Polyethylene has been produced at pressures in the ranges 3–4, 20–30, 40–60, and 1000–3000 atm. The last is probably the highest pressure yet used in the commercial synthesis of an organic chemical product. The ethylene is polymerized in a stainless steel tubular reactor at 375°F (191°C) with small amounts of oxygen as a catalyst.

Phenol can be formed from chlorobenzene mixed with 18% sodium hydroxide solution at a pressure of 330 atm. Pressure is employed in this instance to maintain the mixture in the liquid phase at a temperature high enough for the hydrolysis reaction to proceed at an acceptable rate.

Hydrocracking and hydrodesulfurization in the refining of gasoline and fuel oils are carried out at pressures up to 200 atm and temperatures of 800°F (427°C) and higher. *See* HYDROCRACKING; HYDROGENATION. [E.W.C.]

High-temperature chemistry The study of chemical phenomena occurring above 500 K (227°C or 440°F). High temperatures represent one of the important variables available to scientists for increasing the variety of possible chemical reactions over that expected for classical ground-state atoms and molecules. The relative population of excited rotational, vibrational, and electronic states can be enhanced by increasing the temperature and thus can effectively create new species and new mechanisms for reaction. The potentialities of this approach are well illustrated by the three laws of high-temperature chemisty: (1) At high temperatures everything reacts with everything. (2) The higher the temperature, the faster the reaction. (3) The products may be anything.

High temperatures also provide a common tie among the various options for energy production, conversion, or storage. For maximum thermodynamic efficiency, an energy production cycle should operate with a working fluid at as high a temperature as possible, and exhaust the spent fluid at as low a temperature as possible. Thus, in the combustion of coal to produce electric power or in the combustion of gasoline or diesel fuel to propel a car or an airplane, there is a need for materials of construction which allow operation of such devices at higher temperatures. *See* HIGH-TEMPERATURE MATERIALS.

It is convenient to discuss temperatures in terms of energy and to note that 11,500 K (20,200°F) corresponds to 1 electronvolt. In this sense, the particles emitted by radioactive nuclei or accelerated in cyclotrons and synchrotrons, which have energies in the keV, MeV, and BeV ranges, are effectively at temperatures of $\sim 10^7$ K, $\sim 10^{10}$ K, and $\sim 10^{13}$ K, respectively, and "high-energy physics" is synonymous with "ultra-high-temperature chemistry."

Traditional high-temperature chemistry in the last several decades has been mainly concerned with phenomena in the range of 500–3000 K, although exotic flames can produce temperatures up to $\sim$6000 K, shock waves can generate temperatures up to $\sim$25,000 K, electric arcs can be operated in constricted modes to produce temperatures of $\sim$50,000 K, and nuclear processes begin to occur at temperatures in the millions-of-degrees range. Laser excitation of selected energy states can produce species with effective temperatures in the range of 10^8 K. [J.L.M.]

High-temperature materials A metal or alloy which serves above about 1000°F (540°C). More specifically, the materials which operate at such temperatures consist principally of some stainless steels, superalloys, refractory metals, and certain ceramic materials. The giant class of alloys called steels usually see service below 1000°F. The most demanding applications for high-temperature materials are found in aircraft jet engines, industrial gas turbines, and nuclear reactors. However, many furnaces, ductings, and electronic and lighting devices operate at such high temperatures.

In order to perform successfully and economically at high temperatures, a material must have at least two essential characteristics: it must be strong, since increasing temperature tends to reduce strength, and it must have resistance to its environment, since oxidation and corrosion attack also increase with temperature. *See* CORROSION; HIGH-TEMPERATURE CHEMISTRY.

High-temperature materials, always vital, have acquired an even greater importance because of developing crises in providing society with sufficient energy. The machinery which produces electricity or some other form of power from a heat source operates according to the basic Carnot cycle law, where the efficiency of the device depends on the difference between its highest operating temperature and its lowest temperature. Thus, the greater this difference, the more efficient is the device—a result giving great impetus to create materials that operate at very high temperatures. *See* CARNOT CYCLE; EFFICIENCY. [C.T.S.]

Highway engineering A branch of civil engineering that includes planning, design, construction, operation, and maintenance of roads, bridges, and related infrastructure to ensure effective movement of people and goods. *See* CIVIL ENGINEERING.

Highway planning involves the estimation of current and future traffic volumes on the road network. For purposes of design, traffic volumes are needed for a representative period of traffic flow. The capacity is the maximum theoretical traffic flow rate that a highway section is capable of accommodating under a given set of environmental, highway, and traffic conditions. The capacity of a highway depends on factors such as the number of lanes, lane width, effectiveness of traffic control systems, frequency and duration of traffic incidents, and efficiency of collection and dissemination of highway traffic information. Traffic conditions arising from the interplay of volume and capacity are perceived by road users in a way that is quantitatively termed level of service. *See* TRAFFIC-CONTROL SYSTEMS.

Highway facilities often cause adverse effects on the environment, such as noise pollution, air pollution, water pollution, and ecological impacts. Tire/pavement interaction, vehicle exhausts, and engines cause traffic noise. Highway engineers strive to predict and mitigate all possible impacts of highway systems. *See* AIR POLLUTION.

Through highway design, the most appropriate location, alignment, and shape of the highway are selected. Highway design involves the consideration of three major factors (human, vehicular, and roadway) and how these factors interact to provide a safe highway. Human factors include reaction time for braking and steering, visual acuity for traffic signs and signals, and car-following behavior. Vehicle considerations include vehicle size and dynamics that are essential for determining lane width and maximum slopes, and for the selection of design vehicles. Engineers design road geometry to ensure stability of vehicles when negotiating curves and grades and to provide adequate sight distances for undertaking passing maneuvers along curves on two-lane, two-way roads.

Location involves fitting the road efficiently onto the surrounding terrain and environment. Horizontal alignment is represented by an aerial view of the highway. It consists of straight lines and curves. Curves are fitted to provide a smooth transition between straight highway sections.

Intersections and interchanges occur where two or more highways cross each other at the same level. Since various vehicle maneuvers (turning, crossing, and through movements) all occur within a limited area as the volumes of these movements increase, there is increased likelihood of traffic conflicts and crashes. One way of reducing such danger is to use channelization to limit each stream to a unique path. In high traffic volume areas, movement of streams can be separated in time using multiphased traffic signals. The vertical alignment of a highway is represented by its longitudinal profile, which gives the elevation of all points along the length of the highway. The purpose of vertical alignment design is to determine the level of the highway at each point in order to ensure adequate safety and drainage.

Highway cross section refers to the profile of the road, perpendicular to the direction of travel and extending to the limits of the right of way within which the facility is constructed. Highway cross-section elements may include driving lanes, bicycle/pedestrian lanes, shoulders, medians, barriers, cross slope for drainage, and superelevation.

Pavement design is the process of selecting pavement layer types and thicknesses in order to withstand expected traffic loads in a cost-effective manner. Each pavement layer usually consists of mineral aggregates such as natural river or pit sand, natural gravel, and crushed rock. For rigid pavements, portland cement is mixed with water and aggregates to produce a viscous concrete mix that is poured into prepared forms and vibrated. *See* CEMENT.

There are generally three types of pavements specified for pavement design. Gravel pavement is the simplest type of pavement and is often designed for lightly traveled roads. Flexible pavement is a multilayered structure that includes a subbase, a base, and an asphaltic wearing course. Rigid pavement consists of a plain or steel-reinforced portland cement concrete slab laid on a prepared crushed-stone base course. *See* GRAVEL; PAVEMENT; PRECAST CONCRETE.

Highway construction usually follows planning and design, and involves new or reconstructed facilities such as pavements, drainage structures, and traffic control devices. Road construction is often preceded by detailed stakeout surveys and preparation of the subgrade. *See* CONSTRUCTION ENGINEERING; CONSTRUCTION EQUIPMENT.

Traffic signals are the most important traffic control devices. The typical traffic signal for an intersection displays a sequence of green, amber, and red. One complete signal sequence is called a cycle. Traffic signals are either pretimed or demand-actuated. Flow-concentration controllers are capable of sensing detailed demand information and responding to it by revising the cycle length and phasing patterns of the signal.

The performance of highway infrastructure is measured in terms of pavement and bridge condition, level of service, and safety. Pavement condition is monitored over a period of time using a condition index or serviceability rating. Through the development and implementation of bridge management systems, many agencies have in place a decision support tool that supplies analyses and summaries of data, uses mathematical models to make predictions of bridge conditions, and provides the means by which alternative policies and programs may be efficiently evaluated. Congestion management is maintained by implementing measures to mitigate the magnitude and duration of traffic congestion. Safety management is a systematic process that has the goal of reducing the number and severity of traffic crashes by ensuring that all opportunities and identified, considered, implemented as appropriate, and evaluated in all phases of highway planning design, construction, maintenance, and operation. *See* BRIDGE. [K.C.S.; S.Lab.]

Hilbert space

Hilbert space is an abstract notion of great power and beauty which has been central to the development of mathematical analysis and forms the backdrop for many applications of analysis to science and engineering. Its essence lies in the fact that the objects of primary interest in analysis (namely, functions) enjoy geometrical properties which are in important ways analogous to the geometry of physical space. Thus the highly developed human visual and spatial intuition can lead to significant truths about functions. *See* EUCLIDEAN GEOMETRY.

Generalizations of euclidean space. Vectors (or directed line segments) in euclidean space have a rich structure. If certain of the desirable properties of euclidean space are isolated and adopted as postulates, a class of spaces is defined that may include spaces of functions that are of concern in analysis. During the early decades of the twentieth century it was gradually realized that it is possible to select a small number of properties in such a way that the resulting spaces possess virtually all the desirable features of euclidean space except those which are closely linked to finite dimensionality. These spaces are named after David Hilbert, who took a decisive step toward their introduction in 1906 when he proved the spectral theorem.

Role of Hilbert space. Hilbert's innovation occurred while he was investigating integral equations which arose from mathematical physics. These equations are continuous analogs of the systems of simultaneous linear equations which are encountered in elementary algebra, but the unknown entity, instead of being a finite set of numbers, is a function. Just as graphical methods give insight into the solution of a pair of simultaneous linear equations in two unkowns, so the development of Hilbert-space geometry had great consequences for the understanding of integral equations. Hilbert space is a truly fundamental mathematical structure which appears in widely disparate branches of pure and applied mathematics. A striking instance is quantum mechanics, where observable quantities are modeled by linear transformations of Hilbert space. *See* INTEGRAL EQUATION; LINEAR SYSTEMS OF EQUATIONS; OPERATOR THEORY; QUANTUM MECHANICS. [N.J.Y.]

Hill and mountain terrain

Land surfaces characterized by roughness and strong relief. The distinction between hills and mountains is usually one of relative size or height, but the terms are loosely and inconsistently used.

Uplift of the Earth's crust is necessary to give mountain and hill lands their distinctive elevation and relief, but most of their characteristic features—peaks, ridges, valleys, and so on—have been carved out of the uplifted masses by streams and glaciers. Hill lands, with their lesser relief, indicate only lesser uplift, not a fundamentally different course of development. The features of hill and mountain lands are chiefly valleys and divides produced by sculpturing agents, especially running water and glacier ice. Local peculiarities in the form and pattern of these features reflect the arrangement and character of the rock materials within the upraised crustal mass that is being dissected.

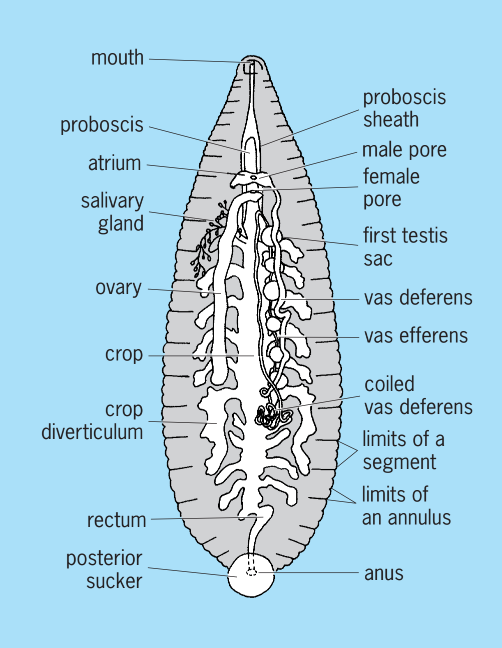
Hill and mountain terrain occupies about 36% of the Earth's land area. The greater portion of that amount is concentrated in the great cordilleran belts that surround the Pacific Ocean, the Indian Ocean, and the Mediterranean Sea. Additional rough terrain, generally low mountains and hills, occurs outside the cordilleran systems in eastern North and South America, northwestern Europe, Africa, and western Australia. Eurasia is the roughest continent, more than half of its total area and most of its eastern portion being hilly or mountainous. Africa and Australia lack true cordilleran belts. The broad-scale pattern of crustal disturbance, and hence of rough lands, is now known to be related to the relative movements of a worldwide system of immense crustal plates. *See* MOUNTAIN; PLATE TECTONICS. [E.H.Ha.]

Hippopotamus The name for two species of even-toed (artiodactylid) ungulates which form the family Hippopotamidae. Both species occur in Africa; the great African hippopotamus (*Hippopotamus amphibius*) inhabits the rivers of tropical Africa, and the pygmy hippopotamus (*Choeropsis liberiensis*) lives near the rivers of western Africa but is more terrestrial.

The great African hippopotamus is the largest living artiodactylid. The ears are small and flexible, and the nostrils and eyes protrude so that they are out of the water as the animal floats. The skin is almost devoid of hair. The feet end in four toes enclosed in round hoofs. The pygmy hippopotamus is about the size of a large pig and is a more solitary species and does not live in large herds, as does the common species.

These animals migrate regularly, following the river upstream during the rainy season and downstream during the dry season to new pastures. They come onto land, especially at night, to feed on vegetation. The males of the common species occupy and maintain territories within which are small herds of females and juveniles. *See* ARTIODACTYLA. [C.B.C.]

Hirudinea A class of the annelid worms commonly known as leeches. These organisms are parasitic or predatory and have terminal suckers for attachment and locomotion. Most inhabit inland waters, but some are marine and a few live on land in damp places. The majority feed by sucking the blood of other animals, including humans.



General structure of a leech. Male reproductive system Is shown on the right, the female on the left. (*After K. H. Mann, A key to the British freshwater leeches, Freshwater Blol. Ass. Scl. Publ., 14:3–21, 1954*)

Leeches differ from other annelids in having the number of segments in the body fixed at 34, chaetae or bristles lacking, and the coelomic space between the gut and the body wall filled with packing tissue (see illusration). In a typical leech the first six segments of the body are modified to form a head, bearing eyes, and a sucker, and the last seven segments are incorporated into a posterior sucker.

The mouth of a leech opens within the anterior sucker, and there are two main methods of piercing the skin of the host to obtain blood: an eversible proboscis or three jaws, each shaped like half a circular saw, placed just inside the mouth. The process of digestion is very slow, and a meal may last a leech for 9 months. The carnivorous forms have lost most or all of their gut diverticula and resemble earthworms in having a straight, tubular gut. Leeches are hermaphroditic, having a single pair of ovaries and several pairs of testes.

The importance of leeches as a means of making incisions for the letting of blood or the relief of inflammation is declining, and in developed countries the bloodsucking parasites of mammals are declining, because of lack of opportunity for contact with the hosts. In other countries they are still serious pests. *See* ARHYNCHOBDELLAE; RHYNCHOBDELLAE. [K.H.M.]

Histamine A biologically active amine that is formed by the decarboxylation of the amino acid histidine. It is widely distributed in nature and is found in plant and animal tissues as well as in insect venoms. In humans, histamine is a mediator of inflammatory reactions, and it functions as a stimulant of hydrochloric acid secretion in the stomach.

Most tissue histamine is found stored in mast cells, where it can be released by a variety of stimuli. Once released, it can cause many effects, including constriction of bronchiolar, gastrointestinal, uterine smooth muscle, and lowering of blood pressure. If histamine is released in the skin, itching, a flare (area of redness) due to vasodilation, and a wheal due to leaking of fluid into the tissue are observed. The increase in vascular permeability that permits this leakage is due to an action on the endothelial cells of postcapillary venules.

All of these actions of histamine are mediated by the activation of histamine receptors, designated either H-1 or H-2. Antihistamine drugs exert their effects by blocking the combination of histamine with these receptors. *See* ANTIHISTAMINE.

Histamine release can be caused by tissue injury, by physical stimuli such as cold or pressure, by drugs such as heroin, and most importantly by immunologic mechanisms. Mast cells in the skin, the lung, the nasal passages, or other sites may become sensitized to antigens such as ragweed or other pollens, and then release histamine and other biologically active substances upon exposure to them. The released histamine may then cause the effects commonly associated with allergic responses. If the allergic reaction becomes generalized and severe, life-threatening anaphylactic shock may ensue. The prompt administration of epinephrine, which exerts effects opposite to those of histamine, can be life-saving in such cases. *See* ALLERGY; ANTIGEN; EPINEPHRINE; HYPERSENSITIVITY; IMMUNOLOGY. [A.Bu.]

Histocompatibility A term used to describe the genes that influence acceptance or rejection of grafts. When grafts of tissue are exchanged between genetically dissimilar individuals, profound immunological rejection generally takes place. In contrast, grafts between genetically similar individuals, such as identical twins, are normally tolerated; they are histocompatible. Most known examples of histocompatibility (or H) genes encode polymorphic (that is, tending to differ between individuals) cell-surface proteins.

The major histocompatibility complex (MHC) contains a set of histocompatibility genes, termed major because mismatching at these genes invokes rapid rejection. The main function of MHC genes involves distinguishing self from nonself in the immune system, as part of preventing the spread of infectious disease. The body employs special mechanisms to avoid rejection of the fetus, which is effectively an allograft, that is, a graft from a donor to a genetically dissimilar recipient of the same species; in this case, the mechanisms include a diminution of MHC gene expression.

The MHC contains a spectrum of genes, many of which influence processing and presentation of antigens to the immune system. In mice, the MHC is designated the H-2 complex; in humans, it is referred to as the HLA complex (for human leukocyte A system). Mice and other mammals seem to have a similar arrangement of genes in their MHCs. *See* ANTIGEN; CELLULAR IMMUNOLOGY; MENDELISM; TRANSPLANTATION BIOLOGY. [J.Tr.]

Histogenesis The developmental processes by which the definite cells and tissues which make up the body of an organism arise from embryonic cells. Among animals, the ectoderm, endoderm, and mesoderm, also known as the primary germ layers, provide the stem cells which gradually transform into distinctive kinds of cells and tissues. In the higher plants, meristematic cells, which occur wherever extensive growth takes place, provide the basis for tissue formation. *See* APICAL MERISTEM; EMBRYOLOGY; GERM LAYERS; HISTOLOGY; LATERAL MERISTEM. [C.B.C.]

Histology The study of the structure and chemical composition of tissues of animals and plants as related to their function. The primary aim is to understand how tissues are organized at all structural levels, including the molecular and macromolecular, the entire cell and intercellular substances, and the tissues and organs.

The four tissues of the animal body include cells and intercellular substances. They are (1) epithelium, in which the cells are generally closely applied to each other and separated by very little intercellular substance; (2) connective tissue, in which the cells are usually separated by greater amounts of intercellular substance, which may indeed form the great bulk of the tissue; (3) muscular tissue, whose cells are primarily concerned with contractility; and (4) nervous tissue, whose components are concerned primarily with rapid conduction of impulses. *See* CONNECTIVE TISSUE; EPITHELIUM; MUSCULAR SYSTEM; NERVOUS SYSTEM (VERTEBRATE).

The major fields of histological studies are morphological descriptions; developmental studies; histo- and cytophysiology; histo- and cytochemistry; and (5) fine (or submicroscopic) structure. [I.G.]

Historadiography The technique for taking x-ray pictures of cells, tissues, or sometimes the whole animal or plant, if it is a small one. Soft x-rays, those with low penetrating power and relatively long wavelengths, are required for this type of picture. The best pictures are obtained when the tissues contain deposits of metallic elements which have a high absorption capacity for x-rays. *See* X-RAYS.

In applying the technique to tissues, a relatively thin section is placed against an x-ray film and irradiated with a beam of x-rays. When the film is developed, a picture of the object or section of tissue shows on the film. Another method attempts to focus the x-rays after they pass through the specimen. *See* X-RAY MICROSCOPE. [J.H.T.]

Hodgkin's disease A malignant lymphoid neoplasm, usually arising in lymph nodes characterized by morphological heterogeneity and bizarre giant tumor cells referred to as Reed-Sternberg cells. The etiology of Hodgkin's disease is unknown, although current epidemiological data suggest an infectious (viral) etiology.

Persons with Hodgkin's disease usually seek medical advice because of enlarged painless lymph nodes. They may also have fever, weight loss, anorexia, pruritus, and anemia. The clinical extent of the disease is determined by a process of staging based on physical examination, various biopsies, and usually a laparotomy for examination of the spleen and liver.

Hodgkin's disease more commonly affects males than females, except for the nodular sclerosing variety, which occurs with equal frequency in both sexes. It generally is a disease of persons between the ages of 20 and 40, but it may affect the very young and the very old. Characteristically, persons with Hodgkin's disease exhibit a loss of cell-mediated immunity and become susceptible hosts for infection with a variety of microorganisms such as tubercle bacilli.

The treatment of Hodgkin's disease is dependent on its clinical stage and microscopic appearance. A combination of chemotherapy and radiation therapy is commonly used. *See* LYMPHATIC SYSTEM. [S.P.H.]

Hog cholera A highly contagious epizootic disease of pigs, also known as classical (or European) swine fever. The causative agent is a virus in the genus *Pestivirus*. This disease is the subject of statutory controls in a majority of countries, and has been eradicated from many areas, including the United States, Canada, Australasia, and parts of Europe. Clinically and pathologically, it closely resembles African swine fever, which is caused by an unrelated virus. *See* ANIMAL VIRUS.

Hog cholera can occur in European wild boar, but among domestic species only pigs are affected. Humans are not susceptible. The primary mode of transmission is by contact or proximity. Infected animals shed virus in all bodily secretions, including aerosols of respiratory mucus. The virus survival time in aerosol is short, and airborne transmission over long distances is not a factor. Virus may also be spread by contact with contaminated equipment and vehicles. It can survive for many months in frozen or refrigerated meat from infected pigs, and is not inactivated by mild forms of curing.

Pigs of any age may be affected. There are typically a high fever, loss of appetite, and dullness. Other symptoms include blotchy discoloration of the skin (particularly the extremities), incoordination and weakness of the hindquarters, constipation followed by diarrhea, gummed-up eyes, and coughing. Death occurs within 4–7 days, and the mortality is usually high.

The chronic form of disease is characterized by dullness, unthriftiness, capricious appetite, and variable degrees of coughing, diarrhea, and emaciation. There may be joint swellings and ulceration of the skin.

Strains vary in virulence, and hog cholera may still be suspected when milder signs occur in epizootic form. Low-virulence strains may produce few signs apart from reproductive failure in sows or congenital tremors in their offspring. [S.E.]

Hoisting machines Mechanisms for raising and lowering material with intermittent motion while holding the material freely suspended. Hoisting machines are capable of picking up loads at one location and depositing them at another anywhere within a limited area. In contrast, elevating machines move their loads only in a fixed vertical path, and monorails operate on a fixed horizontal path rather than over a limited area. *See* ELEVATING MACHINES; MONORAIL.

The principal components of hoisting machines are: sheaves and pulleys, for the hoisting mechanisms; winches and hoists, for the power units; and derricks and cranes, for the structural elements.

Sheaves and pulleys or blocks are a means of applying power through a rope, wire, cable, or chain. Sheaves are wheels with a grooved periphery that change the direction or the point of application of a force transmitted by means of a rope or cable. Pulleys are made up of one or more sheaves mounted in a frame, usually with an attaching swivel hook, eye, or similar device at one or both ends. Pulley systems are a combination of blocks. *See* BLOCK AND TACKLE; PULLEY.

Normally, winches are designed for stationary service, while hoists are mounted so that they can be moved about, for example, on wheel trolleys in connection with overhead crane operations. A winch is basically a drum or cylinder around which cordage is coiled for hoisting or hauling. The drum may be operated either manually or by power, using a worm gear and worm wheel, or a spur gear arrangement. A ratchet and pawl prevent the load from slipping; large winches are equipped with brakes, usually of the external band type.

A derrick is distinguished by a mast in the form of a slanting boom pivoted at its lower end and carrying load-supporting tackle at its outer end. In contrast, jib cranes always have horizontal booms. Derricks are standard equipment on construction jobs; they are also used on freighters for loading and unloading cargo, and on barges for dredging operations. Hoisting machines with a bridgelike structure spanning the area over which they operate are overhead-traveling or gantry cranes. *See* BULK-HANDLING MACHINES; DERRICK. [A.M.P.]

Holasteroida An order of irregular echinoids (sea urchins) of the superorder Atelostomata, with a strongly bilaterally symmetrical test. They have a small oval mouth lacking buccal notches that lies close to the anterior on the lower surface: a lantern is never present.

The 105 Recent species are divided into 13 genera. All are deep-sea forms. Their fossil record indicates that they were much more common and diverse in the past, with 61 genera divided into seven families, most of these being shallow-water forms. They are all deposit feeders, living either epifaunally or shallowly buried in unconsolidated substrata. *See* ATELOSTOMATA; ECHINODERMATA. [A.Sm.]

Hole states in solids Vacant electron energy states near the top of an energy band in a solid are called holes. A full band cannot carry electric current; a band nearly full with only a few unoccupied states near its maximum energy can carry current, but the current behaves as though the charge carriers are positively charged. *See* BAND THEORY OF SOLIDS.

The process of conduction in such a system may be visualized in the following way. An electron moves against an applied electric field by jumping into a vacant state. This transfers the position of the vacant state, or propagates the hole, in the direction of the field.

Hole conduction is important in many semiconductors, notably germanium and silicon. The occurrence of hole conduction in semiconductors can be favored by alloying with a material of lower valence than the "host." Semiconductors in which the conduction is primarily due to holes are called *p* type. *See* SEMICONDUCTOR. [J.C.]

Holectypoida An extinct order of primitive irregular sea urchins of the class (Echinoidea), which retain a functioning lantern throughout life. Although their periproct opens on the oral surface in the posterior interambulacrum, the test still shows considerable radial symmetry. The mouth is large, circular, and centrally positioned and is indented by sharp buccal notches. The holectypoids are distinguished from other primitive irregular echinoid groups by the presence of a fifth genital plate in the apical disc that may be perforated by a gonopore.

The approximately 130 nominal species are divided into nine genera and two families, Holectypidae and Discoididae. Holectypoids first appeared in the late Lower Jurassic and survived to the end of the Cretaceous (Maastrichtian), when they became extinct. They were mostly infaunal deposit feeders living in relatively coarse, permeable substrata. *See* ECHINOIDEA. [A.Sm.]

Holly The American species of holly (*Ilex opaca*) has evergreen leaves. It grows naturally in the eastern and southeastern United States close to the Atlantic and Gulf coasts, in the Mississippi Valley, and westward to Oklahoma and Missouri. It is best known for its bright red berries. The heartwood takes a high polish and is used for cabinet work and musical instruments; because it resembles ivory, it is sometimes used for keys for pianos and organs.

The English holly (*I. aquifolium*) is cultivated extensively in the extreme northwestern United States, but is not hardy in the northeastern states. Its spiny leaves are glossier than those of the American holly and have wavier margins. [A.H.G./K.P.D.]

Holmium A chemical element, Ho, atomic number 67, atomic weight 164.93, a metallic element belonging to the rare-earth group. The stable isotope ^{165}Ho makes up 100% of the naturally occurring element. The metal is paramagnetic, but as the temperature is lowered, it changes to antiferromagnetic and then to the ferromagnetic system. *See* ANTIFERROMAGNETISM; PERIODIC TABLE; RARE-EARTH ELEMENTS. [F.H.Sp.]

Holocene That portion of geologic time that postdates the latest episode of continental glaciation. The Holocene Epoch is synonymous with the Recent or Postglacial interval of Earth's geologic history and extends from 10,000 years ago to the present day. It was preceded by the Pleistocene Epoch and is part of the Quaternary Period, a time characterized by dramatic climatic oscillations from warm (interglacial) to cold (glacial) conditions that began about 1.6 million years ago. The term Holocene is also applied to the sediments, processes, events, and environments of the epoch.

As the interval of time closest to us, the Holocene Epoch is very convenient to study. Holocene sediments cover virtually every part of the Earth's surface and represent almost every environment of deposition. With the development of ^{14}C dating (a method of age determination based on the measurement of radioactive carbon decay), Holocene sediments are relatively easy to date. From a scientific standpoint, the Holocene Epoch is of great interest because it provides a recent analog for past environments and processes. Its sediments and landforms provide important clues to changes that occurred as a result of the last shift from the glacial to the nonglacial climatic mode. *See* DEPOSITIONAL SYSTEMS AND ENVIRONMENTS; RADIOCARBON DATING.

The Pleistocene/Holocene transition was a time of dramatic environmental change. The huge ice sheets that had developed over the northern and western parts of North America (Laurentide and Cordilleran, respectively) and most of Scandinavia were at their maximum geographic extent about 18,000 ^{14}C years B.P. (before present, where present is defined as the year 1950) and in full retreat by 14,000 ^{14}C years B.P. By 10,000 ^{14}C years B.P., the Laurentide ice sheet had withdrawn from the Great Lakes. The ice sheets survived in the northern latitudes for another 3000 ^{14}C years or so. The progress of deglaciation was complex, because the overall glacial meltback was interrupted by intervals of glacier readvance. It remains unclear whether these readvances were synchronous on a hemispheric or global scale and what role ice sheet/oceanic interactions played in the deglaciation. *See* PLEISTOCENE.

The early phase of the Holocene was geologically the most eventful. The periglacial (near the edge of the ice) landscape was unstable and very dynamic. As the Pleistocene ice sheets melted, enormous volumes of water, stored as glacier ice for many thousands of years, returned to the oceans via meltwater streams or by way of ice streams that flowed directly to the ocean.

As the ice sheets shrank, sea level rose an average of 130 m (426 ft), drowning the continental margins and closing many land bridges, including the land bridge across the Bering Strait between Asia and North America that had enabled humans to migrate to the Americas. In parts of Canada and Scandinavia, temporary marine invasions occurred when the ice melted from low areas where the Earth's crust had been depressed by the weight of the ice sheets.

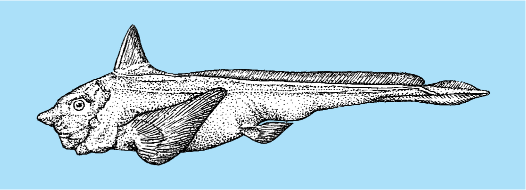
As the ice sheets waned, the Earth's crust rose, rebounding from the release of the weight of thousands of meters of glacier ice and creating uplifted shoreline features and sediments. Parts of Hudson Bay and Scandinavia were uplifted several hundred meters. Maximum uplift occurred in the early Holocene, but uplift continues even today although at much slower rates.

The middle phase of the Holocene has been called the hypsithermal, a name for the warmest interval of the present interglacial episode. It has also been referred to as the climatic optimum, a term which is more appropriately applied to the peak warmth of the hypsithermal phase. At the climatic optimum, world temperature was probably 2 or 3°C (3.6 or 5.4°F) higher than today. The climate was warm enough to melt much of the sea ice in the Arctic Ocean, as indicated by the occurrence of fossil driftwood (dated at 4000–6000 ^{14}C years B.P.) on uplifted beaches.

After the climatic optimum, the Earth experienced climatic cooling. The shift to a cooler, moister climate began about 5000–4000 ^{14}C years B.P. in the midcontinent. In western North America at about 5000 ^{14}C years B.P., the mountain glaciers began to expand again. This renewed glacial activity is called Neoglaciation. At least three intervals of glacial expansion have occurred in the late Holocene. The glacial advances are cyclic. In the mountains of the western United States, the three advances have been dated at about 5000, 2800, and 300 ^{14}C years B.P. The most impressive of the three glacial intervals is the last, called the Little Ice Age. It is well documented because it occurred in historic time. Between the intervals of glacier expansion were times of climatic warming. One, called the Little Climatic Optimum to differentiate it from the hypsithermal of the middle Holocene, peaked about 1800 ^{14}C years B.P.

During the late Holocene, human populations expanded and human culture developed into the complex agricultural, industrial, and technological society of today. The result is that humans have become significant factors in altering the Earth's surface environment, including, most believe, Holocene climate. *See* GEOLOGIC TIME SCALE; GLACIAL EPOCH; QUATERNARY. [A.K.H.]

Holocephali One of two Recent subclasses of the cartilaginous fishes, or Chondrichthyes. The Holocephali, or chimaeras, differ from the other subclass, the Elasmobranchii, in having only four pairs of gill arches and gills that open to the exterior from a single pair of apertures; in the erectile dorsal fin and spine (see illustration); in the naked skin in adults; and in the absence of a cloaca and of ribs.



Deepwater chimaera (*Hydrolagus affinis*). (*After G. B. Goode and T. H. Bean, Oceanic Ichthyology, U.S. Nat. Mus. Spec. Bull. no. 2, 1895*)

Chimaeras date from the early Mesozoic. They are classified into a single order, the Chimaeriformes, one family, the Chimaeridae, four or five genera, and about 24 species. All chimaeras are marine, most living in deep water. They are of little economic importance. *See* CHONDRICHTHYES. [R.M.B.]

Holography A technique for recording, and later reconstructing, the amplitude and phase distributions of a coherent wave disturbance. Invented by Dennis Gabor in 1948, the process was originally envisioned as a possible method for improving the resolution of electron microscopes. While this original application has not proved feasible, the technique is widely used as a method for optical image formation, and in addition has been successfully used with acoustical and radio waves. *See* ACOUSTICAL HOLOGRAPHY.

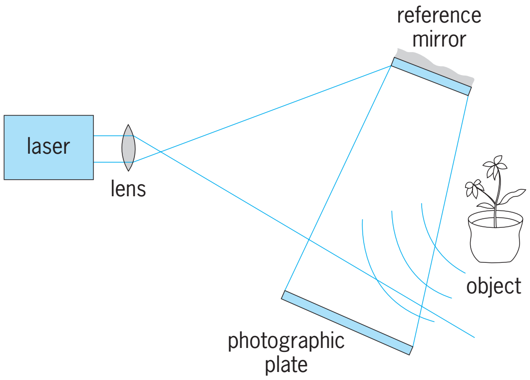


Fig. 1. Recording a hologram.

The technique is accomplished by recording the pattern of interference between the unknown "object" wave of interest and a known "reference" wave (Fig. 1). In general, the object wave is generated by illuminating the (possibly three-dimensional) subject of concern with a highly coherent beam of light, such as supplied by a laser source. The waves reflected from the object strike a light-sensitive recording medium, such as photographic film or plate. Simultaneously a portion of the light is allowed to bypass the object, and is sent directly to the recording plane, typically by means of a mirror placed next to the object. Thus incident on the recording medium is the sum of the light from the object and a mutually coherent "reference" wave. *See* LASER.

The photographic recording obtained is known as a hologram (meaning a "total recording"); this record generally bears no resemblance to the original object, but rather is a collection of many fine fringes which appear in rather irregular patterns. Nonetheless, when this photographic transparency is illuminated by coherent light, one of the transmitted wave components is an exact duplication of the original object wave (Fig. 2). This wave component therefore appears to originate from the object (although the object has long since been removed) and accordingly generates a virtual image of it, which appears to an observer to exist in three-dimensional space behind the transparency. The image is truly three-dimensional in the sense that the observer's eyes must refocus to examine foreground and background, and indeed can "look behind" objects in the foreground simply by moving his or her head laterally.

Holography has been demonstrated to offer the capability of several unique kinds of interferometry. This capability is a consequence of the fact that holographic images are coherent; that is, they have well-defined amplitude and phase distributions. Any use of holography to achieve the superposition of two coherent images will result in a potential method of interferometry. *See* INTERFEROMETRY.

Optical memories for storing large volumes of binary data in the form of holograms have been developed for commercial use. Such a memory consists of an array of small holograms, each

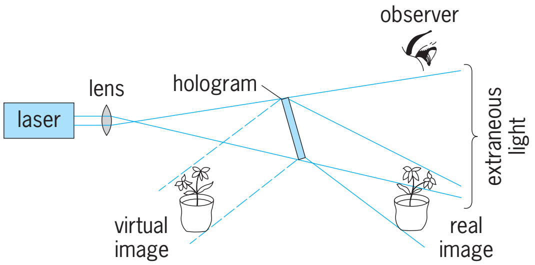

Fig. 2. Obtaining images from a hologram.

capable of reconstructing a different “page” of binary data. When one of these holograms is illuminated by coherent light, it generates a real image consisting of an array of bright or dark spots, each spot representing a binary digit. *See* Computer storage technology.

There has been interest in the use of holography for purposes of display of three-dimensional images. Applications have been found in the field of advertising, and there is increased use of holography as a medium for artistic expression. [J.W.Goo.]

Microwave holography is microwave imaging by means of coherent continuous-wave electromagnetic radiation in the wavelength range from 1 mm to 1 m. As a long-wavelength imaging modality, it differs from techniques which employ echo timing (for example, conventional radar) by its requirement for phase information. In this respect it resembles optical holography, from which it has departed significantly. The technique usually involves small-scale systems, that is, systems in which the effective data acquisition aperture is of the order of tens or hundreds of wavelengths. Microwave holographic imaging is characterized by high lateral-resolution capability in comparison with images obtained from echo timing. The natural image format of the data it presents to the human observer enhances its diagnostic potential. In particular, it conveniently produces phase imagery which increases further its diagnostic capability. *See* Microwave; Radar.

Microwave holography is useful in applications where images of concealed structure are required. Microwave radiation penetrates a variety of dielectric media to a depth depending on the attenuation of a given wavelength in a particular medium. One such application is the mapping of subsurface pipes and cables. Plastic pipes as well as metal pipes can be imaged. Hence this noninvasive microwave technique has a diagnostic power greater than the normal metal detectors. *See* Nondestructive evaluation.

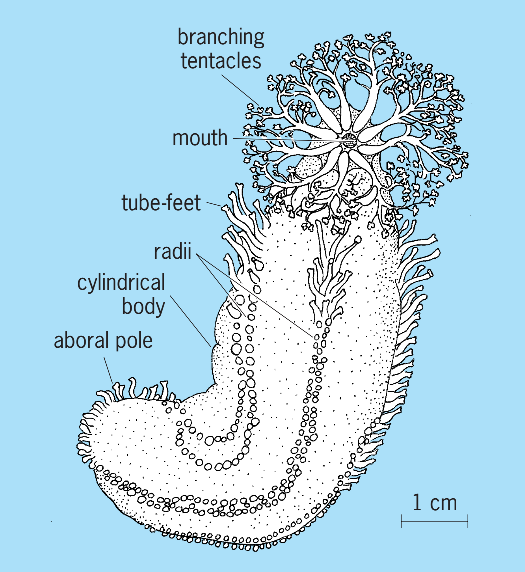
The major limitation of the microwave holographic techniques is that the images produced are essentially two-dimensional. The reason is that the microwave wavelength is so long (10^4–10^6 times that of light) that the depth of focus of the microwave hologram is prohibitive. This disadvantage is overcome by employing a tomographic mode of imaging which exploits the ability of microwaves to penetrate many materials and thereby characterize their three-dimensional structure more accurately. Microwave holographic tomography requires holograms to be recorded from different views of the object and synthesized. *See* Computerized tomography. [A.P.An.]

Holostei One of three organizational levels (infraclasses) of the subclass Actinopterygii, or rayfin fishes. The holosteans are descended from the older Chondrostei and in turn are ancestral to the great mass of modern bony fishes, the Teleostei. *See* Chondrostei; Teleostei.

Holosteans made their first appearance in the Upper Permian as the order Semionotiformes; three additional orders arose in the Triassic Period, and the fifth and last order, the Aspidorhynchiformes, evolved in the Middle Jurassic. In the Jurassic and Lower Cretaceous, holosteans dominated actinopterygian fish life, but by the Late Cretaceous they had been largely replaced by teleosts.

Holosteans, although highly varied in body form, were structurally as well as temporally intermediate between chondrosteans, and teleosts, to which group they passed on substantial advances. In living holosteans the swim bladder is highly vascularized, and auxiliary aerial respiration is possible, a sometimes essential faculty in oxygen-poor waters of swamps. *See* Actinopterygii; Amiiformes; Aspidorhynchiformes; Pholidophoriformes; Pycnodontiformes; Semionotiformes. [R.M.B.]

Holothuroidea A class of Echinozoa characterized by a cylindrical body and smooth leathery skin, and known as sea cucumbers. There are no arms, but a ring of five or more tentacles may surround the mouth, which is usually at one end of the body. There are no pedicellariae. Tube feet may be present or lacking. There are no ambulacral grooves. *See* Echinozoa.



***Cucumaria*, a representative holothurian.**

Holothurians resemble worms because the pentamerous symmetry is largely concealed by a secondary bilateral symmetry, and the general absence of external spines distinguishes them from the other extant echinoderms (see illustration).

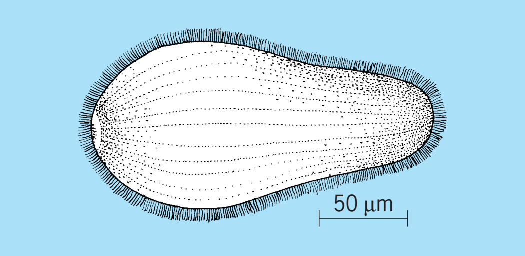
The 1100 living species have been grouped in 170 genera arranged in six orders: the Dendrochirotida, Dactylochirotida, Aspidochirotida, Elasipodida, Molpadida, and Apodida. Colors vary widely; the most brilliant colors are found among the Synaptidae. Yellow, red, violet, and fawn tints occur, but many species are somber shades or black.

Holothurians occur in all seas, from low-tide level down to the greatest depths explored. At depths below 5.5 mi (8.8 km) holothurians comprise 90% of the total mass of living matter, the rest being mainly starfishes. Two pelagic genera are known. [H.B.F.]

Holotrichia A major subclass of the class Ciliatea. These protozoans have a fairly uniform body ciliation, as the name implies. Separate articles appear on the groups listed in the following classification:

Subclass Holotrichia
Order: Gymnostomatida
Trichostomatida
Chonotrichida
Apostomatida
Astomatida
Hymenostomatida
Thigmotrichida

The cilia are typically arranged in longitudinal rows over the body, although scattered exceptions exist. A mouth is often,



***Prorodon*, a primitive holotritch.**

although not always, present. The prototype of the Holotrichia is exemplified by the form portrayed in the illustration. [J.O.C.]

Homalozoa A subphylum of echinoderms, made up of members having a flattened theca or body lacking pentameral symmetry. Homalozoans (also called carpoids) include four extinct classes of relatively uncommon primitive echinoderms ranging in age from the Early or Middle Cambrian to the Late Carboniferous. Homalozoans have a flattened, asymmetrical to bilaterally symmetrical theca often composed of a marginal frame of large elongate plates surrounding top and bottom central areas that had numerous smaller plates and were probably flexible. All homalozoans were apparently mobile, benthic, detritus or suspension feeders that had adopted a flatfish way of life. *See* CARPOIDS; ECHINODERMATA. [J.Sp.]

Homeosis The formation of a normal plant or animal body structure or organ in place of another at an abnormal site. Examples of homeosis (also called homeotic transformation) are most obvious in insect appendages, where an appendage that is characteristic of one segment, for example the antennae on an insect head segment, are transformed into insect legs that normally develop only on trunk segments. Similar examples of homeotic transformations can also occasionally be found in vertebrates where lumbar vertebrae are transformed into thoracic vertebrae which then extend into rib processes, or in floral organs where petals are transformed into sepals. Homeotic transformations rarely occur in nature in living organisms, and are due to genetic defects in a class of proteins called homeotic proteins, the products of homeotic genes. Homeotic transformations may also be induced in the laboratory by the accidental or deliberate manipulation of homeotic gene expression so that homeotic proteins are produced in the wrong place or at the wrong time in developing plants and animals. *See* CELL DIFFERENTIATION; DEVELOPMENTAL BIOLOGY; DEVELOPMENTAL GENETICS; GENE ACTION; MUTATION. [W.McG.]

Homeostasis The relatively constant conditions within organisms, or the physiological processes by which such conditions are maintained in the face of external variation.

Similar homeostatic controls are used to keep factors such as temperature and blood pressure nearly constant despite changes in an organism's activity level or surroundings. Such systems operate by detecting changes in the variable that the system is designed to hold constant and initiating some action that offsets any change. All incorporate a sensor within the system that responds when the actual condition differs from the desired one, a device to ensure that any action taken will reduce the difference between actual and desired, and an effector to take the needed action as directed. The crucial aspect is that information is fed back from effector to sensor and action is taken to reduce any imbalance—hence the term negative feedback.

Blood pressure is, at least on a moment-to-moment basis, regulated by a system for which the sensors are stretch-sensitive cells located in the neck arteries that carry blood from heart to brain. An increase in blood pressure triggers sensor activity; their signal passes to the brain; and, in turn, the nerve supplying the heart (the vagus) is stimulated to release a chemical (acetylcholine) that causes the heart to beat more slowly—which decreases blood pressure.

The volume of the blood is subject to similar regulation. Fluid (mainly plasma) moves between the capillaries and the intercellular fluid in response to changes in pressure in the capillaries. A decrease in blood volume is detected by sensors at the base of the brain; the brain stimulates secretion of substances that cause contraction of tiny muscles surrounding the blood vessels that lead into the capillaries. The resulting arteriolar constriction reduces the flow of blood to, and the pressure within, the capillaries, so fluid moves from intercellular space into capillaries, thus restoring overall blood volume.

Body temperature in mammals is regulated by a sensor that consists of cells within the hypothalamus of the brain. Several effectors are involved, which vary among animals. These include increasing heat production through nonspecific muscle activity such as shivering; increasing heat loss through sweating, panting, and opening more blood vessels in the skin (vasodilation); and decreasing heat loss through thickening of fur (piloerection) and curling up. Humans sweat, but they retain only a vestige of piloerection ("goose flesh"). *See* THERMOREGULATION.

While the homeostatic mechanisms described involve the neural and endocrine systems of mammals, it is clear that such arrangements pervade systems from genes to biological communities, and that they are used by the simplest and the most complex organisms.

Organisms of every kind develop, mature, and even shift physiological states periodically—between day and night, with seasons, or as internal rhythms. Thus organisms cannot be considered constant except over short periods. However, all such changes appear to involve the same basic sensing of the results of the past activity of the system and the adjusting of future activity in response to that information. Development of an organism from a fertilized egg is far from a direct implementation of a genetic program; probably no program could anticipate all the variation in the external context in which an organism must somehow successfully develop. *See* BIOLOGICAL CLOCKS; ENDOCRINE MECHANISMS; NERVOUS SYSTEM (VERTEBRATE); SERVOMECHANISM. [S.V.]

Homing A process of navigation by which a destination is approached by keeping some navigation parameter constant. In its early uses, the most commonly chosen parameter was the relative bearing from the vehicle to destination as determined from a signal emitted at or near the destination point. The vehicle then steers to travel in the direction of its destination. The signal can be of many forms, ranging from a visual image to a radio wave or even an odor. This simple form of homing requires minimal on-board equipment, but the path taken by the vehicle over the Earth's surface is influenced by vehicle drift due to winds, currents, or other causes. *See* DIRECTION-FINDING EQUIPMENT.

A higher level of homing is available through certain radio navigation aids (navaids), such as the very high frequency omnidirectional range (VOR) and the aircraft instrument landing system (ILS). While the signals from these aids define a path in space that can be followed by the user, the signals themselves do not indicate the courses that should be selected to remain on the path. In the case of VOR, the signals define the azimuth to or from the station, with the user being required to adjust the vehicle heading to acquire the desired path and to compensate for any drift in order to remain on the path. The ILS signals define a precise fixed path in space, which the user equipment processes to yield deviation indications in the lateral and vertical directions. *See* ELECTRONIC NAVIGATION SYSTEMS; INSTRUMENT LANDING SYSTEM (ILS).

The advent of affordable on-board digital processing accompanied by extensive geographical databases has resulted in supporting direct-to paths from present position to destinations that need not radiate a signal. The navigation aids used most for establishing direct-to paths include VOR/DME (distance-measuring equipment), DME/DME, Loran-C, and the Global Positioning System (GPS). *See* DISTANCE-MEASURING EQUIPMENT; LORAN; SATELLITE NAVIGATION SYSTEMS.

One of the most useful navigation features developed after the advent of radionavigation is vehicle-to-vehicle homing, where a vehicle homes on signals radiated by another vehicle. This is especially valuable in rescue operations. In the United States, aircraft are required to carry emergency locator transmitters (ELTs) which automatically turn on when the aircraft crashes.

The most serious military homing mode is that which enables a missile to home on any source of radiation. Typical sources are radio transmitters of all kinds, including radar and navigation aids, and the infrared exhausts of jet engines, tanks, and ships. *See* Electronic warfare; Guided missile; Missile. [E.O.F.]

Homogeneous catalysis A process in which a catalyst is in the same phase as the reactant. A homogeneous catalyst is molecularly dispersed (dissolved) in the reactants, which are most commonly in the liquid state. Catalysis of the transformation of organic molecules by acids or bases represents one of the most widespread types of homogeneous catalysis. In addition, the catalysis of organic reactions by metal complexes in solution has grown rapidly in both scientific and industrial importance. *See* Catalysis. [D.F.]

Homoptera An order of the class Insecta related to the order Hemiptera. This is a major group of sucking insects, with more than 30,000 species, even though in Asia and Africa the number of undiscovered species probably still exceeds the discovered ones. Common examples are the cicadas, aphids, and leafhoppers. The group is difficult to characterize because of the large number and diverse forms of the species it contains.

The head of these insects is hypognathous or opisthognathous, the beak appearing to arise from the ventral posterior margin of the head or even from the prosternum. The gula is membranous or absent. As in the Heteroptera, the beak consists of two pairs of stylets, formed by the maxillae and the mandibles, ensheathed in the labium. The maxillary stylets fit together to form a double tube, one channel serving for the passage of food and the other for saliva.

Most winged species have four wings, but male scale insects have only two. In most forms both pairs of wings are membranous and transparent, but in some, the forewings are somewhat thickened and may then be either coriaceous and translucent, or opaque, and with or without an apical membranous area. When the insects are at rest, the forewings are usually held, rooflike, over the dorsum, with the apex of one of them slightly overlapping the apex of its complement (Fig. 1).

In most species metamorphosis is gradual, but in a few it is practically holometabolous. Adults and nymphs of most species are terrestrial, but a few species are subterranean in all stages and others are subterranean only in immature stages. A number of species are vectors of virus diseases of plants.

Series Coleorrhyncha. This group is characterized by the origin of the beak, formed at the anteroventral extremity of the face, and by the fact that the propleura form a sheath for the base of the beak. The hindwings are absent, and the forewings are held flat over the abdomen in repose. The flight function has been lost. They occur in Tasmania, New Zealand, and South America.

Series Auchenorrhyncha. This series and the Sternorrhyncha are the major groups of the Homoptera. In the Auchenorrhyncha the beak arises at the anteroventral extremity of the face and is not sheathed by the propleura. The Auchenorrhyncha includes a large number of species. A number of classifications have been proposed; the classification adopted here is a common one. It divides the series into the superfamily Fulgoroidea and the families Cicadidae, Cercopidae, Membracidae, and Cicadellidae. These families are not subordinate to the superfamily Fulgoroidea.

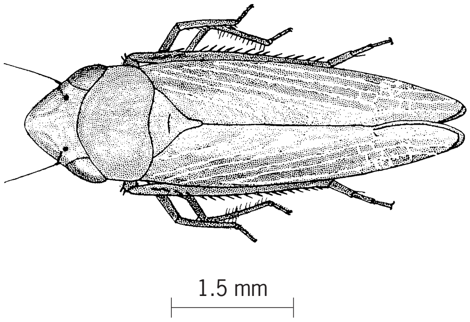


Fig. 1. A cicadellid, dorsal view.

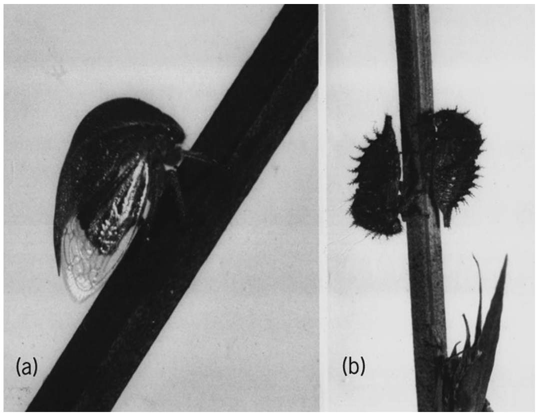

Fig. 2. Membracids on stems. (*a*) Adult. (*b*) Nymphs. (*Courtesy of C. H. Hanson*)

Superfamily Fulgoroidea includes insects commonly known as lantern flies. This group is subdivided into 20 families and includes many species which are important because of the economic damage they do while feeding or because they carry virus diseases of plants.

Included in the family Cicadidae are the cicadas, harvest flies, and jar flies. The insects in this family are probably better known to the layperson than any other homopterous family because of their large size and the strident songs of the males. Adults are usually found on trees or shrubs. At least in some species, the songs of the males assemble local populations.

Spittle bugs and froghoppers are common examples of the family Cercopidae. Insects in this group attract attention in the immature stages, during which they surround themselves with a mass of froth or spittle. One species, the meadow spittle bug, is very common in the temperate portion of the Northern Hemisphere, and its masses of spittle are familiar sights. Some species of Australia and the East Indies live within a calcium carbonate tube attached to stems or leaves.

The treehoppers (family Membracidae) are small to medium in size and seldom attract attention (Fig. 2*a*). Most of them feed on woody plants and are found on the stems in sunny locations. Frequently a number of specimens are arranged in a vertical row on the stem, all with their heads downward.

The greatest number of species occurs in the warmer regions of the world. In many species the enlarged pronotum has adornments, excrescences, and processes which are astonishing in appearance, some of them nearly as large as the remainder of the insect. The nymphs (Fig. 2*b*) leave the trees and feed on herbaceous plants, often occurring in great numbers in pastures. The adults return to woody plants before oviposition.

The leafhoppers are included in the large family Cicadellidae. These usually small insects are known to many people by sight but not by name, because of their common occurrence in great numbers at night near lights (Fig. 1). Probably the greatest number of species occurs in tropical areas, but the majority of these have not been described. Leafhoppers occasionally bite humans, but apparently they have never been seen taking blood. Several species have been found to be vectors of virus diseases of plants.

Series Sternorrhyncha. In this group of families, the beak appears to arise either between the fore coxae or behind them. The antennae are usually long, filamentous, and have no well-differentiated terminal setae. Wingless forms are common.

The Sternorrhyncha includes a large number of species, many of them of great economic importance. The winged forms are not strong flyers, but they are so light that they may be borne considerable distances by air currents.

The family Psyllidae are known as jumping plant lice. Its representatives resemble cicadas in appearance, but are much smaller. About 1000 species are known. Some psyllids produce severe damage to their food plants. This damage may result from the mere feeding by tremendous numbers of individuals, from the resulting yellowing or rolling of leaves, or from galls produced on the leaves. Indirect damage may result from the growth of fungi on leaves which have become coated with the sugary excrement, the honeydew, of the psyllids.

The whiteflies (family Aleyrodidae) are 0.28 in. (7 mm) or less in length and usually lightly covered with a white, powdery, waxy material which has led to their common name. Whiteflies directly damage plants by their feeding. Indirectly, damage results from spotting at the feeding site, growth of fungus on the excreted honeydew, or from increased susceptibility of leaves to winter damage.

Members of the large superfamily Aphidoidea have four wings, or none. The wings are usually membranous or whitish and opaque. The forewings are much larger than the hindwings. Honeydew is usually produced. This superfamily includes the families Aphididae and Chermidae. The true aphids (Aphididae) are very attractive to ants, and colonies of very small aphid species which otherwise might escape notice can often be located by observing the attending ants. In a few species, this relationship has progressed to the point where ants are necessary for the survival of the aphid species, as in the corn root aphid. Many aphid species are important because of damage done in feeding.

Chermidae is a small family of minute insects, the adelgids and phylloxeriids. Both winged and wingless forms occur. The grape phylloxera has been a severe pest of cultivated grapes and once threatened the entire wine industry of France.

The scale insects and mealy bugs (superfamily Coccoidea) are usually small. More than 4000 species have been described. In the males, the hindwings are reduced to clublike halteres. The wings are usually held flat over the back in repose, and the venation is greatly reduced. The females are wingless.

Scale insects injure the host plant by their feeding on leaves, stems, or roots, and a number of species are very important economically. Most species produce large quantities of honeydew. A few species have been shown to be vectors of virus diseases of cucumbers, tobacco, and cacao. *See* ENTOMOLOGY, ECONOMIC; INSECTA. [D.A.Y.]

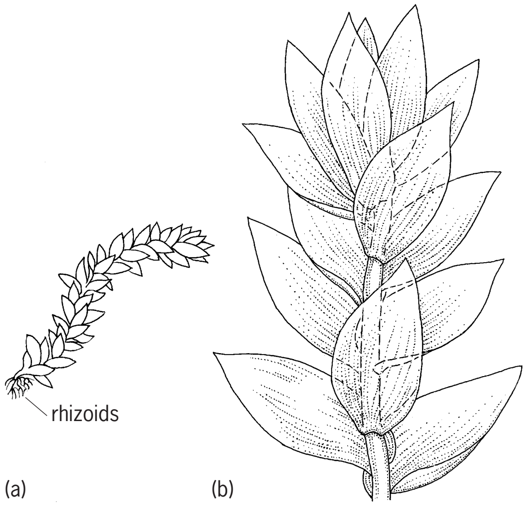
Homosclerophorida An order of primitive sponges of the class Demospongiae, subclass Tetractinomorpha, with a skeleton consisting of equirayed, tetraxonid, siliceous spicules and their derivatives formed through reduction in number of rays.

Homosclerophorid sponges are mostly small in size and encrusting to massive in shape. They occur in tidal and shallow waters, down to depths of at least 1640 ft (500 m). Fossil sponges with spicules suggesting homosclerophorid affinities are scattered through the fossil record from Carboniferous strata upward. *See* DEMOSPONGIAE. [W.D.H.]

Honey Dew melon A long-keeping cultivar of muskmelon, *Cucumis melo inodorus*, of the gourd family, Cucurbitaceae. Vines are vigorous and prolific and have large leaves and stems. The fruits are large, slightly oval, (diameter 6–7 in. or 15–18 cm), smooth, creamy yellow to ivory when ripe, and with little or no net. The flesh is thick, light green, tender, juicy, and very sweet with mild aroma and flavor; it contains 10% or more sugar when ripe and is rich in potassium and vitamin C, but not as rich in vitamin A as the orange-fleshed cantaloupe.

Honey Dew is of African origin, has been grown in France for many years, and was introduced into the United States in 1911. Most of the crop is harvested in the summer in California; almost all of the remaining crop is harvested in the spring in Texas, with less than 5% harvested in the fall in Arizona. *See* MUSKMELON; VIOLALES. [O.A.L.]

Hookeriales An order of the mosses, many species of which occur in the tropics. The plants are small to robust, procumbent, and often flaccid, and frequently appear flattened. The stems are irregularly branched, and the cells of the peripheral layer are enlarged. The leaves vary in shape and size. They occur in many rows in some species, four rows in others, and appear to be in one plane (see illustration). *See* BRYOPSIDA. [W.H.W.]



***Hookeria acutifolia*. (*a*) A portion of an entire plant, (*b*) Apical portion enlarged. (*After W. H. Welch, Mosses of Indiana, Indiana Department of Conservation, 1957*)**

Hooke's law A generalization applicable to all solid materials, stating that stress is directly proportional to strain and expressed as

$$\frac{\text{Stress}}{\text{Strain}} = \frac{S}{\epsilon} = \text{constant} = E$$

where E is the modulus of elasticity, or Young's modulus, in pounds per square inch. The constant relationship between stress and strain applies only to stress below the proportional limit. *See* STRESS AND STRAIN; YOUNG'S MODULUS. [W.J.K./W.G.B.]

Hop A plant (*Humulus lupulus*) belonging to the family Urticaceae. The plant is perennial, with the clockwise twining vine dying back to the ground each year. The male and female flowers are borne on separate plants.

The mature hop cone—the hop of commerce—consists of papery bracts and bracteoles. As the cone matures, numerous golden-yellow granules (lupulin) develop on the bracteoles. These granules contain the resins and essential oils to which the hop owes its brewing value. *See* MALT BEVERAGE.

Hops are found primarily in the temperate areas of the world. In the United States the cultivated hop is grown in Washington, Oregon, Idaho, and California. [C.B.S.]

Hophornbeam The genus *Ostrya* of the birch family, represented in North America by two species. *Ostrya virginiana* is widely distributed in the eastern half of the United States and in the highlands of southern Mexico and Guatemala. It can be recognized by its fruit, which closely resembles that of the hop vine, and by its very scaly bark. The scales usually occur in narrow, more or less parallel, vertical strips. The leaves are sharply and doubly serrate. This is one of several trees known as ironwood because of its hard, strong wood; it is used for fence posts, tool handles, mallets, and other articles requiring hardness and strength. *Ostrya knowltonii* is a small rare tree of the southwestern United States. *See* FAGALES. [A.H.G./K.P.D.]

Hoplocarida A subclass of Crustacea, with a single extant order, Stomatopoda, commonly known as mantis shrimps. The Haplocarida was formerly included as a taxon within the Eumalacostraca, and disagreement regarding its independent origin still persists. The controversy is centered on the question of whether those elements of the eumalacostracan caridoid facies observed in haplocarids represent examples of homology or convergence. Investigations of fossil (Paleostomatopoda) and Recent Stomatopoda suggest that a distinct set of morphological features, sometimes referred to as a hoploid morphotype, clearly delineate the Hoplocarida from the Eumalacostraca. Morphological aspects of feeding observed in modern-day species, as well as features of the digestive system and abdominal musculature, tend to support the hypothesis of a distinct origin. *See* Crustacea; Stomatopoda. [P.A.McL.]

Hoplonemertini An order of the class Enopla of the phylum Rhynchocoela, characterized by possession of an elaborate armed proboscis consisting of an anterior thick-walled tube, a median portion armed with stylets, and a posterior blind tube. In some species the foregut (stomach) can be everted into the prey to achieve extracorporeal digestion prior to ingestion. There are two suborders, the Monostylifera and Polystylifera, separated on the number of stylers in the proboscis. Monostylifera include fresh-water, terrestrial, and symbiotic species, as well as the more common marine littoral forms. *See* Anopla; Bdellonemertini; Enopla; Rhynchocoela. [J.B.J.]

Horizon The visible horizon is the apparent boundary line between sky and earth or sea. The astronomical horizon is the great circle of the celestial sphere 90° from the zenith and the nadir. *See* Astronomical coordinate systems. [G.M.C.]

Hormone One of the chemical messengers produced by endocrine glands, whose secretions are liberated directly into the bloodstream and transported to a distant part or parts of the body, where they exert a specific effect for the benefit of the body as a whole. The endocrine glands involved in the maintenance of normal body conditions are pituitary, thyroid, parathyroid, adrenal, pancreas, ovary, and testis. However, these organs are not the only tissues concerned in the hormonal regulation of body processes. For example, the duodenal mucosa, which is not organized as an endocrine gland, elaborates a substance called secretin which stimulates the pancreas to produce its digestive juices. The placenta is also a very important hormone-producing tissue. See separate articles on the individual glands.

The hormones obtained from extracts of the endocrine glands may be classified into four groups according to their chemical constitution: (1) phenol derivatives, such as epinephrine, norepinephrine, thyroxine, and triiodothyronine; (2) proteins, such as the anterior pituitary hormones, with the exception of adrenocorticotropic hormone (ACTH), human chorionic gonadotropin, pregnant-mare-serum gonadotropin, and thyroglobulin; (3) peptides, such as insulin, glucagon, ACTH, vasopressin, oxytocin, and secretin; and (4) steroids, such as estrogens, androgens, progesterone, and corticoids. Hormones, with a few exceptions like pituitary growth hormone and insulin, may also be classified as either tropic hormones or target-organ hormones. The former work indirectly through the organs or glands which they stimulate, whereas the latter exert a direct effect on peripheral tissues. *See* Endocrine system (vertebrate). [C.H.L.]

Hornbeam The genus *Carpinus* of the birch family, represented in the United States by *C. caroliniana*, the American hornbeam or blue beech. Hornbeam is a small tree, and it has a smooth, steel-gray, fluted bark. It grows throughout the eastern half of the United States, especially in moist soil along banks of streams; it is sometimes called water beech. When mature, it is easily recognized by its peculiar bark, by the doubly serrate leaves resembling those of sweet birch, and by the small, pointed, angular winter buds with scales in four rows. The fruit is a small nutlet subtended by a three-lobed serrate bract. The wood is very hard, giving rise to the name iron-wood.

The European hornbeam (*C. betulus*) is often cultivated in parks and estates. It can be distinguished by its larger size, larger winter buds, and larger three-lobed, almost entire fruiting bracts. *See* Fagales. [A.H.G./K.P.D.]

Hornblende The name that was traditionally assigned to common calcic amphiboles of metamorphic and igneous rocks. However, a nomenclature scheme for amphiboles was introduced in 1997 in which the names now carry strict compositional restrictions. Magnesiohornblende (contains magnesium) and ferrohornblende (contains iron) are monoclinic amphiboles with end-member compositions $Ca_2(Mg_4Al)(Si_7Al)O_{22}(OH)_2$ and $Ca_2(Fe^{2+}{}_4Al)(Si_7Al)O_{22}(OH)_2$, respectively (Ca = calcium, MG = magnesium, Al = aluminum, Si = silicon, O = oxygen, Fe = iron, OH = hydroxyl). Most natural compositions differ significantly from these ideal end members. Significant deviations from these compositions are denoted by the addition and replacement of prefixes and adjectival modifiers characteristic of the compositions involved. Thus fluorohornblende (contains fluorine, F) has the end-member composition $Ca_2(Mg_4Al)(Si_7Al)O_{22}F_2$, in which all of the OH in hornblende has been replaced by F. When used to denote an amphibole of known chemical composition, the term hornblende is never used without a prefix or adjectival modifier. The unmodified term hornblende specifically refers to a calcic amphibole identified by physical or optical properties without characterization of the chemical composition.

Hornblende is a common rock-forming mineral in medium- and high-grade metamorphic rocks, particularly those of mafic and ultramafic composition. In mafic rocks, it first appears in the upper part of the low grade by a chemical reaction involving the disappearance of actinolite, a nonaluminous calcic amphibole. This change is extremely noticeable in thin sections, very pale-green actinolite giving way to blue-green hornblende. With prograde metamorphism, the composition of the hornblende gradually changes in a highly complex manner that is a function of temperature, pressure, oxygen fugacity (a measure of the activity of oxygen), and the chemical composition of the rock. This causes a gradual color change from blue-green through various shades of green to olive green and brown. At the middle of the high grade, hornblende becomes unstable and breaks down to form pyroxene (plus other minerals). The prominence of hornblende in medium-grade metabasic rocks has led to these rocks being called amphibolites. *See* Pyroxene.

Hornblende is commonly found as a minor phase in a wide variety of igneous rocks. Magnesium-rich hornblendes do occur as primary phases in basic and ultrabasic rocks, but this is not common. Igneous amphiboles are most abundant in calcic-alkaline diorites, granodiorites, and granites, becoming more iron-rich with increasing acidity of the host rock. This compositional trend is also characterized by a progressive increase in the alkali content of the amphibole, and hornblende grades into hastingsite, riebeckite, and arfvedsonite in granitic rocks. *See* Granite; Granodiorite; Igneous rocks.

Due to its complex structure and chemistry, hornblende contains much information on its formation. Its behavior is understood reasonably well, and hornblende is of considerable use in interpreting the geological history of the rocks in which it occurs. *See* Amphibolite; Metamorphism. [F.C.Ha.]

Hornfels A metamorphic rock that has been subjected to heating during contact metamorphism around intrusive igneous rocks. Hornfels is typically fine-grained, although where it is subjected to high temperatures, large crystals called porphyroblasts can form. Mineral grains in hornfels are randomly oriented, with no preferred alignment of crystals to form foliation or cleavage planes. This texture indicates that the hornfels was not subjected to significant stresses during contact metamorphism.

Hornfels generally originates from sediments that undergo mineralogical changes, the nature of which depend on the magnitude of heating. The types of minerals that form are strongly dependent on the bulk composition. Minerals in hornfels formed from metamorphism of limestones, which are rich in calcium oxide (CaO), carbon dioxide (CO_2), and various amounts of magnesium oxide (MgO), iron oxide (FeO), and aluminum oxide (Al_2O_3), include (from high to low temperature) fosterite, diopside, tremolite, talc, and brucite. Other minerals that may be present include wollastonite, vesuvianite, anorthite, and grossular garnet, depending on the bulk composition of the rock. *See* Limestone.

Pelitic sediments are rich in chemical constituents such as silicon dioxide (SiO_2), Al_2O_3, MgO, FeO, potassium oxide (K_2O), and water (H_2O), with relatively minor amounts of CaO, sodium oxide (Na_2O), manganese oxide (MnO), and titanium dioxide (TiO_2). Metamorphism of these sediments to form hornfels results in formation of minerals such as chlorite, muscovite, biotite, andalusite, sillimanite, cordierite, garnet, staurolite, and K-feldspar. At extremely high temperatures ($>800^\circ$C or 1470°F) aluminum-rich minerals such as sapphirine, spinel, and corundum form. Deposits of emery, utilized for abrasives, are aluminum-rich hornfels that are products of high-temperature contact metamorphism. Chemical study of emeries indicates a general lack of alkali elements (K, Na, and Ca), which has been used to argue that they form as a result of extraction of a melt phase during high-temperature contact metamorphism. *See* Emery.

During contact metamorphism, hornfels typically forms in the highest-temperature part of aureoles adjacent to the pluton. Further away from the pluton, metamorphism of sediments results in development of schists and phyllites. Around the pluton, low-grade chlorite-bearing slates are progressively metamorphosed, resulting in the systematic appearance from low to higher temperature of cordierite + biotite + muscovite phyllite to cordierite + K-feldspar + biotite hornfels. In hornfels of a slightly different composition, muscovite is preserved, resulting in a hornfels with the composition andalusite + K-feldspar + cordierite + biotite + muscovite. Adjacent to the contact with the pluton, these muscovite-bearing hornfels undergo partial melting, resulting in the segregation of K-feldspar + plagioclase + quartz from the metamorphosed sediment as a result of partial melting. *See* Pluton; Slate.

Metamorphic studies of hornfels provide an important avenue to documenting the temperature and, in particular, the pressure (that is, the depth) during emplacement of the intrusive igneous rock that provides the heat. *See* Metamorphic rocks; Metamorphism; Mineralogy. [M.W.N.]

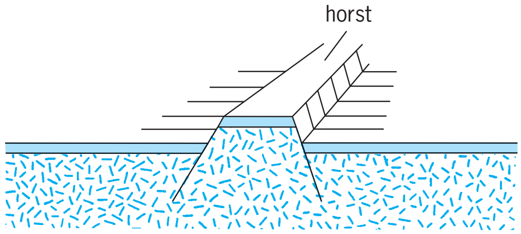
Horology Measurement of the time dimension. In practice, horology is the search for a steady or repetitive action, and the design of an instrument to perform that action and to indicate (read out) a measure of the action. Until early in the twentieth century, horology dealt with mechanical instruments, with effort distributed between improving accuracy and decreasing size of timepieces. Increasingly, however, electronic instruments provided means for meeting these objectives. *See* Chronometer; Clock; Quartz clock; Time.

An advance in accurate measurement of time came by replacement of dynamic mechanical oscillators with quantum energy transitions. Two standards in common use are the cesium atomic beam clock and the rubidium gas cell. More recently, trapped ion clocks, which use quantum transitions in elements such as mercury, have been developed. A small cloud of ions is trapped in a quadrupole electric field. The ions' thermal motions are then reduced by a technique called laser cooling. The quantum transitions in these clouds can then be measured with high precision. *See* Atomic clock; Laser cooling; Particle trap. [F.H.R.; D.C.Ba.]

Radio astronomers require precise time for two areas of experimentation: very long-baseline interferometry (VLBI) and pulsars. Both areas have the capability of providing precise time information. Very long-baseline interferometry involves multiplying samples of an incident electric field that are recorded independently at telescopes situated around the globe while being trained on the same object in the sky. Solar time, or Coordinated Universal Time (UTC), is offset from International Atomic Time (TAI) to allow for the variable rotation of the Earth. The most precise measurement of Earth rotation comes from VLBI measurements. Pulsars are highly magnetized and rapidly rotating neutron stars that emit intense beams of radio emission. Astronomers keep track of the rotations of these stars by referencing pulse arrival times to TAI, but not even the TAI time scale is sufficiently accurate because of the relativistic effects, gravitational redshift, and time dilation that result from the motion of the Earth. A new time scale, Terrestrial Time (TT), is derived from TAI without the relativistic effects. Timing measurements of the fastest pulsars, which rotate more than 600 times per second, are now as precise as the best Earth clocks over durations of a year or more. Time, which in prehistory was reckoned solely by astronomical events, has again become the province of astronomical observations. *See* Atomic time; Dynamical time; Pulsar; Radio astronomy; Radio telescope; Time. [D.C.Ba.]

Horseradish A hardy perennial crucifer, *Armoracia rusticana*, of eastern European origin belonging to the plant order Capparales. Horseradish is grown for its pungent roots, which are generally grated, mixed with vinegar and salt, and used as a condiment or relish. Production in the United States is limited to northern areas; Illinois, Wisconsin, and Missouri are important producing states. *See* Capparales. [H.J.C.]

Horst A segment of the Earth's crust, generally long as compared to its width, that has been upthrown relative to the adjacent rocks (see illustration). Horsts range in size from those that have lengths and upward displacement of a few inches to those that are tens of miles long with upward displacements of thousands of feet. The faults bounding a horst on either side commonly have inclinations of 50–70° toward the down-thrown blocks, and the direction of movement on these displacements indicates that they are gravity faults. These relationships suggest that horsts develop in regions where the crust has undergone extension. They may form in the crests of anticlines or domes, or may be related to broad regional warpings. *See* Fault and fault structures. [P.H.O.]



A simple horst with associated faults. (*After A.K. Lobeck, Geomorphology, McGraw-Hill, 1939*)

Horticultural crops Intensively managed plants cultivated for food or for esthetic purposes. Plant agriculture is divided traditionally into the fields of agronomy (herbaceous field crops, mainly grains, forages, oilseeds, and fiber crops), forestry (forest trees and products), and horticulture (garden crops, particularly fruits, vegetables, spices and herbs, and all plants grown for ornamental use). Most horticultural plants are utilized in the living state, with water essential to quality; thus most horticultural plants and products are highly perishable. *See* Agricultural science (plant); Agronomy; Floriculture; Forest and forestry.

Horticultural crops are usually classified as edibles or ornamentals. Edible crops which are used for direct human consumption are commonly subdivided into fruits or vegetables, but this classification is traditional and difficult to define precisely.

Fruit crops in the horticultural sense are cultivated for tissues associated with the botanical fruit, that is, seed-bearing structures derived from the flower, which are usually pulpy and tasteful. Trees or shrubs bearing nuts, characterized by a hard shell separated by a firm inner kernel (the seed), are often treated as a special category of fruit crops. *See* Fruit; Nut crop culture.

Vegetable crops in the horticulture sense are commonly herbaceous plants grown as annuals or biennials and occasionally as perennials that have edible parts (including, confusingly, the botanical fruit). Examples of edible parts include the root (sweet potato), tuber (potato), young shoot (asparagus), leaf (spinach), flower buds (cauliflower), fruit (tomato), and seed (pea).

Plants grown for ornamental use, such as cut flowers, bedding plants, interior foliage plants, or landscape plants, represent an enormous group and include thousands of species. *See* Ornamental plants. [J.J.]

Hospital infections Infections acquired during a hospital stay; also known as nosocomial infections. They may be recognized during or after hospitalization. They usually appear during hospitalization, but as many as 25% of infections related to surgery occur after discharge. Most nosocomial infections (93%) are caused by bacteria; fungi account for about 6%; and viruses, protozoa, and parasites account for the remaining 1%.

Nosocomial infections occur most frequently in the urinary tract, in surgical wounds, as a complication of pneumonia, and in association with bacteremia. *See* Pneumonia; Surgery; Urinary tract disorders.

Viral infections, although sometimes difficult to recognize, are becoming an increasing concern in hospitals, particularly because of the possibility of transmitting the human immunodeficiency virus (HIV), the causative organism for acquired immune deficiency syndrome (AIDS). Since the virus is not transmitted by the respiratory route or by casual contact, no one is endangered simply by being in the same hospital with HIV-infected patients. *See* Acquired immune deficiency syndrome (AIDS); Infection; Medical bacteriology. [B.B.D.]

Hot spots (geology) The surface manifestations of plumes, that is, columns of hot material, that rise from deep in the Earth's mantle. Hot spots are widely distributed around the Earth. One of their characteristics is an abundance of volcanic activity which persists for long time periods (greater than 1 million years). When the lithosphere (the rigid outer layer of the Earth) moves over a plume, a chain of volcanoes is left behind that progressively increases in age along its length. Hot spots are believed to be fixed with respect to each other and the deep mantle so that the age and orientation of these chains provide information on the absolute motions of the tectonic plates. *See* Lithosphere; Plate tectonics.

The Hawaiian-Emperor seamount chain in the central Pacific Ocean is a good example of a volcanic chain that was generated at a hot spot. The 3400-mi-long (5700-km) chain is made up mainly of tholeiitic lavas and ash tuff and pumice deposits. The lavas may have evolved from an initial submarine shield-building stage, through an explosive stage as they build up to sea level, and finally to a subaerial post-erosional stage. *See* Lava; Seamount and guyot.

Not all hot-spot volcanism is expressed in terms of highly lineated, multistage, volcanic chains. Aseismic ridges that extend up to or close to the axes of mid-oceanic ridges are another example of hot-spot volcanism. When a hot spot (for example, Iceland) is centered on the axis, pairs of ridges such as the Iceland-Faeroes Rise and the Greenland Rise are formed. Sometimes the plate (for example, Africa) has migrated off the hot spot (such as Tristan da Cunha), leaving behind ridge systems that no longer extend to the ridge axis (such as Rio Grande Rise and Western Walvis). *See* Mid-Oceanic Ridge; Volcano; Volcanology.

Another characteristic of hot spots is their association with broad swells in the Earth's topography. The Hawaiian hot-spot swell is believed to have been formed in response to either thermal or dynamic effects in an underlying mantle plume. The crustal and upper-mantle structure, which is constrained by seismic refraction data, shows that the oceanic crust is of uniform thickness beneath the swell. The long-wavelength correlation that is observed between the gravity anomaly and the topography (about 37 mGal mi^{-1} or 22 mGal km^{-1}) indicates that the mass excess of the swell is compensated by a low-density, high-temperature region below the crust. The uplift of hot-spot swells is believed to result from thermal perturbations in the underlying plume. The excess heights of swells suggest, on isostatic grounds, that temperature differences of about 450°F (250°C) occur between the plume and the surrounding mantle. Hot ascending plumes may raise the temperature of the overlying lithosphere, thereby thinning it.

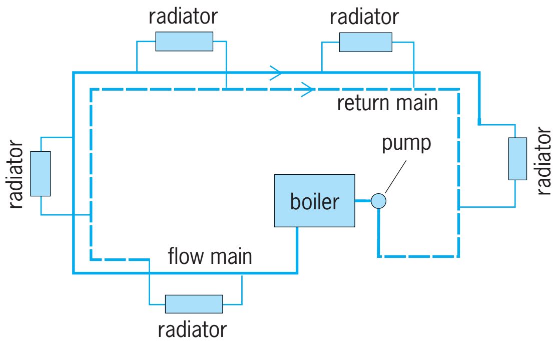
Two classes of models have been proposed to explain hot-spot swells. In the reheating model, uplift is produced by thermal expansion that is confined to the conducting portion of the lithosphere (the thermal boundary layer). In the dynamic model, however, there is a contribution to the uplift that is produced by vertical normal stresses exerted to the seismically defined base of the lithosphere (the mechanical boundary layer) by convection.

The main distinguishing feature between the uplift models is that the reheating model predicts a higher heat flow than the dynamic model. Discrimination between these models therefore depends on how the subsidence history, heat flow, and long-term strength (which is controlled mainly by the temperature) differ from those for unperturbed lithosphere of the same age. [A.B.W.]

Hot-water heating system A heating system for a building in which the heat-conveying medium is hot water. A hot-water heating system consists essentially of water-heating or -cooling means and of heat-emitting means such as radiators, convectors, baseboard radiators, or panel coils. A piping system connects the heat source to the various heat-emitting units and includes a method of establishing circulation of the water or other medium and an expansion tank to hold the excess volume of water as it is heated and expands.

In a one-pipe system, radiation units are bypassed around a one-pipe loop. This type of system should only be used in small installations. In a two-pipe system (see illustration), radiation units are connected to separate flow and return mains, which may run in parallel or preferably on a reverse return loop, with no limit on the size of the system. In either type of system, circulation may be provided by gravity or pump.

One outstanding advantage of hot-water systems is the ability to vary the water temperature according to requirements imposed by outdoor weather conditions, with consequent savings in fuel. Radiation units may be above or below water heaters, and piping may run in any direction as long as air is eliminated.



Two-pipe reverse return hot-water heating system.

Hot water is admirably adapted to extensive central heating where high temperatures and high pressures are used and also to low-temperature panel-heating and -cooling systems. *See* COMFORT HEATING; DISTRICT HEATING; OIL BURNER. [E.L.W.]

Hubble constant A number that characterizes the expansion rate of the universe and is required to determine its age. In the standard big bang model, the universe expands uniformly according to the Hubble law, $v = H_0 d$, where v is the velocity of a galaxy at a distance d, and H_0 is the Hubble constant. The wavelength of radiation is stretched due to the expansion of space so that the spectra of objects become progressively redder at greater distances. (For nearby objects, the observed redshift can be described as a Doppler effect.) The constant is named after Edwin P. Hubble, who discovered that the velocity of recession of a galaxy is proportional to its distance. A reliable and accurate measurement of the Hubble constant, an independent estimate of the ages of the oldest objects in the universe, and a further measurement of the average density in the universe are all separately required in order to test and ultimately provide strong constraints on cosmological models. *See* DOPPLER EFFECT; REDSHIFT.

Measurement of the Hubble constant is extraordinarily difficult in practice. First, measuring distances has turned out to be immensely challenging. Second, while the velocities can be measured very simply and accurately (from measurements of the positions of spectral lines in galaxies), they are perturbed by the gravitational interactions of galaxies with the neighbors (inducing what are referred to as peculiar motions superimposed on the general expansion). Hence, an extragalactic distance scale must be established at distances great enough that peculiar motions of galaxies are small compared to the overall cosmic expansion velocity, the Hubble flow. *See* ASTRONOMICAL SPECTROSCOPY.

In general, the basis for estimating distances in astronomy is the inverse-square radiation law. If objects can be identified whose luminosities are either constant (standard candles), or perhaps related to a quantity that is independent of distance (for example, period of oscillation, rotation rate, velocity dispersion, or color), then, given an absolute calibration, their distances can be gauged.

Primary among the distance indicators are the Cepheid variables, stars whose outer atmospheres pulsate regularly with periods ranging from 2 to about 100 days. Empirically it has been established that the period of pulsation (a quantity independent of distance) is very well correlated with the intrinsic luminosity of the star. High resolution is the key to discovering Cepheids in other galaxies. The resolution of the Hubble Space Telescope is about 10 times better than can be generally obtained through the Earth's atmosphere, and, moreover, it is stable. The reach of Cepheid variables as distance indicators is limited, however, even with the Hubble Space Telescope. For distances beyond 20 megaparsecs or so (1 Mpc = 3.08×10^{22} m = 3.26×10^{6} light-years), brighter objects than ordinary stars are required, for example, luminous supernovae or the luminosities of entire galaxies. The Cepheid distances from the Hubble Space Telescope Key Project have provided a means of calibrating and comparing a number of relative distance methods, and, to within an uncertainty of ±10%, all of these methods are consistent with a value of the Hubble constant of about 72 kilometers per second per megaparsec.

The Hubble constant sets the expansion time scale for the universe. In order to measure the time since the big bang, it is necessary to determine the expansion rate, and the average matter-plus-energy density of the universe. Increasing evidence suggests that the total matter density of the universe is about 20–30% of the critical density. (Below a critical density the universe will expand forever, whereas above the critical density the universe will recollapse.) The theory of inflation provides a strong theoretical motivation for a critical-density universe; however, if the mass density is only 20–30% of critical, as observations suggest, then inflation would require a missing energy component to bring the total energy density up to the critical density. Measurements of type Ia supernovae provide evidence for such a missing energy component, called the cosmological constant. *See* BIG BANG THEORY; COSMOLOGY; INFLATIONARY UNIVERSE COSMOLOGY; UNIVERSE. [W.L.F.]

Huebnerite A mineral with the chemical composition $MnWO_4$. Huebnerite is the manganese member of the wolframite solid-solution series. It commonly contains small amounts of iron. It occurs in monoclinic, short, prismatic crystals. Fracture is uneven. Luster varies from adamantine to resinous. Hardness is 4 on Mohs scale and specific gravity is 7.2. Huebnerite is transparent and yellowish to reddish-brown in color; streak is brown. *See* WOLFRAMITE. [E.C.T.C.]

Human-computer interaction An interdisciplinary field focused on the interactions between human users and computer systems, including the user interface and the underlying processes which produce the interactions. The contributing disciplines include computer science, cognitive science, human factors, software engineering, management science, psychology, sociology, and anthropology. Early research and development in human-computer interaction focused on issues directly related to the user interface. Some typical issues were the properties of various input and output devices, interface learnability for new users versus efficiency and extensibility for experienced users, and the appropriate combination of interaction components such as command languages, menus, and graphical user interfaces (GUI). Recently, the field of human-computer interaction has broadened and become more attentive to the processes and context for the user interface. The focus of research and development is now on understanding the relationships among users' goals and objectives, their personal capabilities, the social environment, and the designed artifacts with which they interact. As an applied field, human-computer interaction is also concerned with the development process used to create the interactive system and its value for the human user.

The interfaces and processes that make up human-computer interaction are understood and advanced through a variety of methods. At one level, this interaction can be characterized by the capabilities and processes of the human and the computer to accept input, process that input, and generate output. The computer capabilities include the hardware (input and output devices) such as the monitor, mouse, keyboard, and Internet connection. These devices reflect contributions from computer science and engineering, whereas the human capabilities, both mental and physical, are understood through cognitive science and ergonomics. At another level, the interaction between the computer and the human consists of user interface software which governs the meanings of the inputs and outputs for the computer, as well as the corresponding rules and expectations that the user applies to generate meaningful actions. The user's internal model of the interaction is supported by visual cues in the interface and designed in accordance with principles of human factors. At a higher level, this interaction includes the context of goals, motivations, and other people and resources that determine what the person is doing. Understanding the process at this level requires insights from social and organizational sciences. *See* HUMAN-FACTORS ENGINEERING.

Advances in computer science have significantly increased the processing power of computers while decreasing their size. These advances have provided the underlying technology for creating a wider variety of human-computer interactions. For example, streaming audio and video over the Internet, now common, would not be possible without the increased processing power and network connectivity of computers. These technological developments were influenced by the discovery of useful applications in human-computer interaction. Increasingly sophisticated software has become available to address input through natural speech and immersive environments, providing a virtual reality experience. *See* VIRTUAL REALITY.

Developing human-computer interactions involves design on both sides of the interaction. On the technology side, the designer must have a thorough understanding of the available hardware and software components and tools. On the human side, the designer must have a good understanding of how humans learn and work with computers, including envisioning new modes of working. The designer's task is to create effective, efficient, and satisfying interactions by balancing factors such as cost, benefits, standards, and the environmental constraints in which the interaction will take place.

