearl oyster (*Pinctada*), and a number of genera of freshwater clams. Usually, jewelers refer to salt-water pearls as Oriental pearls, regardless of their place of discovery, and to those from fresh-water bivalves as fresh-water pearls.

Between the body mass and the valves of the mollusk extends a curtainlike tissue called the mantle. In order for a pearl to form, a tiny object such as a parasite or a grain of sand must work through the mantle. When this happens, secretion of nacre around the invading object builds a pearl within the body of the mollusk. Whole pearls form within the body mass of the mollusk, in contrast to blister pearls, which form as protrusions on the inner surface of the shell. Edible oysters produce lusterless concretions, but never pearls.

The substitute for natural pearls, to which the name cultured pearl has been given, is usually made by inserting a large bead into a mollusk to be coated with nacre. [R.T.L.]

Peat A dark-brown or black residuum produced by the partial decomposition and disintegration of mosses, sedges, trees, and other plants that grow in marshes and other wet places. Forest-type peat, when buried and subjected to geological influences of pressure and heat, is the natural forerunner of most coal. Moor peat is formed in relatively elevated, poorly drained moss-covered areas, as in parts of Northern Europe. *See* Coal; Humus. [G.H.C.]

Pebble mill A tumbling mill that grinds or pulverizes materials without contaminating them with iron. Because the pebbles have lower specific gravity than steel balls, the capacity of a given size shell with pebbles is considerably lower than with steel balls. The lower capacity results in lower power consumption. The shell has a nonmetallic lining to further prevent iron contamination, as in pulverizing ceramics or pigments (see illustration). Selected hard pieces of the material being ground can be used as pebbles to further prevent contamination. *See* Tumbling mill. [R.M.H.]



Diagrammatic sketch of a conical pebble mill.

Pecan A large tree (*Carya illinoensis*) of the family Juglandaceae, and the nut from this tree. Native to valleys of the Mississippi River and tributaries as far north as Iowa, to other streams of Texas, Oklahoma, and northern and central Mexico, this nut tree has become commercially important throughout the southern and southwestern United States and northern Mexico. [R.H.S.]

Pectin A group of polysaccharides occurring in the cell walls and intercellular layers of all land plants. They are extractable with hot water, dilute acid, or ammonium oxalate solutions. Pectins are precipitated from aqueous solution by alcohol and are commercially used for their excellent gel-forming ability.

Commercially, the primary source of pectin is the peel of citrus fruits such as lemon and lime, although orange and grapefruit may be used. A secondary source is apple pomace and sunflower heads.

Pectin is widely used in the food industry, principally in the preparation of gels. It is used as a base for jelly and as a stabilizer in some dairy products and frozen desserts, such as sherbet, and also as edible protective coatings for sausages, almonds, candied dried fruit, and soft dates. *See* Gel; Polysaccharide. [R.L.Wh.; J.R.D.]

Pectolite A mineral inosilicate with composition $Ca_2NaSi_3O_8(OH)$. The hardness is 5 on Mohs scale, and the specific gravity is 2.75. The mineral is colorless, white, or gray with a vitreous to silky luster. Pectolite is found in the United States at Paterson, Bergen Hill, and Great Notch, New Jersey. *See* Silicate minerals. [C.S.Hu.]

Pediculosis Human infestation with lice. There are two biological varieties of the human louse, *Pediculus humanus*, var. *capitis* and var.*corporis*, each showing a strong preference for a specific location on the human body. *Pediculus humanus capitis* colonizes the head and *P. h. corporis* lives in the body-trunk region.

These lice are wingless insects which are ectoparasites. Their mouthparts are modified for piercing skin and sucking blood. The terminal segments of their legs are modified into clawlike structures which are utilized to grasp hairs and clothing fibers.

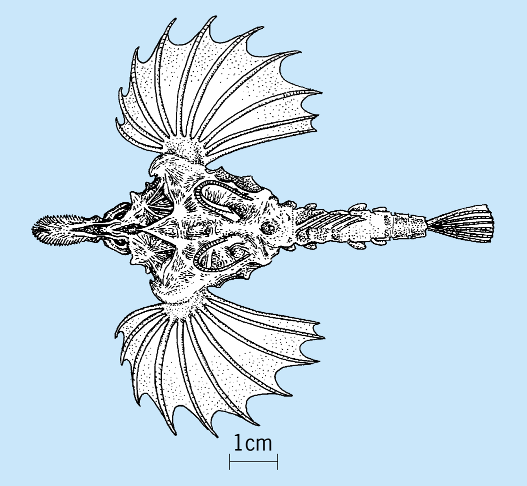
Lice are important vectors of human diseases. Their habit of sucking blood and their ability to crawl rapidly from one human to another transmit such diseases as typhus (rickettsial) and epidemic relapsing fever (spirochetal). The body fluids and feces of infected lice transmit these diseases. [R.Su.]