Modern prototyping tools allow for the use of an iterative development model where a representative portion of the interface is designed and implemented with each iteration. Feedback from testers is used to enhance the design with each iteration. The final design consists of many elements: the resulting artifacts for use by the target population, as well as supporting elements such as an analysis of needs and tasks, descriptions of the dialog rules and users' conceptual models, expected scenarios of use, and the designer's rationale and reflections from the development process. [T.Ca.; K.Ha.]

Human ecology The study of how the distributions and numbers of humans are determined by interactions with conspecific individuals, with members of other species, and with the abiotic environment. Human ecology encompasses both the responses of humans to, and the effects of humans on, the environment. Human ecology today is the combined result of humans' evolutionary nature and cultural developments. *See* BIOSPHERE; ECOLOGICAL COMMUNITIES; ECOSYSTEM.

Humans' strong positive and negative emotional responses to components of the environment evolved because our ancestors' responses to environmental information affected survival and reproductive success. Early humans needed to interpret signals from other organisms and the abiotic environment, and they needed to evaluate and select habitats and the resources there. These choices were emotionally driven. For example, food is one of the most important resources provided by the environment. Gathering food requires decisions of where to forage and what items to select. Anthropologists often use the theory of optimal foraging to interpret how these decisions are made. The theory postulates that as long as foragers have other valuable ways to spend their time or there are risks associated with seeking food, efficient foraging will be favored even when food is not scarce. This approach has facilitated development of simple foraging models and more elaborate models of food sharing and gender division of labor, symbolic communication, long-term subsistence change, and cross-cultural variation in subsistence practices.

Significant modification of the environment by people was initiated by the domestication of fire, used to change vegetation structure and influence populations of food plants and animals. Vegetation burning is still common in the world, particularly in tropic regions. The arrival of humans with sophisticated tools precipitated the next major transformation of Earth, the extinction of large vertebrates. Agriculture drove the third major human modification of environments. Today about 35–40% of terrestrial primary production is appropriated by people, and the percentage is rising.

Humans will continue to exert powerful influences on the functioning of the Earth's ecological systems. The human population is destined to increase for many years. Rising affluence will be accompanied by increased consumption of resources and, hence, greater appropriation of the Earth's primary production. Nevertheless, many future human ecology scenarios are possible, depending on how much the human population grows and how growth is accommodated, the efficiency with which humans use and recycle resources, and the value that people give to preservation of biodiversity. *See* ANTHROPOLOGY; ECOLOGY; ENVIRONMENT; SOCIOBIOLOGY. [G.H.O.]

Human-factors engineering The application of experimental findings in behavioral science and physiology to the design and operation of technical systems in which humans are users or operators. This includes design of hardware, software, training, and documentation as well as manufacturing and maintenance. Human-factors professionals are trained in some combination of experimental or cognitive psychology, physiology, and engineering—typically industrial, mechanical, electrical, or software engineering. Human-factors engineering seeks to ensure that humans' tools and environment are best matched to their physical size, strength, and speed and to the capabilities of the senses, memory, cognitive skill, and psychomotor preferences. These objectives are in contrast to forcing humans to conform or adapt to the physical environment.

Human-factors engineering has also been termed human factors, human engineering, engineering psychology, applied experimental psychology, ergonomics, and biotechnology. It is related to the field of human-machine systems engineering but is more general, comprehensive, and empirical and not so wedded to formal mathematical models and physical analysis. *See* HUMAN-MACHINE SYSTEMS.

Among the problems of human-factors engineering are design of visual displays for ease and speed of interpretation; design of tonal signaling systems and voice communication systems for accuracy of communication; design of seats, workplaces, cockpits, and consoles in terms of humans' physical size, comfort, strength, and visibility. Human-factors engineering addresses problems of physiological stresses arising from such environmental factors as heat and cold, humidity, high and low atmospheric pressure, vibration and acceleration, radiation and toxicity, illumination or lack of it, and acoustic noise. Finally, the field includes psychological stresses of work speed and load and problems of memory, perception, decision making, and fatigue.

A fundamental problem of ever-increasing importance for human-factors engineers is what tasks should be assigned to people and what to machines. It is a fallacy to think that any given whole task can be accomplished best either by a human or by a machine without the aid of the other, because often some elements of both provide a mixture superior to either alone. Machines are superior in speed and power; are more reliable for routine tasks, being free of boredom and fatigue; can perform computations at higher rates; and can store and recall specific quantitative facts from memory faster and more dependably. Humans, by contrast, have remarkable sensory capacities which are difficult to duplicate in range, size, and power with artificial instruments (the ratio of the greatest to the least energy which people can either see or hear is about 10^{13}). Humans' ability to perceive patterns, make relevant associations in memory, and induce new generalizations from empirical data remains far superior to that of any computer existing or planned. Thus, while people's overt information-processing rate in simple skills is low, their information-processing rate for these pattern recognition and inductive- reasoning capabilities (of which little is understood) appears far greater. [T.B.S.]

In cognitive engineering, one of the major issues in human-factors engineering is the concern that modern sophisticated hardware and software technology may be too complex for the people who will eventually use it. Requiring people to perform difficult or cognitively complex tasks is perhaps the leading cause of human–machine errors or accidents. Tasks can be cognitively difficult for a number of reasons. The number of steps required to use the system may exceed people's memory limitations, the user may be required to divide his or her attention between several different sources of information, or the person may be required to perform difficult mental operations. All of these factors burden an individual's cognitive capacity and, if that capacity is exceeded, errors may occur.

Two major trends have led to increased emphasis on the cognitive complexity of human-machine systems. One of these is the move toward larger and more complex systems where human error can have serious consequences for the systems' users and the general public. The other trend is the rapid development of modern information technology based upon powerful yet inexpensive microcomputers.

An important aspect in addressing this problem is the early identification and control of the cognitive complexity or mental difficulty of performing a task required of the new technology application. The best procedure (in terms of cost and effectiveness) for addressing this problem is to use cognitive analysis to develop specifications or guidelines that can be used during the initial design technology application. Through such design guidance, human cognitive limitations are controlled early in the technology application design when it is easiest and most cost-effective to make changes. If the technology application has developed to the point where design guides would no longer be useful (for example, much design work has already been completed), an alternative approach is to use cognitive engineering to evaluate the design as it exists. The results of the cognitive analysis will indicate which aspects of the design may be too difficult for people to perform and could lead to human–machine errors. The final use of cognitive engineering analysis is in preparing training materials. Cognitive analyses can identify the aspects of a person–machine interface that will be most difficult for people to perform. These aspects can then be given special training aids or more intensive hands-on training in order to reduce the potential of human–machine error. [P.G.Ro.]

Human genetics A discipline concerned with genetically determined resemblances and differences among human beings. Technological advances in the visualization of human chromosomes have shown that abnormalities of chromosome number or structure are surprisingly common and of many different kinds, and that they account for birth defects or mental impairment in many individuals as well as for numerous early spontaneous abortions. Progress in molecular biology has clarified the molecular structure of chromosomes and their constituent genes and the ways in which change in the molecular structure of a gene can lead to a disease. Concern about possible genetic damage through environmental agents and the possible harmful effects of hazardous substances in the environment on prenatal development has also stimulated research in human genetics. The medical aspects of human genetics have become prominent as nonhereditary causes of ill health or early death, such as infectious disease or nutritional deficiency, have declined, at least in developed countries.

In normal humans, the nucleus of each normal cell contains 46 chromosomes, which comprise 23 different pairs. Of each chromosome pair, one is paternal and the other maternal in origin. In turn, only one member of each pair is handed on through the reproductive cell (egg or sperm) to each child. Thus, each egg or sperm has only 23 chromosomes, the haploid number; fusion of egg and sperm at fertilization will restore the double, or diploid, chromosome number of 46. *See* CHROMOSOME; FERTILIZATION.

The segregation of chromosome pairs during meiosis allows for a large amount of "shuffling" of genetic material as it is passed down the generation. Two parents can provide $2^{23} \times 2^{23}$ different chromosome combinations. This enormous source of variation is multiplied still further by the mechanism of crossing over, in which homologous chromosomes exchange segments during meiosis. *See* CROSSING-OVER (GENETICS); MEIOSIS.

Twenty-two of the 23 chromosome pairs, the autosomes, are alike in both sexes; the other pair comprises the sex chromosomes. A female has a pair of X chromosomes; a male has a single X, paired with a Y chromosome which he has inherited from his father and will transmit to each of his sons. Sex is determined at fertilization, and depends on whether the egg (which has a single X chromosome) is fertilized by an X-bearing or a Y-bearing sperm. *See* SEX DETERMINATION.

Any gene occupies a specific chromosomal position, or locus. The alternative genes at a particular locus are said to be alleles. If a pair of alleles are identical, the individual is homozygous; if they are different, the individual is heterozygous. *See* ALLELE.

Genetic variation has its origin in mutation. The term is usually applied to stable changes in DNA that alter the genetic code and thus lead to synthesis of an altered protein. The genetically significant mutations occur in reproductive cells and can therefore be transmitted to future generations. Natural selection acts upon the genetic diversity generated by mutation to preserve beneficial mutations and eliminate deleterious ones.

A very large amount of genetic variation exists in the human population. Everyone carries many mutations, some newly acquired but others inherited through innumerable generations. Though the exact number is unknown, it is likely that everyone is heterozygous at numerous loci, perhaps as many as 20%. *See* MUTATION.

The patterns of inheritance of characteristics determined by single genes or gene pairs depend on two conditions: (1) whether the gene concerned is on an autosome (autosomal) or on the X chromosome (X-linked); (2) whether the gene is dominant, that is, expressed in heterozygotes (when it is present on only one member of a chromosomal pair and has a normal allele) or is recessive (expressed only in homozygotes, when it is present at both chromosomes). *See* DOMINANCE. [M.W.T.]

A quantitative trait is one that is under the control of many factors, both genetic and environmental, each of which contributes only a small amount to the total variability of the trait. The phenotype may show continuous variation (for example, height and skin color), quasicontinuous variation (taking only integer values—such as the number of ridges in a fingerprint), or it may be discontinuous (a presence/absence trait, such as diabetes or mental retardation). With discontinuous traits, it is assumed that there exists an underlying continuous variable and that individuals having a value of this variable above (or below) a threshold possess the trait.

A trait that "runs in families" is said to be familial. However, not all familial traits are hereditary because relatives tend to share common environments as well as common genes.

The variability of almost any trait is partly genetic and partly environmental. A rough measure of the relative importance of heredity and environment is an index called heritability. For example, in humans, the heritability of height is about 0.75. That is, about 75% of the total variance in height is due to variability in genes that affect height and 25% is due to exposure to different environments. [C.De.]

Hereditary diseases. Medical genetics has become an integral part of preventive medicine (that is, genetic counseling, including prenatal diagnostics). Hereditary diseases may be subdivided into three classes: chromosomal diseases; hereditary diseases with simple, mendelian modes of inheritance; and multifactorial diseases.

One out of 200 newborns suffers from an abnormality that is caused by a microscopically visible deviation in the number or structure of chromosomes. The most important clinical abnormality is Down syndrome—a condition due to trisomy of chromosome 21, one of the smallest human chromosomes. This chromosome is present not twice but three times; the entire chromosome complement therefore comprises 47, not 46, chromosomes. Down syndrome occurs one to two times in every 1000 births; its pattern of abnormalities derives from an imbalance of gene action during embryonic development. Down syndrome is a good example of a characteristic pattern of abnormalities that is produced by a single genetic defect. *See* DOWN SYNDROME.

Other autosomal aberrations observed in living newborns that lead to characteristic syndromes include trisomies 13 and 18 (both very rare), and a variety of structural aberrations such as translocations (exchanges of chromosomal segments between different chromosomes) and deletions (losses of chromosome segments). Translocations normally have no influence on the health status of the individual if there is no gain or loss of chromosomal material (these are called balanced translocations). However, carriers of balanced translocations usually run a high risk of having children in whom the same translocation causes gain or loss of genetic material, and who suffer from a characteristic malformation syndrome.

Clinical syndromes caused by specific aberrations vary, but certain clinical signs are common: low birth weights (small for date); a peculiar face; delayed general, and especially mental, development, often leading to severe mental deficiency; and multiple malformations, including abnormal development of limbs, heart, and kidneys. *See* CONGENITAL ANOMALIES.

Less severe signs than those caused by autosomal aberrations are found in individuals with abnormalities in number (and, sometimes, structure) of sex chromosomes. This is because in individuals having more than one X chromosome, the additional X chromosomes are inactivated early in pregnancy. For example, in women, one of the two X chromosomes is always inactivated. Inactivation occurs at random so that every normal woman is a mosaic of cells in which either one or the other X chromosome is active. Additional X chromosomes that an individual may have received will also be inactivated; in trisomies, genetic imbalance is thus avoided to a certain degree. However, inactivation is not complete; therefore, individuals with trisomies—for example, XXY (Klinefelter syndrome), XXX (triple-X syndrome), or XYY—or monosomies (XO; Turner syndrome) often show abnormal sexual development, intelligence, or behavior.

In contrast to chromosomal aberrations, the genetic defects in hereditary diseases with simple, mendelian modes of inheritance cannot be recognized by microscopic examination; as a rule, they must be inferred more indirectly from the phenotype and the pattern of inheritance in pedigrees. The defects are found in the molecular structure of the DNA. Often, one base pair only is altered, although sometimes more complex molecular changes, such as deletions of some bases or abnormal recombination, are involved. Approximately 1% of all newborns have, or will develop during their lives, a hereditary disease showing a simple mendelian mode of inheritance.

In medical genetics, a condition is called dominant if the heterozygotes deviate in a clearly recognizable way from the normal homozygotes, in most cases by showing an abnormality. Since such dominant mutations are usually rare, almost no homozygotes are observed.

In some dominant conditions, the harmful phenotype may not be expressed in a gene carrier (this is called incomplete penetrance), or clinical signs may vary in severeness between carriers (called variable expressivity). Penetrance and expressivity may be influenced by other genetic factors; sometimes, for example, by the sex of the affected person, whereas in other instances, the constitution of the “normal” allele has been implicated. Environmental conditions may occasionally be important. In most cases, however, the reasons are unknown.

X-linked modes of inheritance occur when the mutant allele is located on the X chromosome. The most important X-linked mode of inheritance is the recessive one. Here, the males (referred to as hemizygotes since they have only one allele) are affected, since they have no normal allele. The female heterozygotes, on the other hand, will be unaffected, since the one normal allele is sufficient for maintaining function. A classical example is hemophilia A, in which one of the serum factors necessary for normal blood clotting is inactive or lacking. (The disease can now be controlled by repeated substitution of the deficient blood factor—a good example for phenotypic therapy of a hereditary disease by substitution of a deficient gene product.) Male family members are affected whereas their sisters and daughters, while being unaffected themselves, transmit the mutant gene to half their sons. Only in very rare instances, when a hemophilic patient marries a heterozygous carrier, are homozygous females observed. *See* SEX-LINKED INHERITANCE.

There are thousands of hereditary diseases with simple mendelian modes of inheritance, but most common anomalies and diseases are influenced by genetic variability at more than one gene locus. Most congenital malformations, such as congenital heart disease, cleft lip and palate, neural tube defects and many others, fall into this category, as do the constitutional diseases, such as diabetes mellitus, coronary heart disease, anomalies of the immune response and many mental diseases, such as schizophrenia or affective disorders. All of these conditions are common and often increase in frequency with advanced age. [F.V.]

Biochemical genetics. Biochemical genetics began with the study of inborn errors of metabolism. These are diseases of the body chemistry in which a small molecule such as a sugar or amino acid accumulates in body fluids because an enzyme responsible for its metabolic breakdown is deficient. This molecular defect is the result of mutation in the gene coding for the enzyme protein. The accumulated molecule, dependent on its nature, is responsible for the causation of a highly specific pattern of disease.

The field of biochemical genetics expanded with the recognition that similar heritable defective enzymes interfere with the breakdown of very large molecules, such as mucopolysaccharides and the complex lipids that are such prominent components of brain substance. The resultant storage disorders present with extreme alterations in morphology and bony structure and with neurodegenerative disease.

The majority of hereditary disorders of metabolism are inherited in an autosomal recessive fashion. In these families, each parent carries a single mutant gene on one chromosome and a normal gene on the other. Most of these mutations are rare. In populations with genetic diversity, most affected individuals carry two different mutations in the same gene. Some metabolic diseases are coded for by genes on the X chromosome. Most of these disorders are fully recessive, and so affected individuals are all males, while females carrying the gene are clinically normal. The disorders that result from mutations in the mitochondrial genome are inherited in nonmendelian fashion because mitochondrial DNA is inherited only from the mother. Those that carry a mutation are heteroplasmic; that is, each carries a mixed population of mitochondria, some with the mutation and some without.

Phenylketonuria (PKU) is a prototypic biochemical genetic disorder. It is an autosomally recessive disorder in which mutations demonstrated in a sizable number of families lead, when present in the genes on both chromosomes, to defective activity of the enzyme that catalyzes the first step in the metabolism of phenylalanine. This results in accumulation of phenylalanine and a recognizable clinical disease whose most prominent feature is severe retardation of mental development. *See* PHENYLKETONURIA.

The diseases that result from mutation in mitochondrial DNA have been recognized as such only since the 1990s. They result from point mutations, deletions, and other rearrangements. A majority of these disorders express themselves chemically in elevated concentrations of lactic acid in the blood or cerebrospinal fluid. Many of the disorders are known as mitochondrial myopathies (diseases of muscles) because skeletal myopathy or cardiomyopathy are characteristic features. [W.L.Ny.]

Human Genome Project

An organized international scientific endeavor to determine the complete structure of the human genetic material deoxyribonucleic acid (DNA) and understand its function. *See* HUMAN GENETICS.

History. The idea for the Human Genome Project (HGP) first arose in the mid-1980s. Several scientific groups met to discuss the feasibility, and various reports were published. The most influential report was prepared by the National Research Council

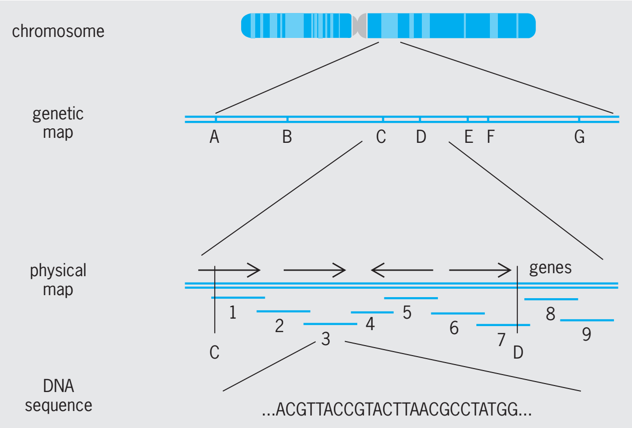
(NRC) of the U.S. National Academy of Sciences. It proposed a detailed scientific strategy that persuaded many scientists that the project was possible. October 1, 1990, was declared the official start time for the HGP in the United States; significant funding had become available and research groups were starting their work. Major contributions to the HGP have been made by the United Kingdom, France, Japan, and Germany, with smaller contributions from many other quarters. Coordination among the countries has been informal, relying largely on scientist-to-scientist collaborations, but has proved to be very effective.

Scientific strategy. First, markers are placed on the chromosomes by genetic mapping, that is, observing how the markers are inherited in families. Second, a physical map is created from overlapping cloned pieces of the DNA. Third, the sequence of each piece is determined, and the sequences are lined up by computer until a continuous sequence along the whole chromosome is obtained. The second and third steps can be reversed or done in parallel. As the pieces are sequenced, the sequences at the overlapping ends can be used to help order the pieces. If the sequencing is done before the pieces are mapped, the process is called whole-genome shotgun sequencing. *See* Deoxyribonucleic acid (DNA); Gene.

Because the human genome is so big (human DNA consists of about 3 billion nucleotides connected end to end in a linear array), it was necessary to break the task down into manageable chunks (see illustration).

Model organisms. An important element of the overall strategy was to include the study of model organisms in the HGP. There were two reasons for this: (1) Simpler organisms provide good practice material. (2) Comparisons between model organisms and humans yield very valuable scientific information. The HGP initially adopted five model organisms to have their DNA sequenced: the bacterium *Escherichia coli*, the yeast *Saccharomyces cerevisiae*, the roundworm *Caenorhabditis elegans*, the fruitfly *Drosophila melanogaster*, and the laboratory mouse *Mus musculus*. The mouse genome is just as complex as the human genome, but the mouse offers the advantages that it can be bred and other experiments can be conducted that are not possible on humans.

Findings. How many genes are there is probably the most common question regarding the human genome. The first two human chromosomes to be sequenced, chromosomes 22 and 21, provided some interesting observations. Although the two chromosomes are approximately the same length, chromosome 22 has more than twice as many genes as chromosome 21. Extrapolation of the number of genes found on chromosomes 22 and 21 led to the estimate that the whole human genome contains about 36,000 genes. This is quite a surprise because previous estimates were 80,000 to 100,000 genes. Preliminary examination of the draft sequence of the entire human genome confirmed that the number of genes is much lower than previously thought. This does not necessarily mean that the human genome is less complex, because many genes can produce more than one protein by alternate splicing of their exons (protein-encoding regions of the gene) during translation into the constituents of proteins. *See* Chromosome; Genetic code.



Steps in analyzing a genome.

Another fascinating feature of the human genome sequence is the large fraction that consists of repeated sequence elements; 40% of chromosome 21 and 42% of chromosome 22 are composed of repeats. The function of any of these repeats is not yet known, but elucidating their distribution in the genome may help to reveal it.

Another statistic that is of interest is the base composition, the percent of the DNA that is made of guanine-cytosine (GC) base pairs as opposed to adenine-thymine (AT) base pairs. Chromosome 22 has a 48% GC content, whereas chromosome 21 has 41% and the average over the genome is 42%. Again, the significance of this is not yet known, but higher GC content seems to correlate with higher gene density.

The type of analysis performed initially on chromosomes 21 and 22 has been extended to the entire human sequence. However, a full understanding will take decades to achieve.

Future research. With the complete sets of genes of organisms available, how genes are turned on and off and how genes interact with each other can be studied. What the different genes do and how they affect human health must also be learned. Consequently, much effort is now directed to studying the regulation of gene expression and annotating the sequence with useful biological information about function.

Another key challenge is to understand how DNA function varies with differences in the DNA sequence. Each human being has a unique DNA sequence which differs from that of any other human being by about 0.1%, regardless of ethnic origin. Yet this small difference affects characteristics such as how humans look and to what diseases they are susceptible. The differences also provide clues about the evolution of the human species and the historical migration patterns of people across the world. *See* Molecular biology; Nucleic acid. [F.Co.; E.Jor.]

Human-machine systems Complex systems that comprise both humans and machines. Human-machine systems engineering is the analysis, modeling, and design of such systems. It is distinguished from the more general field of human factors and from the related fields of human-computer interaction, engineering psychology, and sociotechnical systems theory in three general ways. First, human-machine systems engineering focuses on large, complex, dynamic control systems that often are partially automated (such as flying an airplane, monitoring a nuclear power plant, or supervising a flexible manufacturing system). Second, human-machine systems engineers build quantitative or computational models of the human-machine interaction as tools for analysis and frameworks for design. Finally, human-machine systems engineers study human problem-solving in naturalistic settings or in high-fidelity simulation environments. *See* Human-computer interaction; Human-factors engineering.

Thus, human-machine systems engineering focuses on the unique challenges associated with designing joint technological and human systems. Historically it has grown out of work on cybernetics, control engineering, information and communication theory, and engineering psychology. Subsequently, researchers who focus on cognitive human-machine systems (in which human work is primarily cognitive rather than manual) have also referred to their specialization as cognitive engineering or cognitive systems engineering. *See* Cybernetics; Information theory.

The four major aspects of human-machine systems, in roughly historical order, are systems in which the human acts as a manual controller, systems in which the human acts as a supervisory controller, human interaction with artificial-intelligence systems, and human teams in complex systems. This general progression is related to advances in computer and automation technology. With the increasing sophistication and complexity of such technology, the human role has shifted from direct manual control to supervisory control of physical processes, to supervision of intelligent systems, and finally, with an increasing emphasis on the social and organizational aspects of complex systems, to teamwork in complex environments.

Aviation is an example of a human-machine system in which all of these developments have occurred. Early work in aircraft systems focused on manual control models of pilot performance. With increasing levels of automation, the pilot shifted to a more supervisory role in which tasks such as planning and programming the flight management computer became the predominant form of work. *See* AIRCRAFT INSTRUMENTATION; AUTOPILOT; FLIGHT CONTROLS. [P.M.J.]

Human variation Attempting to describe and explain the manner in which people differ from one another constitutes one of the traditionally central research questions in anthropology. This also affords a classic illustration of the manner in which humans interpret the world by imposing patterns upon it, and of the social functions of science.

The first to suggest that the human species might actually be divisible into a small number of natural groups was a French traveler and physician, Francois Bernier, in 1684. He proposed dividing the human species into the peoples of Europe, North Africa, India, and the Near East; the peoples of sub-Saharan Africa; the people of east Asia; the Lapps (Saami) of Scandinavia; and the Hottentots (Khoi) of southern Africa. The apparent naturalness of this system was so powerful that the father of biological classification, Carolus Linnaeus, formally incorporated it into his *System of Nature* in the eighteenth century. Here, four landmasses became eponymous homes to four formally designated subspecies of humans: red Americans, yellow Asians, white Europeans, and black Africans. Subsequent studies attempted to fine-tune the classification, observing the distinctive physical features of many different peoples, but still failing to question the fundamental assumption that there were indeed a small number of basic types of people to be identified and classified. *See* TAXONOMY.

Not until the advent of genetic data did the racial paradigm begin to be seriously questioned. It was shown that the vast bulk of the genetic differences in the human species occurred within and between local populations, the differences between continental regions accounting for only about 6% of the total. Thus, racial (continental) differences were found to be quantitatively trivial.

Genetic variation appears to be patterned in two principal ways. Ubiquitous polymorphisms, like the ABO blood group, constitute the majority of detectable genetic variation, where most populations contain most alleles. Private polymorphisms constitute another component of human variation, in which a particular variant is found mostly in a restricted region of the world. Even then, it will be found only in low frequency. *See* GENE; HUMAN GENETICS.

In the twenty-first century the study of race has been superseded by studies of human variation and ethnicity, reflecting two significant discoveries. First, race (that is, contrasts among the most biologically divergent peoples) amounts to little in the overall biological variation in the human species. Second, “racial” issues transcend biology; they are issues of equality, rights, opportunities, and prejudices.

However, several biological generalizations can be made. First, the continuity found across human populations in nature is precisely what should be expected from microevolutionary processes operating. Second, some differences among populations are adaptations, molded by the action of natural selection on the gene pool. Third, the most divergent peoples are simply the most adapted to different circumstances—not the most primordial. Fourth, specific populations are not reliable as representatives of large continents. Finally, the observation of consistent differences between populations is not a sufficient basis on which to infer that those differences are innate. It is nearly impossible to control all the relevant social, economic, and developmental variables and to study simply innate biological differences between populations. *See* PHYSICAL ANTHROPOLOGY; SOCIOBIOLOGY. [J.M.]

Humidification The process of increasing the water-vapor content (humidity) of a gas. This process and its reverse operation, dehumidification, are important steps in air conditioning for human comfort and in many industrial operations. *See* AIR CONDITIONING; COMFORT HEATING; DEHUMIDIFIER; HUMIDITY.

Air (or other gas) can be humidified by direct injection of water vapor (steam) or, more commonly, by the evaporation of liquid water in contact with the airstream. When evaporation occurs, heat is required to provide the latent heat of vaporization. If no external source of heat is provided, either the water or the air, or both, will be cooled. The cooling of water by this process is the basis of operation for industrial cooling towers, whereas evaporative air coolers often used in hot, dry climates depend upon the air-cooling effect. In both these types of apparatus, humidification of the air occurs, although it is not the prime objective of the operation. In units designed primarily for humidification, the incoming air is usually heated to provide the latent heat of evaporation and to permit the air to leave the unit at controlled levels of both temperature and humidity. *See* COOLING TOWER. [A.L.K.]

Humidistat A controller that measures and controls relative humidity. A humidistat may be used to control either humidifying or dehumidifying equipment by the regulation of electric or pneumatic switches, valves, or dampers. Most methods for measuring humidity rely upon the swelling and shrinking of materials, such as human hair, silk, horn, goldbeater’s skin, and wood, with increases and decreases in relative humidity.

An electronic humidistat includes a sensing element and a relay amplifier. The sensing element consists of alternate metal conductors on a small, flat plate with a plastic coating. An increase or decrease of the relative humidity causes a decrease or increase in the electrical resistance between the two sets of conductors; the change in resistance is measured by the relay amplifier. *See* HUMIDITY; PSYCHROMETRICS. [J.E.H./R.L.K.]

Humidity Atmospheric water-vapor content, expressed in any of several measures, especially relative humidity, absolute humidity, humidity mixing ratio, and specific humidity.

Relative humidity is the ratio, in percent, of the moisture actually in the air to the moisture it would hold if it were saturated at the same temperature and pressure. It is a useful index of dryness or dampness for determining evaporation, or absorption of moisture. *See* PSYCHROMETRICS.

Absolute humidity is the weight of water vapor in a unit volume of air expressed, for example, as grams per cubic meter or grains per cubic foot.

Humidity mixing ratio is the weight of water vapor mixed with unit mass of dry air, usually expressed as grams per kilogram. Specific humidity is the weight per unit mass of moist air and has nearly the same values as mixing ratio. [J.R.F.]

Humidity control Regulation of the degree of saturation (relative humidity) or quantity (absolute humidity) of water vapor in a mixture of air and water vapor. Humidity is commonly mistaken as a quality of air. *See* HUMIDITY.

When the mixture of air and water vapor is heated at constant pressure, not in the presence of water or ice, the ratio of vapor pressure to saturation pressure decreases; that is, the relative humidity falls, but absolute humidity remains the same. If the warm mixture is brought in contact with water in an insulated system, adiabatic humidification takes place; the warm gases and the bulk of the water are cooled as heat is transferred to that portion of the water which evaporates, until the water vapor reaches its saturation pressure corresponding to the resultant water-air-vapor mixture temperature. Relative humidity is then 100% and absolute humidity has increased. Heating of the mixture and use of the heated mixture to evaporate water is typical of many industrial drying processes, as well as such common domestic applications as hair drying. This same sequence occurs when warm furnace air is passed over wetted, porous surfaces to humidify air for comfort conditioning. *See* AIR CONDITIONING.

To remove moisture from the air-vapor mixture, the mixture is commonly cooled to the required dew point temperature (corresponding to the absolute humidity to be achieved) by passage over refrigerated coils or through an air washer where the mixture is brought in contact with chilled water. The result is a nearly saturated mixture which can be reheated, if required, to achieve the desired relative humidity. *See* DEHUMIDIFIER.

Moisture is also removed without refrigeration by absorption, a process in which the mixture passes through a spray of liquid sorbent that undergoes physical or chemical change as it becomes more dilute. Typical sorbents include lithium and calcium chloride solutions and ethylene glycol. *See also* ABSORPTION.

Another means of dehumidification, by adsorption, uses silica gel or activated bauxite which, through capillary action, reduces the vapor pressure on its surface so that the water vapor in its vicinity, being supersaturated, condenses. *See* ADSORPTION; PSYCHROMETRICS. [R.L.K.]

Humite A homologous series of magnesium nesosilicate minerals having the general composition $Mg_{2n+1}(SiO_4)_n(F, OH)_2$. The known species include norbergite ($n = 1$), chondrodite ($n = 2$), humite ($n = 3$), and clinohumite ($n = 4$). All are based on hexagonal close-packed oxygen and fluorine atoms, the Mg atoms occupying octahedral interstices and the Si atoms occupying tetrahedral interstices. Forsterite, norbergite, and humite are orthorhombic; chondrodite and clinohumite are monoclinic; brucite is trigonal. Manganese analogs of these minerals occur as pink grains in metamorphosed manganese ores derived from preexisting siliceous carbonates and sedimentary manganese oxides. Other cations which can occur as substituents are Fe^{2+}, Ca^{2+}, Al^{3+}, and Ti^{4+}.

The minerals of the humite group have similar physical properties. The luster is resinous, and the color usually light yellow, brown, orange, or red. The pure synthetic Mg end members are colorless. Hardness is 6–6$^1/_2$ on Mohs scale, specific gravity is 3.1–3.2. They are very difficult to distinguish visually, and x-ray diffraction, electron microprobe, or optical techniques are required. They are found in regionally crystallized marbles, usually the skarn minerals associated with iron ores. *See* SILICATE MINERALS. [P.B.M.]

Humus The amorphous, ordinarily dark-colored, colloidal matter in soil, representing a complex of the fractions of organic matter of plant, animal, and microbial origin that are most resistant to decomposition.

Humus consists of the combined residues of organic materials which have lost their original structure following the rapid decomposition of the simpler ingredients and includes synthesized cell substance as well as by-products of microorganisms. It is not a definite substance and is in a continual state of flux, disappearing by slow decomposition, and being constantly renewed by incorporation of residual matter. With a balance between these processes, humus, though not static, remains relatively uniform in nature and amount in a given soil. It constitutes a reservoir of stabilizing material which imparts beneficial physical, chemical, and biological properties to soil. Fertile soils are rich in humus.

Humus improves the texture of soils. It exerts a binding effect on sandy soils, and loosens the harder, clayey soils, thus increasing their porosity and permeability. It increases the moisture-holding capacity and improves the granular structure by cementing mineral particles into stable crumbs. This helps soils resist the pulverizing and eroding action of wind, water, and cultivation. As a storehouse of elements important to plants, humus functions as a regulator of soil processes by liberating gradually nutrients that would otherwise drain away. A soil rich in humus provides optimum conditions for the development of beneficial microorganisms and constitutes the best medium for growth of plants.

Peat is a type of humus that results from the decomposition of plant material under conditions of excessive moisture or in areas submerged in water. It is an organic deposit formed in marshes and swamps by the partial decomposition of countless generations of a variety of plants. *See* BOG; PEAT. [A.G.L.]

Hunger A term most commonly used to refer to the subjective feelings that accompany the need for food; however, the study of this topic has come to include consideration of the overall control of food intake. More specifically, experimental work on the problem of hunger has been concerned with the sensory cues that give rise to feelings of hunger, the physiological mechanisms that determine when and how much food will be ingested, and the mechanism governing the selection of the food to be eaten.

Food consumption is basically controlled by the organism's nutritional status. Food deprivation leads to eating, and the ingestion of food materials terminates hunger sensations. The issues are to determine which physiological processes vary quantitatively with nutritional status, and to find out if these changes can be detected by the nervous system in a manner that would instigate and terminate food consumption.

Blood-sugar level, which has received more attention than any other factor, can be used as a case in point. The concentration of blood sugar does indeed vary appropriately in a general way with the periodicity of the food cycle. Detailed analyses of normal life variations of blood sugar, however, reveal that the relation between the concentration of blood sugar and hunger is not sufficiently close for this single humoral factor to be able to control hunger in any simple and direct manner. The evaluation of more local tissue utilization of food has proved a more promising approach to this problem. There is now some evidence suggesting that the status of the liver is pivotal in the control of feeding. Depletion of liver glycogen stimulates feeding; its repletion terminates feeding in rats and rabbits. *See* CARBOHYDRATE METABOLISM; LIVER.

Many stimuli that terminate feeding have been identified. Eating in food-deprived animals is inhibited by the reduction of either cellular water or of plasma fluid. It is also reduced by gastric distension and by infusing nutrients into the intestine and into the systemic, especially venous hepatic, circulation. Satiation produced by nutrient absorption from the intestine may be mediated, in part, by the gut hormone cholecystokinin. It is likely that cholecystokinin is effective because it reduces the rate at which food passes through the stomach. The previously held notions of discrete neural centers for the onset and termination of feeding have been abandoned, as the complexity of the feeding act and its corresponding neural complexity have become more widely appreciated.

Deprivation of certain, specific food substances precipitates an increased appetite for the needed substance. This so-called specific hunger behavior has been demonstrated experimentally with many substances, such as salt, calcium, fats, proteins, and certain vitamins in children and in the lower animals studied. It is now clear that only the hunger for salt in salt-deprived animals appears before the animal has learned about the beneficial consequences of salt ingestion. Specific hungers for other minerals, proteins, and vitamins appear only gradually and reflect the animal's learning that certain foods are no longer beneficial and, in fact, may be harmful. *See* THIRST AND SODIUM APPETITE. [E.M.B.]

Huntington's disease A rare hereditary disorder of the basal ganglia causing progressive motor incoordination, abnormal involuntary movements (chorea), and intellectual decline. The disease, which progresses gradually over 15–20 years, is invariably fatal. Inherited as an autosomal dominant mendelian trait, Huntington's disease inevitably develops in those who carry the gene if they live long enough. Men and women are affected equally. The average age at onset is between 35 and 40 years, but the disease can begin as early as 2 years or as late as 80 years.

Therapy is merely supportive: no medications significantly affect the course of the disease or functional capacity of the sufferer. Depression or psychosis, however, can be temporarily alleviated by antidepressant and antipsychotic medications.

The gene for Huntington's disease, termed IT15, has been localized at the end of the short arm of chromosome 4. The IT15 gene is thought to encode a protein, huntingtin, which does not resemble any known protein. Offspring of individuals suffering from the disease have a 50% risk of developing it, and can be tested by recombinant genetic technology. *See* Chromosome; Human genetics; Mutation; Nervous system disorders. [A.Y.]

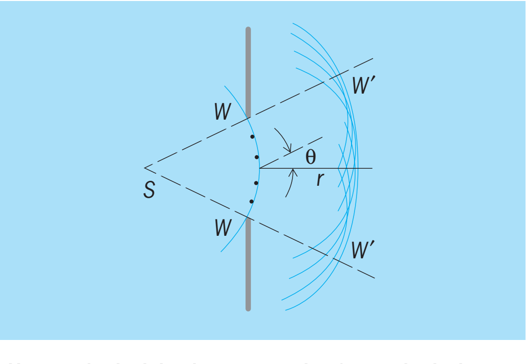
Hurricane A tropical cyclone whose maximum sustained winds reach or exceed a threshold of 119 km/h (74 mi/h). In the western North Pacific ocean it is known as a typhoon. Many tropical cyclones do not reach this wind strength. *See* Cyclone.

Maximum surface winds in hurricanes range up to about 200 mi (320 km) per hour. However, much greater losses of life and property are attributable to inundation from hurricane tidal surges and riverine or flash flooding than from the direct impact of winds on structures.

Tropical cyclones of hurricane strength occur in lower latitudes of all oceans except the South Atlantic and the eastern South Pacific, where combinations of cooler sea temperatures and prevailing winds whose velocities vary sharply with height prevent the establishment of a central warm core through a deep enough layer to sustain the hurricane wind system.

In the United States, property losses resulting from hurricanes have climbed steadily because of the increasing number of seashore structures. However, the loss of life, which has been huge in many storms, has decreased markedly. This is due mainly to the fact that warnings, aided by a more complete surveillance from aircraft and satellite, and extensive programs of public education, have become more accurate and more effective. Improvements in methodology for hurricane prediction have reduced the error in pinpointing hurricane landfall and have greatly reduced the probability of larger errors in prediction. *See* Storm; Tropical meteorology. [R.Sim.; J.Sim.]

Huygens' principle An assumption regarding the behavior of light waves, originally proposed by C. Huygens in the seventeenth century to explain the fact that light travels in straight lines and casts sharp shadows. Large-scale waves, such as sound waves or water waves, bend appreciably into the shadow. The special behavior of light may be explained by Huygens' principle, which states that "each point on a wavefront may be regarded as a source of secondary waves, and the position of the wavefront at a later time is determined by the envelope of these secondary waves at that time." Thus a wave *WW* originating at *S* is shown in the illustration at the instant it passes through an aperture. If a large number of circular secondary waves, originating at various points on *WW*, are drawn with the radius *r* representing the distance the wave would travel in time *t*, the envelope of these secondary waves is the heavily drawn circular arc *W′W′*. This represents the wave after *t*. If, as Huygens' principle requires, the disturbance is confined to the envelope, it will be 0 outside the limits indicated by points *W′*.



Huygens' principle: the construction for a spherical wave.

Careful observation shows that there is a small amount of light beyond these points, decreasing rapidly with distance into the geometrical shadow. This is called diffraction. *See* Diffraction. [F.A.J./W.W.W.]

Hyades A small cluster of stars that makes up the nearest well-defined open cluster (galactic cluster) to the Earth. With a total mass of about 300 suns and a population of 400–500 mostly low-mass stars, the Hyades is a typical example of the 2000 or so small star clusters in the Milky Way Galaxy. Most of its stars are located in a loose, roughly spherical system approximately 40 light-years (2.4×10^{14} mi or 3.8×10^{14} km) in diameter. It is located primarily in the constellation Taurus, the Bull. *See* Taurus.

For many years the Hyades was the backbone of the stellar distance scale in the Milky Way Galaxy and beyond. However, in 1967, evidence was found suggesting that the distance to the Hyades (and, therefore, almost all other distances in the Milky Way Galaxy and beyond) had been underestimated by 20%. This conclusion was confirmed in 1996, when the European space telescope *Hipparcos* was able to make a more direct and more precise measure of the Hyades distance of 149 light-years (8.7×10^{14} mi or 1.4×10^{15} km). *See* Astrometry; Parallax (astronomy).

The age of the cluster is approximately 6.5×10^8 years. Thus the Hyades were formed quite recently, after about 95% of the life of the Milky Way Galaxy had already occurred. *See* Milky Way Galaxy; Star clusters. [P.H.]

Hyaluronic acid A polysaccharide which is an integral part of the gel-like substance of animal connective tissue; it supposedly serves as a lubricant and shock absorbent in the joints. Hyaluronic acid has also been isolated from umbilical cord, synovial fluid, skin, certain fowl tumors, and other sources. Treatment of this polysaccharide with the enzyme hyaluronidase, followed by acid hydrolysis, yields a disaccharide consisting of *N*-acetyl-D-glucosamine and D-glucuronic acid. This disaccharide appears to be the basic repeating structural unit that constitutes the hyaluronic acid molecule. *See* Hyaluronidase; Polysaccharide. [W.Z.H.]

Hyaluronidase Any one of a family of enzymes, also known as hyaluronate lyases or spreading factors, produced by mammals, reptiles, insects, and bacteria, which catalyze the breakdown of hyaluronic acid. Some hyaluronidases also attack other similar polysaccharides. Since all liquefy the polysaccharide gel which fills the tissue spaces, they effectively accelerate diffusion so that injected, dissolved, or particulate matter (bacteria, viruses, toxins, or pigments) can diffuse through a larger volume of tissue. *See* Hyaluronic acid.

The biological importance of the enzyme depends upon its source. That found in the culture filtrates of many strains of virulent bacteria permits the microorganisms to gain access to a larger volume of the host's tissue and, hence, to additional nutriment. That found in the venom of certain snakes and bees permits the toxin to produce more extensive damage to the victim. *See* Enzyme. [R.H.P.]

Hybrid dysgenesis A syndrome of abnormal traits that appears in the hybrids between certain strains of the fruit fly *Drosophila melanogaster*. The traits include partial sterility and greatly elevated rates of genetic mutations and chromosome rearrangements. Strains can be classified as P for paternally contributing or M for maternally contributing, so that only the hybrid sons and daughter of M females mated to P males show hybrid dysgenesis.

Hybrid dysgenesis is caused by the action of a family of transposable genetic elements, that is, segments of the genetic material (deoxyribonucleic acid, or DNA) with the special ability to move from one chromosomal site to another. Such elements range in size from a few hundred to a few thousand nucleotide pairs and typically occur in 10–100 genetic locations scattered throughout the chromosomes. Altogether, transposable elements are thought to compose 10–15% of the entire genetic complement of *Drosophila melanogaster* and are probably also common in most animal and plant species. The family of transposable elements that causes most cases of hybrid dysgenesis is called the P family, and the individual elements are called P factors because they occur only in the paternally contributing strains. *See* Gene; Gene action; Mutation; Transposons. [W.R.E.]

Hydatellales An order of flowering plants, division Magnoliophyta (Angiospermae), in the subclass Commelinidae of the class Liliopsida (monocotyledons). The order consists of a single family with five species native to Australia, New Zealand, and Tasmania. The plants are small, submersed or partly submersed aquatic annuals with greatly simplified internal anatomy. The leaves are tufted at the base of the stem, and the inflorescence is a terminal head with two to several bracts, each subtending one to several reduced, unisexual flowers. These plants have sometimes been included within the Restionales, but the structural details of the ovary and seed set them apart. They are of no economic significance. *See* Commelinidae; Plant kingdom; Restionales. [T.M.B.]

Hydrate A particular form of a solid compound which has water in the form of H_2O molecules associated with it. For example, anhydrous copper sulfate is a white solid with the formula $CuSO_4$. When crystallized from water, a blue crystalline solid which contains water molecules as part of the crystals is formed. Analysis shows that the water is present in a definite amount, and the hydrate may be given the formula $CuSO_4 \cdot 5H_2O$. Four of the water molecules are attached to the copper ion in the manner of coordination complexes, and the fifth water molecule is related to the sulfate and presumably held by hydrogen bonding. *See* Hydrogen bond.

Water can also be present in definite proportions in the crystal without being associated directly with the anion or cation. The water occupies a definite place in the crystal lattice. Alums, with their 12 molecules of water, are examples of this. *See* Alum.

Gas hydrates (gas clathrates) are crystalline compounds in which an isometric (cubic) ice (H_2O) lattice contains cages that incorporate small guest gas molecules. They are stable at moderate to high pressures and low temperatures, above and below the ice point. These ice lattices are stable only when the cages contain a gas molecule. The pressure and temperature constraints restrict them to oceanic continental margins in the uppermost few hundred meters of slope and rise sediments where water depths exceed 300–500 m (1000–1600 ft), and to permafrost in polar regions. Under the ocean, the amount of gas hydrates is at least an order of magnitude higher than in permafrost.

Methane (CH_4) hydrate is the dominant natural gas hydrate on Earth. One cubic meter of methane hydrate when dissociated can contain 165–180 m^3 of methane gas. The total amount of methane in gas hydrates is estimated to be very large; about 10^{19} g of methane carbon is stored in them, approximately twice that in fossil fuels.

Recent interest in natural gas hydrates, most of which are methane hydrates, has resulted from the recognition that global warming may destabilize the enormous quantities of methane hydrate in shallow marine slope sediments and permafrost. The environmental impact of releasing large quantities of methane into the ocean and atmosphere could have important consequences. The fossil fuel resource potential of the enormous quantities of marine methane hydrates is being evaluated. *See* Marine sediments; Methane; Permafrost. [F.W.; M.Ka.]

Hydration The incorporation of molecular water into a complex with the molecules or units of another species. The complex may be held together by relatively weak forces or may exist as a definite compound. Many salts form solid hydrates when exposed to water vapor under certain conditions of temperature and pressure. Water is lost from these compounds when they are heated or when the water vapor pressure falls below a minimum value. Solids forming hydrates at low pressures are used as drying agents. *See* Deliquescence; Desiccant; Efflorescence; Hydrate; Solution; Solvation. [F.J.J.]

Hydraulic accumulator A pressure vessel which oper-ates as a fluid source device or shock absorber. It is used to store fluid under pressure or to absorb excessive pressure increases. The hydraulic accumulator is an energy-efficient component, which allows the use of a smaller pump to achieve the same end results in terms of cylinder rod actuation speeds. In certain circuit designs, the accumulator will permit a pump motor to be completely shut down for an extended period of time while the accumulator supplies the necessary fluid to the circuit.

The operation of the hydraulic accumulator is induced by a pressurized gas (usually nitrogen), a spring, or a weighted plunger. The accumulator supplies fluid for actuator movement or to replace fluid lost by leakage. The gas-charged accumulator and the spring-type accumulator discharge their fluid into the system at pressures which are decreasing as the gas or spring expands. The weighted accumulator allows stored fluid to be discharged into the system at a constant pressure for the entirety of its downward stroke. *See* Control systems; Hydraulics; Pump; Shock absorber. [J.E.A.]

Hydraulic actuator A cylinder or fluid motor that converts hydraulic power into useful mechanical work. The mechanical motion produced may be linear, rotary, or oscillatory. Operation exhibits high force capability, high power per unit weight and volume, good mechanical stiffness, and high dynamic response. These features lead to wide use in precision control systems and

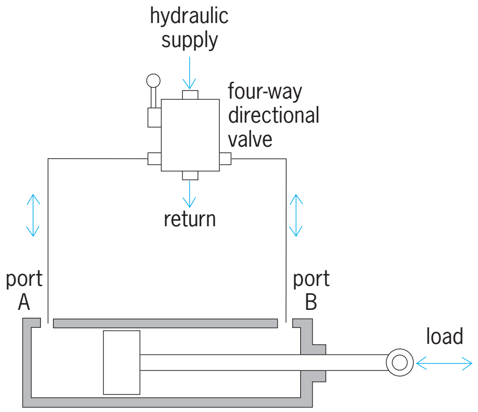


Fig. 1. Function of a hydraulic double-acting cylinder.

in heavy-duty machine tool, mobile, marine, and aerospace applications. *See* CONTROL SYSTEMS.

Cylinder actuators provide a fixed length of straight-line motion. They usually consist of a tight-fitting piston moving in a closed cylinder. The piston is attached to a rod that extends from one end of the cylinder to provide the mechanical output. The double-acting cylinder (Fig. 1) has a port at each end of the cylinder to admit or return hydraulic fluid. A four-way directional valve functions to connect one cylinder port to the hydraulic supply and the other to the return, depending on the desired direction of the power stroke.

Limited-rotation actuators are used for lifting, lowering, opening, closing, indexing, and transferring movements by producing limited reciprocating rotary force and motion. Rotary actuators are compact and efficient, and produce high instantaneous torque in either direction. Figure 2 shows a piston-rack type of rotary actuator. Hydraulic fluid is applied to either the two end chambers or the central chamber to cause the two pistons to retract or extend simultaneously so that the racks rotate the pinion gear.

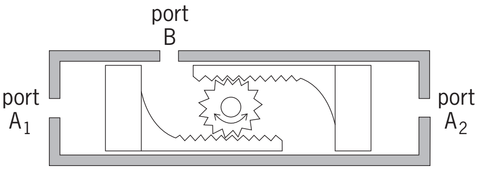

Fig. 2. Piston-rack type rotary actuator.

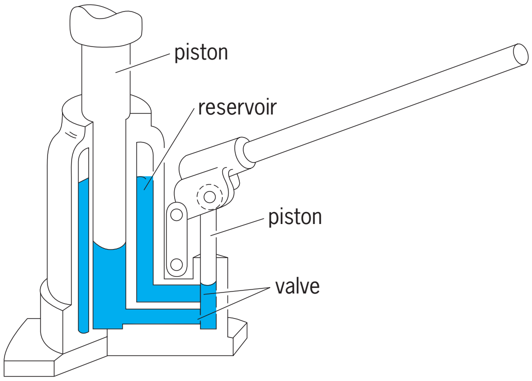
Rotary motor actuators are coupled directly to a rotating load and provide excellent control for acceleration, operating speed, deceleration, smooth reversals, and positioning. They allow flexibility in design and eliminate much of the bulk and weight of mechanical and electrical power transmissions.

Motor actuators are generally reversible and are of the gear or vane type. [C.M.]

Hydraulic jump An abrupt increase of depth in a free-surface liquid flow. A hydraulic jump is characterized by rapid flow and small depths on the upstream side, and by larger depths and smaller velocities on the downstream side. A jump can form only when the upstream flow is supercritical, that is, when the fluid velocity is greater than the propagation velocity c of a small, shallow-water gravity wave ($c = \sqrt{gh}$, where g is the acceleration of gravity and h is the depth). A considerable amount of energy is dissipated in the conversion from supercritical to subcritical flow. *See* OPEN CHANNEL; WAVE MOTION IN LIQUIDS. [D.R.F.H.]

Hydraulic press A combination of a large and a small cylinder connected by a pipe and filled with a fluid so that the pressure created in the fluid by a small force acting on the piston in the small cylinder will result in a large force on the large piston. The operation depends upon Pascal's principle, which states that when a liquid is at rest the addition of a pressure (force per unit area) at one point results in an identical increase in pressure at all points.

The principle of the hydraulic press is used in lift jacks, earth-moving machines, and metal-forming presses (see illustration). A comparatively small supply pump creates pressure in the hydraulic fluid. The fluid then acts on a substantially larger piston to produce the action force. Heavy objects are accurately weighed on hydraulic scales in which precision-ground pistons introduce negligible friction. *See* MECHANICAL ADVANTAGE; SIMPLE MACHINE. [R.M.Ph.]



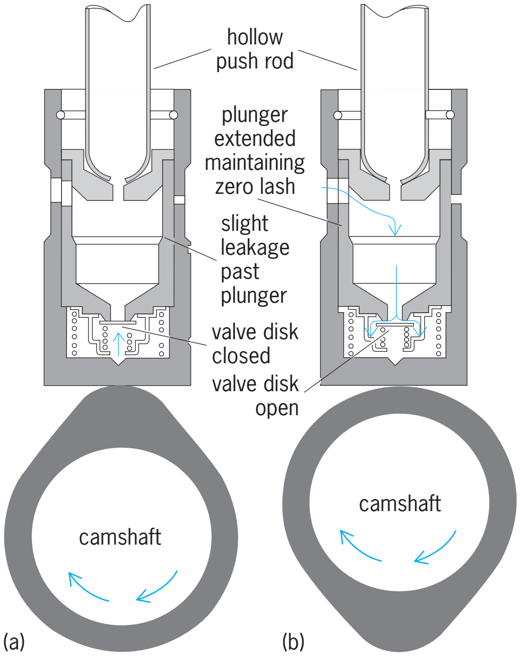
Hydrulic jack.

Hydraulic turbine A machine which converts the energy of an elevated water supply into mechanical energy of a rotating shaft. Most old-style waterwheels utilized the weight effect of the water directly, but all modern hydraulic turbines are a form of fluid dynamic machinery of the jet and vane type operating on the impulse or reaction principle and thus involving the conversion of pressure energy to kinetic energy. The shaft drives an electric generator, and speed must be of an acceptable synchronous value. *See* GENERATOR; IMPULSE TURBINE; TURBINE.

Efficiency of hydraulic turbine installations is always high, more than 85% after all allowances for hydraulic, shock, bearing, friction, generator, and mechanical losses. Material selection is not only a problem of machine design and stress loading from running speeds and hydraulic surges, but is also a matter of fabrication, maintenance, and resistance to erosion, corrosion, and cavitation pitting.

Pumped-storage hydro plants have employed various types of equipment to pump water to an elevated storage reservoir during off-peak periods and to generate power during on-peak periods where the water flows from the elevated reservoir through hydraulic turbines. *See* WATERPOWER. [T.Ba.]

Hydraulic valve lifter A device that eliminates the need for mechanical clearance in the valve train of internal combustion engines. Clearance is normally required to prevent the valve's being held open and destroyed as the valve train



Positions of the hydraulic valve lifter, with engine valve (*a*) open and (*b*) closed. (*After W. H. Crouse, Automotive Mechanics, 5th ed., McGraw-Hill, 1965*)

undergoes thermal expansion. However, clearance requires frequent adjustment and is responsible for much operating noise. The hydraulic lifter is a telescoping compression strut in the linkage between cam and valve, consisting of a piston and cylinder (see illustration). When no opening load exists, a weak spring moves the piston, extending the strut and eliminating any clearance. This action sucks oil into the cylinder past a check valve. The trapped oil transmits the valve-opening forces with little deflection. A slight leakage of oil during lift shortens the strut, assuring valve closure. The leakage oil is replaced as the spring again extends the strut at no load. [A.R.R.]

Hydraulics The branch of engineering that focuses on the practical problems of collecting, storing, measuring, transporting, controlling, and using water and other liquids. It differs from fluid mechanics, which is more theoretical and includes the study of gases as well as liquids; and from hydrology, which is the study of the properties, distribution, and circulation of the Earth's water. *See* Fluid mechanics; Hydrology.

Many problems in hydraulics involve pipe flow. Pipe flow occurs in the direction of decreasing energy. The primary forms of energy in pipes are position energy (height of the fluid), pressure energy, and kinetic energy according to Bernoulli's theorem. Fluids can be forced to flow uphill if the pressure energy and kinetic energy are large enough to overcome the position energy. This can be accomplished with a pump that adds pressure energy to the fluid. *See* Bernoulli's theorem; Pump.

Liquids in motion produce forces whenever the velocity or flow direction changes. For example, forces develop at the nozzle of a fire hose, at pipe bends, and when flowing water is used to turn a turbine. The force is generally proportional to the flow rate, the mass density, and the velocity change. *See* Fluid flow; Hydrodynamics; Jet flow; Turbine.

Liquids are often transported in open channels instead of pipes. An energy imbalance produces flow in open channels, just as it does in pipes. The primary forms of energy are position energy, flow depth, and kinetic energy. Energy balance methods are used to solve many problems in gradually varied flow (that is, the depth changes slowly over short distances), but a momentum balance is required for rapidly varied flow.

Hydraulic principles apply to many other scientific and engineering endeavors. For example, ground-water flow is studied in geology but is governed by the principles of hydraulics. Coastal hydraulics is an important subset of oceanography. The design of certain structures, such as jetties, dams, spillways, locks, piers, levees, dry docks, and tanks, requires an understanding of hydraulic concepts. Scale models are often used to better understand some of the complex forces and currents associated with these large structures. *See* Coastal engineering; Dam; Dimensional analysis; Geology; Ground-water hydrology; River engineering. [R.J.Ho.]

Hydrazine A colorless liquid, H_2NNH_2 (boiling point 114°C or 237°F), with a musty, ammonialike odor. Physically it is similar to water, but chemically it is reducing, decomposable, basic, and bifunctional. Its derivatives range from simple salts to ring compounds, polymers, and coordination complexes. Major uses of hydrazine include such diverse applications as rocket fuels, corrosion inhibition in boilers, syntheses of biologically active materials and in rubber curing and foam-rubber production. [T.H.D.]

Hydride The isolated atomic hydrogen anion, H^-. It consists of a singly charged positive nucleus and two electrons. The electron-electron repulsion almost overwhelms the nuclear-electron attraction. Thus, the "extra" electron is held weakly and is readily donated. Ionic salts containing this large and easily polarized ion are highly reactive, strongly basic, and powerfully reducing. This makes them important reagents despite the fact that they are readily destroyed by the presence of the relatively acidic compound water (H_2O) or by exposure to the relatively oxidizing dioxygen (O_2) as found in air. *See* Electron configuration.

The term hydride also refers to salts containing the H^- anion and a highly electropositive alkali or alkaline-earth metal as the cation. The salt names reflect this high ionic character, for example, sodium hydride (NaH). In such salts the ionic radius of H^- is comparable to that of Cl^-.

There are complex metal hydrides that are formed from the formal reaction of H^- salts with some more covalent metal or metalloid hydrogen compound. Among the earliest to be investigated were lithium aluminum hydride ($LiAlH_4$) and sodium borohydride ($NaBH_4$).

There are compounds with metal-hydrogen bonds that are also referred to as hydrides. For example, hydridocarbonyl [$HCo(CO)_4$] and dihydridotetracarbonyl iron [$H_2Fe(CO)_4$] are often named cobalt tetracarbonyl hydride and iron tetracarbonyl dihydride by analogy to corresponding halides. *See* Coordination complexes; Metal hydrides.

Ideally, the term hydride should be reserved for those species that contain H^- or that at least formally transfer this ion to another substance in a so-called hydride transfer reaction. Such reactions are found in the industrial synthesis of 2,2,4-trimethylpentane (isooctane) from isobutylene and isobutane, as well as in many of the classical organic chemistry named reactions. Hydride transfer is also important in most of the biologically important oxidation-reduction reactions of the vitamin niacin (nicotinamide) as found in the forms of nicotinamide adenine dinucleotide/hydrogenated nicotinamide adenine dinucleotide (NAD^+/NADH) and nicotinamide adenine dinucleotide phosphate ($NADP^+$)/NADPH. *See* Niacin; Nicotinamide adenine dinucleotide (NAD); Nicotinamide adenine dinucleotide phosphate (NADP). [J.F.Li.]

Hydrido complexes Complex hydrides containing a hydride ligand bonded to a central atom. The prefix hydro instead of hydrido is sometimes used. All are soluble in aromatic hydrocarbons. They are rather expensive, but their specific reducing powers make them attractive for synthesizing high-value products, such as pharmaceuticals, flavorings, fragrances, dyes, and insecticides. *See* Coordination complexes; Metal hydrides. [J.C.W.]

Hydroboration The process of producing organoboranes by the addition of diborane to unsaturated organic compounds. In ether solvents the addition of diborane to such molecules is exceedingly rapid and essentially quantitative. This reaction therefore makes the organoboranes readily available. Such organoboranes are finding increasing application as intermediates for organic synthesis.

Diborane is highly soluble in tetrahydrofuran, where it exists as the addition compound tetrahydrofuran-borane. Such solutions are often used for hydroboration, and merely involve bringing the two reactants together as indicated by reaction (1).

$$3RCH=CH_2 + C_4H_8O{:}BH_3 \rightarrow (RCH_2CH_2)_3B + C_4H_8O \qquad (1)$$

Alternatively, sodium borohydride may be utilized to achieve hydroboration by the addition of boron trifluoride etherate. This is shown by reaction (2).Usually the organoborane is not

$$12RCH=CH_2 + 3NaBH_4 + 4(C_2H_5)_2O{:}BF_3 \rightarrow$$
$$4(RCH_2CH_2)_3B + 3NaBF_4 + 4(C_2H_5)_2O \qquad (2)$$

isolated but is utilized in place, similar to applications of the Grignard reagent in synthesis.

Organoboranes are among the most versatile synthetic intermediates that are available to the organic chemist. The hydroboration reaction has made these intermediates readily available. *See* Borane. [H.C.B.]

Hydrocharitales An order of aquatic flowering plants, division Magnoliophyta (Angiospermae), in the subclass Alismatidae of the class Liliopsida (monocotyledons). The order consists of the single family Hydrocharitaceae, with about 100 species. Within the subclass the order is marked by its inferior, compound ovary with basically laminar placentation. The ovules are scattered over the walls of the individual carpels. The familiar aquarium plant, *Vallisneria spiralis*, called tape grass or eelgrass, is not a grass but belongs to the Hydrocharitaceae. *See* ALISMATIDAE; FLOWER; LILIOPSIDA. [A.Cr.]

Hydrocracking A catalytic, high-pressure process flexible enough to produce either of the two major light fuels—high octane gasoline or aviation jet fuel. It proceeds by two main reactions: adding hydrogen to molecules too massive and complex for gasoline and then cracking them to the required fuels. The process is carried out by passing oil feed together with hydrogen at high pressure (1000–2500 pounds per square inch gage or 7–17 megapascals) and moderate temperatures (500–750°F or 260–400°C) into contact with a bifunctional catalyst, comprising an acidic solid and a hydrogenating metal component. Gasoline of high octane number is produced, both directly and through a subsequent step such as catalytic reforming; jet fuels may also be manufactured simply by changing conditions with the same catalysts.

Generally, the process is used as an adjunct to catalytic cracking. Oils, which are difficult to convert in the catalytic process because they are highly aromatic and cause rapid catalyst decline, can be easily handled in hydrocracking, because of the low cracking temperature and the high hydrogen pressure, which decreases catalyst fouling. However, the most important components in any feed are the nitrogen-containing compounds, because these are severe poisons for hydrocracking catalysts and must be almost completely removed.

The products from hydrocracking are composed of either saturated or aromatic compounds; no olefins are found. In making gasoline, the lower paraffins formed have high octane numbers. The remaining gasoline has excellent properties as a feed to catalytic reforming, producing a highly aromatic gasoline which, with added lead, easily attains 100 octane number. Another attractive feature of hydrocracking is the low yield of gaseous components, such as methane, ethane, and propane, which are less desirable than gasoline. *See* GASOLINE.

The hydrocracking process is being applied in other areas, notably, to produce lubricating oils and to convert very asphaltic and high-boiling residues to lower-boiling fuels. *See* AROMATIZATION; CRACKING; HYDROGENATION. [C.P.B.]

Hydrodynamics The study of fluids in motion. The study is based upon the physical conservation laws of mass, momentum, and energy. The mathematical statements of these laws may be written in either integral or differential form. The integral form is useful for large-scale analyses and provides answers that are sometimes very good and sometimes not, but that are always useful, particularly for engineering applications. The differential form of the equations is used for small-scale analyses. In principle, the differential forms may be used for any problem, but exact solutions can be found only for a small number of specialized flows. Solutions for most problems must be obtained by using numerical techniques, and these are limited by the computer's inability to model small-scale processes. *See* CONSERVATION OF ENERGY; CONSERVATION OF MASS; CONSERVATION OF MOMENTUM; FLUID FLOW; FLUID MECHANICS.

Applications of hydrodynamics include the study of closed-conduit and open-channel flow, and the calculation of forces on submerged bodies.

Flow in closed conduits, or pipes, has been extensively studied both experimentally and theoretically. If the pipe Reynolds number, given by the equation below, where V is the average velocity

$$\mathrm{Re}_D = \frac{VD\rho}{\mu}$$

and D is the pipe diameter, is less than about 2000, the flow in the pipe is laminar. In this case, the solution to the continuity, momentum, and energy equations is readily obtained, particularly in the case of steady flows. If Re_D is greater than about 4000, the flow in the pipe is turbulent, and the solution to the continuity, momentum, and energy equations can be obtained only by employing empirical correlations and other approximate modeling tools. The Re_D region between 2000 and 4000 is the transition region in which the flow is intermittently laminar and turbulent. *See* LAMINAR FLOW; REYNOLDS NUMBER; TURBULENT FLOW.

Confined flows that have a liquid surface exposed to the atmosphere (a free surface) are called open-channel flows. Flows in rivers, canals, partially full pipes, and irrigation ditches are examples. The difficulty with these flows is that the shape of the free surface is one of the unknowns to be calculated.

In most open-channel flows the bottom slope and the water depth change with position, and the free surface is not parallel to the channel bottom. If the slopes are small and the changes are not too sudden, the flow is called a gradually varied flow. An energy balance between two sections of the channel yields a differential equation for the rate of change of the water depth with respect to the distance along the channel. The solution of this equation, which must be accomplished by using one of many available numerical techniques, gives the shape of the water surface.

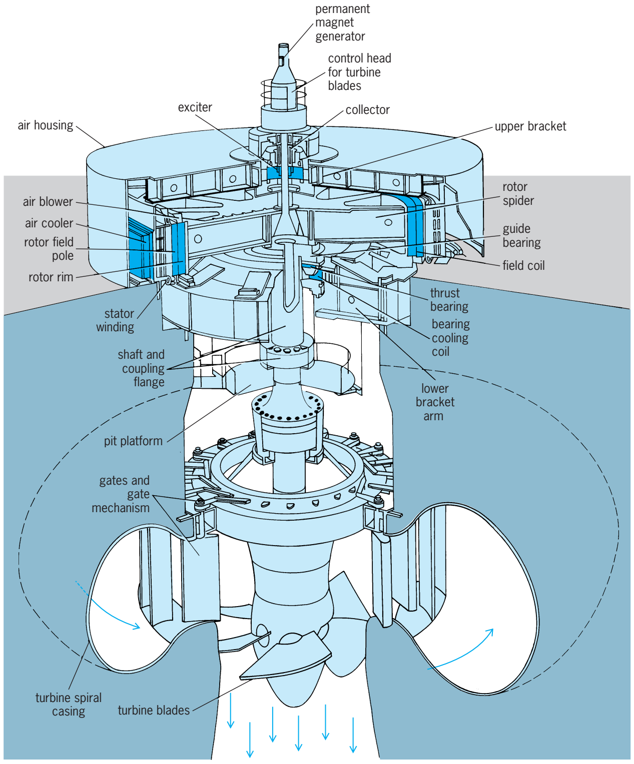
Flow over spillways and weirs and flow through a hydraulic jump are examples of rapidly varying flows. In these cases, changes of water depth with distance along the channel are large. Here, because of large accelerations, the pressure distribution with depth may not be hydrostatic as it is in the cases of gradually varied and uniform flows. Solutions for rapidly varying flows are accomplished by using approximation techniques. *See* HYDRAULIC JUMP; OPEN CHANNEL.

The force exerted by a fluid flowing past a submerged body is calculated by integrating the pressure distribution over the surface of the body. The pressure distribution is determined from the simultaneous solution of the continuity and momentum equations along with the appropriate boundary conditions. In almost all cases, this solution must be accomplished by using an appropriate approximation. *See* BOUNDARY-LAYER FLOW.

Usually the force exerted on the body is resolved into two components, the lift and the drag. The drag force is the component parallel to the velocity of the undisturbed stream (flow far away from the body), and the lift force is the component perpendicular to the undisturbed stream. [W.M.H.]

Hydroelectric generator A low-speed generator driven by water turbines. Hydrogenerators may have a horizontal or vertical shaft. The horizontal units are usually small with speeds of 300–1200 revolutions per minute (rpm). The vertical units are usually larger and more easily adapted to small hydraulic heads. The rotor diameters range from 2 to 62 ft (0.6 to 19 m) and capacities from 50 to 900,000 kVA. The generators are rated in kVA (kilovolts times amperes). The kilowatt output is the product of kVA and power factor. The normal power-factor rating of small synchronous generators is between 0.8 and 1.0 with 0.9 being common. For large generators a rating of 0.9–0.95 is common with the machines able to operate up to 1.0 when the load requires. The generators may also supply reactive power. *See* ALTERNATING CURRENT; ELECTRIC POWER MEASUREMENT; VOLT-AMPERE.

The turbine shown in the illustration has an adjustable blade propeller, typical of large, low-head units that are common on large river power plants. The water enters the turbine spiral scroll casing, falls down through the turbine, causing rotation, and empties into the river. The shaft transmits the rotation to the



Large hydroelectric generator. (***Westinghouse Electric Corp.***)

generator spider or hub and thence to the rotor rim and poles. The magnetic field of the rotor poles transmits the torque to the stator and changes the mechanical power to electrical power. *See* HYDRAULIC TURBINE; TURBINE.

The poles are spaced around the rotor rim and are magnetized by direct current flowing in the turns of the field coil around each pole. The magnetic field, or flux, crosses the air gap between rotor and stator, flows radially through the stator teeth and thence to the area one pole pitch away, and back to the adjacent pole on the rotor. The magnetic flux is stationary with respect to the rotor poles but sweeps around the stator at the peripheral rotor speed. Coils are installed in the stator slots between the teeth. Thus there is an ever-changing flux linking stator coils, which causes an induced electromotive force in the coils according to Faraday's law. *See* ALTERNATING-CURRENT GENERATOR; MAGNETISM.

[E.C.W.]

Hydrofoil craft

A form of high-speed ship that supports its weight by means of wings (properly called hydrofoils, or simply foils) beneath the surface of the water. The hydrofoils generate lift by movement in the same manner as an airplane wing. The hydrofoil was conceived in order to produce faster ships. The most effective means of developing a faster ship is to find a way to lift the ship's hull clear of the water. This greatly reduces the drag on the hull, in turn greatly reducing the power required to drive the ship. The hydrofoil ship is one means to this end. *See* AIRFOIL; SHIP POWERING, MANEUVERING, AND SEAKEEPING.

There are two basic types of hydrofoils: fully submerged and partially submerged.

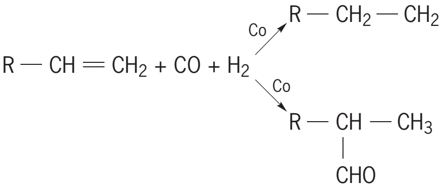
The most efficient hydrofoil craft, from a powering standpoint, are those with fully submerged foils; that is, the wings are completely below the surface of the water. They are thus not subject to surface interactions such as air drawing, or to the danger of broaching through small waves. They are also relatively unaffected by wave action, resulting in excellent ship ride comfort. However, because they are fully submerged, they require an active control system which senses the craft's height and attitude and adjusts the wings as necessary to maintain the desired condition. *See* CONTROL SYSTEMS.

In a partially submerged hydrofoil, the foils are generally V-shaped when viewed head on, with the apex of the V below the water and the tips of the wings above the water. In this case the amount of lift generated will increase if the foils are more deeply submerged, and it will decrease if the foils are less submerged. (The increase and decrease in lift are due to the change in the wetted area of the foils.) This behavior results in a steady ride attitude at an equilibrium balance of lift. A disadvantage of partially submerged foils is that the ride is not as smooth, especially in rough water, since the foils will react to each wave they encounter.

[C.B.McK.]

Hydroformylation

An aldehyde synthesis process that falls under the general classification of a Fischer-Tropsch reaction but is distinguished by the addition of an olefin feed along with the characteristic carbon monoxide and hydrogen. In the oxo process for alcohol manufacture, hydroformylation of olefins to aldehydes is the first step. The second step is the hydrogenation of the aldehydes to alcohols. At times the term "oxo process" is used in reference to the hydroformylation step alone. In the hydroformylation step, olefin, carbon monoxide, and hydrogen are reacted over a cobalt catalyst to produce an aldehyde which has one more carbon atom than the feed olefin. As in the reaction below, the olefin conversion takes place by the addition of a formyl group (CHO) and a hydrogen atom across the double bond. *See* FISCHER-TROPSCH PROCESS.



$$R-CH=CH_2+CO+H_2 \xrightarrow{Co} R-CH_2-CH_2-CHO$$

$$R-CH=CH_2+CO+H_2 \xrightarrow{Co} R-\underset{\displaystyle CHO}{\underset{|}{CH}}-CH_3$$

The aldehyde is then treated with hydrogen to form the alcohol. In commercial operations, the hydrogenation step is usually performed immediately after the hydroformylation step in an integrated system.

A wide range of carbon-number olefins, C_2–C_{16}, have been used as feeds. Propylene, heptene, and nonene are frequently used as feedstocks to produce normal and isobutyl alcohol, isooctyl alcohol, and primary decyl alcohol, respectively. Feed streams to oxo units may be single-carbon-number or mixed-carbon-number olefins.

The lower-carbon-number alcohols such as butanols are used primarily as solvents, while the higher-carbon-number alcohols go into the manufacture of plasticizers, detergents (surfactants), and lubricants.

[D.L.H.]

Hydrogen

The first chemical element in the periodic system. Under ordinary conditions it is a colorless, odorless, tasteless gas composed of diatomic molecules, H_2. The hydrogen atom, symbol H, consists of a nucleus of unit positive charge and a single electron. It has atomic number 1 and an atomic weight of 1.00797. The element is a major constituent of water and all organic matter, and is widely distributed not only on the Earth but throughout the universe. There are three isotopes of hydrogen: protium, mass 1, makes up 99.98% of the natural element; deuterium, mass 2, makes up about 0.02%; and tritium, mass 3, occurs in extremely small amounts in nature but may be produced artificially by various nuclear reactions. *See* DEUTERIUM; ISOTOPE; PERIODIC TABLE; TRITIUM.

Uses. The largest single use of hydrogen is in the synthesis of ammonia. A rapidly expanding use for hydrogen is in petroleum-refining operations, such as hydrocracking and hydrogen

Properties of hydrogen

Property	Value
Melting point	−259.2°C
Boiling point at 1 atm	−252.8°C
Density of solid at −259.2°C	0.0866 g/cm^3
Density of liquid at −252.8°C	0.0708 g/cm^3
Critical temperature	−240.0°C
Critical pressure	13.0 atm
Critical density	0.0301 g/cm^3

treatment for removal of sulfur. Large quantities of hydrogen are consumed in the catalytic hydrogenation of unsaturated liquid vegetable oils to make solid fats. Hydrogenation is used in the manufacture of organic chemicals. Large quantities of hydrogen are used as a rocket fuel, in conjunction with oxygen or fluorine, and as a propellent for nuclear-powered rockets.

Properties. Ordinary hydrogen has a molecular weight of 2.01594. The gas has a density at 0°C and 1 atm of 0.08987 g/liter. Its specific gravity, compared to air, is 0.0695. Hydrogen is the lightest substance known. Some additional properties of hydrogen are listed in the table.

Hydrogen is somewhat more soluble in organic solvents than in water. Many metals adsorb hydrogen. The adsorption of hydrogen in steel may cause "hydrogen embrittlement," which sometimes leads to the failure of chemical processing equipment.

At ordinary temperatures hydrogen is a comparatively unreactive substance unless it has been activated in some manner, for example, by a suitable catalyst. At elevated temperatures it is highly reactive.

Although ordinarily diatomic, molecular hydrogen dissociates at high temperatures into free atoms. Atomic hydrogen is a powerful reducing agent, even at room temperature. It reacts with the oxides and chlorides of many metals, including silver, copper, lead, bismuth, and mercury, to produce the free metals. It reduces some salts, such as nitrates, nitrites, and cyanides of sodium and potassium, to the metallic state. It reacts with a number of elements, both metals and nonmetals, to yield hydrides such as NaH, KH, H_2S, and PH_3. With oxygen atomic hydrogen yields hydrogen peroxide, H_2O_2. With organic compounds atomic hydrogen reacts to produce a complex mixture of products. With ethylene, C_2H_4, for example, the products include ethane, C_2H_6, and butane, C_4H_{10}. The heat liberated when hydrogen atoms recombine to form hydrogen molecules is used to obtain very high temperatures in atomic hydrogen welding.

Hydrogen reacts with oxygen to form water. At room temperature this reaction is immeasurably slow, but is accelerated by catalysts, such as platinum, or by an electric spark, and then may take place with explosive violence.

With nitrogen, hydrogen undergoes an important reaction to give ammonia. Hydrogen reacts at elevated temperatures with a number of metals to give hydrides. The oxides of many metals are reduced by hydrogen at elevated temperatures either to the free metal or to lower oxides. Hydrogen reacts at room temperature with the salts of the less electropositive metals and reduces them to the metallic state. In the presence of a suitable catalyst hydrogen reacts with unsaturated organic compounds and adds to the double bond. *See* Hydrogenation.

Principal compounds. Hydrogen is a constituent of a very large number of compounds containing one or more other elements. Such compounds include water, acids, bases, most organic compounds, and many minerals. Compounds in which hydrogen is combined with a single other element are commonly referred to as hydrides. For additional details on the compounds of hydrogen *see* Acid and base; Hydrazine; Hydride; Hydrido complexes; Hydrogen fluoride; Hydrogen peroxide; Water.

Preparation. A large number of methods may be used to prepare hydrogen gas. The choice of method is determined by such factors as the quantity of hydrogen desired, the purity required, and the availability and cost of raw materials. Among the processes frequently used are the reactions of metals with water or acids, the electrolysis of water, the reaction of steam with hydrocarbons or other organic materials, and the thermal decomposition of hydrocarbons. The principal raw materials for hydrogen production are hydrocarbons, such as natural gas, oil refinery gas, gasoline, fuel oil, and crude oil. [L.K.]

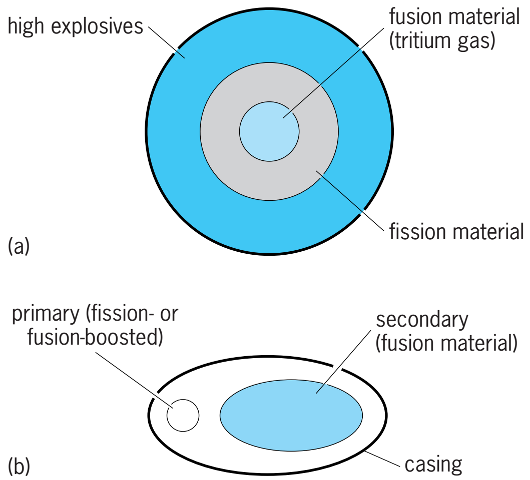
Hydrogen bomb A device in which an uncontrolled, self-sustaining, thermonuclear fusion reaction is carried out in heavy hydrogen (deuterium or tritium) to produce an explosion. In a fusion reaction, the collision of two energy-rich nuclei results in a mutual rearrangement of their protons and neutrons to produce two or more reaction products, together with a release of energy of amount *E* given by A. Einstein's formula $E = mc^2$, where *m* is the mass difference between the original and produced nuclei, and *c* is the velocity of light. *See* Nuclear fusion; Thermonuclear reaction.

For the hydrogen bomb reaction to become self-sustaining, a so-called critical temperature of about 3.5×10^7 K (6.3×10^7 °F) must be attained with the aid of the enormous temperature created by a fission explosive. Once this temperature is achieved, the energy released in the initial reaction maintains the temperature, and the chain proceeds either until the supply of fusionable material is exhausted or until sufficient expansion has taken place that the material is cooled below the critical temperature. *See* Atomic bomb.

There are two ways to use fusion: boosting of fission explosive yields or generating multistage thermonuclear reactions.

In a fusion-boosted warhead (illus. *a*), when the sphere of fissile materials is compressed (imploded) by the chemical explosion, an uncontrolled fission chain reaction begins. If there is fusionable material inside the device, thermonuclear reactions will boost the fission yield. The fusion reactions do not directly contribute very much to the explosive energy, but instead enhance the fission rate, due to the release of a large number of additional neutrons. *See* Atomic bomb.

Multistage thermonuclear weapons contain three physically separated components, (illus. *b*): a small fission or fusion-boosted explosive called a primary or trigger, an assembly of lithium-deuteride fusion material called the secondary, and a massive casing surrounding the primary and secondary. Explosive detonation is generated in three phases: ignition caused by the fission-explosive primary stage, coupling of x-radiation to the secondary fusion stage, and secondary-stage implosion induced by fission x-rays, which compresses the lithium-deuteride.



Design configuration of two types of fusion weapons: (*a*) fusion-boosted atomic bomb, (*b*) multistage hydrogen bomb. (*After A. DeVolpi et al., Born Secret: The H-Bomb, the Progressive Case and National Security, Pergamon, 1981*)

As neutrons from the primary traverse the compressed lithium-deuteride compound, they are absorbed in enriched lithium-6, which immediately decomposes into tritium and an alpha particle. If the tritium thus created fuses with deuterium, an energetic alpha particle and a 14-MeV neutron are released. Soon the fusion materials reach densities and temperatures where thermonuclear ignition occurs, liberating many times more energy than that which came originally from the trigger. *See* HEAT RADIATION.

If the massive casing is made mostly of uranium-238 (natural or depleted uranium), neutrons from the thermonuclear reactions will cause the uranium nuclei to undergo fission, giving off still more energy. A device of this sort can be regarded as a three-stage fission-fusion-fission bomb.

The yield, or total energy, of a hydrogen bomb is expressed in megatons (1 megaton equals 10^{15} calories or 4.18×10^{15} joules). Typical fusion-boosted weapons yield hundreds of kilotons (tenths of megatons), and typical multistage weapons yield megatons. *See* NUCLEAR EXPLOSION. [A.DeV.]

Hydrogen bond The interaction which occurs when a hy-drogen atom, covalently bonded to an electronegative atom (as in A—H), interacts with another atom to form the aggregate A—H ··· Y. The shortest and strongest bond is indicated as A—H, while the secondary and weaker interaction is written as H ··· Y. Thus A—H is a proton donor, while (Y) is a proton acceptor which often contains lone pair electrons and can act as a base. The strongest hydrogen bonds are formed between the most electronegative (A) atoms such as fluorine, nitrogen, and oxygen which interact with (Y) atoms having electronegativity greater than that of hydrogen (C, N, 0, S, Se, F, Cl, Br, I). The weakest of hydrogen bonds are formed by acidic protons of C—H groups, as in chloroform and acetylene, and by olefinic and aromatic π-electrons acting as (Y).

The weaker the hydrogen bond, the shorter the lifetime of the complex it forms. An important aspect of weak hydrogen bond formation is that the different molecular aggregates which do form can be easily and reversibly transformed. Thus the small energy changes resulting in the rapid making and breaking of hydrogen bonds in biological systems are of great importance; for example, hydrogen bonding determines the configuration of the famous α-helix of DNA, and the structures of most proteins, thereby serving an important function in determining the nature of all living things. *See* CHEMICAL BONDING; DEOXYRIBONUCLEIC ACID (DNA); PROTEIN. [J.M.Wi.]

Hydrogen fluoride The hydride of fluorine and the first member of the family of halogen acids. Anhydrous hydrogen fluoride is a mobile, colorless liquid that fumes strongly in air. It has the empirical formula HF, melts at −83°C, and boils at 19.8°C. The vapor is highly aggregated, and gaseous hydrogen fluoride deviates from perfect gas behavior to a greater extent than any other gaseous substance known. Aggregate formation in both the vapor and liquid phase arises from unusually strong hydrogen-bond interactions. *See* HYDROGEN BOND.

Anhydrous hydrogen fluoride is an extremely powerful acid, exceeded in this respect only by 100% sulfuric acid. Because anhydrous hydrogen fluoride is a superacid, many organic solutes dissolve in it to form stable carbonium ions. Alkali metal fluorides and silver fluoride dissolve readily in hydrogen fluoride to form conducting solutions. Anhydrous hydrogen fluoride dissolves a wide variety of organic compounds. Aqueous solutions of hydrogen fluoride (hydrofluoric acid) are relatively weakly acidic as compared to hydrochloric acid.

Hydrogen fluoride is a widely used industrial chemical. The largest use is in making fluorine-containing refrigerants (Freons, Genetrons). An increasingly important use of hydrogen fluoride is in the preparation of organic fluorocarbon compounds.

Both hydrogen fluoride and hydrofluoric acid cause unusually severe burns; appropriate precautions must be taken to prevent any contact of the skin or eyes with either the liquid or the vapor. *See* FLUORINE; HALOGENATED HYDROCARBON. [J.J.K.]

Hydrogen ion A proton combined with a number of water molecules. It is often written as H_3O^+ and called the hydronium ion. However, this species is best considered as an excess proton on a tetrahedral group of four water molecules and so would be designated as $H_9O_4{}^+$. For simplicity, it is most commonly written as H^+ (aq). *See* PROTON.

Since it is formed by the self-ionization of water, the hydrogen ion is present in all aqueous solutions. This formation also means that H^+(aq) is always found in the company of the hydroxide ion, OH^- (aq). The equilibrium relationship between the concentrations of these two species is a very important property of water. *See* IONIC EQUILIBRIUM.

The H^+(aq) and OH^- (aq) concentrations in pure water are equal to each other with a value of 10^{-7} mole/liter. Any aqueous solution with this concentration of H^+(aq) is called a neutral solution. If the H^+(aq) concentration is greater than 10^{-7} mole/liter, the solution is called acidic. Basic solutions are those in which the H^+(aq) concentration is less than 10^{-7} mole/liter. As the H^+(aq) concentration increases the OH^- (aq) concentration must decrease, and vice versa. In the most straightforward system, acids are substances that can donate an H^+(aq), and bases are substances that can accept one. *See* ACID AND BASE.

Hydrogen ion concentration determines the course of many chemical reactions that occur in living organisms and in the chemical industry. The control of hydrogen ion concentration is achieved in living organisms and in the laboratory by buffer systems. These are chemical mixtures designed to resist change in hydrogen ion concentration.

Another property of the H^+(aq) is important in both theoretical and practical ways. H^+(aq) is the best conductor of electricity of any ion in aqueous solution. Its conductance at 77°F (25°C) is almost five times as large as the next-most-conducting ion. *See* ELECTROLYTIC CONDUCTANCE; HYDROGEN ELECTRODE.

The hydrogen ion concentration can vary over fourteen powers of 10. To avoid dealing with such exponentials, the concept of pH is used. Since all aqueous solutions contain both hydrogen ion and hydroxide ion, it is possible to define ail degrees of acidity and basicity on the pH scale. *See* PH.

Two general methods are used for the determination of hydrogen ion concentrations. For relatively crude work, colorimetric methods are commonly used. These methods depend on the fact that certain natural and synthetic dyes have colors that depend on the hydrogen ion concentration. At times, paper is impregnated with such an indicator. In most precise work, a potentiometric method is used for the determination of hydrogen ion concentration. This method depends on an electrode whose potential is sensitive to hydrogen ion concentration. The only electrode commonly in use for practical pH measurements is the glass electrode. *See* ACID-BASE INDICATOR; COLORIMETRY; TITRATION. [G.A.]

Hydrogen peroxide A binary compound of hydrogen and oxygen, empirical formula H_2O_2, used mostly in dilute aqueous solutions as an oxidizing agent. Its most remarkable feature is its tendency to decompose readily into water and oxygen.

Anhydrous hydrogen peroxide is a clear, colorless liquid, of nearly the same viscosity and dielectric constant as water, but of greater density. Like water, it is strongly associated through hydrogen bonds. It boils at 150°C (300°F) with violent, sometimes explosive decomposition. Decomposition by light begins only in the near ultraviolet. As a solvent, hydrogen peroxide resembles water, except that acids and bases show much lower electrical conductivity. Although a fairly strong oxidant, it can act as a mild reducing agent, for example, with permanganates and perchromates.

Hydrogen peroxide is used mainly for bleaching cotton and other fibers, natural or synthetic. Increasing amounts are used in the pulp and paper industry. Its well-known cosmetic use as hair bleach consumes relatively little of the commercial 10% (30 volume) solution. In medicine it is useful for cleansing wounds and cuts, although its antiseptic action is rather slow. A limited but important use of the concentrated peroxide is for energy production in rockets, submarines (during submersion), airplanes (at takeoff), and the steering of space vessels. *See* Bleaching; Chemical fuel.

Hydrogen peroxide, especially when concentrated, requires great care in handling and storing. When dropped on paper or wood, it can start a fire. Contact with the skin causes blotches that can be painful, but they disappear after a few hours without leaving traces. *See* Hydrogen; Oxygen; Peroxide. [P.A.G.]

Hydrogenation The chemical reaction of hydrogen with another substance, generally an unsaturated organic compound, and usually under the influence of temperature, pressure, and catalysts. There are several types of hydrogenation reactions. They include: (1) the addition of hydrogen to reactive molecules; (2) the incorporation of hydrogen accompanied by cleavage of the starting molecules (hydrogenolysis); and (3) reactions in which isomerization, cyclization, and so on, result.

Hydrogenation is synonymous with reduction in which oxygen or some other element (most commonly nitrogen, sulfur, carbon, or halogen) is withdrawn from, or hydrogen is added to, a molecule. When hydrogenation is capable of producing the desired reduction product, it is generally the simplest and most efficient procedure.

Hydrogenation is used extensively in industrial processes. Important examples are the synthesis of methanol, liquid fuels, hydrogenated vegetable oils, fatty alcohols from the corresponding carboxylic acids, alcohols from aldehydes prepared by the aldol reaction, cyclohexanol and cyclohexane from phenol and benzene, respectively, and hexamethylenediamine for the synthesis of nylon from adiponitrile. *See* Dehydrogenation; Fischer-Tropsch process; Hydroformylation; Hydrogen; Oxidation-reduction. [R.Le.]

Hydrography The measurement and description of the physical features and conditions of navigable waters and adjoining coastal areas, including oceans, rivers, and lakes. It involves geodesy, physical oceanography, marine geology, geophysics, photogrammetry (in coastal areas), remote sensing, and marine cartography. Basic parameters observed during a hydrographic survey are time, geographic position, depth of water, and bottom type. However, observation, analysis, and prediction of tides and currents area are also normally included in order to reduce depth measurements to a common vertical datum. *See* Geodesy; Photogrammetry.

A principal objective of hydrography is to provide for safe navigation and protection of the marine environment through the production of up-to-date nautical charts and related publications. In addition, hydrographic data are essential to a multitude of other activities such as global studies, for example, shoreline erosion and sediment transport studies; coastal construction; delimitation of maritime boundaries; environmental protection and pollution control; exploration and exploitation of marine resources, both living and nonliving; and development of marine geographic information systems (GIS). *See* Geographic information systems; Navigation.

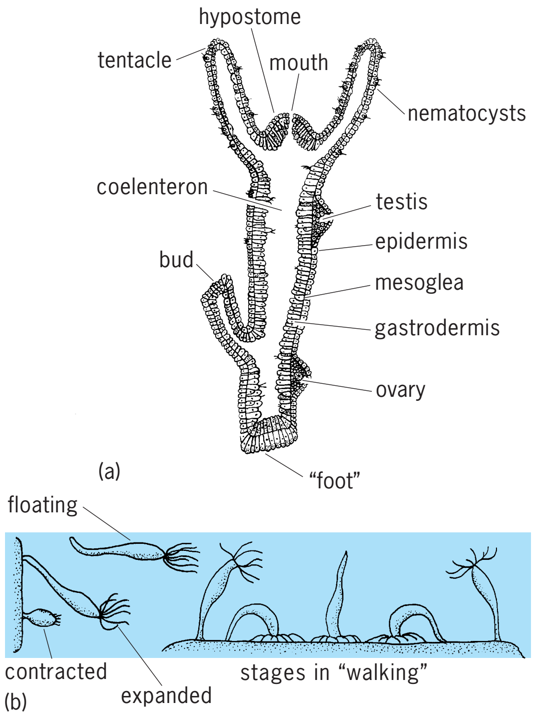
Modern depth information is achieved with sonar measurements. Dual-frequency echo sounders are used, with a high-frequency, narrow beam to measure the depth below the vessel, and a lower-frequency, wider beam to obtain larger coverage of the terrain. Side-scan sonar, an instrument that transmits acoustic signals obliquely through the water, is normally towed behind the survey vessel and displays the returning echoes via an onboard graphic recorder. Although this technique does not allow exact determination of position and depth (both can be approximated), it provides excellent resolution with a depiction with what lies to either side of the vessel. Multibeam hydrographic survey systems consist of hull-mounted arrays such that a fan-shaped array of sound beams is transmitted perpendicular to the direction of the ship%s track. This provides for the possibility of 100% coverage of the sea floor. *See* Echo sounder; Sonar.

Laser airborne systems mounted in fixed-wing aircraft or helicopters are also available for hydrographic surveys. The system emits a two-color laser beam, usually green and red, such that a return is received from the surface of the water by the red laser and from the bottom by the lower-frequency green laser, allowing the depth to be determined from the time difference. They can be operated in depths down to 165 ft (50 m), but more normally to 66 ft (20 m), depending on water clarity. Hydrographers use tide-coordinated aerial photography to delineate the high and low water lines for charting, which in turn is used for base-line determination of offshore boundaries. Satellite positioning of the aircraft using the Global Positioning System with carrier phase measurement and postprocessing of the data provides for determination of the position of the aircraft of the decimeter level. *See* Aerial photograph; Laser. [C.An.; G.An.]

Hydroida An order of the coelenterates which includes the fresh-water hydras, the attached and usually colonial hydroids, and many of the smaller jellyfish. It is the largest order of the class Hydrozoa.

The order Hydroida includes two principal suborders, Gymnoblastea and Calyptoblastea. The Gymnoblastea are those hydroids which lack protective cups around the hydranths and gonozoids. Jellyfish produced by these athecate hydroids are Anthomedusae. The Calyptoblastea include the hydroids with protective cups around the hydranths (hydrothecae) and around the gonozoids (gonothecae). Jellyfish of these thecate hydroids are called Leptomedusae. Two minor suborders are Limnomedusae and Chondrophora.

Anthomedusae are typically ovoid jellyfish, often with eyespots. Leptomedusae are usually flattened or saucer-shaped, have statocysts (sense organs of balance), and lack eyespots. The gonads of Anthomedusae are generally on the wall of the



Hydra. **(*a*) Longitudinal section. (*b*) Movements. (*After T. I. Storer et al., General Zoology, 6th ed., McGraw-Hill, 1979*)**

stomach just above the mouth, and those of Leptomedusae below the radial canals.

Young hydranths of gymnoblastic hydroids are small with five or more tentacles, but subsequently grow much larger and add more tentacles. Calyptoblastic hydranths, in contrast, emerge from a bud with a full complement of parts; they do not grow, live for only about a week, undergo regression and absorption by the colony, and are then replaced by new hydranths.

The fresh-water hydras are simple, motile polyps which do not produce colonies (see illustration). Buds separate from the parent and become individual polyps. Simple gonads develop on the body and there is no medusa. Hydras are sometimes included in the Gymnoblastea and sometimes placed in a suborder by themselves, the Hydrida.

Hydroids are species in which the polyp stage is usually dominant. Most hydroids are found near the shore attached to various supports such as rocks, wharves, boats, mussels, barnacles, worm tubes, crab and snail shells, and seaweeds. Sometimes the medusa stage is well developed and the hydroid stage may be lacking. Medusae are abundant both in coastal waters and in the open sea.

Hydras and hydroids have been used extensively in research on problems of growth, development, and regeneration. They have a high capacity for reorganization. Missing parts are quickly replaced, a bit of stem can produce a new hydranth, and completely disorganized masses of cells can reconstitute a new polyp. *See* Hydrozoa; Regeneration (biology). [S.Cr.]

Hydrology The study of the waters of the Earth: their occurrence, circulation, and distribution; their chemical and physical properties; and their reaction with the environment, including their relation to living things. *See* Terrestrial water.

Water in liquid and solid form covers most of the crust of the Earth. By a complex process powered by gravity and the action of solar energy, an endless exchange of water, in vapor, liquid, and solid forms, takes place between the atmosphere, the oceans, and the crust. This is known as the hydrologic cycle. Water circulates in the air and in the oceans, as well as over and below the surface of landmasses. The distribution of water in the planet is uneven. General patterns of circulation are present in the atmosphere, the oceans, and the landmasses, but regional features are very irregular and seemingly random in detail. Therefore, while causal relations underlie the overall process, it is believed that important elements of chance affect local hydrological events. *See* Atmospheric general circulation.

Whereas the global linkages of the hydrologic cycle are recognized, the science of hydrology has traditionally confined its direct concern to the detailed study of the portion of the cycle limited by the physical boundaries of the land; thus, it has generally excluded specialized investigations of the ocean (which is the subject of the science of oceanography) and the atmosphere (which is the subject of the science of meteorology). The heightened interest in anthropogenically induced environmental impacts has, however, underlined the critical role of the hydrologic cycle in the global transport and budgeting of mass, heat, and energy. Hydrology has become recognized as a science concerned with processes at the local, regional, and global scales. This enhanced status has strengthened its links to meteorology, climatology, and oceanography. *See* Climatology; Meteorology; Oceanography.

A number of field measurements are performed for hydrologic studies. Among them are the amount and intensity of precipitation; the quantities of water stored as snow and ice, and their changes in time; discharge of streams; rates and quantities of infiltration into the soil, and movement of soil moisture; rates of production from wells and changes in their water levels as indicators of ground-water storage; concentration of chemical elements, compounds, and biological constituents in surface and ground waters; amounts of water transferred by evaporation and evapotranspiration to the atmosphere from snow, lakes, streams, soils, and vegetation; and sediment lost from the land and transported by streams.

In addition, hydrology is concerned with research on the phenomena and mechanisms involved in all physical and biological components of the hydrologic cycle, with the purpose of understanding them sufficiently to permit quantitative predictions and forecasting. The field investigations and measurements not only provide the data whereby the behavior of each component may be evaluated in detail, permitting formulation in quantitative terms, but also give a record of the historical performance of the entire system. Thus, two principal vehicles for hydrological forecasting and prediction become available: a set of elemental processes, whose operations are expressible in mathematical terms, linked to form deterministic models that permit the prediction of hydrologic events for given conditions; and a group of records or time series of measured hydrologic variables, such as precipitation or runoff, which can be analyzed by statistical methods to formulate stochastic models that permit inferences to be made on the future likelihood of hydrologic events. *See* Ground-water hydrology; Hydrosphere. [M.A.Ma.]

Hydrolysis A chemical reaction in which splitting of a molecule by water occurs. Hydrolysis as applied to organic molecules can be considered a reversal of such reactions as esterification and amide formation. The hydrolysis of esters [reaction (1)] and of amides [reaction (2)] is shown. Other classes of organic compounds that are subject to hydrolysis include acetals, acyl and alkyl halides, ketals, and peptides. While the overall hydrolysis reaction [as in reactions (1) and (2)] appears to involve the addition of the water molecule (H_2O), the reaction is in fact more complicated. There are several reaction steps, such as the formation of a complex with either a proton (H^+; acid-catalyzed hydrolysis) or a hydroxyl ion (OH^-; base-catalyzed hydrolysis), followed by elimination of these ions to give the overall equation. The hydrolysis reaction is frequently encountered in biological systems. The kinetics of these reactions are greatly enhanced by the action of enzymes (biological catalysts) such as the esterases and the peptidases. *See* Enzyme; Hydrogen ion.

$$\underset{\text{Ethyl acetate}}{CH_3COOC_2H_5} + H_2O \rightarrow \underset{\text{Acetic acid}}{CH_3COOH} + \underset{\text{Ethanol}}{C_2H_5OH} \quad (1)$$

$$\underset{\text{Acetamide}}{CH_3CONH_2} + H_2O \rightarrow \underset{\text{Acetic acid}}{CH_3COOH} + \underset{\text{Ammonia}}{NH_3} \quad (2)$$

In inorganic chemistry, hydrolysis, also called aquation, represents a class of reactions involving metal coordination complexes in which one of the coordinated ligands is displaced by either H_2O or OH^-. Hydrolysis is a special case of the class of reactions termed ligand displacement reactions [reaction (3), where M is a metal, L and X are ligands, and Y is the displacing ligand (H_2O in hydrolytic reactions)]. *See* Coordination complexes; Ligand. [H.Frei.]

$$L_nMX + Y \rightarrow L_nMY + X \quad (3)$$

Hydrolytic processes Reactions of both organic and inorganic chemistry wherein water effects a double decomposition with another compound, hydrogen going to one component, hydroxyl to another, as in reactions (1)–(3). Although the word “hydrolysis” means decomposition by water, cases in which water brings about effective hydrolysis unaided are rare, and high temperatures and pressures are usually necessary. *See* Hydrolysis.

$$XY + H_2O \rightarrow HY + XOH \quad (1)$$

$$KCN + H_2O \rightarrow HCN + KOH \quad (2)$$

$$C_5H_{11}Cl + H_2O \rightarrow HCl + C_5H_{11}OH \quad (3)$$

Hydrolytic reactions may be classified as follows: (1) hydrolysis with water alone; (2) hydrolysis with dilute or concentrated acid;

(3) hydrolysis with dilute or concentrated alkali; (4) hydrolysis with fused alkali with little or no water at high temperature.

In the field of organic chemistry, the term “hydrolysis” has been extended to cover the numerous reactions in which alkali or acid is added to water. An example of an alkaline-condition hydrolytic process is the hydrolysis of esters, reaction (4), to

$$CH_3COOC_2H_5 + NaOH \rightarrow CH_3COONa + C_2H_5OH \qquad (4)$$

produce alcohol. An example of an acidic-condition process is the hydrolysis of olefin to alcohol in the presence of phosphoric acid, reaction (5). The addition of acids or alkalies hastens such

$$C_2H_4 + H_2O \xrightarrow{H_3PO_4} C_2H_5OH \qquad (5)$$

reactions even it it does not initiate the reaction.

Perhaps some of the oldest and largest-volume hydrolysis technology is involved in soap manufacture. In the first step, glyceryl stearate acid, a fat, is hydrolyzed with water to yield stearic acid and glycerin. In the second step, the stearic acid is neutralized with caustic soda to give sodium stearate, the soap, and water. *See* FAT AND OIL.

Hydrolytic processes account for a huge product volume. Conversion of starch such as corn starch into maltose and glucose (sugar syrups) by treatment with hydrochloric acid is a major industry. Similarly, the production of furfural from pentosans of oat hulls or other cereal by-products such as corn cobs, rice hulls, or cottonseed bran is another commercial hydrolytic process. [D.L.H.]

Hydrometallurgy The extraction and recovery of metals from their ores by processes in which aqueous solutions play a predominant role. Two distinct processes are involved in hydrometallurgy: putting the metal values in the ore into solution via the operation known as leaching; and recovering the metal values from solution, usually after a suitable solution purification or concentration step, or both. The scope of hydrometallurgy is quite broad and extends beyond the processing of ores to the treatment of metal concentrates, metal scrap and revert materials, and intermediate products in metallurgical processes. Hydrometallurgy enters into the production of practically all nonferrous metals and of metalloids, such as selenium and tellurium. Hydrometallurgical and pyrometallurgical processes complement each other. *See* LEACHING; PYROMETALLURGY.

Hydrometallurgy occupies an important role in the production of aluminum, copper, nickel, cobalt, zinc, gold, silver, platinum, selenium, tellurium, tungsten, molybdenum, uranium, zirconium, and other metals. *See* METALLURGY. [W.C.Co.]

Hydrometeorology The study of the occurrence, movement, and changes in the state of water in the atmosphere. The term is also used in a more restricted sense, especially by hydrologists, to mean the study of the exchange of water between the atmosphere and continental surfaces. This includes the processes of precipitation and direct condensation, and of evaporation and transpiration from natural surfaces. Considerable emphasis is placed on the statistics of precipitation as a function of area and time for given locations or geographic regions.

Water occurs in the atmosphere primarily in vapor or gaseous form. The average amount of vapor present tends to decrease with increasing elevation and latitude and also varies strongly with season and type of surface. Precipitable water, the mass of vapor per unit area contained in a column of air extending from the surface of the Earth to the outer extremity of the atmosphere, varies from almost zero in continental arctic air to about 6 g/cm^2 in very humid, tropical air.

Although a trivial proportion of the water of the globe is found in the atmosphere at any one instant, the rate of exchange of water between the atmosphere and the continents and oceans is high. Evaporation from the ocean surface and evaporation and transpiration from the land are the sources of water vapor for the atmosphere. Water vapor is removed from the atmosphere by condensation and subsequent precipitation in the form of rain, snow, sleet, and so on. The amount of water vapor removed by direct condensation at the Earth’s surface (dew) is relatively small. *See* HYDROLOGY; METEOROLOGY; PRECIPITATION (METEOROLOGY). [E.M.R.]

Hydrometer A direct-reading instrument for indicating the density, specific gravity, or some similar characteristic of liquids. Almost all hydrometers are made of a high-grade glass tubing. The main body is the float section in the bottom of which ballast, such as small shot, is secured. A small-diameter tube, the stem, extends from the upper end of the float section. Inside the stem is the scale, printed on heavy-grade paper, and well-secured within the stem so its position will not change. When the hydrometer is placed in a liquid, the stem extends vertically above the surface for a portion of its length.

Hydrometers may be classified according to the indication provided by graduations of the scale as follows: (1) density hydrometers, to indicate densities at a particular temperature, and usually for a particular liquid; (2) specific gravity hydrometers to indicate specific gravity of a liquid, with reference to water, at a particular temperature; (3) percentage hydrometers to indicate, at a particular temperature, the percentage of a substance such as salt, sugar, or alcohol dissolved in water (alcoholometers are an example); and (4) arbitrary scale hydrometers, indicating the density, specific gravity, or concentration of a liquid in terms of an arbitrarily defined scale, at a defined temperature. The last group includes the saccharimeter (indicates percentage of pure sucrose solutions); the Baumé hydrometer (measures specific gravity of liquids lighter than water); the lactometer (tests milk); and the barkometer (tests tanning extracts). *See* DENSITY; SPECIFIC GRAVITY. [H.S.B.]

Hydrophone A device which receives underwater sound waves and converts them to essentially equivalent electric waves. A hydrophone is the underwater analog of a microphone. Hydrophones are used in sonar apparatus, sonobuoys, and certain underwater weapons. *See* ACOUSTIC TORPEDO; MICROPHONE; SONAR; SONOBUOY; UNDERWATER SOUND. [H.F.O.]

Hydroponics Techniques for supplying nutrients and water directly to the roots of plants, without soil or other media. Methods that utilize an inert medium such as sand, gravel, peat, or vermiculite to provide the root environment, with water and nutrients added in solution, are soilless culture but are not hydroponic in the strict sense.

Hydroponic systems range in complexity from a single plant supported above an aerated jar of nutrient solution to thousands of plants supported above a large area of flowing solution in which pH, temperature, and nutrient concentrations are controlled by using a sophisticated computer system and automated chemical analysis. In hydroponic culture, precise control of the pH and the concentrations of elements in the solution is critical; all essential elements must be provided and in the correct ratios for plant growth. *See* PLANT MINERAL NUTRITION.

Hydroponic systems offer a number of advantages when compared to soil culture. They reduce water, pH, and nutrient stress; yield clean roots and leaves; and facilitate rapid crop turnaround and automation. The disadvantages are that disease may spread more rapidly, pH and nutrient control are required, and initial expenses are higher. In theory, the growth-limiting factors in hydroponic systems are the availability of photosynthetic light and carbon dioxide. *See* PHOTOSYNTHESIS.

Among typical hydroponic systems are aerated standing culture, intermittent-flow culture, and continuous-flow culture. These techniques require careful preparation of the nutrient solution, continued monitoring, and adjustment or periodic replacement of the solution.

Hydroponic culture is widely used in research on plant nutrition and on the effect of temperature and pH on roots. Hydroponics can also be used to study the effect of microbes on plant health. Hydroponic systems also have obvious value in the field of education and for the amateur horticulturist, who can grow flowers or vegetables in a confined space with an indoor hydroponic garden. *See* PLANT GROWTH. [T.W.D.]

Hydrosphere The water portion of the Earth as distinguished from the solid part and from the gaseous outer envelope (atmosphere). Approximately 74% of the Earth's surface is covered by water, in either the liquid or solid state. These waters, combined with minor contributions from ground waters, constitute the hydrosphere.

The oceans account for about 97% of the weight of the hydrosphere, while the amount of ice reflects the Earth's climate, being higher during periods of glaciation. There is a considerable amount of water vapor in the atmosphere. The circulation of the waters of the hydrosphere results in the weathering of the landmasses. The annual evaporation from the world oceans and from land areas results in an annual precipitation of 320,000 km^3 (76,000 mi^3) on the world oceans and 100,000 km^3 (24,000 mi^3) on land areas. The rainwater falling on the continents, partly taken up by the ground and partly by the streams, acts as an erosive agent before returning to the seas.

The unique chemical properties of water make it an effective solvent for many gases, salts, and organic compounds. Circulation of water and the dissolved material it contains is a highly dynamic process driven by energy from the Sun and the interior of the Earth. Each component has its own geochemical cycle or pathway through the hydrosphere, reflecting the component's relative abundance, chemical properties, and utilization by organisms. The introduction of materials by humans has significantly altered the composition and environmental properties of many natural waters. *See* GROUND-WATER HYDROLOGY; HYDROLOGY; LAKE; TERRESTRIAL WATER. [J.S.H.]

Hydrostatics The study of liquids at rest. In the absence of motion, there are no shear stresses; the internal state of stress at any point is determined by pressure alone. Hence, the pressure at a point is the same in all directions. Pressure acts normally to all boundary surfaces. For equilibrium under gravity, regardless of the shape of the containing vessel, the pressure is uniform over any horizontal cross section. Pressure varies with height or depth. Two different reference levels are used in measuring pressure. For many engineering purposes, gage pressure is used with pressure measured relative to atmospheric pressure as zero. For most scientific purposes, pressure is referred to true zero. Normal atmospheric pressure at sea level caused by the weight of the air above is approximately 101 kilopascals or 14.7 pounds per square inch absolute.

The buoyant force is the force exerted vertically upward by a fluid on a body wholly or partly immersed in it. Its magnitude is equal to the weight of the fluid displaced by the body. This value is also the vertical component of the fluid pressure force acting upward against the bottom of the body minus the fluid pressure force component (if any) acting vertically downward against the top of the body. If this buoyant force equals the weight of the body, the body will remain at the given level. If it exceeds the weight of the body, the latter will rise, and vice versa. The buoyant force as a single magnitude acts vertically upward through the center of buoyancy which is the center of gravity of the displaced fluid. *See* ARCHIMEDES' PRINCIPLE.

Pressure applied to a confined liquid is transmitted with equal intensity throughout the liquid and by it to all surfaces of the confining vessel or piping. Hence, a small force applied to a small area of a confined liquid can create a large force against a large area. If the small and large areas are pistons the device may be a hydraulic press or jack. Because the transmitting liquid is practically incompressible and its volume virtually constant, the linear movement of the large piston will be to that of the small piston in inverse proportion to their areas. The principle of multiplying a force by means of liquid pressure applies also to hydraulic brakes, power steering, control systems, and the like; the actuating force may be a pump instead of a small piston. *See* HYDRAULICS. [W.A.]

Hydrothermal vent A hot spring on the ocean floor, where heated fluids exit from cracks in the Earth's crust. Most hydrothermal vents occur along the central axes of mid-oceanic ridges, which are underwater mountain ranges that wind through all of the deep oceans. The best-studied vents are at tectonic spreading centers on the East Pacific Rise and at the Mid-Atlantic Ridge. However, vents are also found over hot spots such as the Hawaiian Islands and Iceland, in back-arc basins such as those in the western Pacific, in shallow geothermal systems such as those off the Kamchatka Peninsula, and on the flanks of some underwater volcanoes and seamounts. Hydrothermal vent sites, or closely grouped clusters of vent deposits and exit ports, may cover areas from hundreds to thousands of square feet (tens to hundreds of square meters). Individual vent sites may be separated along mid-ocean ridges by more than 1000 mi (1600 km). *See* MID-OCEANIC RIDGE; SEAMOUNT AND GUYOT.

All of the hydrothermal vent sites occur in areas where quantities of magma exist below the sea floor. Cold seawater is drawn down into the oceanic crust toward the heat source. As the seawater is heated and reacts with surrounding rock, its composition changes. Sulfate and magnesium are major components of seawater lost during the reactions; sulfide, metals, and gases such as helium and methane are major components gained. This modified seawater is known as hydrothermal fluid. Buoyant, hot hydrothermal fluid rises toward the sea floor in a concentrated zone of upflow to exit from the sea floor at temperatures ranging from 50°F (10°C) to greater than 750°F (400°C), depending on the degree of cooling and of mixing with seawater during the ascent. If the sea floor is shallow enough and the fluid hot enough, the solution may boil; but it usually does not because of the pressure of overlying seawater. *See* MAGMA.

Hydrothermal fluid that mixes extensively with seawater below the sea floor surface may reach the sea floor as warm springs, with temperatures of 50–86°F (10–30°C). This outflow is usually detectable as cloudy or milky water, but the flow is slow and no mineral deposits accumulate except for some hydrothermal staining or oxidation of sea floor basalts. When hotter, relatively undiluted hydrothermal fluid reaches the sea floor, it is still buoyant with respect to seawater, so that the hot solution rises out of cracks in the sea floor at velocities up to about 6 ft (2 m) per second, mixing turbulently with seawater as it rises. Mixing of hydrothermal fluid with seawater leads to precipitation of minerals from solution, forming mineral deposits at the exit from the sea floor and so-called smoke, tiny mineral particles suspended in the rising plume of fluid. Black smoker vents are distinguished by the presence of such large quantities of minute mineral particles that the plumes become virtually opaque.

Formation and outflow of hydrothermal fluid makes a major contribution to the concentration and balance of elements in the oceans by changing the composition of seawater. The quantities of elements added or removed from the oceans by hydrothermal venting around the world are comparable to quantities contributed by the worldwide flow of rivers into the oceans. Hydrothermal venting also represents a major flow of heat from the Earth's crust and a major mechanism for cooling of new oceanic lithosphere. *See* LITHOSPHERE; SEAWATER.

Perhaps the most striking feature of sea-floor hydrothermal vents is their dense biologic communities. Vent faunas tend to be dominated by mollusks, annelids, and crustaceans, whereas faunas on nonvent hard-bottom habitats consist predominantly of cnidarians, sponges, and echinoderms. Biologically, vents are among the most productive ecosystems on Earth. Sulfide from hydrothermal fluids provides the energy to drive these productive systems. Whereas most animal life depends on food of photosynthetic origin (inorganic carbon converted to useful sugars by plants using energy from the Sun), the animals at hydrothermal vents obtain most or all of their food by a process of chemosynthesis. Chemosynthesis is accomplished by specialized bacteria residing in hydrothermal fluids, in mats on the sea floor, or in symbiotic relationships with other organisms. The bacteria convert inorganic carbon to sugars by mediating the oxidation of hydrogen sulfide, thereby exploiting the energy stored in chemical bonds. A few vent animals are also known to use methane gas as a source of energy and carbon. The physical and chemical conditions at hydrothermal vents would be lethal to most marine animals, but vent species have adapted to the conditions there. *See* DEEP-SEA FAUNA.

In a remarkable discovery, it was shown that chemosynthetic microbes known as Archaea are flushed from cavities deep within the Earth's crust by hydrothermal and volcanic activity. These microbes are hyperthermophilic (hot-water-loving) and thrive at temperatures exceeding 90°C (194°F). It is now suspected that an entire community of such microbes inhabits the rocks deep within the water-saturated portions of the Earth's crust. *See* MARINE GEOLOGY. [M.Go.]

Hydroxide A compound containing the hydroxide ion (OH^-) and having the general formula $M(OH)_n$, where M represents a metal. Hydroxides are a subset of compounds containing the hydroxyl group (—OH) and range in chemical character from strongly basic, to amphoteric (having both acidic and basic characteristics), to essentially acidic. The hydroxide ion has a closed-shell electronic structure with a singlet ground state.

In the Lewis acid-base scheme, where a base is defined as an electron pair donor and an acid as an electron pair acceptor, a typical hydroxide decreases in base strength as attraction for electrons of the cation increases. For example, the hydroxides of electropositive elements such as the alkali metals and alkaline earths tend to be bases. When these ionic compounds are dissolved in water, they form metal ions and hydroxide ions, as in reaction (1), where S represents a solid and aq represents a water

$$M^+(OH^-)_n(S) + nH_2O \longrightarrow M^{n+}(aq) + nOH^-(aq) \qquad (1)$$

solution. The hydroxides of nonmetals (X) such as boron hydroxide [$B(OH)_3$], where the X-O bonds are covalent, are generally acidic, as shown in reaction (2), where H_3O^+ is the hydronium

$$X(OH)_n + nH_2O \longrightarrow XO_n^{n-}(aq) + nH_3O^+(aq) \qquad (2)$$

ion. The amphoteric hydroxides may dissociate by either mechanism, depending on the presence of strong acids or bases. *See* ACID AND BASE; HYDROGEN ION.

The alkali metal hydroxides such as sodium hydroxide (NaOH) are extremely important as reagents in metallurgy and photography and in the manufacture of soaps and detergents. Calcium hydroxide [$Ca(OH)_2$], known as slaked lime, is used in the preparation of mortar for brick laying. Minerals such as brucite [$Mg(OH)_2$] and pyrochroite [$Mn(OH)_2$] are naturally occurring hydroxides. [T.J.Me.]

Hydroxyl A chemical group in which oxygen and hydrogen are bonded and act as a single entity. In inorganic chemistry the hydroxyl group is known as the hydroxide ion (OH^-), and it is frequently bonded to metal cations, for example, sodium hydroxide (NaOH). In organic chemistry it frequently acts as a functional group, for example, in an alcohol (ROH, where R represents an alkyl group). *See* ACID AND BASE.

Many of the intermediate redox forms of dioxygen are toxic and damage important biomolecules. Much of this toxicity is thought to involve the generation and reactivity of hydroxyl (·OH), which is sometimes called the hydroxy radical. The most common means for producing hydroxyl is the reaction of a reducing agent with hydrogen peroxide (H_2O_2). Transition-metal ions, such as ferrous ion (Fe^{2+}), are the most common reducing agents for generating ·OH.

Once generated, hydroxyl is a potent one-electron oxidant that forms the very stable OH^- ion, and it abstracts hydrogen atoms from organic molecules that contain C-H bonds to form the stronger O-H bond in water. The reaction of a radical, which contains an uneven number of electrons, with a molecule, which contains an even number of electrons paired in bonds, must generate a radical, because the number of electrons cannot change during the reaction. Thus, most reactions of radicals generate new radicals in processes called radical chain reactions. Reactions of radicals with molecules will continue to produce new radicals until other odd-electron species (such as transition-metal ions or other radicals) react with the radicals to produce even-electron molecules via termination reactions. *See* TRANSITION ELEMENTS. [H.H.T.]

Hydrozoa A class of the phylum Coelenterata which includes the fresh-water hydras, the marine hydroids, many of the smaller jellyfish, a few special corals, and the Portuguese man-of-war. The Hydrozoa may be divided into six orders: the Hydroida, Milleporina, Stylasterina, Trachylina, Siphonophora, and Spongiomorphida. See separate article on each order.

The form of the body varies greatly among the hydrozoans. This diversity is due in part to the existence of two body types, the polyp and the medusa. A specimen may be a polyp, a medusa, a colony of polyps, or even a composite of the first two. Polyps are somewhat cylindrical, attached at one end, and have a mouth surrounded by tentacles at the free end. Medusae are free-swimming jellyfish with tentacles around the margin of the discoidal body.

In a representative life cycle, the fertilized egg develops into a swimming larva which soon attaches itself and transforms into a polyp. The polyp develops stolons (which fasten to substrates), stems, and other polyps to make up a colony of interconnected polyps. Medusae are produced by budding and liberated to feed, grow, and produce eggs and sperm.

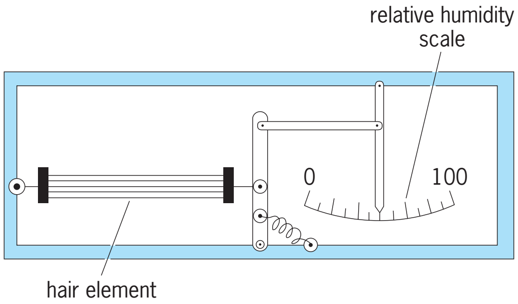
Most hydrozoans are carnivorous and capture animals which come in contact with their tentacles. The prey is immobilized by poison injected by stinging capsules, the nematocysts. Most animals of appropriate size can be captured, but small crustaceans are probably the most common food. *See* COELENTERATA. [S.C.]

Hyena An African carnivore represented by three species of the family Hyaenidae. Hyenas resemble dogs superficially, but they are more closely related to the felids (cats). They are four-toed digitigrade (walking on the toes) animals with blunt, nonretractile claws that are used for digging and disinterring bodies. The gestation period is about 13 weeks, with two to four young composing the yearly litter. The maximum lifespan of this animal is about 25 years. *See* CARNIVORA. [C.B.C.]

Hyeniales An order of Devonian plants considered to be related to the Sphenopsida. The small dichotomously forked leaves tend to be borne in whorls. Some leaves bear terminal sporangia, but these appendages are neither aggregated into a tight cone nor separated by bracts. *See* PALEOBOTANY. [H.P.B.]

Hygrometer An instrument for giving a direct indication of the amount of moisture in the air or other gas, the indication usually being in terms of relative humidity as a percentage that the moisture present bears to the maximum amount of moisture that could be present at the location temperature without condensation taking place. There are three major types of hygrometers: mechanical, electrical, and cold-spot or dew-point. *See* DEW POINT; HUMIDITY.

In a simple mechanical type of hygrometer the sensing element is usually an organic material which expands and contracts with changes in the moisture in the surrounding air or gas. The



Hygrometer which uses hair as the sensing element. (*After D. M. Considine and S. D. Ross, Process Instruments and Controls Handbook, 2d ed., McGraw-Hill, 1974*)

material used most is human hair. As shown in the illustration, the bundle of hair is held under a slight tension by a spring, and a magnifying linkage actuates a pointer.

In an electrical hygrometer the change in the electrical resistance of a hygroscopic substance is measured and converted to percent relative humidity.

In a third group of hygrometers, commonly called dew-point apparatus, the dew-point temperature is determined; this is the temperature at which the moisture in the gas is at the point of saturation, or 100% relative humidity. The usual procedure is to chill a polished surface until dew or a film of moisture just starts to appear and to measure the temperature of the surface. [H.S.B.]

Hymenomycetes An artificial class of fungi in the phylum Basidiomycota. It was traditionally divided into two subclasses: Holobasidiomycetidae, delimited by nonseptate basidia and the absence of a yeast phase; and Phragmobasidiomycetidae, frequently with septate basidia and often forming a yeast phase. A typical hymenomycete produces a fruit body or basidiome with spore-bearing basidia organized in a membranelike layer called the hymenium. The shape of the hymenium varies from lamellate (gilled as in mushrooms), poroid (as in conk or bracket fungi), toothed (in hedge hog fungi), coralloid (coral fungi), labyrinthoid (daedaleoid fungi), wrinkled (merulioid fungi), or smooth to diffuse (corticioid fungi). Exceptional hymenomycetes may be aquatic, lack a mycelial phase, or lack a fruit body.

Antibiotics have been isolated from many species. Commercially grown edible species include the button mushroom (*Agaricus bisporus*), Shiitake (*Lentinula edodes*), Paddy Straw mushroom (*Volvariella volvacea*), and Wood Ear (*Auricularia polytricha*). Wild harvested species include the Matsutake (*Tricholoma matsutake* and *T. magnivelare*), chanterelles (*Cantharellus cibarius* and allies), and the King Bolete (*Boletus edulis*).

Most genera are either saprophytic (for example, *Agaricus* and *Polyporus*), or mycorrhizal with trees (*Albatrellus, Cortinarius, Ramaria*, and *Thelephora*). Others are parasites. *Heterobasidion* causes destructive tree diseases; *Rhizoctonia* and *Typhula* (snow molds) cause field crop losses; *Mycena citricolor* blights coffee leaves; and *Exobasidium*, an obligate plant pathogen, induces the formation of galls and leaf curls. Other notable pathogens include *Hohenbuehelia* and *Pleurotus*, which capture nematodes; *Serpula*, a major dry-rot agent; *Dictyonema*, a basidiolichen; and *Septobasidium*, which harnesses living scale insects. *See* BASIDIOMYCOTA; EUMYCOTA; FUNGI; PLANT PATHOLOGY. [S.A.R.]

Hymenoptera The third largest order of insects, containing the sawflies, ants, wasps, bees, and related forms. Conservative estimates suggest that the world fauna may comprise well over 100,000 described species of this order, with many thousands still to be described. *See* INSECTA.

This order is of great importance to humans. Some members such as the sawflies, certain chalcidoids, and most cynipoids, feed during the larval stage on foliage or other plant tissues. Many species, such as the ichneumon flies, most chalcid flies, and wasps, are parasites or predators of other insects or spiders during their larval stage. Bees are indispensable in the pollination of many fruits, vegetables, and forage crops. *See* BEE.

Hymenoptera occur in all major faunal zones but are more abundant and have greater diversity of species in the tropical and temperate zones.

Adult Hymenoptera usually may be recognized by having two pairs of membranous wings with reduced venation, the hind pair smaller than the front pair, and by mouthparts formed for biting and often for lapping or sucking. In the higher forms, the abdomen is constricted basally, its first segment fused with the hind part of the thorax. Females always have an ovipositor modified for sawing, piercing, or stinging. Metamorphosis is complete.

The first four superfamilies of the Apocrita—the Ichneumonoidea, Chalcidoidea, Cynipoidea, and Proctotrupoidea—are commonly called the Parasitica, and the remaining superfamilies are known as the Aculeata. The Aculeata are stinging forms and the Parasitica are parasites of other insects. It is impossible to demarcate these two groups sharply because some Aculeata are parasites and some Parasitica are phytophagous. However, except for the phytophagous species of Parasitica, these insects lay their eggs in or on an insect or spider host while the Aculeata place theirs in nests with a provision of food. The table presents the major classification of the order as recognized in North America.

Morphology. The adult hymenopteran has a clearly differentiated head, thorax, and abdomen. Wings, when present, and legs are attached to the thorax.

Typically the head is so oriented that mouthparts are directed downward; however, all variations occur, and in some species the mouthparts are directed forward. The large compound eyes occupy much of the sides of the head, though they are reduced in size in many ants and some Parasitica. Three ocelli are typically present on the top of the head, but may be reduced or absent in wingless forms. The paired antennae arise from the face between the eyes, and they may be close to the mouthparts or removed from them.

The thorax consists of three segments, tightly fused together. Each segment bears a pair of legs, and each of the last two segments bears a pair of wings. In flight, the fore- and hind-wings are joined by a row of tiny hooks along the fore margin of the posterior wing, which fit into the downfolded hind margin of the anterior wing. Flightless species with shortened, nonfunctional wings, or no wings at all occur in most major groups, except the sawflies and bees.

The abdomen primitively consists of 10 segments, though the number appears to be less because of modification or loss in the higher forms. The female ovipositor, or sting, is formed from processes of the eighth and ninth sterna.

In the Apocrita there is a pair of acid glands opening into a poison sac connected with the ovipositor. The secretion of these glands produces either a temporary paralysis when injected into their hosts by some Parasitica, or, usually, permanent paralysis when injected into their prey by aculeate wasps. Bees use their stings purely for defense. When a human is stung, the enzymes react with the tissues to release histamine. Death may occasionally result from anaphylactic shock, or from mechanical suffocation due to swelling of the lymphatic system. Medical assistance should be sought if severe swelling occurs following a sting, especially one on the face or throat.

Biology. Practically all hymenopterous adults are terrestrial forms, living in, on, or near the Earth's surface. A few species are secondarily aquatic, the adults swimming or walking under water to search out and parasitize aquatic or subaquatic hosts.

Most adults feed on plant nectar or honeydew secretions of various insects. A few sawflies prey on other insects. Some

Families of Hymenoptera

Classification	Common name	No. of species
Suborder Symphyta	Sawflies	1009
Superfamily Megalodontoidea		120
Xyelidae		33

Apidae	Honeybees, bumblebees, and carpenter bees	1076

species of Parasitica and Aculeata imbibe body juices of the host or prey which they attack primarily for oviposition.

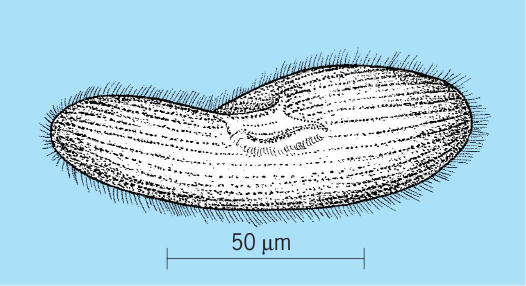
Mating takes place in a variety of situations, but it is always of rather short duration. Most species are represented by both males and females. Males are usually produced from unfertilized eggs and have half the normal number of chromosomes, while females are produced from fertilized eggs and have the normal number of chromosomes.

Hymenoptera exhibit complete metamorphosis during development and pass through an egg, larval, and pupal state. So far as is known, Hymenoptera always lay eggs. These are deposited in a protected situation on or near the supply of larval food. The hymenopterous egg is usually ovoid or sausage-shaped, and many species in some groups have stalked eggs.

Some species have only one generation a year in temperate zones, others have two, and many breed continually during the warmer months. Hymenoptera usually overwinter as prepupae but occasionally ants, social wasps, and some bees overwinter as adults or as larvae, as in some Parasitica.

Sexual dimorphism is often very marked. The two sexes of some species are so dissimilar that earlier students placed them in different genera or families. Even today there are many puzzles, and sexes have not been associated for many of the species having wingless females and winged males. Ordinarily the males are somewhat smaller than females, though the reverse is true in most species having wingless females. *See* SEXUAL DIMORPHISM; SOCIAL INSECTS. [K.V.K.]

Hymenostomatida An order of the Holotrichia which contains many species that often are of small size and fairly uniform ciliation. Primarily, these protozoans are of importance as the first possessors of a definite, though inconspicuous, buccal ciliature. This ciliature consists of an undulating membrane on the right side of the buccal cavity and an adoral zone of membranelles that is primitively composed of three membranelles on the left side. This tetrahymenal, or four-part, buccal ciliary apparatus is considered the fundamental condition from which the



A representative *Paramecium*.

oral ciliature of many subsequent higher groups evolved. *See* CILIOPHORA.

The majority of hymenostomes are free-living fresh-water forms. *Paramecium* (see illustration) is the best-known genus of ciliates. It is a good-sized, widely distributed ciliate, and is a much-studied form. *Tetrahymena*, beginning to rival *Paramecium* as a favorite ciliate in much experimental work, owes its scientific popularity primarily to its ability to grow axenically, that is, free from all other organisms, in a chemically defined medium. *See* PROTOZOA. [J.O.C.]

Hyperbaric oxygen chamber A specially equipped pressure vessel used in medicine and physiological research to administer oxygen at elevated pressures.

Basic principle. Under normal conditions the red blood cells provide the main transport mechanism for distributing oxygen through the bodies of warm-blooded animals. In humans less than 5% of the oxygen in the body is dissolved in body fluids. The transport capacity of red blood cells permits warm-blooded animals to maintain high body temperatures even in cold climates, and to supply the heavy oxygen demand of a large active brain. However, circulation of the red cells through the blood vessels requires a great amount of work by the heart and can be reduced or stopped by damage or blockage of the blood vessels.

The amount of oxygen dissolved in the body fluids is related to the pressure of oxygen in the lungs (Henry's law). When a person breathes pure oxygen, the amount of oxygen dissolved in body fluids is about six times that when breathing air. This is still too low to supply the needs of the human body. However, breathing pure oxygen at three times normal air pressure causes the amount of oxygen dissolved in body fluids to be equal to that normally carried by the red cells. Research animals have been kept alive in a hyperbaric chamber for some time with all the red cells removed from their blood. At the end of the experimental period the red cells were returned and the animals subsequently led perfectly normal lives.

A principal advantage of dissolved oxygen is that it can be transported throughout the body wherever there is fluid of any sort. It is not limited to circulation through blood vessels. A second advantage is that a given volume of blood contains twice the normal amount of oxygen. The high level of oxygen in the body aids the patient in the following ways: (1) Oxygen can be carried past an obstruction in the circulatory system, thus relieving oxygen-starved tissues. (2) The work load on the heart can be reduced, since one-half the normal blood flow will provide the normal amount of oxygen required by the body. (3) Poisons such as carbon monoxide can be eliminated. (4) Anaerobic bacteria such as tetanus can be destroyed. (5) The effectiveness of radiation treatment of cancer is increased. *See* RADIATION BIOLOGY; TETANUS.

Equipment. For physiological studies and for some types of patient treatment chambers just large enough for one person have been built. These chambers are relatively inexpensive to build but have limited usefulness because the patient cannot be treated or cared for while sealed up inside the oxygen-filled pressure chamber.

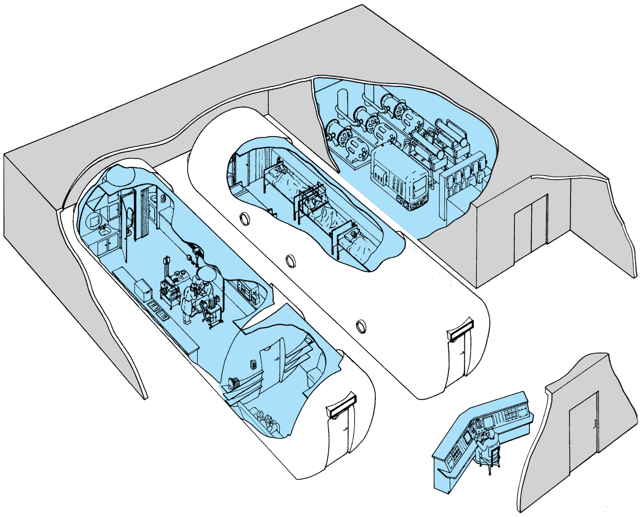
In order to give the patient adequate care or to perform surgery, it is necessary to use much larger equipment. The illustration shows a hyperbaric facility consisting of two large chambers. One chamber contains a fully equipped operating room, while the other contains a small medical ward. These large chambers are filled with ordinary air that is compressed to the appropriate pressure. The patients breathe pure oxygen through masks or tents; the attending doctors and nurses breathe the air that fills the chamber.

Each chamber consists of a steel pressure vessel which is roughly 12 ft (4 m) in diameter and about 45 ft (14 m) long. Larger vessels have been employed, but they are extremely difficult to install and require excessively large compressors to provide a fresh air supply.

Inside, the vessel is divided into three areas. In the front area is a large entry lock in which patients on stretchers can be compressed or decompressed while the main section remains at elevated pressure. The main area of the chamber is a room about 30 ft (9 m) wide because of the curvature of the walls. In one of the chambers this room contains a fully equipped surgical operating table. In the other chamber, beds for six patients can be accommodated. Beyond the main section there is a small lavatory and another small lock through which attending personnel can enter or leave quickly during an operation. There is also an instrument lock through which small equipment and supplies can be passed.

In a nearby room outside the chambers air compressors and air conditioning equipment are located. From a central console the operator can monitor all that is happening in each of the chamber areas and can activate any of the mechanical equipment by remote control.

Proper conditioning of the air under a wide variety of operating pressures is necessary for the comfort and safety of the people in the chamber. When air is compressed, that part of the total pressure represented by each component increases to the same extent (Dalton's law). For example, on a comfortable day relative humidity is about 50–75%. This means that the water vapor is 50–75% of the saturation pressure. If this air is compressed to three times its normal pressure, the pressure of each component including the water vapor will be increased threefold. On the other hand, the water vapor saturation pressure will remain constant as long as the temperature remains the same. Therefore, the humidity will rise to 150–225% which means that some of the water vapor must condense as fog or even rain. Without any special provision to remove moisture the hyperbaric chamber



Hyperbaric oxygen treatment facility.

would always be foggy and damp, and the atmosphere would have a very unpleasant effect on the senses. To keep the atmosphere clean and comfortable, the air in the chamber is changed completely every 20 min. The fresh air is dried and cooled after being compressed.

Providing normal facilities in a hyperbaric chamber presents novel problems. For example, normal water pressure may not be sufficient to make the water flow out of a faucet into the high-pressure environment in the chamber. Booster pumps raise the pressure enough to ensure normal flow. Draining wastewater out of the chamber under 3 atm (300 kilopascals) pressure could have rather spectacular results if the drain lines led directly to the sewers. Special waste-receiving tanks are provided which permit the high pressure to bleed off before releasing the wastewater to the normal drainage system.

Changes in pressure must take place rather gradually for the comfort and safety of the people in the chamber. The ear-popping problems that commonly occur in express elevators and airplanes are considerably magnified because the total change in pressure is considerably greater. Normally a period of 5–10 min is required to pressure up or down.

A special problem exists for the attending personnel who breathe the compressed air. This is the well-recognized problem of the elimination of dissolved nitrogen from the body. For working periods in the chamber up to about 1 h no problem is involved, because nitrogen dissolves slowly. However, for periods of more than 1 h enough nitrogen will accumulate to cause formation of gas bubbles in the bloodstream if decompression takes place too fast. These gas bubbles cause the condition known as caisson disease, or the bends. Tables governing the safe decompression schedules for various working times and pressures have been prepared by the U.S. Navy.

For example, if a surgical team conducts an open- heart operation lasting 3 h in a hyperbaric chamber at three times normal pressure, the Navy tables indicate that decompression should include a 19-min hold at $1^2/_3$ times normal pressure and another hold of 79 min at $1^1/_3$ times normal pressure. Altogether this means that decompression requires almost 2 h after a 3-h working period. This would not be required for the patient, since the pure oxygen administered during the surgery does not present any hazard. *See* DECOMPRESSION ILLNESS.

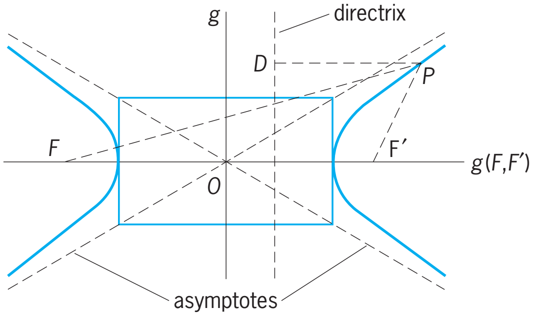
Because of the potentially long periods of time which may be required to decompress, the people in the chamber are relatively isolated from the outside world. They are highly dependent on the chamber operator, who remains at the control console continually as long as any person is in the chamber. Communication is maintained by closed-circuit television with the main section and each of the personnel locks. The operator continually observes the pressure, temperature, and gas composition in the chamber.

While loss of electric power would not of itself be dangerous, the chamber would soon become rather uncomfortable without the constant flow of fresh air, and it would soon become necessary to decompress and leave the chamber. This could mean stopping an operation before completion, which could pose serious problems. Emergency power supplies are therefore provided, and clean dry air is stored in high-pressure cylinders so that no interruption disrupts the work of the physicians. During the great power failure that blacked out the Northeast on November 9–10, 1965, the hyperbaric facility at Mount Sinai Hospital in New York City was an island of light in otherwise complete darkness.

History. Physicians have long been interested in the medical applications of elevated pressures. Orval Cunningham observed beneficial results from such conditions when treating influenza victims during World War I. However, treatment with oxygen at atmospheric pressure produced the same benefits with much less difficulty. It was not until the 1950s that the combination of elevated pressure and pure oxygen was suggested, especially for open-heart surgery. In 1965 a large chamber was built at the University of Amsterdam in the Netherlands. Since that time facilities have been constructed at a number of medical schools and large hospitals in the United Kingdom, Canada, and the United States. *See* OXYGEN; RESPIRATION. [A.W.F.]

Hyperbola

Hyperbola A curve cut from a cone or revolution by a plane that intersects both nappes of the cone and does not contain the apex. In analytic geometry it is shown (see illustration) that a hyperbola is the locus of points P in a plane, such that $PF = \epsilon \cdot PD$, where PF and PD denote the distances of P from a fixed point F (focus) and a fixed line (directrix) of the plane, respectively, and ϵ is a constant, greater than 1. A hyperbola is also the locus of points P, the difference of whose distances from two fixed points F,F' (foci), $PF - PF'$, is a constant $2a$ that is less than the distance $2c$ between the foci. The curve is symmetric to the line $g(F,F')$ determined by F,F' and to O, their midpoint. It consists of two branches that are images of each other in the line g through O, perpendicular to $g(F,F')$. There are two lines through O, making equal angles with $g(F,F')$, and to each of which points on each branch get indefinitely close; that is, if point P traverses either branch of the hyperbola, its distance from these lines approaches zero. These lines are called asymptotes of the hyperbola. *See* ANALYTIC GEOMETRY; CONIC SECTION. [L.M.Bl.]



Hyperbola as a locus of points.

Hyperbolic function

Hyperbolic function The hyperbolic sine and cosine of a real or complex variable z are defined by Eqs. (1). Both sinh z and cosh z have a period $2\pi i$ of e^z. From $De^z = de^z/dz = e^z$, Eqs. (2) are obtained.

$$\sinh z = \frac{e^z - e^{-z}}{z} \qquad \cosh z = \frac{e^z + e^{-z}}{z} \tag{1}$$

$$D \sinh z = \cosh z \qquad D \cosh z = \sinh z \tag{2}$$

Since

$$e^z = \sum_{n=0}^{\infty} z^n/n!$$

by definition, Eqs. (3) hold and the series converge for all z and yield relations (4). Thus relations between the circular functions

$$\sinh z = \sum_{n=0}^{\infty} \frac{z^{2n+1}}{(2n+1)!} \qquad \cosh z = \sum_{n=0}^{\infty} \frac{z^{2n}}{(2n)!} \tag{3}$$

$$\begin{array}{ll} \sinh iz = i \sin z & \cosh iz = \cos z \\ \sin iz = i \sinh z & \cos iz = \cosh z \end{array} \tag{4}$$

become hyperbolic (and vice versa) when z is replaced by iz.

The hyperbolic tangent and cotangent are defined by Eqs. (5).

$$\tanh z = \frac{\sinh z}{\cosh z} \qquad \coth z = \frac{\cosh z}{\sinh z} \tag{5}$$

They have the period πi and have simple poles at the zeros of cosh z and sinh z, respectively. Moreover Eqs. (6) hold true.

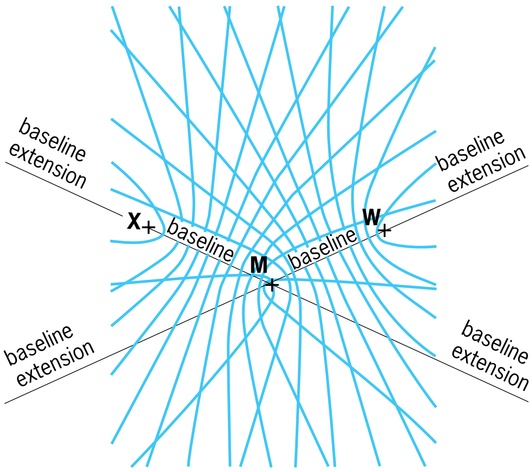
$$D \tanh z = \frac{1}{\cosh^2 z} \qquad D \coth z = -\frac{1}{\sinh^2 z} \tag{6}$$

By definition Eqs. (7) hold.

$$\operatorname{sech} z = \frac{1}{\cosh z} \qquad \operatorname{csch} z = \frac{1}{\sinh z} \tag{7}$$

See Hyperbola; Trigonometry. [L.Br.]

Hyperbolic navigation system A navigation system that produces hyperbolic lines of position (LOPs) through the measurement of the difference in times of reception (or phase difference) of radio signals from two or more synchronized transmitters at fixed points. Such systems require the use of a receiver which measures the time difference (or phase difference) between arriving radio signals. Assuming the velocity of signal propagation is relatively constant across a given coverage area, the difference in the times of arrival (or phase) is constant on a hyperbola having the two transmitting stations as foci (see illustration). Therefore, the receiver measuring time or phase difference between arriving signals must be located somewhere along the hyperbolic line of position corresponding to that time or phase difference. If a third transmitting station is available, the receiver can measure a second time or phase difference and obtain another hyperbolic line of position. The intersection of the lines of position provides a navigational fix (see illustration). User receivers typically convert this navigational fix to latitude and longitude for operator convenience.



Typical grid of hyperbolic lines of position formed by a master (M) and two secondary stations (W and X).

The choice of frequency and locations of transmitters determines both the utility and the accuracy of hyperbolic navigation systems. In general, longer baselines (see illustration) enhance accuracy; however, transmitter power limitations may constrain a system to shorter baselines in order to maintain accurate synchronism. [B.B.P.; R.J.Ha.]

Hypercharge A quantized attribute, analogous to electric charge, introduced in the classification of a subset of elementary particles—the so-called baryons—including the proton and neutron as its lightest members. As far as is known, electric charge is absolutely conserved in all physical processes. Hypercharge was introduced to formalize the observation that certain decay modes of baryons expected to proceed by means of the strong nuclear force simply were not observed. *See* Electric charge.

Unlike electric charge, however, the postulated hypercharge was found not to be conserved absolutely; the weak nuclear interactions do not conserve hypercharge—and indeed can change hypercharge by ±1 or 0 units.

When the known baryons are classified according to their electric charge and their hypercharge, they naturally group into octets in the scheme first proposed by M. Gell-Mann and K. Nishijima. The quarks, hypothesized as the fundamental building blocks of matter, must have fractional hypercharge as well as electrical charge; the simplest quark model suggests values of 1/3 and 2/3, respectively. *See* Baryon; Elementary particle; Quantum mechanics; Quarks; Unitary symmetry. [D.A.B.]

Hyperfine structure A closely spaced structure of the spectrum lines forming a multiplet component in the spectrum of an atom or molecule, or of a liquid or solid. In the emission spectrum for an atom, when a multiplet component is examined at the highest resolution, this component may be seen to be resolved, or split, into a group of spectrum lines which are extremely close together. This hyperfine structure may be due to a nuclear isotope effect, to effects related to nuclear spin, or to both. *See* Isotope shift; Spin (quantum mechanics).

The measurement of a hyperfine structure spectrum for a gaseous atomic or molecular system can lead to information about the nuclear magnetic and quadrupole moments, and about the atomic or molecular electron configuration. Important methods for the measurement of hyperfine structure for gaseous systems may employ an interferometer, or use atomic beams, electron spin resonance, or nuclear spin resonance. *See* Electron paramagnetic resonance (EPR) spectroscopy; Interferometry; Magnetic resonance; Nuclear magnetic resonance (NMR). [L.D.R.]

Hypergeometric functions The analytic continuation of the function defined by the series in Eq. (1), where the shifted factorial $(a)_n$ is defined by Eq. (2). It satisfies differential equation (3), and for $|z| < 1$, Re $c >$ Re $b > 0$, is given by the integral representation of Eq. (4), where Γ represents the gamma function.

$$_2F_1\,(a,b;c;z) = \sum_{n=0}^{\infty} \frac{(a)_n (b)_n}{(c)_n n!} z^n \qquad |z| < 1 \tag{1}$$

$$(a)_n = a(a+1)\cdots(a+n-1) \qquad n = 1, 2, \ldots \qquad (a)_0 = 1 \tag{2}$$

$$z(1-z)y'' + [c - (a+b+1)z]y' - aby = 0 \tag{3}$$

$$_2F_1\,(a,b;c;z) = \frac{\Gamma(c)}{\Gamma(b)\Gamma(c-b)} \int_0^1 (1-zt)^{-a} t^{b-1} (1-t)^{c-b-1} dt \tag{4}$$

See Complex numbers; Gamma function; Series.

The interest in hypergeometric functions comes from the many important functions which are special cases of the general hypergeometric function, the rich theory which has been developed for the general hypergeometric function, and the many times they occur in applications. Classically hypergeometric functions have arisen in science as solutions to differential equations. As discrete, rather than continuous, models of physical phenomena have become increasingly useful, hypergeometric functions have continued to arise as solutions to the equations governing these models. *See* Differential equation. [R.A.]

Hyperiidea A suborder of amphipod crustaceans. Most hyperiids can be recognized by the large eyes which cover nearly the entire surface of the head. The first maxillae and especially the maxillipeds are greatly reduced in comparison to the suborder Gammaridea. In the prehensile pereiopods, the claw is formed by the fifth and sixth segments rather than by the sixth and seventh segments, as in the Gammaridea. The second and third somites of the urosome are always fused, a condition rarely found in the Gammaridea. *See* Amphipoda; Gammaridea.

The Hyperiidea are exclusively pelagic and marine. They are found in all the oceans, from the surface to great depths. Most are characteristic of oceanic rather than neritic waters, although there are some species that frequent inshore waters in the tropics. After the Copepoda and Euphausiacea, the Hyperiidea are the most abundant planktonic crustaceans. Some species are frequently found in association with other animals. Other species are truly free-living. Some hyperiids are luminescent; the whole body glows with a greenish-yellow light. *See* Bioluminescence. [T.E.B.]

Hypermastigida An order of the Protozoa in the class Zoomastigophorea comprising the most complex flagellates, both structurally and in modes of division. All inhabit the alimentary canal of termites, cockroaches, and woodroaches. These organisms are multiflagellate. The nucleus is single and the organisms are plastic and slow-moving, generally ovoid to elongate. Flagella occur in spiral rows, in tufts, or over the enfire body. These flagellates vary from 15 to 350 micrometers in size. *See* Protozoa; Zoomastigophorea. [J.B.L.]

Hypernuclei Nuclei that consist of protons, neutrons, and one or more strange particles such as lambda particles. The lambda particle is the lightest strange baryon (hyperon); its lifetime is 2.6×10^{-10} s. Because strangeness is conserved in strong interactions, the lifetime of the lambda particle remains essentially unchanged in the nucleus also. Lambda hypernuclei live long enough to permit detailed study of their properties. *See* Baryon; Elementary particle; Hyperon; Nuclear structure; Strong nuclear interactions. [B.Po.]

Hyperon A collective name for any baryon with nonzero strangeness number *s*. The name hyperon has generally been limited to particles which are semistable, that is, which have long lifetimes relative to 10^{-22} s and which decay by photon emission or through weaker decay interactions. Hyperonic particles which are unstable (that is, with lifetimes shorter than 10^{-22} s) are commonly referred to as excited hyperons. The known hyperons with spin $^{1}/_{2}\,\hbar$ (where $\hbar$ is Planck's constant divided by 2π) are Λ, Σ^-, Σ^0, and Σ^+ with $s = -1$, and Ξ^- and Ξ^0, with $s = -2$, together with the Ω^- particle, which has spin $^{3}/_{2}\,\hbar$ and $s = -3$. The corresponding antihyperons have baryon number $B = -1$, opposite strangenesse *s*, and charge *Q*; they are all known empirically.

There is no deep distinction between hyperons and excited hyperons, beyond the phenomenological definition above. Indeed, the hyperon $\Omega(1672)^-$ and the excited hyperons $\Xi(1530)$ and $\Sigma(1385)$, together with the unstable nucleonic states $\Delta(1236)$, are known to form a unitary decuplet of states with spin $^{3}/_{2}\,\hbar$. *See* Baryon; Elementary particle; Symmetry laws (physics); Unitary symmetry. [R.H.D.]

Hypersensitivity Heightened reactivity to antigens (molecules capable of stimulating an immune response). Many different examples of hypersensitivity have been recognized in animals and humans. These are often referred to collectively as allergies, and clinically may take such forms as asthma, hives, hay fever, anaphylactic reactions to certain foods or insect venoms, some forms of eczema and kidney diseases, and skin reactions to poison ivy antigens and many other substances. *See* Antigen.

Because molecules foreign to the body are often antigenic, the various forms of hypersensitivity are most commonly induced either by exposure to foreign antigens derived from microorganisms during infections, or by contact with certain noninfectious agents (some plant pollens, some drugs, and certain simple chemicals such as components of poison ivy). However, under certain circumstances, molecules of the body itself can induce an immune response. In these cases, hypersensitivity reactions can be directed against antigens of the body's own organs or tissues. Whether foreign or derived from the body itself, antigenic substances often produce little or no tissue reaction in unsensitized individuals. But once hypersensitivity develops, additional exposure to antigen can give rise to clinically obvious symptoms (hives, sneezing, runny nose), tissue damage, or even (in certain extreme cases) death. *See* Autoimmunity.

The development of hypersensitivity in animals or humans may be divided into two phases. During the first phase, induction of hypersensitivity, exposure of the organism to antigen results in (1) recognition of the antigen by cells of the immune system; (2) proliferation (multiplication) of the types of immune cells that recognize and respond to that antigen; and (3) long-term storage of the information required to recognize and respond to the antigen in immune "memory" cells. Although a variety of cell types assist in these processes, all of the three functions are primarily dependent on various types of lymphocytes.

Once the state of hypersensitivity has been induced, reexposure of the organism to the antigen that induced the response usually leads to the second phase, expression of a hypersensitivity reaction. Hypersensitivity reactions historically have been classified according to two characteristics: the delay between the exposure of a previously sensitized (hypersensitive) individual to antigen and the development of a clinically recognizable reaction; and the types of cells and humoral substances thought to be responsible for the induction and expression of the reaction. According to this scheme, classical delayed hypersensitivity reactions differ from other forms of hypersensitivity in first becoming clinically prominent in sensitized individuals approximately 1 day after exposure to the specific antigen against which the individual expresses hypersensitivity; and depending for their expression on the activity of certain lymphocytes (thymic-dependent lymphocytes, or T cells) rather than soluble antibodies. By contrast, immediate hypersensitivity reactions may develop within seconds or minutes of exposure to specific antigen, and require the participation of antibodies. *See* Antibody.

In addition to its association with certain infections, delayed hypersensitivity has been implicated in a variety of noninfectious disease processes. These include the annoying reactions induced in some individuals by contact with certain plants (for example, poison ivy), detergents, or drugs, as well as certain of the immune responses resulting in the rejection of transplanted tissues such as skin, kidneys, and hearts. In many of these processes, the immunological reactions are thought largely to reflect the activity of T lymphocytes (as in classical delayed hypersensitivity), whereas in others soluble antibodies may also have a role. *See* Cellular immunology; Transplantation biology. [S.J.Ga.]

Immediate hypersensitivity reactions, collectively known as allergies, occur usually within minutes or up to a few hours after inhalation, ingestion, or injection of an antigen. Such reactions may be severe, even life-threatening, such as anaphylactic shock and asthma, or relatively minor but uncomfortable, such as hay fever or urticaria (hives). They may be of short duration—hours for anaphylaxis—or prolonged for several days or even weeks, as in immune complex-induced vasculitis. *See* Allergy.

Hypersensitivities have been classified into four main types with different mechanisms: type I, anaphylaxis or atopy; type II, cytotoxic or cytolytic; type III, immune complex or Arthus reaction; and type IV, delayed or cellular-immune; the last type has been described above.

In type I the antigen is recognized immunologically upon first exposure and initiates antibody formation, usually of immunoglobulin E (IgE) or IgG class. IgE-mediated allergy, known as atopy, has a strong hereditary component, and occurs commonly in humans and dogs, while IgG-mediated anaphylaxis can occur in most vertebrates. The antibodies (IgE or IgG) attach or fix to target cells, such as tissue mast cells and blood basophils. Upon subsequent exposure to the antigen, the target cell–fixed antibodies react with antigen to cause degranulation and release of chemical mediators, such as histamine. *See* Histamine; Immunoglobulin.

In cytotoxic or cytolytic (type II) reactions, the antigen may be certain altered body cells themselves; they may be altered physically or by chemicals and drugs attached to the cells. These are usually circulating cells, such as red blood cells coated with penicillin, platelets coated with a drug, or white blood cells coated with sulfonamides. Altered cells are recognized by the body's immune system as foreign or altered self, and IgG or IgM antibodies are formed which react with the altered cells and activate the serum complement enzymatic cascade that culminates in the lysis of the altered cells. Thus, cytotoxic hypersensitivity leads to anemia, bleeding due to low platelet levels, and increased infections from loss of white blood cells (agranulocytosis).

In immune complex or Arthus (Type III) reaction, neither antibody nor antigen is fixed to cells. Rather, they combine in various ratios in blood and tissues. If they are in the proper ratio, they form microprecipitates, or immune complexes, in capillaries and venules. The immune complexes activate complement to form chemoattractants for neutrophils and monocytes. Microprecipitates and phagocytosing neutrophils block the small vessels, resulting in a typical Arthus reaction—lack of blood to the tissue and subsequent tissue necrosis and death. [O.L.F.]

Hypersonic flight Flight at speeds well above the local velocity of sound. By convention, hypersonic flight starts at about Mach 5 (five times the speed of sound) and extends upward in speed indefinitely. Supersonic vehicles also fly at speeds greater than the local speed of sound. However, when the Mach number is high, the flow field around an object exhibits a special behavior, which is worth studying separately from supersonic flight. This behavior is characteristic of hypersonic flight.

A body entering the Earth's atmosphere from space (for example, a meteorite, a ballistic reentry vehicle, or a spacecraft) has high velocity and hence large kinetic and potential energy. During reentry, drag forces act upon a reentry vehicle or spacecraft and cause it to decelerate, thus dissipating its kinetic and potential energy. The energy lost by the reentry vehicle is then transferred to the air within the flow field around the reentry vehicle. The flow field around the forward portion of a blunt-nosed vehicle (body of revolution or leading edge of a wing) generally exhibits (1) a distinct bow shock wave, (2) a shock layer of highly compressed hot gas, and (3) a highly sheared boundary layer over the surface. The flow field is defined as the region of disturbed air between the body surface and the shock wave. The temperature of the shock layer is so high that molecules begin to dissociate during collisions at about 4000°F (2500 K), or at Mach 7. At about Mach 12, gas in the stagnation region reaches a temperature of 6700°F (4000 K) and becomes ionized.

In general, at high hypersonic flight speed the characteristic temperature in the shock layer of a blunted body and in the boundary layer of a slender body is proportional to the square of the Mach number. Heat energy is then transferred from the hot gases to the vehicle surface by conduction and diffusion of chemical species in the boundary layer and by radiation from the shock layer near the nose. Heat energy is also radiated from the vehicle surface to space or to adjacent objects. One important problem confronting the designer of reentry vehicles or spacecraft is therefore to design a minimum-weight vehicle able to withstand large heat loads from adjacent hot-gas layers during reentry while retaining the ability to carry a given useful payload. *See* ATMOSPHERIC ENTRY. [S.-Y.C.]

Hypertension High blood pressure. Blood pressure is expressed in two numbers: the higher number is the systolic blood pressure, which is the pressure exerted by the blood against the walls of the blood vessels while the heart is contracting. The lower number is the diastolic blood pressure, which is the residual pressure that exists between heart contractions, or while the heart is relaxing. Normal blood pressure provides sufficient blood flow to the vital organs, including the brain, heart, kidneys, intestine, and skeletal muscle.

It is not entirely accurate to think of high blood pressure as a distinct disease; high blood pressure appears to be both a disease and a risk factor for other diseases. At the highest end of the blood pressure distribution, there is an increased probability of premature death secondary to stroke, heart disease, or kidney failure. Lower on the distribution curve (for example, diastolic blood pressure of 90–104 mmHg, which is referred to as mild hypertension), the absolute risk of premature mortality is lower and continues to decline with further decreases in blood pressure. High blood pressure is thus a disease when its value is very high and a risk factor throughout its distribution. For diagnostic purposes, blood pressure is considered high when persistently above 140/90 mmHg.

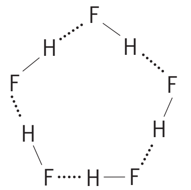
Some cases of very high blood pressure are due to specific causes that may be surgically remediable. Most hypertension, however, results from the combination of a genetic predisposition and an environmental factor such as excessive sodium intake, sedentary habits, and stress.

High blood pressure can be controlled. Mild cases are treated by losing excess weight and reducing the intake of sodium and alcohol. More serious cases are treated with drugs such as diuretics, beta blockers, calcium antagonists, angiotensin-converting enzyme inhibitors, alpha blockers, and centrally acting compounds that affect regulatory centers in the brain. Treatment can usually assure a normal life. *See* HEART DISORDERS. [M.Ho.]

Hypervalent compounds Group 1, 2, and 13–18 compounds which contain a number (*N*) of formally assignable electrons of more than eight (octet) in a valence shell directly associated with the central atom (X) in direct bonding with a number of ligands (*L*). The designation *N*-X-*L* is conveniently used to describe hypervalent molecules. *See* ELECTRON CONFIGURATION; LIGAND; VALENCE.

In the periodic table, compounds of main group elements in the second row (such as carbon, nitrogen, and oxygen) have eight valence electrons. As such, the fundamental shapes of their atoms are linear (such as acetylene, sp orbital), triangular, (such as ethylene, sp^2 orbital), and tetrahedral (such as methane, sp^3 orbital). In contrast, main group elements in the third row of the periodic table (such as silicon, phosphorus, and sulfur) may contain more than eight electrons in a valence shell. These are called hypervalent compounds. Fundamental shapes of *10*-X-*5* molecules (including *10*-X-*4* molecules bearing a pair of unshared electrons) are trigonal bipyramid (TBP) or square pyramid (SP), and those of *12*-X-*6* (including *12*-X-*5* bearing a pair of unshared electrons) are octahedral. Hence, there is an apparent similarity in shape between hypervalent compounds and organotransition metal compounds. *See* MOLECULAR ORBITAL THEORY.

The hydrogen bond is one of the best examples of a hypervalent bond. The covalent nature of the hydrogen bond of the [N—H···N] system has recently been established experimentally and theoretically. The structure of $(HF)_5$, shown below, is pentagonal, with a bond length for F—H of 1 Å and H···F of 1.5 Å. The hydrogen atom shifts rapidly between the two fluorines in the range of 0.5 Å. However, $[F—H—F]^-K^+$, (*4*-H-*2*), is linear, and the two F—H bond lengths are equal to 1.13 Å, which is typical for a hypervalent bond. *See* CHEMICAL BONDING.



In order to accept extra electrons in a valence shell, an electron-rich and polarized sigma bond contains an apical bond (three-center, four-electron bond, which is defined as a hypervalent bond by molecular orbital theory) on the central atom. One of the most unstable hypervalent molecules is $[F{-}F{-}F]^-Li^+$, (*10-F-2*). It is linear and the F—F bond is calculated to be 1.701 Å, which is elongated from that of F—F (1.412 Å) by accepting a fluoride ion. This is essentially the same as that of $[F{-}H{-}F]^-Li^+$, (*4-F-2*). [K.Ak.]

Hyphochytriomycetes A class of the subdivision Mastigomycotina; a taxonomically small group of about 20 species of fungallike organisms characterized by the presence of a uniflagellate zoospore in the life cycle. In contrast to the Chytridiomycetes, the flagellum is anteriorly directed, with two rows of tripartite hairs. From similarities in ultrastructure and cellular chemistry, and from molecular analysis, it has been determined that hyphochytrids are related to the biflagellated Oomycetes and heterokont algae, and they have been classified within the Kingdom Protista, Kingdom Chromista, Kingdom Protoctista, and most recently Kingdom Stramenopila.

Two species, *Rhizidiomyces apophysatus* and *Hyphochytrium catenoides*, are widely distributed, possibly cosmopolitan, and occur as saprobes in soil and water. *Rhizidiomyces apophysatus* has a unicellular thallus comprising a single zoosporangium with delicate rhizoids for anchorage and the absorption of nutrients. *Hyphochytrium catenoides* is filamentous with numerous intercalary hyphal swellings; under favorable conditions these swellings develop into zoosporangia. Sexual reproduction is unknown in these species and has not been well documented in the class. All species parallel the Chytridiomycetes in morphology and distribution, and they cannot be distinguished except by the position and morphology of the flagellum, the zoospore ultrastructure, and nucleic acid sequence. *See* EUMYCOTA; FUNGI. [D.J.S.B.]

Hyphomycetes A class of mitosporic or anamorphic (asexual or imperfect) fungi belonging to the Deuteromycotina. They lack locular fruit bodies (conidiomata), and so sporulation occurs on separate or aggregated hyphae, which may or may not be differentiated; the thallus consists of septate hyphae. About 1400 genera comprising more than 11,500 species are recognized.

The Hyphomycetes, like other groups of Deuteromycetes, is an artificial one composed almost entirely of anamorphic fungi of ascomycete affinity. The majority are known anamorphs of Ascomycetes, although some have basidiomycete affinities. Several of the latter are aquatic or aero-aquatic. Taxa are referred to as form genera and form species, because the absence of a sexual or perfect teleomorph state forces classification and identification by artificial rather than phylogenetic means. The unifying feature of the group is the production of conidia from superficial, exposed conidiogenous cells arising separately from vegetative hyphae or cells (mononematous), or incorporated on conidiophores that may be entirely separate or aggregated in cushion-like sporodochia or stalk-like synnemata. Differences in insertion and arrangement of conidiogenous cells and conidiophores traditionally have been used to separate three orders. In the Hyphomycetales they are solitary or at most fasciculate and tufted; in the Tuberculariales they are produced over the outer surface of a cushion-shaped-to-flattened conidioma (sporodochium), and in the Stilbellales they are united into a stipitate conidioma (synnema). An alternative means of classifying hyphomycetes is based on differences in the ways that conidia are produced and conidiogenous cells grow before, during, and after conidiogenesis. *See* ASCOMYCOTA; BASIDIOMYCOTA; COELOMYCETES.

To the naked eye, hyphomycete colonies are conspicuous as black, brown, green, gray, and white growths on substrata. In size, hyphomycete conidia vary from the minute to extremely long or wide. Shapes vary markedly within and between genera. Many hyphomycetes produce conidia in mucilaginous matrices. As in the Coelomycetes, the matrix inhibits or retards germination until the conidia become dispersed, and maintains germinability during periods of environmental stress. Other genera produce conidia in powdery masses, such hydrophobic conidia being more suited for air dispersal. Sterile elements in the form of simple or branched setae are commonly present among conidiophores or on conidiomata, and since they are particularly common among leaf-litter fungi they are thought to function as a form of predator defense.

The Hyphomycetes draw nourishment from living or dead organic matter and are adapted to grow, reproduce, and survive in a wide range of ecological situations. They can also be either stress-tolerant or combative. Some species grow among rubbish, and because their thin-walled, hyaline vegetative and reproductive structures make them more prone to attack and decay, they are ephemeral. Their ability to colonize, decompose, and use substrates and to interact with or parasitize other organisms is a result of the enzymes, antibiotics, toxins, and other metabolites they produce, coupled with wide genetic diversity. They are extremely common in soils of all types and on leaf litter and other organic debris of both natural and manufactured origin. They also cause extensive problems in food spoilage and occur in saline, stagnant, and fresh water.

Some hyphomycetes are found on or associated with fungi, including pathogens such as *Verticillium*, *Mycogone*, and *Cladobotryum*, and on lichens. Several are of medical importance, being associated with superficial, cutaneous, subcutaneous, and systemic infections. They are often opportunistic organisms that cause infections in immunocompromised patients. Toxic metabolites, or mycotoxins, are formed by many hyphomycetes, notably *Aspergillus*, *Fusarium*, and *Penicillium*. Others are nematophagous, capturing or consuming nematodes and other microfauna. *Beauveria*, *Metarhizium*, *Hirsutella*, and *Entomophthora*, for example, have been exploited for insect control. Many also cause economically important diseases in all types of vascular plants, especially agricultural and forestry crops. Hyphomycetes are primary pathogens of plants and weeds, causing root, stem, and leaf necrosis; diebacks; cankers; wilts; and blights. By infesting or contaminating seed, they can transmit seed-borne defects or reduce seed viability. *See* MEDICAL MYCOLOGY; MYCOTOXIN; PLANT PATHOLOGY.

Hyphomycetes produce a wide variety of primary and secondary metabolites and are capable of effecting many different chemical and biochemical changes. By harnessing that capability in industrial processes, organic acids, enzymes, antibiotics, growth substances, alcohol, and cheese, among others, can be produced and steroid transformation can take place. *See* DEUTEROMYCOTINA; FUNGI. [B.C.S.]

Hypnales An order of the true mosses (subclass Bryidae). Also known as the Hypnobryales, this order consists of 14 families and some 135 genera, primarily put together because they share a hypnoid peristome. The families show considerable sporophytic unity; it is gametophyte structure that determines family membership.

Hypnales are often known as feather mosses owing to their freely branched stems, with branches regularly or irregularly arranged in two rows. The plants form mats, especially in woodlands. The leaves are most commonly acute or acuminate, and the costa is generally short and double or nearly lacking. The sporophytes are lateral with elongate, smooth setae, and the capsules are generally inclined and asymmetric with well-developed double peristomes. *See* BRYIDAE; BRYOPHYTA; BRYOPSIDA. [H.Cr.]

Hypnosis A presumed altered state of consciousness in which the hypnotized individual is usually more susceptible to suggestion than in his or her normal state. In this context, a suggestion is understood to be an idea or a communication carrying an idea that elicits a covert or overt response not mediated by the higher critical faculties (that is, the volitional apparatus).

Hypnosis cannot be physiologically distinguished from the normal awake state of an individual, and for this reason its existence has been questioned by some investigators. There are few phenomena observed in association with hypnosis, if any, that are specific to the hypnotic state. Most are directly or indirectly produced by suggestions. Through suggestions given to hypnotized individuals, it is possible to induce alterations in memory, perception, sensation, emotions, feelings, attitudes, beliefs, and muscular state. Such changes can be, and usually are, incorporated into the complex behavior of the individual, resulting in amnesias and paramnesias, fuguelike conditions, paralysis, loss of sensory functions, changes in attention, personality alterations, hallucinatory and delusional behavior, and even physiological changes. Enhanced recall is sometimes possible. Although sometimes remarkable, the effects produced through hypnosis with the majority of individuals are much less spectacular than popularly believed. [A.M.W.]

Hypodermis The outermost cell layer of the cortex, also called the exodermis, of plants. It forms a prominent layer immediately under the epidermis in many but not all plants. Like the endodermis, it develops Casparian strips, suberin deposits, and cellulose deposits impregnated with phenolic or quinoidal substances. The hypodermis may produce substances that act as a barrier to the entry of pathogens, and in some plants it may function in the absorption of water and the selection of ions that enter the plant. *See* CORTEX (PLANT); ENDODERMIS. [D.S.V.F.]

Hypohalous acid An oxyacid of a halogen [fluorine (F), chlorine (Cl), bromine (Br), iodine (I), or astatine (At)] possessing the general chemical formula HOX, where X is the halogen atom. The chemical behavior of hypofluorous acid (HOF) is dramatically different from the heavier hypohalous acids which, as a group, exhibit similar properties. These differences are attributed primarily to the high electronegativity and small size of the fluorine atom, which cause HOF to be an extremely strong oxidant with an anomalously weak O-F bond. Thus, the molecule is highly reactive and relatively unstable. (Gaseous HOF decomposes to HF and O_2 at room temperature with a half-life of about 1 h, and the liquid has a tendency to explode.) Because the most electronegative element in HOF is fluorine, whereas the other halogen atoms are less electronegative than oxygen, the O-X bond polarities are reversed in HOF and the heavier congeners. HOF therefore acts primarily as an oxygenating and hydroxylating agent, whereas the other hypohalous acids are electrophilic halogenating agents. For example, HOF hydroxylates aromatic compounds to form phenols and reacts instantaneously with water to give hydrogen peroxide (H_2O_2), whereas hypochlorous acid (HOCl) chlorinates aromatic compounds and is unreactive toward water. *See* ASTATINE; HALOGEN ELEMENTS.

Hypochlorous, hypobromous, and hypoiodous acid solutions are formed by disproportionation of the corresponding halogen, as in the reaction below.

$$X_2 + H_2O \rightleftharpoons H^+ + X^- + HOX$$

Hypohalous acids are weak acids, that is, $HOX \rightleftharpoons H^+ + OX^-$ acids whose dissociation constants increase in the order HOI < HOBr < HOCl. The decomposition mechanisms are complex with rates that vary widely, increasing in the order $X = Cl^- < Br^- < I^-$. Hypochlorite solutions (for example, commercial bleach) are stable at room temperature and below for months but decompose at elevated temperatures; hypobromite solutions are stable only at reduced temperatures; and hypoiodite generally decays within minutes of its formation.

HOCl and HOBr and their anions are powerful oxidants that react rapidly with a wide range of organic and inorganic reductants. In addition, both acids halogenate aromatic compounds and form halohydrins with unsaturated organic compounds, and N-chloro compound with nitrogen bases. In general, HOCl reacts much more rapidly than OCl^-.

HOCl and HOBr are potent cytotoxins. Hypochlorite was first used as a disinfectant around the beginning of the nineteenth century, and has subsequently been widely applied to problems in public sanitation. Recent studies with bacteria indicate that death is accompanied by disruption of metabolic functions associated with the plasma membrane, including inactivation of the adenosine triphosphate synthase and proteins involved with active transport of metabolites, and (in aerobes) inhibition of respiration. This pattern of reactivity suggests that toxicity arises from disruption of the energy-transducing capabilities of the cell. [J.K.Hu.]

Hypothermia A condition in which the internal temperature of the (human) body is at least 3.6°F (2.0°C) below an internal temperature of 98.6°F (37°C). Hypothermia represents a continuum of effects that vary with the severity of cold on physiological systems. The human body needs a specific internal temperature that is regulated on a minute-by-minute basis to maintain all normal body functions. The many physiological and behavioral processes involved in maintaining the internal temperature constant are called thermoregulation. *See* THERMOREGULATION.

Various environmental situations predispose humans to hypothermia, which can occur even in the absence of cold. In fact, hypothermia is more common in temperate regions than in the colder climates. Because of the uniqueness of the situations in which hypothermia can occur, various kinds of hypothermia have been classified, all of which can prove fatal.

Primary hypothermia. Primary hypothermia is a decrease in internal temperature that is caused by environmental factors in which the body's physiological processes are normal but thermoregulation capability is overwhelmed by environmental stress.

Air (formerly exposure) hypothermia is thought to be the most common form. A person exposed to cold air experiences the same processes as a person in cold water, but air hypothermia occurs more slowly. The induction of air hypothermia is more subtle and therefore more dangerous since it can occur over a number of weeks. The degree to which a person reacts to a cold air stress is dependent on such factors as age, physical stamina, the intensity of the cold stress, and the responsiveness of the thermoregulatory system. One of the most convenient ways to determine whether someone is suffering from hypothermia is a noted change in personality: Complaints of fatigue, sluggish speech, and confusion are common, and in some cases the behavior resembles that of intoxication.

Initially, skin temperature falls rapidly, blood vessels to the skin constrict, and shivering begins. After 5–10 min, shivering ceases for about 10–15 min, but this is followed by uncontrollable shivering. In a cold situation, the nervous system causes blood to be redistributed away from the skin as the blood vessels of the skin close down to minimize heat transfer to the cold environment. The decrease in skin temperature coupled with vasoconstriction makes the person feel cold, and sometimes the fingers and toes can become painful. Internally, there is an increase in the levels of hormones that control metabolism, and blood is shunted primarily to the lungs, heart, and brain. The person becomes dehydrated as the inspired air is warmed and humidified. If the tense and shivering muscles do not generate enough heat, the hypothermic process begins and progresses for at least 3–5 h. As hypothermia continues, the arms become rigid, and the person loses the ability to make fine movements. During this period of time the heart rate initially increases, then stabilizes and as the person's internal temperature becomes progressively colder, the heart rate and respiration slow. In severely hypothermic persons, it is very difficult to detect a slow heart rate or determine if the person is breathing. A temperature of 95°F (35°C) is only the beginning of mild hypothermia and shivering can continue for hours, depending on the muscle and fat supplies available. Eventually, the environment becomes overwhelming. At 86°F

(30°C), the person loses consciousness and shivering ceases. Death does not occur until the internal temperature drops further: Death results at 68–77°F (20–35°C) because of cardiac standstill.