Pedinoida An order of Diadematacea, making up those genera which possess solid spines and a rigid test. The ambulacra show typical diadematoid structure, and the tubercles are noncrenulate. The single known family, Pedinidae, includes 15 genera, ranging from the Late Triassic onward, though only one genus, *Caenopedina*, survives today. *See* DIADEMATACEA. [H.B.F.]

Pedology Defined narrowly, a science that is concerned with the nature and arrangement of horizons in soil profiles; the physical constitution and chemical composition of soils; the occurrence of soils in relation to one another and to other elements of the environment such as climate, natural vegetation, topography, and rocks; and the modes of origin of soils. Pedology so defined does not include soil technology, which is concerned with uses of soils.

Broadly, pedology is the science of the nature, properties, formation, distribution, and function of soils, and of their response to use, management, and manipulation. The first definition is widely used in the United States and less so in other countries. The second definition is worldwide. *See* SOIL; SOIL MECHANICS. [R.W.S.]

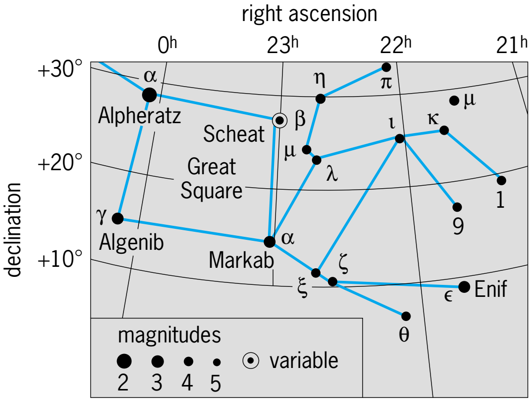
Pegasiformes The sea moths or sea dragons, a small order of peculiar actinopterygian fishes also known as the Hypostomides. The body is encased in a broad, bony framework anteriorly and has bony rings posteriorly, simulating the seahorses and pipefishes (see illustration). Unlike those fishes, which have the mouth at the tip of the produced snout, sea moths have enlarged nasal bones which form a rostrum that projects well forward of the small, toothless mouth. The greatly expanded horizontal pectoral fin belies its appearance and does not function in aerial gliding. The pelvic fin is abdominal and consists of a slender spine and one or two long rays. The short, opposed dorsal and anal fins have no spines. There is no swim bladder. *See* GASTEROSTEIFORMES.



Sea moth (*Pegasus draconis*). (*After D. S. Jordan and J. O. Snyder, vol. 24, Leland Stanford University Contributions to Biology, 1901*)

There is a single family, Pegasidae, with one genus, *Pegasus*, and four or five species. They live amidst vegetation on Indo-Pacific shores from East Africa to Japan, Australia, and Hawaii. There is no fossil record. *See* ACTINOPTERYGII. [R.M.B.]

Pegasus The Winged Horse, in astronomy, an autumnal constellation. Pegasus is usually identified by the four bright stars α, β, γ, and α (Alpha Andromedae) situated on the corners of a large square known as the Great Square in Pegasus (see illustration). The star Alpheratz at the northeastern corner of the square is really in the constellation Andromeda. *See* CONSTELLATION. [C.-S.Y.]



Line pattern of the constellation Pegasus. The grid lines represent the coordinates of the sky. The apparent brightness, or magnitude, of the stars is shown by the sizes of the dots, graded by appropriate numbers.

Pegmatite Exceptionally coarse-grained and relatively light-colored crystalline rock composed chiefly of minerals found in ordinary igneous rocks. Extreme variations in grain size also are characteristic, and close associations with dominantly fine-grained aplites are common. Pegmatites are widespread and very abundant where they occur, especially in host rocks of Precambrian age, but their aggregate volume in the Earth's crust is small. Many pegmatites have been economically valuable as sources of clays, feldspars, gem materials, industrial crystals, micas, silica, and special fluxes, as well as beryllium, bismuth, lithium, molybdenum, rare-earth, tantalumniobium, thorium, tin, tungsten, and uranium minerals. *See* APLITE; IGNEOUS ROCKS.

Essential minerals (1) in granitic pegmatities are quartz, potash feldspar, and sodic plagioclase; (2) in syenitic pegmatites, alkali feldspars with or without feldspathoids; and (3) in diorite and gabbro pegmatities, soda-lime or lime-soda plagioclase. Varietal minerals such as micas, amphiboles, pyroxenes, black tourmaline, fluorite, and calcite further characterize the pegmatites of specific districts. Accessory minerals include allanite, apatite, beryl, garnet, magnetite, monazite, tantalite-columbite, lithium tourmaline, zircon, and a host of rarer species. [R.H.J.]