When a person falls into cold water, a gasping response is triggered by the thermal receptors on the skin. For some individuals, the cold stress may trigger a heart attack. Although as much of the body as possible should be kept out of the water, many victims of immersion hypothermia stay in the cold water because they cannot tell how cold they are. Shivering becomes generalized and, unlike its effect in cold air, may cause a faster drop in internal temperature since the water layer closest to the body is stirred and convective heat loss is promoted. Although the greater conductive property of water relative to air is a major heat sink, physiological and behavioral responses act to minimize the heat loss. Survival in 50°F (10°C) water is possible for several hours at most if the person is dressed in street clothes and a life jacket.

The cooling of the body in submersion hypothermia allows the brain and heart to withstand approximately 45 min of oxygen debt. This is most operative for young children. A child can survive for an extended period of time while completely submerged because the body is undergoing both internal and external cooling. As the child is drowning, cold water is swallowed and enters the lungs, which cools the core. At the same time, the cold water that bathes the skin rapidly cools the periphery. The multiple effects of the internal and external cooling decrease the metabolic rate and give the child a window of safety of approximately 45 min. In warm water, survival is possible for only 5–7 min.

Secondary hypothermia. A decrease in core temperature caused by an underlying pathology that prevents the body from generating enough core heat is referred to as secondary hypothermia. If any of the thermoregulatory systems are altered, the body's ability to generate heat decreases and hypothermia can then develop without warning. Insufficient muscle mass to generate heat, medications that interfere with metabolism, an underlying systemic infection, decreased thyroid hormone production, and paralysis predispose to hypothermia. Premature infants with low body fat and a large surface-to-volume ratio lose heat rapidly and are at risk for becoming hypothermic. The elderly are perhaps the most susceptible to secondary hypothermia. However, whether the process of aging with no associated debility also alters the thermoregulatory system in the elderly remains to be determined.

Clinical hypothermia. Some cardiac surgical procedures require clinically induced cooling to stop the heart from beating. Induced hypothermia lowers the oxygen demand of the body tissues, so that oxygenated blood need not circulate. In the case of coronary bypass surgery, the entire body is cooled, enabling the surgeons to work for an extended period of time on the cold heart.

Frostbite. In hypothermia, the body's internal temperature decreases, but no solid freezing takes place. In frostbite, which is freezing of the digits or the limbs, there is actual formation of ice crystals. Basically the digits go through various stages of cooling. Initially, in the prefreeze phase, the finger temperature is 37.4–50°F (3–10°C). Next, at 24.8°F (−4°C) ice crystals form outside the cells of the digits, circulation is limited, and cell death takes place if the process is allowed to continue. The cells of the digits and limbs can tolerate low temperatures that would be lethal to brain or nerve cells. However, once they are rewarmed and thawed, they develop an increased sensitivity to the cold and become more susceptible to frostbite. Any part of the body can become frostbitten, but the fingers, toes, ears, nose, and cheeks are most often affected. *See* HOMEOSTASIS.

[R.W.Po.; L.E.W.; J.Ho.]

Hypothesis

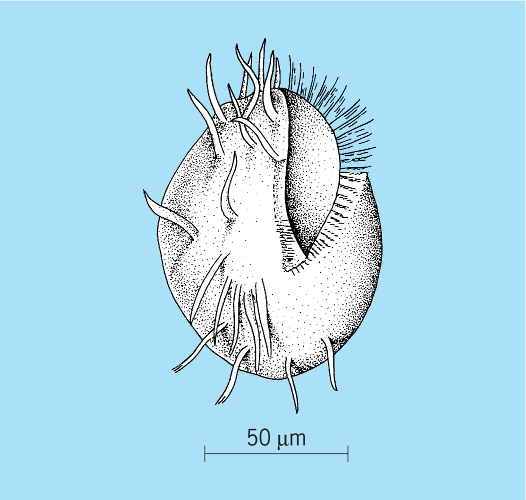
A tentative supposition with regard to an unknown state of affairs, the truth of which is thereupon subject to investigation by any available method, either by logical deduction of consequences which may be checked against what is known, or by direct experimental investigation or discovery of facts not hitherto known and suggested by the hypothesis.

[P.W.Br./H.Ma.]

Hypotrichida

An order of Spirotrichia. These protozoans are commonly considered to represent the pinnacle of specialized development in the evolution of ciliates. Somatic ciliature of the ventral surface has been replaced by cirri; on the dorsal surface it is absent or represented by inconspicuous sensory bristles (see illustration). The adoral zone of membranelles is very prominently developed, and the buccal area may occupy a large part of the ventral surface of the body. The whole body is generally rigid. Hypotrichs occur ubiquitously in fresh- and saltwater habitats. *See* SPIROTRICHIA.

[J.O.C.]



***Euplotes*, an example of a hypotrich.**

Hypoxia

The failure of oxygen to gain access to, or to be utilized by, the body. Although the term anoxia is commonly used, a more precise term, hypoxia, is more often applicable because there is seldom a complete oxygen defect.

Oxygen deprivation may result from interference with some stage of the inspiration, lung diffusion, blood transport, cellular absorption, and final utilization by enzyme systems. A defect at any one or more of these major stages quite often induces a decreased ability of other related mechanisms to survive. This is seen most dramatically in any form of hypoxia in which the brain is deprived of the necessary oxygen for more than a few minutes. Nerve cell degeneration begins quickly, and although the original cause of hypoxia is removed, damage to the respiratory centers prevents resumption of breathing. *See* RESPIRATORY SYSTEM.

The term anoxia is used by many authorities to indicate an oxygen deficiency at the tissue level, and failure of cellular respiration may be designated histotoxic anoxia. There are other terms employed to differentiate the type of oxygen deficiency or the stage in the total respiratory process where defects occur.

[E.G.St./N.K.M.]

Hyracoidea

An order of mammals closely related to elephants. Hyracoids were a diverse and successful group of mammals in Africa during the Eocene and Oligocene epochs (early part of the Age of Mammals, 55 to 34 million years ago), and they are still represented by a few living species. The early hyracoids ranged from animals as small as rabbits to ones as large as modern Sumatran rhinoceroses. The fossil skeletons of the early hyracoids indicate that some species were active runners and leapers, while others were heavy, piglike quadrupeds. Their teeth suggest herbivorous diets, ranging from fibrous leaves in some species to pulpy fruits and roots in others. Hyracoids originated in Africa but later extended their range into Europe and Asia, eventually attaining a distribution encompassed by China, Spain, and South Africa. In contrast to the early diversity of the order, the only living species are a few small-bodied animals (1.5–5.5 kg or 3.3–12 lb) that inhabit forests, scrubby brushlands, and rocky deserts in Africa and the Middle East. Hyracoidea represents a classic case of a spectacular adaptive radiation on an isolated continent, now reduced to a few remnant living taxa. *See* MAMMALIA.

The modern hyracoids, the hyraxes, include about 7 to 12 species classified in three genera, *Procavia*, *Heterohyrax*, and *Dendrohyrax*. All are members of the family Procaviidae. *Gigantohyrax* is a fourth, extinct genus of Procaviidae known from Plio-Pleistocene caves in southern and eastern Africa. All of the remaining fossil hyracoids, representing at least 18 genera, are often classified in a separate, very diverse family, Pliohyracidae, pending better understanding of the phylogenetic relationships among forms.

Morphological and molecular lines of evidence indicate that hyracoids are close relatives of elephants (order Proboscidea) and manatees and dugongs (order Sirenia). Therefore, the orders Hyracoidea, Proboscidea, and Sirenia are best classified together in the superorder Paenungulata. *See* PROBOSCIDEA; SIRENIA. [D.T.Ra.]

Hysteriales (lichenized) An order of the Ascolichenes shared by the Ascomycetes, comprising those species with a so-called ascolocular structure. The hymenium consists of densely interwoven, branched pseudoparaphyses and irregularly scattered locules in which the asci are located.

The growth form of the Hysteriales is either crustose or fruticose. There are five or six families now included here. Arthoniaceae is the largest family, with two genera, *Arthonia* and *Arthothelium*, both widespread on bark, rarely on leaves, in temperate and tropical regions. The Roccellaceae is a family of conspicuous fruticose species that grow profusely on trees and rocks along the coastlines of Portugal, California, Baja California, and parts of western South America. These plants were collected by the ton in the Middle Ages for use as dyestuffs. These same lichens, on a smaller scale, now yield the dye used in litmus paper. [M.E.H.]

Hysteresis A phenomenon wherein two (or more) physical quantities bear a relationship which depends on prior history. More specifically, the response Y takes on different values for an increasing input X than for a decreasing X.

If one cycles X over an appropriate range, the plot of Y versus X gives a closed curve which is referred to as the hysteresis loop. The response Y appears to be lagging the input X.

Hysteresis occurs in many fields of science. Perhaps the primary example is of magnetic materials where the input variable H (magnetic field) and response variable B (magnetic induction) are traditionally chosen. For such a choice of conjugate variables, the area of the hysteresis loop takes on a special significance, namely the conversion of energy per unit volume to heat per cycle. For mechanical hysteresis, it is customary to take the variables stress and strain, where the energy density loss per cycle is related to the internal friction. Thermal hysteresis is characteristic of many systems, particularly those involving phase changes, but here the hysteresis loops are not usually related to energy loss. *See* FERROELECTRICS; STRESS AND STRAIN.

[H.B.H.; R.K.MacC.]

Hysteresis motor A type of synchronous motor in which the rotor consists of a central nonmagnetic core upon which are mounted rings of magnetically hard material. The rings form a thin cylindrical shell of material with a high degree of magnetic hysteresis. The cylindrical stator structure is identical to that of conventional induction or synchronous motors and is fitted with a three-phase or a single-phase winding, with an auxiliary winding and series capacitor for single-phase operation. *See* INDUCTION MOTOR; SYNCHRONOUS MOTOR.

When the motor is running at synchronous speed, the hysteresis material is in a constant state of magnetization and acts as a permanent magnet. Full-speed performance is therefore exactly the same as in a permanent-magnet synchronous motor.

The outstanding special feature of a hysteresis motor is the production of nearly constant, ripple-free torque during starting. Hysteresis motors are widely used in synchronous motor applications where very smooth starting is required, such as in clocks and other timing devices and record-player turntables, where smooth starting torque reduces record slippage. Hysteresis motors are limited to small size by the difficulty of controlling rotor losses caused by imperfections in the stator mmf wave. *See* ALTERNATING-CURRENT MOTOR; MOTOR. [D.W.N.]

I

I-spin A quantum-mechanical variable or quantum number applied to quarks and their compounds, the strongly interacting fundamental hadrons, and the compounds of those hadrons (such as nuclear states) to facilitate consideration of the consequences of the charge independence of the strong (nuclear) forces. This variable is also known as isotopic spin, isobaric spin, and isospin.

The many strongly interacting particles (hadrons) and the compounds of these particles, such as nuclei, are observed to form sets or multiplets such that the members of the multiplet differ in their electric charge and magnetic moments, and other electromagnetic properties but are otherwise almost identical. For example, the neutron and proton, with electric charges that are zero and plus one (in units of the magnitude of the electron charge), form a set of two such states. The pions, one with a unit of positive charge, one with zero charge, and one with a unit of negative charge, form a set of three. It appears that if the effects of electromagnetic forces and the closely related weak nuclear forces (responsible for beta decay) are neglected, leaving only the strong forces effective, the different members of such a multiplet are equivalent and cannot be distinguished in their strong interactions. The strong interactions are thus independent of the different electric charges held by different members of the set; they are charge-independent. *See* ELEMENTARY PARTICLE; FUNDAMENTAL INTERACTIONS; HADRON; STRONG NUCLEAR INTERACTIONS.

The I-spin (I) of such a set or multiplet of equivalent states is defined such that Eq. (1) is satisfied, where N is the number of

$$N = 2I + 1 \tag{1}$$

states in the set. Another quantum number I_3, called the third component of I-spin, is used to differentiate the numbers of a multiplet where the values of I_3 vary from $+I$ to $-I$ in units of one. The charge Q of a state and the value of I_3 for this state are connected by the Gell-Mann–Okubo relation, Eq. (2), where Y,

$$Q = I_3 + \frac{Y}{2} \tag{2}$$

the charge offset, is called hypercharge. For nuclear states, Y is simply the number of nucleons. Electric charge is conserved in all interactions; Y is observed to be conserved by the strong forces so that I_3 is conserved in the course of interactions mediated by the strong forces. *See* HYPERCHARGE.

This description of a multiplet of states with I-spin is similar to the quantum-mechanical description of a particle with a total angular momentum or spin of j (in units of $\hbar$, Planck's constant divided by 2π). Such a particle can be considered as a set of states which differ in their orientation or component of spin j_z in a z direction of quantization. There are $2j + 1$ such states, where j_z varies from $-j$ to $+j$ in steps of one unit. To the extent that the local universe is isotropic (or there are no external forces on the states that depend upon direction), the components of angular momentum in any direction are conserved, and states with different values of j_z are dynamically equivalent.

There is then a logical or mathematical equivalence between the descriptions of (1) a multiplet of states of definite I and different values of I_3 with respect to charge-independent forces and (2) a multiplet of states of a particle with a definite spin j and different values of j_z with respect to direction-independent forces. In each case, the members of the multiplet with different values of the conserved quantity I_3 on the one hand and j_z on the other are dynamically equivalent; that is, they are indistinguishable by any application of the forces in question. *See* ANGULAR MOMENTUM; SPIN (QUANTUM MECHANICS).

The charge independence of the strong interactions has important consequences, defining the intensity ratios of different charge states produced in those particle reactions and decays which are mediated by the strong interactions. I-spin considerations also provide insight into the total energies or masses of nuclear and particle states. The basis for the symmetry described by I-spin is to be found in the quark structure of the strongly interacting particles and the character of the interactions between quarks. *See* QUARKS; SELECTION RULES (PHYSICS); SYMMETRY LAWS (PHYSICS). [R.K.A.]

Ice cream A commercial dairy food made by freezing while stirring a pasteurized mix of suitable ingredients. The product may include milk fat, nonfat milk solids, or milk-derived ingredients; other ingredients may include corn syrup, water, flavoring, egg products, stabilizers, emulsifiers, and other non-milk-derived ingredients. Air incorporated during the freezing process is also an important component.

The composition of ice cream may vary depending on whether it is an economy brand satisfying minimal requirements, a trade brand of average composition, or a premium brand of superior composition. The components by weight of an average-composition ice cream are 12% fat, 11% nonfat milk solids, 15% sugar, and 0.3% vegetable gum stabilizer.

Ice cream manufacturing ranges from small-batch operations, in which the ingredients are weighed or measured by hand, to large automated operations, where the ingredients are metered into the mix-making equipment. The liquid materials, including milk, cream, concentrated milk, liquid sugar syrup, and water, are mixed. The dry solids, such as nonfat dry milk, dried egg yolk, stabilizer, and emulsifier, are blended with the liquid ingredients. This liquid blend is known as the mix. Following the blending operation, the mix is pasteurized, homogenized, cooled, and aged. Pasteurization destroys all harmful microorganisms and improves the storage properties of the ice cream. Soluble flavoring materials are usually added to the mix just before the freezing process, but fruits, nuts, and candies are not added until the ice cream is discharged from the freezer. *See* PASTEURIZATION. [W.S.A.; R.T.M.]

Ice field A network of interconnected glaciers or ice streams, with common source area or areas, in contrast to ice sheets and ice caps. (An ice sheet is a broad, cakelike glacial mass with a relatively flat surface and gentle relief. Ice caps are properly defined as domelike glacial masses, usually at high elevation.) Being generally associated with terrane of substantial relief, ice-field glaciers are mostly of the broad-basin, cirque, and mountain-valley type. Thus, different sections of an ice field are often separated by linear ranges, bedrock ridges, and nunataks. [M.M.Mi.]

Ice point The temperature at which liquid and solid water are in equilibrium under atmospheric pressure. The ice point is by far the most important "fixed point" for defining temperatures scales and for calibrating thermometers. A closely related point is the triple point, which has gained favor as the primary standard since it can be attained with great accuracy in a simple closed vessel, isolated from the atmosphere. *See* TEMPERATURE; TRIPLE POINT. [R.A.Bu.]

Iceberg A large mass of glacial ice broken off and drifted from parent glaciers or ice shelves along polar seas. Icebergs should be distinguished from polar pack ice which is sea ice, or frozen sea water, though rafted or hummocked fragments of the latter may resemble small bergs. *See* GLACIOLOGY; SEA ICE.

Icebergs are classified by shape and size. The terms used are arched, blocky, dome, pinnacled, tabular, valley, and weathered for berg description, and bergy-bit and growler for berg fragments ranging smaller than cottage size above water. The lifespan of an iceberg may be indefinite while the berg remains in cold polar waters, eroding only slightly during summer months. But under the influence of ocean currents, an iceberg that drifts into warmer water will disintegrate rapidly.

Arctic iceberg, eroded to form a valley or dry-dock type: grotesque shapes are common to the glacially produced icebergs of the North.

In the Arctic, icebergs (see illustration) originate chiefly from glaciers along Greenland coasts. It is estimated that a total of about 16,000 bergs are calved annually in the Northern Hemisphere, of which over 90% are of Greenland origin; but only about half of these have a size or source location to enable them to achieve any significant drift. No icebergs are discharged or drift into the North Pacific Ocean or its adjacent seas, except a few small bergs each year that calve from the piedmont glaciers along the Gulf of Alaska.

In the Southern Ocean, bergs originate from the giant ice shelves all along the Antarctic continent. These result in huge, tabular bergs or ice islands several hundred feet high and often over a hundred miles in length, which frequent the entire waters of the Antarctic seas. [R.P.D.]

Icebreaker A ship designed to break floating ice. Since the 1960s, potential resource development in the Arctic regions has led to the construction of icebreaking ships that can transit to all areas of the world, including the North Pole. Icebreakers provide the platforms from which polar science and research can be conducted on a year-round basis. *See* ANTARCTIC OCEAN; ARCTIC OCEAN.

Icebreakers may be classed as polar or subpolar, depending on their primary geographic area of operation. Polar icebreakers can operate independently in first-year, second-year, and multiyear ice in the Arctic or the Antarctic. Subpolar icebreakers operate in the ice-covered waters of coastal seas and lakes outside the polar regions. *See* MARITIME METEOROLOGY; SEA ICE.

The combined shapes of the bow, midbody, and stem constitute the hull form. The icebreaker's bow must be designed to break ice efficiently, and it consists of an inclined wedge that forms an angle of about 20° with the ice surface. As the icebreaker advances, the bow rides up on the edge of the ice until the weight of the ship becomes sufficiently large that the downward force causes the ice to fail. The broken ice pieces move under the hull, and the process is repeated. Traditionally, icebreakers have sloped sides of 5–20° to reduce the frictional resistance. The stern of the icebreaker is designed in a manner similar to the bow so that the ship can break ice while going astern. *See* SHIP DESIGN.

The hull of a polar icebreaker is built very strong so that it can withstand tremendous ice forces. Because frequent and high loads occur at very low air temperatures, specialty steels are used on polar icebreakers. It is common to have bow and stern plating of 1.5–2.0 in. (4–5 cm) in thickness.

Most icebreakers are powered with diesel engines. However, when the horsepower required for icebreaking is sufficiently great, gas turbines or nuclear steam turbines are needed. *See* MARINE ENGINE.

Many auxiliary methods have been developed to improve the performance of icebreakers by reducing the friction between the hull and the ice. One widely used method is to roll or heel the ship from side to side. In addition, most icebreakers use a low-friction coating or a stainless-steel ice belt to reduce icebreaking resistance. [R.P.V.]

Ichneumon The common name for medium- to large-sized insects (wasps) comprising 25,000 species and belonging to the family Ichneumonidae (Hymenoptera); together with the Braconidae (with an additional 15,000 species) they form the superfamily Ichneumonoidea. The majority of ichneumons are slender wasps with long filiform antennae, freely rotating head, and permanantly extruded ovipositor. The ichneumons, found worldwide, are most abundant in heavy vegetational areas such as the edges of woodlands, hedgerows, and in secondary growth vegetation, and are often seen in the woodland canopy or in the litter of the forest floor. Ichneumons are more commonly seen in the spring and fall, as these wasps avoid hot, dry weather. *See* HYMENOPTERA; INSECTA.

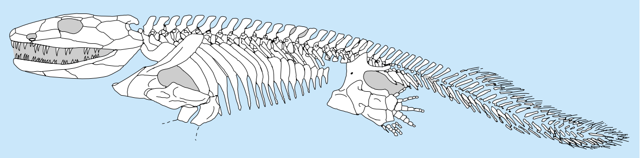
All members of the family Ichneumonidae are parasitic during their immature stages. They attack a wide variety of insects, usually the larval stages of beetles, butterflies, moths, flies, and other Hymenoptera. Since many of their insect hosts are considered pests of forest and agricultural crops, ichneumons are beneficial and important in biological control. *See* ENTOMOLOGY, ECONOMIC. [S.B.V.]

Ichthyopterygia A subclass of Mesozoic reptiles consisting of the highly specialized aquatic order Ichthyosauria. Ichthyosaurs are known from the Lower Triassic to near the end of the Cretaceous. Their body form broadly resembles that of living dolphins. Advanced ichthyosaurs have a spindle-shaped trunk, a narrow caudal peduncle, and a lunate tail with a high aspect ratio. This configuration corresponds closely to that of the fastest swimming modern sharks and bony fish such as the tuna and swordfish. *See* REPTILIA. [R.L.C.]

Ichthyornithiformes A small order of flying, toothed fossil birds that dates from the Cretaceous and contains only the family Ichthyornithidae of North America. Placement of the Ichthyornithiformes in the superorder Odontognathae, together with the Hesperornithiformes, is based only on their common possession of teeth; the relationship must still be supported with additional evidence. *See* HESPERORNITHIFORMES; ODONTOGNATHAE.

The original finds of *Ichthyornis* were from the Niobrara chalk beds of Kansas, but recent discoveries have extended the range of those birds over much of North America as well as into the Early Cretaceous. *Ichthyornis* disappeared in the Late Cretaceous Period, perhaps with the loss of the extensive inland seas that covered much of central North America during that period. *See* Aves. [W.J.B.]

Ichthyostega Four-legged vertebrates (basal tetrapods) that evolved from their lobe-finned fish ancestors during the later Devonian Period (400–350 million years ago) [see illus.]. *Ichthyostega* was the first Devonian tetrapod to be described and was found in East Greenland during the 1930s. For many decades it remained the only representative of the "fish-tetrapod transition" which was known from articulated skeletal fossils. Subsequently, a second genus from the same beds, *Acanthostega*, was more fully described, and during the 1990s Devonian tetrapod genera were recognized in other parts of the world.



Reconstruction of the skeleton of *Ichthyostega* based on recent information. The animal was about 1 m (3 ft) long.

Like other very early tetrapods, *Ichthyostega* had a skull composed of an outer casing of bone (the skull roof) with a separate box containing the brain (the braincase) inside it. The braincase shows some highly unusual features, especially in the ear region, which are difficult to interpret and do not resemble those of any other early tetrapod.

The postcranial skeleton shows some primitive and some very specialized features. The tail bore a fringe of fin-rays like those of a fish; these are lost in all other known early tetrapods except *Acanthostega*. The neural arches supporting the spinal cord articulated with one another via well-developed joint surfaces (zygapophyses). The ribs were massive overlapping blades which formed a corset around the body and gave it rigidity.

The massive shoulder girdle bore the large complex humerus which articulated with the shoulder at right angles to the body. The large pelvic girdle was attached to the vertebral column only by ligaments and muscles—no bony joint surfaces were involved as they are in modern tetrapods. The femur appears to have been about half the length of the humerus, and the hindlimb was paddlelike with tibia, fibula, and ankle bones all broad and flattened. The foot bore seven toes, which seems were enclosed in a web of skin. *See* Amphibia; Labyrinthodontia. [J.A.Cla.]

Igneous rocks Those rocks which have congealed from a molten mass. They may be composed of crystals or glass or both depending on the conditions of formation. The molten matter from which they come is called magma; where erupted to the surface, it is commonly known as lava. Solidification of the hot rock melt occurs in response to loss of heat. Generated at depth the magma tends to rise. It commonly breaks through the Earth's crust and spills out on the Earth's surface or ocean floor to form volcanic or extrusive rocks. At the surface where cooling is rapid, fine-grained or glassy rocks are formed.

Where unable to reach the surface, magma cools more slowly, insulated by the overlying rocks; and a coarser texture develops. The resulting igneous rocks appear intrusive relative to adjacent rocks. In general, deeply formed (plutonic) rocks display the coarsest texture. Igneous rocks formed at shallow depths (hypabyssal) display features somewhat intermediate between those of volcanic and plutonic types. *See* Magma; Pluton; Volcano; Volcanology.

Texture refers to the mutual relation of the rock constituents within a uniform aggregate. It is dependent upon the relative amounts of crystalline and amorphous (glassy) matter as well as the size, shape, and arrangement of the constituents. Rock textures are highly significant; they shed light on the problem of rock genesis, and tell much about the conditions and environment under which the rock formed.

Schemes for classifying igneous rocks are numerous. Three principal methods of classification are used. (1) Megascopic schemes are based on the appearance of the rock-in-hand specimen or as seen with a magnifying glass (hand lens). Such schemes are useful in the field study of rocks. (2) Microscopic schemes (largely mineralogical) are employed in laboratory investigations where more detailed information is needed. (3) Chemical schemes are very useful but have more limited application. The mineral content and texture of a rock generally tell much more about the rock's origin than does a bulk chemical analysis. Igneous rocks show great variations chemically, mineralogically, texturally, and structurally with few if any natural boundaries.

Plutonic rocks occur in large intrusive masses (batholiths, stocks, and other large plutons). They form at great depth and are often referred to as abyssal rocks. They are generated from large bodies of magma which cooled slowly.

Volcanic rocks are formed as lava flows or as pyroclastic rocks (heterogeneous accumulations of volcanic ash and coarser fragmental matter). They have solidified rapidly, and expanding gas bubbles formed by escaping volatiles frequently create highly porous rocks.

Hypabyssal rocks exhibit characteristics more or less intermediate between those of volcanic and plutonic types. They differ from volcanic rocks in that they are intrusive and generally free from glass and vesicular structures. They differ from plutonic rocks in that they occur in small bodies (dikes and sills) or in larger bodies formed at shallow depths (laccoliths) and they have textures characteristically resulting from more rapid cooling. *See* Anorthosite; Basalt; Feldspar; Feldspathoid; Gabbro; Granite; Granodiorite; Labradorite; Leucite rock; Pyroxenite; Quartz; Rhyolite; Syenite; Trachyte.

Igneous rock-forming minerals may be classed as primary or secondary. The primary minerals are those formed by direct crystallization from the magma. Secondary minerals may form at any subsequent time. The principal primary minerals are relatively few and may be classed as light-colored (felsic) or dark-colored (mafic) varieties. Felsic is a mnemonic term for feldspathic minerals (feldspar and feldspathoids) and silica (quartz, tridymite, and cristobalite). Mafic is mnemonic for magnesium and iron-rich minerals (biotite, amphibole, pyroxene, and olivine). Felsic minerals are composed largely of silica, alumina, and alkalies. Mafics are rich in iron, magnesium, and calcium.

Secondary minerals include minerals formed by addition of material subsequent to solidification of the rock or by alteration of minerals already present in the rock. Alteration in which certain minerals become more or less reconstituted is common and widespread. The common alteration products derived from the essential primary minerals are as follows.

Primary mineral	*Secondary mineral*
Quartz	Not altered
Potash feldspar	Kaolinite, sericite
Plagioclase	Kaolinite, sericite (paragonite), epidote, zoisite, calcite
Nepheline	Cancrinite, analcite, natrolite
Leucite	Nepheline and potash feldspar
Sodalite	Analcite, cancrinite
Biotite	Chlorite, sphene, epidote, rutile, iron oxide
Hornblende	Actinolite, biotite, chlorite, epidote, calcite
Orthopyroxene	Antigorite, actinolite, talc
Clinopyroxene	Hornblende, actinolite, biotite, chlorite, epidote, antigorite
Olivine	Serpentine, magnetite, talc, magnesite

See Petrology. [C.A.C.]

Ignimbrite A pyroclastic rock deposit formed by one or more ground-hugging flows of hot volcanic fragments and particles, essentially synonymous with pyroclastic-flow deposit, ash-flow tuff, flood tuff, or welded tuff.

Ignimbrites are commonly produced during explosive eruptions and are associated with most of the world's volcanic systems. They vary in size by orders of magnitude (10^{-3} to 10^3 km^3 of erupted material) and have chemical compositions that span the entire range commonly exhibited by igneous rocks (basaltic to rhyolitic). An ignimbrite can be of any form and size, but most deposits have sheetlike shapes and cover many thousands of square kilometers.

Ignimbrite deposits are characterized by a poorly sorted aggregate of ash (crystals and glass shards) and pumice. In the larger deposits, the pumice fragments may be flattened and stretched to yield ovoid-to-lenticular shapes, reflecting the compaction and welding of the deposit after or during emplacement. *See* IGNEOUS ROCKS; PUMICE; PYROCLASTIC ROCKS; TUFF; VOLCANIC GLASS; VOLCANO. [R.I.T.]

Ignition system The system in an internal combustion engine that initiates the chemical reaction between fuel and air in the cylinder charge by producing a spark. An ignition system for a multicylinder internal combustion engine has three basic functions: (1) to provide a sufficiently energetic spark to initiate the burning of the fuel-air mixture within each cylinder; (2) to control spark timing for optimum efficiency so that cylinder pressure reaches its maximum value shortly after the piston reaches the top of its compression stroke; and (3) to select the correct cylinder fired.

In an inductive ignition system, there are three possible types of control-vacuum-mechanical, electronic spark, or full electronic engine. Prior to spark discharge, electrical energy is stored inductively in the coil primary. The current to the coil primary winding is turned on and off by the ignition module in response to the spark-timing trigger signal. The current-off time marks the beginning of the sparking event. An accurate spark-timing schedule is a complex function of many engine variables, such as fuel-air composition, engine revolutions per minute (rpm), temperature, cylinder pressure, exhaust gas recirculation rate, knock tendency, and engine design.

The ignition coil stores electrical energy during the dwell (current-on) period and acts as a transformer at the end of dwell by converting the low-voltage-high-current energy stored in the primary to high-voltage-low-current energy in the secondary. The distributor selects the fired spark plug by positioning the rotor opposite the terminal connected to one spark plug. The plug selected depends on the cylinder firing order, which in turn depends on the engine design. The distributor is driven at one-half engine speed from the camshaft. *See* SPARK PLUG.

When high voltage (10–30 kV) is created in the coil secondary, a spark jumps from the rotor to a distributor cap terminal, establishing a conducting path from the ignition coil high-voltage terminal along a high-voltage wire to the spark plug. Each cylinder usually has one spark plug. (High-efficiency engines may have two spark plugs per cylinder and two complete ignition systems.) The plug electrodes project as far into the cylinder as possible. After high voltage is applied to the plug, an electrical discharge is generated between its two electrodes. The energy and temperature of this discharge must be sufficient to reliably ignite the fuel-air mixture under all encountered conditions of composition, temperature, and pressure.

Among the several other types of ignition systems for internal combustion engines are capacitive discharge, multiple-firing capacitive discharge, continuous sustaining, magneto, and distributorless ignitions. The input energy for capacitive discharge systems is stored on a capacitor at several hundred volts (generated by a dc-dc converter). A semiconductor switch (thyristor) controls the discharge of the capacitor into the primary winding. In a multiple-firing capacitive discharge ignition, the ignition module repetitively fires a capacitive discharge ignition during one spark event, increasing both the energy and effective time duration of the spark. In a continuous sustaining ignition, supplemental electrical power is added to the spark after it is established, resulting in electronically controlled extended duration rather than uncontrolled duration as for conventional ignitions. In a magneto ignition, electric current and energy are generated in the primary by relative rotational motion between a magnet and a coil (electromagnetic induction). High voltage is generated in the secondary when a set of contacts in the primary circuit is mechanically opened. Magnetos require no external source of electrical power.

The distributorless ignition system eliminates the need for mechanical distribution of spark energy by using a single coil for one, two, or four cylinders. For the two-cylinder-single-coil system, a double-ended ignition coil simultaneously fires a cylinder in a compression stroke together with a second in an exhaust stroke. The exhaust stroke cylinder accepts the waste spark to complete the electrical circuit through the engine block. A design variation uses alternating polarity high voltage from a special type of double-ended coil and four high-voltage rectifiers to fire four plugs. The rectifiers steer the voltage to the correct pair of plugs.

In diesel or compression ignition engines, sparkless ignition occurs almost immediately after fuel injection into the cylinder due to high in-cylinder air temperatures. High temperatures result from the high compression ratio of diesel engines. Mechanical or electronic injection timing systems determine ignition timing. *See* COMBUSTION CHAMBER; DIESEL ENGINE; INTERNAL COMBUSTION ENGINE. [J.R.As.]

Illiciales An order of flowering plants, division Magnoliophyta (Angiospermae), in the subclass Magnoliidae of the class Magnoliopsida (dicotyledons). The order consists of two families, Illiciaceae and Schisandraceae, with fewer than a hundred species in all. They are all woody, with scattered spherical cells containing volatile oils. The leaves are alternate and simple. The flowers are solitary or a few clustered together, regular, and hypogynous; the perianth has five to many segments that are not clearly differentiated into sepals and petals. The Illiciales are related to the Magnoliales and have sometimes been included in that order, but they are apparently more advanced in having fundamentally triaperturate pollen. *See* MAGNOLIOPSIDA. [T.M.Ba.]

Illite A clay-size, micaceous mineral; a common component of soil, sediments, sedimentary rocks, and hydrothermal deposits. Illite is considered to possess a smaller layer charge and potassium (K) content than muscovite. It is characterized by the ideal formula $Al_2(Si_{3.2}Al_{0.8})O_{10}(OH)_2K_{0.8}$.

Illite frequently is interlayered with smectite, and can be considered the nonswelling end member in an illite-smectite mixed-layer clay series. Pure end-member illite, with no interlayer smectite, is rare.

Illitic clays are used for manufacturing structural clay products such as brick and tile. Some degraded illites (vermiculites) are used for molding sands. Illite may also be useful for storing certain types of radioactive wastes, because it is less subject to transformation by heat than are other common clays and because it is highly specific for the sorption of cesium. *See* CLAY, COMMERCIAL; CLAY MINERALS. [D.D.E.]

Illuminance A term expressing the density of luminous flux incident on a surface. This word has been proposed by the Colorimetry Committee of the Optical Society of America to replace the term illumination. The definitions are the same. The symbol of illumination is E, and the equation is $E = dF/dA$, where A is the area of the illuminated surface and F is the luminous flux. *See* ILLUMINATION; LUMINOUS FLUX; PHOTOMETRY. [R.C.Pu.]

Illumination In a general sense, the science of the application of lighting. Radiation in the range of wavelengths of 0.38–0.76 micrometer produces the visual effect, commonly called light, by the response of the average human eye for normal (photopic) brilliance levels. Illumination engineering pertains to the sources of lighting and the design of lighting systems which distribute light to produce a comfortable and effective environment for seeing. In a specific quantitative sense, illumination is the combination of the spatial density of radiant power received at a surface and the effectiveness of that radiation in producing a visual effect. *See* ILLUMINANCE. [W.B.Bo.]

Ilmenite A rhombohedral mineral with composition $Fe^{2+}Ti^{4+}O_3$. The hardness is $5^1/_2$ on Mohs scale, specific gravity 4.72. Color is black, and there is no cleavage. The mineral usually occurs massive or in thin plates. Two other minerals belonging to the ilmenite structure type are geikielite, $MgTiO_3$, and pyrophanite, $MnTiO_3$.

Ilmenite is the most abundant titanium mineral in igneous rocks and the most important ore of titanium. Important occurrences include the Ilmen Mountains, Russia (whence the name); Kragerø, Norway; and Allard Lake, Quebec, Canada. *See* TITANIUM. [P.B.M.]

Image processing Manipulating data in the form of an image through several possible techniques. An image is usually interpreted as a two-dimensional array of brightness values, and is most familiarly represented by such patterns as those of a photographic print, slide, television screen, or movie screen. An image can be processed optically, or digitally with a computer.

To digitally process an image, it is first necessary to reduce the image to a series of numbers that can be manipulated by the computer. Each number representing the brightness value of the image at a particular location is called a picture element, or pixel. A typical digitized image may have 512 × 512 or roughly 250,000 pixels, although much larger images are becoming common. Once the image has been digitized, there are three basic operations that can be performed on it in the computer. For a point operation, a pixel value in the output image depends on a single pixel value in the input image. For local operations, several neighboring pixels in the input image determine the value of an output image pixel. In a global operation, all of the input image pixels contribute to an output image pixel value. These operations, taken singly or in combination, are the means by which the image is enhanced, restored, or compressed.

An image is enhanced when it is modified so that the information it contains is more clearly evident, but enhancement can also include making the image more visually appealing. An example is noise smoothing. To smooth a noisy image, median filtering can be applied with a 3 × 3 pixel window. This means that the value of every pixel in the noisy image is recorded, along with the values of its nearest eight neighbors. These nine numbers are then ordered according to size, and the median is selected as the value for the pixel in the new image. As the 3 × 3 window is moved one pixel at a time across the noisy image, the filtered image is formed.

Another example of enhancement is contrast manipulation, where each pixel's value in the new image depends solely on that pixel's value in the old image; in other words, this is a point operation. Contrast manipulation is commonly performed by adjusting the brightness and contrast controls on a television set, or by controlling the exposure and development time in printmaking. Another point operation is that of pseudocoloring a black-and-white image, by assigning arbitrary colors to the gray levels. This technique is popular in thermography (the imaging of heat), where hotter objects (with high pixel values) are assigned one color (for example, red), and cool objects (with low pixel values) are assigned another color (for example, blue), with other colors assigned to intermediate values.

The aim of restoration is also to improve the image, but unlike enhancement, knowledge of how the image was formed is used in an attempt to retrieve the ideal (uncorrupted) image. Any image-forming system is not perfect, and will introduce artifacts (for example, blurring, aberrations) into the final image that would not be present in an ideal image. A point spread function, called a filter, can be constructed that undoes the blurring. By imaging the blurred image with the filter point spread function, the restored image results. The filter point spread function is spread out more than the blurring point spread function, bringing more pixels into the averaging process. This is an example of a global operation, since perhaps all of the pixels of the blurred image can contribute to the value of a single pixel in the restored image. This type of deblurring is called inverse filtering, and is sensitive to the presence of noise in the blurred image. By modifying the deblurring filter according to the properties of the noise, performance can be improved. An example of the need to deblur images from an optical system is the Hubble Space Telescope before its spherical aberration was corrected with new optics. *See* SATELLITE ASTRONOMY.

Compression is a way of representing an image by fewer numbers, at the same time minimizing the degradation of the information contained in the image. Compression is important because of the large quantities of digital imagery that are sent electronically and stored. Digital high-definition television relies heavily on image compression to enable transmission and display of large-format color images. Once the image is compressed for storage or transmission, it must be uncompressed for use, by the inverse of the compression operations. There is a trade-off between the amount of compression and the quality of the uncompressed image. High compression rates are acceptable with television images, for example. However, where high image quality must be preserved (as in diagnostic medical images), only compression rates as low as three to four may be acceptable. *See* DATA COMPRESSION.

Image processing is an active area of research in such diverse fields as medicine, astronomy, microscopy, seismology, defense, industrial quality control, and the publication and entertainment industries. The concept of an image has expanded to include three-dimensional data sets (volume images), and even four-dimensional volume-time data sets. An example of the latter is a volume image of a beating heart, obtainable with x-ray computed tomography (CT). CT, PET, single-photon emission computed tomography (SPECT), MRI, ultrasound, SAR, confocal microscopy, scanning tunneling microscopy, atomic force microscopy, and other modalities have been developed to provide digitized images directly. Digital images are widely available from the Internet, CD-ROMs, and inexpensive charge-coupled-device (CCD) cameras, scanners, and frame grabbers. Software for manipulating images is also widely available. *See* CHARGE-COUPLED DEVICES; COMPACT DISK; COMPUTER STORAGE TECHNOLOGY; COMPUTERIZED TOMOGRAPHY; CONFOCAL MICROSCOPY; DATA COMMUNICATIONS; DIGITAL COMPUTER; ELECTRON MICROSCOPE; MEDICAL ULTRASONIC TOMOGRAPHY; NUCLEAR MEDICINE; SCANNING TUNNELING MICROSCOPE; TELEVISION CAMERA. [W.E.Sm.]

Immittance The impedance or admittance of an alternating-current circuit. It is sometimes convenient to use the term immittance when referring to a complex number which may be either the impedance (ratio of voltage to current) or the admittance (ratio of current to voltage) of an electrical circuit. The units of impedance and admittance are, of course, different and so units cannot be assigned to an immittance. However, in certain theoretical work it may be necessary to deal with general functions which afterward will be specialized to become either an impedance or an admittance by the assignment of suitable units; in such cases it is convenient to refer to the functions as immittances. *See* ADMITTANCE; ALTERNATING CURRENT; ELECTRICAL IMPEDANCE. [J.O.S.]

Immune complex disease Local or systemic tissue injury caused by the vascular deposition of products of antigen-antibody interaction, termed immune complexes. Immune complex formation with specific antibodies causes the inactivation or elimination of potentially harmful consequences only when immune complexes deposit in tissues, inciting various mediators of inflammation. When the reaction takes place in the extravascular fluids near the site of origin of the antigen (by injection, secretion, and such), focal injury can occur, as exemplified by the Arthus reaction or such conditions as experimental immune thyroiditis. Systemic disease may occur when soluble antigens combine with antibodies in the vascular compartment, forming circulating immune complexes that are trapped nonspecifically in the vascular beds of various organs, causing such clinical diseases as serum sickness or systemic lupus erythematosus with vasculitis and glomerulonephritis. The term immune complex disease usually signifies this systemic immune complex formation and vascular deposition. *See* ANTIGEN-ANTIBODY REACTION; CONNECTIVE TISSUE DISEASE.

Circulating immune complex disease occurs when the host's antibody production, relative to the amount of antigens, is inadequate for prompt elimination of antigen. Normally, excess amounts of antibody are formed which generate large immune complexes that are removed very rapidly from the circulation and are disposed of by the mononuclear phagocytic system. If the antibody response is very poor, only a few very small complexes are formed which are not prone to vascular deposition. When the relative antibody production is such that complexes of intermediate size form, vascular trapping can occur and injury results from the effects of inflammation. In addition to immune complex size, other factors influence vessel deposition, including the efficiency of systemic clearance of immune complexes, the hemodynamics of blood flow, and vasoactive amine-influenced changes in vascular permeability. Through dynamic equilibrium, continual modification of the deposits occurs as antigen and antibody fluctuate in the body fluids.

Treatment of immune complex disease can be divided into nonspecific and more specific modalities. Primary among the specific measures is the identification and elimination of the offending antigen. This may be possible with some infections when specific therapies are available, and in certain instances where the antigenic source can be removed, such as a neoplasm. More frequently, nonspecific anti-inflammatory (corticosteroids) and immunosuppressive agents (such as cyclophosphamide and azathioprine) are used to attempt to blunt the person's immune response, thereby lessening the amount of immune complexes produced. *See* AUTOIMMUNITY; IMMUNOLOGY. [E.H.C.; C.B.W.]

Immunity A state of resistance to an agent, the pathogen, that normally produces an infection. Pathogens include microorganisms such as bacteria and viruses, as well as larger parasites. The immune response that generates immunity is also responsible in some situations for allergies, delayed hypersensitivity states, autoimmune disease, and transplant rejection. *See* ALLERGY; AUTOIMMUNITY; HYPERSENSITIVITY; TRANSPLANTATION BIOLOGY.

Immunity is engendered by the host immune system, reacting in very specific ways to foreign components (such as proteins) of particular parasites or infective agents. It is influenced by many factors, including the environment, inherited genes, and acquired characteristics. Reaction to a pathogen is through a nonadaptive or innate response as well as an adaptive immune response. The innate response is not improved by repeated encounters with the pathogen. An adaptive response is characterized by specificity and memory: if reinfection occurs, the host will mount an enhanced response.

The components of the pathogen that give rise to an immune response, to which antibodies are generated, are called antigens. There are two types of specific responses to an antigen, antibodies and the cellular response. Antibodies help to neutralize the infectious agent by specifically binding it. A series of proteins in the blood (called complement) act in conjunction with antibodies to destroy pathogenic bacteria. In the cellular response, cytotoxic T cells are recruited to kill cells infected with intracellular agents such as viruses. Helper T cells may also be generated, which influence B cells to produce appropriate antibodies. Inflammatory responses and activation of other kinds of cells, such as macrophages, in conjunction with lymphocytes, is another important aspect of the immune response, as in delayed hypersensitivity. This kind of response seems to be common in certain chronic infections. *See* ANTIBODY; ANTIGEN; COMPLEMENT.

Complex immune systems (antibody and specific cellular responses) have been demonstrated in mammals, birds, amphibians, and fish, and are probably restricted to vertebrates.

Natural or innate immunity. There are natural barriers to infection, both physical and physiological, which are known collectively as innate immunity, and include the effects of certain cells (macrophages, neutrophils and natural killer cells) and substances such as serum proteins, cytokines, complement, lectins, and lipid-binding proteins. The skin or mucous membranes of the respiratory tract are obvious barriers and may contain bacteriostatic or bactericidal agents (such as lysozyme and spermine) that delay widespread infection until other defenses can be mobilized.

If organisms manage to enter tissues, they are often recognized by molecules present in serum and by receptors on cells. Bacterial cell walls, for example, contain substances such as lipopolysaccharides that activate the complement pathway or trigger phagocytic cells. Host range is dramatic in its specificity. Animals and plants are generally not susceptible to each other's pathogens. Within each kingdom, infectious agents are usually adapted to affect a restricted range of species. For example, mice are not known to be susceptible to pneumococcal pneumonia under natural conditions. The health of the host and environmental conditions may also make a difference to susceptibility. This is readily apparent in fish that succumb to fungal infections if their environment deteriorates. Genetic factors have an influence on susceptibility. Some of these genes have been identified, in particular the genes of the major histocompatibility complex which are involved in susceptibility to autoimmune diseases as well as some infectious disorders. *See* HISTOCOMPATIBILITY.

Once parasites gain entry, phagocytic cells attack them. They may engulf and destroy organisms directly, or they may need other factors such as antibody, complement, or lymphokines, secreted by lymphocytes, which enhance the ability of the phagocytes to take up antigenic material. In many cases these cells are responsible for alerting cells involved in active immunity so there is two-way communication between the innate and adaptive responses. *See* PHAGOCYTOSIS.

Adaptive immune response. Adaptive immunity is effected in part by lymphocytes. Lymphocytes are of two types: B cells, which develop in the bone marrow or fetal liver and may mature into antibody-producing plasma cells, and T cells, which develop in the thymus. T cells have a number of functions, which include helping B cells to produce antibody, killing virus-infected cells, regulating the level of immune response, and controlling the activities of other effector cells such as macrophages.

Each lymphocyte carries a different surface receptor that can recognize a particular antigen. The antigen receptor expressed by B cells consists of membrane-bound antibody of the specificity that it will eventually secrete; B cells can recognize unmodified antigen. However, T cells recognize antigen only when parts of it are complexed with a molecule of the major histocompatibility complex. The principle of the adaptive immune response is clonal recognition: each lymphocyte recognizes only one antigenic structure, and only those cells stimulated by antigen respond. Initially, in the primary response, there are few lymphocytes with the appropriate receptor for an antigen, but these cells proliferate. If the antigen is encountered again, there will be a proportionally amplified and more rapid response. Primed lymphocytes either differentiate into immune effector cells or form an expanded pool of memory cells that respond to a secondary challenge with the same antigen.

The acquired or adaptive immune response is characterized by exquisite specificity such that even small pieces of foreign proteins can be recognized. This specificity is achieved by the receptors on T cells and B cells as well as antibodies that are secreted by activated B cells. The genes for the receptors are arranged in multiple small pieces that come together to make novel combinations, by somatic recombination. Each T or B cell makes receptors specific to a single antigen. Those cells with receptors that bind to the foreign protein and not to self tissues are selected out of a large pool of cells. For T cells, this process takes place in the thymus. The extreme diversity of T- and B-cell receptors means that an almost infinite number of antigens can be recognized. It has been calculated that potentially about 3×10^{22} different T-cell receptors are made in an individual. Even if 99% of these are eliminated because they bind to self tissues, 3×10^{20} would still be available.

Inflammation takes place to activate immune mechanisms and to eliminate thoroughly the source of infection. Of prime importance is the complement system, which consists of tens of serum proteins. A variety of cells are activated, including mast cells and macrophages. Inflammation results in local attraction of immune cells, increased blood supply, and increased vascular permeability. *See* CELLULAR IMMUNOLOGY.

Autoimmunity. The immune system is primed to react against foreign antigens while avoiding responses to self tissue by immunological tolerance. Although most T cells which might activate against host proteins are deleted in the thymus, these self-reactive cells are not always destroyed. These exceptions to self tolerance are frequently associated with disease, the autoimmune diseases, which are widespread pathological conditions, including Addison's disease, celiac disease, Goodpasture's syndrome, Hashimoto's thyroiditis, juvenile-onset diabetes mellitus, multiple sclerosis, myasthenia gravis, pemphigus vulgaris, rheumatoid arthritis, Sjögren's disease, and systemic lupus erythematosus. In these diseases, antibodies or T cells activate against self components. *See* AUTOIMMUNITY.

Immunization. Adaptive immunity is characterized by the ability to respond more rapidly and more intensely when encountering a pathogen for a second time, a feature known as immunological memory. This permits successful vaccination and prevents reinfection with pathogens that have been successfully repelled by an adaptive immune response. Mass immunization programs have led to the virtual eradication of several very serious diseases, although not always on a worldwide scale. Living attenuated vaccines against a variety of agents, including poliomyelitis, tuberculosis, yellow fever, and bubonic plague, have been used effectively. Nonliving vaccines are commonly used for prevention of bacterial diseases such as pertussis, typhoid, and cholera as well as some viral diseases such as influenza and bacterial toxins such as diphtheria and tetanus. *See* CANCER (MEDICINE); VACCINATION.

Passive immunization. Protective levels of antibody are not formed until some time after birth, and to compensate for this there is passive transfer of antibody across the placenta. Alternatively, in some animals antibody is transferred in the first milk (colostrum). Antibody may also be passively transferred artificially, for example, with a concentrated preparation of human serum gamma globulin containing antibodies against hepatitis. Protection is temporary. Horse serum is used for passive protection against snake venom. Serum from the same (homologous) species is tolerated, but heterologous serum is rapidly eliminated and may produce serum sickness. On repeated administration, a sensitized individual may experience anaphylactic shock, which in some cases is fatal. Cellular immunity can also be transferred, particularly in experimental animal situations when graft and host reactions to foreign tissue invariably occur unless strain tissue types are identical. [J.Tr.]

Immunoassay An assay that quantifies antigen or antibody by immunochemical means. The antigen can be a relatively simple substance such as a drug, or a complex one such as a protein or a virus. *See* ANTIBODY; ANTIGEN.

The reactants are first mixed so that a varying quantity of one (A) is added to a constant amount of the other (B). The formation of an immune (antigen-antibody) complex is measured as a function of the varied reactant (A). The result is represented by a "standard curve" for reactant A. An unknown sample is tested by adding it to reactant B. The extent of the measured change is referred to the standard curve, and thereby is obtained the amount of reactant A which produces a comparable change. The amount is represented as the content of reactant A in the unknown sample. *See* IMMUNOFLUORESCENCE; IMMUNOLOGY; IMMUNONEPHELOMETRY; RADIOIMMUNOASSAY. [A.B.]

Immunochemistry A discipline concerned both with the structure of antibody (immunoglobulin) molecules and with their ability to bind an apparently limitless number of diverse chemical structures (antigens); with the structure, organization, and rearrangement of the genes coding for the immunoglobulin molecules; and with the structure and function of molecules on the surface of animal cells, such as the transplantation (histocompatibility) antigens, which recognize antibodies and the thymus-derived lymphocytes mediating the cellular immune response. *See* ANTIGEN; IMMUNOASSAY; IMMUNOGLOBULIN; RADIOIMMUNOASSAY; TRANSPLANTATION BIOLOGY. [W.H.K.; F.F.R.]

Immunoelectrophoresis A combination of the techniques of electrophoresis and immunodiffusion used to separate the components of a mixture of antigens and make them visible by reaction with specific antibodies. *See* ELECTROPHORESIS.

A medium such as agar is deposited on a convenient base, for example, a microscopic slide. A small well is cut in the medium. A test solution is deposited in the well, and the contained substances are separated by electrophoresis along one axis of the plate. A trough is then cut in the medium parallel to, but at some distance from, the line of the separated substances. The trough is filled with antiserum which contains antibodies to one or more of the separated substances. The antiserum and substances diffuse toward one another and, where they meet, form curvilinear patterns of precipitation. These can be seen directly in clear media or can be visualized after washing out unreacted materials and staining in opaque media. *See* IMMUNOASSAY. [A.B.]

Immunofluorescence A technique that uses a fluorochrome to indicate the occurrence of a specific antigen-antibody reaction. The fluorochrome labels either an antigen or an antibody. The labeled reactant is then used to detect the presence of the unlabeled reactant. The use of a labeled reactant (such as an antibody which both detects and indicates the antigen) to reveal the presence of an unlabeled one is termed direct immunofluorescence. The use of a labeled indicator antibody, which reacts with an unlabeled detector antibody that has previously reacted with an antigen, is termed indirect immunofluorescence. Substitution of a light meter for the human eye permits a quantitative measurement in immunofluorometry. *See* FLUORESCENCE; IMMUNOASSAY. [A.B.]

Immunogenetics A scientific discipline that uses immunological methods to study the inheritance of traits. Traditionally, immunogenetics has been concerned with moieties that elicit immune response, that is, with antigens (antigenic determinants). It has now broadened its scope to study also the genetic control of the individual's ability to respond to an antigen. *See* ANTIGEN.

The immunological methods used in immunogenetics are of two principal kinds, serological and histogenetical. In serological methods, antibodies are used to detect antigens, either in solution or on a cell surface. In histogenetical methods, immune cells (lymphocytes) are used to detect antigens on the surface of other cells. In modern immunogenetics research, the serological and histogenetical methods are combined with molecular methods in which the researcher isolates and works with the genes that code for the traits. This approach of going back and forth from classical to molecular methods has proved to be very successful and has led to the elucidation of several complex genetic systems. *See* ANTIBODY.

Animal immunogenetics relies heavily on the use of inbred, congenic, and recombinant inbred strains. Inbred lines result when individuals that are more closely related to each other than randomly chosen individuals mate together, for many generations. The advantage in working with inbred strains rather than outbred animals is that inbred strains restrict the variability of the conditions of an experiment. However, when two strains are compared and it is found that they respond differently to a treatment, it is not known to what gene this difference should be attributed. The strains may differ at as many genetic loci as two unrelated individuals in an outbred population do. To study the effect of single, defined genes, immunogeneticists have developed congenic lines. These lines always come in groups, the smallest group being a pair, which consists of a congenic line and its inbred partner strain. The two are homozygous at more than 97% of their loci (that is, they are inbred) and are identical except, ideally, at one locus—the locus that is to be studied. To find out whether two loci are on the same or on different chromosomes, two individuals that differ in the traits controlled by these loci are mated and then the F_1 hybrids are intercrossed. In the F_2, generation that results from this intercross, the genes assort either independently, if they are on different chromosomes, or nonrandomly, if they are the same chromosome—that is, when they are linked. Each time the strains are tested for linkage, this laborious procedure must be repeated. To avoid this repetition, immunogeneticists have prepared a “frozen” F_2 generation by establishing separate inbred lines from the different F_2 individuals. Such lines are called the recombinant inbred strains.

Contemporary immunogenetic research concentrates on two main categories of antigenic substances—those present in body fluids, primarily blood serum or plasma, and those expressed on surfaces of various cells. In the body-fluid antigens category, a prominent position is occupied by immunoglobulins. Although antibodies are usually used to detect antigens, they themselves may also serve as antigens, and antibodies can be produced against them. These antibodies against antibodies detect three principal kinds of antigenic determinants: isotypic, allotypic, and idiotypic. The main categories of cell-surface molecules studied by immunogenetical methods are blood-group antigens, histocompatibility antigens, tissue-restricted antigens, and receptors. Blood-group antigens are alloantigens found on erythrocytes. Histocompatibility antigens are antigens capable of inducing cellular immune responses and hence are detectable by histogenetical methods. Tissue-restricted antigens are expressed on some tissues but not on others and therefore serve as markers for cell sorting. Receptors are molecules that are capable of specifically interacting with certain other molecules. The interaction often leads to activation or inhibition of the receptor-bearing cell. *See* BLOOD GROUPS; GENETICS; HISTOCOMPATIBILITY; IMMUNOGLOBULIN; IMMUNOLOGY. [J.K.]

Immunoglobulin Any of the glycoproteins in the blood serum that are induced in response to invasion by foreign antigens and that protect the host by eradicating pathogens. Antibodies belong to this group of proteins. An antigen is any substance capable of inducing an immune response. Intact antigens are able to specifically interact with the induced immunoglobulins. Normally, the immune system operates in a state known as self-tolerance, and does not attack the host's own tissues, but occasionally the immune system targets host-specific antigens, resulting in autoimmune disease. *See* AUTOIMMUNITY.

Immunoglobulins are composed of two identical heavy (H) and two identical light (L) polypeptide chains. Each H and L chain has an amino-terminal variable (V) region and a carboxyl-terminal constant (C) region. Although V regions from different antibodies exhibit considerable sequence variation, there is a large degree of sequence similarity among C regions of different antibodies. In the living animal, antibodies first bind to antigen at the antigen combining site and then, ideally, eliminate it as a threat to the host.

Immunoglobulins are heterogeneous with respect to charge, size, antigenicity, and function. There are three categories of antigenic determinants present on immunoglobulins: isotypes are found in all individuals, allotypes are found in some individuals, and idiotypes are associated with the amino-terminal variable region. Isotypic determinants are located on the carboxyl-terminal constant region and are used to group immunoglobulin H and L chains into isotypes or classes. In total, there are five human H-chain classes. IgM contains mu (μ) H chains, IgG contains gamma (γ) H chains, IgA contains alpha (α) H chains, IgD contains delta (δ) H chains, and IgE contains epsilon (ϵ) H chains. IgG has four subclasses, IgG1, IgG2, IgG3, and IgG4, while IgA has two subclasses, IgA1 and IgA2. There are two L-chain isotypes named kappa (κ) and lambda (λ). Kappa and lambda chains may be associated with H chains of any isotype, and a complete description of an immunoglobulin molecule requires identification of both H and L chains.

IgG is the most abundant immunoglobulin class in the serum. IgG isotypes are associated with complement fixation, opsonization (that is, rendering more susceptible to phagocytosis), fixation to macrophages, and membrane transport. Of the two IgA subclasses, IgA1 is the predominant subclass of IgA in human serum. IgA1 is the dominant subclass in all external secretions, including milk, saliva, tears, and bronchial fluids. The percentage of subclass IgA2 is higher in these fluids than in serum. IgM is the first immunoglobulin to appear during the primary immune response. IgD and IgE are present in minute amounts in normal human serum. No function has been clearly attributed to IgD. IgE is active against parasites and acts as a mediator of immediate hypersensitivity. *See* ANAPHYLAXIS; ANTIBODY; ANTIGEN; ANTIGEN-ANTIBODY REACTION; HYPERSENSITIVITY; IMMUNOLOGY; PROTEIN. [J.D.C.; K.N.P.]

Immunologic cytotoxicity The mechanism by which the immune system destroys or damages foreign or abnormal cells. Immunologic cytotoxicity may lead to complete loss of viability of the target cells (cytolysis) or an inhibition of the ability of the cells to continue growing (cytostasis). Immunologic cytotoxicity can be manifested against a wide variety of target cells, including malignant cells, normal cells from individuals unrelated to the responding host, and normal cells of the host that are infected with viruses or other microorganisms. In addition, the immune system can cause direct cytotoxic effects on some microorganisms, including bacteria, parasites, and fungi.

Immunologic cytotoxicity is a principal mechanism by which the immune response copes with, and often eliminates, foreign materials or abnormal cells. Cytotoxic reactions are frequently observed as a major component of an immune response that develops following exposure to foreign cells or microorganisms. In addition, there is increasing evidence that cytotoxic reactions represent a major mechanism for natural immunity and resistance to such materials. In most instances, cytotoxicity by immune components involves the recognition of particular structures on the target cells; also, the targets need to be susceptible to attack by the immune components. Some cells are quite resistant to immunologic cytotoxicity, and this appears to represent a major mechanism by which they can escape control by the immune system.

There are a variety of mechanisms for immunologic cytotoxicity. The two main categories are antibody- and cell-mediated cytotoxicity. Within cell-mediated cytotoxicity, there is a multiplicity of effector cell types and mechanisms that can be involved, including cytotoxic T lymphocytes, macrophage-mediated cytotoxicity, natural killer cells, granulocyte cytoxicity, and antibody-dependent cell-mediated cytotoxicity. *See* IMMUNOLOGY. [R.B.He.]

Immunological deficiency A state wherein the immune mechanisms are inadequate in their ability to perform their normal function, that is, the elimination of foreign materials (usually infectious agents such as bacteria, viruses, and fungi). Immune mechanisms are also responsible for the rejection of transplanted organs. These processes are accomplished by white blood cells known as lymphocytes, of which there are two major types, T lymphocytes (thymus-derived) and B lymphocytes (bone marrow-derived). *See* CELLULAR IMMUNOLOGY; TRANSPLANTATION BIOLOGY.

Immunological deficiency states result from a failure at any point in the complex set of interactions involving lymphocytes and immunoglobulins. In general, the diseases are due to absence of cell populations; failure of cells to mature; failure to secrete the products necessary for effective cell interactions; or failure of accessory cell populations or protein systems (for example, complement) which are necessary for the complete competence of B-cell immune function. Some of the diseases are carried on the X-chromosome and affect only males, being carried by females. *See* COMPLEMENT; SEX-LINKED INHERITANCE.

The prime symptom of immunodeficiency is an increased suceptibility to infections. Many of the organisms to which people are constantly exposed do not ordinarily have the capability to cause infections in immunocompetent individuals because these organisms are so weak that they cannot establish themselves in normals. In immunodeficients, however, they can cause fatal infections.

In general, immunodeficiency states are inherited. Immunodeficiency can also be acquired as a complication of other disease processes. One of the most common forms of deficiency is caused by aggressive treatment of leukemia. Another cause of induced immunodeficiency is seen with transplant rejection therapy. To prevent organ rejection, drugs which destroy lymphocytes must be administered. Certain viruses, such as the Epstein-Barr virus (EBV), which causes infectious mononucleosis, infect lymphocytes. Involvement of the lymphoid system is nearly always only temporary, but in a small number of individuals the virus cannot be eliminated, and a chronic infection of B cells leads to the loss of normal lymphocyte function. Another immunodeficiency disorder caused by virus infection is acquired immune deficiency syndrome (AIDS). Immunodeficiency can also be observed secondary to dietary deficiency. Two main varieties are seen. In protein-calorie malnutrition, serious deficiency primarily involving the T-cell system predisposes affected individuals to overwhelming infection by the agents of measles or tuberculosis. In the second variety, deficiency of single substances is the cause; the two most commonly observed deficiencies are those of zinc and biotin. *See* ACQUIRED IMMUNE DEFICIENCY SYNDROME (AIDS); TRANSPLANTATION BIOLOGY. [Ri.H.]

Immunological ontogeny The origin and development (ontogeny) of the lymphocyte system, from its earliest stages to the two major populations of mature lymphocytes: the thymus-dependent or T lymphocytes, and the thymus-independent or B lymphocytes. The T lymphocytes carry out those aspects of function which are called cell-mediated immunity, including graft rejection, elimination of tumor cells, and delayed hypersensitivity. B cells are responsible for humoral or antibody-mediated immunity. *See* CELLULAR IMMUNOLOGY; IMMUNITY.

For both systems, development or differentiation proceeds in discrete stages. In the first stage, pluripotent hematopoietic stem cells, which originate in the yolk sac in the embryo and then successively in fetal liver and fetal bone marrow, develop into precursor cells committed to becoming T or B cells. Hematopoiesis in human fetal liver begins at about 4 weeks of gestational age and in fetal bone marrow after 20 weeks. *See* HEMATOPOIESIS.

The thymus plays a strategic role in the development of T lymphocytes. Precursor cells are attracted into the thymus where, under the influence of this microenvironment, they undergo rapid proliferation and maturation. These maturing T cells also begin to express a variety of cell-surface markers, which parallels developing immunocompetence. From the thymus, the maturing T cells are exported to the peripheral lymphoid tissues. *See* THYMUS GLAND.

The earliest B cells identified in fetal liver are pre-B cells. As the cells mature, they express immunoglobulin M (IgM) and subsequently IgD on their surface. At this stage, the cell is a specific, competent B cell ready to interact with an antigen. In the course of B-lymphocyte differentiation, diversity of immunoglobulin classes is generated by an orderly switch from IgM to IgG to IgA with expression of the respective immunoglobulin on the cell surface. *See* ANTIGEN; IMMUNOGLOBULIN. [E.W.Ge.]

Immunological phylogeny The study of immunology and the immune system in evolution. All vertebrates can recognize and respond to nonself-molecular configurations on microorganisms, cells, or organic molecules by utilizing a complex recognition system termed the immune response. The presence of lymphocytes and circulating antibodies has been documented in all extant vertebrate species. However, the existence of induced, specific reactions directly homologous to the immune repertoire of vertebrates has not been clearly established in invertebrates.

The role of phagocytic cells in engulfing foreign pathogens has been documented in virtually all metazoan organisms. Phagocytic cells possess a limited capacity to discriminate self from nonself, and this is due in part to the presence of lectins (molecules capable of binding specifically to various sugars) on their surface. Although there is no evidence to suggest that invertebrate lectins and vertebrate immunoglobulins are homologous structures, sufficient diversity exists within lectins of certain species to indicate that these types of molecules and their cellular expression on phagocytes might serve as a primitive and universal recognition mechanism. *See* IMMUNOGLOBULIN; LECTINS.

All true vertebrates possess cells clearly recognizable as lymphocytes and can carry out T-cell functions, such as graft rejection, and show the capacity of B cells to synthesize and secrete immunoglobulins. True lymph nodes are not present in vertebrate species more primitive than mammals, but birds possess aggregates of lymphoid tissue probably serving a similar function. *See* CELLULAR IMMUNOLOGY; LYMPHATIC SYSTEM.

Humans possess five major classes or isotypes of immunoglobulin: IgG, IgM, IgA, IgE, and IgD. The IgM molecule is the first immunoglobulin to appear in ontogeny, and the first to appear in phylogeny. Immunoglobulins of cyclostomes, elasmobranchs (sharks and rays), and many teleost fishes consist only of IgM polymers. Immunoglobulins possessing heavy chains distinct from the μ-like heavy chains of those groups are present in some lungfish (Dipnoi) and in anuran amphibians (frogs and toads). Dipnoi have a low-molecular-weight non-IgM immunoglobulin (termed IgN). Birds possess IgM and IgA immunoglobutins, but also possess a non-IgM immunoglobulin similar to that of amphibians as their major immunoglobulin class. This immunoglobulin has been termed IgY. IgG immunoglobulins containing gamma chains clearly homologous to those of the humans and of true mammals are found only within the three subclasses of living mammals, namely, eutherians, metatherians (marsupials), and monotremes (for example, the echidna). *See* IMMUNOLOGICAL ONTOGENY.

Although the precise nature of the precursors of the specific elements of the immune system in evolution remains to be determined, the genetic and cellular events which lead to the capacity for specific immune recognition, diversification, and reactivity occurred early in vertebrate evolution. *See* IMMUNITY; IMMUNOLOGY. [J.J.Ma.]

Immunology The division of biological science concerned with the native or acquired response of complex living organisms to the intrusion of other organisms or foreign substances. The immune system allows the host organism to distinguish between self and nonself and to respond to a target (termed an antigen).

It was not until the germ theory of infectious disease was established that the full implication of immunology was realized. First came the recognition that certain bacteria caused corresponding diseases. Second came the recognition that it was a specific resistance to that bacterium or its toxins that prevented recurrence of the same disease. Third came the discovery that after recovery from an infectious disease, protective substances called antibodies could be found in the blood of animals and humans. Antigens, such as bacteria and their products, triggered the production of antibodies and indeed all kinds of chemical and biological molecules. The action of these effector mechanisms, however, has come to be recognized as being not always protective or conferring immunity, but sometimes becoming grossly exaggerated or inappropriate, or capable of turning upon the host in a destructive fashion that causes disease. These responses are classified as allergies. Illnesses associated with a misguided response of the immune system that is directed against the self and results from a breakdown in the normal immunological tolerance of, or unresponsiveness to, self antigens are termed autoimmune. The mechanisms responsible for these disorders are unknown but probably include the intervention of factors such as viruses that either modify or naturally resemble self molecules. Subsequently, the immune response, in seeking out what is foreign, proceeds to attack the self. *See* ALLERGY; AUTOIMMUNITY.

Immunology is also concerned with assaying the immune status of the host through a variety of serological procedures, and in devising methods of increasing host resistance through prophylactic vaccination. There has also been much important investigation of induced resistance and tolerance to transplants of skin and organs, including tumors. *See* BLOOD GROUPS; HYPERSENSITIVITY; IMMUNITY; IMMUNOASSAY; ISOANTIGEN; PHAGOCYTOSIS; PRECIPITIN; SEROLOGY; TRANSPLANTATION BIOLOGY; VACCINATION. [A.B.; M.J.Po.]

Immunonephelometry An application of nephelometry to the quantification of antigen or antibody. The technique depends on the light-scattering properties of microparticles. The initial antigen-antibody complexes are macromolecular in size and do not scatter light. However, such complexes have the ability to aggregate. The size of the aggregates increases with time until they do scatter light. This process takes from several minutes to hours before it attains maximum, depending on various properties of the reactants. If other aspects are kept constant, including, for example, the concentration of one reactant, then both the rate at which the scatter of light increases and its maximal value increase with the concentration of the other reactant. Either the increase in the rate of scatter or its maximal value can be calibrated for various concentrations of a reactant to yield a concentration-response calibration curve. Unknown concentrations of that reactant can then be quantified by measuring the response and comparing it with the calibration curve. *See* ANTIBODY; ANTIGEN; IMMUNOASSAY. [A.B.]

Immunosuppression The natural or induced active suppression of the immune response, as contrasted with deficiency or absence of components of the immune system. Like many other complex biological processes, the immune response is controlled by a series of regulatory factors. A variety of suppressor cells play a role in essentially all of the known immunoregulatory mechanisms, such as maintenance of immunological tolerance; limitation of antibody response to antigens of both thymic-dependent and thymic-independent types, as well as to antigens that stimulate reaginic antibody (antibodies involved in allergic reactions); genetic control of the immune response; idiotype suppression; control of contact and delayed hypersensitivity; and antigenic competition. All of the major cell types involved in the positive side of cellular interactions required for an immune response have also been found capable of functioning as suppressors in different regulatory systems. *See* IMMUNOLOGICAL DEFICIENCY.

Suppressor cells. Some suppressor functions are antigen- or carrier-specific. (A carrier is a molecule that can be chemically bound to another small molecule, called a hapten, in such a way that the combination induces an immune response that the hapten alone would not induce.) Others may not be carrier-specific, but may be specific for the type of response, such as immunoglobulin production but not delayed hypersensitivity. In the case of immunoglobulin production, the suppressor T cell may regulate the production of all immunoglobulin classes, a single class of immunoglobulins, or molecules that bind only a given antigen. Other suppressors may affect only cellular immunity and not humoral immunity. *See* CELLULAR IMMUNOLOGY; IMMUNOGLOBULIN.

Suppressor cells are critical in the regulation of the normal immune response. Immunological tolerance refers to the ability of an individual's immune system to distinguish between its own and foreign antigens and to mount a response only to foreign antigens. A major role has been established for suppressor T lymphocytes in this phenomenon. Suppressor cells also play a role in regulating the magnitude and duration of the specific antibody response to an antigenic challenge.

Reagin, or IgE, is the class of immunoglobulin that mediates allergic reactions such as asthma and urticaria. The reaginic antibody response depends heavily on nonspecific cooperator T cells and specific helper T cells as well as the B cells that produce the antibody. In a negative direction, IgG-blocking antibodies regulate the response, but antigen-specific and antigen-nonspecific suppressor T cells also play a critical role in regulating this response. *See* ALLERGY.

T cells are the major cells involved in immunosuppression, although activated phagocytic mononuclear cells are also significant as nonspecific suppressors in many systems. Helper T cells and suppressor T cells are different cell populations that are distinguished to a considerable extent by surface antigens that react with monoclonal antibodies or receptors for specific substances such as histamine.

No single model explains the entire array of cellular suppressor phenomena. In different systems, other T cells, macrophages, or even B cells may be the immediate targets of the suppressor cells and their secretions. Some suppression requires direct cell-cell interaction, whereas other suppression may be mediated by suppressor lymphokines. Both antigen-specific and antigen-nonspecific factors are known, and they may be secreted to act upon other cells, or especially in the case of antigen-specific factors, they may be integral parts of the cell membrane. The soluble immune-response suppressor factor, produced by activated T cells and then activated by monocytes, inhibits B-cell proliferation and immunoglobulin production in response to antigens. Macrophages also secrete suppressor factors, including prostaglandins that act on T cells and other soluble factors that are B-cell-specific.

There is a variety of disorders of immunoglobulin production in humans. In many cases these involve intrinsic defects in the bone marrow stem cells that normally mature into immunoglobulin-producing plasma cells. Defects in cell-mediated immunity occur in individuals who are infected with various fungal organisms. Suppressor T cells have been implicated, although it is not clear whether the appearance of suppressor cells is the initial event allowing development of the fungal infection or whether they develop secondarily after infection. Those individuals found to have suppressor T cells are at high risk for dissemination of the fungal infection and relapse following therapy. Although probably only one of many mechanisms, suppressor cells interfere with the host tumor-growth-inhibiting immune response to the foreign tumor-specific transplantation antigens that occur on malignant cells, thus allowing the tumors to progress. Both animal and human studies indicate a major role for both an activation of immunoglobulin-producing B cells as well as the absence or reduced numbers or function of suppressor T cells in autoimmune disorders such as Coombs-positive hemolytic anemia, systemic lupus erythematosus, rheumatoid disorders, and thyroid disorders in which antithyroid antibodies appear in the serum. *See* AUTOIMMUNITY. [K.S.W.; T.A.Wa.]

Immunosuppressors. Suppression of the immune response may be specific to a particular antigen or may be a response to a wide range of antigens encountered. The whole immune response may be depressed, or a particular population of immunologically active lymphocytes may be selectively affected. In some cases, the effect may be preferentially on T cells rather than B cells. If B cells are affected, it may be on a specific subclass of antibody-producing cells. Antigen-specific immunosuppression may be the result of deletion or suppression of a particular clone of antigen-specific cells, or the result of enhanced regulation of the immune response by antigen-specific suppressor cells. It can also be the result of increased production of antiidiotypic antibody.

Nonspecific suppression of the immune response occurs in a number of rare immunological deficiency diseases of childhood. Acquired deficiency states affecting mainly T-cell function occur in states of malnutrition and in the presence of tumors, particularly those of the lymphoreticular system. Acquired deficiencies may also occur secondary to a number of infectious diseases. The acquired immune deficiency syndrome (AIDS) is probably of similar origin; its manifestations are similar although more severe and more dramatic. *See* ACQUIRED IMMUNE DEFICIENCY SYNDROME (AIDS); IMMUNE COMPLEX DISEASE.

There are a number of compounds capable of suppressing the immune response. The main stimulus for studies designed to identify these substances has been to devise means for controlling organ graft rejection. However, there has also been considerable activity in looking for compounds that will suppress the immune response and reduce the inflammatory process in experimental models of rheumatoid arthritis. The ideal immunosuppressive drug should fulfill five main requirements: (1) There should be a wide margin of safety between a toxic and a therapeutic dose. (2) The drug should have a selective effect on lymphoid cells and not cause damage to the rest of the body. (3) If possible, this effect should be only on those cells which are involved in the specific immune process to be suppressed. (4) The drug should need to be administered for only a limited period until the immunological processes become familiar with the foreign antigen and begin to recognize it as part of "self." (5) The drug should be effective against immune processes once they have developed. *See* TRANSPLANTATION BIOLOGY.

The result of any immune response is a balance between the action of effector cells mediating the phenomenon and suppressor cells regulating the response. Anything that reduces the regulatory function of suppressor cells will functionally increase the immune response. As suppressor cells are derived from rapidly turning-over precursor cells, and effector cells of T-cell-mediated immunity are derived from slowly dividing precursors, it is possible preferentially to depress the action of suppressor cells without affecting effector cells. This may be done by the use of alkylating agents such as cyclophosphamide given before immunization. Cyclophosphamide used in this way can increase a normal cell-mediated immune response, reverse immunological tolerance caused by increased regulatory activity of suppressor cells, and even reverse antigenic competition. It is likely that the chemotherapeutic effect of alkylating agents which are used extensively in the treatment of cancer in humans is partially due to these agents modifying the biological response to the tumor, producing an immunopotentiating action. *See* CHEMOTHERAPY; IMMUNITY; IMMUNOLOGY. [J.L.T.]

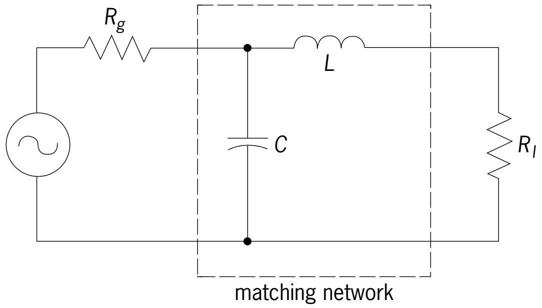
Immunotherapy The treatment of cancer by improving the ability of a tumor-bearing individual (the host) to reject the tumor immunologically. There are molecules on the surface of tumor cells, and perhaps in their interior, that are recognized as different from normal structures by the immune system and thus generate an immune response. The two components of the immune response are cell-mediated and antibody-mediated immunity, which must work in concert to overcome tumor cells. One type of thymus-derived lymphocyte (also called a cytotoxic T cell) can destroy tumor cells directly, while another recruits other white blood cells, the macrophages, that do the killing. Natural killer cells and perhaps other white blood cells may also participate. However, elements that normally regulate immunity, such as suppressor T cells, are stimulated excessively by the tumor, which leads to an immune response that is deficient and unable to reject the growing tumor. Thus the strategy of immunotherapy is to stimulate within or transfer to the tumor-bearing individual the appropriate antitumor elements while avoiding further stimulation of suppressor elements. *See* CELLULAR IMMUNOLOGY; IMMUNOLOGIC CYTOTOXICITY; IMMUNOSUPPRESSION.

There are four broad categories of immunotherapy: active, adoptive, restorative, and passive. Active immunotherapy attempts to stimulate the host's intrinsic immune response to the tumor, either nonspecifically or specifically. Nonspecific active immunotherapy utilizes materials that have no apparent antigenic relationship to the tumor, but have modulatory effects on the immune system, stimulating macrophages, lymphocytes, and natural killer cells. Specific active immunotherapy attempts to stimulate specific antitumor responses with tumor-associated antigens as the immunizing materials. Adoptive immunotherapy involves the transfer of immunologically competent white blood cells or their precursors into the host. Bone marrow transplantation, while performed principally for the replacement of hematopoietic stem cells, can also be viewed as adoptive immunotherapy. Restorative immunotherapy comprises the direct and indirect restoration of deficient immunological function through any means other than the direct transfer of cells. Passive immunotherapy means the transfer of antibodies to tumor-bearing recipients. This approach has been made feasible by the development of hybridoma technology, which now permits the production of large quantities of monoclonal antibodies specific for an antigenic determinant on tumor cells. *See* CANCER (MEDICINE); GENETIC ENGINEERING; IMMUNOLOGY; MONOCLONAL ANTIBODIES. [J.K.M.; M.S.Mi.]

Impact A force, also known as impulsive force, which acts only during a short time interval but which is sufficiently large to cause an appreciable change in the momentum of the system on which it acts. The momentum change produced by the impulsive force is described by the momentum-impulse relation. *See* COLLISION (PHYSICS); IMPULSE (MECHANICS). [P.W.S.]

Impedance matching The use of electric circuits and devices to establish the condition in which the impedance of a load is equal to the internal impedance of the source. This condition of impedance match provides for the maximum transfer of power from the source to the load. *See* ELECTRICAL IMPEDANCE.

The maximum power transfer theorem of electric network theory states that at any given frequency the maximum power is transferred from the source to the load when the load impedance



L-section impedance matching network with indirector *L* and capacitor *C* used in radio-frequency circuits. R_l = load resistance; R_g = generator resistance.

is equal to the conjugate of the generator impedance. When these conditions are satisfied, the power is delivered with 50% efficiency; that is, as much power is dissipated in the internal impedance of the generator as is delivered to the load. In general, the load impedance will not be the proper value for maximum power transfer. A network composed of inductors and capacitors may be inserted between the load and the generator to present to the generator an impedance that is the conjugate of the generator impedance (see illustration). [C.C.H.]

Impsonite A black, naturally occurring carbonaceous material having specific gravity 1.10–1.25 and fixed carbon 50–85%. The origin of impsonite is not well understood, but it appears to be derived from a fluid bitumen that polymerized after it filled the vein in which it is found. *See* Asphalt and asphaltite. [I.A.B.]

Impulse (mechanics) The integral of a force over an interval of time. For a force **F**, the impulse **J** over the interval from t_0 to t_1 can be written as Eq. (1). The impulse thus

$$\mathbf{J} = \int_{t_0}^{t_1} \mathbf{F}\, dt \qquad (1)$$

represents the product of the time interval and the average force acting during the interval. Impulse is a vector quantity with the units of momentum.

The momentum-impulse relation states that the change in momentum of a mass m over a given time interval equals the impulse of the resultant force acting during that interval. The momentum change can be expressed in terms of the velocities $\mathbf{v}_1$ and $\mathbf{v}_0$ at times t_1 and t_0, respectively, giving Eq. (2).

$$\mathbf{J} = m(\mathbf{v}_1 - \mathbf{v}_0) \qquad (2)$$

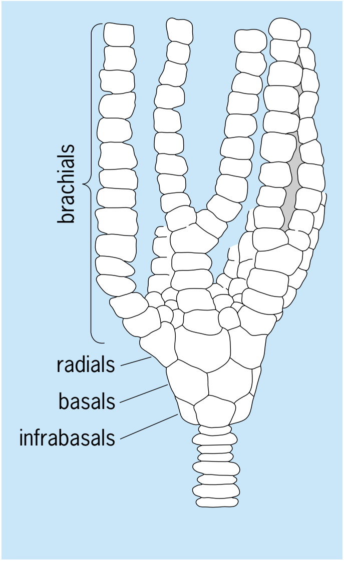
See Impact; Momentum. [P.W.S.]

Impulse generator An electrical apparatus which produces very short high-voltage or high-current surges. Such devices can be classified into two types: impulse voltage generators and impulse current generators. High impulse voltages are used to test the strength of electric power equipment against lightning and switching surges. Also, steep-front impulse voltages are sometimes used in nuclear physics experiments. High impulse currents are needed not only for tests on equipment such as lightning arresters and fuses but also for many other technical applications such as lasers, thermonuclear fusion, and plasma devices. *See* Fuse (electricity); Laser; Lightning and surge protection; Nuclear fusion; Particle accelerator; Plasma (physics).

An impulse voltage generator (sometimes called a Marx generator, after E. Marx who first proposed it in 1923) consists of capacitors, resistors, and spark gaps. The capacitors are first charged in parallel through charging resistors by a high-voltage, direct-current source and then connected in series and discharged through a test object by a simultaneous spark-over of the spark gaps. The impulse current generator comprises many capacitors that are also charged in parallel by a high-voltage, low-current, direct-current source, but it is discharged in parallel through resistances, inductances, and a test object by a spark gap. [C.Wa.; T.C.C.]

Impulse turbine A turbine in which fluid is deflected without a pressure drop in the blade passages. A turbine is a power-producing machine fitted with shaft-mounted wheels. Turbine blades, attached to the wheels' periphery, are driven by the through-flow of water, steam, or gas. The rotary motion of the wheel is maintained by forces imparted to the blades by the impingement against them of high-speed fluid streams. Before the stream of fluid reaches the moving turbine blades, it is accelerated in stationary passages called nozzles. The nozzles are shaped to convert mechanical or thermal energy of the fluid into kinetic energy; that is, the nozzles increase the fluid's velocity while decreasing its pressure and temperature. Upon leaving the nozzles the high-speed fluid strikes the moving blades, and a force is imparted to the blades as the fluid is deflected by them. If the fluid's deflection in the blade passage is accompanied by a pressure drop and a relative velocity rise, the turbine is called a reaction turbine; if the fluid is deflected without a pressure drop in the blade passages, it is called an impulse turbine. *See* Nozzle; Reaction turbine. [E.Lo.]

Inadunata One of three Paleozoic subclasses of the Crinoidea consisting of over 350 genera ranging from the Ordovician to the Permian. Its members generally lack fixed brachials such that the arms are free above the level of the radials. The calyx may be monocyclic, consisting of a circlet of basal and a circlet of radial plates, or dicyclic, having an additional circlet of infrabasal plates (see illustration). The arms, constructed of serially arranged brachials, may be simple or branched.



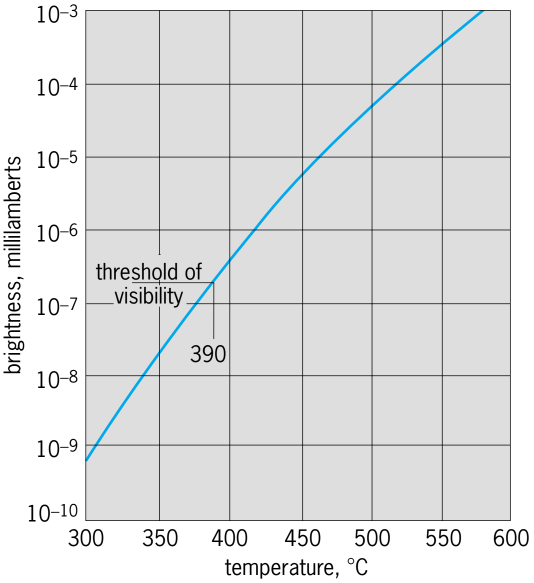
Dicyclic Inadunate.

The generic diversity of the Inadunata reached its peak during the Late Paleozoic, when it became the dominant crinoid group; all post-Paleozoic crinoids, members of the subclass Articulata, descended from one of the clades of the Inadunata. *See* Crinoidea; Echinodermata. [T.K.B.]

Inarticulata A class of phylum Brachiopoda. It is presently divided into four orders: Paterinida, Obolellida, Acrotretida, and Lingulida. *See* Lingulida; Obolellida; Paterinida.

The two valves of the shell are typically not articulated and are held together only by soft tissue of the living animal. A few genera developed hinge mechanisms posteriorly. The posterior sector of one or both valves is commonly flattened. Internally, muscle scars and mantle canal impressions are usually the only features present; a median ridge or elevated septum may be developed, particularly in the brachial valve. In all inarticulates, the fibrous secondary layer characteristic of the Articulata is undeveloped. *See* BRACHIOPODA. [A.J.R.]

Incandescence The emission of visible radiation by a hot body. A theoretically perfect radiator, called a blackbody, will emit radiant energy according to Planck's radiation law at any temperature. Prediction of the visual brightness requires additional consideration of the sensitivity of the eye, and the radiation will be visible only for temperatures of the blackbody which are above some minimum. The relation between brightness and temperature is plotted in the illustration. As shown, the minimum temperature for incandescence for the dark-adapted eye is about 390°C (730°F). Under these ideal observing conditions, the incandescence appears as a colorless glow. The dull red light commonly associated with incandescence of objects in a lighted room requires a temperature of about 500°C (930°F). *See* BLACKBODY; HEAT RADIATION; INCANDESCENT LAMP; VISION. [H.W.Ru./G.R.H.]



Relation between brightness of blackbody and temperature.

Incandescent lamp A lamp that creates radiant energy when its metallic filament is heated by an electric current. The filament is designed to produce radiant energy in the visible portion of the electromagnetic spectrum (light). The filament is of a special material that is supported in an envelope (bulb) that has been evacuated or filled with an inert gas such as argon, nitrogen, or krypton. In addition to light, the heated filament emits infrared and ultraviolet energy. When either of these radiations is accentuated, the lamp may be used as a source of that energy.

The important parts of an incandescent lamp are the bulb (envelope), the filament, and the base. The bulb may be clear, colored, inside-frosted, or coated with diffusing or reflecting material. Most lamps have soft-glass bulbs; hard glass is used when the lamp will be subjected to sudden and severe temperature changes. Lamps have a variety of bulb shapes, base types, and filament structures.

The efficient design of an incandescent lamp centers on obtaining a high temperature at the filament without the loss of heat or disintegration of the filament. The early selection of carbon, which has the highest melting point of any element (3872 K or 6510°F) was a natural one. However, carbon evaporates from its solid phase (sublimates) below this temperature, so carbon filaments must be operated at relatively low temperatures to obtain reasonable life. Ductile tungsten is a nearly perfect filament material, with a tensile strength four times that of steel, high melting point (3655 K or 6120°F), and relatively low evaporation.

Most lamps are rated in watts at a specified voltage. The most common voltage is 120 V for lamps to be used for general lighting service. General-service lamps are also available with voltage ratings of 125, 130, 230, 250, and 277. Lamps for special lighting service where the voltage may not be relatively constant may have ratings such as 115–125 V. Typical of such lamps are the rough-service lamps for use on extension cords where supplementary lighting is needed. Lamps for various special uses have voltage ratings which range from 1.5 V for flashlight lamps, 6 V for projector lamps, 12 V for automotive lamps, to 300 V for mines and special industrial usage.

Incandescent lamps have been developed for many services. Most common are those used in general service and the miniature lamp. Special types have been developed for rough service applications, bake-oven use, severe vibration applications, showcase lamps, multiple lights (three-way lamp), sign lamps, spotlights, floodlights, and insect-control lamps.

Tungsten-halogen lamps are made with a fill gas that includes a small amount of one of the halogen elements such as iodine, bromine, or chlorine. The special changes that result from the halogen addition are: (1) the filament temperature can be increased, giving a whiter light output; (2) the depreciation in light output with time is greatly decreased; and (3) the lumen output and the life are increased. The filament is enclosed in a small-diameter tubing made of fused quartz instead of glass to withstand the 500°F or 260°C bulb wall temperature required for proper functioning of the halogen gas fill.

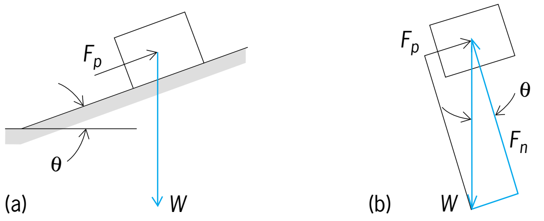
For other types of incandescent lamps *see* ARC LAMP; INFRARED LAMP. [G.R.P.; R.L.Sm.]

Inclined plane A plane surface inclined at an angle with the line of action of the force that is to be exerted or overcome. In the free-body diagram shown here, three forces act on the object when no friction is present. The forces are its weight W, the force F_p parallel to the surface, and a force F_n normal to the surface. The summation of the forces acting in any direction on a body in static equilibrium equals zero; therefore, the summation of forces parallel to and forces normal to the surface are given by Eqs. (1) and (2). A force slightly greater than $W \sin\theta$ moves the

$$F_p - W \sin\theta = 0 \qquad (1)$$

$$F_n - W \cos\theta = 0 \qquad (2)$$

object up the incline, but the inclined plane supports the greater part of the weight of the object. The principal use of the inclined plane is as ramps for moving goods from one level to another. *See* SIMPLE MACHINE. [R.M.Ph.]



Weight resting on an inclined plane (*a*) with principal forces applied, and (*b*) their resolution into normal force.

Incompressible flow Fluid motion with negligible changes in density. No fluid is truly incompressible, since even liquids can have their density increased through application of sufficient pressure. But density changes in a flow will be negligible if the Mach number, Ma, of the flow is small. This condition for incompressible flow is given by the equation below, where V

$$\mathrm{Ma} = \frac{V}{a} < 0.3$$

is the fluid velocity and a is the speed of sound of the fluid. It is nearly impossible to attain Ma = 0.3 in liquid flow because of the very high pressures required. Thus liquid flow is incompressible. *See* MACH NUMBER.

Gases may easily move at compressible speeds. Doubling the pressure of air—from, say, 1 to 2 atm—may accelerate it to supersonic velocity. In principle, practically any large Mach number may be achieved in gas flow. As Mach number increases above 0.3, the four compressible speed ranges occur: subsonic, transonic, supersonic, and hypersonic flow. Each of these has special characteristics and methods of analysis.

Air at 68°F (20°C) has a speed of sound of 760 mi/h (340 m/s). Thus inequality indicates that air flow will be incompressible at velocities up to 228 mi/h (102 m/s). This includes a wide variety of practical air flows: ventilation ducts, fans, automobiles, baseball pitches, light aircraft, and wind forces. The result is a wide variety of useful incompressible flow relations applicable to both liquids and gases. *See* COMPRESSIBLE FLOW; FLUID FLOW. [F.M.Wh.]

Index fossil The ancient remains and traces of a plant or animal that lived during a particular span of geologic time and that geologically dates the containing rocks. Index fossils are almost exclusively confined to sedimentary rocks which originated in such diverse environments as open oceans, tropical lagoons, coral reefs, beaches, lakes, and rivers.

The choice of a fossil as an index depends on several criteria. In general, the fossil represents a group that evolved rapidly. The greater the rate of evolution, the shorter the period of time represented by any given index fossil and the narrower the limits of relative age assigned to the rocks containing the index. Commonly, the span of geologic time during which a fossil lived is referred to as its range, and the thickness of rocks through which a particular index fossil or selected group of fossils occurs is referred to as a faunal zone. An index fossil also must be present in the rocks in sufficient numbers to be found with reasonable effort, must be relatively easy to collect or identify, and must be geographically extensive so that the zone it defines is widely applicable.

The fossil groups most useful as index fossils are generally marine and either floaters or open ocean swimmers, such as cephalopods, or bottom dwellers that had a floating or swimming stage in their life cycles, such as the medusa stage in the brachiopods. Such characteristics are necessary for rapid dispersal of newly evolved forms. On land, such mobile forms as the horses or wind-borne pollen and spores were relatively unrestricted by environmental barriers and became widely dispersed. All of these groups have provided biochronological zones of worldwide extent.

During the Cambrian Period (5.7×10^8 years before present) the oldest highly developed animals appeared; among them the trilobites provide the first important group of index fossils. Small plantlike floating colonial animals called graptolites have proved useful in correlating Ordovician (4.75×10^8 years B.P.) and Silurian (4.25×10^8 years B.P.) rocks. Ammonoids are a classic example of the internationally useful index fossil and are important beginning in the Devonian Period (4.13×10^8 years B.P.) and extending to the end of the Cretaceous Period (6.5×10^8 years B.P.). From the Pennsylvanian Period (3.1×10^8 years B.P.), fusulinids, a family of Foraminiferida, and pollen and spores from the coal forests are important indices. Small phosphatic teethlike fossils known as conodonts have been useful for detailed zonation throughout the Paleozoic Era as well as the early part of the Mesozoic. Closer to present time, the bones and teeth of vertebrate animals serve as index fossils for the Tertiary Era, while the remains of primitive humans have been used to date the Recent past. *See* BRACHIOPODA; CEPHALOPODA; CONODONT; FORAMINIFERIDA; FOSSIL; FUSULINACEA; GEOLOGIC TIME SCALE; GRAPTOLITHINA ; STRATIGRAPHY. [C.C.]

Indian Ocean The smallest and geologically the most youthful of the three oceans. It differs from the Pacific and Atlantic oceans in two important aspects. First, it is landlocked in the north, does not extend into the cold climatic regions of the Northern Hemisphere, and consequently is asymmetrical with regard to its circulation. Second, the wind systems over its equatorial and northern portions change twice each year, causing an almost complete reversal of its circulation.

The eastern and western boundaries of the Indian Ocean are 147 and 20°E, respectively. In the southeastern Asian waters the boundary is usually placed across Torres Strait, and then from New Guinea along the Lesser Sunda Islands, across Sunda Strait and Singapore Strait.

The ocean floor is divided into a number of basins by a system of ridges. The largest is the Mid-Ocean Ridge, the greater part of which has a rather deep rift valley along its center. It lies like an inverted Y in the central portions of the ocean and ends in the Gulf of Aden. The Sunda Trench, stretching along Java and Sumatra, is the only deep-sea trench in the Indian Ocean. East of the Mid-Ocean Ridge, deep-sea sediments are chiefly red clay; in the western half of the ocean, globigerina ooze prevails and, near the Antarctic continent, diatom ooze.

Atmospheric circulation over the northern and equatorial Indian Ocean is characterized by the changing monsoons. In the southern Indian Ocean atmospheric circulation undergoes only a slight meridional shift during the year. The surface circulation is caused largely by winds and changes in response to the wind systems. In addition, strong boundary currents are formed, especially along the western coastline, as an effect of the Earth's rotation and of the boundaries created by the landmasses.

North of 10°S the changing monsoons cause a complete reversal of surface circulation twice a year. In February, during the Northeast Monsoon, flow north of the Equator is mostly to the west and the North Equatorial Current is well developed. Its water turns south along the coast of Somaliland and returns to the east as the Equatorial Countercurrent between about 2 and 10°S. In August, during the Southwest Monsoon, the South Equatorial Current extends to the north of 10°S; most of its water turns north along the coast of Somaliland, forming the strong Somali Current. North of the Equator flow is from west to east and is called the Monsoon Current. Parts of this current turn south along the coast of Sumatra and return to the South Equatorial Current. During the two transition periods between the Northeast and the Southwest monsoons in April–May and in October, a strong jetlike surface current flows along the Equator from west to east in response to the westerly winds during these months. *See* OCEAN CIRCULATION.

Both semidiurnal and diurnal tides occur in the Indian Ocean. The semidiurnal tides rotate around three amphidromic points situated in the Arabian Sea, southeast of Madagascar, and west of Perth. The diurnal tide also has three amphidromic points: south of India, in the Mozambique Channel, and between Africa and Antarctica. It has more the character of a standing wave, oscillating between the central portions of the Indian Ocean, the Arabian Sea, and the waters between Australia and Antarctica. *See* TIDE. [K.W.]

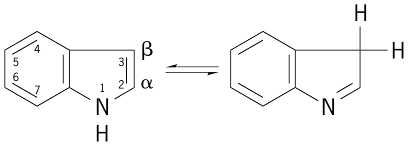
Indium A chemical element, In, atomic number 49, a member of group III and the fifth period of the periodic table. Indium has a relative atomic weight of 114.82. Indium occurs in the

Earth's crust to the extent of about 0.000001% and is normally found in concentrations of 0.1% or less. It is widely distributed in many ores and minerals but is largely recovered from the flue dusts and residues of zinc-processing operations. *See* Periodic table.

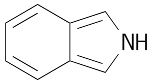
Indium is used in soldering lead wires to germanium transistors and as a component of the intermetallic semiconductor used for germanium transistors. Indium arsenide, antimonide, and phosphide are semiconductors with unique properties. Other uses of indium are sleeve-type bearings to reduce corrosion and wear, glass-sealing alloys, and dental alloys. *See* Germanium. [E.M.L.]

Indole The parent compound of a group of organic heterocyclic compounds containing the indole nucleus, which is a benzene ring fused to a pyrrole ring as in indole itself (**1**). The importance of the indole ring lies in its presence in a large number of naturally occurring compounds. *See* Pyrrole.

Indole can exist in two tautomeric forms, the more stable enamine form (**1**) and the 3-H-indole or imine form (**2**). Unsubstituted 3-H-indoles (sometimes called indolenines) and a structural isomer of indole, isoindole (**3**), are not stable, but have been shown to be reaction intermediates. They are isolable when properly substituted.



(1) (2)



(3)

Indole (I) is a steam-volatile, colorless solid, melting point 52.5°C (126.5°F), boiling point 253°C (487°F). It is found in small amounts in coal tar, feces, and flower oils. Despite the presence of nitrogen, indole is not basic in the sense that it dissolves in aqueous acid or turns litmus blue. In fact, the hydrogen on the nitrogen is about as acidic as an aliphatic alcohol hydrogen. Indole is an aromatic compound and undergoes electrophilic substitutions much like benzene, although it is much more reactive than benzene. Its reactivity is comparable to that of phenol, and it undergoes a number of reactions similar to those of phenol. Indole itself reacts slowly with air and rapidly with most oxidizing agents to give intractable polymeric tars.

The indole alkaloids are a large group of substances containing the indole nucleus and can be isolated from plants. They contain a number of physiologically active materials, such as strychnine, reserpine, some forms of curare poison, and the rye-fungus drug, ergot. Lysergic acid diethylamide (LSD) is a synthetic, and not a naturally occurring, substance. There are many hundreds of other indole alkaloids. *See* Alkaloid; Heterocyclic compounds. [J.M.Bo.]

Inductance That property of an electric circuit or of two neighboring circuits whereby an electromotive force is induced (by the process of electromagnetic induction) in one of the circuits by a change of current in either of them. The term inductance coil is sometimes used as a synonym for inductor, a device possessing the property of inductance. *See* Electromagnetic induction; Electromotive force (emf); Inductor.

For a given coil, the ratio of the electromotive force of induction to the rate of change of current in the coil is called the self-inductance of the coil. An alternative definition of self-inductance is the number of flux linkages per unit current. Flux linkage is the product of the flux and the number of turns in the coil. Self-inductance does not affect a circuit in which the current is unchanging; however, it is of great importance when there is a changing current, since there is an induced emf during the time that the change takes place. For example, in an alternating-current circuit, the current is constantly changing and the inductance is an important factor.

The mutual inductance of two neighboring circuits is defined as the ratio of the emf induced in one circuit to the rate of change of current in the other circuit.

The International System (SI) unit of mutual inductance is the henry, the same as the unit of self-inductance. The same value is obtained for a pair of coils, regardless of which coil is the starting point.

The mutual inductance of two circuits may also be expressed as the ratio of the flux linkages produced in a circuit by the current in a second circuit to the current in the second circuit. *See* Inductance measurement. [K.V.M.]

Inductance measurement The measurement of self- or mutual inductance. An electrical reactance such as the angular frequency ($2\pi f$, where f is the frequency) times self- or mutual inductance is the ratio of the alternating voltage having the appropriate phase, which appears across specified terminals, to the current through the device. Commercial instruments often measure inductance from this ratio by comparing it with the voltage-to-current ratio associated with a noninductive resistor. *See* Electrical impedance.

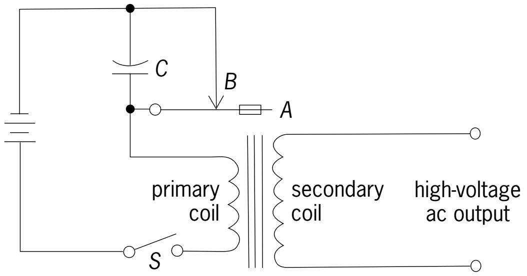
Some practical precautions must be taken if accurate results are to be obtained. Any magnetic field associated with the inductor must not interact significantly with magnetic or conducting material in the vicinity of the inductor, since the field, and therefore the inductance, would be altered. The varying magnetic field of an inductor will induce eddy currents in any nearby conducting material, which will in turn produce a magnetic field which interacts with the inductor and measuring system. Errors in a measurement of inductance may also arise from the interaction of the magnetic field of an inductor with the rest of the measuring circuit. Capacitance to other parts or to the surroundings of an inductor arising from its associated electric field will inevitably affect the impedance or apparent inductance of an inductor by a frequency-dependent amount but capacitive currents associated with screening of the measuring circuit can be routed in such a way as not to affect the measurement. *See* Eddy current; Inductor.

If the magnetic circuit of an inductor includes magnetic material whose permeability depends on its previous magnetic history, or the magnetic flux caused by a direct current flowing simultaneously in the coil, its inductance will also be current- or history-dependent, and these conditions must be specified if the measurement is to be meaningful.

The electrical property of self- or mutual inductance is only defined for complete circuits. Since a measuring device or network forms part of the complete circuit when it is connected to an inductor to perform a measurement, it is necessary to ensure that either the inductance associated with the measuring circuit is negligible or that the measured quantity is defined as the change in inductance occurring when the unknown is replaced by a short circuit. The former procedure is usual for mutual inductors, and the latter for self-inductors. *See* Electrical measurements; Inductance. [B.P.K.]

Induction coil A device for producing a high-voltage alternating current or high-voltage pulses from a low-voltage direct current. The largest modern use of the induction coil is in the ignition system of internal combustion engines, such as automobile engines. Devices of similar construction, known as vibrators, are used as rectifiers and synchronous inverters. *See* Ignition system.

The illustration shows a typical circuit diagram for an induction coil. The primary coil, wound on the iron core, consists of only a

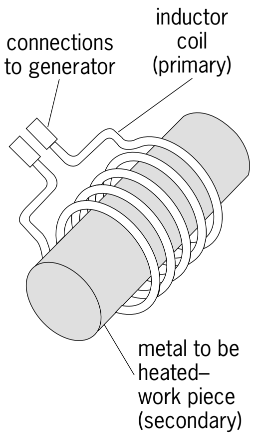


Typical circuit for an induction coil.

few turns. The secondary coil, wound over the primary, consists of a large number of turns.

Induction coils of a different type are used in telephone circuits to step up the voltage from the transmitter and match the impedance of the line. The direct current in the circuit varies in magnitude at speech frequencies; therefore, no interrupter contacts are necessary. Still another type of induction coil, called a reactor, is really a one-winding transformer designed to produce a definite voltage drop for a given current. *See* Reactor (electricity). [N.R.B.]

Induction heating The heating of a nominally electrical conducting material by eddy currents induced by a varying electromagnetic field. The principle of the induction heating process is similar to that of a transformer. In the illustration, the inductor coil can be considered the primary winding of a transformer, with the workpiece as a single-turn secondary. When an alternating current flows in the primary coil, secondary currents will be induced in the workpiece. These induced currents are called eddy currents. The current flowing in the workpiece can be considered as the summation of all of the eddy currents.



Basic elements of induction heating.

In the design of conventional electrical apparatus, the losses due to induced eddy currents are minimized because they reduce the overall efficiency. However, in induction heating, their maximum effect is desired. Therefore close spacing is used between the inductor coil and the workpiece, and highcoil currents are used to obtain the maximum induced eddy currents and therefore high heating rates. *See* Core loss.

Induction heating is widely employed in the metalworking industry for a variety of industrial processes. While carbon steel is by far the most common material heated, induction heating is also used with many other conducting materials such as various grades of stainless steel, aluminum, brass, copper, nickel, and titanium products. *See* Brazing; Heat treatment (metallurgy); Soldering.

The advantages of induction heating over the conventional processes (like fossil furnace or salt-bath heating) are the following: (1) Heating is induced directly into the material. It is therefore an extremely rapid method of heating. It is not limited by the relative slow rate of heat diffusion in conventional processes using surface-contact or radiant heating methods. (2) Because of skin effect, the heating is localized and the heated area is easily controlled by the shape and size of the inductor coil. (3) Induction heating is easily controllable, resulting in uniform high quality of the product. (4) It lends itself to automation, in-line processing, and automatic-process cycle control. (5) Startup time is short, and standby losses are low or nonexistent. (6) Working conditions are better because of the absence of noise, fumes, and radiated heat. *See* Electric heating. [G.F.B.]

Induction motor An alternating-current motor in which the currents in the secondary winding (usually the rotor) are created solely by induction. These currents result from voltages induced in the secondary by the magnetic field of the primary winding (usually the stator). An induction motor operates slightly below synchronous speed and is sometimes called an asynchronous (meaning not synchronous) motor.

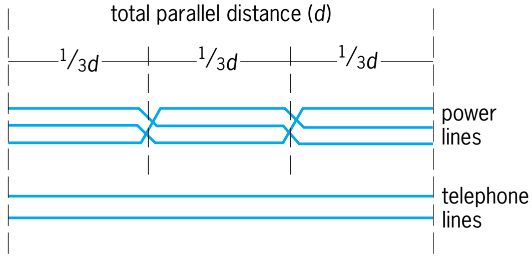
Induction motors are the most common electric motors due to their simple construction, efficiency, good speed regulation, and low cost. Polyphase induction motors come in all sizes and find wide use where polyphase power is available. Single-phase induction motors are found mainly in fractional-horsepower (1 horsepower = 746 W) sizes, and those up to 25 hp are used where only single-phase power is available.

There are two principal types of polyphase induction motors: squirrel-cage and wound-rotor machines. The difference in these machines is in the construction of the rotor. The stator construction is the same and is also identical to the stator of a synchronous motor. Both squirrel-cage and wound-rotor machines can be designed for two- or three-phase current.

Single-phase induction motors display poorer operating characteristics than polyphase machines, but are used where polyphase voltages are not available. They are most common in small sizes ($^1/_2$ hp or less) in domestic and industrial applications. Their particular disadvantages are low power factor, low efficiency, and the need for special starting devices. [A.G.C.]

Inductive coordination The avoidance of inductive interference. Electric power systems, like almost everything run by electricity, depend on internal electric and magnetic fields; some of these fields find their way into the environment. The strongest of these fields can then induce voltages and currents in nearby devices and equipment and, in some cases, can interfere with the internal fields being used by electrical equipment in the vicinity. These induced voltages and currents, which are due to the coupling between the energized source and the electrical equipment, are called inductive interference. *See* Electric field; Electromagnetic induction.

Overhead power lines cause practically all of the problems due to inductive coupling. For this reason and for safety



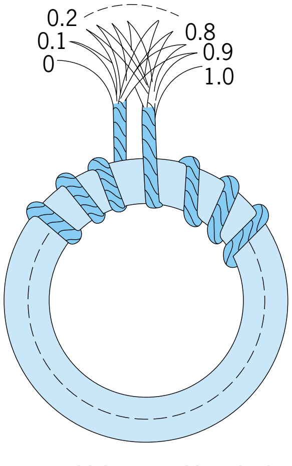
Transposition: the induced voltage and currents are canceled by transposing the power line as shown.

considerations, power lines are restricted as far as possible to specific corridors or rights of way. Spacing between them and the requirements of their surroundings are considered and carefully calculated to minimize possible interference. These corridors are often shared by telephone lines, communication circuits, railroads, and sometimes trolley buses, each of which must be considered for possible inductive coupling.

Modern telephone and communication circuits are well shielded and rarely encounter interference from nearby power lines. However, where a long parallel exposure exists, inductive coupling can be reduced by balancing the operation of the power line and by transposition of power and communication lines (see illustration). Fences, long irrigation pipes, and large ungrounded objects within the right of way may experience considerable inductive coupling and must be grounded for safety. *See* ELECTRICAL INTERFERENCE; ELECTRICAL SHIELDING; GROUNDING; TRANSMISSION LINES. [A.A.M.]

Inductive voltage divider An autotransformer that has its winding divided into a number of equal-turn sections (usually 10) so that when an alternating voltage V is applied to the whole winding, the voltage across each section is nominally $V/10$. The progressive voltages from one end to the section junctions are thus $V/10$, $2V/10$, $3V/10$, . . . , and $9V/10$. This voltage division can be realized with errors considerably less than 1 part per million of V, and such units therefore find wide use as standards of ac voltage ratio in the discipline of electrical measurements. *See* TRANSFORMER.

The division of voltage will be in error if there are differences of resistance and leakage inductance from section to section, and these errors will be significant if the differences are significant in relation to the input impedance of the winding. Leakage inductance is caused by that very small fraction of the flux from one section's winding which fails to thread the rest of the windings. The most commonly used constructional technique for minimizing such errors is to take 10 equal lengths of insulated copper wire and twist them into a "rope". The rope is wound onto a toroidal core made of thin, high-permeability, low-iron-loss magnetic material. The strands of the winding are then connected in series so that each strand forms the winding of one section of the 10-section divider (see illustration). The resistances of the sections are very nearly equal since the strands are the same length, and the leakage inductances are also closely equal and small because of the close flux coupling of this type of winding. The low-reluctance magnetic path of the core ensures a very high value of input impedance. Thus, voltage division at low audio frequencies can be accurate to a few parts in 10^8 of V.



Rope winding on toroidal core making single-decade inductive voltage divider.

Inductive voltage dividers operate most accurately in the frequency range 20–1592 Hz but can be constructed to operate at frequencies up to 1 MHz. They are usually designed to accept an input voltage of up to about 0.25 times the frequency in hertz. *See* VOLTAGE MEASUREMENT. [T.A.D.; B.P.K.]

Inductor A device for introducing inductance into a circuit. The term covers devices with a wide range of uses, sizes, and types, including components for electric-wave filters, tuned circuits, electrical measuring circuits, and energy storage devices.

Inductors are classified as fixed, adjustable, and variable. All are made either with or without magnetic cores. Inductors without magnetic cores are called air-core coils, although the actual core material may be a ceramic, a plastic, or some other nonmagnetic material. Inductors with magnetic cores are called iron-core coils. A wide variety of magnetic materials are used, and some of these contain very little iron.

In fixed inductors coils are wound so that the turns remain fixed in position with respect to each other. Adjustable inductors have either taps for changing the number of turns desired, or consist of several fixed inductors which may be switched into various series or parallel combinations. Variable inductors are constructed so that the effective inductance can be changed. Means for doing this include (1) changing the permeability of a magnetic core; (2) moving the magnetic core, or part of it, with respect to the coil or the remainder of the core; and (3) moving one or more coils of the inductor with respect to one or more of the other coils, thereby changing mutual inductance. *See* INDUCTANCE. [B.L.R.; W.S.P.]

Industrial ecology The multidisciplinary study of industrial and economic systems and their linkages with fundamental natural systems. Industrial ecology incorporates research involving energy supplies, materials, technologies, and technological systems; physical, biological, and social sciences; economics; law; and business management. Industrial and economic systems are viewed not in isolation but in their cultural and ecological context. Both demand-side (consumer) and supply-side (producer) activities are included, as are all sectors of economic activity, such as mining, agriculture, forestry, fisheries, manufacturing, and service activities. Industrial ecology also includes subsistence activities at the fringes of formal economic systems, which generate a number of important impacts on natural systems. Industrial ecology provides the understanding to support the reasoned improvement of the economic, environmental, and social efficiency of current industrial systems.

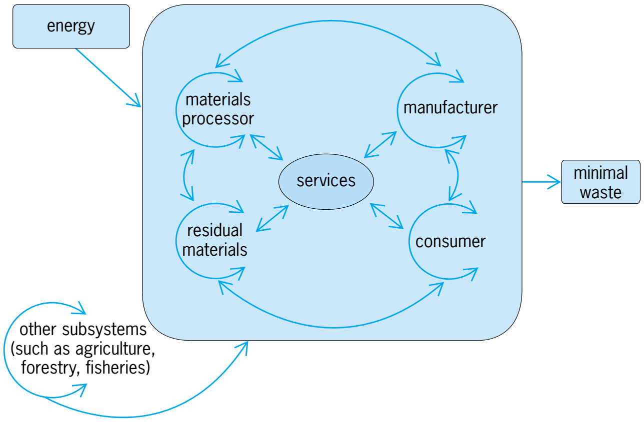
Some of the obvious principles of industrial ecology can be illustrated by analogy to biological communities. For example: (1) Creation of economic systems where material flows are reused rather than becoming waste is a critical element of industrial ecology (see illustration). (2) The focus is on systems and integrative analysis rather than specific elements. Key techniques which support such an approach are a focus on material stocks and flows, and energy consumption, throughout the system. (3) Industrial ecology is concerned not just with static analyses of systems but with their responses over time, and particularly with their resilience (how well they maintain system coherence and function when stressed).

Five key concepts of industrial ecology are:

1. Design of products, processes, facilities, infrastructure, services, and technology systems so that they can be easily adapted to environmentally preferable innovation with minimal waste. Modular design of complex technologies is an example.

2. Minimization of waste production and energy consumption in all activities.

3. Use of the least toxic alternatives whenever possible, particularly when the materials may be dispersed into the environment. This principle would have argued against adding lead to gasoline, since predictably the pollutant subsequently would be dispersed throughout the environment.



Energetically open, low-waste economy. Materials are cycled through the economy at different scales and in different sectors to minimize overall waste production while quality of life is enhanced.

4. Design of products, facilities, infrastructure, and technology systems to preserve the embedded utility of materials and energy used in initial manufacture. Thus, in many cases designs which extend the life of products and support the recycling of subassemblies or components, rather than materials, are preferable.

5. Design of physical products at all scales not just to perform their intended function but also to be used in creating other useful products at the end of their current life. *See* CLIMATE MODIFICATION; CONSERVATION OF RESOURCES; ECOLOGY; ECOLOGY, APPLIED; ENVIRONMENT; ENVIRONMENTAL ENGINEERING; HUMAN ECOLOGY; SYSTEMS ENGINEERING. [B.R.A.]

Industrial engineering A branch of engineering dealing with the design, development, and implementation of integrated systems of humans, machines, and information resources to provide products and services. Industrial engineering encompasses specialized knowledge and skills in the physical, social, engineering, and management sciences, such as human and cognitive sciences, computer systems and information technologies, manufacturing processes, operations research, production, and automation. The industrial engineer integrates people into the design and development of systems, thus requiring an understanding of the physical, physiological, psychological, and other characteristics that govern and affect the performance of individuals and groups in working environments.

Industrial engineering is a broad field compared to other engineering disciplines. The major activities of industrial engineering stem from manufacturing industries and include work methods analysis and improvement; work measurement and the establishment of standards; machine tool analysis and design; job and workplace design; plant layout and facility design; materials handling; cost reduction; production planning and scheduling; inventory control, maintenance, and replacement; statistical quality control; scheduling; assembly-line balancing, systems, and procedures; and overall productivity improvement. Computers and information systems have necessitated additional activities and functions, including numerically controlled machine installation and programming; manufacturing systems design; computer-aided design/computer-aided manufacturing, design of experiments, quality engineering, and statistical process control; computer simulation, operations research, and management science methods; computer applications, software development, and information technology; human-factors engineering and ergonomics; systems design and integration; and robotics and automation.

The philosophy and motivation of the industrial engineering profession is to find the most efficient and effective methods, procedures, and processes for an operating system, and to seek continuous improvement. Thus, industrial engineering helps organizations grow and expand efficiently during periods of prosperity, and streamline costs and consolidate and reallocate resources during austere times. Industrial engineers, particularly those involved in manufacturing and related industries, work closely with management. Therefore, some understanding of organizational behavior, finance, management, and related business principles and practices is needed. *See* COMPUTER-AIDED DESIGN AND MANUFACTURING; HUMAN-FACTORS ENGINEERING; OPERATIONS RESEARCH; PRODUCTION PLANNING. [M.U.T.]

Industrial health and safety An interdisciplinary field that focuses on preventing occupational illnesses and injuries. The disciplines of engineering, epidemiology, toxicology, medicine, psychology, and sociology provide the methods for study and prevention.

Tens of thousands of occupational hazards exist. Occupational hazards can be organized in terms of plants and equipment, the physical work environment, hazards of materials, and task demands. Significant interactions occur between these categories. For example, equipment can modify the work environment by producing noise, potentially hazardous materials, or heat, but will be hazardous only if inappropriate procedures are followed.

Plant hazards are often associated with energy sources and power transmission, processes at the point of operation, vehicles and materials-handling systems, walking and climbing surfaces, ingress-egress, and confined spaces. Hazards in the physical work environment include vibration and noise, thermal extremes, pressure extremes, and ionizing or nonionizing radiation.

Materials used in industrial processes vary greatly in nature and form. Mists, vapors, gases, liquids, dusts, and fumes from certain materials may be hazardous. Some materials pose fire and explosion hazards. Others are chemically or biologically active when they contact or enter the human body. Even chemically inert materials can cause injuries or illness.

The task performed by a worker can be hazardous. Lifting, pushing, pulling, and other physical activity can cause injury when applied or reactive forces, pressures, or torques exceed the tolerance of the body. Repeated performance of manual tasks over prolonged periods, excessive reaches, twisting motions, rapid movements, and postures that concentrate forces can significantly increase the risk of injury. Tasks that are stressful or monotonous can also contribute to human error. Changes in work conditions requiring deviations from ordinary routines, such as when equipment is being repaired, are particularly likely to increase the chance of errors.

A fundamental safety and health activity is to identify potential hazards and then to analyze them in terms of severity and probability. This process allows the cost of control measures to be compared with expected loss reduction and helps justify choices between control alternatives.

Hazard identification is guided by past experience, codes and regulations, checklists, and other sources. This process can be organized by separately considering each step in the making of a product. Numerous complementary hazard analysis methods are available, including failure modes and effects analysis, work safety analysis, human error analysis, and fault tree analysis. Failure mode and effects analysis systematically documents the effects of malfunctions on work sheets that list the components of a system, their potential failure modes, the likelihood and effects of each failure, and potential countermeasures. Work safety analysis and human error analysis are related techniques that organize the analysis around tasks rather than system components.

This process involves an initial division of tasks into subtasks. For each subtask, potential effects of product malfunctions and human errors are then documented. Fault tree analysis takes an approach that begins with a potential accident and then works down to its fundamental causes. Fundamental causes may be system malfunctions, human errors, or ordinary nonmalfunction states. Probabilities are often assigned to the fundamental causes, allowing the probability of accidents to be calculated. *See* OPERATIONS RESEARCH; RISK ASSESSMENT AND MANAGEMENT; SYSTEMS ANALYSIS.

Determining which standards, codes, and regulations are relevant and then ensuring compliance are essential health and safety activities. In the United States the best-known governmental standards are the general industry standards specified by the Occupational Safety and Health Administration (OSHA). OSHA also specifies standards for the construction, maritime, and agriculture industries. Other standards include those specified by the Environmental Protection Agency (EPA) on disposal and cleanup of hazardous materials, the Federal Aviation Administration (FAA) standards on worker safety in air travel, the Federal Highway Administration (FHWA) standards regarding commercial motor carriers, the Mine Safety and Health Administration (MSHA) standards for mine workers, the Nuclear Regulatory Commission's and Department of Energy's standards regarding employees working with radioactive materials, and the U.S. Coast Guard standards regarding safety of workers on tank and passenger vessels. State and local governments may also implement safety and health standards.

Methods of controlling or eliminating hazards include plant or process design; job design; employee selection, training, and supervision; personal protective equipment; and warnings. Accident investigations, plant inspections, and environmental monitoring are complementary ways of ensuring that implemented control strategies are fulfilling their intended function. They can uncover deficiencies in existing controls and help formulate needed changes. [M.R.L.]

Industrial meteorology The application of meteorological information to industrial, business, or commercial problems. Generally, industrial meteorology is a branch of applied meteorology, which is the broad field where weather data, analyses, and forecasts are put to practical use. The term "private sector meteorology" has taken on the broader context of traditional industrial meteorology, expanding to include the provision of weather instrumentation/remote sensing devices, systems development and integration, and various consulting services to government and academia as well as value-added products and services to markets in industry (such as media, aviation, and utilities). Some areas in which industrial meteorology may be applied include environmental health and air-pollution control, weather modification, agricultural and forest management, and surface and air transportation. *See* AERONAUTICAL METEOROLOGY; AGRICULTURAL METEOROLOGY; METEOROLOGICAL INSTRUMENTATION.

Specific examples of the uses of industrial meteorology include many in the public sphere. For example, electric utilities need hourly predictions of temperature, humidity, and wind to estimate system load. In addition, they need to know when and where thunderstorms will impact their service area, so that crews can be deployed to minimize or correct disruptions to their transmission and distribution systems. Highway departments need to know when and where frozen precipitation will affect their service areas so that crews can be alerted, trucks loaded with sand and salt, and, if necessary, contractors hired to assist. Since a few degrees' change in temperature, or a slight change in intensity of snow or ice, determines the type of treatment required, early prediction and close monitoring of these parameters are critical.

Agricultural enterprises, from farmers to cooperatives to food manufacturers, rely on precise weather information and forecasts. Weather is the single most important factor in determining crop growth and production. Thus, monitoring and prediction of drought, floods, heat waves, and freezes are of extreme importance. *See* WEATHER FORECASTING AND PREDICTION.

Professionals involved with the meteorological aspects of air pollution are generally concerned with the atmospheric transport, distribution, transformation, and removal mechanisms of air pollutants. They are often called upon to evaluate the effectiveness of pollution control technologies or regulatory (policy) actions used to achieve and maintain air-quality goals. *See* AIR POLLUTION. [T.S.G.]

Industrial microbiology A field concerned with the development of technologies to control and manipulate the growth and activities of selected biological agents to create desirable products and economic gain or to prevent economic loss. In addition to bacteria and yeasts, animal and plant cell cultures are now used to produce sophisticated products such as monoclonal antibodies, immunomodulating compounds, and complex plant metabolites.

Although fermented products have been consumed for thousands of years, only in the nineteenth century was microbial activity associated with the fermentation process. Soon after that discovery, microorganisms, especially bacteria, were selectively introduced on the commercial level. Techniques were developed gradually for pure-culture fermentation and strain improvement, but the major advance in industrial microbiology occurred during World War II with the large-scale production of penicillin by submerged-culture fermentation. In the 1950s, industrial microbiology shifted its focus to the production of therapeutic agents, especially antibiotics. Advances in molecular biology have greatly increased the potential applications of industrial microbiology in areas such as therapeutics, diagnostics, environmental protection, and agriculture. The techniques of genetic engineering, along with technology developments in bioprocessing, make possible large-scale production of complex natural compounds that would otherwise be very difficult to obtain.

With the exception of the food industry, few commercial fermentation processes use wild strains of microorganisms. Of the many thousands of microbial species, few are used commercially, and fewer still are used as hosts for genetically engineering genes. Process development occurs in large part by strain improvement directed at increasing product yield, enhancing growth on cheaper substrates, and simplifying purification.

Strain development is achieved by either a traditional mutation and selection program or direct genetic manipulation. The recombinant DNA approach has succeeded in introducing new genetic material into a convenient host microorganism and amplifying genetic material. About 20% of the synthesizing capacity of a bacterium can be devoted to a single polypeptide or protein. *See* RECOMBINATION (GENETICS).

Commercial microbial compounds are produced in two distinct phases: fermentation and product recovery. Production usually occurs in a batch fermentor, where gas of controlled composition and flow is bubbled through a stirred pure microbial culture suspended in a liquid medium of optimum nutrient composition. Product recovery and purification involves a series of operations. The first steps usually involve cell disruption or the separation of the cell or cellular debris from the fluid medium, typically through centrifugation and filtration. Later stages of purification include finer membrane filtration, extraction, precipitation, and chromatography. *See* CENTRIFUGATION; FERMENTATION; FILTRATION; FOOD FERMENTATION; STERILIZATION.

The production of certain foods and beverages was an early application of industrial microbiology. Now, the fields of mineral recovery, medicine, environmental protection, and food and agriculture are using similar techniques.

Bacterial leaching reactions have been used to alter metal-bearing minerals, usually converting them to more soluble forms before the metals are extracted. Such operations can result in improved extraction rates in comparison to those of conventional processes, which are usually conducted on ore waste dumps and heaps. Large-scale commercial applications of biochemical mining and extraction have been limited mainly to copper and uranium. Besides enhancing or inhibiting the recovery of metal values from ores, bacteria are being used to precipitate or accumulate metal. The process, known as bioaccumulation, normally involves the adsorption of metal ions on the bacteria, which are then chemically transformed to an insoluble precipitate.

The most visible products of industrial microbiology are therapeutics for human health. Microbial synthesis is the preferred method of production for most health care drugs with complex chemistry. Microorganisms still have a remarkable ability for producing new commercial antibiotics, the largest class of drugs, and for continued yield improvement. With recombinant DNA technology, many proteins and polypeptides that are present naturally in the human body in trace amounts can be produced in large amounts during fermentation of recombinant microorganisms. *See* ANTIBIOTIC; INSULIN.

Microbial activities have long been the basis for sewage treatment facilities, and industrial and hazardous waste cleanup, or bioremediation, has become important. Bioremediation successes have been achieved by using native bacteria to degrade petroleum products, toxic chlorinated herbicides, and toxic biocides. *See* HAZARDOUS WASTE; SEWAGE.

Some of the oldest and most established areas of industrial microbiology concern food and beverage products, such as the production and use of brewer's yeast and baker's yeast. The food industry and the detergent industry are the major users of industrial enzymes produced by microbial fermentation. Detergents, especially in Europe, often contain protein-degrading enzymes (proteases). In the food industry, amylases convert starch to glucose, and glucose isomerase converts glucose to fructose. *See* DETERGENT; FOOD MANUFACTURING. [R.Kor.]

Industrial trucks Manually propelled (handtrucks) or powered carriers for transporting materials over level, slightly inclined, or slightly declined running surfaces. Some industrial trucks can lift and lower their loads, and others can also tier them. In any event, all such trucks maintain contact with the running surface over which they operate and, except when towed by a chain conveyor, follow variable paths of travel as distinct from conveying machines or monorails.

In industry the principle of handling materials in unit loads has developed in parallel with the increased use of powered industrial trucks, particularly the forklift type. These mobile mechanical handling aids have removed the limitations that existed when the weight and size of a load for movement and stacking depended mainly on the ability of a person to lift it manually. The unit-load principle of materials handling underlies the skid-platform and the pallet-forklift methods of operation. Both methods, especially the latter, have revolutionized handling techniques and equipment and even production equipment. [A.M.P.]

Industrial wastewater treatment A group of unit processes designed to separate, modify, remove, and destroy undesirable substances carried by wastewater from industrial sources. United States governmental regulations have been issued that involve volatile organic substances, designated priority pollutants; aquatic toxicity asdefined by a bioassay; and in some cases nitrogen and phosphorus. As a result, sophisticated technology and process controls have been developed for industrial wastewater treatment.

Wastewater streams that are toxic or refractory should be treated at the source, and there are a number of technologies available. For example, wet air oxidation of organic materials at high temperature and pressure (2000 lb/in. or 14 kilopascals and 550°F or 288°C) is restricted to very high concentrations of these substances. Macroreticular (macroporous) resins are specific for the removal of particular organic materials, and the resin is regenerated and used again. Membrane processes, particularly reverse osmosis, are high-pressure operations in which water passes through a semipermeable membrane, leaving the contaminants in a concentrate. *See* HAZARDOUS WASTE; MEMBRANE SEPARATIONS.

Pretreatment and primary treatment processes address the problems of equalization, neutralization, removal of oil and grease, removal of suspended solids, and precipitation of heavy metals. *See* ELECTROCHEMICAL PROCESS; ION EXCHANGE; PH; SEDIMENTATION (INDUSTRY).

Aerobic biological treatment is employed for the removal of biodegradable organics. An aerated lagoon system is applicable (where large land areas are available) for treating nontoxic wastewaters, such as generated by pulp and paper mills. Fixed-film processes include the trickling filter and the rotating biological contactor. In these processes, a biofilm is generated on a surface, usually plastic. As the wastewater passes over the film, organics diffuse into the film, where they are biodegraded. Anaerobic processes are sometimes employed before aerobic processes for the treatment of high-strength, readily degradable wastewaters. The primary advantages of the anaerobic process is low sludge production and the generation of energy in the form of methane (CH_4) gas. *See* BIODEGRADATION; SEWAGE DISPOSAL; SEWAGE TREATMENT.

Biological processes can remove only degradable organics. Nondegradable organics can be present in the influent wastewater or be generated as oxidation by-products in the biological process. Many of these organics are toxic to aquatic life and must be removed from the effluent before discharge. The most common technology to achieve this objective is adsorption on activated carbon. *See* ACTIVATED CARBON; ADSORPTION.

In some cases, toxic and refractory organics can be pretreated by chemical oxidation using ozone, catalyzed hydrogen peroxide, or advanced oxidation processes. In this case the objective is not mineralization of the organics but detoxification and enhanced biodegradability.

Biological nitrogen removal, both nitrification and denitrification, is employed for removal of ammonia from wastewaters. While this process is predictable in the case of municipal wastewaters, many industrial wastewaters are inhibitory to the nitrifying organisms.

Volatile organics can be removed by air or steam stripping. Air stripping is achieved by using packed or tray towers in which air and water counterflow through the tower. In steam stripping, the liquid effluent from the column is separated as an azeotropic mixture. *See* AZEOTROPIC MIXTURE; STRIPPING.

Virtually all of the processes employed for industrial wastewater treatment generate a sludge that requires some means of disposal. In general, the processes employed for thickening and dewatering are the same as those used in municipal wastewater treatment. Waste activated sludge is usually stabilized by aerobic digestion in which the degradable solids are oxidized by prolonged aeration. *See* SEWAGE SOLIDS.

Most landfill leachates have high and variable concentrations of organic and inorganic substances. All municipal and most industrial landfill leachates are amenable to biological treatment and can be treated anaerobically or aerobically, depending on the effluent quality desired. Activated carbon has been employed to remove nondegradable organics. In Europe, some plants employ reverse osmosis to produce a high-quality effluent. *See* WATER POLLUTION. [W.W.E.]

Inert gases The inert gases, listed in the table, constitute group 18 of the periodic table of the elements. They are now better known as the noble gases, since stable compounds of xenon have been prepared. The noble gases are all monatomic.

All these gases occur to some extent in the Earth's atmosphere, but the concentrations of all but argon are exceedingly low. Argon is plentiful, constituting almost 1% of the air.

The inert gases

Name	Symbol	Atomic number	Atomic weight
Helium	He	2	4.0026
Neon	Ne	10	20.183
Argon	Ar	18	39.948
Krypton	Kr	36	83.80
Xenon	Xe	54	131.30
Radon	Rn	86	(222)

All the gases are colorless, odorless, and tasteless. They are all slightly soluble in water, the solubility increasing with increasing molecular weight. They can be liquefied at low temperatures, the boiling point being proportional to the atomic weight. All but helium can be solidified by reducing the temperature sufficiently, and helium can be solidified at temperatures of less than 2°F above absolute zero (0–1 K) by the application of an external pressure of 25 atm (2.5 megapascals) or more. *See* ARGON; HELIUM; KRYPTON; NEON; RADON; XENON. [A.W.F.]

Inertia That property of matter which manifests itself as a resistance to any change in the motion of a body. Thus when no external force is acting, a body at rest remains at rest and a body in motion continues moving in a straight line with a uniform speed (Newton's first law of motion). The mass of a body is a measure of its inertia. *See* MASS. [L.N.]

Inertia welding A welding process used to join similar and dissimilar materials at very rapid speed. It is, therefore, a very attractive welding process in mass production of good-quality welds. The ability to join dissimilar materials provides further flexibility in the design of mechanical components. The automotive and truck industry is the major user of this process.

Inertia welding is a type of friction welding which utilizes the frictional heat generated at the rubbing surfaces to raise the temperature to a degree that the two parts can be forged together to form a solid bond. The energy required for inertia welding comes from a rotating flywheel system built into the machine. Like an engine lathe, the inertia welding machine has a headstock and a tailstock. One workpiece held in the spindle chuck (usually with an attached flywheel) is accelerated rapidly, while the other is clamped in a stationary holding device of the tailstock. When a predetermined spindle speed is reached, the drive power is cut and the nonrotating part on the tailstock is pushed against the rotating part under high pressure. Friction between the rubbing surfaces quickly brings the spindle to a stop. At the same time the stored kinetic energy in the flywheel is converted into frictional heat which raises the temperature at the interface high enough to forge the two parts together without melting. [K.K.W.]

Inertial guidance system A self-contained system which can automatically determine the position, velocity, and attitude of a moving vehicle for the purpose of directing its future course. Based on prior knowledge of time, gravitational field, initial position, initial velocity, and initial orientation relative to a known reference frame, an inertial guidance system is capable of determining its present position, velocity, and orientation without the aid of external information. The generated navigational data are used to determine the future course for a vehicle to follow in order to bring it to its destination. Such systems have found application in the guidance and control of submarines, ships, aircraft, missiles, and spacecraft. *See* GUIDANCE SYSTEMS. [W.E.H.]

Infant diarrhea Diarrhea and its complications are the most important causes of infant death in most developing regions. The causes of the illness vary from dietary incompatabilities to intestinal infection. The most important infectious causes are, in approximate order of importance: rotavirus, the bacteria *Shigella* (causing dysentery) and *Salmonella*, the parasite *Giardia lamblia*, and enteropathogenic *Escherichia coli* bacteria (a common cause of hospital nursery outbreaks). Breast-feeding is associated with a decreased occurrence of diarrhea and represents a major means of preventing infantile diarrhea in the developing world. *See* DIARRHEA. [H.L.D.]

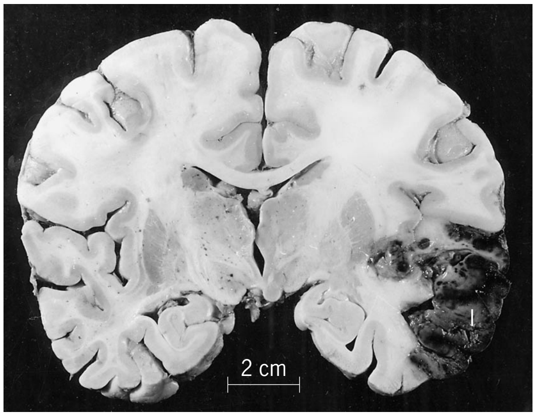
Infant respiratory distress syndrome A common disorder of premature (or preterm) birth, defined by respiratory difficulty (including rapid respiration, retractions of the rib cage, nasal flaring, grunting or whining upon exhaling, and a bluish discoloration of the skin and mucous membranes), which requires oxygen or assisted ventilation, and a characteristic on chest x-ray showing a uniform, diffuse haziness of both lungs due to their poor aeration. It is primarily the result of deficiency in surface-active lipids (contained within pulmonary surfactant) which serve to stabilize the air spaces (alveoli) within the lung. Although cases of infant respiratory distress syndrome rarely result in a fatal outcome in developed countries, all require specialized care in a neonatal intensive care unit. The incidence of respiratory distress syndrome increases with greater prematurity as well as with maternal diabetes and asphyxia around the time of delivery.

Prevention of prematurity and administration of good prenatal care reduce the incidence of infant respiratory distress syndrome. Corticosteroids given before birth to the mother at risk for premature delivery is a well-established therapy for reducing the incidence of respiratory distress syndrome; this treatment enhances pulmonary maturation in the infant.

Surfactant therapy is now widely used for treatment of infants with moderate or severe respiratory distress syndrome. This requires introducing a tube into the trachea for direct placement of surfactant into the infant's lungs; this is done one or more times over the first 48 h of life. Surfactant therapy must be performed in conjunction with conventional treatment such as maintenance of an optimal-temperature environment and use of intravenous fluids. *See* RESPIRATORY SYSTEM DISORDERS. [R.J.Ma.]

Infarction The process of anoxic tissue death. The usual cause is occlusion of an artery by a thrombus or embolus and sometimes by severe atherosclerosis. The development of the infarct depends to a great extent on the collateral circulation. If the collateral blood supply is inadequate or if the vessel is the sole source of blood supply to the region, an infarct results. *See* ARTERIOSCLEROSIS; THROMBOSIS.

Infarcts commonly occur in the lungs, heart, brain (see illustration), spleen, and kidneys. The common cause of infarcts of the heart is thrombosis of the coronary artery, usually secondary to atherosclerosis. Hemorrhage into an atherosclerotic plaque can also result in thrombosis of an artery. Myocardial infarcts usually involve the left ventricle or interventricular septum and only rarely involve the right ventricle or atria. The location of the infarct usually depends on the coronary artery occluded. *See* HEART DISORDERS.



Gross photograph of a brain section, showing a wedge-shaped infarct that resulted from a thrombus. Secondary hemorrhage has occurred.

Infarction of a portion of bowel will result in death unless surgical intervention is forthcoming. Embolization to the lungs is a rather frequent occurrence. However, because of the collateral blood supply of the lungs, infarction follows only when there is some interference with the circulation, such as chronic pulmonary venous congestion. An extensive collateral circulation also exists in the liver, hence the rarity of infarcts in this organ. *See* CIRCULATION DISORDERS. [R.A.V.; I.N.]

Infection A term considered by some to mean the entrance, growth, and multiplication of a microorganism (pathogen) in the body of a host, resulting in the establishment of a disease process. Others define infection as the presence of a microorganism in host tissues whether or not it evolves into detectable pathologic effects. The host may be a bacterium, plant, animal, or human being, and the infecting agent may be viral, rickettsial, bacterial, fungal, or protozoan.

A differentiation is made between infection and infestation. Infestation is the invasion of a host by higher organisms such as parasitic worms. *See* EPIDEMIOLOGY; HOSPITAL INFECTIONS; MEDICAL BACTERIOLOGY; MEDICAL MYCOLOGY; MEDICAL PARASITOLOGY; OPPORTUNISTIC INFECTIONS; PATHOGEN; VIRUS. [D.N.La.]

Infectious disease A pathological condition spread among biological species. Infectious diseases, although varied in their effects, are always associated with viruses, bacteria, fungi, protozoa, multicellular parasites and aberrant proteins known as prions. A complex series of steps, mediated by factors contributed by both the infectious agent and the host, is required for microorganisms or prions to establish an infection or disease. Worldwide, infectious diseases are the third leading cause of human death.

The most common relationship between a host and a microorganism is a commensal one, in which advantages exist for both organisms. For example, hundreds of billions of bacteria of many genera live in the human gastrointestinal tract, coexisting in ecological balance without causing disease. These bacteria help prevent the invasion of the host by more virulent organisms. In exchange, the host provides an environment in which harmless bacteria can readily receive nutrients. There are very few microorganisms that cause disease every time they encounter a host. Instead, many factors of both host and microbial origin are involved in infectious disease. These factors include the general health of the host, previous exposure of the host to the microorganism, and the complement of molecules produced by the bacteria.

Spread of a pathogenic microorganism among individual hosts is the hallmark of an infectious disease. This process, known as transmission, may occur through four major pathways: contact with the microorganism, airborne inhalation, through a common vehicle such as blood, or by vector-borne spread.

The manner in which an infectious disease develops, or its pathogenesis, usually follows a consistent pattern. To initiate an infection, there must be a physical encounter as which the microorganism enters the host. The most frequent portals of entry are the respiratory, gastrointestinal, and genitourinary tracts as well as breaks in the skin. Surface components on the invading organism determine its ability to adhere and establish a primary site of infection. The cellular specificity of adherence of microorganisms often limits the range of susceptible hosts. For example, although measles and distemper viruses are closely related, dogs do not get measles and humans do not get distemper. From the initial site of infection, microorganisms may directly invade further into tissues or travel through the blood or lymphatic system to other organs.

Microorganisms produce toxins that can cause tissue destruction at the site of infection, can damage cells throughout the host, or can interfere with the normal metabolism of the host. The damage that microorganisms cause is directly related to the toxins they produce. Toxins are varied in their mechanism of action and host targets. *See* CHOLERA; STAPHYLOCOCCUS; TETANUS.

The host's reaction to an infecting organism is the inflammatory response, the body's most important internal defense mechanism. Although the inflammatory response is also seen as secondary to physical injury and nonspecific immune reactions, it is a reliable indicator of the presence of pathogenic microorganisms. Immune cells known as lymphocytes and granulocytes are carried by the blood to the site of infection. These cells either engulf and kill, or secrete substances which inhibit and neutralize, microorganisms. Other white blood cells, primarily monocytes, recognize foreign organisms and transmit chemical signals to other cells of the host's immune system, triggering the production of specific antibodies or specialized killer cells, both of which are lethal to the infecting microorganism. Any influence that reduces the immune system's ability to respond to foreign invasion, such as radiation therapy, chemotherapy, or destruction of immune cells by an immunodeficiency virus such as HIV, increases the likelihood that a organism will cause disease within the host. *See* INFLAMMATION.

Chemical compounds that are more toxic to microorganisms than to the host are commonly employed in the prevention and treatment of infectious disease; however, the emergence of drug-resistant organisms has led to increases in the morbidity and mortality associated with some infections. Other methods for controlling the spread of infectious diseases are accomplished by breaking a link in the chain of transmission between the host, microorganism, and mode of spread by altering the defensive capability of the host. Overall, the three most important advances to extend human life are clean water, vaccination, and antibiotics (in that order of importance).

Water-borne infections are controlled by filtration and chlorination of municipal water supplies. Checking food handlers for disease, refrigeration, proper cooking, and eliminating rodent and insect infestation have markedly reduced the level of food poisonings. The transmission of vector-borne diseases can be controlled by eradication of the vector. Blood-borne infections are reduced by screening donated blood for antibodies specific for HIV and other viruses and by rejecting donations from high-risk donors. For diseases such as tuberculosis, the airborne spread of the causative agent, *Mycobacterium tuberculosis*, can be reduced by quarantining infected individuals. The spread of sexually transmitted diseases, including AIDS, syphilis, and herpes simplex, can be prevented by inhibiting direct contact between the pathogenic microorganism and uninfected hosts. *See* ACQUIRED IMMUNE DEFICIENCY SYNDROME (AIDS); FOOD POISONING; VACCINATION; WATER-BORNE DISEASE. [P.J.McN.]

Infectious mononucleosis A disease of children and young adults, characterized by fever and enlarged lymph nodes and spleen. EB (Epstein-Barr) herpesvirus is the causative agent.

Onset of the disease is slow and nonspecific with variable fever and malaise; later, cervical lymph nodes enlarge, and in about 50% of cases the spleen also becomes enlarged. The disease lasts 4–20 days or longer. Epidemics are common in institutions where young people live. EB virus infections occurring in early childhood are usually asymptomatic. In later childhood and adolescence, the disease more often accompanies infection—although even at these ages inapparent infections are common. *See* EPSTEIN-BARR VIRUS. [J.L.Me.]

Infectious myxomatosis A viral disease of European rabbits (*Oryctolagus*) and domestic rabbits, spread mainly by biting insects (mosquitoes and rabbit fleas) and characterized by edematous swellings of the skin, particularly on the head and anogenital area. The disease is caused by infection with myxoma virus, a pox virus, which occurs naturally in certain species of the genus *Sylvilagus* in North, Central, and South America. In these rabbits, infection results generally in localized, nonmalignant tumors that disappear in weeks or months. There is no effective treatment once clinical signs have appeared. Preventive measures include restriction of contact with insect vectors and vaccination with active or inactivated myxoma virus or with Shope fibroma virus. *See* ANIMAL VIRUS. [J.Ro.]

Infectious papillomatosis A nonfatal viral disease that occurs naturally in cottontail rabbits in states bordering the Mississippi River as well as in Oklahoma and Texas, and in brush rabbits in California. Cottontail rabbits from other parts of the United States and domestic rabbits (*Oryctolagus*) are also susceptible. The disease is caused by infection with Shope papilloma virus; it is spread naturally by contamination of broken skin or by the rabbit tick. The disease is characterized by cutaneous warts (papillomas) which can persist for months or years, sometimes becoming very prominent. Rabbits can be immunized against papillomatosis by injection of active or inactivated virus. *See* ANIMAL VIRUS. [J.Ro.]

Infertility Inability to conceive or induce conception. Of all cases of infertility, 35% may be attributed to the male and 55% to the female; the remaining 10% is undetermined.

The principal cause of increasing rates of infertility is the postponement of pregnancy: adverse effects of increasing age on reproductive capacity include decreased conception rates and increased pregnancy losses. The increasing incidence of pelvic inflammatory disease is also thought to be a major cause. Pelvic infections lead to scar formation around the ovaries and the fallopian tubes, thereby impeding the transport of oocytes for fertilization.

Ovulatory dysfunction accounts for approximately 20% of cases of infertility. Ovulation is dependent on the timely secretion of the two gonadotropic hormones from the pituitary gland, follicle-stimulating hormone (FSH) and luteinizing hormone (LH). Gonadotropic hormone release can be impeded by certain medications and by many disease states, including stress, anorexia nervosa, weight loss, and thyroid disease. Anovulation can be treated by replacing the deficient gonadotropins with human menopausal gonadotropin, a mixture of follicle-stimulating and luteinizing hormones. In addition, the drug clomiphene citrate increases the endogenous secretion of those hormones from the pituitary gland. *See* ENDOCRINE MECHANISMS; PITUITARY GLAND.

Fallopian tube and uterine abnormalities account for 25% of the cases of infertile couples. These abnormalities include defective development as well as scar formation after surgery or infection. Not uncommonly the region of the fallopian tube closest to the uterus may be obstructed by scar tissue, but the obstruction can be microscopically removed or the fallopian tube can be surgically cut and reconnected.

In endometriosis, tissue that normally lines the uterus is found on the pelvic lining. Severe forms of endometriosis involve the ovaries and fallopian tubes, which doubles the likelihood of infertility in those women. The condition is treated either by surgical excision of the aberrant tissue or by subsequent medical treatment. *See* OVARIAN DISORDERS.

Abnormalities in cervical mucus production may result from trauma, surgery, and diethylstilbestrol (DES) exposure before birth. The treatment of cervical abnormalities remains controversial, but may include estrogen; or another approach is to bypass this obstruction by using intrauterine transfer of semen (artificial insemination).

Male infertility resulting from abnormal semen may be due to developmental defects, genitourinary infections, or varicocele. An evaluation of sperm count, motility, and morphology is helpful, but in most cases the cause of the abnormality remains undetermined. No treatment other than donor insemination is available for these couples.

In approximately 10% of infertile couples, a thorough evaluation reveals no cause, and unexplained infertility is diagnosed. In nearly 50% of women with unexplained infertility, pelvic abnormalities are found and are most often caused by endometriosis and scar formation.

One method of assisted reproduction is in vitro fertilization, which takes place through the controlled hyperstimulation of ovulation followed by surgical extraction of mature oocytes from the ovaries. In another method of assisted reproduction, gamete intrafallopian tube transfer (GIFT), ovulation is stimulated, as with in vitro fertilization, but the extracted oocytes are placed directly into the fallopian tube with the semen specimen. Incubation occurs within the fallopian tube rather than outside the body. *See* FERTILIZATION; PREGNANCY; REPRODUCTIVE SYSTEM; REPRODUCTIVE SYSTEM DISORDERS; REPRODUCTIVE TECHNOLOGY. [R.E.Le.; R.D.K.]

Infinity The terms infinity and infinite have a variety of related meanings in mathematics. The adjective finite means "having an end," so infinity may be used to refer to something having no end. In order to give a precise definition, the mathematical domain of discourse must be specified.

Set theory provides a simple and basic example of an infinite collection—the class of natural numbers, or positive integers. A fundamental property of positive integers is that after each integer there follows a next one, so that there is no last integer. Now it is necessary in mathematics to treat the collection of all positive integers as an entity, and this entity is the simplest infinity, or infinite collection.

The term infinity appears in mathematics in a different sense in connection with limits of functions. For example, consider the function defined by $y = 1/x$. When x tends to 0, y approaches infinity, and the expression may be written as shown below.

$$\lim_{x\to 0} y = \infty$$

Precisely, this means that for an arbitrary number $a > 0$, there exists a number $b > 0$ such that when $0 < x < b$, then $y > a$, and when $-b < x < 0$, then $y < -a$. This example indicates that it is sometimes useful to distinguish $+\infty$ and $-\infty$. The points $+\infty$ and $-\infty$ are pictured at the two ends of the y axis, a line which has no ends in the proper sense of euclidean geometry.

In geometry of two or more dimensions, it is sometimes said that two parallel lines meet at infinity. This leads to the conception of just one point at infinity on each set of parallel lines and of a line at infinity on each set of parallel planes. With such agreements, parts of euclidean geometry can be discussed in the terms of projective geometry. For example, one may speak of the asymptotes of a hyperbola as being tangent to the hyperbola at infinity. [L.M.G.]

Inflammation The local response to injury, involving small blood vessels, the cells circulating within these vessels, and nearby connective tissue.

The early phases of the inflammatory response are stereotyped: A similar sequence of events occurs in a variety of tissue sites in response to a diversity of injuries. The response characteristically begins with hyperemia, edema, and adherence of the circulating white blood cells to endothelial cells. The white cells then migrate between the endothelial cells of the blood vessel into the tissue. The subsequent development of the inflammatory process is determined by factors such as type and location of injury, immune state of the host, and the use of therapeutic agents. *See* Circulation; Edema.

A local inflammatory response is usually accompanied by systemic changes: fever, malaise, an increase in circulating leukocytes (leukocytosis), and increases in specific circulating proteins called acute-phase reactants. Such signals and symptoms are often helpful to the physician, first as clues to the presence of inflammation and later as an indication of its course.

The process of inflammation, both vascular and cellular, is orchestrated by an array of molecules produced locally. These mediators include histamine, leukotrienes, prostaglandins, complement components, kinins, antibodies, and interleukins. Many anti-inflammatory drugs function by preventing the formation of those mediators or by blocking their actions on the target cells whose behavior is modified by the mediators.

Inflammation is basically a protective mechanism. The leakage of water and protein into the injured area brings humoral factors, including antibodies, into the locale and may serve to dilute soluble toxic substances and wash them away. The adherence and migration of leukocytes brings them to the local site to deal with infectious agents. There are also instances in which no causative toxic substance or infectious agent can be found to account for the inflammation. This is the case in rheumatoid arthritis and rheumatic fever. Such diseases may be examples in which an uncontrolled or misdirected inflammatory response with an autoimmune component is turned against the host. *See* Arthritis; Autoimmunity; Infection; Rheumatic fever. [D.L.]

Inflammatory bowel disease Inflammatory bowel disease is a general term for two closely related conditions, ulcerative colitis and Crohn's disease. The diseases can affect the colon, distal, small intestine and sometimes other portions of the gastrointestinal tract as well as several sites outside the gastrointestinal tract. In 15–25% of cases limited to the colon, ulcerative colitis and Crohn's disease cannot be distinguished by clinical manifestations, x-ray examination, or even pathology. For this reason the broad term inflammatory bowel diseases is useful. The cause of these diseases is unknown.

Ulcerative colitis, an inflammatory condition limited to the colon, primarily affects the mucosa or lining of the colon. Marked inflammation gives rise to small ulcerations and microscopic abscesses that produce bleeding. The condition tends to be chronic, alternating between periods of complete remission and episodes of active and even life-threatening disease.

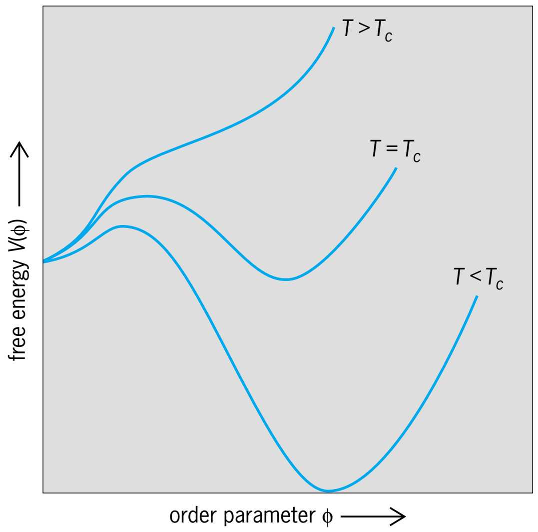
Crohn's disease, also known as regional enteritis, granulomatous colitis, and terminal ileitis, affects the colon and small intestine, and rarely the stomach or esophagus. Like ulcerative colitis, it is chronic and of unknown etiology. *See* Digestive system. [L.A.Ka.]

Inflationary universe cosmology A theory of the evolution of the early universe, motivated by considerations from elementary particle physics as well as certain paradoxes of standard big bang cosmology, which asserts that at some early time the observable universe underwent a period of exponential, or otherwise superluminal, expansion. During this inflationary epoch the scale of the universe increased by at least 28 orders of magnitude.

"Old" inflationary model. The suggestion of an inflationary period during the early universe, in connection with a specific model, was first made in 1980 by A. Guth. Guth reasoned that if grand unified symmetries are broken at some large energy scale, then a phase transition could occur in the early universe as the temperature cooled below the critical temperature where symmetry breaking occurs. According to the standard big bang model of expansion, the time at which this would occur would be about 10^{-35} s after the initial expansion had begun. *See* Grand unification theories; Phase transitions; Symmetry breaking; Symmetry laws (physics).

As Guth demonstrated, the effects of such a phase transition in the early universe could be profound. In order to calculate the dynamics of a phase transition it is necessary to follow the behavior of the relevant order parameter for the transition. This is done by determining the free energy of a system as a function of the order parameter, and following the changes in this energy as the temperature changes. The illustration shows a typical example of what might be expected for the case of symmetry breaking in grand unification theories. At some high temperature T the minimum of the relevant function is at zero value of the order parameter, the vacuum expectation value of a certain field. Thus the ground state of the system, which occurs when this energy is a minimum, will be the symmetric ground state. As the temperature is decreased, however, at a certain critical temperature T_c, a new minimum of the energy appears at a nonzero value of the order parameter. This is the symmetry-breaking ground state of the system. *See* Free energy.

In the illustration it is seen that there is a barrier between the two minima. This means that classically the system cannot make a transition between the two states. However, it is a well-known property of quantum mechanics that the system can, with a certain very small probability, tunnel through the barrier and arrive in the new phase. Such a transition is called a first-order phase transition. Because the probability of such a tunneling process is small the system can remain for a long time in the symmetric phase before the transition occurs. This phenomenon is called supercooling. When the transition finally begins, "bubbles" of new phase locally appear throughout the original phase. As more and more bubbles form, and the original bubbles grow, eventually they combine and coalesce until all of the system is in the new phase. *See* Quantum mechanics.



Free energy as a function of the order parameter for the case of a first-order transition.

The metastable symmetric phase has a higher energy than the new lower energy symmetry breaking phase. Until the transition occurs, this means that the symmetric phase has associated with it a large constant energy density, independent of temperature. When this constant energy density is placed on the right hand side of Einstein's equations, where the energy density of matter appears, it is found that the resultant Hubble parameter describing expansion is a constant. Mathematically this implies that the scale size of the universe increases exponentially during this supercooling phase. This rapid expansion is what is referred to as inflation. *See* HUBBLE CONSTANT; RELATIVITY.

Successes of inflation. Guth pointed out that a period of exponential expansion at some very early time could solve a number of outstanding paradoxes associated with standard big bang cosmology.

Present observations seem to imply that either the present era is a unique time in the big bang expansion, or else the initial conditions of expansion had to be fine-tuned to an incredible degree. Measurements of the observed expansion rate combined with measurements of the observed mass density of the universe yield a value for the density parameter Ω which rapidly approaches zero for an open universe, infinity for a closed universe, and is exactly equal to one for a flat universe. All measurements of Ω yield values between about 0.1 and 2. However, theory suggests that once the value of Ω deviates even slightly from one, it very quickly approaches its asymptotic value far away from one for open or closed universes. Thus, it is difficult to understand why, after 10^{10} years of expansion, the value of Ω is now so close to one.

Inflation naturally explains why Ω should exactly equal one in the observable universe today. During inflation $\Omega(t)$ is driven arbitrarily close to one within the inflated region. If there are some 28 orders of magnitude of exponential expansion, then $\Omega(t)$ need not have been finely tuned to be close to one.

An equally puzzling problem which inflationary cosmology circumvents has to do with the observed large-scale uniformity of the universe. In particular, the 3-K microwave radiation background is known to be uniform in temperature to about one part in 10,000. However, in the standard big bang model the sources of this radiation observed coming from opposite directions in the sky were separated by more than 90 times the horizon distance (the distance a light ray could have travelled since the big bang explosion) at the time of emission. Since these regions could not possibly have been in physical contact, it is difficult to see why the temperature at the time of emission was so uniform in all directions. *See* COSMIC BACKGROUND RADIATION.

Inflation solves the horizon problem very simply. If the observed universe expanded by 28 orders of magnitude, then it originated from a region 10^{28} times smaller than the comparable region in the standard big-bang model. This makes it quite possible that at early times the entire observed universe was contained in a single horizon volume.

Unfortunately, the original inflationary scenario was fundamentally flawed. The phase transition began by the formation of bubbles of one phase nucleating amidst the initial metastable phase of matter. While these bubbles grow at the speed of light once they form, the space in between the bubbles is expanding exponentially. Thus, it is extremely difficult for bubbles to eventually occupy all of space, as is required for the completion of the transition.

"New" inflationary cosmology. In 1981, it was suggested that if the energy function (potential) of the illustration were slightly changed then it might be possible to maintain the successful phenomenology of the old inflationary model while avoiding its problems. In particular a special form of the potential was considered which is extremely flat at the origin. Such functions have essentially no barrier separating the metastable from the stable phase at low temperature. When the universe cooled down below the critical temperature, the order parameter could continuously increase from zero instead of tunnelling discretely to a large nonzero value. As long as the potential is sufficiently flat near the origin, however, it can take a long time before the order parameter approaches its value at the true minimum of the potential (a so-called slow-rollover transition). During this time the region of interest can again be expanding exponentially. Thus, in some sense a single bubble can undergo inflation in this scenario.

New inflation, too, is not without its problems. In order to have such a slow-rollover transition, the parameters of particle physics models must be finely tuned to some degree. No clear candidate model for new inflation has emerged from particle physics.

Another potential problem for any inflationary scenario concerns initial conditions. As discussed above, if an inflationary phase precedes the standard big bang expansion, then it is possible to resolve problems of the standard big bang model related to the unphysical fine tunings that seem necessary at time zero in order for the big bang to evolve into its presently observed form. However, if the initial preinflationary conditions are unphysical, then inflation may not have really solved any fundamental problems.

In 1983, Linde proposed a version of inflation, which he called chaotic inflation, that may in principle address this issue. He argued that the early universe may have been arbitrarily inhomogeneous. In some regions, inflation may have successfully taken place, even without the spontaneous symmetry breaking associated with a grand unified theory, and in other regions it may not have. He then suggested that the regions in which inflation did take place are in fact most probable. In addition, he pointed out that life would form only in those regions that became sufficiently isotropic so that, if many different regions of the universe now exist, it is not surprising that humans live in one that has undergone inflation. The issue of initial conditions for inflation remains the subject of much research, but may require an understanding of quantum gravity for its eventual resolution. *See* CHAOS; QUANTUM GRAVITATION.

Primordial fluctuations. It has been demonstrated that new inflationary cosmology naturally allows a derivation from first principles of the spectrum of primordial energy density fluctuations responsible for galaxy formation. The spectrum that emerges from inflationary models is a so-called scale-invariant spectrum of perturbations. The first observation of anisotropies in the microwave background was announced in 1992, based on the analysis of data from the differential microwave radiometer experiment aboard the *Cosmic Background Explorer* (*COBE*) satellite. A quadrupole anisotropy in the background was observed at a level of about 5×10^{-6}, just in the range that might be expected for primordial fluctuations from inflation that might also result in the observed distribution of galaxies. Moreover, the correlation of temperature deviations observed across the sky on scales greater than about 10° is remarkably consistent with the scale-invariant spectrum predicted by inflationary models. While neither of these observations conclusively proves the existence of an inflationary phase in the early universe, the fact that they are clearly consistent with such a possibility, and at present with no other scenario, gives great confidence that inflationary models may provide the correct description of the universe in the era preceding the present observed isotropic expansion.

Open inflation and a cosmological constant. Since 1995 it has been increasingly clear, based on measurements of the total clustered mass in the universe in galaxies and clusters of galaxies, that there is not sufficient matter to result in a flat universe today. There are two possibilities. The first possibility is that the universe is not flat but open. While this would deal a severe blow to standard inflationary models, a number of groups have proposed inflationary models, called open inflation models, which are tuned so that there is sufficient inflation to solve the horizon problem but not enough to result in a flat universe. The second possibility is that matter accounts for only part of the total energy density of the universe, with the remainder being associated with some new form of energy, possibly energy stored in the ground state of empty space, called a cosmological constant. This energy is in fact identical to the energy which is stored during the inflationary phase itself. If this is true, then we live in an inflationary universe today. Preliminary measurements of the expansion rate of the universe as a function of cosmic time, by observing the recession velocities of certain types of exploding stars, called type 1a supernovae in very distant galaxies, in fact argue that this is precisely the case. Other current data favors the second possibility, including ground-based measurements of the cosmic microwave background anisotropies on small scales, the distribution of which suggests a flat universe rather than an open one. *See* BIG BANG THEORY; COSMOLOGY; SUPERNOVA; UNIVERSE. [L.M.Kr.]

Inflorescence A flower cluster segregated from any other flowers on the same plant, together with the stems and bracts (reduced leaves) associated with it. Certain plants produce inflorescences, whereas others produce only solitary flowers. *See* FLOWER. [G.J.W.]

Influenza An acute respiratory viral infection characterized by fever, chills, sore throat, headache, body aches, and severe cough. The term flu, which is frequently used incorrectly for various respiratory and even intestinal illnesses (such as stomach flu), should be used only for illness with these classic symptoms. The onset is typically abrupt, in contrast to common colds which begin slowly and progress over a period of days. Influenza is usually epidemic in occurrence. The first documented pandemic, or global epidemic, of influenza is considered to have been in 1580. The influenza pandemic of 1918, the most famous occurrence, was responsible for at least 20 million deaths worldwide.

The three types of influenza viruses, types A, B, and C, are classified in the virus family Orthomyxoviridae, and they are similar, but not identical, in structure and morphology. Types A and B are more similar in physical and biologic characteristics to each other than they are to type C. Influenza viruses may be spherical or filamentous in shape, and they are of medium size among common viruses of humans. *See* ANIMAL VIRUS.

When a cell is infected by two similar but different viruses of one type, especially type A, various combinations of the original parental viruses may be packaged or assembled into the new progeny; thus, a progeny virus may be a mixture of gene segments from each parental virus and therefore may gain a new characteristic, for example, a new surface protein. This phenomenon is called genetic reassortment, and the frequency with which it occurs and leads to viruses with new features is a significant cause of the constant appearance of new variants of the virus. In the laboratory, reassortment occurs between animal and human strains as well as between human strains. It probably occurs in nature also, and is thought to contribute to the appearance of new strains that infect humans. Generally, if a new variant is sufficiently different from the vaccine currently in use, the vaccine will provide limited or no protection.

The influenza virus has a short incubation period; that is, there is only a period of 1–3 days between infection and symptoms, and this leads to the abrupt development of symptoms that is a hallmark of influenza infections. The virus is typically shed in the throat for 5–7 days. Complete recovery from uncomplicated influenza usually takes several days, and the individual may feel weak and exhausted for a week or more after the major symptoms disappear. The two main complications of influenza are primary influenza virus pneumonia and secondary bacterial pneumonia. Primary influenza pneumonia is relatively infrequent, occurring in less than 1% of cases during an epidemic, although mortality may be 25–30%. The damage to epithelial cells and subsequent loss of the ability to clear particles from the respiratory tract can lead to secondary bacterial pneumonia. This problem commonly occurs in elderly individuals or those with underlying chronic lung disease or similar problems. Influenza-induced pneumonia may cause as many as 20,000 deaths in a typical influenza season. Another complication, known as Reye's syndrome, may follow influenza, and is more common in children. This disease of the brain develops within 2–12 days of a systemic viral infection, and can result in vomiting, liver damage, coma, and sometimes death.

All three types of influenza viruses can cause disease in humans, but there are significant differences in severity of the disease and the range of hosts. In contrast to the large number of animal species infected by type A virus, types B and C are only rarely isolated from animals and infect predominantly humans.

The presence or absence of antibodies is very important in the epidemiology of influenza. In individuals with no immunity, attack rates may reach 70% and severe illness may result. Even low levels of antibody may provide partial protection in an individual and decrease the severity of the illness to only coldlike symptoms.

During an epidemic, one strain of influenza is predominant, but it is not unusual for two or more other strains to be present as minor infections in a population. Outbreaks of influenza occur during cold-weather months in temperate climates, and typically most cases cluster on a period of 1–2 months, in contrast to broader periods of illness with many other respiratory viruses. An increased death rate due to primary pneumonia and bacterial superinfection is common and is one of the ways that public health authorities monitor an epidemic.

Control and prevention of influenza are attempted through the use of drugs and vaccines. Inactivated viral vaccines are used to prevent influenza, although use of attenuated live strains of the virus may better stimulate the cell-mediated immune response and provide higher-quality and longer-lasting immunity. The makeup of the vaccine is modified annually, based upon predictions of the expected prevalent strain for each flu season, but usually contains antigens of two type A viruses and one type B virus. These vaccines take advantage of the natural ability of the viral nucleic acid to reassort and form new strains. The vaccines utilize strains that are not virulent and will replicate at lower temperatures, as found in the nasopharnyx, but not at higher temperatures as found in the lower respiratory tract. The techniques of modern biotechnology are employed to clone copies of parts of the virus or to provide oligonucleotides corresponding to crucial functional areas of the virus, to obtain improved protection and reduced side effects. *See* BIOTECHNOLOGY; VACCINATION. [J.M.Q.]

Information management The functions associated with managing the information assets of an enterprise, typically a corporation or government organization. Increasingly, companies are taking the view that information is an asset of the enterprise in much the same way that a company's financial resources, capital equipment, and real estate are assets. Properly employed, assets create additional value with a measurable return on investment. Forward-looking companies carry this view a step further, considering information as a strategic asset that can be leveraged into a competitive advantage in the markets served by the company.

The scope of the information management function may vary between organizations. As a minimum, it will usually include the origination or acquisition of data, its storage in databases, its manipulation or processing to produce new (value-added) data and reports via application programs, and the transmission (communication) of the data or resulting reports. Many companies include the management of voice communications (telephone systems, voice messaging, and, increasingly, computer-telephony integration or CTI), and even intellectual property and other knowledge assets.

There is a significant difference between the terms "data" and "information." Superficially, information results from the processing of raw data. However, the real issue is getting the right information to the right person at the right time and in a usable form. In this sense, information may be a perishable commodity. Thus, perhaps the most critical issue facing information managers is requirements definition, or aligning the focus of the information systems with the mission of the enterprise. The best technical solution is of little value if the final product fails to meet the needs of users.

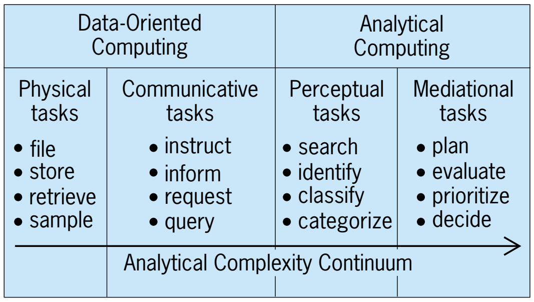
One formal approach to determining requirements is information engineering. By using processes identified variously as business systems planning or information systems planning, information engineering focuses initially on how the organization does its business, identifying the lines from where information originates to where it is needed, all within the context of a model of the organization and its functions. While information systems personnel may be the primary agents in the information engineering process, success is critically dependent on the active participation of the end users, from the chief executive officer down through the functional staffs.

A major advantage of the application of information engineering is that it virtually forces the organization to address the entire spectrum of its information systems requirements, resulting in a functionally integrated set of enterprise systems. In contrast, ad hoc requirements may result in a fragmented set of systems (islands of automation), which at their worst may be incompatible, contain duplicate (perhaps inconsistent) information, and omit critical elements of information. [A.B.Sa.]

Information systems engineering The process by which information systems are designed, developed, tested, and maintained. The technical origins of information systems engineering can be traced to conventional information systems design and development, and the field of systems engineering. Information systems engineering is by nature structured, iterative, multidisciplinary, and applied. It involves structured requirement analyses, functional modeling, prototyping, software engineering, and system testing, documentation, and maintenance.

Modern information systems solve a variety of data, information, and knowledge-based problems. In the past, most information systems were exclusively data-oriented; their primary purpose was to store, retrieve, manipulate, and display data. Application domains included inventory control, banking, personnel record keeping, and the like. The airline reservation system represents the quintessential information system of the 1970s. Since then, expectations as to the capabilities of information systems have risen considerably. Information systems routinely provide analytical support to users. Some of these systems help allocate resources, evaluate personnel, and plan and simulate large events and processes. The users expect information systems to perform all the tasks along the continuum shown in the illustration.

Systems engineering extends over the entire life cycle of systems, including requirement definitions, functional designs, development, testing, and evaluation. The systems engineer's perspective is different from that of the product engineer, software designer, or technology developer. The product engineer deals with detail, whereas the systems engineer takes an overall viewpoint. Systems engineering is based upon the traditional skills of the engineer combined with additional skills derived from applied mathematics, psychology, management, and other disciplines. The systems engineering process is a logical sequence of activities and decisions that transform operational needs into a description of system performance configuration. The process is by nature iterative and multidisciplinary. *See* SYSTEMS ENGINEERING. [S.J.A.]



Data-oriented and analytical computing, suggesting the range of information systems applications.

Information technology The field of engineering involving computer-based hardware and software systems, and communication systems, to enable the acquisition, representation, storage, transmission, and use of information. Successful implementation of information technology (IT) is dependent upon being able to cope with the overall architecture of systems, their interfaces with humans and organizations, and their relationships with external environments. It is also critically dependent on the ability to successfully convert information into knowledge.

Information technology is concerned with improvements in a variety of human and organizational problem-solving endeavors through the design, development, and use of technologically based systems and processes that enhance the efficiency and effectiveness of information in a variety of strategic, tactical, and operational situations. Ideally, this is accomplished through critical attention to the information needs of humans in problem-solving tasks and in the provision of technological aids, including electronic communication and computer-based systems of hardware and software and associated processes. Information technology complements and enhances traditional engineering through emphasis on the information basis for engineering.

The knowledge and skills required in information technology come from the applied engineering sciences, especially information, computer, and systems engineering sciences, and from professional practice. Professional activities in information technology and in the acquisition of information technology systems range from requirements definition or specification, to conceptual and functional design and development of communication and computer-based systems for information support. They are concerned with such topics as architectural definition and evaluation. These activities include integration of new systems into functionally operational existing systems and maintenance of the result as user needs change over time. This human interaction with systems and processes, and the associated information processing activities, may take several diverse forms. *See* REENGINEERING; SYSTEMS ARCHITECTURE; SYSTEMS ENGINEERING.

The hardware and software of computing and communications form the basic tools for information technology. These are implemented as information technology systems through use of systems engineering processes. While information technology and information systems engineering does indeed enable better designs of systems and existing organizations, it also enables the design of fundamentally new organizations and systems such as virtual corporations. Thus, efforts in this area include not only interactivity in working with clients to satisfy present needs but also awareness of future technological, organizational, and human concerns so as to support transition over time to new information technology-based services. [A.P.Sa.]

Information theory A branch of communication theory devoted to problems in coding. A unique feature of information theory is its use of a numerical measure of the amount of information gained when the contents of a message are learned. Information theory relies heavily on the mathematical science of probability. For this reason the term information theory is often applied loosely to other probabilistic studies in communication theory, such as signal detection, random noise, and prediction. *See* ELECTRICAL COMMUNICATIONS; PROBABILITY.

In designing a one-way communication system from the standpoint of information theory, three parts are considered beyond the control of the system designer: (1) the source, which generates messages at the transmitting end of the system, (2) the destination, which ultimately receives the messages, and (3) the channel, consisting of a transmission medium or device for conveying signals from the source to the destination. The source does not usually produce messages in a form acceptable as input by the channel. The transmitting end of the system contains another device, called an encoder, which prepares the source's messages for input to the channel. Similarly the receiving end of the system will contain a decoder to convert the output of the channel into a form that is recognizable by the destination. The encoder and the decoder are the parts to be designed. In radio systems this design is essentially the choice of a modulator and a detector. *See* MODULATION.