Pelecaniformes A small order of diverse aquatic, mainly marine, fish-eating birds that includes the pelicans, boobies, and cormorants. The members of the order, which is found worldwide, are very different, and some researchers believe that it is an artificial group; however, all members are characterized by several unique features. There are nine families (six living and three fossil) of the order Pelecaniformes. The living families include Phaethontidae (tropic birds; 3 species), Pelecanidae (pelicans; 8 species), Sulidae (boobies, gannets; 9 species), Phalacrocoracidae (cormorants; 33 species), Anhingidae (anhingas; 4 species), and Fregatidae (frigate birds; 5 species).

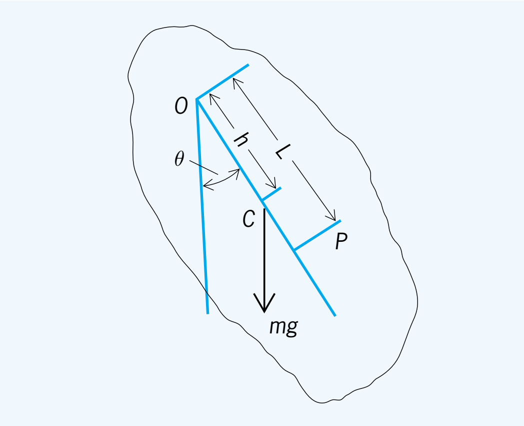
The pelecaniforms are medium-sized to large marine birds that were characterized by a foot with four toes united in a common web (totipalmate). The legs are short and stout or weak, and they are used for swimming and perching. The birds are poor walkers, but all living forms—with the exception of the flightless Galápagos cormorant—are excellent fliers, particularly the frigate birds. The bill varies widely in size and shape, from the short, stout bill of tropical birds to the long, hooked bill of frigate birds and the long, flat, flexible bill of pelicans. All species have a bare throat pouch; the largest such pouch is found in the pelicans, which use it as a fishing net. The plumage is black, gray, or white. All pelecaniforms feed on fish, crustaceans, and squid that are caught by diving from the air or the water surface, taken from the water surface, or stolen from other birds. *See* AVES. [W.J.B.]

Pelmatozoa A division of the Echinodermata made up of those forms which are anchored to the substrate during at least a part of the life history. Formerly treated as a formal unit of classification with the rank of subphylum, pelmatozoans are now realized to be a heterogeneous assemblage of forms with similar habits but dissimilar ancestry, their common features having arisen by convergent evolution. Most pelmatozoan echinoderms are members of the subphylum Crinozoa, but some echinozoans also exhibit a sedentary, anchored life, with modifications for such existence. *See* CRINOZOA; ECHINODERMATA; ECHINOZOA; ELEUTHEROZOA. [H.B.F.]

Peltier effect A phenomenon discovered in 1834 by J. C. A. Peltier, who found that at the junction of two dissimilar metals carrying a small current the temperature rises or falls, depending upon the direction of the current. In view of experiments, which establish that the rate of intake or output of heat is proportional to the magnitude of the current, it can be shown that an electromotive force resides at a junction. Electromotive forces of this type are called Peltier emf's. *See* SEEBECK EFFECT; THERMOELECTRICITY; THOMSON EFFECT. [J.W.St.]

Pelycosauria An extinct order of primitive, mammallike reptiles of the subclass Synapsida. They are characterized by a temporal fossa that lies low on the side of the skull. The group is known from rocks of the Upper Carboniferous and lower and middle Permian. Three suborders are included: Ophiacodonta, Edaphosauria, and Sphenacodontia. Late in the early Permian the sphenacodonts gave rise to more advanced mammallike reptiles, the therapsids. *See* SYNAPSIDA; THERAPSIDA. [E.C.O.]

Pendulum A rigid body mounted on a fixed horizontal axis, about which it is free to rotate under the influence of gravity. The period of the motion of a pendulum is virtually independent of its amplitude and depends primarily on the geometry of the pendulum and on the local value of g, the acceleration of gravity. Pendulums have therefore been used as the control elements in clocks, or inversely as instruments to measure g.



Schematic diagram of a pendulum. *O* represents the axis, *C* is the center of mass, and *P* the center of oscillation.

Motion. In the schematic representation of a pendulum shown in the illustration, O represents the axis and C the center of mass. The line OC makes an instantaneous angle θ with the vertical. In rotary motion of any rigid body about a fixed axis, the angular acceleration is equal to the torque about the axis divided by the moment of inertia I about the axis. If m represents the mass of the pendulum, the force of gravity can be considered as the weight mg acting at the center of mass C.