A source is called discrete if its messages are sequences of elements (letters) taken from an enumerable set of possibilities (alphabet). Thus sources producing integer data or written English are discrete. Sources which are not discrete are called continuous, for example, speech and music sources. The treatment of continuous cases is sometimes simplified by noting that signal of finite bandwidth can be encoded into a discrete sequence of numbers.

The output of a channel need not agree with its input. For example, a channel might, for secrecy purposes, contain a cryptographic device to scramble the message. Still, if the output of the channel can be computed knowing just the input message, then the channel is called noiseless. If, however, random agents make the output unpredictable even when the input is known, then the channel is called noisy. *See* COMMUNICATIONS SCRAMBLING; CRYPTOGRAPHY.

Many encoders first break the message into a sequence of elementary blocks; next they substitute for each block a representative code, or signal, suitable for input to the channel. Such encoders are called block encoders. For example, telegraph and teletype systems both use block encoders in which the blocks are individual letters. Entire words form the blocks of some commercial cablegram systems. It is generally impossible for a decoder to reconstruct with certainty a message received via a noisy channel. Suitable encoding, however, may make the noise tolerable.

Even when the channel is noiseless, a variety of encoding schemes exists and there is a problem of picking a good one. Of all encodings of English letters into dots and dashes, the Continental Morse encoding is nearly the fastest possible one. It achieves its speed by associating short codes with the most common letters. A noiseless binary channel (capable of transmitting two kinds of pulse 0, 1, of the same duration) provides the following example. Suppose one had to encode English text for this channel. A simple encoding might just use 27 different five-digit codes to represent word space (denoted by #), A, B, . . . , Z; say # 00000, A 00001, B 00010, C 00011, . . . , Z 11011. The word #CAB would then be encoded into 00000000110000100010. A similar encoding is used in teletype transmission; however, it places a third kind of pulse at the beginning of each code to help the decoder stay in synchronism with the encoder. [E.N.G.]

Infrared astronomy The field of astronomical observations specializing in detecting photons from the infrared portion of the electromagnetic spectrum. The infrared portion of the spectrum spans the range from the red limit of human vision (approximately 0.7 micrometer) to the shortest wavelengths accessible to heterodyne radio receivers (several hundred micrometers). *See* ELECTROMAGNETIC RADIATION; INFRARED RADIATION.

Astronomers observing the universe with infrared light encounter a number of fundamental differences relative to those observing with visible light:

1. Infrared observations are more sensitive to cooler objects than visible-wavelength observations. Blackbodies at a temperature cooler than 2000 kelvins (3100°F) radiate virtually all of their light in the infrared part of the spectrum. Infrared observations are particularly well suited to detect both forming stars and evolved stars (that is, stars in the final stages of their lives) since both classes of objects are cool. Since starlight often heats nearby dust grains to temperatures of tens or hundreds of degrees, reprocessing the visible starlight into exclusively infrared radiation, warm dust is also a common target for infrared observations. *See* HEAT RADIATION.

2. Interstellar dust is substantially more transparent at infrared wavelengths than at visible wavelengths. Infrared observations thus enable astronomers to view distant objects through the obscuring dust that permeates the Milky Way Galaxy. Forming and evolved stars often reside in dense clouds of interstellar dust grains and can be observed only at infrared and even longer radio wavelengths. *See* INTERSTELLAR EXTINCTION; INTERSTELLAR MATTER; SCATTERING OF ELECTROMAGNETIC RADIATION.

3. The quantized energies of molecular rotational and vibrational transitions, which give rise to molecular spectral lines, fall largely in the infrared part of the spectrum, as do many hyperfine lines of individual atoms. *See* INFRARED SPECTROSCOPY.

In addition to these astrophysical differences, the technology and practice of infrared astronomy differs from visible-wavelength astronomy in fundamental ways:

1. The Earth's atmosphere is opaque to infrared radiation through a substantial fraction of the spectrum. This opacity arises largely from water in the Earth's lower atmosphere.

2. Planck's law dictates that only photons with wavelength shorter than about 1 μm can induce chemical reactions or liberate free electrons. Thus physics limits photography and photon-counting photomultiplier tubes to operation mainly in the visible-wavelength domain. Infrared detection technology relies largely on either mimicking the photoelectric effect inside a crystalline semiconductor material or monitoring the temperature change of a semiconductor under the influence of infrared radiation. *See* PHOTOEMISSION.

3. Objects at room temperature (300 K or 80°F) emit radiation throughout most of the infrared spectrum. This glow interferes with the detection of faint astronomical sources, limiting the sensitivity of observations. Cooling of the entire telescope—impractical on the ground but possible in the vacuum of space—can substantially reduce the thermal glow of the telescope optics and result in unprecedented sensitivity to faint astronomical sources.

Infrared technology. Detectors of infrared radiation divide into two classes: bolometers and photovoltaic or photoconductive devices. Bolometer detectors have temperature-sensitive electrical conductivity. Incident radiation warms the detector, and the resulting subtle change in the electrical resistance of the detector is measured. Infrared photodetectors are crystalline semiconductors in which some electrons in the crystal lattice lie only a short distance in energy away from becoming unbound and behaving like metallic conducting electrons. Infrared light with energy in excess of the binding energy creates free charge carriers, either changing the bulk conductivity of the device (photoconductors) or charging or discharging a semiconductor junction (photovoltaics). *See* BOLOMETER; PHOTOCONDUCTIVITY; PHOTOVOLTAIC EFFECT.

Since the mid-1980s, large-scale integration of semiconductor components has permitted the production of arrays of infrared detectors. These arrays now exist in formats as large as 2048 × 2048 elements (4 million detectors on a single device). Each detector on such an array is also substantially more sensitive than its 1980s counterpart.

Astronomical targets. The targets of infrared observations include ordinary stars and galaxies, planets, brown dwarfs, young stellar objects, evolved stars, starburst galaxies, and red-shifted radiation.

Although popular interest in infrared astronomy focuses on exotic objects observable only using infrared light, infrared observations continue to play a fundamental role in understanding the more pedestrian stars and galaxies that constitute most of the visible-wavelength universe. At infrared wavelengths longer than 10 μm, infrared light emitted from dust warmed by stars in normal galaxies begins to dominate the infrared light from stars, making dusty spiral galaxies prime targets for mid-infrared observations. *See* Galaxy, external; Hertzsprung-Russell diagram; Milky Way Galaxy; Star.

At infrared wavelengths longer than 3 μm, thermal radiation from the planets begins to dominate over reflected sunlight. Jupiter, still cooling from its initial formation, emits twice as much energy as it receives from the Sun—nearly all of it at infrared wavelengths. *See* Asteroid; Jupiter; Planet; Planetary physics.

An object with a mass less than 8% that of the Sun (equivalent to 80 times the mass of Jupiter) is incapable of fusing hydrogen in its core to sustain its luminosity—the hallmark of being a star. At the time of their formation, the interiors of such substellar objects are warmed by their gravitational contraction from an initially diffuse interstellar cloud of gas. Even at this most luminous point in their evolution, most of the light emerges in the infrared part of the spectrum. Infrared surveys of the entire sky are beginning to reveal large numbers of these brown dwarfs, and they appear to be more common than ordinary stars in the Milky Way Galaxy. *See* Brown dwarf.

Young stellar objects (YSOs) are newly formed or forming stars. These stars are being assembled by gravity out of dense (1000 atoms per cubic centimeter) interstellar clouds. The environment surrounding the forming star is naturally very dusty, and the slight rotation of the natal cloud combined with gravity drives the infalling material to form a thin flattened disk around the star. Virtually all of the disk emission emerges at infrared wavelengths. Planets accrete within these disks, and infrared observations provide the primary astrophysical insight into the process of planetary formation. *See* Protostar.

After exhausting the initial supply of hydrogen in the stellar core, stars reconfigure themselves to liberate the energy of hydrogen shell burning around the core and helium burning within the core. Stellar physics dictates that the star must grow to large size and become cool at its surface in order to dissipate the energy being produced within. Dust grains condensing in the expanding envelope can completely enshroud the star. Under these circumstances, the observed radiation emerges entirely in the infrared part of the spectrum. These evolved stars are ideal tracers of the structure of the Galaxy. *See* Giant star; Stellar evolution.

Starburst galaxies, which are undergoing active bursts of star formation, can produce most of their radiation at wavelengths of 10 μm or longer. The radiation emerges in this part of the spectrum because the star-forming regions are embedded in dust clouds which absorb the starlight and, having been warmed to temperatures of tens of kelvins, reradiate energy largely in the infrared portion of the spectrum. *See* Starburst galaxy.

The gravitational interaction between two gas-rich galaxies can induce both objects to undergo an extensive burst of star formation. The resulting energy release can augment the flux of the galaxy by a factor of 10 or more with most of the radiation arising in the infrared part of the spectrum. Such "ultraluminous" infrared galaxies are among the most luminous galaxies in the universe.

The apparent Doppler shift due to the expansion of the universe causes the ultraviolet and visible light originally emitted by extremely distant stars and galaxies to be shifted into the infrared part of the spectrum. Redshifts this large originate from objects at distances of 10^{10} light-years or more. Since the light collected from these objects was emitted by them 10^{10} years ago, these observations probe the state of the universe at the earliest times. *See* Big bang theory; Cosmology; Redshift.

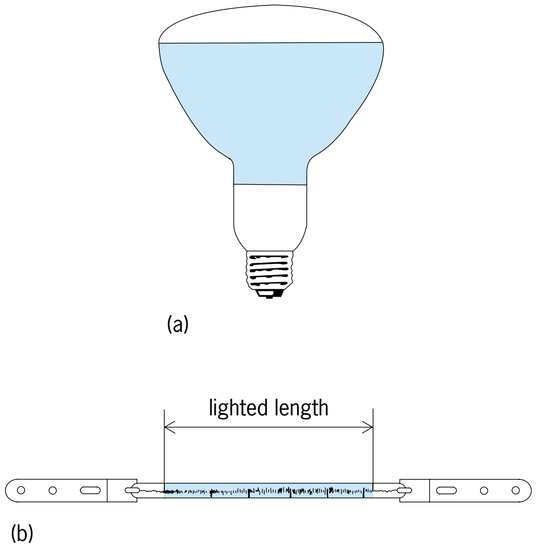
Ground-based infrared astronomy. Telescopes dedicated to visible-wavelength astronomy are also effective collectors of infrared radiation. Equipped with infrared focal-plane-array imagers and spectrographs, these telescopes can observe the infrared universe through the accessible atmospheric windows. Such observations are particularly effective shortward of 2 μm, where thermal emission from the telescope is negligible relative to other backgrounds.

Infrared space missions. The opacity of the Earth's atmosphere at most infrared wavelengths and the need to place a telescope in an environment where the entire telescope structure can be cooled to cryogenic temperatures have motivated a number of extremely successful satellite missions largely devoted to infrared astronomy, including the *Infrared Astronomy Satellite* (*IRAS*), launched in 1983; the *Infrared Space Observatory* (*ISO*), launched in 1995; and the *Space Infrared Telescope Facility* (*SIRTF*), renamed the *Spitzer Space Telescope*, following its launch in 2003. [M.F.S.]

Infrared imaging devices Devices that convert an invisible infrared image into a visible image. The radiation available for imaging may be emitted from objects in the scene of interest (usually at the longer wavelengths called thermal radiation) or reflected. Reflected radiation may be dominated by sunlight or may be from controlled sources such as lasers used specifically as illuminators for the imaging device. The latter systems are called active, while those relying largely on emitted radiation are called passive. Active optical imaging systems were developed to achieve a nighttime aerial photographic capability, and work during World War 11 pushed such systems into the near-infrared spectral region. Development of passive infrared imaging systems came after the war, but only the advent of lasers allowed creation of active infrared imagers at wavelengths much longer than those of the photographic region. *See* Infrared radiation; Laser.

Although developed largely for military purposes, infrared imaging devices have been valuable in industrial, commercial, and scientific applications. These range from nondestructive testing and quality control to earth resources surveys, pollution monitoring, and energy conservation. Infrared images from aerial platforms are used to accomplish "heat surveys," locating points of excessive heat loss. Calibration allows association of photographic tones with values of apparent (that is, equivalent blackbody) temperatures. Dark areas are "colder" than light ones. *See* Remote sensing. [G.J.Z.]

Infrared lamp A special type of incandescent lamp that is designed to produce energy in the infrared portion of the electromagnetic spectrum. The lamps produce radiant thermal energy which can be used to heat objects that intercept the radiation. An infrared lamp with a filament operating at 4000°F (2500 K) will release about 85% of its energy in the form of thermal



Typical shapes of infrared lamps. (*a*) R lamp, with built-in reflector unit. (*b*) Tubular configuration with a quartz bulb.

radiant energy, about 15% as visible light, and a tiny fraction of a percent as ultraviolet energy. *See* Heat radiation.

The lamps are supplied in two shapes. The most common shape, for general use, is the R lamp (illus. *a*), since the reflector unit is built in and the lamp needs only a suitable socket to form an infrared heating system. The other type of infrared lamp, the tubular quartz bulb lamp (illus. *b*), is used with a separate external reflector designed to distribute the heat as desired.

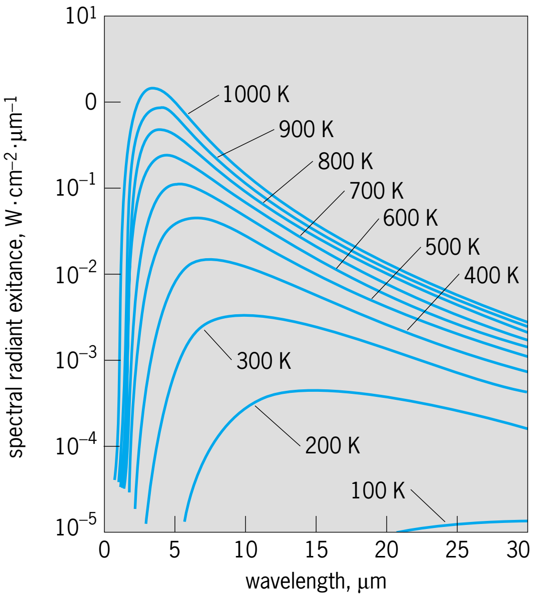
The major advantage of infrared heating is that it is possible to heat a surface that intercepts the radiation without heating the air or other objects that surround the surface. Infrared lamps have many uses, including paint drying, evaporative drying, farm heating of animals, heating of food, control heating, and therapeutic heating of portions of the body to relieve muscle strains. *See* Incandescent lamp; Infrared radiation; Thermotherapy. [G.R.P.]

Infrared radiation Electromagnetic radiation in which wavelengths lie in the range from about 1 micrometer to 1 millimeter. This radiation therefore has wavelengths just a little longer than those of visible light and cannot be seen with the unaided eye. The radiation was discovered in 1800 by William Herschel.

An infrared source can be described by the spectral distribution of power emitted by an ideal body (a blackbody curve). This distribution is characteristic of the temperature of the body. A real body is related to it by a radiation efficiency factor or emissivity which is the ratio at every wavelength of the emission of a real body to that of a blackbody under identical conditions. The illustration shows curves for these ideal blackbodies radiating at a number of different temperatures. The higher the temperature, the greater the total amount of radiation. *See* Emissivity.

Infrared detectors are based either on the generation of a change in voltage due to a change in the detector temperature resulting from the power focused on it, or on the generation of a change in voltage due to some photon-electron interaction in the detector material. This latter effect is sometimes called the internal photoelectric effect.

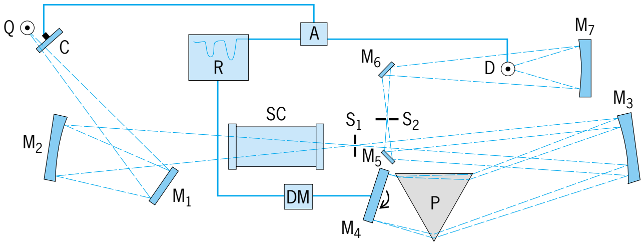
Infrared techniques have been applied in military, medical, industrial, meteorological, ecological, forestry, agricultural, chemical, and other disciplines. Weather satellites use infrared imaging devices to map cloud patterns and provide the imagery seen in many weather reports. Infrared imaging devices have also been used for breast cancer screening and other medical diagnostic applications. In most of these applications, the underlying principle is that pathology produces inflammation, and these locations of increased temperature can be found with an infrared imager. Airborne infrared imagers have been used to locate the edge of burning areas in forest fires. *See* Infrared imaging devices; Remote sensing. [W.L.Wo.]



Radiation from blackbodies at different temperatures, shown on a logarithmic scale.

Infrared spectroscopy The spectroscopic study of the interaction of matter with infrared radiation. Electromagnetic waves from the long-wavelength limit of visible light at 800 nanometers to the shortest microwaves at 1 mm are used. In the wave-number units usually employed (oscillations per centimeter, read as reciprocal centimeters), this corresponds to 12,500–10 cm^{-1}. *See* Infrared radiation.

The broad wavelength range of infrared radiation, and the few transparent optical materials available, require that infrared instruments be designed with reflecting optics: radiation is focused with front-surface aluminized mirrors rather than lenses. Because of strong infrared absorption by water vapor and carbon dioxide, operation takes place in a vacuum or the optical path is purged with dry nitrogen. Absorption spectroscopy is the principal method, where attention centers on the frequencies absorbed by the sample from a broadly emitting source. However, spectrometers and interferometers can easily be adapted to emission spectroscopy.



Basic single-beam recording infrared prism spectrometer. The monochromator (the portion from the entrance slit S_1 to the exit slit S_2) is a Littrow mounting, a common arrangement for infrared instruments.

In a dispersive spectrometer (see illustration), infrared radiation from the source Q is focused by a spherical mirror M_2 onto the entrance slit S_1 of the monochromator, after passing through the sample cell SC. The beam is collimated by the off-axis paraboloid mirror M_3, dispersed by refraction through the prism P, and focused in the plane of the exit slit S_2 by a second reflection from M_3. A narrow spectral region of the dispersed radiation passes the exit slit and is focused by the ellipsoidal mirror M_7 onto the detector D, which converts the radiant energy into an electrical signal. Since the beam has been chopped at constant frequency by a rotating mechanical chopper C, this signal is an alternating current that is amplified by the lock-in amplifier A, controlling the pen of the chart recorder R. To scan the spectrum, M_4 is rotated by the drive mechanism DM, which also drives the recorder. Successive frequencies are thus moved across the exit slit, producing a record of signal intensity as a function of mirror position; with a proper mechanical linkage, this record is made linear in wavelength or wave number. The same arrangement can be used with a diffraction grating as the dispersive element; the prism is removed and mirror M_4 is replaced by the grating.

In the near-infrared, quartz prisms are used, and in the mid-infrared, alkali-metal halide or calcium fluoride (CaF_2) prisms, but no prism material is suitable beyond about 50 μm. Diffraction gratings can be used in all regions with the advantage, for equivalent optical configurations, of significantly higher resolving power than prisms. Prism instruments have resolutions of little better than 1 cm^{-1} near wavelengths of maximum dispersion, and much poorer than this elsewhere. Grating resolution can be several tenths of a reciprocal centimeter for commercial spectrometers; some specially built instruments can resolve a few hundredths of a reciprocal centimeter. In most laboratories these instruments are being replaced by other techniques, although inexpensive double-beam grating spectrometers are still manufactured. *See* DIFFRACTION GRATING; OPTICAL PRISM; RESOLVING POWER (OPTICS).

In a Michelson interferometer, light from the source strikes a thin, partially reflecting beam splitter at an angle of 45° and is divided into two beams that are returned by mirrors and recombined at the beam splitter. The intensity of the recombined and interfering beams, recorded as a function of the optical path difference (or retardation) as one mirror is moved, yields an interferogram. From this, the desired spectrum (that is, the source intensity as a function of wave number) can be recovered by the mathematical procedure known as a Fourier transform. *See* FOURIER SERIES AND TRANSFORMS; INTEGRAL TRANSFORM; INTERFEROMETRY.

Fourier-transform spectroscopy offers several advantages over dispersive methods; these are especially important for effective use of the limited radiant power available from most infrared sources. Whereas a spectrometer samples only one small frequency range at any given instant and must scan these frequencies sequentially to produce a spectrum, an interferometer processes information from all frequencies simultaneously (multiplex or Fellgett advantage). Furthermore, an interferometer passes a much greater light flux for a given resolving power than a spectrometer, which can accept only a very limited solid angle of source radiation because of the narrow slits required (throughput or Jacquinot advantage). These advantages can be translated into improvements of orders of magnitude in any one of the three interrelated important parameters of resolution, signal-to-noise ratio, and scan time. Another advantage is that the mirror movement is monitored to high precision with a fixed-frequency laser, so that the wave-number scale of the transformed spectrum is highly accurate compared with spectrometer readings.

Commercial Fourier-transform spectrometers are marketed with resolutions from a few reciprocal centimeters for routine qualitative analyses to research instruments that can resolve better than 0.002 cm^{-1}. Typically, they operate from 4000 to 400 cm^{-1} on one beam splitter such as germanium-coated potassium bromide (KBr); this range can be extended broadly in either direction with different beam-splitter materials. For the far-infrared, Mylar films in various thicknesses are used. These instruments are controlled by microprocessors and include a digital computer to handle the Fourier transform. This computing power allows data manipulation such as repetitive scanning and signal averaging; background subtraction; spectral smoothing, fitting, and scaling; and searching digitized spectral libraries and databases to identify unknowns. Although backgrounds can be subtracted with software, some Fourier-transform instruments are designed for true optical double-beam operation. Many offer rapid-scan capability for the study of short-lived species and can be adapted to recording Fourier-transform Raman spectra. *See* MICROPROCESSOR; RAMAN EFFECT.

Infrared spectra are usually plotted as percent transmittance T or absorbance A on a scale linear in wave number ν (less commonly, in wavelength λ). Transmittance is the ratio of the intensity of radiation transmitted by the sample (I) to that incident on the sample (I_0), expressed as a percentage, so that $T = 100I/I_0$.

Infrared spectra are ideal for identifying chemical compounds because every molecule [except homonuclear diatomics such as nitrogen (N_2), oxygen (O_2), and chlorine (Cl_2)] has an infrared spectrum. Since the vibrational frequencies depend upon the masses of the constituent atoms and the strengths and geometry of the chemical bonds, the spectrum of every molecule is unique (except for optical isomers). Pure unknowns can thus be identified by comparing their spectra with recorded spectra; catalogs are available in digitized versions, and searches can be made rapidly by computer.

Simple mixtures can be identified with the help of computer software that subtracts the spectrum of a pure compound from that of the unknown mixture. More complex mixtures may require fractionation first. This has led to the development of combinations of analytical techniques, such as gas chromatography used together with Fourier-transform infrared spectroscopy; instruments that combine these functions are available commercially.

Many functional groups have characteristic infrared frequencies that are relatively independent of the molecular environment. Often, specific conclusions can be drawn from frequencies, and it may be possible to identify even a new compound from its spectrum. Group frequencies are most useful above about 1500 cm^{-1}; below this the absorptions are due to, or are influenced more by, the skeletal vibrations of the molecule. This is the "fingerprint" region, where even similar molecules may have quite different spectra. *See* QUALITATIVE CHEMICAL ANALYSIS.

Many details of molecular structure and dynamics can be extracted from an infrared spectrum, especially for light molecules that can be examined in the gas phase and therefore exhibit rotational structure.

Other applications include calculation of thermodynamic quantities from vibrational and rotational energy levels; studies of intermolecular forces in condensed phases; distinguishing between free or hindered internal rotation (as of methyl groups); quantitative intensity measurements to obtain bond dipole moments; studies of molecular interactions in adsorption, surface chemistry, and catalytic processes; time-resolved monitoring of transient species and chemical reaction kinetics; characterization of reactive molecules isolated at cryogenic temperatures in rare-gas lattices (matrix isolation); electronic energy states in semiconductors and superconductors; studies of biological molecules and membranes (effects of hydrogen bonding); and analysis of energy levels in laser systems. Double-resonance techniques, in which molecules are excited by an intense pulse of ultraviolet, infrared, or microwave energy, and simultaneously probed by infrared or microwave spectroscopy, are useful in monitoring population changes in molecular energy levels, energy transfer and relaxation, and multiphoton absorption processes. *See* ADSORPTION; CATALYSIS; CHEMICAL DYNAMICS; HYDROGEN BOND; INTERMOLECULAR FORCES; SEMICONDUCTOR; SPECTROSCOPY; SUPERCONDUCTIVITY. [R.S.McD.]

Infrasound Sound waves, particularly in the atmosphere, whose frequencies of pressure variation and of vibration are below the audible range, that is, lower than about 20 Hz. Earthquake and seismic waves are elastic waves which occur at infrasonic frequencies in the Earth's crust and in the oceans and seas. The physical laws of propagation in the atmosphere are essentially the same as for audible sound. The local speed of infrasound in air at ambient temperatures near 20°C (68°F) is about 340 m/s (1115 ft/s), the same as for audible sound.

At frequencies less than about 1.0 Hz, infrasound propagates through the atmosphere for distances of thousands of kilometers without substantial loss of energy. Sounds at these frequencies are almost always present at measurable intensities. Those of natural origin have many causes, including tornadoes, volcanic explosions, earthquakes, the aurora borealis, waves on the seas, large meteorites, and lightning discharges. When the wind blows, turbulent pressure fluctuations in the atmosphere occur at amplitudes up to tens of pascals, at infrasonic frequencies. People are unaware of these pressures via the sensation of hearing.

Sufficiently strong infrasound is "audible," contrary to simple acoustic tradition. The threshold sound pressure level (the least intensity for audibility) is about 92 dB at 16 Hz, and increases 12 dB per octave to about 140 dB at 1.0 Hz. However, there is no sensation of tone. Listeners variously describe audible infrasound as pumping, popping effect, or chugging. For vibration at very low frequencies, motion sickness of people in boats must have been one of the earliest noticeable effects. The human body is particularly sensitive to vibrations and infrasound near 7 Hz, at which frequency there is an overall mechanical resonance of organs in the abdominal and chest cavities. *See* ATMOSPHERIC ACOUSTICS; SOUND. [R.K.C.]

Inhibitor (chemistry) A substance which is capable of stopping or retarding a chemical reaction. To be technically useful, such compounds must be effective in low concentrations, usually under 1%. The type of reaction which is most easily inhibited is the free-radical chain reaction. Vinyl polymerization and autoxidation are two important examples of the class. Another reaction type for which inhibitors have been found is corrosion, particularly in aqueous systems. *See* ANTIOXIDANT; CORROSION; FREE RADICAL; POLYMERIZATION. [L.R.M.]

Ink A dispersion of a pigment or a solution of a dye in a carrier vehicle, yielding a fluid, paste, or powder to be applied to and dried on a substrate. Printing, writing, marking, and drawing inks are applied by several methods to paper, metal, plastic, wood, glass, fabric, or other substrates. Inks perform communicative, decorative, and even protective functions.

Printing inks can be classified according to their characteristic properties, the method of application, or other considerations such as end use or manner of drying. The composition of an ink can be oil-, solvent-, or water-based; the ink may be a high-viscosity paste or a low-viscosity liquid. The most important printing methods that utilize inks are lithography, flexography, letterpress, and gravure. The inks can be applied in four-color process (screen), as spot colors (solid or screen), or as line work. The end uses are news, publication, commercial, folding carton, book, corrugated box, paper bag, wrapper, label, metal container, plastic container, plastic film, foil, laminating, food insert, sanitary paper, and textile. The various drying manners are oxidizing, evaporating, penetrating, precipitating, polymerizing, reactive, including radiation-cured, gelling, cold-setting or quick-setting, and thermosetting. Some 900,000 ink formulations exist to meet the various needs and conditions.

Fundamentally, inks are composed of four major material categories: (1) Colorants (which include pigments, toners, and dyes) provide the color contrast with the substrate. (2) Vehicles, or varnishes, act as carriers for the colorants during the printing operation. Upon drying, the vehicles bind the colorants to the substrate. (3) Additives influence the printability, film characteristics, drying speed, and end-use properties. (4) Solvents (including water), besides participating in formation of the vehicles, are used to reduce ink viscosity and adjust drying ease and resin compatibility. Ingredients from these four classes are weighed, mixed, and ground (dispersed) together or separately, according to the formulas preestablished in the laboratory. *See* PRINTING.

Inks developed for ball-point pens are newtonian fluids of high tinctorial strength. These must be free of particles and premature drying so as to continue the feed to the paper without clogging. Rapid penetration into the paper accomplishes drying. They are dye solutions or pigment dispersions in oleic acid, castor oil, sulfonamide, or in aqueous solutions of gums or glues. *See* NEWTONIAN FLUID. [F.Ci.; N.Im.; T.M.De.]

Inland waterways transportation The movement of cargo on inland and intracoastal waterways by barge. About 14% of the bulk movement of commerce in the United States moves by barge, amounting to over 6×10^8 tons (5.4×10^8 metric tons) annually. Barges directly serve 87% of all major United States cities, accounting for 65% of all domestic waterborne traffic.

Barges move on the 25,543-mi (41,107-km) network of commercially navigable inland and intracoastal waterways. Generally, barges are either pushed or towed by towboats on the inland waters. Barges require standard operating depths of at least 9 ft (about 3 m). Certain sections of the inland waterways are deep enough to support ocean-going vessels, including the Hudson River to Albany, New York, the Lower Mississippi north to Baton Rouge, Louisiana, the Houston Ship Channel, the Delaware River, the James River, and portions of the Columbia-Snake River.

Three major types of barges are used on the inland and intracoastal waterways: the open hopper, the covered dry cargo, and the tank barge. The open hopper barge is used to transport cargo that does not need to be protected from the elements, such as coal, sand, and gravel. Cargoes that need protection, such as grain, are shipped on covered dry cargo barges. Tank barges carry liquid commodities, such as petroleum and chemicals.

Towboats with barge flotillas commonly operate on the inland waterways, where they are fully protected by land on either side. The barges are kept together by wire rigging and are lashed against the towing knees of the towboat which pushes them ahead. On open channels, such as the Atlantic and Gulf intracoastal waterways, tugboats are used, which pull barges on a hawser.

With the exception of the New York State Barge Canal, which is state-run, the inland waterways of the United States are maintained on a federal level by the Army Corps of Engineers. Since 1980, barge operators have paid a fuel tax that pays for a percentage of the construction, operation, and maintenance costs for inland waterway projects. Before this time, all projects were entirely federally funded with appropriations from Congress. [J.Fa.]

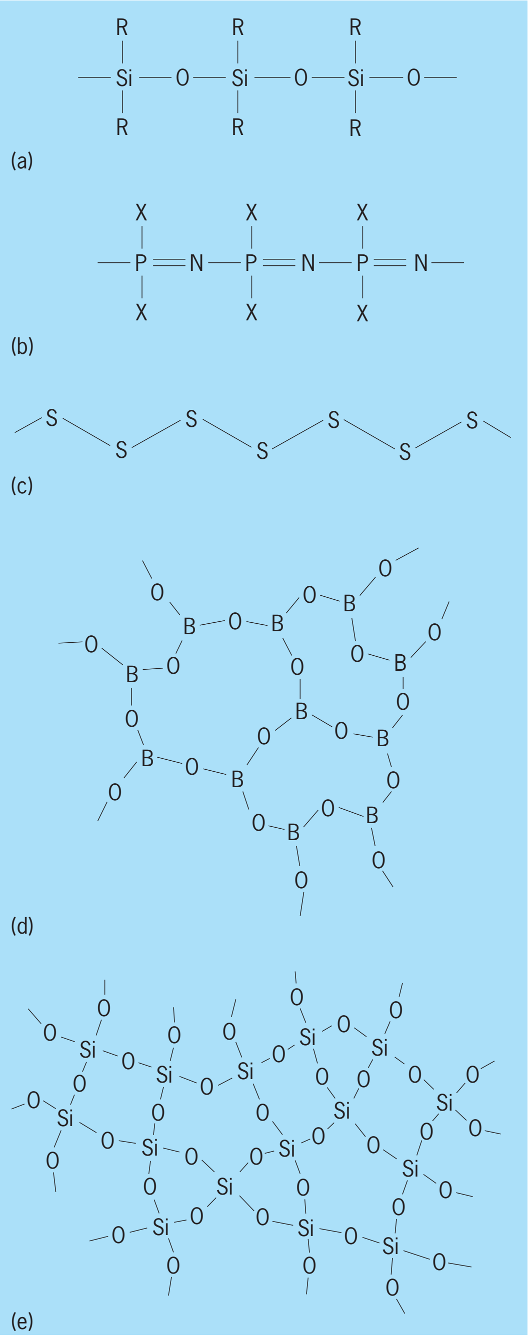
Inoculation The process of introducing a microorganism or suspension of microorganism into a culture medium. The medium may be (1) a solution of nutrients required by the organism or a solution of nutrients plus agar; (2) a cell suspension (tissue culture); (3) embryonated egg culture; or (4) animals, for example, rat, mouse, guinea pig, hamster, monkey, birds, or human being. When animals are used, the purpose usually is the activation of the immunological defenses against the organism. This is a form of vaccination, and quite often the two terms are used interchangeably. Both constitute a means of producing an artificial but active immunity against specific organisms, although the length of time given by such protection may vary widely with different organisms. *See* IMMUNITY; VACCINATION. [E.G.St./N.K.M.]

Inorganic chemistry The chemical reactions and properties of all the elements in the periodic table and their compounds, with the exception of the element carbon. The chemistry of carbon and its compounds falls in the domain of organic chemistry. The boundaries of inorganic chemistry with the other major areas of chemistry are not precisely defined, and it is often a matter of taste as to whether a particular topic is to be included in the field of inorganic chemistry or is to be considered physical or even organic chemistry. Investigations into theoretical inorganic chemistry or the study of problems in inorganic chemistry by quantitative and sophisticated physical methods may be considered either inorganic or physical chemistry quite arbitrarily. In similar fashion, organometallic compounds may be considered to be in the sphere of either inorganic or organic chemistry. To an increasing extent, the inorganic chemist is concerned with problems that once were considered the prerogative of physical chemists, organic chemists, or even biochemists. *See* BIOINORGANIC CHEMISTRY; CHEMICAL DYNAMICS; COORDINATION CHEMISTRY; GEOCHEMISTRY; NUCLEAR CHEMISTRY; ORGANOMETALLIC COMPOUND; PHYSICAL CHEMISTRY; SOLID-STATE CHEMISTRY. [J.J.K.]

Inorganic photochemistry The study of the light-induced behavior of various metal compounds. The physical and chemical properties of substances are generally altered by the absorption of light. Typical metal compounds have a characteristic number (coordination number) of molecules or ions (ligands) directly bonded to the metal center. For example a six-coordinate compound has the general formula ML_6^{n+}. Many of these compounds are colored, and much interest has been aroused by speculation that some metal compounds could mediate the transformation of solar radiation into useful chemical or electrical energy.

The photochemistry of metal compounds has grown in concert with modern theories of the electronic structure of molecules and of chemical bonding in molecules. Photochemical studies are often designed to probe and test these theories. The range of pertinent studies spans most of the subdisciplines of chemistry and includes or bears on such topics as photo-physics, the development of laser materials, catalysis, photo-synthesis, oxidation-reduction chemistry, acid-base chemistry, organometallic chemistry, metalloenzyme chemistry, solid-state chemistry, and surface chemistry. *See* CHEMICAL BONDING; CHEMICAL DYNAMICS; COORDINATION CHEMISTRY; LASER PHOTOCHEMISTRY; PHOTOCHEMISTRY. [J.F.E.]

Inorganic polymer A giant molecule linked by covalent bonds but with an absence or near-absence of hydrocarbon units in the main molecular backbone; these may be included as pendant side chains. Carbon fibers, graphite, and so forth are considered inorganic polymers.



Polymers with varying connectivities: (*a*) siloxanes, two; (*b*) phosphazenes, two; (*c*) sulfur, two; (*d*) boric oxide, three; (*e*) amorphous silica, four. (*After N. H. Ray, Inorganic Polymers, Academic Press. 1978*)

Some special characteristics of many inorganic polymers are a higher Young's modulus and a lower failure strain compared with organic polymers. Relatively few inorganic polymers dissolve in the true sense, or alternatively, if they swell, few can revert. Crystallinity and high glass transition temperatures are also much more common than in organic polymers. In highly cross-linked inorganic polymers, stress relaxation frequently involves bond interchange. *See* YOUNG'S MODULUS.

Inorganic polymers can be classified in a number of ways. Some are based on the composition of the backbone, such as the silicones (Si—O), the phosphazenes (P—N), and polymeric sulfur (S—S). Others are based on their connectivity, that is, the number of network bonds linking the repeating unit into the network. Thus the silicones based on R_2SiO, the phosphazenes based on NPX_2, and polymeric sulfur each have a connectivity of two, while boric oxide based on B_2O_3 has a connectivity of three, and amorphous silica based on SiO_2 has one of four (see illustration).

Among the well-known inorganic polymers are silicones, chalcogenide glasses, graphite, boron polymers, and silicate polymers. *See* GRAPHITE; SILICONE RESINS. [R.A.S.]

Inositol The generic name for hexahydroxycyclohexanes, which are classified as carbohydrates. The inositols have exceptional chemical stability and are easily crystallized. Of the forms common in nature, the most ubiquitous and biologically important is myoinositol, a water-soluble crystalline compound. Many biological functions require myoinositol, and thus it is identified as an essential metabolite. Although originally classified as a vitamin, myoinositol is now known to be a cellular precursor of phospholipids that serve as a source of metabolic regulators and as membrane anchors for certain proteins. Some microorganisms require exogenous myoinositol for growth. *See* CARBOHYDRATE; LIPID. [C.E.Ba.]

Insect control, biological The use of parasitoids, predators, and pathogens to reduce injurious pest insect populations and consequently the damage they cause. Viruses and bacteria are the most commonly used pathogens, but fungi, protozoa, and nematodes may also be important biological control agents. *See* PARASITOLOGY.

Three ecological assumptions underlie biological control. First, natural enemies are among the prime factors responsible for the regulation, or control, of pest populations. Second, the influence exerted by parasitoids, predators, and pathogens is density-dependent. Density dependence means that the killing power of the natural enemy increases as the prey or host density increases. Conversely, the mortality induced by density-dependent natural enemies decreases as host density increases. In the dominant, or classical, form of biological control the third assumption is found: when an insect species escapes into a new area without its natural enemies, it reaches outbreak levels and becomes a pest. Biological-control practitioners believe regulation can be reestablished by importing the natural enemies of the pest from its area of origin.

In classical biological control, all efforts are typically directed toward establishing the natural enemies that were left behind in the area of origin. Classical biological control is by far the most frequently used form, assuming one excludes the use of resistant plant varieties as biological control.

Conservation involves manipulation of the environment in order to favor survival, reproduction, or any other aspect of the natural enemy's biology that affects its function as a biological control agent.

Aspects of research on and application of biological control may provide new or improved approaches. The improvement of biological control agents through selection, hybridization, or genetic engineering techniques may play an important role. A major strategy for control of pest insects may involve the use of genetic engineering to introduce traits into natural enemies that enhance their performance, or mortality-causing traits of natural enemies, such as insect pathogens, into plants. *See* Breeding (plant); Genetic engineering. [P.B.]

Insect pathology A biological discipline embracing the general principles of pathology (disease in the broadest sense) as applied to insects. It refers to human observations and actions concerning the cause, symptomatology, gross pathology, histopathology, pathogenesis, and epizootiology of the diseases of insects; it is concerned with whatever can go wrong or become abnormal in an insect. A diseased insect may be suffering from an infectious disease caused by a microorganism or a noninfectious disease, such as metabolic disturbance, a genetic abnormality, a fetal malformation, a nutritional deficiency, a physical or chemical injury, or an injury caused by parasites or predators.

Insect pathology draws upon and contributes to the general field of microbiology and provides understanding of certain of the biological relationships existing between insects and microorganisms not pathogenic to them. Insect pathology finds applications in agriculture, medicine, and biology generally. Microbial control, the use of microorganisms in biological control, is one area of applied insect pathology. Microorganisms are introduced to control insect pests for the protection of humans and other animals and agricultural crops. However, the suppression of disease in beneficial insects, such as the silkworm, honeybee, and ladybird beetle, is also of significant practical importance. *See* Insect control, biological.

An important facet of insect pathology is concerned with the epizootiology of diseases, which involves the study of disease in populations of insects rather than in individual animals. Any epizootic affecting an insect population is concerned with three primary natural entities: the infectious agent, the insect host, and the environment. Each of these factors has certain attributes that, when properly related to the attributes of the others, play their appropriate role in determining the initiation, rise, and decline of an epizootic. Knowledge concerning the nature of epizootics is extremely important in insect ecology generally and in an understanding of insect-microbe ecosystems. The degree to which disease-producing microorganisms are dependent upon the density of the host population, the susceptibility of the host insect to the disease, the influence of weather and other environmental conditions on epizootics, the mode of transmission of insect pathogens, the success of the microorganism remaining alive, and other factors are important aspects of the epizootiology of insect disease. In the microbial control of an injurious insect, humans can initiate and increase the rapid rate of development of an epizootic by controlling the amount, method of distribution, and time of introduction of an effective microorganism.

Most of the activity in insect pathology has been with the infectious diseases. The infectious agents responsible for diseases in insects belong to the same major groups as those that cause such diseases in other organisms: the bacteria, fungi, viruses, rickettsiae, protozoa, and nematodes. In general, however, insects are not normally susceptible to those particular microorganisms that cause diseases of humans, other animals, and plants. Moreover, most of the microorganisms that cause fatal diseases in insects are harmless to plants and to higher animals. Insects often can resist infection by humoral and cellular types of immunity; acquired humoral immunity is manifested in the hemolymph. However, it appears that the antibody immunity characteristic of higher animals does not occur in insects.

Bacillus thuringiensis is one of the most intensively studied bacterial pathogens of insects because it has proved to be an effective microbial control agent against a number of insect pests, such as the alfalfa caterpillar, larvae of the cabbage butterfly, and larval forms of certain mosquitoes, black flies, and beetles. A number of closely related species of this bacillus are known to cause diseases of beneficial insects, such as silkworms. Several different strains or varieties of *B. thuringiensis* are known. Certain types affect only Lepidoptera, others only Diptera or Coleoptera. These bacteria are characterized by the formation of a protein crystal in the sporangium at the time of spore formation. The protein material comprising the crystal is highly toxic for certain insects, but apparently harmless for other forms of life. *Bacillus thuringiensis* and related species also produce a heat-stable, water-soluble substance, distinct from the crystal and from lecithinase, that is toxic for certain insects when injected, and to larval Diptera when they are exposed to it in a rearing medium. Preparations containing the spores and crystals of *B. thuringiensis* or its varieties may be sprayed or dusted on crops or into aquatic habitats to destroy lepidopterous, dipterous, or coleopterous pests. Commercial products containing the bacillus are available. One of the primary advantages of this type of control is that this and other entomophilic microorganisms are nontoxic and noninfectious for plants and higher animals. *See* Insect physiology; Insecta; Insecticide. [J.D.Br.]

Insecta A class of the phylum Arthropoda, sometimes called the Hexapoda. In fact, Hexapoda is a superclass consisting of both Insecta and the related class Parainsecta (containing the springtails and proturans). Class Insecta is the most diverse group of organisms, containing about 900,000 described species, but there are possibly as many as 5 million to perhaps 20 million actual species of insects. Like other arthropods, they have an external, chitinous covering. Fossil insects dating as early as the Early Devonian have been found. *See* Parainsecta.

Classification. The class Insecta is divided into orders on the basis of the structure of the wings and the mouthparts, on the type of metamorphosis, and on various other characteristics. There are differences of opinion among entomologists as to the limits of some of the orders. The orders of insects (and their relatives the parainsects) are shown below.

- Superclass Hexapoda
  - Class Parainsecta
    - Order: Protura; proturans
    - Collembola; springtails
  - Class Insecta
    - Subclass Monocondylia
      - Order: Diplura; telsontails
      - Archaeognatha; bristletails
    - Subclass Dicondylia
      - Infraclass Apterygota
        - Order: Zygentoma; silverfish, firebrats
      - Infraclass Pterygota
        - Section Palaeoptera
          - Order: Ephemeroptera; mayflies
          - Odonata; damselflies and dragonflies
        - Section Neoptera
          - Hemimetabola
            - Order: Plecoptera; stoneflies
            - Grylloblattodea; rockcrawlers
            - Orthoptera; grasshoppers, katy-dids, crickets
            - Phasmatodea; walkingsticks
            - Mantodea; mantises
            - Blattodea; cockroaches
            - Isoptera; termites
            - Dermaptera; earwigs
            - Embioptera; webspinners
            - Zoraptera; zorapterans
            - Psocoptera; psocids, booklice
            - Phthiraptera; lice
            - Thysanoptera; thrips
            - Hemiptera; cicadas, hoppers, aphids, whiteflies, scales

Holometabola
  Order: Megaloptera; dobsonflies, alderflies
    Raphidioidea; snakeflies
    Neuroptera; lacewings, antlions
    Coleoptera; beetles
    Strepsiptera; twisted-wing parasites
    Mecoptera; scorpionflies
    Siphonaptera; fleas
    Diptera; true flies
    Trichoptera; caddisflies
    Lepidoptera; moths, butterflies
    Hymenoptera; sawflies, wasps, ants, bees

Morphology. Insects are usually elongate and cylindrical in form, and are bilaterally symmetrical. The body is segmented, and the ringlike segments are grouped into three distinct regions: the head, thorax, and abdomen. The head bears the eyes, antennae, and mouthparts; the thorax bears the legs and wings, when wings are present; the abdomen usually bears no locomotor appendages but often bears some appendages at its apex. Most of the appendages of an insect are segmented.

The skeleton is primarily on the outside of the body and is called an exoskeleton. However, important endoskeletal structures occur, particularly in the head. The body wall of an insect serves not only as a covering, but also as a supporting structure to which many important muscles are attached. The body wall of an insect is composed of three principal layers: the outer cuticula, which contains, among other chemicals, chitin; a cellular layer, the epidermis, which secretes the chitin; and a thin noncellular layer beneath the epidermis, the basement membrane. The surface of an insect's body consists of a number of hardened plates, or sclerites, separated by sutures or membranous areas, which permit bending or movement. *See* CHITIN.

A pair of compound eyes usually cover a large part of the head surface. In addition most insects also possess two or three simple eyes, the ocelli, usually located on the upper part of the head between the compound eyes; each of these has a single lens. *See* EYE (INVERTEBRATE).

Insect mouthparts typically consist of a labrum, or upper lip; a pair each of mandibles and maxillae; a labium, or lower lip; and a tonguelike structure, the hypopharynx. These structures are variously modified in different insect groups and are often used in classification and identification. The type of mouthparts an insect has determines how it feeds and what type of damage it is capable of causing.

Several forms of antennae are recognized, to which various names are applied; they are used extensively in classification. The antennae are usually located between or below the compound eyes and are often reduced to a very small size. They are sensory in function and act as tactile organs, organs of smell, and in some cases organs of hearing.

Insects are the only winged invertebrates, and their dominance as a group is probably due to their wings. Immature insects do not have fully developed wings, except in the mayflies. The wings may be likened to the two sides of a cellophane bag that have been pressed tightly together. The form and rigidity of the wing are due to the stiff chitinous veins which support and strengthen the membranous portion. At the base are small sclerites which serve as muscle attachments and produce consequent wing movement. The wings vary in number, placement, size, shape, texture, and venation, and in the position at which they are held at rest. Adult insects may be wingless or may have one pair of wings on the mesothorax, or, more often two pairs. There is a common basic pattern of wing venation in insects which is variously modified and in general quite specific for different large groups of insects. Much of insect classification depends upon these variations. A knowledge of fossil insects depends largely upon the wings, because they are among the more readily fossilized parts of the insect body.

Internal anatomy. The intake of oxygen, its distribution to the tissues, and the removal of carbon dioxide are accomplished by means of an intricate system of tubes called the tracheal system. The principal tubes of this system, the tracheae, open externally at the spiracles. Internally they branch extensively, extend to all parts of the body, and terminate in simple cells, the tracheoles. Many adaptations for carrying on respiration are known.

Insects possess an alimentary tract consisting of a tube, usually coiled, which extends from the mouth to the anus. It is differentiated into three main regions: the foregut, midgut, and hindgut. Valves between the three main divisions of the alimentary canal regulate the passage of food from one region to another.

The excretory system consists of a group of tubes with closed distal ends, the Malpighian tubules, which arise as evaginations of the anterior end of the hindgut. They vary in number from 1 to over 100, and extend into the body cavity. Various waste products are taken up from the blood by these tubules and passed out via the hindgut and anus.

The circulatory system of an insect is an open one. The only blood vessel is a tube located dorsal to the alimentary tract and extending through the thorax and abdomen. The posterior portion of this tube, the heart, is divided into a series of chambers, each of which has a pair of lateral openings called ostia. The anterior part of the tube is called the dorsal aorta.

The nervous system consists of a brain, often called the supraesophageal ganglion, located in the head above the esophagus; a subesophageal ganglion, connected to the brain by two commissures that extend around each side of the esophagus; and a ventral nerve cord, typically double, extending posteriorly through the thorax and abdomen from the subesophageal ganglion. In the nerve cords there are enlargements, called ganglia. Typically, there is a pair to each body segment. From each ganglion of the chain, nerves extend to each adjacent segment of the body, and also extend from the brain to part of the alimentary canal.

Reproduction in insects is nearly always sexual, and the sexes are separate. Variations from the usual reproductive pattern occur occasionally. In many social insects, such as the ants and bees, certain females, the workers, may be unable to reproduce because their sex organs are undeveloped; in some insects, individuals occasionally occur that have characters of both sexes, called gynandromorphs. Also, parthenogenesis—the process of females giving rise to females—is known in some species.

Metamorphosis. After insects hatch from an egg, they begin to increase in size and will also usually change, to some degree at least, in form and often in appearance. This developmental process is metamorphosis. The growth of an insect is accompanied by a series of molts, or ecdyses, in which the cuticle is shed and renewed.

The molt involves not only the external layers of the body wall, the cuticula, but also the cuticular linings of the tracheae, foregut, and hindgut; the cast skins often retain the shape of the insects from which they were shed. The shedding process begins with a splitting of the old cuticle. This split grows and the insect eventually wriggles out of the old cuticle. The new skin, remains soft and pliable long enough for the body to expand to its fullest capacity before hardening.

Insects differ regarding the number of molts during their growing period. Many have as few as four molts; a few species have 40 or more, and the latter continue to molt throughout life.

Insects have been grouped or classified on the basis of the type of metamorphosis they undergo. Although all entomologists do not agree upon the same classification, the following outline is presented:

1. Ametabolous or primitive: No distinct external changes are evident with an increase in size.
2. Hemimetabolous: Direct metamorphosis that is simple and gradual; immature forms resemble the adults except in size, wings, and genitalia. Immatures are referred to as nymphs or naiads if aquatic.

3. Holometabolous: Complete, or indirect, metamorphosis; stages in this developmental type are: egg→larva→pupa→adult (or imago). [D.M.DeL.]

Fossils. Insects and parainsects have a rich fossil record that extends to 415 million years, representing all taxonomic orders and 70% of all families that occur today, Insect deposits are characterized by an abundance of exceptionally well-preserved deposits known as Lagerstätten. Lagerstätten refer not only to the familiar amber deposits that entomb insects in hardened tree resin, but more importantly to a broad variety of typically laminar, sedimentary deposits. These deposits, formed in lake basins, are the most persistent of insect-bearing deposits and document the evolution of insect biotas during the past 300 million years. By contrast, the oldest amber is approximately 120 million years old and extends modern lineages and associated taxa to the Early Cretaceous. Other major types of insect deposits include terrestrial shales and fine-grained sandstones marginal to marine deposits during the Early and Middle Devonian, a proliferation of nodular ironstone-bearing strata of late Carboniferous age from the equatorial lowlands of the paleocontinent Euramerica, and distinctive lithographic limestones worldwide from the Middle Jurassic to Early Cretaceous. More modern deposits are Miocene to Recent sinter deposits created by hydrothermal zones with mineral-rich waters, and similarly aged asphaltum, representing the surface accumulation of tar. Lastly, insects are abundant in many Pleistocene glacial deposits of outwash and stranded lake sediments, formed by the waxing and waning of alpine and continental glaciers.

Various types of fossil documentation are important for understanding insect paleobiology, such as the body-fossil history of mouthparts. A recent study of insect mouthparts reveals a fivefold phase of increasing mouthpart disparity through time. This geochronologic deployment of the 34 basic types of modern insect mouthparts began during the Early Devonian with a few generalized types, was expanded during the late Carboniferous to early Permian to include major modifications of mandibulate and piercing-and-sucking types, and increased significantly again during the Late Triassic to Early Jurassic to include filter-feeding mouthpart types and others involved in the ecologic penetration of aquatic ecosystems, and also intricate interactions with other animal and seed-plant hosts. During the Late Jurassic, there was expansion of mouthpart types involved in fluid-feeding on plant, fungal, and animal tissues and during the Early Cretaceous mouthpart innovation was completed by the addition of a few specialized mouthpart types involved in blood-feeding and other specialized associations. A comparison of taxonomic diversity and mouthpart disparity reveals that the generation of taxa has proceeded overall in a semilogarithmic increase reflected in a concave curve, whereas morphologic innovation, as revealed by mouthpart disparity, is a logistic process evidenced by a convex curve. This suggests that the deployment of basic morphologic types typically precedes taxonomic diversification in insect fossil history. [C.C.La]

Insecticide

A material used to kill insects and related animals by disruption of vital processes through chemical action. Insecticides may be inorganic or organic chemicals. The principal source is from chemical manufacturing, although a few are derived from plants.

Insecticides are classified according to type of action as stomach poisons, contact poisons, residual poisons, systemic poisons, fumigants, repellents, attractants, insect growth regulators, or pheromones. Many act in more than one way. Stomach poisons are applied to plants so that they will be ingested as insects chew the leaves. Contact poisons are applied in a manner to contact insects directly, and are used principally to control species which obtain food by piercing leaf surfaces and withdrawing liquids. Residual insecticides are applied to surfaces so that insects touching them will pick up lethal dosages. Systemic insecticides are applied to plants or animals and are absorbed and translocated to all parts of the organisms, so that insects feeding upon them will obtain lethal doses. Fumigants are applied as gases, or in a form which will vaporize to a gas, so that they can enter the insects' respiratory systems. Repellents prevent insects from closely approaching their hosts. Attractants induce insects to come to specific locations in preference to normal food sources. Insect growth regulators are generally considered to act through disruption of biochemical systems or processes associated with growth or development, such as control of metamorphosis by the juvenile hormones, regulation of molting by the steroid molting hormones, or regulation of enzymes responsible for synthesis or deposition of chitin. Pheromones are chemicals which are emitted by one sex, usually the female, for perception by the other, and function to enhance mate location and identification; pheromones are generally highly species-specific.

Formulation of insecticides is extremely important in obtaining satisfactory control. Common formulations include dusts, water suspensions, emulsions, and solutions. Accessory agents, including dust carriers, solvents, emulsifiers, wetting and dispersing agents, stickers, deodorants or masking agents, synergists, and antioxidants, may be required to obtain a satisfactory product.

Proper timing of insecticide applications is important in obtaining satisfactory control. Whatever the technique used, the application of insecticides should be correlated with the occurrence of the most susceptible or accessible stage in the life cycle of the pest involved. By and large, treatments should be made only when economic damage by a pest appears to be imminent.

Among problems associated with insect control are the development of strains of insects resistant to insecticides; the assessment of the significance of small, widely distributed insecticide residues in and upon the environment; the development of better and more reliable methods for forecasting insect outbreaks; the evolvement of control programs integrating all methods—physical, physiological, chemical, biological, and cultural—for which practicality was demonstrated; the development of equipment and procedures to detect chemicals much below the part-per-million and microgram levels. As a consequence of the provisions of the Federal Insecticide, Fungicide, and Rodenticide Act as amended by the Federal Environmental Pesticide Control Act of 1972, there have been increased efforts to obtain data delineating mammalian toxicology, persistence in the environment, and immediate chronic impact of pesticides upon nontarget invertebrate and vertebrate organisms occupying aquatic, terrestrial, and arboreal segments of the environment. *See* FUMIGANT; INSECT CONTROL, BIOLOGICAL; INSECT PHYSIOLOGY; INSECTA; PESTICIDE. [G.F.L.]

Insectivora

An order of placental mammals including shrews, moles, and hedgehogs. The tree shrews (Tupaiidae) and elephant shrews (Macroscelididae) are now recognized as unrelated, and they are placed in separate orders (Scandentia and Macroscelidea). Formerly thought to be the basal placental order, from which other orders were derived, the Insectivora is now restricted to members of the former suborder Lipotyphla. It evolved side by side with the other placental orders, with a fossil record going back to the Paleocene. A number of fossil families from the Cretaceous and early Tertiary, formerly included in the Insectivora, are classified as Proteutheria. *See* MACROSCELIDEA.

Living lipotyphlous insectivores are small animals: the largest (*Potamogale*) weighs about 1 kg (2 lb). Most eat insects, worms, and other invertebrates, for which they search in ground litter and vegetation, using their highly developed olfactory sense and their mobile, sensitive snouts. Some burrow, such as moles; some are aquatic, such as the desman. Anatomically, they are distinguished by the absense of a cecum on the intestine, reduction of the pubic symphysis, and characters of the skull. The cheek teeth typically have sharp cusps and crests, and the incisors are often enlarged to act as forceps. Insectivores are found on all continents except Australia and Antarctica, but only one genus (*Cryptotis*, a shrew) has reached South America.

Three suborders can be distinguished: Erinaceomorpha, Soricomorpha, and Chrysochloromorpha. Living erinaceomorphs belong to the family Erinaceidae, comprising the spiny hedgehogs (Erinaceinae) of Eurasia and Africa and the hairy moonrats (Echinosoricinae) of Southeast Asia.

Four living families are included in the Soricomorpha: Soricidae (shrews), Talpidae (moles, desman), Tenrecidae (Madagascan tenrecs and African otter shrews), and Solenodontidae (*Solenodon*, confined to Cuba and Hispaniola). True moles did not reach North America until the Miocene; they were preceded in the Oligocene by the Proscalopidae. The living *Solenodon*, in the West Indies, is one of the largest insectivores, but nevertheless shrewlike. The Tenrecidae are far removed geographically from other soricomorphs. They probably evolved in Africa, where their fossil history goes back to the early Miocene, and the otter shrews (Potamogalinae) survive on the continent of Africa today. The remainder are in Madagascar where, like the lemurs, they have evolved in diverse directions during a long time of isolation. In some ways, for example brain size, they have remained more primitive than other insectivores.

The golden moles (Chrysochloridae) are put into a separate suborder, Chrysochloromorpha. They are highly specialized burrowers, using large claws on the forefoot. They are confined to Africa, where fossils show that they were already specialized in the early Miocene. *See* Mammalia; Mole (zoology); Shrew; Solenodon; Tenrec. [P.M.B.; M.C.McK.]

Insectivorous plants Plants having variously modified, highly specialized leaves which capture and digest insects. The proteins of the digested insect bodies supply nitrogen, which otherwise may be unavailable to these plants in the places where they grow. Sometimes they are also called carnivorous (flesh-eating) plants. *See* Nepenthales; Pitcher plant; Secretory structures (plant); Sundew; Venus' flytrap. [P.D.St./E.L.C.]

Insolation The incident radiant energy emitted by the Sun, which reaches a unit horizontal area of the Earth's surface. The term is a contraction of incoming solar radiation. About 99.9% of the Sun's energy is in the spectral range of 0.15–4.0 micrometers. About 95% of this energy is in the range of 0.3–2.4 μm; 1.2% is below 0.3 μm and 3.6% is above 2.4 μm. The bulk of the insolation (99%) is in the spectral region of 0.25–4.0 μm. About 40% is found in the visible region of 0.4–0.7 μm and only 10% is in wavelengths shorter than the visible. Energy of wavelengths shorter than 0.29 μm is absorbed high in the atmosphere by nitrogen, oxygen, and ozone.

Insolation depends on several factors: (1) the solar constant—that is, the amount of energy that in a unit time reaches a unit plane surface perpendicular to the Sun's rays outside the Earth's atmosphere, when the Earth is at its mean distance from the Sun; (2) the Sun's elevation in the sky; (3) the amount of solar radiation returned to space at the Earth-atmosphere boundary; and (4) the amount of solar radiation absorbed by the atmosphere and the amount of solar radiation reflected at the lower boundary of the Earth. Insolation is commonly expressed in units of watts per square meter, or calories per square centimeter per minute, also known as langley/min. For instance, the mean value of the solar constant has been estimated as 1368 W/m^2 ($\sim$1.96 ly/min), and the average insolation in summer for a midlatitude clear region could be 340 W/m^2 (700 ly/day), while for a cloudy region it is only about 120 W/m^2 (250 ly/day). *See* Albedo; Atmosphere; Solar radiation; Terrestrial radiation. [R.T.P.]

Inspection and testing Industrial activities which ensure that manufactured products, individual components, and multicomponent systems are adequate for their intended purpose. Inspection and testing are the operational parts of quality control, which is the most important factor to the survival of any manufacturing company. Quality control directly supports the other factors of cost, productivity, on-time delivery, and market share. Therefore, all quality standards needed to produce the components of a product and perform its assembly must be specified in a manner such that customers' expectations are met. Global competitive pressures force manufacturing companies to become more customer-oriented and focused in terms of offering higher-quality products and services. *See* Quality control.

Inspection and testing are performed before, during, and after manufacturing to ensure that the quality level of the product is within acceptable design standards.

Whereas inspection is the activity of examining the product or its components to determine if they meet the design standards, testing is a procedure in which the item is observed during operation in order to determine whether it functions properly for a reasonable period of time. *See* Design standards.

In statistical quality control, inferences are made about quality based on a sample taken from the population of the items. The sample of items is generated randomly from the population. Each item in the sample is inspected or tested for certain quality characteristics. For example, the diameter of a cylindrical part is measured after the turning operation that generated the part is completed.

The objective of statistical quality control is to determine when the process has gone out of statistical control, so that corrective action can be taken. The two principal techniques in statistical quality control are acceptance sampling and control charts. In acceptance sampling, a sample is taken from a batch of parts and, depending on the number of parts that pass the inspection or testing, the batch is accepted or rejected. A control chart is designed to be a simple graphical technique to monitor and control a single characteristic of the process output. The objective is to obtain an estimate of the principal parameter that describes the variability of this characteristic and then to use a test of hypothesis to determine if the process is in control. A control chart contains three horizontal lines: the central line represents the mean of the process output, and the upper and lower control limits indicate extreme statistical values of the process output. If a measured value of the output is outside these limits, the process is out of control and needs to be examined to determine the reason. The natural tolerance limits (±3 standard deviations) are normally used to specify the upper and lower limits in a control chart. *See* Control chart; Statistics.

Sensor technologies for automated inspection can be divided into two broad categories: contact and noncontact inspection methods. Contact inspection methods involve the use of a mechanical probe or another device that makes contact with the object being inspected. The purpose of the probe is to measure or gage some physical dimension of the object. These methods are used predominantly in the mechanical manufacturing industries. Coordinate measurement machines, flexible inspection systems, and inspection probes represent the high end of this technology. Noncontact inspection methods involve the use of a sensor located at a certain distance from the object to measure or gage the desired features. Two significant advantages of noncontact inspection methods are shorter inspection times and avoidance of damage to the object. Noncontact inspection methods include machine vision, electrical field techniques, radiation techniques, and ultrasonics. [J.A.V.]

Instinctive behavior A relatively complex response pattern which is usually present in one or both sexes of a given species. These responses have a genetic basis, are essentially unlearned, and are generally adaptive.

Instinctive behavior occurs when an animal has a particular internal state while it is in the presence of a specific external stimulation called a releaser or a sign stimulus. Neither the internal state nor the external stimulus alone is adequate for the elicitation of the response. Many animals show particular instinctive behaviors only during the mating season, when hormonal changes associated with sexual behavior sensitize specific portions of the central nervous system, which will then be active in the presence of the releaser. The external stimulus may be relatively simple or incredibly complex.

Within limits, the instinctive behaviors can be modified by learning. There is evidence, for example, that some predators learn to attack their prey at the back of the neck because when held in that position the prey cannot counterattack. *See* MIGRATORY BEHAVIOR; REPRODUCTIVE BEHAVIOR. [K.E.M.]

Instrument landing system (ILS) A collection of discrete radio navigation aids used by pilots of all types of aircraft for approach guidance to a specific airport runway, especially during times of limited visibility. Typically, three components constitute the instrument landing system: a localizer, which provides lateral guidance; a glide slope, which gives vertical guidance; and one to three marker beacons, which give position fixes along the approach path (see illustration). A distance-measuring-equipment (DME) readout or a non-directional, low-frequency radio beacon (NDB) is sometimes substituted for the outer marker beacon, usually located about 5 mi (8 km) from the runway. *See* DISTANCE-MEASURING EQUIPMENT.

The localizer, glide slope, and markers function by radiating continuous-wave, horizontally polarized, fixed beams of radio-frequency energy into the air space. The localizer operates in the band of 108–112 MHz, the glide slope in the band of 329–335 MHz, and the marker beacons on the discrete frequency of 75 MHz. The localizer and glide-slope frequencies are paired; for example, every localizer operating at 109.5 MHz has a glide slope operating at 329.6 MHz. If there is a DME present, it is also paired. Only the localizer receiver in the aircraft needs to be tuned.

Over 1000 instrument landing systems operate in the United States, with an additional 300 systems in use worldwide. A major contender for ultimate replacement of the instrument landing system appears to be a Global Navigation Satellite System (GNSS), in which the Global Positioning System (GPS) would play a major role. *See* SATELLITE NAVIGATION SYSTEMS. [R.H.McF.]

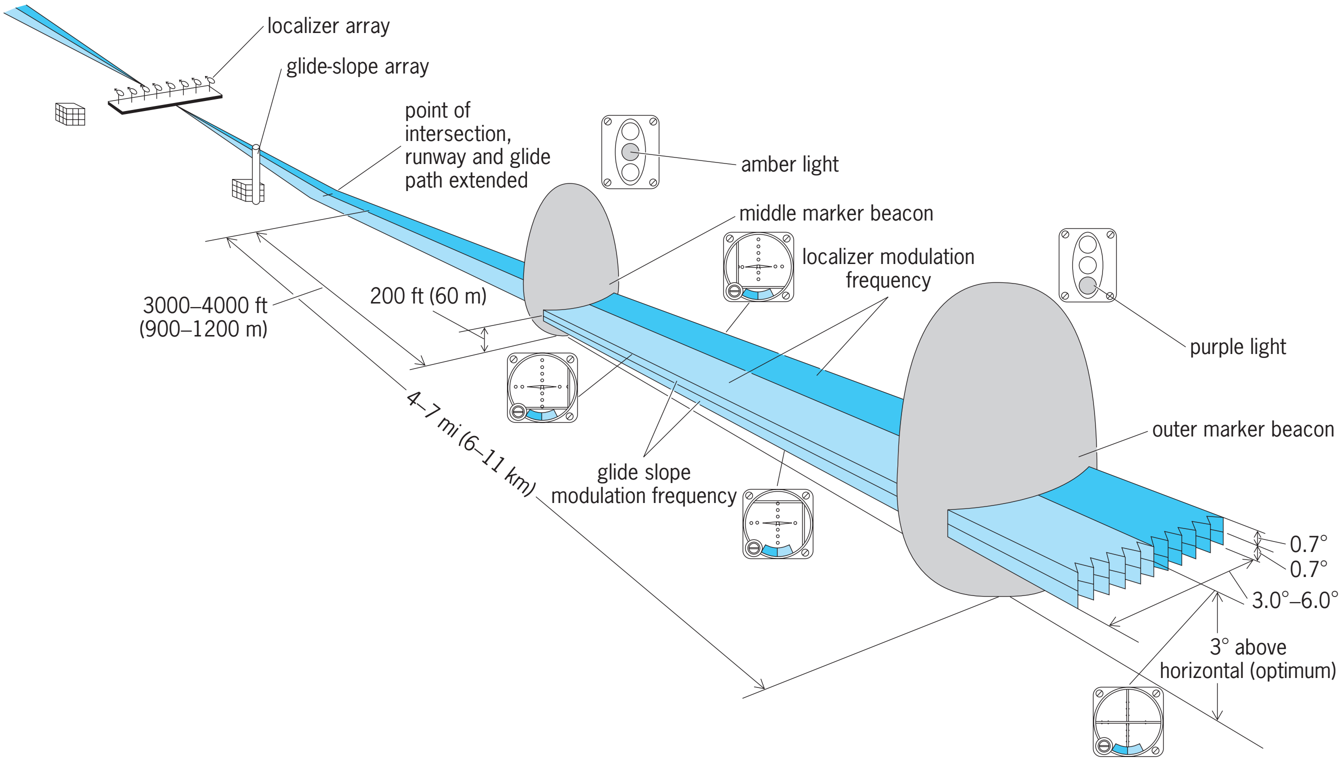
Instrument science The systematically organized body of general concepts and principles underlying the design, analysis, and application of instruments and instrument systems.

Instruments are very diverse in function and form. They differ according to measurands, range of magnitudes and the dynamic variations of the measurand, required accuracy, and nature and environment of application. Equally diverse is the range of technologies that can be used to realize a particular instrument function. To enable this information to be handled in such a way that it can be usefully applied to the design, analysis, or application of instruments, it must be organized on the basis of a systematic framework of general concepts and principles. This framework is termed instrument science.

The basis of instrument science is: first, the consideration of instruments as members of the general class of information machines; and second, an analysis and synthesis of the instruments as systems, applying the principles of system engineering.

There exists a wide class of machines whose function is to acquire, process, and feed out information. This class includes measuring instruments, control apparatus, communication equipment, and computers. These machines function by the transformation of an input physical variable into an output variable in such a way that the output is functionally related to the input. Thus the output carries information about the input. This basic principle of functioning determines the general features of the analysis and synthesis of information machines. *See* COMPUTER; CONTROL SYSTEMS; ELECTRICAL COMMUNICATIONS.

Instruments and indeed other forms of information machines are conveniently analyzed and synthesized as systems. A system is a set of interconnected components functioning as a unit. There is a set of general principles and techniques for treating complex entities as systems. It is known as the systems approach, and is based on the decomposition of the complex whole into



Components of instrument landing system (ILS), and resulting signals used by the pilot. (*Federal Aviation Administration*)

individual components. The individual components are considered in the first instance in terms of function rather than form.

Considering systems, such as instruments, as structures of functional building blocks makes clear that a very wide variety of instruments can be constructed from a much smaller variety of building blocks organized into a small variety of basic structures, such as a chain or loop connection. Further, it makes clear that apparently different systems—say, electrical and mechanical, or physical and biological—are essentially analogous. *See* INSTRUMENTATION; SYSTEMS ANALYSIS; SYSTEMS ENGINEERING. [L.Fi.]

Instrument transformer A device that serves as an input source of currents and voltages from an electric power system to instruments, relays, meters, and control devices. The basic design is that of a transformer with the primary winding connected to the power system, and the secondary winding to the sensing and measuring equipment. Data from these devices are necessary for the operation, control, and protection of the power system. The primary reason for setting up the instrument-transformer interface is to provide analog information at low voltage levels, insulated from the higher system voltages. The range of use is from 480 V through the maxima of the 765–1000-kV power systems. *See* ELECTRIC POWER SYSTEMS; TRANSFORMER.

Current transformers are connected in series with the power conductor. In many cases this conductor serves as the one-turn primary. The principal types are the window type, where the power conductor is passed through a hole in the center of the current transformer; the bar type, where the power conductor is fastened to a one-turn bar which is part of the current transformer; and the bushing type, a toroidal core and winding that is slipped over the insulating bushings of circuit breakers, transformers, and so forth.

Voltage transformers and coupling capacitor voltage transformers are connected in parallel from one conductor to another or to ground. The coupling capacitor voltage transformer is widely used at the higher system voltages of 115 kV and above. It is a voltage transformer tapped across part of a capacitor unit connected from the conductor to ground. [J.L.Bl.]

Instrumental conditioning Learning based upon the consequences of behavior. For example, a rat may learn to press a lever when this action produces food. Instrumental or operant behavior is the behavior by which an organism changes its environment. The particular instances of behavior that produce consequences are called responses. Classes of responses having characteristic consequences are called operant classes; responses in an operant class operate on (act upon) the environment. For example, a rat's lever-press responses may include pressing with the left paw or with the right paw, sitting on the lever, or other activities, but all of these taken together constitute the operant class called lever pressing.

Consequences of responding that produce increases in behavior are called reinforcers. For example, if an animal has not eaten recently, food is likely to reinforce many of its responses. Whether a particular event will reinforce a response or not depends on the relation between the response and the behavior for which its consequences provide an opportunity. Some consequences of responding called punishers produce decreases in behavior. The properties of punishment are similar to those of reinforcement, except for the difference in direction.

The consequences of its behavior are perhaps the most important properties of the world about which an organism can learn, but few consequences are independent of other circumstances. Organisms learn that their responses have one consequence in one setting and different consequences in another. Stimuli that set the occasion on which responses have different consequences are called discriminative stimuli (these stimuli do not elicit responses; their functions are different from those that are simply followed by other stimuli). When organisms learn that responses have consequences in the presence of one but not another stimulus, their responses are said to be under stimulus control. For example, if a rat's lever presses produce food when a light is on but not when it is off and the rat comes to press only when the light is on, the rat's presses are said to be under the stimulus control of the light. *See* CONDITIONED REFLEX; LEARNING MECHANISMS. [A.C.Ca.]

Instrumentation amplifier A special-purpose linear amplifier, used for the accurate amplification of the difference between two (often small) voltages, often in the presence of much larger common-mode voltages, and having a pair of differential (usually high-impedance) input terminals, connected to sources $V_{\mathrm{in}1}$ and $V_{\mathrm{in}2}$; a well-defined differential-mode gain A_{DM}; and a voltage output V_{out}, satisfying the relationship given in the equation below. It differs from an operational amplifier (op-amp), which ideally has infinite open-loop gain and must be used in conjunction with external elements to define the closed-loop transfer function.

$$V_{\mathrm{out}} = A_{\mathrm{DM}}(V_{\mathrm{in}1} - V_{\mathrm{in}2})$$

At one time built in discrete or hybrid form using operational amplifier and resistor networks, instrumentation amplifiers are readily available as inexpensive monolithic integrated circuits. Typical commercial amplifiers provide present gains of 1, 10, 100, and 1000. In some cases, the gain may be set to a special value by one or more external resistors. The frequency response invariably is flat, extending from 0 (dc) to an upper frequency of about 1 kHz to 1 MHz. *See* INTEGRATED CIRCUITS; OPERATIONAL AMPLIFIER; RESISTOR.

Instrumentation amplifiers are used to interface low-level devices, such as strain gages, pressure transducers, and Hall-effect magnetic sensors, into a subsequent high-level process, such as analog-to-digital conversion. *See* AMPLIFIER; DIFFERENTIAL AMPLIFIER; HALL EFFECT; PRESSURE TRANSDUCER; STRAIN GAGE. [B.Gi.]

Instrumented buoys Unattended, floating structures equipped with systems for collecting, processing, and transmitting meteorological and oceanographic data. Such information is useful for many purposes, including storm warnings and forecasts, coastal engineering, climatology, and oceanographic and atmospheric research.

Moored systems, anchored to the ocean bottom, record currents and water properties as the flow passes the buoy (the eulerian framework). Drifting buoys move with the waters, indicating where they go (the lagrangian framework). In both cases, additional sensors may record a variety of parameters, such as temperature, pressure, acceleration, and water properties.

Surface moorings come in many shapes and sizes depending upon a number of factors, such as research versus operational requirements, duration of deployment, surface versus subsurface measurements, strength of currents, and weather considerations. To operate for a long time, moored buoys require highly reliable components, including a strong mooring line to prevent failure due to wear and tear in heavy seas. This in turn requires large buoys with substantial surface flotation to support the weight of the line. These buoys support a suite of atmospheric sensors and power systems for their operation and data telemetry.

Studies of the subsurface ocean typically employ moorings with flotation below the surface. Subsurface moorings experience much less fatigue of the hardware and mooring line due to the absence of wave motion, permitting the use of lighter-weight, less expensive hardware. More importantly, the absence of surface wave motion results in a much calmer mooring line, greatly facilitating accurate current measurements. Subsurface moorings also eliminate the risk of piracy and entanglement with fishing nets, a major source of equipment and data loss for surface moorings. However, these moorings require costly subsurface flotation devices because they must have the strength to withstand the higher hydrostatic pressure. Large steel spheres are used for near-surface flotation applications, and glass balls are used at greater pressures. Syntactic foam, consisting of a matrix of glass microspheres embedded in epoxy, has proven very effective in applications where the flotation must have a special shape to support instruments, yet remain streamlined to minimize drag forces in strong currents.

Drifting buoys drift with the waters, either as surface drifters or as subsurface floats. In order to follow the waters while minimizing the effect of winds, surface drifters have very little exposure at the surface but have large drag elements hanging beneath. Today, the nearly universal drifter design includes a spherical flotation element and a long, large-diameter canvas tube with large holes, known as a holey sock. Its large size guarantees that the drifter moves with the waters around the sock, readily pulling the small surface sphere with it. Depending upon the application, the sock might hang just to 10 m or as deep as 100 m. The movement of the drifters are tracked by satellites. These drifters have made major contributions to our knowledge of the surface circulation of all the oceans. Some new designs come equipped with temperature sensors, and increasingly, with barometric pressure gauges. They also telemeter valuable sea surface weather information, including acoustic measurements of winds. These buoys cost-effectively complement the functions of the surface buoys.

Buoy sensors can be categorized according to whether they measure scalar or vector properties. Scalar sensors measure the state of a fluid, such as temperature, pressure, humidity, salinity, and light intensity. Vector sensors measure speed and direction of winds and currents. In the past, precipitation measurement presented formidable problems, but the tropical moorings across the Pacific have successfully measured rainfall. An acoustic method that measures the noise generated by raindrops as they hit the surface also shows promise. *See* OCEAN CIRCULATION. [H.T.R.]

Insulation resistance testing The measurement of direct current or voltage drop across an electrical insulating material to determine its resistance by the application of Ohm's law. Insulation resistance testing is performed either on samples of the insulation material or on the electrical equipment which uses the insulation.

Insulation resistance in solids is made up of a combination of volume resistance and surface resistance. These two types of resistances arise because the current can physically flow through the volume of the insulation material or it can find other parallel paths over the surface of the insulation. Volume resistance can be used as an indirect measure of the quality of the material with regard to processing or to detect impurities. Surface resistance measurements can be used to characterize the condition of the insulation surface, such as deposition of contaminants and insulation breakdown strength.

In all cases, the conditions under which resistance measurements on insulators are performed must be fully specified. Several factors can significantly affect the test results. Among them are the geometry of the electrode system, the nonuniformity of the material, the time period that the sample is energized, the magnitude and polarity of the voltage, the time required for charge to build up or decay in the sample, and the contour of the specimen. The measured value of insulation resistance will be most useful when the test samples and the electrodes have the same arrangement and are tested in a similar environment as that expected under actual use. Modern electronic instrumentation has simplified and improved insulation resistance measurements because of the high input impedance available with these devices, their fast response time, their memory storage capability, and their ease of operation. [T.C.C.]

Insulin Produced and secreted by the beta cells of the islets (insulae) of Langerhans of the pancreas, the hormone which regulates the use and storage of foodstuffs, especially the carbohydrates. Chemically insulin is a small, simple protein. Insulins from various species differ in the composition; these differences account for the fact that diabetics treated with animal insulins develop antibodies which may sometimes interfere with the action of the hormone. The structure has been verified by synthesis of insulin from pure amino acids in the laboratory. *See* CARBOHYDRATE METABOLISM; IMMUNOLOGY; PANCREAS.

Insulin, being a polypeptide, can also be broken down by many proteolytic enzymes to its constituent amino acids. Because of these breakdown systems, the turnover of insulin in the body is rapid; its "half-life" has been estimated to be 10–30 min. The liver alone is capable of destroying about 50% of the insulin passing through it on its way from the pancreas to the bodily tissues.

The role played by insulin in the body is most clearly approached by considering the abnormalities resulting from removing insulin from an organism by surgical excision of the pancreas or by the chemical destruction of the insulin-producing cells: A state of severe diabetes is produced. Normally the blood glucose level is about 100 mg/100 ml. A carbohydrate meal raises the blood sugar to about 150 mg and the premeal value is reached again within 1.5 h. The normal organism manages to dispose of food by storage and oxidation within this period because insulin is present. When food (carbohydrate and protein) reaches the upper intestine, a substance is liberated which in turn stimulates the beta cells to secrete extra insulin. Insulin acts on most tissues to speed the uptake of glucose. In the cells the glucose is burned for energy, stored as glycogen, or transformed to and stored as fat. The human pancreas probably produces 1–2 mg of the hormone per day. This is sufficient to regulate the metabolism of more than 250 g of carbohydrate, 70 g of protein, and 75 g of fat, the usual composition of an ordinary 2000-calorie diet.

In diabetes the rate of glucose uptake is slowed, the level of circulating blood sugar rises, and sugar spills over into the excreted urine. Calories are wasted, more water is excreted, and there is muscular weakness and weight loss; hence urinary frequency, hunger, thirst, and fatigue. Whenever glucose metabolism is defective, stored fat is broken down to fatty acids because of the actions of adrenaline and the pituitary growth hormone. Insulin is able to reverse all these phenomena by favoring storage and swift intake of glucose into the tissues, by decreasing the breakdown of stored fat, and by promoting protein synthesis. *See* DIABETES.

When insulin is secreted or given in excess, it may lower the blood sugar level much below its normal value, causing hypoglycemia. Hypoglycemia is dangerous because the metabolism in the brain cells depends primarily upon an adequate supply of glucose.

The precise molecular mechanisms of insulin action are still not known. The initial step is the binding of the hormone to a specific receptor on the cell membrane. This event somehow activates a set of transport molecules, so that glucose, potassium, and amino acids enter cells more freely. At the same time, fat breakdown is slowed and glycogen storage increased. All these actions depend upon the integrity of the outer cell membrane. *See* CELL PERMEABILITY.

Not all the cells of the body require or respond to insulin. The insulin-responsive tissues are the liver, skeletal muscle, the heart, and the adipose tissue. Sensitivity to insulin is affected by many conditions. Obesity, antibodies to the hormone or its receptor, oversecretion of growth hormone or adrenal steroids, ketosis, and unknown genetic factors all cause insulin resistance. Muscular exercise, correction of obesity, and a deficiency of pituitary or adrenal hormones are associated with an increased sensitivity to the hormone. *See* ENDOCRINE MECHANISMS. [R.Lev.; B.F.]

Intaglio (gemology) The name given to the type of carved gemstone in which the figure is engraved into the surface of the stone, rather than left in relief by cutting away the background, as in a cameo. Intaglios are almost as old as recorded history, for this type of carving was popular in ancient Egypt in the form of cylinders. Intaglios have been carved in a variety of gem materials, including emerald, crystalline quartz, hematite, and the various forms of chalcedony. *See* CAMEO. [R.T.L.]

Integral equation An equation of the form typified by Eq. (1). The major problem is to decide when there is a function

$$\int_a^b K(x, y, \phi(y))dy + f(x) = a(x)\phi(x) \qquad (1)$$

$\phi(x)$ which is a solution to the equation. Equations such as (1) arise from the analysis of ordinary differential equations. Integral equation (1) is an equation of the first kind if $a(x) \equiv 1$, and an equation of the second kind if $a(x) \equiv 0$.

If $K(x,y,\phi) = 0$ for $x \lesssim y \lesssim b$, Eq. (1) is called a Voltera equation. Under mild assumptions the Volterra equation of the second kind can be solved by the method of successive approximations (also known as the method of Picard).

A special case of some interest is that of linear integral equations. The function $K(x,y,\phi)$ is a linear function of ϕ. The linear equations of the first and second kind are shown in Eqs. (2) and (3) respectively. The function $K(x,y)$ is called the kerne, and

$$f(x) = \int_a^b K(x, y\phi)(x)dy \qquad (2)$$

$$\phi(x) = f(x) + \lambda \int_a^b K(x,\, y\phi)(y)dy \qquad (3)$$

the complex number λ is called the parameter. The equation of the second kind, Eq. (3), is homogeneous if $f(x) \equiv 0$. In typical cases, the homogeneous equations will have only the trivial solution $\phi(x) \equiv 0$. For some values of the parameter λ, however, there will be nontrivial solutions. Such a value of the parameter λ is called a characteristic value for K, and the corresponding function ϕ is called a characteristic function for K. These concepts are related to corresponding concepts in linear algebra and operator theory. *See* EIGENVALUE (QUANTUM MECHANICS); MATRIX THEORY; OPERATOR THEORY.

The integral equation, Eq. (2) or (3), is called a Fredholm equation, and $K(x,y)$ is called a Fredholm kernel if $\|K\| < \infty$, where $\|K\|$, the norm of K, is defined by Eq. (4). This is certainly true

$$\|k\|^2 = \int_a^b \int_a^b |K(x, y)|^2 dxdy \qquad (4)$$

if K is continuous or even bounded. Even some infinite discontinuities are allowable. Fredholm equations of the second kind for which the parameter satisfies the inequality $|\lambda|\ \|K\| < 1$ can be shown to have unique solutions by the method of Picard. As a result there are no characteristic values for which $|\lambda| \lesssim 1/\|K\|$. In general, for any constant $M > 0$ there are only finitely many characteristic values which satisfy $|\lambda| \lesssim M$. Further, only finitely many linearly independent characteristic functions are associated with each characteristic value. *See* INTEGRAL TRANSFORM; INTEGRATION. [J.P.]

Integral transform An integral relation between two classes of functions. For example, a relation such as Eq. (1) is

$$f(x) = \int_{-\infty}^{\infty} G(x, y)\phi(y)dy \qquad (1)$$

said to define an integral transform. More generally, the integral may be a multiple integral, and the functions f, G, and ϕ may depend on a larger number of variables. Equation (1) is thought of as transforming a whole class, or space, of functions $\phi(y)$ into another class of functions $f(x)$. The function $G(x,y)$ is the kernel of the transform. One of the important uses of such a transform is based on the fact that a problem posed in one of the two spaces in question may be more easily solved in the other. For example, a differential equation to be solved for the function $\phi(y)$ may become an algebraic equation for the unknown function $f(x)$. *See* LAPLACE TRANSFORM.

The two basic problems for any integral transform are inversion and representation. In inversion the aim is to recover $\phi(y)$ from $f(x)$, the kernel $G(x,y)$ being known. That is, Eq. (1) is thought of as an integral equation (of the first kind) to be solved for the unknown function $\phi\ (y)$. A means of calculating $\phi(y)$ from $f(x)$ is called an inversion formula, and in its presence the transform achieves maximum utility, since explicit passage from each space to the other is thus assured. In representation the question is which functions $f(x)$ may be written or represented in the form (1). That is, one asks which functions $f(x)$ will make Eq. (1) solvable for $\phi(y)$. Usually this problem becomes more tractable when the solutions $\phi(y)$ are restricted to some subspace such as the class of positive or bounded functions. *See* INTEGRAL EQUATION.

An important special case of Eq. (1) is the convolution transform, when the kernel is a function of $(x - y)$, Eq. (2). An equivalent form of Eq. (2) is Eq. (3), since the change of variable

$$f(x) = \int_{-\infty}^{\infty} G(x - y)\phi(y)dy \qquad (2)$$

$$F(x) \int_0^{\infty} K(xy)\phi(y)dy \qquad (3)$$

$x = e^t$, $y = e^{-u}$ carries Eq. (3) into Eq. (2) after a suitable change in notation. *See* INTEGRATION. [D.V.W.]

Integrated-circuit filter An electronic filter implemented as an integrated circuit, as contrasted with filters made by interconnecting discrete electrical components. The design of an integrated-circuit filter (also called simply an integrated filter) is constrained by the unavailability of certain types of components, such as piezoelectric resonators, that are often valuable in filtering. However, integrated filters can benefit from small size, close integration with other parts of a system, and the low cost of manufacturing very complex integrated circuits.

Filters have many applications. An important one is to smooth signal waveforms sufficiently to allow accurate sampling or to interpolate smoothly between given samples of a signal. Since the analog-to-digital converters that sample signals are usually made as integrated circuits (chips), it is often convenient to put the associated filters on the same chip. *See* ANALOG-TO-DIGITAL CONVERTER.

Passive filters, made by interconnecting inductors and capacitors, are not easily integrated because integrated-circuit inductors are usually of poor quality. This problem is less serious at frequencies above 1 GHz, so microwave filters can be passive. *See* MICROWAVE FILTER.

Because amplifiers are very cheap in integrated-circuit technology, active filters are widely implemented. The five main types of active filter—active-RC, MOSFET-C, transconductance-C, switched-capacitor (or switched-C), and active-RLC— are distinguished by their frequency-sensitive components. The switched-capacitor filters operate on samples of signals, while the other types operate without sampling (in continuous time). There is also a trend toward digital filters, which are easily integrated but require that analog signals be converted to digital form, which in turn requires filtering. *See* DIGITAL FILTER.

Discrete active-RC filters were widely used in the 1970s, and modern integrated filters are derived from them. The frequency-sensitive mechanism in active-RC filters is the charging of a capacitor C through a resistor R, giving a characteristic frequency $\omega_0 = 1/RC$ radians per second, at which the impedances of the resistor and capacitor are equal. Unfortunately, integrated-circuit manufacturing techniques do not control the product RC at all accurately, with variations of 20–50% being possible. This limits active-RC filtering to those applications where accuracy is unimportant, where external passive components are tolerable, or where tuning circuitry is available.

MOSFET-C filters replace the resistors of an active-RC filter with metal-oxide-semiconductor (MOS) transistors, in which a conducting channel along the surface can be enhanced or depleted by applying an electrical field from a gate electrode, thereby changing the resistance of the channel. The result is a tunable variant of an active-RC filter. *See* Transistor.

Transconductance-C filters combine the functions of the amplifier and the simulated resistor into a transconductance amplifier, whose output current (rather than output voltage) is proportional to its input voltage. Transconductance amplifiers can be very simple and hence are capable of high-frequency operation (up to approximately 1 GHz) but tend to have poor linearity when designed for high speeds.

A technique known as active-RLC filtering combines the ideas of active filtering with the use of physical inductors (made as spirals of metallization on the top layer of the chip). In this method, amplifiers, connected to simulate negative resistors, are used to enhance the performance of the inductors, whose losses can be modeled (to a first approximation) as being caused by a parallel positive resistance.

The primary advantage of switched-capacitor filters is that they can be very accurate, since critical frequencies are determined by the product of a clock frequency and a ratio of capacitors (rather than a single capacitor). Switched-capacitor filters are probably the most prevalent integrated filters. Most telephone systems, for example, use them to smooth signals before sampling them for digital transmission. *See* Electric filter; Integrated circuits; Switched capacitor. [M.Sn.]

Integrated circuits Miniature electronic circuits produced within and upon a single semiconductor crystal, usually silicon. Integrated circuits range in complexity from simple logic circuits and amplifiers, about $^1/_{20}$ in. (1.3 mm) square, to large-scale integrated circuits up to about $^1/_2$ in. (12 mm) square. They can contain millions of transistors and other components that provide computer memory circuits and complex logic subsystems such as microcomputer central processor units. *See* Semiconductor; Silicon.

Integrated circuits consist of the combination of active electronic devices such as transistors and diodes with passive components such as resistors and capacitors, within and upon a single semiconductor crystal. The construction of these elements within the semiconductor is achieved through the introduction of electrically active impurities into well-defined regions of the semiconductor. The fabrication of integrated circuits thus involves such processes as vapor-phase deposition of semiconductors and insulators, oxidation, solid-state diffusion, ion implantation, vacuum deposition, and sputtering.

Generally, integrated circuits are not straightforward replacements of electronic circuits assembled from discrete components. They represent an extension of the technology by which silicon planar transistors are made. Because of this, transistors or modifications of transistor structures are the primary devices of integrated circuits. Methods of fabricating good-quality resistors and capacitors have been devised, but the third major type of passive component, inductors, must be simulated with complex circuitry or added to the integrated circuit as discrete components. *See* Transistor.

Integrated circuits can be classified into two groups on the basis of the type of transistors which they employ: bipolar integrated circuits, in which the principal element is the bipolar junction transistor; and metal oxide semiconductor (MOS) integrated circuits, in which the principal element is the MOS transistor. Both depend upon the construction of a desired pattern of electrically active impurities within the semiconductor body, and upon the formation of an interconnection pattern of metal films on the surface of the semiconductor.

Bipolar circuits are generally used where highest logic speed is desired, and MOS for largest-scale integration or lowest power dissipation. High-performance bipolar transistors and complementary MOS (CMOS) transistors have been combined on the same chip (BiCMOS) to obtain circuits combining high speed and high density.

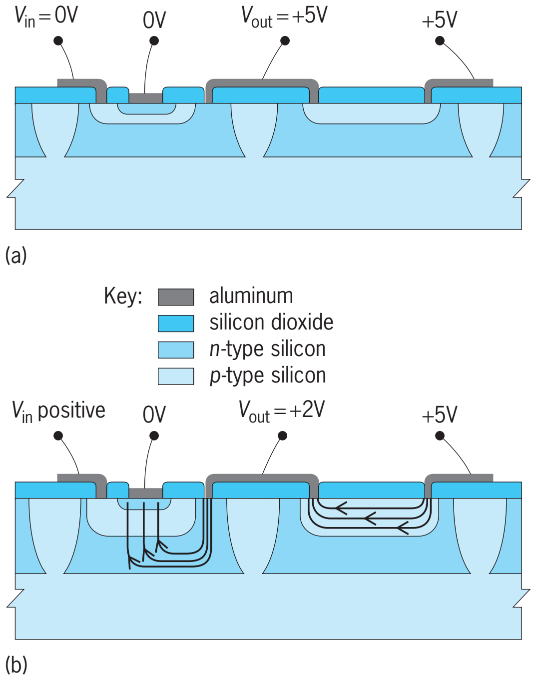


Fig. 1. Operation of bipolar inverter circuit (cross-sectional view). (*a*) Input voltage V_{in} is zero. (*b*) Positive input voltage applied; arrows indicate direction of current flow.

Bipolar integrated circuits. A simple bipolar inverter circuit using a diffused resistor and an *npn* transistor is shown in Fig. 1. The input voltage V_{in} is applied to the base of the transistor. When V_{in} is zero or negative with respect to the emitter, no current flows. As a result, no voltage drop exists across the resistor, and the output voltage V_{out} will be the same as the externally applied biasing voltage, +5 V in this example. When a positive input voltage is applied, the transistor becomes conducting. Current now flows through the transistor, hence through the resistor: as a result, the output voltage decreases. Thus, the change in input voltage appears inverted at the output.

The tendency toward increased complexity is dictated by the economics of integrated circuit manufacturing. Because of the nature of this manufacturing process, all circuits on a slice are fabricated together. Consequently, the more circuitry accommodated on a slice, the cheaper the circuitry becomes. Because testing and packaging costs depend on the number of chips, it is desirable, in order to keep costs down, to crowd more circuitry onto a given chip rather than to increase the number of chips on a wafer.

Integrated circuits based on amplifiers are called linear because amplifiers usually exhibit a linearly proportional response to input signal variations. However, the category includes memory sense amplifiers, combinations of analog and digital processing functions, and other circuits with nonlinear characteristics. Some digital and analog combinations include analog-to-digital converters, timing controls, and modems (data communications modulator-demodulator units). *See* Analog-to-digital converter; Data communications.

In the continuing effort to increase the complexity and speed of digital circuits, and the performance characteristics and versatility of linear circuits, a significant role has been played by the discovery and development of new types of active and passive semiconductor devices which are suitable for use in integrated circuits. Among these devices is the *pnp* transistor which, when used in conjunction with the standard *npn* transistors described above, lends added flexibility to the design of integrated circuits.

MOS integrated circuits. The other major class of integrated circuits is called MOS because its principal device is a metal oxide semiconductor field-effect transistor (MOSFET). It is more suitable for very large-scale integration (VLSI) than bipolar circuits because MOS transistors are self-isolating and can have an average size of less than 10^{-7} in.$^{-2}$ (10^{-5} mm^2). This has made it practical to use millions of transistors per circuit. Because of this high-density capability, MOS transistors are used for high-density random-access memories (RAMs), read-only memories (ROMs), and microprocessors. *See* COMPUTER STORAGE TECHNOLOGY; MICROPROCESSOR; SEMICONDUCTOR MEMORIES.

Several major types of MOS device fabrication technologies have been developed since the mid-1960s. They are (1) metal-gate *p*-channel MOS (PMOS), which uses aluminum for electrodes and interconnections; (2) silicon-gate *p*-channel MOS, employing polycrystalline silicon for gate electrodes and the first interconnection layer; (3) *n*-channel MOS (NMOS), which is usually silicon gate; and (4) complementary MOS (CMOS), which employs both *p*-channel and *n*-channel devices.

Both conceptually and structurally the MOS transistor is a much simpler device than the bipolar transistor. In fact, its principle of operation has been known since the late 1930s, and the research effort that led to the discovery of the bipolar transistor was originally aimed at developing the MOS transistor. What kept this simple device from commercial utilization until 1964 is the fact that it depends on the properties of the semiconductor surface for its operation, while the bipolar transistor depends principally on the bulk properties of the semiconductor crystal. Hence MOS transistors became practical only when understanding and control of the properties of the oxidized silicon surface had been perfected to a very great degree.

A simple CMOS inverter circuit is shown in Fig. 2. The gates of the *n*-channel and *p*-channel transistors are connected together as are the drains. The common gate connection is the input node while the common drain connection is the output node. A capacitor is added to the output node to model the loading expected from the subsequent stages on typical circuits.

When the input node is in the "low state," at 0 V, the *n*-channel gate to source voltage is 0 V while the *p*-channel gate to source voltage is −5 V. The *n*-channel transistor requires a positive gate-to-source voltage, which is greater than the transistor threshold voltage (typically 0.5–1 V), before it will start conducting current between the drain and source. Thus, with a 0-V gate-to-source voltage it will be off and no current will flow through the drain and source regions. The *p*-channel transistor, however, requires a negative voltage between the gate and source which is less than its threshold voltage (typically −0.5 to −1.5 V). The −5-V gate-to-source potential is clearly less than the threshold voltage, and the *p*-channel will be turned on, conducting current from the source to the drain, and thereby charging up the loading capacitor. Once the capacitor is charged to the "high state" at 5 V, the transistor will no longer conduct because there will no longer be a potential difference between the source and drain regions.

When the input is now put to the "high state" at 5 V, just the opposite occurs. The *n*-channel transistor will be turned on while the *p*-channel will be off. This will allow the load capacitor to discharge through the *n*-channel transistor resulting in the output voltage dropping from a "high state" at 5 V to a "low state" at 0 V. Again, once there is no potential difference between the drain and source (capacitor discharged to 0 V), the current flow will stop, and the circuit will be stable.

This simple circuit illustrates a very important feature of CMOS circuits. Once the loading capacitor has been either charged to 5 V or discharged back to 0 V, there is no current flow, and the standby power is very low. This is the reason for the high popularity of CMOS for battery-based systems. None of the other MOS technologies offers this feature without complex circuit techniques, and even then will typically not match the low standby power of CMOS. The bipolar circuits discussed above require even more power than these other MOS technologies. The price for CMOS's lower power are the additional fabrication steps required (10–20% more) when compared to NMOS.

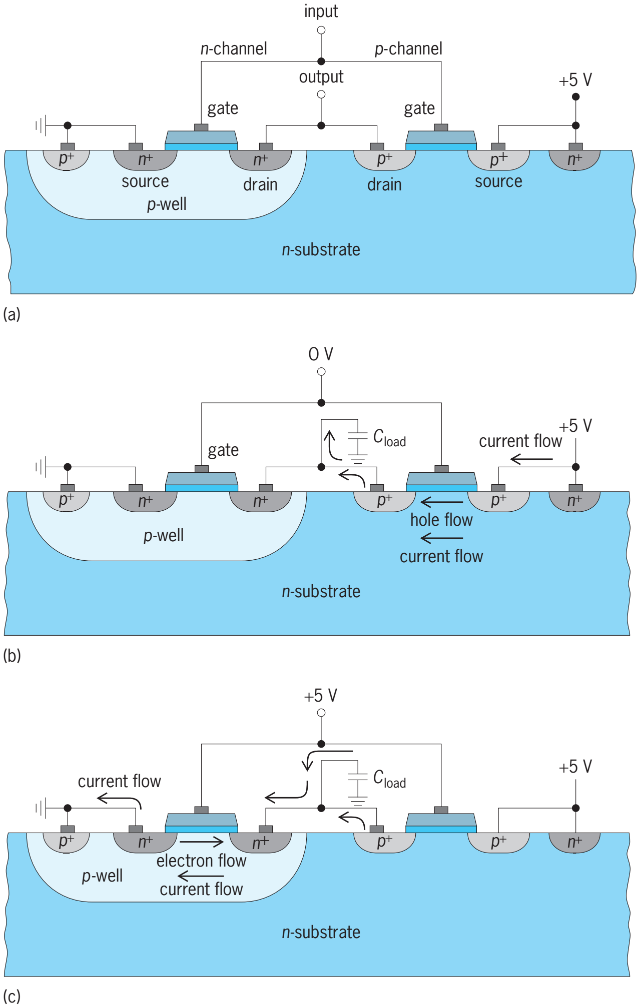

Fig. 2. Simple CMOS inverter circuit. (*a*) Schematic cross section. (*b*) Current flow when input is "low" at 0 V. (*c*) Current flow when input is "high" at 5 V.

BiCMOS integrated circuits. There is a strong interest in combining high-performance bipolar transistors and high-density CMOS transistors on the same chip (BiCMOS). This concept originated with work on bipolar circuits when power limitations became important as more functionality (and thus more transistors) was added to the chip. It is possible to continue adding more circuits on a chip without increasing the power by combining the low-power CMOS circuits with the bipolar circuits. This is done with both memory circuits and logic circuits, resulting in speeds somewhere between those of typical CMOS and bipolar-only circuits, but with the functional density of CMOS. The disadvantage of BiCMOS is its additional cost over plain CMOS or bipolar circuits, because the number of processing steps increases 20–30%. However, this increased complexity is expected to be used when either the additional functionality over bipolar circuits or the increased speed over CMOS circuits justifies the cost. [R.Bu.; Y.E.M.; N.Be.]

Fabrication. Integrated-circuit fabrication begins with a thin, polished slice of high-purity, single-crystal semiconductor (usually silicon) and employs a combination of physical and chemical processes to create the integrated-circuit structures described above. Junctions are formed in the silicon slice by the processes of thermal diffusion or high-energy ion implantation. Electrical isolation between devices on the integrated circuit is achieved with insulating layers grown by thermal oxidation or deposited by chemical deposition. Conductor layers to provide the necessary electrical connections on the integrated circuit are obtained by a variety of deposition techniques. Precision lithographic processes are used throughout the fabrication sequence to define the geometric features required. [B.L.G.; E.A.I.]

Design. VLSI chips containing 10^6 transistors and operating at tens of megahertz have been designed and fabricated and are commercially available. Projections indicate that silicon chips containing as many as 10^8 transistors may be feasible for digital applications and that perhaps even a 10^9 transistor chip is feasible for dynamic random access memories (DRAMs) before fundamental limits constrain the growth of complexity. (The limits beyond which the size of a transistor cannot be reduced are thought to depend on the degradation of its material properties when it is operated at high-field conditions and the general degradation of its performance and reliability.) Computer-aided engineering (CAE) systems provide the environment, specific computer tools, data management, and other services that are intended to support the design of these very complex, high-performance products. In many cases, the design of complex chips requires the cooperative endeavors of large design teams; thus the CAE system must also manage the design process to ensure that proper documentation has occurred, needed changes in the design database are made, and a chosen design methodology is enforced. The design process must be adapted to the very short design cycle times from product conception to production of a salable product that are characteristic of the semiconductor industry. [R.K.Ca.]

Gallium arsenide circuits. Integrated circuits based on gallium arsenide (GaAs) have come into increasing use since the late 1970s. The major advantage of these circuits is their fast switching speed.

The gallium arsenide field-effect transistor (GaAs FET) is a majority carrier device in which the cross-sectional area of the conducting path of the carriers is varied by the potential applied to the gate. Unlike the MOSFET, the gate of the GaAs FET is a Schottky barrier composed of metal and gallium arsenide. Because of the difference in work functions of the two materials, a junction is formed. The depletion region associated with the junction is a function of the difference in voltage of the gate and the conducting channel, and the doping density of the channel. By applying a negative voltage to the gate, the electrons under the gate in the channel are repelled, extending the depletion region across the conducting channel. The variation in the height of the conducting portion of the channel caused by the change in the extent of the depletion region alters the resistance between the drain and source. Thus the negative voltage on the gate modulates the current flowing between the drain and the source. As the height of the conducting channel is decreased by the gate voltage or as the drain voltage is increased, the velocity of charge carriers (electrons for *n*-type gallium arsenide) under the gate increases (similar to water in a hose when its path is constricted by passing through the nozzle). The velocity of the carriers continues to increase with increasing drain voltage, as does the current, until their saturated velocity is obtained (about 10^7 cm/s or 3×10^5 ft/s for gallium arsenide). At that point the device is in the saturated region of operation; that is, the current is independent of the drain voltage. [P.T.G.]

Integrated optics

The study of optical devices that are based on light transmission in planar waveguides, that is, dielectric structures that confine the propagating light to a region with one or two very small dimensions, on the order of the optical wavelength. The principal motivation for these studies is to combine miniaturized individual devices through waveguides or other means into a functional optical system incorporated into a small substrate. The resulting system is called an integrated optical circuit (IOC) by analogy with the semiconductor type of integrated circuit. An integrated optical circuit could include lasers, integrated lenses, switches, interferometers, polarizers, modulators, detectors, and so forth. Important uses envisioned for integrated optical circuits include signal processing (for example, spectrum analysis and analog-to-digital conversion) and optical communications through glass fibers, which are themselves circular (or elliptical) waveguides. Integrated optical circuits could be used in such systems as optical transmitters, switches, repeaters, and receivers. *See* INTEGRATED CIRCUITS; OPTICAL COMMUNICATIONS; OPTICAL FIBERS.

The advantages of having an optical system in the form of an integrated optical circuit rather than a conventional series of components include (apart from miniaturization) reduced sensitivity to air currents and to mechanical vibrations of the separately mounted parts, low driving voltages and high efficiency, robustness, and (potentially) reproducibility and economy. As in the case of semiconductor integrated circuits, an integrated optical circuit might be fabricated on or just within the surface of one material (the substrate) modified for the different components by shaping structures (using etching, for example) or incorporating suitable substitutes or dopants, or alternatively, by depositing or expitaxially growing additional layers. It is also possible to construct independent components which are then attached to form the integrated optical circuit. This option, called hybrid, has the advantage that each component could be optimized, for example, by using gallium aluminum arsenide lasers as sources for an integrated optical circuit and silicon detectors. In the former case, the integrated optical circuit is called monolithic, and is expected to have the advantage of ease of processing, similar to the situation for monolithic semiconductor integrated circuits. Perhaps the most promising materials for monolithic integrated optical circuits are direct band-gap semiconductors composed of III–V materials such as gallium aluminum arsenide [(GaAl)As] and indium gallium arsenide phosphide [(InGa)(AsP)] since with suitable processing they may perform almost all necessary operations as lasers, switches, modulators, detectors, and so forth. *See* ELECTROOPTICS; LASER; OPTICAL MODULATORS; SEMICONDUCTOR HETEROSTRUCTURES; SPECTRUM ANALYZER; WAVEGUIDE. [W.Str.]

Integrated services digital network (ISDN)

A generic term referring to the integration of communications services transported over digital facilities such as wire pairs, coaxial cables, optical fibers, microwave radio, and satellites. ISDN provides end-to-end digital connectivity between any two (or more) communications devices. Information enters, passes through, and exits the network in a completely digital fashion.

Since the introduction of pulse-code-modulation (PCM) transmission in 1962, the worldwide communications system has been evolving toward use of the most advanced digital technology for both voice and nonvoice applications. Pulsecode modulation is a sampling technique which transforms a voice signal with a bandwidth of 4 kHz into a digital bit stream, usually of 64 kilobits per second (kbps). *See* PULSE MODULATION.

Many aspects of telecommunications are improved with digital technology. For example, digital technology lends itself to very large-scale integration (VLSI) technology and its associated benefits of miniaturization and cost reduction. In addition, computers operate digitally. Digital transport provides for human-to-human, computer-to-computer, and human-to-computer interactions. The ISDN is capable of transporting voice, data, graphics, text, and even video information over the same equipment. *See* DATA COMMUNICATIONS; DIGITAL COMPUTER; INTEGRATED CIRCUITS.

The customer has access to a wide spectrum of communications services by way of a single access link. This is in contrast to existing methods of service access, which segregate services into specialized lines.

Associated with integrated access and ISDN is the concept of a standard interface. The objective of a standard interface is to allow any ISDN terminal to be plugged into any ISDN interface, resulting in terminal portability, flexibility, and ease in operation. *See* ELECTRICAL COMMUNICATIONS. [R.M.Wi.; A.E.J.]

Integration An operation of the infinitesimal calculus which has two aspects. The roots of one go back to antiquity, for Archimedes and other Greek mathematicians used the "method of exhaustion" to compute areas and volumes. A simple example of this is the approximation to the area of a circle obtained by inscribing a regular polygon of known area, and then repeatedly doubling the number of sides. The areas of the successive polygons are computable with the help of elementary geometry. The limit of the sequence of these areas gives the area of the circle. The area of each polygon can be regarded as being made up of the sum of the areas of triangles with vertices at the center of the circle, and so the process described is a constructive definition of an integral which is the limit of a sum. Modern definitions of integrals as limits of sums are discussed in this article.

The other aspect of integration is the process of finding antiderivatives, that is, for a given function $f(x)$ to find another function $g(x)$ whose derivative is $f(x)$. This aspect is related to the first by the fundamental theorem of integral calculus, so both processes are called integration.

In the early 19th century A. L. Cauchy gave a clear-cut definition of the definite integral for continuous functions and a proof of its existence. Later, G. F. B. Riemann discussed the integral for discontinuous functions and gave a necessary and sufficient condition for its existence. Thus the most generally used definition of the integral as the limit of a sum has come to be called the Riemann integral.

The precise definition of the Riemann integral for a real function f of one real variable x on a finite interval $a \leqq x \leqq b$ may be formulated as follows. Let P be a partition of the interval $[a,b]$ into n subintervals by points t_i where $t_{i-1} < t_i$, $t_0 = a$, $t_n = b$ and consider a sum S of the form of Eq. (1), where $t_{i-1} \leqq x_i \leqq t_i$. The

$$S = \sum_{i=1}^{n} f(x_i)(t_i - t_{i-1}) \qquad (1)$$

sum S depends not only on the partition P but on the choice of the intermediate points x_i. It may happen that the sum S approaches a definite limit I when the maximum of the numbers $(t_i - t_{i-1})$ tends to zero, and in this case I is called the Riemann integral (or the definite integral) of f from a to b, and is denoted by the Leibnitzian symbol (2).

$$\int_a^b f(x)dx \qquad (2)$$

Also, f is said to be integrable on $[a,b]$. When f is a continuous function with positive values on the interval $[a,b]$, the integral has a simple geometrical interpretation as the area bounded by the x axis, the ordinates $x = a$ and $x = b$, and the graph of $y = f(x)$ (Fig. 1).

It can be proved that a function f is integrable on $[a,b]$ if and only if the following two conditions are satisfied: f is bounded on $[a,b]$; and the set of points where f is discontinuous can be enclosed in a series (possibly infinite) of intervals, the sum of whose lengths is arbitrarily near to zero.

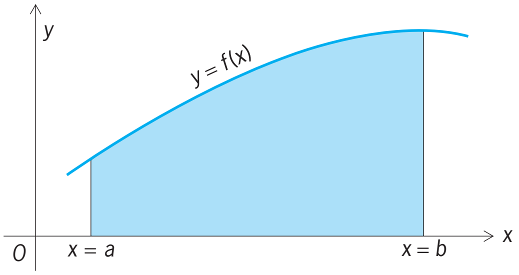

Fig. 1. Graph of $y = f(x)$.

To develop the fundamental theorem of integral calculus let u be a variable in the interval $[a,b]$, on which f is integrable; then formula (3) defines a function of u which may be noted by

$$\int_a^u f(x)dx \qquad (3)$$

$I(u)$. If f is continuous on $[a,b]$, then f is integrable, and it is also true that $I(u)$ has a derivative $I'(u) = f(u)$. Now let h be any antiderivative of f, that is, $h'(u) = f(u)$ on $[a,b]$. Then $I'(u) - h'(u) = 0$, so $I(u) - h(u) = \text{constant} = -h(a)$, by the theorem of the mean for derivatives and the fact that $I(a) = 0$, so relation (4) can be

$$I = I(b) = h(b) - h(a) \qquad (4)$$

written, This is the fundamental theorem of integral calculus, and it shows that definite integrals may be calculated by the process of finding antiderivatives. For this reason antiderivatives are frequently called indefinite integrals and denoted by $\int f(x)\,dx$, and special methods of finding indefinite integrals for frequently occurring functions occupy a large part of elementary calculus. The standard notation for an indefinite integral of $f(x)$ is formula (5).

$$\int f(x)dx \qquad (5)$$

The term improper integral refers to an extension of the notion of definite integral to cases in which the integrand is unbounded or the domain of integration is unbounded.

The concept called the Riemann integral can be extended to functions of several variables. The case of a function of two variables illustrates sufficiently the additional features which arise. To begin with, let $f(x,y)$ denote a real function defined on a rectangle of the form (6). Let P be a partition of R into n nonoverlapping

$$R{:}a \leqq x \leqq b \qquad c \leqq y \leqq d \qquad (6)$$

rectangles R_i with areas A_i, and let (x_i,y_i) be a point of R_i. Define S by Eq. (7). In case the sum S tends to a definite limit I when

$$S = \sum_{i=1}^{n} f(x_i, y_i)A_i \qquad (7)$$

the maximum diagonal of a rectangle R_i tends to zero, then f is said to be integrable over R, and the limit I is called the Riemann integral of f over R. It will be denoted here by the abbreviated symbol $\iint_R f$.

To define the integral of a function $f(x,y)$ over a more general domain D where it is defined, suppose that D is enclosed in a rectangle R, and define $F(x,y)$ by Eqs. (8). Then f is said to be integrable over D in case F is integrable over R, and Eq. (9) holds, by definition.

$$\begin{aligned} F(x,y) &= f(x,y) \text{ in } D \\ F(x,y) &= 0 \text{ outside } D \end{aligned} \qquad (8)$$

$$\iint_D f = \iint_R F \qquad (9)$$

When the function $f(x,y)$ is continuous on D, and D is defined by inequalities of the form (10), where the functions $\alpha(x)$ and

$$a \leqq x \leqq b \qquad \alpha(x) \leqq y \leqq \beta(x) \qquad (10)$$

$\beta(x)$ are continuous, the double integral of f over D always exists, and may be represented in terms of two simple integrals by Eq. (11). In many cases, this formula makes possible the evaluation of the double integral.

$$\iint_D f = \int_a^b \left[\int_{\alpha(x)}^{\beta(x)} f(x,y)dy \right] dx \qquad (11)$$

In the study of the "space" of real functions defined, for example, on the interval $a \leqq x \leqq b$, it is frequently useful to take formula (12) as the distance between the functions *f* and *g*. This

$$\int_a^b |f(x) - g(x)|\,dx \qquad (12)$$

distance already has a meaning when *f* and *g* are Riemann-integrable, that is, bounded and not too discontinuous, in the sense specified for the Riemann integral. There is no generally useful extension of the concept of integral to apply to all real functions on [*a*,*b*], but is desirable to extend it to apply to the functions obtained from the continuous ones by certain limiting processes. In particular, it is desirable to have correspond to each sequence (f_n) of functions satisfying the Cauchy condition for convergence in terms of the distance (12), namely Eq. (13),

$$\lim_{\substack{m\to\infty\\ n\to\infty}} \int_a^b |f_m(x) - f_n(x)|\,dx = 0 \qquad (13)$$

a function *g* which is integrable (in the extended sense), and for which Eq. (14) holds. An extended definition of integral having

$$\lim_{n\to\infty} \int_a^b |f_n(x) - g(x)|\,dx = 0 \qquad (14)$$

this property was given by H. L. Lebesgue.

F. Riesz devised an equivalent definition which can be stated quite simply, at least for the case of a bounded function *g*(*x*). As a first definition, a point set *S* in the interval [*a*,*b*] has measure zero in case it can be enclosed in a sequence (finite or infinite) of intervals, the sum of whose lengths is arbitrarily small. Also, a step function *f*(*x*) is defined as one which is constant on each interval of a partition of [*a*,*b*], as in Fig. 2. The Riemann integral of a step function is expressible as a finite sum. Then a bounded function *g*(*x*) is integrable in Lebesgue's sense in case it is the limit of a uniformly bounded sequence of step functions $f_n(x)$, at each point of [*a*,*b*] except those in a set *S* wih measure zero, and by definition Eq. (15) can be written. In case the step functions f_n in

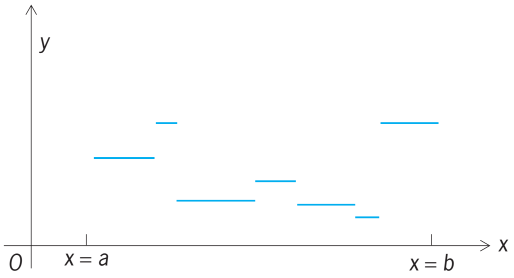

Fig. 2. Step function *f*(*x*).

$$\int_a^b g(x)dx = \lim_{n\to\infty} \int_a^b f_n(x)dx \qquad (15)$$

Eq. (15) are replaced by Lebesgue-integrable functions forming a uniformly bounded sequence, no new functions *g* are obtained.

The integral of Lebesgue is also defined for unbounded functions, but the points of infinite discontinuity do not need to be considered one by one. For each function *g*(*x*) and each positive integer *N* let $g_N(x)$ denote the lesser of *g*(*x*) and *N*. If each $g_N(x)$ is Lebesgue-integrable in the sense already defined, expressed (16) forms a nondecreasing sequence, and so if expression (16)

$$\int_a^b g_N(x)dx \qquad (16)$$

is bounded, it tends to a finite limit, which is taken as the value of integral (17).

$$\int_a^b g(x)dx \qquad (17)$$

If $\alpha(x)$ is a fixed function defined on the interval [*a*,*b*], the sum *S* defined by Eq. (1) may be replaced by that in Eq. (18).

$$S = \sum_{i=1}^{n} f(x)_i\,[\alpha(t_i) - \alpha(t_{i-1})] \qquad (18)$$

Then if the limit *I* of *S* exists in this case, it is called the stieltjes integral of *f* with respect to α, and is denoted by integral (19).

$$\int_a^b f(x)d\alpha(x) \qquad (19)$$

It has many of the properties of the Riemann integral, especially in case the function α is nondecreasing. *See* Calculus; Fourier Series; Series. [L.M.G.]

Integumentary patterns All the features of the skin and its appendages that are arranged in designs, both in humans and other animals. Examples are scales, hairs, and feathers; coloration; and epidermal ridges of the fingers, palms, and feet. In its common usage, the term applies to the configurations of epidermal ridges, collectively named dermatoglyphics. Dermatoglyphics are characteristic of primates. *See* Epidermal ridges; Feather; Hair; Scale (zoology).

The superficial ridges are associated with a specific inner organization of skin. Skin is composed of two chief layers, the epidermis on the outside and the dermis underlying it. These two layers are mortised by pegs of dermis, a double row of pegs corresponding to each ridge; these pegs accordingly form a patterning like that of the ridges.

The patterning of ridges, including that of the epidermal-dermal mortising, is determined during the third and fourth fetal months. All characteristics of single ridges and of their alignments are then determined definitively. Ridge alignments reflect directions of stress in growth of the hand and foot at the critical period of ridge differentiation. An important element in the production of localized patterns, for example, on the terminal segment of each digit, is the development in the fetus of a series of elevations, the volar pads.

The pads are homologs of the prominent pads on the paws of some mammals, but in primates they attain little elevation and soon tend to subside. The volar pads are disposed in a consistent topographic plan. Localized patterns have the same placement because growth of the pad is the determiner of the specific local pattern. When a pad has subsided before ridges are formed, its area does not present a localized pattern, and the ridges follow essentially straight, parallel courses. Variations in contours of the pads are accompanied by wide variations in the designs formed by the ridges overlying them.

Variability of patterning is a major feature of dermatoglyphics and the basis for various applications. In personal identification, prints, customarily of fingers, are classified for filing in accordance with variables of pattern type and counts of ridges. In anthropological and medical investigations, groups of individuals are compared statistically in reference to the occurrence of these variables. Deductions may be drawn in accordance with likeness or unlikeness in the directions of variation. *See* Fingerprint; Skin. [H.Cu.]

Intelligence General mental ability due to the integrative and adaptive functions of the brain that permit complex, unstereotyped, purposive responses to novel or changing situations, involving discrimination, generalization, learning, concept formation, inference, mental manipulation of memories, images, words and abstract symbols, eduction of relations and correlates, reasoning, and problem solving.

Intelligence tests are diverse collections of tasks (or items), graded in difficulty. The person's performance on each item can be objectively scored (for example, pass or fail); the total number of items passed is called the raw score. Raw scores are converted to some form of scaled scores which can be given a statistical interpretation.

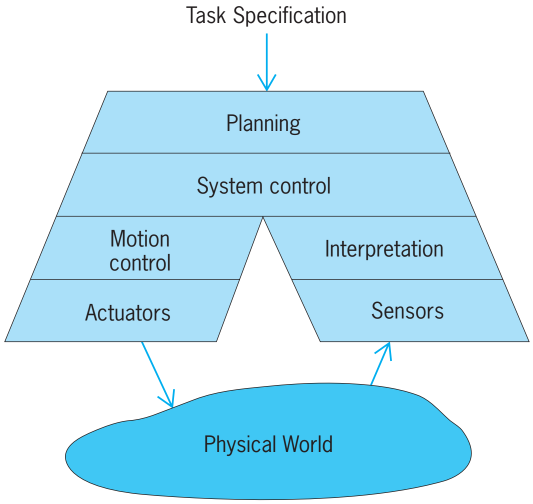
The first practical intelligence test for children, devised in 1905 by the French psychologist Alfred Binet, converted raw scores to a scale of “mental age,” defined as the raw score obtained by the average of all children of a given age. Mental age (MA) divided by chronological age (CA) yields the well known intelligence quotient or IQ. When multipled by 100 (to get rid of the decimal), the average IQ at every age is therefore 100, with a standard deviation of approximately 15 or 16. Because raw scores on mental tests increase linearly with age only up to about 16 years, the conversion of raw scores to a mental-age scale beyond age 16 must resort to statistical artifices. Because of this problem and the difficulty of constructing mental-age scales which preserve exactly the same standard deviation of IQs at every age, all modern tests have abandoned the mental-age concept and the calculation of IQ from the ratio of MA to CA. Nowadays the IQ is simply a standardized score with a population mean of 100 and a standard deviation (σ) of 15 at every age from early childhood into adulthood. The middle 50%, considered “average,” fall between IQs of 90 and 110. IQs below 70 generally indicate “mental retardation,” and above 130, “giftedness.” [A.R.J.]

Intelligent machine Any machine that can accomplish its specific task in the presence of uncertainty and variability in its environment. The machine’s ability to monitor its environment, allowing it to adjust its actions based on what it has sensed, is a prerequisite for intelligence. The term intelligent machine is an anthropomorphism in that intelligence is defined by the criterion that the actions would appear intelligent if a person were to do it. A precise, unambiguous, and commonly held definition of intelligence does not exist.

Examples of intelligent machines include industrial robots equipped with sensors, computers equipped with speech recognition and voice synthesis, self-guided vehicles relying on vision rather than on marked roadways, and so-called smart weapons, which are capable of target identification. These varied systems include three major subsystems: sensors, actuators, and control. The class of computer programs known as expert systems is included with intelligent machines, even though the sensory input and output functions are simply character-oriented communications. The complexity of control and the mimicking of human deductive and logic skills makes expert systems central in the realm of intelligent machines. *See* Computer vision; Expert systems; Guidance systems; Robotics; Speech recognition; Voice response.

Since the physical embodiment of the machine or the particular task performed by the machine does not mark it as intelligent, the appearance of intelligence must come from the nature of the control or decision-making process that the machine performs. Given the centrality of control to any form of intelligent machine, intelligent control is the essence of an intelligent machine. The control function accepts several kinds of data, including the specification for the task to be performed and the current state of the task from the sensors. The control function then computes the signals needed to accomplish the task. When the task is completed, this also must be recognized and the controller must signal the supervisor that it is ready for the next assignment (see illustration). *See* Adaptive control; Control systems.

Automatic, feedback, or regulatory systems such as thermostats, automobile cruise controls, and photoelectric door openers are not considered intelligent machines. Several important concepts separate these simple feedback and control systems from intelligent control. While examples could be derived from any of the classes of intelligent machines, robots will be used here to illustrate five concepts that are typical of intelligent control. (1) An intelligent control system typically deals with many sources of information about its state and the state of its environment. (2) An intelligent control system can accommodate incomplete or inconsistent information. (3) Intelligent control is characterized by the use of heuristic methods in addition to algorithmic control methods. (A heuristic is a rule of thumb, a particular solution or strategy to be used for solving a problem that can be used for only very limited ranges of the input parameters.) (4) An intelligent machine has a builtin knowledge base that it can use to deal with infrequent or unplanned events. (5) An algorithmic control approach assumes that all relevant data for making decisions is available. [J.F.Ja.]



Flow of information and data in a typical intelligent machine.

Intercalation compounds Crystalline or partially crystalline solids consisting of a host lattice containing voids into which guest atoms or molecules are inserted. Candidate hosts for intercalation reactions may be classified by the number of directions (0 to 3) along which the lattice is strongly bonded and thus unaffected by the intercalation reaction. Isotropic, three-dimensional lattices (including many oxides and zeolites) contain large voids that can accept multiple guest atoms or molecules. Layer-type, two-dimensional lattices (graphite and clays) swell up perpendicular to the layers when the guest atoms enter. The chains in one-dimensional structures (polymers such as polyacetylene) rotate cooperatively about their axes during the intercalation reaction to form channels that are occupied by the guest atoms. In the intercalation family based on solid C_{60} (buckminsterfullerene), the zero-dimensional host lattice consists of 60-atom carbon clusters with strong internal bonding but weak intercluster bonding. These clusters pack together like hard 1-nm-diameter spheres, creating interstitial voids which are large enough to accept most elements in the periodic table. The proportions of guest and host atoms may be varied continuously in many of these materials, which are therefore not true compounds. Many ternary and quaternary substances, containing two or three distinct guest species, are known. The guest may be an atom or inorganic molecule (such as an alkali metal, halogen, or metal halide), an organic molecule (for example, an aromatic such as benzene, pyridine, or ammonia), or both. *See* Crystal structure; Fullerene; Graphite; Polymer; Zeolite.

Many applications of intercalation compounds derive from the reversibility of the intercalation reaction. The best-known example is pottery: Water intercalated between the silicate sheets makes wet clay plastic, while driving the water out during firing results in a dense, hard, durable material. Many intercalation compounds are good ionic conductors and are thus useful as electrodes in batteries and fuel cells. A technology for lightweight rechargeable batteries employs lithium ions which shuttle back and forth between two different intercalation electrodes as the battery is charged and discharged: vanadium oxide (three-dimensional) and graphite (two-dimensional). Zeolites containing metal atoms remain sufficiently porous to serve as catalysts for gas-phase reactions. Many compounds can be used as convenient storage media, releasing the guest molecules in a controlled manner by mild heating. *See* Battery; Clay, commercial; Fuel cell; Solid-state battery. [J.E.Fi.]

Intercommunicating system A privately owned system that allows voice communication between a limited number of locations, usually within a relatively small area, such as a building, office, or residence. Intercommunicating systems are generally known as intercoms. Intercom systems can vary widely in complexity, features, and technology. Though limited in size and scope, intercom systems can provide easy and reliable communication for their users.

An extremely simple intercom is a two-station arrangement in which one station is connected to the other via a dedicated wire. Other systems have multiple stations, as many as 10 to 20, any of which can connect with any other station. The user must dial a one- or two-digit code to signal the intended destination.

Still other intercom systems work in conjunction with key and hybrid key telephone/private branch exchange telephone systems. They support internal station-to-station calling rather than access to outside lines. Normally the telephone intercom is incorporated in the same telephone instrument that is used to access the public switched network. *See* Key telephone system; Private branch exchange.

A third type of intercom is the wireless intercom system for intrabuilding communications, which consists of a base unit radio transmitter, equipped with an antenna, and a number of roving units tuned to different frequencies. The base can selectively communicate with individual roving units by dialing the code corresponding to each roving unit's specific frequency. *See* Mobile radio. [B.W.B.; V.F.R.]

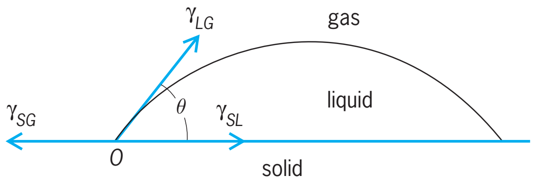
Interface of phases The boundary between any two phases. Among the three phases—gas, liquid, and solid—five types of interfaces are possible: gas-liquid, gas-solid, liquid-liquid, liquid-solid, and solid-solid. The abrupt transition from one phase to another at these boundaries, even though subject to the kinetic effects of molecular motion, is statistically a surface only one or two molecules thick.

A unique property of the surfaces of the phases that adjoin at an interface is the surface energy which is the result of unbalanced molecular fields existing at the surfaces of the two phases. Within the bulk of a given phase, the intermolecular forces are uniform because each molecule enjoys a statistically homogeneous field produced by neighboring molecules of the same substance. Molecules in the surface of a phase, however, are bounded on one side by an entirely different environment, with the result that there are intermolecular forces that then tend to pull these surface molecules toward the bulk of the phase. A drop of water, as a result, tends to assume a spherical shape in order to reduce the surface area of the droplet to a minimum.

At an interface, there will be a difference in the tendencies for each phase to attract its own molecules. Consequently, there is always a minimum in the free energy of the surfaces at an interface, the net amount of which is called the interfacial energy in units of joules/cm^2. The interfacial energy can also be expressed as surface tension in units of millinewtons per meter.

The surface energy at an interface may be altered by the addition of solutes that migrate to the surface and modify the molecular forces there, or the surface energy may be changed by converting the planar interfacial boundary to a curved surface.

At liquid-solid interfaces, where the confluence of the two phases is usually termed wetting, a critical factor called the contact angle is involved. A drop of water placed on a paraffin surface, for example, retains a globular shape, whereas the same drop of water placed on a clean glass surface spreads out into a thin layer. In the first instance, the contact angle is practically 180°, and in the second instance, it is practically 0°. The study of contact angles reveals the interplay of interfacial energies at three boundaries. The illustration is a schematic representation of the cross section of a drop of liquid on a solid. There are solid-liquid, solid-gas, and liquid-gas interfaces that meet in a linear zone at *O*.



Contact angle at interface of three phases.

The measurement of interfacial energies is made directly only upon liquid-gas and liquid-liquid interfaces. In measuring the liquid-gas interfacial energy (surface tension), the methods of capillary rise, drop weight on pendant drop, bubble pressure, sessile drops, Du Nuoy ring, vibrating jets, and ultrasonic action are among those used. There is a small but appreciable temperature effect upon surface tension, and this property is used to determine small differences in the surface tension of a liquid by placing the two ends of a liquid column in a capillary tube whose two ends are at different temperatures. The determination of interfacial energies at other types of interfaces can be inferred only by indirect methods. *See* Flotation; Foam; Free energy; Phase equilibrium; Surface tension. [W.H.S.]

Interference filter An optical filter in which the wavelengths that are not transmitted are removed by interference phenomena rather than by absorption or scattering. In addition to being able to duplicate most of the spectral characteristics of absorption color filters, these devices can be made to transmit a very narrow band of wavelengths. They can thus be used as monochromators to examine a radiation source at the wavelength of a single spectrum line. For example, the solar disk can be observed in light of the hydrogen line Hα and thus the distribution of excited hydrogen over the disk can be determined. Most narrow-band interference filters are based on the Fabry-Perot interferometer. *See* Interference of waves; Interferometry. [B.H.Bi.]

Interference microscope An instrument for visualizing and measuring differences in the phase of light transmitted through or reflected from microscopic specimens. It is closely allied to the phase-contrast microscope. *See* Phase-contrast microscope.

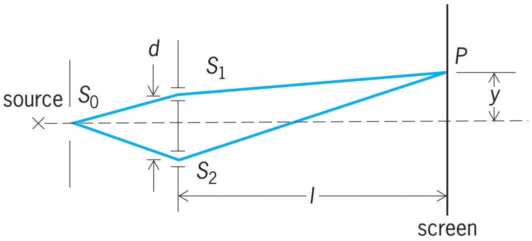
A microscopic image is formed by the interaction of all light waves passing through the optical system. In a phase-contrast microscope, light diffracted by a transparent object is spatially separated from nondiffracted light in the back focal plane of the objective, where a phase plate alters the relative phases of the diffracted and nondiffracted beams so that they interfere in the image plane to produce a visible, intensity-modulated image. In an interference microscope, the diffracted and nondiffracted waves are not spatially separated, but light (the object beam) that passes through or is reflected from the object interferes with light (the reference beam) that passes through or is reflected from a different region of the specimen plane or is reflected from a comparison (reference) surface. For interference to be visible, the light beams must be coherent; in other words, the beams must maintain a constant relationship of wavelength, phase, and polarization over a relatively long period. The easiest way to achieve coherence is by using a device such as a semireflecting mirror, which splits a light beam into two beams. Random changes in the properties of successive photons from a given point in the source then affect both beams simultaneously. Differences in optical path introduced by various parts of the object can be seen as variations in intensity or color. *See* Interference of waves. [D.J.G.]

Interference of waves The process whereby two or more waves of the same frequency or wavelength combine to form a wave whose amplitude is the sum of the amplitudes of the interfering waves. The interfering waves can be electromagnetic, acoustic, or water waves, or in fact any periodic disturbance.

The most striking feature of interference is the effect of adding two waves in which the trough of one wave coincides with the peak of another. If the two waves are of equal amplitude, they can cancel each other out so that the resulting amplitude is zero. This is perhaps most dramatic in sound waves; it is possible to generate acoustic waves to arrive at a person's ear so as to cancel out disturbing noise. In optics, this cancellation can occur for particular wavelengths in a situation where white light is a source. The resulting light will appear colored. This gives rise to the iridescent colors of beetles' wings and mother-of-pearl, where the substances involved are actually colorless or transparent.

To observe interference with waves generated by atomic or molecular transitions, it is necessary to use a single source and to split the light from the source into parts which can then be recombined. In this case, the amplitude and phase changes occur simultaneously in each of the parts at the same time.

The simplest technique for producing a splitting from a single source was done by T. Young in 1801 and was one of the first demonstrations of the wave nature of light. In this experiment, a narrow slit is illuminated by a source, and the light from this slit is caused to illuminate two adjacent slits. The light from these two parallel slits can interfere, and the interference can be seen by letting the light from the two slits fall on a white screen. The screen will be covered with a series of parallel fringes. The location of these fringes can be derived approximately as follows: In the illustration, S_1 and S_2 are the two slits separated by a distance d. Their plane is a distance l from the screen. Since the slit S_0 is equidistant from S_1 and S_2, the intensity and phase of the light at each slit will be the same. The light falling on P from slit S_1 can be represented by Eq. (1) and from S_2 by Eq. (2), where



Young's two-slit interference.

$$A = A_0 \sin\, 2\pi f \left(t - \frac{x_1}{c}\right) \tag{1}$$

$$B = A_0 \sin\, 2\pi f \left(t - \frac{x_2}{c}\right) \tag{2}$$

f is the frequency, t the time, c the velocity of light; x_1 and x_2 are the distances of P from S_1 and S_2, and A_0 is the amplitude. This amplitude is assumed to be the same for each wave since the slits are close together, and x_1 and x_2 are thus nearly the same. The square of the amplitude or the intensity at P can then be written as Eq. (3).

$$I = 4A_0^2 \cos^2 \frac{2\pi f}{c}(x_1 - x_2) \tag{3}$$

In general, l is very much larger than y so that Eq. (3) can be simplified to Eq. (4).

$$I = 4A_0^2 \cos^2 \pi \left(\frac{yd}{l\lambda}\right) \tag{4}$$

Equation (4) is a maximum when Eq. (5) holds and a minimum when Eq. (6) holds, where n is an integer.

$$y = n\lambda \frac{l}{d} \tag{5}$$

$$y = (n + 1/2)\lambda \frac{l}{d} \tag{6}$$

Accordingly, the screen is covered with a series of light and dark bands called interference fringes. If the source behind slit S_0 is white light and thus has wavelengths varying perhaps from 400 to 700 nanometers, the fringes are visible only where $x_1 - x_2$ is a few wavelengths, that is, where n is small. At large values of n, the position of the nth fringe for red light will be very different from the position for blue light, and the fringes will blend together and be washed out.

The energy carried by a wave is measured by the intensity, which is equal to the square of the amplitude. The total energy failing on the screen is not changed by the presence of interference. The energy density at a particular point is, however, drastically changed. This fact is most important for those waves of the electromagnetic spectrum which can be generated by vacuum-tube oscillators. The sources of radiation or antennas can be made to emit coherent waves which will undergo interference. This makes possible a redistribution of the radiated energy. Quite narrow beams of radiation can be produced by the proper phasing of a linear antenna array. *See* ANTENNA (ELECTROMAGNETISM); INTERFEROMETRY. [B.H.Bi.]

Interferometry The design and use of optical interferometers. Optical interferometers based on both two-beam interference and multiple-beam interference of light are extremely powerful tools for metrology and spectroscopy. A wide variety of measurements can be performed, ranging from determining the shape of a surface to an accuracy of less than a millionth of an inch (25 nanometers) to determining the separation, by millions of kilometers, of binary stars. In spectroscopy, interferometry can be used to determine the hyperfine structure of spectrum lines. By using lasers in classical interferometers as well as holographic interferometers and speckle interferometers, it is possible to perform deformation, vibration, and contour measurements of diffuse objects that could not previously be performed. There are two basic classes of interferometers: division of wavefront and division of amplitude.

Michelson interferometer. The Michelson interferometer (Fig. 1) is based on division of amplitude. Light from an extended source S is incident on a partially reflecting plate (beam splitter) P_1. The light transmitted through P_1 reflects off mirror M_1 back to plate P_1. The light which is reflected proceeds to M_2 which reflects it back to P_1. At P_1, the two waves are again partially reflected and partially transmitted, and a portion of each wave proceeds to the receiver R, which may be a screen, a photocell, or a human eye. Depending on the difference between the distances from the beam splitter to the mirrors M_1 and M_2,

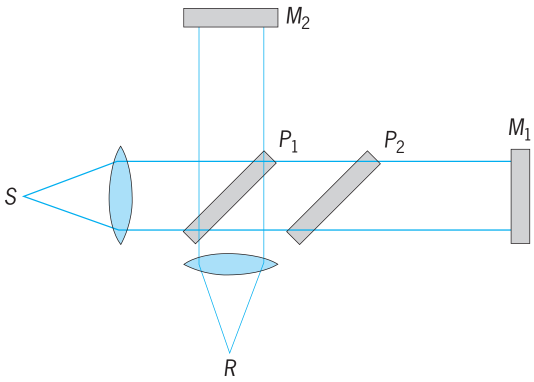


Fig. 1. Michelson interferometer.

the two beams will interfere constructively or destructively. Plate P_2 compensates for the thickness of P_1.

The function of the beam splitter is to superimpose (image) one mirror onto the other. When the mirrors' images are completely parallel, the interference fringes appear circular. If the mirrors are slightly inclined about a vertical axis, vertical fringes are formed across the field of view. These fringes can be formed in white light if the path difference in part of the field of view is made zero. Just as in other interference experiments, only a few fringes will appear in white light.

Twyman-Green interferometer. If the Michelson interferometer is used with a point source instead of an extended source, it is called a Twyman-Green interferometer. The use of the laser as the light source for the Twyman-Green interferometer has made it an extremely useful instrument for testing optical components. The great advantage of a laser source is that it makes it possible to obtain bright, good-contrast, interference fringes even if the path lengths for the two arms of the interferometer are quite different. *See* LASER.

The Twyman-Green interferometer can be used to test a flat mirror. In this case, M_1 in Fig. 1 is a reference surface and M_2 is the flat surface being tested. If the test surface is perfectly flat, then straight, equally spaced fringes are obtained. Departure from the straight, equally spaced condition shows directly how the surface differs from being perfectly flat. A height change of half a wavelength will cause an optical path change of one wavelength and a deviation from fringe straightness of one fringe. Thus, the fringes give surface height information, just as a topographical map gives height or contour information.

The basic Twyman-Green interferometer can be modified to test concave-spherical mirrors. In the interferometer, the center of curvature of the surface under test is placed at the focus of a high-quality diverger lens so that the wavefront is reflected back onto itself. Likewise, a convex-spherical mirror can be tested. Also, if a high-quality spherical mirror is used, the high-quality diverger lens can be replaced with the lens to be tested.

Fizeau interferometer. One of the most commonly used interferometers in optical metrology is the Fizeau interferometer, which can be thought of as a folded Twyman-Green interferometer. In the Fizeau, the two surfaces being compared, which can be flat, spherical, or aspherical, are placed in close contact. The light reflected off these two surfaces produces interference fringes. For each fringe, the separation between the two surfaces is a constant. If the two surfaces match, straight, equally spaced fringes result. Surface height variations between the two surfaces cause the fringes to deviate from straightness or equal separation.

Mach-Zehnder interferometer. The Mach-Zehnder interferometer (Fig. 2) is a variation of the Michelson interferometer and, like the Michelson interferometer, depends on amplitude splitting of the wavefront. Light enters the instrument and is reflected and transmitted by the semitransparent mirror M_1. The reflected portion proceeds to M3, where it is reflected through the cell C_2 to the semitransparent mirror M_4. Here it combines with the light transmitted by M_1 to produce interference. The light transmitted by M_1 passes through a cell C_1, similar to C_2, and is used to compensate for the windows of C_2. The major application of this instrument is in studying airflow around models of aircraft, missiles, or projectiles.

Shearing interferometers. In a lateral-shear interferometer a wavefront is interfered with a shifted version of itself. A bright fringe is obtained at the points where the slope of the wavefront times the shift between the two wavefronts is equal to an integer number of wavelengths. That is, for a given fringe the slope or derivative of the wavefront is a constant. For this reason a lateral-shear interferometer is often called a differential interferometer. Another type of shearing interferometer is a radial-shear interferometer. Here, a wavefront is interfered with an expanded version of itself. This interferometer is sensitive to radial slopes.

Michelson stellar interferometer. A Michelson stellar interferometer can be used to measure the diameter of stars which are as small as 0.01 second of arc. This task is impossible with a ground-based optical telescope since the atmosphere limits the resolution of the largest telescope to not much better than 1 second of arc.

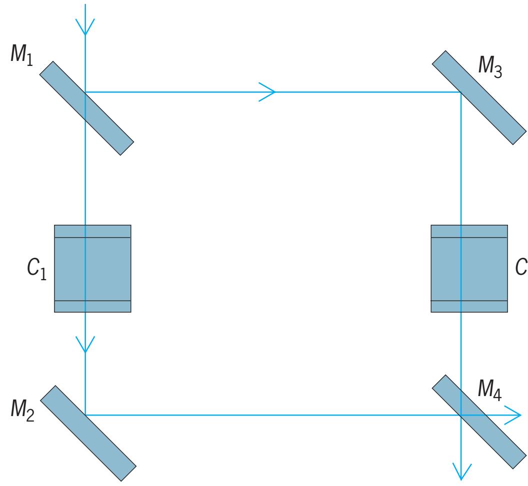

Fig. 2. Mach-Zehnder interferometer.

Fabry-Perot interferometer. All the interferometers discussed above are two-beam interferometers. The Fabry-Perot interferometer is a multiple-beam interferometer since the two glass plates are partially silvered on the inner surfaces, and the incoming wave is multiply reflected between the two surfaces. The position of the fringe maxima is the same for multiple beam interference as two-beam interference; however, as the reflectivity of the two surfaces increases and the number of interfering beams increases, the fringes become sharper.

Holographic interferometry. A wave recorded in a hologram is effectively stored for future reconstruction and use. Holographic interferometry is concerned with the formation and interpretation of the fringe pattern which appears when a wave, generated at some earlier time and stored in a hologram, is later reconstructed and caused to interfere with a comparison wave. It is the storage or time-delay aspect which gives the holographic method a unique advantage over conventional optical interferometry. *See* HOLOGRAPHY.

Speckle interferometry. A random intensity distribution, called a speckle pattern, is generated when light from a highly coherent source, such as a laser, is scattered by a rough surface. The use of speckle patterns in the study of object displacements, vibration, and distortion is becoming of more importance in the nondestructive testing of mechanical components. *See* SPECKLE.

Phase-shifting interferometry. Electronic phase-measurement techniques can be used in interferometers such as the Twyman-Green, where the phase distribution across the interferogram is being measured. Phase-shifting interferometry is often used for these measurements since it provides for rapid precise measurement of the phase distribution. In phase-shifting interferometry, the phase of the reference beam in the interferometer is made to vary in a known manner. This can be achieved, for example, by mounting the reference mirror on a piezoelectric transducer. By varying the voltage on the transducer, the reference mirror is moved a known amount to change the phase of the reference beam a known amount. A solid-state detector array is used to detect the intensity distribution across the interference pattern. This intensity distribution is read into computer memory three or more times, and between each intensity measurement the phase of the reference beam is changed a known amount. From these three or more intensity measurements, the phase across the interference pattern can be determined to within a fraction of a degree. [J.C.Wy.]

Interhalogen compounds

The elements of the halogen family (fluorine, chlorine, bromine, and iodine) possess an

ability to react with each other to form a series of binary interhalogen compounds (halogen halides) of general composition given by XY$_n$, where n can have the values 1, 3, 5, and 7, and where X is the heavier (less electronegative) of the two elements. All possible diatomic compounds of the first four halogens have been prepared. In other groups a varying number of possible combinations is absent. Although attempts have been made to prepare ternary interhalogens, they have been unsuccessful; there is considerable doubt that such compounds can exist. A list of known interhalogen compounds and some of their physical properties is given in the table. *See* HALOGEN ELEMENTS.

The reactivity of the polyhalides reflects the reactivity of the halogens they contain. In general, they behave as strong oxidizing and halogenating agents. Most halogen halides (especially halogen fluorides) readily attack metals, yielding the corresponding halide of the more electronegative halogen. All halogen halides readily react with water. Such reactions can be quite violent and, with halogen fluorides, they may be explosive. They readily react with aliphatic and aromatic hydrocarbons and with oxygen- or nitrogen-containing compounds. [T.Su.]

Intermediate-frequency amplifier

An amplifying circuit in a radio-frequency (RF) receiver that processes and enhances a downconverted or modulated signal. Signal frequency spectrum downconversion is achieved by multiplying the radio-frequency signal by a local oscillator signal in a circuit known as a mixer. This multiplication produces two signals whose frequency content lies about the sum and difference frequencies of the center frequency of the original signal and the oscillator frequency. A variable local oscillator is used in the receiver to hold the difference-signal center frequency constant as the receiver is tuned. The constant frequency of the downconverted signal is called the intermediate frequency (IF), and it is this signal that is processed by the intermediate-frequency amplifier.

Unfortunately, radio-frequency signals both higher and lower than the local oscillator frequency by a difference equal to the intermediate frequency will produce the intermediate frequency. One of these is the desired signal; the undesired signal is called an image. *See* MIXER; OSCILLATOR.

Aside from demodulation and conversion, the purpose of each stage of a radio receiver is to improve the signal-to-noise ratio (SNR) through a combination of signal amplification and noise/interference suppression. Unlike the broadband tunable radio-frequency amplifier, the intermediate-frequency amplifier is designed to operate over a narrow band of frequencies centered about a dedicated fixed frequency (the intermediate frequency); therefore, the intermediate-frequency amplifier can be an extremely efficient stage. If the intermediate frequency is on the order of a few megahertz, the undesirable images may be efficiently rejected, but narrow-band filtering for noise and adjacent-channel-signal rejection is difficult and expensive because of the high ratio of the intermediate frequency to the bandwidth of the intermediate-frequency amplifier. If the intermediate frequency is much smaller, say, on the order of a few hundred kilohertz, then inexpensive and more selective filters are possible that can separate the desired signal from closely packed adjacent signals, but they do not reject images very well. A high-quality double-conversion receiver combines the best of both approaches by cascading both high- and low-frequency intermediate-frequency stages that are separated by a second fixed-frequency mixer.

The superheterodyne structure is common for television, ground-based and satellite communications, cell phones, ground-based and airborne radar, navigation, and many other receivers. The intermediate-frequency amplifier function is ubiquitous. *See* AMPLIFIER; HETERODYNE PRINCIPLE; RADIO-FREQUENCY AMPLIFIER; RADIO RECEIVER; TELEVISION RECEIVER. [S.A.Wh.]

Intermediate vector boson

One of the three fundamental particles that transmit the weak force. (An example of a weak interaction process is nuclear beta decay.) These elementary particles—the W^+, W^-, and Z^0 particles—were discovered in 1983 in very high-energy proton-antiproton collisions. It is through the exchange of W and Z bosons that two particles interact weakly, just as it is through the exchange of photons that two charged particles interact electromagnetically. The intermediate vector bosons were postulated to exist in the 1960s; however, their large masses prevented their production and study at accelerators until 1983. Their discovery was a key step toward unification of the weak and electromagnetic interactions. *See* ELECTROWEAK INTERACTION; ELEMENTARY PARTICLE; FUNDAMENTAL INTERACTIONS; WEAK NUCLEAR INTERACTIONS.

The W and Z particles are roughly 100 times the mass of a proton. Therefore, the experiment to search for the W and the Z demanded collisions of elementary particles at the highest available center-of-mass energy. Such very high center-of-mass energies capable of producing the massive W and Z particles were achieved with collisions of protons and antiprotons at the laboratory of the European Organization for Nuclear Research (CERN) near Geneva, Switzerland. *See* PARTICLE ACCELERATOR; PARTICLE DETECTOR.

Striking features of both the charged W and the Z^0 particles are their large masses. The charged boson (W^+ and W^-) mass is measured to be about 80 GeV/c^2, and the neutral boson (Z^0) mass is measured to be about 91 GeV/c^2. (For comparison, the proton has a mass of about 1 GeV/c^2.) Prior to the discovery of the W and the Z, particle theorists had met with some success in the unification of the weak and electromagnetic interactions. The electroweak theory as it is understood today is due largely to the work of S. Glashow, S. Weinberg, and A. Salam. Based on low-energy neutrino scattering data, which in this theory involves the exchange of virtual W and Z particles, theorists made predictions for the W and Z masses. The actual measured values are in agreement (within errors) with predictions. The discovery of the W and the Z particles at the predicted masses is an essential confirmation of the electroweak theory.

Only a few intermediate vector bosons are produced from 10^9 proton-antiproton collisions at a center-of-mass energy of 540 GeV. This small production probability per $p\bar{p}$ collision is understood to be due to the fact that the bosons are produced by a single quark-antiquark annihilation. The other production characteristics of the intermediate vector bosons, such as longitudinal and transverse momentum distributions (with respect to the $p\bar{p}$ colliding beam axis), all provide support for this theoretical picture. *See* QUARKS. [J.W.R.]

Intermetallic compounds

Materials composed of two or more types of metal atoms, which exist as homogeneous, composite substances and differ discontinuously in structure from that of the constituent metals. They are also called, preferably, intermetallic phases. Their properties cannot be transformed continuously into those of their constituents by changes of composition alone, and they form distinct crystalline species separated by phase boundaries from their metallic components and mixed crystals of these components; it is generally not possible to establish formulas for intermetallic compounds on the sole basis of analytical data, so formulas are determined in conjunction with crystallographic structural information.

The term "alloy" is generally applied to any homogeneous molten mixture of two or more metals, as well as to the solid material that crystallizes from such a homogeneous liquid phase. Alloys may also be formed from solid-state reactions. In the liquid phase, alloys are essentially solutions of metals in one another, although liquid compounds may also be present. Alloys containing mercury are usually referred to as amalgams. Solid alloys may vary greatly in range of composition, structure, properties, and behavior. *See* ALLOY; NONSTOICHIOMETRIC COMPOUNDS; SEMICONDUCTOR; SOLID-STATE CHEMISTRY. [J.L.T.W.]

Intermolecular forces Attractive or repulsive interactions that occur between all atoms and molecules. Intermolecular forces become significant at molecular separations of about 1 nanometer or less, but are much weaker than the forces associated with chemical bonding. They are important, however, because they are responsible for many of the physical properties of solids, liquids, and gases. These forces are also largely responsible for the three-dimensional arrangements of biological molecules and polymers.

Intermolecular forces can be classified into several types, of which two are universal. The attractive force known as dispersion arises from the quantum-mechanical fluctuation of the electron density around the nucleus of each atom. At distances greater than 1 nm or so, the electrons of each atom move independently of the other, and the charge distribution is spherically symmetric. At shorter distances, an instantaneous fluctuation of the charge density in one atom can affect the other. If the electrons of one atom move briefly to the side nearer the other, the electrons of the other atom are repelled to the far side. In this configuration, both atoms have a small dipole moment, and they attract each other electrostatically. At another moment, the electrons may move the other way, but their motions are correlated so that an attractive force is maintained on average. Molecular orbital theory shows that the electrons of each atom are slightly more likely to be on the side nearer to the other atom, so that each atomic nucleus is attracted by its own electrons in the direction of the other atom.

At small separations the electron clouds can overlap, and repulsive forces arise. These forces are described as exchange-repulsion, and are a consequence of the Pauli exclusion principle, a quantum-mechanical effect which prevents electrons from occupying the same region of space simultaneously. To accommodate it, electrons are squeezed out from the region between the nuclei, which repel each other as a result. Each element can be assigned, approximately, a characteristic van der Waals radius; that is, when atoms in different molecules approach more closely than the sum of their radii, the repulsion ennergy increases sharply. It is this effect that gives molecules their characteristic shape, leading to steric effects in chemical reactions. *See* EXCLUSION PRINCIPLE; STERIC EFFECT (CHEMISTRY).

The other important source of intermolecular forces is the electrostatic interaction. When molecules are formed from atoms, electrons flow from electropositive atoms to electronegative ones, so that the atoms become somewhat positively or negatively charged. In addition, the charge distribution of each atom may be distorted by the process of bond formation, leading to atomic dipole and quadrupole moments. The electrostatic interaction between these is an important source of intermolecular forces, especially in polar molecules, but also in molecules that are not normally thought of as highly polar. The electrostatic field of a molecule may cause polarization of its neighbors, and this leads to a further induction contribution to the intermolecular interaction. An induction interaction can often polarize both molecules in such a way as to favor interactions with further molecules, leading to a cooperative network of intermolecular attractions. This effect is important in the network structure of water and ice. *See* WATER.

Intermolecular forces are responsible for many of the bulk properties of matter in all its phases. A realistic description of the relationship between pressure, volume, and temperature of a gas must include the effects of attractive and repulsive forces between molecules. The viscosity, diffusion, and surface tension of liquids are examples of physical properties which depend strongly on intermolecular forces. Intermolecular forces are also responsible for the ordered arrangement of molecules in solids, and account for their elasticity and properties (such as the velocity of sound in materials). [A.J.S.]

Internal combustion engine A prime mover, the fuel for which is burned within the engine, as contrasted to a steam engine, for example, in which fuel is burned in a separate furnace. *See* ENGINE.

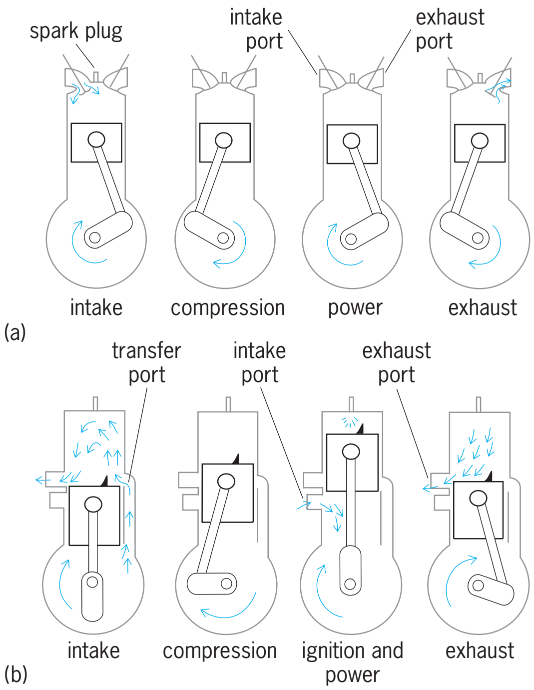
The most numerous of internal combustion engines are the gasoline piston engines used in passenger automobiles, outboard engines for motor boats, small units for lawn mowers, and other such equipment, as well as diesel engines used in trucks, tractors, earth-moving, and similar equipment. For other types of internal combustion engines *see* GAS TURBINE; ROCKET PROPULSION; ROTARY ENGINE; TURBINE PROPULSION.

The aircraft piston engine is fundamentally the same as that used in automobiles but is engineered for light weight and is usually air cooled. *See* RECIPROCATING AIRCRAFT ENGINE.

Characteristic features common to all commercially successful internal combustion engines include (1) the compression of air, (2) the raising of air temperature by the combustion of fuel in this air at its elevated pressure, (3) the extraction of work from the heated air by expansion to the initial pressure, and (4) exhaust. In 1862 Beau de Rochas proposed the four-stroke engine cycle as a means of accomplishing these conditions in a piston engine (see illustration). The engine requires two revolutions of the crankshaft to complete one combustion cycle. The first engine to use this cycle successfully was built in 1876 by N. A. Otto. *See* OTTO CYCLE.

Two years later Sir Dougald Clerk developed the two-stroke engine cycle by which a similar combustion cycle required only one revolution of the crankshaft. In 1891 Joseph Day simplified the two-stroke engine cycle by using the crankcase to pump the required air. Engines using this two-stroke cycle today have been further simplified by use of a third cylinder port which dispenses with the crankcase check valve used by Day. Such engines are in wide use for small units where fuel economy is not as important as mechanical simplicity and light weight. They do not need mechanically operated valves and develop one combustion cycle per crankshaft revolution. Nevertheless they do not develop twice the power of four-stroke cycle engines with the same size working cylinders at the same number of revolutions per minute (rpm). The principal reasons for this are (1) the reduction in effective cylinder volume due to the piston movement required to cover the exhaust ports, (2) the appreciable mixing of burned (exhaust) gases with the combustible mixture, and (3) the loss of some combustible mixture with the exhaust gases.

About 20 years after Otto first ran his engine, Rudolf Diesel successfully demonstrated an entirely different method of igniting fuel. Air is compressed to a pressure high enough for the adiabatic temperature to reach or exceed the ignition temperature of the fuel. Because this temperature is 1000°F (538°C) or higher, compression ratios of 12:1 to 23:1 are used commercially with compression pressures from about 440 to 800 psi (3 to 5.5 megapascals). The fuel is injected into the cylinders shortly before the end of the compression stroke, at a time and rate suitable to control the rate of combustion. *See* DIESEL ENGINE; FUEL INJECTION.



Engine cycles (*a*) The four strokes of a four-stroke engine cycle. On intake stroke, the intake valve (left) has opened and the piston is moving downward, drawing air and gasoline vapor into the cylinder. On compression stroke, the intake valve has closed and the piston is moving upward, compressing the mixture. On power stroke, the ignition system produces a spark that ignites the mixture. As it burns, high pressure is created, which pushes the piston downward. On exhaust stroke, the exhaust valve (right) has opened and the piston is moving upward, forcing the burned gases from the cylinder. (*b*) Three-port two-cycle engine. The same action is accomplished without separate valves and in a single rotation of the crankshaft.

There are many characteristics of the diesel engine which are in direct contrast to those of the Otto engine. The higher the compression ratio of a diesel engine, the less the difficulties with ignition time lag. Too great an ignition lag results in a sudden and undesired pressure rise which causes an audible knock. In contrast to an Otto engine, knock in a diesel engine can be reduced by use of a fuel of higher cetane number, which is equivalent to a lower octane number. *See* CETANE NUMBER; OCTANE NUMBER.

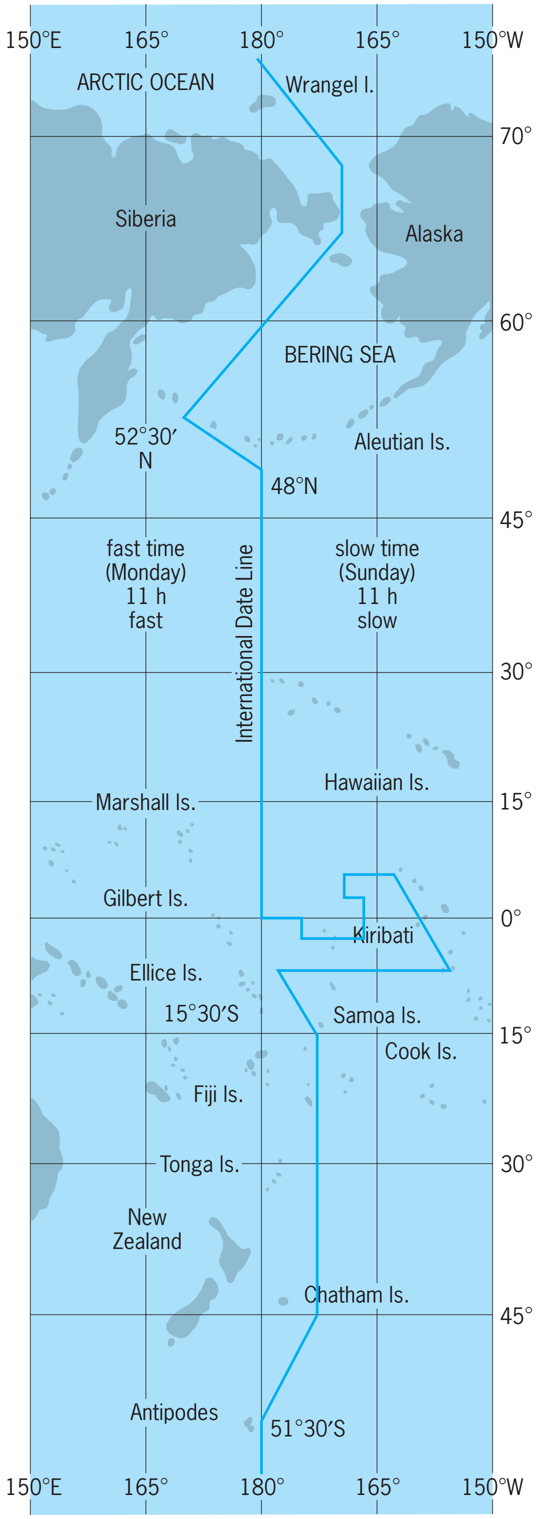
The larger the cylinder diameter of a diesel engine, the simpler the development of good combustion. In contrast, the smaller the cylinder diameter of the Otto engine, the less the limitation from detonation of the fuel.

High intake-air temperature and density materially aid combustion in a diesel engine, especially of fuels having low volatility and high viscosity. Some engines have not performed properly on heavy fuel until provided with a supercharger. The added compression of the supercharger raised the temperature and, what is more important, the density of the combustion air. For an Otto engine, an increase in either the air temperature or density increases the tendency of the engine to knock and therefore reduces the allowable compression ratio.

Diesel engines develop increasingly higher indicated thermal efficiency at reduced loads because of leaner fuel-air ratios and earlier cutoff. Such mixture ratios may be leaner than will ignite in an Otto engine. Furthermore, the reduction of load in an Otto engine requires throttling, which develops increasing pumping losses in the intake system. [N.MacC.; D.L.An.]

Internal energy A characteristic property of the state of a thermodynamic system, introduced in the first law of thermodynamics. For a static, closed system (no bulk motion, no transfer of matter across its boundaries), the change in internal energy for a process is equal to the heat absorbed by the system from its surroundings minus the work done by the system on its surroundings. Only a change in internal energy can be measured, not its value for any single state. For a given process, the change in internal energy is fixed by the initial and final states and is independent of the path by which the change in state is accomplished. *See* THERMODYNAMIC PRINCIPLES. [P.J.B.]

International Date Line The 180° meridian, where each day officially begins and ends. As a person travels eastward, against the apparent movement of the Sun, 1 h is gained for



The International Date Line.

every 15° of longitude; traveling westward, time is lost at the same rate. Two people starting from any meridian and traveling around the world in opposite directions at the same speed would have the same time when they meet, but would be 1 day apart in date. When a traveler goes west across the line, a day is lost; if it is Monday to the east, it will be Tuesday immediately as the traveler crosses the International Date Line.

The 180° meridian is ideal for serving as the International Date Line (see illustration). It is exactly halfway around the world from the zero, or Greenwich, meridian, from which all longitude is reckoned. It also falls almost in the center of the largest ocean; consequently there is the least amount of inconvenience as regards population centers. A few deviations in the alignment have been made, such as swinging the line east around Siberia to keep that area all in the same day, and westward around the Aleutian Islands so that they will be within the same day as the rest of Alaska. Other variations for the same purpose have been made near Kiribati, at the Equator, and the Fiji Islands, in the South Pacific. *See* MATHEMATICAL GEOGRAPHY. [V.H.E.]

Internet A worldwide system of interconnected computer networks. The origins of the Internet can be traced to the creation of ARPANET (Advanced Research Projects Agency Network) as a network of computers under the auspices of the U.S. Department of Defense in 1969. Today, the Internet connects millions of computers around the world in a nonhierarchical manner unprecedented in the history of communications. The Internet is a product of the convergence of media, computers, and telecommunications. It is not merely a technological development but the product of social and political processes, involving both the academic world and the government (the Department of Defense). From its origins in a nonindustrial, noncorporate environment and in a purely scientific culture, it has quickly diffused into the world of commerce.

The Internet is a combination of several media technologies and an electronic version of newspapers, magazines, books, catalogs, bulletin boards, and much more. This versatility gives the Internet its power.

Technological features. The Internet's technological success depends on its principal communication tools, the Transmission Control Protocol (TCP) and the Internet Protocol (IP). They are referred to frequently as TCP/IP. A protocol is an agreed-upon set of conventions that defines the rules of communication. TCP breaks down and reassembles packets, whereas IP is responsible for ensuring that the packets are sent to the right destination.

Data travels across the Internet through several levels of networks until it reaches its destination. E-mail messages arrive at the mail server (similar to the local post office) from a remote personal computer connected by a modem, or a node on a local-area network. From the server, the messages pass through a router, a special-purpose computer ensuring that each message is sent to its correct destination. A message may pass through several networks to reach its destination. Each network has its own router that determines how best to move the message closer to its destination, taking into account the traffic on the network. A message passes from one network to the next, until it arrives at the destination network, from where it can be sent to the recipient, who has a mailbox on that network. *See* ELECTRONIC MAIL; LOCAL-AREA NETWORKS; WIDE-AREA NETWORKS.

TCP/IP. TCP/IP is a set of protocols developed to allow cooperating computers to share resources across the networks. The TCP/IP establishes the standards and rules by which messages are sent through the networks. The most important traditional TCP/IP services are file transfer, remote login, and mail transfer.

The file transfer protocol (FTP) allows a user on any computer to get files from another computer, or to send files to another computer. Security is handled by requiring the user to specify a user name and password for the other computer.

The network terminal protocol (TELNET) allows a user to log in on any other computer on the network. The user starts a remote session by specifying a computer to connect to. From that time until the end of the session, anything the user types is sent to the other computer.

Mail transfer allows a user to send messages to users on other computers. Originally, people tended to use only one or two specific computers. They would maintain "mail files" on those machines. The computer mail system is simply a way for a user to add a message to another user's mail file.

Other services have also become important: resource sharing, diskless workstations, computer conferencing, transaction processing, security, multimedia access, and directory services.

TCP is responsible for breaking up the message into datagrams, reassembling the datagrams at the other end, resending anything that gets lost, and putting things back in the right order. IP is responsible for routing individual datagrams. The datagrams are individually identified by a unique sequence number to facilitate reassembly in the correct order. The whole process of transmission is done through the use of routers. Routing is the process by which two communication stations find and use the optimum path across any network of any complexity. Routers must support fragmentation, the ability to subdivide received information into smaller units where this is required to match the underlying network technology. Routers operate by recognizing that a particular network number relates to a specific area within the interconnected networks. They keep track of the numbers throughout the entire process.

Domain Name System. The addressing system on the Internet generates IP addresses, which are usually indicated by numbers such as 128.201.86.290. Since such numbers are difficult to remember, a user-friendly system has been created known as the Domain Name System (DNS). This system provides the mnemonic equivalent of a numeric IP address and further ensures that every site on the Internet has a unique address. For example, an Internet address might appear as crito.uci.edu. If this address is accessed through a Web browser, it is referred to as a URL (Uniform Resource Locator), and the full URL will appear as http://www.crito.uci.edu.

The Domain Name System divides the Internet into a series of component networks called domains that enable e-mail (and other files) to be sent across the entire Internet. Each site attached to the Internet belongs to one of the domains. Universities, for example, belong to the "edu" domain. Other domains are gov (government), com (commercial organizations), mil (military), net (network service providers), and org (nonprofit organizations).

World Wide Web. The World Wide Web (WWW) is based on technology called hypertext. The Web may be thought of as a very large subset of the Internet, consisting of hypertext and hypermedia documents. A hypertext document is a document that has a reference (or link) to another hypertext document, which may be on the same computer or in a different computer that may be located anywhere in the world. Hypermedia is a similar concept except that it provides links to graphic, sound, and video files in addition to text files.

In order for the Web to work, every client must be able to display every document from any server. This is accomplished by imposing a set of standards known as a protocol to govern the way that data are transmitted across the Web. Thus data travel from client to server and back through a protocol known as the HyperText Transfer Protocol (http). In order to access the documents that are transmitted through this protocol, a special program known as a browser is required, which browses the Web. *See* WORLD WIDE WEB.

Commerce on the Internet. Commerce on the Internet is known by a few other names, such as e-business, Etailing (electronic retailing), and e-commerce. The strengths of e-business depend on the strengths of the Internet. Internet commerce is divided into two major segments, business-to-business (B2B) and business-to-consumer (B2C). In each are some companies that have started their businesses on the Internet, and others that have existed previously and are now transitioning into the Internet world. Some products and services, such as books, compact disks (CDs), computer software, and airline tickets, seem to be particularly suited for online business. [A.V.]

Interplanetary matter Low-density dust or gas that fills the space in a planetary system around or between the planets. Most interplanetary matter in the inner solar system is dust created by collisions among asteroids or released by comets as they pass by the Sun. Ionized gas, launched at high speeds from the Sun as the solar wind, also permeates the solar system and creates a variety of important electromagnetic effects where it interacts with planets.

A cloud of dust, called zodiacal dust, fills the plane of the solar system interior to the asteroid belt. An observer on the Earth can see this dust with the unaided eye on some clear moonless nights because it scatters sunlight in the Earth's direction. *See* ZODIACAL LIGHT.

Two satellites, the *Infrared Astronomical Satellite* (*IRAS*) and the *Cosmic Background Explorer* (*COBE*), made detailed maps of the zodiacal cloud as seen from Earth orbit, using detectors that were sensitive at a wide range of infrared wavelengths (1–200 micrometers). Prominent families of asteroids, groups of asteroids that appear to have fragmented from a single larger body, create bands of dust that both *IRAS* and *COBE* detected. *IRAS* and *COBE* also detected trails of dust left by individual comets, mixing into the background cloud. *See* ASTEROID; COMET; INFRARED ASTRONOMY.

The solar wind flows supersonically in all directions out of the corona of the Sun at typical speeds of 450 km s^{-1} (280 mi/s) and temperatures of 100,000 K. Like the corona, the solar wind consists mostly of ionized hydrogen. At the Earth's orbit, the density of the wind is roughly 5 particles/cm^3 (80 particles/$in.^3$), or about 8×10^{-24} g cm^{-3}. *See* SOLAR WIND.

The region between the asteroid belt and the orbit of Neptune appears to be relatively devoid of interplanetary dust. Beyond Neptune, a ring of comet-sized icy bodies, called the Kuiper Belt, orbits the Sun. Undoubtedly, Kuiper Belt Objects collide with one another and produce a disklike cloud of dust. Dust so far from the Sun is cold, so that it radiates most of its thermal energy at far-infrared wavelengths (30–200 μm). The low temperature makes the cloud too dim to detect from near the Earth, even though it may be just as massive as the zodiacal cloud. *See* KUIPER BELT.

However, other stars have circumstellar clouds of dust that may be analogous to the Kuiper Belt dust in the solar system. The *IRAS* made many observations of individual stars, and detected far-infrared emission from some of them greatly in excess of what the star alone should produce. The first object discovered to be in this category was the bright, nearby star Vega, so this class of objects is called Vega-excess stars. Vega-excess stars have hundreds or thousands of times as much dust as the solar system. However, even the relatively small amount of dust in the solar system emits and reflects at least six times as much light as the Earth.

Several Vega-excess stars, notably Beta Pictoris, HR 4796, and Epsilon Eridani, appear to be surrounded by rings or disks of dust in images taken at a variety of wavelengths from the ground and with the Hubble Space Telescope. These disks generally have an inner edge at distances greater than 10 AU from the stars. Some stars also appear to have clouds of dust orbiting within a few astronomical units of the star. This dust, called exozodiacal dust, may be analogous to the zodiacal dust in the solar system. *See* SPACE TELESCOPE, HUBBLE.

Many Vega-excess stars probably harbor planetary systems. Some have planets that have been detected by close monitoring of the radial velocity of the star to look for the wobble caused by gravitational pull of an orbiting body. Other Vega-excess stars have disks that show structure and central clearings that may indicate the existence of a planet. *See* PLANET. [M.J.Kuc.]

Interplanetary propulsion Means of providing propulsive power for flight to the Moon or to a planet. A variety of different propulsion systems can be used. The space vehicles for these missions consist of a series of separate stages, each with its own set of propulsion systems. When the propellants of a given stage have been expended, the stage is jettisoned to prevent its mass from needlessly adding to the inertia of the vehicle. Although all propulsion systems actually used in interplanetary flight have been chemical rockets, several basically different propulsion systems have been studied. *See* ION PROPULSION; ROCKET PROPULSION; ROCKET STAGING; SPACECRAFT PROPULSION. [G.P.S.]

Interpolation A process in mathematics used to estimate an intermediate value of one (dependent) variable which is a function of a second (independent) variable when values of the dependent variable corresponding to several discrete values of the independent variable are known.

Suppose, as is often the case, that it is desired to describe graphically the results of an experiment in which some quantity Q is measured, for example, the electrical resistance of a wire, for each of a set of N values of a second variable v representing, perhaps, the temperature of the wire. Let the numbers Q_i, i = 1, 2, . . . , N, be the measurements made of Q and the numbers v_i be those of the variable v. These numbers representing the raw data from the experiment are usually given in the form of a table with each Q_i listed opposite the corresponding v_i. The problem of interpolation is to use the above discrete data to predict the value of Q corresponding to any value of v lying between the above v_i. If the value of v is permitted to lie outside these v_i, the somewhat more risky process of extrapolation is used. *See* EXTRAPOLATION. [K.S.K.]

Interstellar extinction Dimming of light from the stars due to absorption and scattering by grains of dust in the interstellar medium. In the absorption process the radiation disappears and is converted into heat energy in the interstellar dust grains. In the scattering process the direction of the radiation is altered. Interstellar extinction produces a dimming of the light from stars situated beyond interstellar clouds of dust. Measures of the radiation from pairs of stars of similar intrinsic properties but with differing amounts of interstellar extinction can be used to obtain information about the dependence of extinction on wavelength, which can then be used to provide clues about the nature of the interstellar dust grains. *See* SCATTERING OF ELECTROMAGNETIC RADIATION.