If the amplitude of motion is small, the motion is simple harmonic. The period T, time for a complete vibration (for example, from the extreme displacement right to the next extreme displacement right), is given by Eq. (1). *See* HARMONIC MOTION.

$$T = 2\pi\sqrt{I/mgh} \tag{1}$$

The actual form of a pendulum often consists of a long, light bar or a cord that serves as a support for a small, massive bob. The idealization of this form into a point mass on the end of a weightless rod of length L is known as a simple pendulum. An actual pendulum is sometimes called a physical or compound pendulum. In a simple pendulum the lengths h and L become identical, and the moment of inertia I equals mL^2. Equation (1) for the period becomes Eq. (2).

$$T = 2\pi\sqrt{L/g} \tag{2}$$

Center of oscillation. Equation (2) can be used to define the equivalent length of a physcal pendulum. Comparison with Eq. (1) shows that Eq. (3) holds. The point P on line OC of the

$$L = I/mh \tag{3}$$

illustration, whose distance from the axis O equals L, is called the center of oscillation. Points O and P are reciprocally related to each other in the sense that if the pendulum were suspended at P, O would be the center of oscillation.

Types. Kater's reversible pendulum is designed to measure g, the acceleration of gravity. It consists of a body with two knife-edge supports on opposite sides of the center of mass as at O and P (and with at least one adjustable knife-edge). If the pendulum has the same period when suspended from either knife-edge, then each is located at the center of oscillation of the other, and the distance between them must be L, the length of the equivalent simple pendulum. The value for g follows from Eq. (2).

The ballistic pendulum is a device to measure the momentum of a bullet. The pendulum bob is a block of wood into which the bullet is fired. The bullet is stopped within the block and its momentum transferred to the pendulum. This momentum is determined from the amplitude of the pendulum swing. *See* BALLISTICS.

The spherical pendulum is a simple pendulum mounted on a pivot so that its motion is not confined to a plane. The bob then moves over a spherical surface. A Foucault pendulum is a spherical pendulum suspended so that its plane of oscillation is free to rotate. Its purpose is to demonstrate the rotation of the Earth. *See* FOUCAULT PENDULUM; SCHULER PENDULUM. [J.M.Ke.]

Penicillin One of the beta-lactam antibiotics, all of which possess a four-ring beta-lactam structure fused with a five-membered thiazolidine ring. These antibiotics are nontoxic and kill sensitive bacteria during their growth stage by the inhibition of biosynthesis of their cell wall mucopeptide. *See* PLANT CELL.

The antibiotic properties of penicillin were first recognized by A. Fleming in 1928 from the serendipitous observation of a mold, *Penicillium notatum*, growing on a petri dish agar plate of a staphylococcal culture. The mold produced a diffuse zone which lysed the bacterial cells. Commercial production of penicillin came from the pioneer work of E. Chain and H. W. Florey in 1938. Penicillin (as penicillin G) was made available to the allied troops in Europe in the latter part of World War II.

Penicillin is produced from the fungal culture *P. chrysogenum* that was isolated from a moldy cantaloupe. The biosynthesis of penicillin is known in detail, and all the enzymes involved in the formation of this secondary metabolite have been isolated and purified.

The fermented penicillin G and penicillin V are susceptible to destruction by an enzyme (beta-lactamase) produced by certain bacteria which makes them resistant. The penicillins methicillin, oxacillin, nafcillin, cloxacillin and dicloxacillin are resistant to hydrolysis by beta-lactamases and are used to treat staphylococcal infections. Cloxacillin and dicloxacillin are used orally. Ampicillin and amoxicillin are penicillins with extended spectra, and they are effective against many gram-negative bacteria. They are used mainly orally against streptococci and other respiratory-tract pathogens, including *Haemophilus influenzae*, in the treatment of sinusitis, bronchitis, and pneumonia. They are used extensively in pediatrics and against *Listeria monocytogenes* and *Salmonella* spp. *See* ANTIBIOTIC; DRUG RESISTANCE; SALMONELLOSES; STREPTOCOCCUS.

Penicillin G, the most commonly fermented penicillin, is produced by the addition of a precursor, phenylacetic acid, to the growing culture. Use of phenoxyacetic acid as a precursor produces penicillin V. Both penicillins are recovered by extraction into organic solvents at acid pH, and precipitation as their potassium or sodium salt. Penicillin G is generally given by injection against penicillin-sensitive streptococci such as pneumococci (meningitis), and in treatment of endocarditis and gonorrhea. Penicillin V is acid stable and is usually given orally. It is effective in the treatment of upper respiratory infections and periodontal work. *See* GONORRHEA; MENINGITIS. [D.A.Lo.]

Penis The male organ of copulation, or phallus. In mammals the penis consists basically of three elongated masses of erectile tissue. The central corpus spongiosum (corpus urethrae) lies ventral to the paired corpora cavernosa. The urethra runs along the underside of the spongiosum and then normally rises to open at the expanded, cone-shaped tip, the glans penis, which fits like a cap over the end of the penis. Loose skin encloses the penis and also forms the retractable foreskin, or prepuce.