A detailed interpretation of this dependence and other data relating to interstellar dust suggests that the interstellar grains of dust range in size from about 0.01 to 1 μm and are composed of silicate grains and probably some type of carbon grain, and that the interstellar dust acquires coatings of water ice and ammonia ice in the densest regions of interstellar space. A comparison of interstellar extinction with the absorption by interstellar atomic hydrogen reveals that the dust contains about 1% of the mass of the interstellar medium. *See* INTERSTELLAR MATTER. [B.D.S.]

Interstellar matter The material between the stars, constituting several percent of the mass of stars in the Milky Way Galaxy. Being the reservoir from which new stars are born in the Galaxy, interstellar matter is of fundamental importance in understanding both the processes leading to the formation of stars, including the solar system, and ultimately the origin of life in the universe. Among the many ways in which interstellar matter is detected, perhaps the most familiar are attractive photographs of bright patches of emission-line or reflection nebulosity. However, these nebulae furnish an incomplete view of the large-scale distribution of material, because they depend on the proximity of one or more bright stars for their illumination. Radio observations of hydrogen, the dominant form of interstellar matter, reveal a widespread distribution throughout the thin disk of the

Galaxy, with concentrations in the spiral arms. The disk is very thin (scale height 135 parsecs for the cold material, where 1 pc is equal to 3.26 light-years, 1.92×10^{13} mi, or 3.09×10^{13} km) compared to its radial extent (the distance from the Sun to the galactic center is about 8000 pc, for example). Mixed in with the gas are small solid particles, called dust grains, of characteristic radius 0.1 micrometer. Although by mass the grains constitute less than 1% of the material, they have a pronounced effect through the extinction of starlight. Striking examples of this obscuration are the dark rifts seen in the Milky Way. On average, the density of matter is only 15 hydrogen atoms per cubic inch (1 hydrogen atom per cubic centimeter; in total, 2×10^{-24} g · cm^{-3}), but because of the long path lengths over which the material is sampled, this tenuous medium is detectable. Radio and optical observations of other spiral galaxies show a similar distribution of interstellar matter in the galactic plane.

A hierarchy of interstellar clouds, concentrations of gas and dust, exists within the spiral arms. Many such clouds or cloud complexes are recorded photographically. However, the most dense, which contain interstellar molecules, are often totally obscured by the dust grains and so are detectable only through their infrared and radio emission. These molecular clouds, which account for about half of the interstellar mass, contain the birthplaces of stars. *See* GALAXY, EXTERNAL; MILKY WAY GALAXY.

Molecules. The presence of molecules in interstellar space was first revealed by optical absorption lines. Unfortunately, most species produce no lines at optical wavelengths, and so the discovery of large numbers of molecules had to await advances in radio astronomy, for it is in this spectral band that molecular rotational transitions take place.

An intriguing phenomenon seen in some molecular emission lines is maser amplification to very high intensities. The relative populations of the energy levels of a particular molecule are determined by a combination of collisional and radiative excitation. The population distribution is often not in equilibrium with either the thermal gas or the radiation field, and if a higher energy sublevel comes to have a higher population than a lower one, the electromagnetic transition between the states is amplified through the process of stimulated emission. The best-understood masers are the hydroxyl (OH), water (H_2O), and silicon monoxide (SiO) masers in the circumstellar envelopes of cool mass-losing red supergiant stars. The other masers are found in dense molecular clouds, in particular near compact sources of infrared and radio continuum emission identified as massive stars just being formed. *See* MASER. [P.G.M.]

At present, 119 interstellar molecular species are identified. The known molecules are largely organic. Only 21 are inorganic and stable. There are 32 stable organic species, and 66 unstable species, mostly organic, including carbon chains as complex as $HC_{11}N$. Most of the unstable species were unknown terrestrially before their interstellar identification.

Astrochemistry. Because of the very low temperatures and densities of the interstellar medium, molecules cannot form from atoms by normal terrestrial processes. The most important interstellar formation process involves gas-phase chemistry, particularly involving molecular ions. Ion-molecule reactions satisfy the requirements of minimal activation energy and of rapid two-body rates. The (positive) ions are initiated by the cosmic-ray ionization of H_2, producing H_3^+, which then reacts with other abundant species such as carbon monoxide (CO) and N_2 to produce a large number of the observed species such as HCO^+ and N_2H^+. Ion fragments themselves react rapidly at low temperatures to form larger ions, which eventually recombine with electrons or neutralize by reaction with easily ionized metals. Slower reactions involving neutral atoms and molecules also produce several species.

Interstellar grains can act as passive repositories of frozen molecular material while a cloud is in a cold dense phase. The same frozen material can undergo chemical reactions within the icy mantle, modifying the chemical composition before subsequent evaporation. Finally, molecules may be catalyzed from interstellar atoms arriving on dust grains. The ubiquitous H_2 molecule is the best example of a species that cannot form in the gas phase at sufficient rate but that catalyzes on grains and desorbs efficiently because of its high volatility.

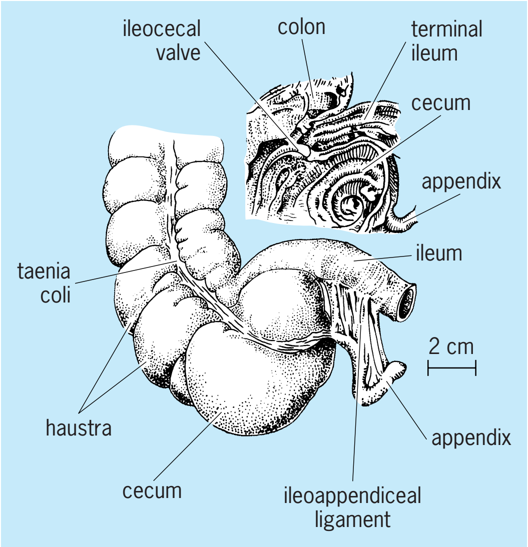
Strong shocks abound in the interstellar medium, resulting from supernovae and expanding H II regions. These shocks briefly heat and compress the gas, producing required conditions for many high-temperature chemical reactions. [B.E.T.]

Intestine The tubular portion of the digestive tract, usually between the stomach and the cloaca or anus. The detailed functions vary with the region, but are primarily digestion and absorption of food.

The structure of the intestine varies greatly in different vertebrates, but there are several common modifications, mainly associated with increasing the internal surface area. One, seen in many fishes, is the development of a spiral valve; this turns the intestine into a structure resembling a spiral staircase. Another, seen in some fish and most tetrapods, is simply elongating and then coiling the intestine. This can reach extremes in large herbivores: Oxen have intestinal lengths of over 150 ft (45 m). In numerous forms there are blind pouches, or ceca, off part of the intestine. In fish these are commonly at the anterior end; in tetrapods they generally lie at the junction between the large and small intestines. In all vertebrates the inner surface of the intestine is irregular, with ridges and projections of various sorts; these reach their maximum development in the extremely fine and numerous finger-shaped villi found in mammals.

In humans the intestine consists of the small and large intestines. The small intestine is further divided into three major parts: the duodenum, the jejunum, and the ileum. The duodenum, 10–12 in. (25–30 cm) long, begins at the pyloric sphincter of the stomach and curves around the head of the pancreas on the right side of the anterior part of the abdomen. It receives the ducts of the biliary system and the pancreas. The jejunum and ileum are about 19 ft (6 m) long and form a much-coiled tube that empties at right angles into the large intestine through the ileocolic valve (see illustration). The large intestine, or colon, consists of five parts: the ascending, transverse, descending, and sigmoid regions, and the terminal rectum which empties into the anal canal.

The microscopic structure of the intestine comprises an inner glandular mucosa, a muscular coat, and an outer serosa of connective tissues which is covered in most areas by peritoneum.



Junction of ileum with large intestine in humans.

The intestine is supported by dorsal mesenteries of varying extent, which contain an extensive system of arteries, veins, lymphatics, and nerves to the various regions. *See* DIGESTIVE SYSTEM. [T.S.P.]

Intra-Americas Sea That area of the tropical and subtropical western North Atlantic Ocean encompassing the Gulf of Mexico, the Caribbean Sea, the Bahamas and Florida, the northeast coast of South America, and the juxtaposed coastal regions, including the Antillean Islands.

Meteorologically, the Intra-Americas Sea is a transition zone between truly tropical conditions in the south and a subtropical climate in the north. The Sea is also the region that either spawns or interacts with the intense tropical storms known locally as the West Indian Hurricane. Air flowing over the Sea acquires moisture that is the source of much of the precipitation over the central plains of North America. *See* HURRICANE .

Ocean currents of the Intra-Americas Sea are dominated by the Gulf Stream system. Surface waters flow into the Sea through the passages of the Lesser Antilles, and to a lesser extent through the Windward Passage between Cuba and Haiti, and the Anegada Passage between Puerto Rico and Anguilla. These inflowing waters form the Caribbean Current, which flows westward and northward into the Gulf of Mexico through the Yucatán Channel. *See* OCEAN CIRCULATION.

River discharge from several South American rivers, notably the Orinoco and Amazon, drifts through the Intra-Americas Sea and carries materials thousands of kilometers from the deltas. The large deltas are heavily impacted by anthropogenic activities, but they remain the source of rich fisheries and plankton communities. Because of the small tidal range in the Sea, most deltas are wind-dominated geological features. *See* DELTA; EARTHQUAKE; MARINE FISHERIES; PLATE TECTONICS; TIDE. [G.A.Ma.]

Intron In split genes, a portion that is included in ribonucleic acid (RNA) transcripts but is removed from within a transcript during RNA processing and is rapidly degraded. Split genes are those in which portions appearing in messenger RNAs (mRNAs) or in structural RNAs, termed exons, are not contiguous in a gene but are separated by lengths of deoxyribonucleic acid (DNA) encoding parts of transcripts that do not survive the maturation of RNA (introns). Most genes in eukaryotes, and a few in prokaryotes, are split. These include not just a large number of different protein-coding genes but also genes encoding transfer RNAs (tRNAs) in such diverse eukaryotes as yeast and frogs, and genes encoding structural RNAs of ribosomes in some protozoa. Introns are also found in mitochondrial genes of lower eukaryotes and in some chloroplast genes. *See* EXON.

The number of introns in a gene varies greatly, from 1 in the case of structural RNA genes to more than 50 in collagen. The lengths, locations, and compositions of introns also vary greatly among genes. However, in general, sizes and locations—but not DNA sequence—are comparable in homologous genes in different organisms. The implication is that introns became established in genes early in the evolution of eukaryotes, and while their nucleotide sequence is not very important, their existence, positions, and sizes are significant.

Speculation on the roles and the evolution of introns is mostly based on correlations that have been seen between domains of protein structure and the exons of genes that are defined by intervening introns. For example, the enzyme alcohol dehydrogenase (ADH) has two domains, one portion of the protein that binds alcohol, and another that binds the enzyme cofactor nicotinamide adenine dinucleotide (NAD). The ADH gene has an intron that cleanly separates the nucleotide sequences which encode each domain, and gene-sequence arrangements such as this are not uncommon. It has been suggested that introns became established in the genes of eukaryotes (and to a limited extent in bacteria) because they facilitate a genetic shuffling or rearrangement of portions of genes which encode various units of function, thus creating new genes with new combinations of properties. The introns allow genetic recombination to occur between the coding units rather than within them, thus providing a means of genetic evolution via wholesale reassortments of functional subunits or building blocks, rather than by fortuitous recombinations of actual protein-coding DNA sequences. *See* GENE; GENETIC CODE; RECOMBINATION (GENETICS). [P.M.M.R.]

Invasion ecology The study of the establishment, spread, and ecological impact of species translocated from one region or continent to another by humans. Biological invasions have gained attention as a tool for basic research, used to study the ecology and evolution of populations and of novel biotic interactions; and as a conservation issue tied to the preservation of biodiversity. The invasion of nonindigenous (also called exotic, alien, or nonnative) species is a serious concern for those charged with managing and protecting natural as well as managed ecosystems. *See* ECOLOGY; POPULATION ECOLOGY.

Ecologists make a distinction between introduced species, meaning any species growing outside its natural habitat including cultivated or domesticated organisms, and invasive species, meaning the subset of introduced species that establish free-living populations in the wild. The great majority of introduced species (approximately 90% as estimated from some studies) do not become invasive. While certain problem invaders, such as the zebra mussel (*Dreissena polymorpha*), exact enormous economic and ecological costs, other introduced species are generally accepted as beneficial additions, such as most major food crops.

Intentional plant introductions have been promoted primarily by the horticulture industry to satisfy the public's desire for novel landscaping. However, plants have also been introduced for agriculture, for silviculture, and for control of soil erosion. Intentional animal introductions include game species brought in for sport hunting or fishing. Unlike these examples, intentional introductions can also include species that are not necessarily intended to form self-sustaining populations, such as those promoted by the aquarium or pet trade.

Species introduced accidentally are "hitchhikers." Shipping ballast has been a major vector, first in the form of soil carrying terrestrial invertebrates and plant seeds or rhizomes, and more recently in the form of ballast water carrying planktonic larvae from foreign ports. While many species are introduced in ballast or by similar means, hitchhikers can also be unwanted parasites that bypass importation and quarantine precautions. For example, many nonindigenous agricultural weeds have been imported in contaminated seed lots.

Certain types of habitats seem to have higher numbers of established nonindigenous species than others. The characteristics that make a site open to invasion must be determined. For example, islands are notably vulnerable to invasions. Islands usually have fewer resident species to begin with, leading to the conjecture that simpler systems have less biotic resistance to invaders. That is, an introduced species is less likely to be met by a resident competitor, predator, or pathogen capable of excluding it. The idea of biotic resistance is also consistent with the idea that complexity confers stability in natural systems. *See* INVASION ECOLOGY.

A second generalization about invasibility is that ecosystems with high levels of anthropogenic disturbance, such as agricultural fields or roadsides, seem to be more invaded. Increased turnover of open space in these sites could provide more opportunities for the establishment of new species. An alternative explanation is that many species that adapted to anthropogenic habitats in Europe simply tagged along as humans re-created those habitats in new places. Those species would naturally have an advantage over native species at exploiting human disturbances. A final suggestion by proponents of ecosystem management is that disturbance (including, in this context, a disruption of natural disturbance regimes, for example, fire suppression) weakens the inherent resistance of ecosystems and promotes invasion.

Invasive species can have several different types of impacts. First, they can affect the traits and behavior of resident organisms (for example, causing a shift in diet, size, or shape of the native species they encounter). Second, impacts can occur at the level of the population, either by changing the abundance of a native population or by changing its genetic composition. Hybridization between an invader and a closely related native can result in introgression and genetic pollution. The endpoint can be the de facto extinction of the native species when the unique aspects of its genome are overwhelmed. Third, impacts can occur at the level of ecological communities. When individual populations are reduced or even driven extinct by competition or predation by an invasive species, the result is a decrease in the overall biodiversity of the invaded site. Finally, invaders can impact not only other species but the physical characteristics of an ecosystem as well.

There are two main contributing factors in determining which species have the biggest impacts: abundance and special characteristics. Invaders that reach extremely high density simply overwhelm all other organisms. Other species have special traits that result in an impact out of proportion to their numbers.

Because of the economic and conservation importance of nonindigenous species, much of invasion ecology focuses on the prevention, eradication, and control of invaders, and the restoration of sites after control. Research has emphasized the importance of early detection and eradication of problem species. Biological control has been touted as an environmentally friendly alternative to herbicides and pesticides. *See* ALLELOPATHY; ECOLOGICAL COMMUNITIES; ECOLOGICAL SUCCESSION; SPECIATION; SPECIES CONCEPT. [I.M.P.]

Inventory control The process of managing the timing and the quantities of goods to be ordered and stocked, so that demands can be met satisfactorily and economically. Inventories are accumulated commodities waiting to be used to meet anticipated demands. Inventory control policies are decision rules that focus on the trade-off between the costs and benefits of alternative solutions to questions of when and how much to order for each different type of item.

The possible reasons for carrying inventories are: uncertainty about the size of future demands; uncertainty about the duration of lead time for deliveries; provision for greater assurance of continuing production, using work-in-process inventories as a hedge against the failure of some of the machines feeding other machines; and speculation on future prices of commodities. Some of the other important benefits of carrying inventories are: reduction of ordering costs and production setup costs (these costs are less frequently incurred as the size of the orders are made larger which in turn creates higher inventories); price discounts for ordering large quantities; shipping economies; and maintenance of stable production rates and work-force levels which otherwise could fluctuate excessively due to variations in seasonal demand.

The benefits of carrying inventories have to be compared with the costs of holding them. Holding costs include the following elements: cost of capital for money tied up in the inventories; cost of owning or renting the warehouse or other storage spaces; materials handling equipment and labor costs; costs of potential obsolescence, pilferage, and deterioration; property taxes levied on inventories; and cost of installing and operating an inventory control policy. Inventories, when listed with respect to their annual costs, tend to exhibit a similarity to Pareto's law and distribution. A small percentage of the product lines may account for a very large share of the total inventory budget (they are called class A items).

Continuous-review and fixed-interval are two different modes of operation of inventory control systems. The former means the records are updated every time items are withdrawn from stock. When the inventory level drops to a critical level called reorder point, a replenishment order is issued. Under fixed-interval policies, the status of the inventory at each point in time does not have to be known. The review is done periodically.

Uncertainties of future demand play a major role in the cost of inventories. That is why the ability to better-forecast future demand can substantially reduce the inventory expenditures of a firm. Conversely, using ineffective forecasting methods can lead to excessive shortages of needed items and to high levels of unnecessary ones.

Material requirements planning (MRP) systems (which are production-inventory scheduling softwares that make use of computerized files and data-processing equipment) are receiving widespread application. MRP systems have not yet made use of mathematical inventory theory. They recognize the implications of dependent demands in multiechelon manufacturing (which includes lumpy production requirements). Integrating the bills of materials, the given production requirements of end products, and the inventory records file, MRP systems generate a complete list of a production-inventory schedule for parts, subassemblies, and end products, taking into account the lead-time requirements. MRP has proved to be a useful tool for manufacturers, especially in assembly operations. [A.Do.]

Inverse scattering theory A theory whose objective is to determine the scattering object, or an interaction potential energy, from the knowledge of a scattered field. This is the opposite problem from direct scattering theory, where the scattering amplitude is determined from the equations of motion, including the potential. The equations of motion are usually linear (operator-valued) equations. *See* SCATTERING EXPERIMENTS (ATOMS AND MOLECULES); SCATTERING EXPERIMENTS (NUCLEI).

Inverse scattering theories can be divided into two types: (1) pure inverse problems, when the data consist of complete, noise-free information of the scattering amplitude; and (2) applied inverse problems, when incomplete data which are corrupted by noise are given. Many different applied inverse problems can be obtained from any pure inverse problem by using different band-limiting procedures and different noise spectra.

The difficulty of determining the exact object which produced a scattering amplitude is evident. It is often a priori information about the scatterer that makes the inversion possible.

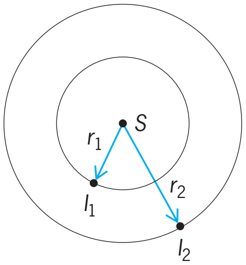
Much of the basic knowledge of systems of atoms, molecules, and nuclear particles is obtained from inverse scattering studies using beams of different particles as probes. For the Schrödinger equation with spherical symmetry or in one dimension, there is an exact solution of the inverse problem.

A number of high-technology areas (nondestructive evaluation, medical diagnostics including acoustic and ultrasonic imaging, x-ray absorption and nuclear magnetic resonance tomography, radar scattering and geophysical exploration) use inverse scattering theory. Several classical waves including acoustic, electromagnetic, ultrasonic, x-rays, and others are used. *See* BIOACOUSTICS; COMPUTERIZED TOMOGRAPHY.

All of the inverse scattering technologies require the solution to ill-posed or improperly posed problems. A model equation is well posed if it has a unique solution which depends continuously on the initial data. It is ill posed otherwise. The ill-posed problems which are amenable to analysis, called regularizable ill-posed problems, are those which depend discontinuously upon the data. This destroys uniqueness, although solutions (in fact, many solutions) exist. [B.DeF.]

Inverse-square law Any law in which a physical quantity varies with distance from a source inversely as the square of that distance. When energy is being radiated by a point source (*see* illustration), such a law holds, provided the space between source and receiver is filled with a nondissipative, homogeneous, isotropic, unbounded medium.

Similar reasoning shows that the same law applies to mechanical shear waves in elastic media and to compressional sound



Point source *S* emitting energy of intensity *I*. The inverse-square law states that $I_1/I_2 = r_2^2/r_1^2$, where r = distance from *S*.

waves. The term is also used for static field laws such as the law of gravitation and Coulomb's law in electrostatics. [W.R.Sm.]

Invertebrate embryology The study of the development or morphogenesis and growth of the invertebrates. The same general principles of development apply to the invertebrates as do to the vertebrates. Much of the basic knowledge of embryology has been the result of studies on the invertebrates. A common phenomenon in the invertebrates is the release of a free and independent form, the larva, before development is completed. The larvae vary considerably and are characteristic of the different animal groups.

Embryonic development begins with the formation of the gametes in a specialized cell bearing the haploid or N number of chromosomes. The process of spermatogenesis consists of a stage of cell proliferation, followed by a period of progressive concentration and streamlining. The essential, heredity-determining material of the chromosomes is packed tightly into a tiny nucleus. The cytoplasm forms the locomotor apparatus, usually a single long flagellum with a centriole at its base and a mitochondrion nearby, as well as an organelle (acrosome) for penetrating the egg coverings. Millions upon millions of such cells are produced in the testis, where they remain quiescent until they are spawned. *See* SPERM CELL; SPERMATOGENESIS.

The egg is specialized for large size and protection of its contents, with less concern for numbers and none at all for motility. In addition, its cytoplasm possesses intrinsic capacities for differentiation and building in exact accordance with the specifications contained in its chromosomes, so that a spider egg, for example, always produces a spider and never a fly. The reserve building and energy-yielding materials are stored in the egg cytoplasm as minute spheres or platelets of yolk, a stable lipoprotein substance. Eggs are large cells even without this inert material. At the end of their growth period, when they have accumulated the full amount of yolk, they are huge in comparison to the body cells of the parent animal. The largest are found among the arthropods, while some marine animals have very small eggs.

During the growth period, while the egg cell is actively synthesizing yolk and increasing the amount of cytoplasm, it has a very large nucleus, the germinal vesicle. When it reaches full size, however, and this synthetic activity subsides, the nuclear membrane breaks down, releasing its contents into the cytoplasm. The two successive nuclear divisions of meiosis follow, but the cytoplasm, instead of dividing equally, pushes out one of the daughter nuclei each time as a polar body. These two minute bodies have no further function in development. The chromosome material left in the egg forms the egg pronucleus, which is ready to unite with the sperm pronucleus. The zygote nucleus, formed by their union, is comparable in size to those of the body cells.

The eggs of invertebrates are always surrounded by a protective covering. In some forms the eggs are laid in batches which may be enclosed in a leathery sac or embedded in a mass of jelly. In other cases each egg has its own separate membranous case, a layer of jelly, or a more complex system of protective structures. Sperm and egg of each individual species have been shown by light and electron microscopy to be characteristic of its particular species. Mechanisms have evolved which normally prevent the egg of one species from being fertilized by the sperm of another. Reproduction among the invertebrates takes place in a variety of ways which differ widely from phylum to phylum.

Fertilization has been studied in several invertebrates, but especially in the sea urchin. Egg and sperm of the sea urchin are released into the seawater. The eggs are covered with a jelly coat to which a receptor on the plasma membrane of the fertilizing sperm binds. The plasma and outer acrosomal membranes of the sperm break down and fuse with each other as a Ca^{2+} influx occurs; the hydrolytic enzymes within the acrosome are released to lyse the egg coat. Next the inner acrosomal membrane everts by the polymerization beneath it of actin, and forms the acrosomal process which makes contact and fuses with the egg plasma membrane. The egg responds to the sperm by forming a fertilization cone. The sperm nucleus enters the egg, and its DNA swells to form the male pronucleus. As the sperm binds to the receptors on the egg plasma membrane, the electrical potential of the egg membrane changes and establishes a rapid block to prevent further sperm from making contact and fusing with the egg. With sperm-egg membrane fusion, Ca^{2+} is released to activate a series of changes in the egg. As changes occur at the egg surface, the egg pronucleus and the sperm pronucleus with associated astral rays move toward the center of the egg, where they fuse.

The union of the two pronuclei (syngamy) marks the completion of the fertilization process. The fusion forms the zygote nucleus, with the full complement of chromosomes, and the dormant egg cell has been aroused to start the series of changes which will produce a new sea urchin. With different time schedules and allowance for the individual characteristics of each species, these basic processes of sperm entry, aster formation, and syngamy make up the complex phenomenon of the fertilization reaction as it occurs in all animals.

The fertilized egg, or zygote, sets about at once to divide the huge mass of the egg into many small cells in order to restore the usual ratio between the amounts of nuclear and cytoplasmic substances. The energy for these repeated mitoses comes from the yolk, which also furnishes at least part of the materials required for synthesis of new nuclear structures. During this cleavage period, which commonly occurs during the first 12 h after fertilization, the blastomeres, as the cleavage stage cells are called, divide more or less synchronously. Generally, cleavage follows one of several patterns characteristic for large groups of animals and often correlated with the amount and mode of distribution of the yolk. Small eggs, which contain little yolk, divide completely and usually very regularly, forming a mass of cells that shows spiral, bilateral, or radial symmetry.

Insect eggs contain a large store of yolk. Following fertilization, the nuclei alone divide and move apart in the layer of cytoplasm after each division so that they distribute themselves all around the egg. After nine such nuclear divisions have taken place (producing 512 nuclei), the cytoplasm also cleaves at the next division, forming a single layer composed of about 1000 cells surrounding the central yolk mass. *See* CLEAVAGE (EMBRYOLOGY).

Among all the invertebrate forms except the insects, the result of 6–10 successive cleavage cycles is the formation of a sphere (blastula) composed of small cells which lie in a single compact layer around a central cavity (blastocoele).

The end of the brief blastula stage occurs when the process of gastrulation begins. In its simplest form, this consists in an indenting (invagination) of the blastula wall in the vegetal region. Meanwhile cell division is going on steadily, and since the larva has as yet no way of taking in solid food from the outside, all the form changes which occur during this period are accomplished with the material originally present in the fertilized egg. The only addition is water (blastocoele fluid) and such dissolved substances, mostly salts, from the environment as can enter through the cell membranes. As the blastomeres become smaller and the blastular wall becomes correspondingly thinner, cells are provided to extend the vegetal indentation into a pocket. With the appearance of this structure (primitive digestive tract) the larva becomes two-layered, possessing an outer layer, the ectoderm, which will later produce the nervous system as well as the outermost body covering, and an inner layer, the endoderm, from which will be formed the lining of the functional digestive tract and its associated organs and glands. As the primitive digestive tract extends into the blastocoele, its opening to the outside becomes smaller and is known as the blastopore. *See* BLASTULATION; GASTRULATION.

At this time the first few cells belonging to a third body layer, the mesoderm, make their appearance. This mesodermal tissue spreads out between the ectoderm and endoderm, and in all phyla more advanced than the flatworms it splits through its center into an inner and an outer layer. The cavity thus formed within the mesoderm is the true body cavity in which the various internal organs lie. The outer layer of mesoderm becomes closely applied to the inner side of the ectoderm, forming body-wall muscles and other supporting layers, while the inner layer of mesoderm surrounds the endoderm with layers of muscle. The organs of circulation, excretion, and reproduction, as well as all muscles and connective tissue, are eventually formed from this mesodermal layer which surrounds the endoderm.

So far it is possible to summarize the development of invertebrate animals as a group but beyond this point each subgroup follows its own course, and these are so widely divergent that every one must be considered separately. Meaningful generalizations are not even possible within a single class in some cases, as attested to by the various modes of development occurring among the Insecta, some of which proceed directly from egg to adult form, while others go through an elaborate series of changes. In very many species there is a sharp break in the life history when the larva, after passing through a number of morphological phases which lead from one to the next with a steady increase in size and complexity, abruptly forms a whole new set of rudimentary adult organs which take over the vital functions. This metamorphosis represents the end of the larval period. The tiny animal which it produces is for the first time recognizable as the offspring of its parents. *See* INSECT PHYSIOLOGY; INSECTA.

[G.Hi.]

Invertebrate pathology The study of diseases affecting invertebrate animals, including etiology, pathogenesis, symptomatology, pathology, histopathology, physiopathology, and epizootiology. Interactions between invertebrates and their diverse pathogens, such as bacteria, viruses, and protozoa, range from obligate parasitism to various associations that may result in disease. Disease is usually described as a disturbance of the equilibrium between the invertebrate animal and the environment, and it should be understood as a process and not a thing. The disease process represents the response of an invertebrate organism to injury. Its occurrence is a normal biological phenomenon, and it has been recognized as a balancing factor in nature. Understanding invertebrate pathology is essential to understanding invertebrate life and behavior.

Infectious diseases of invertebrates have been thoroughly studied, while less attention has been devoted to noninfectious diseases. The latter involve mechanical and physiological injuries caused by chemicals, nutritional disturbances, inherited abnormalities (genetic diseases), tumors, predation, and the actions of other invertebrates.

Numerous diseases and pathogens of invertebrate animals have been described throughout the world. By 1999, in Mollusca as many as 46 diseases of oysters, 20 of clams and cockles, 19 of scallops, and 9 of abalone had been described. Diseases of Crustacea included 17 lobster diseases, 35 diseases of shrimp and prawns, 17 of crabs, and 13 of crayfish.

Immune reactions of invertebrates can be cellular or humoral. In cellular immunity, several types of hemocytes have been demonstrated. Three defense reactions have been recognized: phagocytosis, encapsulation, and hemostasis (coagulation and wound healing). Phagocytosis is localized in the plasma membrane and the cytoskeleton. Encapsulation occurs when bacteria, fungi, nematodes, or protozoa, as well as nonliving objects that are too large to be phagocytyzed, are encapsulated by plasmatocytes or granulocytes. Wound healing and coagulation in invertebrates differs from hemostasis in vertebrate animals.

All types of hemocytes involved in invertebrate immunity are called immunocytes. The recognition of foreign antigens is affected by surface receptors and molecules located on the plasma membrane of immunocytes. Parasitoids and parasites of invertebrates often possess defensive mechanisms that can overcome immunological reactions of their hosts. Humoral immunity of invertebrates provides the second line of defense against massive invasion, when immunocytes become depleted.

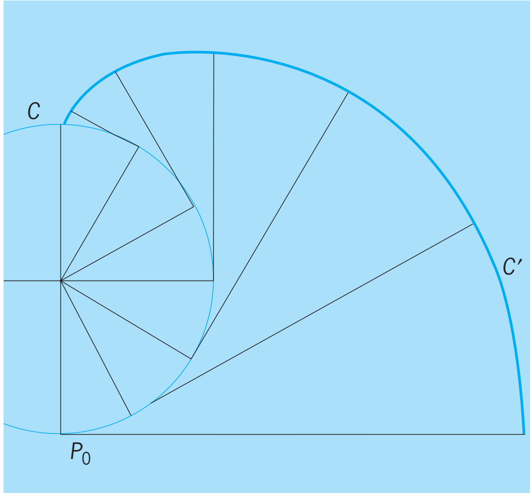
The immune system of invertebrate animals produces antimicrobial proteins in immunocytes or in the fat body. Arthropods do not possess antibodies, but they synthesize lectins that can agglutinate microorganisms. Cytokine-like molecules have been found in mollusks, worms, echinoderms, and arthropods. In many invertebrate animals, a prophenoloxidase-activating system can contribute to humoral immunity. Neuropeptides and opiates mediate phagocytosis in the earthworm, mollusks, arthropods, starfishes, and sea urchins. Complement-like molecules have been detected in all invertebrates, and in some the C-reactive protein has been reported. Obviously the immune system of invertebrates is very sophisticated, sharing many fundamental mechanisms with vertebrates.

Invertebrate pathology has applications in agriculture, medicine, general biology, and biotechnology. In agriculture the prevention of diseases affecting honeybees and silkworm, and the use of bacterial toxins and baculoviruses for microbial control of insect pests, constitute the most important applications of invertebrate pathology. *See* ANNELIDA; ANTIBODY; ARTHROPODA; ECHINODERMATA; IMMUNITY; INSECTA; MOLLUSCA; NEMATA; PORIFERA.

[K.M.]

Involute A term applied to a curve C′ that cuts at right angles all tangents of a curve *C* (see illustration). Each curve *C* has infinitely many involutes and the distance between corresponding points of any two involutes is constant. Let a length of string be coincident with a curve *C*, with one end fastened at a point P_0 of *C*. If the string is unwound, remaining taut, the other end of the string traces an involute C′ of *C*. By varying the length of the string, all involutes of *C* are obtained. *See* ANALYTIC GEOMETRY.

[L.M.Bl.]



An involute *C*′ of curve *C*.

Iodine A nonmetallic element, symbol I, atomic number 53, relative atomic mass 126.9045, the heaviest of the naturally occurring halogens. Under normal conditions iodine is a black, lustrous, volatile solid; it is named after its violet vapor. *See* HALOGEN ELEMENTS; PERIODIC TABLE.

The chemistry of iodine, like that of the other halogens, is dominated by the facility with which the atom acquires an electron to form either the iodide ion I^- or a single covalent bond —I, and by the formation, with more electronegative elements, of compounds in which the formal oxidation state of iodine is +1, +3, +5, or +7. Iodine is more electropositive than the other halogens, and its properties are modulated by: the relative weakness of covalent bonds between iodine and more electropositive elements; the large sizes of the iodine atom and iodide ion, which reduce lattice and solvation enthalpies for iodides while increasing the importance of van der Waals forces in iodine compounds; and the relative ease with which iodine is oxidized, Some properties of iodine are listed in the table. *See* ASTATINE; BROMINE; CHEMICAL BONDING; CHLORINE; FLUORINE.

Iodine occurs widely, although rarely in high concentration and never in elemental form. Despite the low concentration of iodine in sea water, certain species of seaweed can extract and accumulate the element. In the form of calcium iodate, iodine is found in the caliche beds in Chile. Iodine also occurs as iodide ion in some oil well brines in California, Michigan, and Japan.

The sole stable isotope of iodine is ^{127}I (53 protons, 74 neutrons). Of the 22 artificial isotopes (masses between 117 and 139), the most important is ^{131}I, with a half-life of 8 days. It is widely used in radioactive tracer work and certain radiotherapy procedures. *See* RADIOACTIVE TRACER.

Iodine exists as diatomic I_2 molecules in solid, liquid, and vapor phases, although at elevated temperatures (>200°C or 390°F) dissociation into atoms is appreciable. Short intermolecular I. . . I distances in the crystalline solid indicate strong intermolecular van der Waals forces. Iodine is moderately soluble in nonpolar liquids, and the violet color of the solutions suggests that I_2 molecules are present, as in iodine vapor.

Although it is usually less vigorous in its reactions than the other halogens, iodine combines directly with most elements. Important exceptions are the noble gases, carbon, nitrogen, and some noble metals. The inorganic derivatives of iodine may be grouped into three classes of compounds: those with more electropositive elements, that is, iodides; those with other halogens; and those with oxygen. Organoiodine compounds fall into two categories: the iodides; and the derivatives in which iodine is in a formal positive oxidation state by virtue of bonding to another, more electronegative element. *See* GRIGNARD REACTION; HALOGENATED HYDROCARBON; HALOGENATION.

Iodine appears to be a trace element essential to animal and vegetable life. Iodide and iodate in sea water enter into the metabolic cycle of most marine flora and fauna, while in the higher mammals iodine is concentrated in the thyroid gland, being converted there to iodinated amino acids (chiefly thyroxine and iodotyrosines). They are stored in the thyroid as thyroglobulin, and thyroxine is apparently secreted by the gland. Iodine deficiency in mammals leads to goiter, a condition in which the thyroid gland becomes enlarged. *See* THYROID GLAND.

Some important properties of iodine

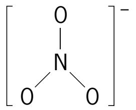
Property	Value
Electronic configuration	[Kr]4d105s25p5
Relative atomic mass	126.9045
Electronegativity (Pauling scale)	2.66
Electron affinity, eV	3.13
lonization potential, eV	10.451
Covalent radius,—I, nm	0.133
Ionic radius, I_-, nm	0.212
Boiling point, °C	184.35
Melting point, °C	113.5
Specific gravity (20/4)	4.940

The bactericidal properties of iodine and its compounds bolster their major uses, whether for treatment of wounds or sterilization of drinking water. Also, iodine compounds are used to treat certain thyroid and heart conditions, as a dietary supplement (in the form of iodized salt), and for x-ray contrast media. *See* ANTIMICROBIAL AGENTS; ANTISEPTIC; SALT (FOOD).

Major industrial uses are in photography, where silver iodide is a constituent of fast photographic film emulsions, and in the dye industry, where iodine-containing dyes are produced for food processing and for color photography. *See* DYE; PHOTOGRAPHIC MATERIALS. [C.A.]

Ion An atom or group of atoms that bears an electric charge. Positively charged ions are called cations, and negatively charged ions are called anions. When a single atom gains or loses an electron, monoatomic ions are formed. For example, reaction of the element sodium (Na) with the element chlorine (Cl) leads to the transfer of electrons from Na to Cl to form Na^+ cations and Cl^- anions. In general, atoms of metallic elements (on the left side of the periodic table) lose electrons to form cations, while atoms of nonmetallic atoms (on the right side of the periodic table) gain electrons to form anions. Ions can bear multiple charges, as in the magnesium ion (Mg^{2+}) or the nitride ion (N^{3-}). The charge on monoatomic ions is usually the same for elements in the same column of the periodic table; for example, hydrogen (H), Na, lithium (Li), potassium (K), rubidium (Rb), and cesium (Cs) all form +1 ions. *See* PERIODIC TABLE.

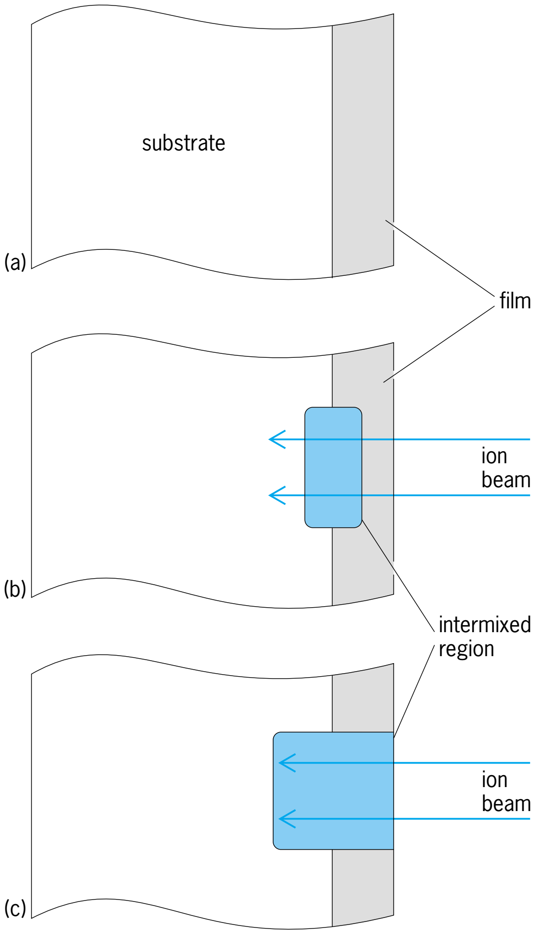
Ions can also comprise more than one atom and are then called polyatomic ions. For example, the ammonium ion ($NH_4{}^+$) carries a positive charge and is composed of one nitrogen atom and four hydrogen atoms. The nitrate ion ($NO_3{}^-$) is composed of one nitrogen atom and three oxygen atoms and carries a single negative charge. Polyatomic ions are usually depicted inside brackets with superscripted charges, as shown in the structure below.



Nitrate ion

Anions and cations can combine to form solid materials called salts, which are named by the cation name followed by the anion name. For a salt composed of the polyatomic ions ammonium and nitrate, the formula is NH_4NO_3 and the name is ammonium nitrate. For monoatomic ions, the cation name is the same as the element and the anion name is the element name with the ending -ide. Thus, common table salt, NaCl, is called sodium chloride. The ratio of anions to cations must always be such that an electrically neutral material is produced. Thus, magnesium nitrate must contain one magnesium for every two nitrates, giving the formula $Mg(NO_3)_2$. *See* SALT (CHEMISTRY). [H.H.T.]

Ion beam mixing A process in which bombardment of a solid with a beam of energetic ions causes the intermixing of the atoms of two separate phases originally present in the near-surface region. In the well-established process of ion implantation, the ions are incident instead on a homogeneous solid, into which they are incorporated over a range of depths determined by their initial energy. In the simplest example of ion beam mixing, the solid is a composite consisting of a substrate and a thin film of a different material (illus. *a*). Ions with sufficient energy pass through the film into the substrate, and this causes mixing of the film and substrate atoms (illus. *b*). If the ion dose is large enough, the original film will completely disappear (illus. *c*). This process may result in the impurity doping of the substrate, in the formation of an alloy or two-phase mixture, or in the production



Ion beam mixing of film and substrate. (*a*) Before ion bombardment. (*b*) Partial intermixing. (*c*) Complete intermixing.

of a stable or metastable solid phase that is different from either the film or the substrate. *See* ION IMPLANTATION.

Like ion implantation, ion beam mixing is a solid-state process that permits controlled change in the composition and properties of the near-surface region of solids. Although not yet employed commercially, it is expected to be useful for such applications as the surface modification of metals and semiconductor device processing. In conjunction with thin-film deposition technology, ion beam mixing should make it possible to introduce many impurity elements at concentrations too high for ion implantation to be practical. [B.Y.T.]

Ion exchange The reversible exchange of ions of the same charge between a solution and an insoluble solid in contact with it; or between two immiscible solvents, one of which contains a soluble material with immobilized ionic groups. Ions are atoms or molecules containing charge-bearing groups. Their interactions are dominated by the electrostatic forces between charge centers. These interactions are attractive when the ions are of opposite charge, or repulsive when the ions have the same charge. Ions with a net negative charge are called anions, and those with a net positive charge are cations.

A unique property of ions is their capacity to render gases and liquids conducting, and conductivity is a universal method of detecting ions. Ions in solution are in rapid motion and have no distinct partners. Ions in an electric field migrate to the electrode of opposite charge with a velocity roughly proportional to their charge-to-size ratio. This process is known as electrophoresis, and it is one method used to separate and identify ions. *See* ELECTROPHORESIS.

Ions can also be separated on the basis of their equilibrium with a system containing immobilized ions of opposite charge. Ions can be immobilized by virtue of their location in a rigid matrix. Associated with these fixed ionic sites are mobile counterions of opposite charge. Solution ions with a higher affinity than the counterions for the fixed sites will displace them from the fixed sites and remain localized in the vicinity of the fixed sites. Simultaneously the solution is enriched in the counterions originally localized at the fixed sites. This exchange process for ions of the same charge type is called ion exchange. In a column containing the immobilized ions as part of the stationary phase and the solution of competing ions as the mobile phase, the sample ions can be separated by the repeated equilibrium steps involved as they are transported through the column until they exit it, and are detected. This is an example of ion-exchange chromatography, an important method of separating and identifying ions.

Ion-exchange materials. Ion-exchange polymers are based on styrene and divinylbenzene and, to a lesser extent, polymers prepared from divinylbenzene, or a similar cross-linking agent, and acrylic, methacrylic, or hydroxyalkyl methacrylic acids and esters. These are usually prepared in bead form.

Ion exchangers prepared for the isolation or separation of cations must have negatively charged functional groups incorporated into the polymer backbone. The most common groups are sulfonic and carboxylic acids. Sulfonic acid groups are introduced by reacting the polymer beads with fuming sulfuric acid or a similar reagent. Similarly, carboxylic acid groups can be introduced by a number of common chemical reactions or by hydrolysis of the ester group or oxidation of hydroxyalkyl groups in methyl methacrylate or hydroxyalkyl methacrylate polymers, respectively. Other common functional groups used in cation exchangers include phosphoric acid and phenol and, to a lesser extent, phosphinic, arsonic, and selenonic acids.

A common approach for the preparation of anion exchangers is to react the styrene-divinylbenzene polymer with chloromethylmethyl ether in the presence of a catalyst, which adds the side chain, —CH_2Cl; then this chloromethylated product is treated with an amine to introduce the charged functional group. A tertiary amine produces a quaternary ammonium group, while primary and secondary amines give products that are charged only in contact with solutions of low pH. As well as simple alkyl and benzyl amines, hydroxyalkyl amines are used to introduce functional groups of the type $[—CH_2N(CH_3)_2C_2H_4OH]^+$. *See* QUATERNARY AMMONIUM SALTS.

Silica-based materials are used primarily in chromatography because of the favorable mechanical and physical properties of the silica (SiO_2) gel support matrix. Ion-exchange groups are introduced by reacting the surface silanol groups of the porous silica particles with silanizing reagents containing the desired functional group (R).

Hydrous oxides of elements of groups 14, 15, and 16 of the periodic table can be used as selective ion exchangers. The most important hydrous oxides used for the separation of organic and inorganic ions are alumina ($Al_2O_3{\cdot}nH_2O$), silica ($SiO_2{\cdot}nH_2O$), and zirconia ($ZrO_2{\cdot}nH_2O$). Silica, by virtue of the presence of surface silanol groups, is used as a cation exchanger at pH > 2. Alumina is amphoteric and can be used as an anion exchanger at low pH and a cation exchanger at high pH. Alumina has the advantage over silica of being chemically stable over a wide pH range. The ion-exchange capacity of silica and alumina is controlled by the pH of the solution in contact with the oxides, since this controls the number of ionized surface functional groups. Alumina is used to isolate nitrogen-containing drugs and biochemically active substances from biological fluids, thus minimizing matrix interferences in their subsequent chromatographic analysis.

Applications. Ion exchange has numerous applications for industry and for laboratory research. By the quantity of materials used, water conditioning is the most important. Ion exchange is one of the primary analytical methods used to identify and quantify the concentration of ions in a wide range of environmental, biological, and industrial samples.

Natural water from rivers and wells is never pure; it is usually hard, that is, it contains calcium and magnesium salts that form curds with soap and leave hard crusts in pipes and boilers. Hard water is softened by passage through a cartridge or bed of cation exchanger in the sodium form (the mobile counterions are sodium in this case).

Many industrial and laboratory processes require a supply of pure water with a very low concentration of salts. This can be achieved by passing water through a bed of mixed strong cation exchanger in the hydrogen form and a strong anion exchanger in the hydroxide form. The cation exchanger removes all the cations from the water by replacing them by hydrogen ions. The anions are removed by the anion exchanger and replaced by hydroxide ions. The hydrogen and hydroxide ions combine to form water.

Toxic ions such as mercury (Hg^{2+}), lead (Pb^{2+}), chromate ($CrO_4{}^{2-}$), and ferrocyanide [$Fe(CN)_6{}^{4-}$] are removed by ion exchange from industrial wastewaters prior to their discharge into the environment. Ion exchangers are used to recover precious metals such as gold (Au^+), platinum (Pt^+), and silver (Ag^+) in a useful form from mine workings and metalworking factories. Ion exchange is frequently used to decontaminate waste and concentrate radioactive elements from the nuclear industry.

Ion exchange is used on the laboratory scale for isolation and preconcentration of ions prior to instrumental analysis and to obtain preparative scale quantities of material for use in laboratory studies. Ion exchange is often employed in conjunction with activation analysis to isolate individual elements for quantification by radiochemical detection. Modern chromatographic techniques employ ion exchangers of small particle size and favorable mass-transfer characteristics, and operate at high pressures, providing better resolution of mixtures in a shorter time than with conventional gravity-flow-controlled separations.

Biotechnology requires reliable, efficient methods to purify commercial-scale quantities of proteins, peptides, and nucleic acids for use in the pharmaceutical, agricultural, and food industries. Ion exchange is widely used in the isolation and purification of these materials. Typical applications include the removal of ionic compounds used in the production process, the elimination of endotoxins and viruses, the removal of host-cell proteins and deoxyribonucleic acid (DNA), and the removal of potentially hazardous variants of the main product. [C.F.P.]

Membranes. Ion-exchange membranes are a class of membranes that bear ionic groups and therefore have the ability to selectively permit the transport of ions through themselves. In biological systems, cell membranes and many other biological membranes contain ionic groups, and the conduction of ions is essential to their function. Synthetic ion-exchange membranes are used in fuel cells, electrochemical processes for chlorine manufacture and desalination, membrane electrodes, and separation processes. Ion-exchange membranes typically consist of a thin-film phase, usually polymeric, to which have been attached ionizable groups. Numerous polymers have been used, including polystyrene, polyethylene, polysulfone, and fluorinated polymers. Ionic groups attached to the polymer include sulfonate ($—SO_3{}^-$), carboxylate ($—COO^-$), tetralkylammonium ($—N(CH_3)_4{}^+$), phosphonate ($—PO_3H^-$), and many others. [N.N.Li; S.F.Y.]

Ion implantation A process that utilizes accelerated ions to penetrate a solid surface. The implanted ions can be used to modify the surface composition, structure, or property of the solid material. This surface modification depends on the ion species, energy, and flux. The penetration depth can be controlled by adjusting the ion energy and the type of ions used. The total number of ions incorporated into the solid is determined by the ion flux and the duration of implantation. This technique allows for the precise placement of ions in a solid at low temperatures. It is used for many applications such as modifying the electrical properties of semiconductors and improving the mechanical or chemical properties of alloys, metals, and dielectrics. *See* ALLOY; DIELECTRIC MATERIALS; METAL; SEMICONDUCTOR.

Wide ranges of ion energy and dose are applied. For ion energy ranging from 1 keV to 10 MeV, the ion penetration depth varies from 10 nanometers to 50 micrometers. In general, it is difficult to get deeper penetration since extremely high energy ions are required. As such, ion implantation is a surface modification technique and not suitable for changing the entire bulk property of a solid. Ion dosage also varies depending on the applications. Doses ranging from 10^{10} to 10^{18} ions/cm^2 are typically applied. For high-dose applications, ion sources providing high ion currents are needed to keep the implantation time reasonable for production purposes. *See* ION.

Ion implantation is used extensively in the semiconductor industry. The fabrication of integrated circuits in silicon often requires many steps of ion implantation with different ion species and energies. The implanted ions serve as dopants in semiconductors, changing their conductivity by more than a factor of 10^8. *See* INTEGRATED CIRCUITS.

Ion implantation is also used to change the surface properties of metals and alloys. It has been applied successfully to improve wear resistance, fatigue life, corrosion protection, and chemical resistance of different materials. Even though the ion projected range is less than 1 μm, surface treatment by ion implantation can extend the lives of metal or ceramic tools by 80 times or more. Ion implantation can form new compounds such as nitrides on the surface, and the implanted ions can be found at much greater depths than the projected range due to diffusion or mechanical mixing. *See* CERAMICS. [S.W.P.]

Ion propulsion Vehicular propulsion caused by the high-speed discharge of a beam of electrically charged minute particles. These particles, usually positive ions, are generated and accelerated in an electrostatic field produced within an ion thruster attached to a spacecraft. Because positive ions cannot be ejected from the thruster without leaving a substantial negative charge on the thruster and spacecraft, electrons must be ejected at the same rate. Ion propulsion systems are attractive because they expel the ions at very high speeds and, therefore, require much less propellant than other thrusters, such as chemical rockets.

The three principal components of an ion propulsion system are the power-generation and -conditioning subsystem, the propellant storage and feed subsystem, and one or more ion thrusters.

The power source can be a nuclear reactor or a radiant-energy collector. In the former, thermal power is released by fission or fusion reactions. Solar radiation can be used to provide electric power directly through photovoltaic (solar) cells or indirectly through a solar collector-heat exchanger system similar to that for a nuclear system. *See* SOLAR CELL; SOLAR ENERGY.

If the power-generation system involves a nuclear reactor or a solar-thermal subsystem, thermal-to-electric conversion subsystems are required. Those most highly developed involve thermodynamic conversion cycles based on turbine generators. Although most traditional systems have operated on the Brayton gas cycle or the Rankine vapor cycle, more recent efforts include the Stirling gas-cycle system.

Ion-thruster propellants that have been investigated include argon, xenon, cesium, mercury, and fullerenes such as C_{60}. Although mercury received most of the early attention, xenon is now being used on all space missions because of toxicity concerns with mercury.

Ion or electrostatic thrust devices contain three functional elements: an ionizer that generates the ions; an accelerator providing an electric field for accelerating the ions and forming them into a well-focused beam; and a neutralizer or electron emitter that neutralizes the electrical charge of the exhaust beam of ions after they have been ejected.

The positive ions needed for acceleration are produced in a strong electric field, by contact with a surface having a work function greater than the ionization potential of the propellant, or by electron-bombardment ionization. The last method has received the most attention and appears to be the most promising.

Some of the ions produced are directed toward the ion-accelerating subsystem which typically consists of two plates containing large numbers of aligned hole pairs. The upstream plate and the body of the ionizer are maintained at a positive potential with respect to the space downstream from the thruster, whereas the downstream plate is biased negative at a smaller value. For a high extracted ion current density, the plates should be as close together as possible.

Ion propulsion is characterized by high specific impulse and low thrust. Because high specific impulse means low propellant consumption, ion propulsion is attractive for a wide variety of applications.

One functional category includes the use of ion thrusters on satellites for orbit control (against weak perturbation forces) and for station keeping (position maintaining of satellite in a given orbit). Substantial commercial use of ion thrusters in this application began at the end of the twentieth century. An ion propulsion system can also be used advantageously for changing the satellite's position in a given orbit, especially shifting a satellite to different longitudes over the Earth in an equatorial geostationary orbit. *See* SATELLITE (SPACECRAFT); SPACECRAFT PROPULSION.

A major functional application of ion propulsion is interplanetary transfer. Here, thrust has to overcome only very weak solar gravitational forces. Because of this, and the long powered flight times of which ion propulsion is capable, transfer times to Venus or Mars need not be longer than transfer times in comparable flights with high thrust drives capable only of short powered flight. At the very large distances to objects in the outer solar system, ion propulsion would yield shorter transfer times than chemical and most high-thrust nuclear concepts. The National Aeronautics and Space Administration (NASA) *Deep Space 1* mission, launched in 1998, used a 30-cm-diameter (12-in.) xenon ion thruster to propel a spacecraft to encounters with the asteroid Braille and the comet Borrelly. *See* ELECTROTHERMAL PROPULSION; INTERPLANETARY PROPULSION; PLASMA PROPULSION; SPACE PROBE. [P.J.Wi.]

Ion-selective membranes and electrodes Membrane-based devices, involving permselective, ion-conducting materials, used for measurement of activities of species in liquids or partial pressures in the gas phase. Permselective means that ions of one sign may enter and pass through a membrane.

Ion-selective electrodes are classified mainly according to the physical state of the ion-responsive membrane material, and not with respect to the ions sensed.

Glass membrane electrodes are mainly used for hydrogen ion activity measurements. They predate the wider variety of membrane electrodes developed after 1960. Electrodes based on water-insoluble inorganic salts include sensors for F^-, Cl^-, Br^-, I^-, CN^-, SCN^-, S^{2-}, Ag^+, Cu^{2+}, Cd^{2+}, and Pb^{2+}. The compounds used are silver salts, mercury salts, sulfides of Cu, Pb, and Cd, and rare-earth salts. All of these are so-called white metals whose aqueous cations (except La^{3+}) are labile. Electrodes using liquid-ion exchangers are supported in the voids of inert polymers such as cellulose acetate, or in transparent films of polyvinyl chloride, and provide extensive examples of devices for sensing. Electrodes with chemical reactions interposed between the sample and the sensor surface permit a new degree of freedom in design of sensors for species which do not directly respond at an electrode surface. Two primary examples are the categories of gas sensors and of electrodes which use enzyme-catalyzed reactions. *See* ELECTRODE; ION EXCHANGE.

Electrodes for many species are, for the most part, commercially available. Applications may be batch or continuous. Important batch examples are potentiometric titrations with ion-selective electrode end-point detection, determination of stability constants of complexes and speciation identity, solubility and activity coefficient determinations, and monitoring of reaction kinetics, especially for oscillating reactions. Ion, selective electrodes serve as liquid chromatography detectors and as quality-control monitors in drug manufacture. Applications occur in air and water quality (soil, clay, ore, natural-water, water-treatment, sea-water, and pesticide analyses); medical and clinical laboratories (serum, urine, sweat, gastric-juices, extra-cellular-fluid, dental-enamel, and milk analyses); and industrial laboratories (heavy-chemical, metallurgical, glass, beverage, and household-product analyses). *See* ANALYTICAL CHEMISTRY; CHROMATOGRAPHY; TITRATION. [R.P.B.]

Ion-solid interactions Physical processes resulting from the collision of energetic ions, atoms, or molecules with condensed matter. These include elastic and inelastic backscattering of the projectile, penetration of the solid by the projectile, emission of electrons and photons from the surface, sputtering of neutral atoms and ions, production of defects in crystals, creation of nuclear tracks in insulating solids, and electrical, chemical, and physical changes to the irradiated matter resulting from the passage or implantation of the projectile.

When an energetic ion impinges upon the surface of condensed matter, it experiences a series of elastic and inelastic collisions with the atoms which lie in its path. These collisions occur because of the electrical forces between the nucleus and electrons of the projectile and those of the atoms which constitute the solid target. They result in the transformation of the kinetic energy of the projectile into internal excitation of the solid.

One of the most simple interactions occurs when the projectile collides with a surface atom and bounces back in generally the opposite direction from which it came. This process is known as backscattering. Its observation in 1911 led Ernest Rutherford to conclude that most of the matter in atoms is concentrated in a small nucleus. Now it is used as an analytical technique to measure the masses and locations of atoms on and near a surface. This technique for surface characterization is appropriately named Rutherford backscattering analysis, and is most commonly performed with alpha particles of about 2 MeV. Another backscattering technique, known as ion-scattering spectrometry, uses projectiles with energies of perhaps 2 keV.

Although backscattering events are well enough understood to be used as analytical tools, they are relatively rare because they represent nearly head-on collisions between two nuclei. Far more commonly, a collision simply deflects the projectile a few degrees from its original direction and slows it somewhat, transferring some of its kinetic energy to the atom that is struck. Thus, the projectile does not rebound from the surface but penetrates deep within the solid, dissipating its kinetic energy in a series of grazing collisions.

The capacity of a solid to slow a projectile is called the stopping power, and is defined as the amount of energy lost by the projectile per unit length of trajectory in the solid. Stopping power is of central importance for many phenomena because it measures the capacity of a projectile to deposit energy within a thin layer of the solid and this energy drives secondary processes associated with penetration. In many insulating solids (including mica, glasses, and some plastics) the passage of an ion with a large electronic stopping power creates a unique form of radiation damage known as a nuclear track. When the substance is chemically etched, conical pits visible under an ordinary microscope are produced where ionizing particles have penetrated. The passage of single projectiles may thereby be observed. *See* PARTICLE TRACK ETCHING.

In the nuclear stopping region it is relatively likely that the projectile will transfer significant amounts of energy to individual target atoms. These atoms will subsequently strike others, and eventually a large number of atoms within the solid will be set in motion. This disturbance is known as a collision cascade. Collision cascades may cause permanent damage to materials, induce mixing of layers in the vicinity of interfaces, or cause sputtering if they occur near surfaces. *See* ION BEAM MIXING; SPUTTERING.

Ion implantation is used in the manufacture of integrated circuits and in the improvement of surface properties of metals. Ion-solid processes permit highly sensitive analyses for trace elements, the characterization of materials and surfaces, and the detection of ionizing radiation. Techniques employing them include secondary ion mass spectrometry (SIMS) for elemental analysis and imaging of surfaces, proton-induced x-ray emission (PIXE), ion-scattering spectrometry (ISS), and Rutherford backscattering analysis (RBS). They are also fundamental to the operation of silicon surface-barrier detectors which are used for the measurement of particle radiation, and of nuclear track detectors which are used in research as diverse as the dating of meteorites and the search for magnetic monopoles. *See* ACTIVATION ANALYSIS; BEAM-FOIL SPECTROSCOPY; ION IMPLANTATION; MAGNETIC MONOPOLES; PARTICLE DETECTOR; PROTON-INDUCED X-RAY EMISSION (PIXE); SECONDARY ION MASS SPECTROMETRY (SIMS); SURFACE PHYSICS. [R.A.We.]

Ion sources Devices which produce positive or negative electrically charged atoms or molecules. *See* ION.

In general, ion sources fall into three major categories: those designed for positive-ion generation, those for negative-ion generation, and a highly specialized type of source designed to produce a polarized ion beam. The positive-ion source category may further be subdivided into sources specifically designed to generate singly charged ions and those designed to produce very highly charged ions.

Ion sources have acquired a wide variety of applications. They are used in a variety of different types of accelerators for nuclear research; have application in the field of fusion research; and are used for ion implantation, in isotope separators, in ion microprobes, as a means of rocket propulsion, in mass spectrometers, and for ion milling. *See* ION IMPLANTATION; ION PROPULSION; MASS SPECTROSCOPE; NUCLEAR FUSION; PARTICLE ACCELERATOR; SECONDARY ION MASS SPECTROMETRY (SIMS). [R.M.]

Ion transport Movement of salts and other electrolytes in the form of ions from place to place within living systems.

Ion transport may occur by any of several different mechanisms: electrochemical diffusion, active-transport requiring energy, or bulk flow as in the flow of blood in the circulatory system of animals or the transpiration stream in the xylem tissue of plants. The best-known system for transporting ions actively is the sodium/potassium (Na/K) exchange pump, which occurs in plasma membranes of virtually all cells.

Experimental studies revealed that many transport processes, such as in bacterial cells and in the mitochondria of eukaryotic cells, are associated with a transport of protons (hydrogen ions, H^+). This fact led to the concept of proton pumps, in which the coupling or transfer of energy between oxidation processes and synthesis of ATP and between hydrolysis of ATP and transport or other cellular work is explained in terms of a flow of protons as the means of energy transfer.

The processes of oxidation in the citric acid cycle of reactions in mitochondria are known to be coupled with the synthesis of adenosine triphosphate (ATP), which is formed from adenosine diphosphate (ADP) and inorganic orthophosphate (P_i), through the system of enzymes and cytochromes known as the electron transfer chain or electron transport system. This system transports electrons, removed in dehydrogenation from the organic molecules of the citric acid cycle on one side of the mitochondrial membrane, to the site of their incorporation into water, formed from two hydrogen ions and an atom of oxygen on the other side of the membrane. The flow of electrons from a relatively high potential level in the organic substrate to a level of lower potential in water constitutes, in effect, a current of negative electricity, and it was proposed that the flow drives a flow of protons in the opposite direction, as a current of positive electricity. This proton flow in turn is proposed as the force that drives the synthesis of three molecules of ATP for every two electrons flowing through the electron transport system. In effect, this is the machinery of the cellular power plant.

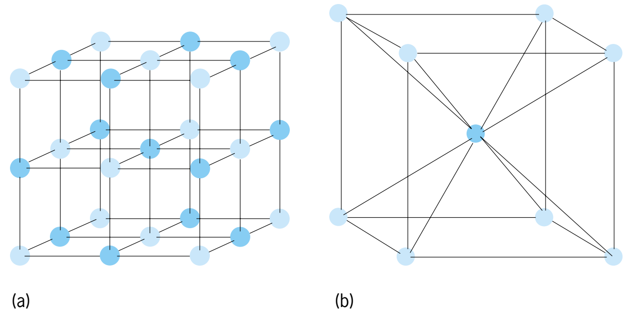
The Na/K ATPase pump then provides an example of a way in which a proton pump may transfer energy between the hydrolysis of ATP and a process of cellular work. The enzyme which is the basis of the pump is known to be bound to the lipid bilayer of the plasma membrane through phosphatides and to function only when so bound. The binding of Na^+, K^+, H^+, and ATP to active sites on the enzyme presumably has an allosteric effect, changing the shape of the enzyme molecule, activating the hydrolysis of ATP, and opening pathways of exchange of Na^+ and K^+. [B.T.S.]

Transport processes are involved in uptake and release of inorganic ions by plants and in distribution of ions within plants, and thus determine ionic relations of plants. The cell wall and the external lipid-protein membrane (plasmalemma) have to be passed by the ions. Intracellular distribution and compartmentation are determined by transport across other membranes within the cells. The most important one is the tonoplast separating the cell vacuole from the cytoplasm.

Within tissues the continuous cell walls of adjacent cells form an apoplastic pathway for ion transport. A symplastic pathway is constituted by the cytoplasm extending from cell to cell via small channels of about 40 nanometers diameter (plasmodesmata) crossing the cell walls. Transport over longer distances is important in organs (roots, shoots, leaves, fruits), which are composed of different kinds of tissues, and in the whole plant. Xylem and phloem serve as pathways for long-distance transport. Roots take up ions from the soil and must supply other plant organs. The nutritional status of roots and shoots regarding both inorganic anions and organic substrates plays a large role in regulation of ionic relations of whole plants. Phytohormones affect transport mechanisms; they are produced in particular tissues, are distributed via the transport pathways, and thus exert a signaling function. *See* PHLOEM; PLANT HORMONES; PLANT TISSUE SYSTEMS; XYLEM.

The pipe system of the xylem in its mature transporting state is composed of rows of dead cells (tracheids, tracheary elements) whose cross-walls are perforated or removed entirely. The driving force for long-distance transport in the xylem is very largely passive. Transport is caused by transpiration, the loss of water from the aerial parts of the plant, driven by the water potential gradient directed from soil to roots, leaves, and atmosphere. A normally much smaller component driving the ascent of sap in the xylem is osmotic root pressure due to the pumping mechanisms concentrating ions in the root xylem, with water following passively. In a simplifying way the xylem can be considered as pathway for long-distance transport of ions from root to shoot, and the phloem for metabolite transport from photosynthesizing source leaves to various sinks in the plant. The long-distance transport pathways of the phloem are the sieve tubes, pipe systems with porous structures in the cross-walls (sieve plates) but, in contrast to vessels of the xylem, having living cytoplasm. Concentration and pressure gradients built up by active loading and unloading of sieve tubes in the source and sink regions, respectively, are the driving forces for transport. *See* PLANTS, SALINE ENVIRONMENTS OF. [U.L.]

Ionic crystals A class of crystals in which the lattice-site occupants are charged ions held together primarily by their electrostatic interaction. Such binding is called ionic binding. Empirically, ionic crystals are distinguished by strong absorption of infrared radiation, good ionic conductivity at high temperatures,



Lattices of (*a*) sodium chloride and (*b*) cesium chloride. The darker circles represent positive ions and the lighter circles negative ions. (*After F. Seitz, The Modern Theory of Solids, Dover, 1987*)

and the existence of planes along which the crystals cleave easily. *See* Crystal structure.

Compounds of strongly electropositive and strongly electronegative elements form solids which are ionic crystals, for example, the alkali halides, other monovalent metal halides, and the alkaline-earth halides, oxides, and sulfides. Crystals in which some of the ions are complex, such as metal carbonates, metal nitrates, and ammonium salts, may also be classed as ionic crystals.

As a crystal type, ionic crystals are to be distinguished from other types such as molecular crystals, valence crystals, or metals. The ideal ionic crystal as defined is approached most closely by the alkali halides (see illustration). Other crystals often classed as ionic have binding which is not exclusively ionic but includes a certain admixture of covalent binding. Thus the term ionic crystal refers to an idealization to which real crystals correspond to a greater or lesser degree, and crystals exist having characteristics of more than one crystal type. *See* Chemical bonding.

Ionic crystals, especially alkali halides, have played a very prominent role in the development of solid-state physics. They are relatively easy to produce as large, quite pure, single crystals suitable for accurate and reproducible experimental investigations. In addition, they are relatively easy to subject to theoretical treatment since they have simple structures and are bound by the well-understood Coulomb force between the ions. This is in contrast to metals and covalent crystals, which are bound by more complicated forces, and to molecular crystals, which either have complicated structures or are difficult to produce as single crystals. Being readily available and among the simplest known solids, they have thus been a frequent and profitable meeting place between theory and experiment. These same features of ionic crystals have made them attractive as host crystals for the study of crystal defects: deliberately introduced impurities, vacancies, interstitials, and color centers. *See* Color centers; Crystal defects. [B.G.D.]

Most ionic crystals have large band gaps, and are therefore generally good electronic insulators. However, electrical conduction occurs by the motion of ions through these crystals. The presence of point defects, that is, deviations from ideal order in the crystalline lattice, facilitates this motion, thus giving rise to transport of electric charge. In an otherwise perfect lattice where all lattice sites are fully occupied, ions cannot be mobile.

Many so-called normal ionic crystals possess conductivities of about 10^{-10} (ohm · cm)$^{-1}$ or lower at room temperature. However, a relatively small number of ionic materials, called superionic conductors or fast ionic conductors, display conductivities of the order of 10^{-1} to 10^{-2} (ohm · cm)$^{-1}$, which imply ionic liquidlike behavior. In most of these crystals, only one kind of ionic species is mobile, and its diffusion coefficient and mobility attain values such as found otherwise only in liquids. Due to their high value of ionic conductivity as well as their ability to selectively transport ionic species, superionic conductors have successfully been employed as solid electrolytes in many applications. *See* Diffusion; Solid-state battery. [T.M.Gü.]

Ionic equilibrium

An equilibrium in a chemical reaction in which at least one ionic species is produced, consumed, or changed from one medium to another.

The wide variety of types of ionic equilibrium possible include: dissolution of an un-ionized substance, for example, the dissolution of hydrogen chloride (a gas) in water (an ionizing solvent), reactions (1)–(3); dissolution of a crystal in water, such as the

$$\mathrm{HCl}(g) \rightleftharpoons \mathrm{H}^+ + \mathrm{Cl}^- \qquad (1)$$

$$\mathrm{HCl}(g) + \mathrm{H_2O} \rightleftharpoons \mathrm{H_3O}^+ + \mathrm{Cl}^- \qquad (2)$$

$$\mathrm{HCl}(g) + 4\mathrm{H_2O} \rightleftharpoons \mathrm{H_9O_4}^+ + \mathrm{Cl}^- \qquad (3)$$

dissociation of solid silver chloride, reaction (4); dissociation of a strong acid, for example, nitric acid, HNO_3, dissociates as it dissolves in water, as in reaction (5); dissociation of an ion in water, for example, the bisulfate ion, $HSO_4{}^-$, dissociates in water, as in reaction (6); and dissociation of water itself, is represented by reaction (7).

$$\mathrm{AgCl(crystal)} \rightleftharpoons \mathrm{Ag}^+ + \mathrm{Cl}^- \qquad (4)$$

$$\mathrm{HNO_3} + \mathrm{H_2O}^+ \rightleftharpoons \mathrm{H_3O}^+ + \mathrm{NO_3}^- \qquad (5)$$

$$\mathrm{HSO_4}^- + \mathrm{H_2O} \rightleftharpoons \mathrm{H_3O}^- + \mathrm{SO_4}^{2+} \qquad (6)$$

$$2\mathrm{H_2O} \rightleftharpoons \mathrm{H_3O}^+ + \mathrm{OH}^- \qquad (7)$$

See Acid and base; Chemical equilibrium; Hydrolysis. [T.F.Y.]

Ionization

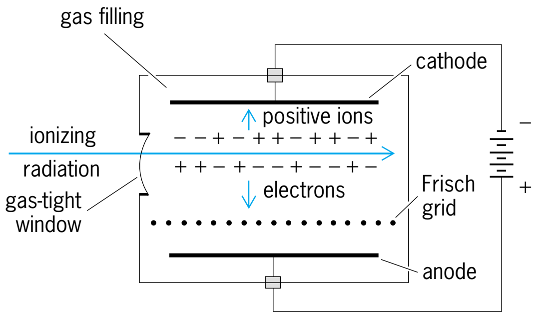
The process by which an electron is removed from an atom, molecule, or ion. It is of basic importance to electrical conduction in gases and liquids. In the simplest case, ionization may be thought of as a transition between an initial state consisting of a neutral atom and a final state consisting of a positive ion and a free electron. In more complicated cases, a molecule may be converted to a heavy positive ion and a heavy negative ion which are separated. [G.H.M.]

Ionization chamber

An instrument for detecting ionizing radiation by measuring the amount of charge liberated by the interaction of ionizing radiation with suitable gases, liquids, or solids.

While the gold leaf electroscope is the oldest form of ionization chamber, instruments of this type are still widely used as monitors of radiations by workers in the nuclear or radiomedical professions. However, for many purposes it is useful to measure the ionization pulse produced by a single ionizing particle. *See* Electroscope.

The simplest form of a pulse ionization chamber consists of two conducting electrodes in a container filled with gas (see illustration). A battery, or other power supply, maintains an electric field between the positive anode and the negative cathode. When



Parallel-plate ionization chamber.

ionizing radiation penetrates the gas in the chamber—entering, for example, through a thin gas-tight window—this radiation liberates electrons from the gas atoms leaving positively charged ions. The electric field present in the gas sweeps these electrons and ions out of the gas, the electrons going to the anode and the positive ions to the cathode.

In a chamber, such as that represented in the illustration, the current begins to flow as soon as the electrons and ions begin to separate under the influence of the applied electric field. The time it takes for the full current pulse to be observed depends on the drift velocity of the electrons and ions in the gas. Because the ions are thousands of times more massive than the electrons, the electrons always travel several orders of magnitude faster than the ions. As a result, virtually all pulse ionization chambers make use of only the relatively fast electron signal.

One of the most important uses of an ionization chamber is to measure the total energy of a particle or, if the particle does not stop in the ionization chamber, the energy lost by the particle in the chamber. In addition to energy information, ionization chambers are now routinely built to give information about the position within the gas volume where the initial ionization event occurred. This information can be important not only in experiments in nuclear and high-energy physics where these position-sensitive detectors were first developed, but also in medical and industrial applications.

Foremost among the other applications is the use of gas ionization chambers for radiation monitoring. Portable instruments of this type usually employ a detector containing approximately 60 in.^{3} (1 liter) of gas, and operate by integrating the current produced by the ambient radiation. Another application of ionization chambers is the use of air-filled chambers as domestic fire alarms. Yet another development in ion chamber usage is that of two-dimensional imaging in x-ray medical applications to replace the use of photographic plates.

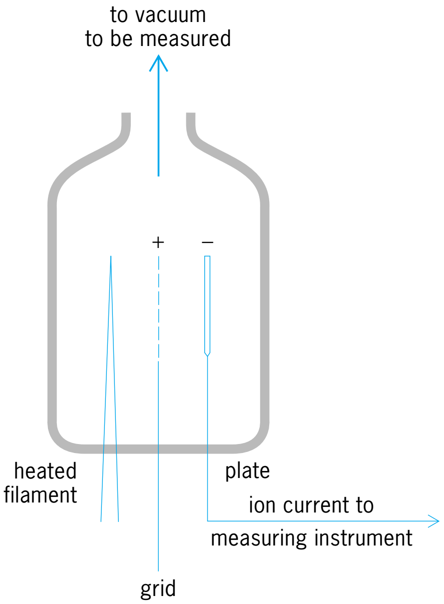
Gaseous ionization chambers have also found application as total-energy monitors for high-energy accelerators. Such applications involve the use of a very large number of interleaved thin parallel metal plates immersed in a gas inside a large container.

Ionization chambers can be made where the initial ionization occurs, not in gases, but in suitable liquids or solids. In the solid-state ionization chamber (or solid-state detector) the gas filling is replaced by a large single crystal of suitably chosen solid material. In this case the incident radiation creates electron-hole pairs in the crystal, and this constitutes the signal charge. Silicon and germanium detectors have proved to be highly successful and have led to detectors that have revolutionized low-energy nuclear spectroscopy. The use of a liquid in an ionization chamber combines many of the advantages of both solid and gas-filled ionization chambers; most importantly, such devices have the flexibility in design of gas chambers with the high density of solid chambers. During the 1970s a number of groups built liquid argon ionization chambers and demonstrated their feasibility. [W.A.L.]

Ionization gage An instrument for measuring vacuum by ionizing the gas present and measuring the ion current. There are two types of ionization gages.

In the hot-filament ionization gage (see illustration), electrons emitted by a filament are attracted toward a positively charged grid electrode. Collisions of electrons with gas molecules produce ions, which are then attracted to a negatively charged electrode. The current measured at this electrode is directly proportional to the pressure or gas density.

In the cold-cathode (Philips or Penning) ionization gage, a high voltage is applied between two electrodes. Fewer electrons are emitted, but a strong magnetic field deflects the electron stream, increasing the length of the electron path which increases the chance for ionizing collisions of electrons with gas molecules. *See* VACUUM MEASUREMENT. [R.C.]



Hot-filament ionization gage.

Ionization potential The potential difference through which a bound electron must be raised to free it from the atom or molecule to which it is attached. In particular, the ionization potential is the difference in potential between the initial state, in which the electron is bound, and the final state, in which it is at rest at infinity.

The ionization potential for the removal of an electron from a neutral atom other than hydrogen is more correctly designated as the first ionization potential. The potential associated with the removal of a second electron from a singly ionized atom or molecule is then the second ionization potential, and so on. [G.H.M.]

Ionophore A substance that can transfer ions from a hydrophilic medium, such as water, into a hydrophobic medium, such as hexane or a biological membrane, where the ions typically would not be soluble; also known as an ion carrier. The ions transferred are usually metal ions, for example, lithium (Li^+), sodium (Na^+), potassium (K^+), magnesium (Mg^{2+}), and calcium (Ca^{2+}); but there are ionophores that promote the transfer of other ions, such as ammonium ion ($NH_4{}^+$) or amines of biological interest. *See* ION.

There are two mechanisms by which ionophores promote the transfer of ions across hydrophobic barriers: ion-ionophore complex formation and ion channel formation. In complex formation, the ion forms a coordination complex with the ionophore in which there is a well-defined ratio (typically 1:1) of ion to ionophore. The ionophore wraps around the ion so that the ion exists in the polar interior of the complex, while the exterior is predominantly hydrophobic in character and as such is soluble in nonpolar media. The ion is coordinated by oxygen atoms present in the ionophore molecule through iondipole interactions. The ionophore molecule essentially acts as the solvent for the ion, replacing the aqueous solvation shell that normally surrounds the ion. *See* COORDINATION COMPLEXES.

Ionophores that act via ion channel formation are found in biological environments. The molecule forms a polar channel in an otherwise nonpolar cell membrane, allowing passage of small ions either into or out of the cell.

Naturally occurring ionophores fall into four classes, each of which has antibiotic activity: peptide, cyclic depsipeptide, macrotetrolide, and polyether ionophores. The biological activity of ionophore antibiotics is due to their ability to disrupt the flow of ions either into or out of cells. Under normal conditions, cells have a high internal concentration of potassium ions but a low concentration of sodium ions. The concentration of ions in the extracellular medium is just the reverse, high in sodium ions but low in potassium ions. This imbalance, which is necessary for normal cell function, is maintained by a specific transport protein (sodium-potassium adenosine triphosphatase) in the cell membrane that pumps sodium ions out of the cell in exchange for potassium ions. Ionophore antibiotics can disrupt this ionic imbalance by allowing ions to penetrate the cell membrane as ion-ionophore complexes or via the formation of ion channels. Gram-positive bacteria appear to be particularly sensitive to the effect of ionophores perturbing normal ion transport. *See* ANTIBIOTIC; ION TRANSPORT. [C.A.V.]

Ionosphere The part of the upper atmosphere that is sufficiently ionized that the concentration of free electrons affects the propagation of radio waves. Existence of the ionosphere was suggested simultaneously in 1902 by O. Heaviside in England and A. E. Kennelly in the United States to explain the transatlantic radio communication that was demonstrated the previous year by G. Marconi; and for many years it was commonly referred to as the Kennelly-Heaviside layer. The existence of the ionosphere as an electronically conducting region had been postulated earlier by B. Steward to explain the daily variations in the geomagnetic field. *See* ATMOSPHERE; IONIZATION; RADIO-WAVE PROPAGATION.

The ionosphere is highly structured in the vertical direction. It was first thought that discrete layers were involved, referred to as the D, E, F_1, and F_2 layers; however, the layers actually merge with one another to such an extent that they are now referred to as regions rather than layers. The very high temperatures in the Earth's upper atmosphere are colocated with the upper ionosphere, since both are related to the effect of x-rays from the Sun. That is, the x-rays both ionize and heat the very uppermost portion of the Earth's atmosphere. Tremendous variations occur in the ionosphere at high latitudes because of the dynamical effects of electrical forces and because of the additional sources of plasma production. The most notable is the visual aurora, one of the most spectacular natural sights.

The aurora has a poleward and equatorward limit during times of magnetic storms. A resident of the arctic regions of the Northern Hemisphere see the "northern" lights in their southern sky, for example. The aurora forms two rings around the poles of the Earth. The size of the rings waxes and wanes while wavelike disturbances propagate along its extent. *See* AURORA; UPPER-ATMOSPHERE DYNAMICS. [M.C.K.; F.S.J.]

Iridium A chemical element, Ir, atomic number 77, relative atomic weight 192.22. Iridium is a transition metal and shares similarities with rhodium as well as the other platinum metals, including palladium, platinum, ruthenium, and osmium. The atom in the gas phase has the electronic configuration $1s^2$, $2s^2$, $2p^6$, $3s^2$, $3p^6$, $3d^{10}$, $4s^2$, $4p^6$ $4d^{10}$, $4f^{14}$, $5s^2$, $5p^6$, $5d^7$, $6s^2$. The ionic radius for Ir^{3+} is 0.068 nanometer and its metallic radius is 0.1357 nm. Metallic iridium is slightly less dense than osmium, which is the densest of all the elements. *See* PERIODIC TABLE.

The abundance of iridium in the Earth's crust is very low, 0.001 ppm. For mining purposes, it is generally found alloyed with osmium in materials known as osmiridium and iridiosmium, with iridium contents ranging from 25 to 75%.

Solid iridium is a silvery metal with considerable resistance to chemical attack. Upon atmospheric exposure the surface of the metal is covered with a relatively thick layer of iridium dioxide (IrO_2). Important physical properties of metallic iridium are given in the table.

Physical properties of iridium metal

Property	Value
Crystal structure	Face-centered cubic
Lattice constant *a* at 25°C, nm	0.38394
Thermal neutron capture cross section, barns	440
Density at 25°C, g/cm^3	22.560
Melting point	2443°C (4429°F)
Boiling point	4500°C (8130°F)
Specific heat at 0°C, cal/g	0.0307
Thermal conductivity 0–100°C, cal cm/cm^2 s °C	0.35
Linear coefficient of thermal expansion	
20–100°C, μin./in./°C	6.8
Electrical resistivity at 0°C, microhm-cm	4.71
Temperature coefficient of electrical resistance	
0–100°C/°C	0.00427
Tensile strength (1000 lb/in.^{2})	
Soft	160–180
Hard	300–360
Young's modulus at 20°C	
lb/in.^{2}, static	75.0×10^6
lb/in.^{2}, dynamic	76.5×10^6
Hardness, diamond pyramid number	
Soft	200–240
Hard	600–700
ΔH_{fusion}, kJ/mol	26.4
$\Delta H_{\text{vaporization}}$, kJ/mol	612
ΔH_f monoatomic gas, kJ/mol	669
Electronegativity	2.2

Because of its scarcity and high cost, applications of iridium are severely limited. Although iridium metal and many of its complex compounds are good catalysts, no large-scale commercial application for these has been developed. In general, other platinum metals have superior catalytic properties. The high degree of thermal stability of elemental iridium and the stability it imparts to its alloys does give rise to those applications where it has found success. Particularly relevant are its high melting point (2443°C or 4429°F), its oxidation resistance, and the fact that it is the only metal with good mechanical properties that survives atmospheric exposure above 1600°C (2910°F). Iridium is alloyed with platinum to increase tensile strength, hardness, and corrosion resistance. However, the workability of these alloys is decreased. These alloys find use as electrodes for anodic oxidation, for containing and manipulating corrosive chemicals, for electrical contacts that are exposed to corrosive chemicals, and as primary standards for weight and length. Platinum-iridium alloys are used for electrodes in spark plugs that are unusually resistant to fouling by antiknock lead additives. Iridium-rhodium thermocouples are used for high-temperature applications, where they have unique stability. Very pure iridium crucibles are used for growing single crystals of gadolinium gallium garnet for computer memory devices and of yttrium aluminum garnet for solid-state lasers. The radioactive isotope, ^{192}Ir, which is obtained synthetically from ^{191}Ir by irradiation of natural sources, has been used as a portable gamma source for radiographic studies in industry and medicine. *See* HIGH-TEMPERATURE MATERIALS; PLATINUM. [A.L.Ba.]

Iron A chemical element, Fe, atomic number 26, and atomic weight 55.847. Iron is the fourth most abundant element in the crust of the Earth (5%). It is a malleable, tough, silver-gray, magnetic metal. It melts at 1540°C, boils at 2800°C, and has a density of 7.86 g/cm^3. The four stable, naturally occurring isotopes have masses of 54, 56, 57, and 58. The two main ores are hematite, Fe_2O_3, and limonite, $Fe_2O_3 \cdot 3H_2O$. Pyrites, FeS_2, and chromite, $Fe(CrO_2)_2$, are mined as ores for sulfur and chromium, respectively. Iron is found in many other minerals, and it occurs in groundwaters and in the red hemoglobin of blood. *See* PERIODIC TABLE.

The greatest use of iron is for structural steels; cast iron and wrought iron are made in quantity, also. Magnets, dyes (inks, blueprint paper, rouge pigments), and abrasives (rouge) are among the other uses of iron and iron compounds. *See* CAST IRON; IRON ALLOYS; IRON METALLURGY; STAINLESS STEEL; STEEL MANUFACTURE; WROUGHT IRON.

There are several allotropic forms of iron. Ferrite or α-iron is stable up to 760°C (1400°F). The change of β-iron involves primarily a loss of magnetic permeability because the lattice structure (body-centered cubic) is unchanged. The allotrope called γ-iron has the cubic close-packed arrangements of atoms and is stable from 910 to 1400°C (1670 to 2600°F). Little is known about δ-iron except that it is stable above 1400°C (2600°F) and has a lattice similar to that of α-iron.

The metal is a good reducing agent and, depending on conditions, can be oxidized to the 2+, 3+, or 6+ state. In most iron compounds, the ferrous ion, iron(II), or ferric ion, iron(III), is present as a distinct unit. Ferrous compounds are usually light yellow to dark green-brown in color; the hydrated ion, $Fe(H_2O)_6^{2+}$, which is found in many compounds and in solution, is light green. This ion has little tendency to form coordination complexes except with strong reagents such as cyanide ion, polyamines, and porphyrins. The ferric ion, because of its high charge (3+) and its small size, has a strong tendency to hold anions. The hydrated ion, $Fe(H_2O)_6^{3+}$, which is found in solution, combines with OH_-, F_-, Cl^-, CN^-, SCN^-, N_3^-, $C_2O_4^{2-}$, and other anions to form coordination complexes. *See* COORDINATION CHEMISTRY.

An interesting aspect of iron chemistry is the array of compounds with bonds to carbon. Cementite, Fe_3C, is a component of steel. The cyanide complexes of both ferrous and ferric iron are very stable and are not strongly magnetic in contradistinction to most iron coordination complexes. The cyanide complexes form colored salts. *See* TRANSITION ELEMENTS. [J.O.E.]

Iron alloys Solid solutions of metals, one metal being iron. A great number of commercial alloys have iron as an intentional constituent. Iron is the major constituent of wrought and cast iron and wrought and cast steel. Alloyed with large amounts of silicon, manganese, chromium, vanadium, molybdenum, niobium (columbium), selenium, titanium, phosphorus, or other elements, singly or sometimes in combination, iron forms the large group of materials known as ferroalloys that are important as addition agents in steelmaking. Iron is also a major constituent of many special-purpose alloys developed to have exceptional characteristics with respect to magnetic properties, electrical resistance, heat resistance, corrosion resistance, and thermal expansion. *See* ALLOY; FERROALLOY; STEEL. [H.E.McG.]

Iron metabolism A nearly continuous cycle whereby iron from organic and inorganic sources is converted to form iron-porphyrin compounds, which can be utilized by the body. One such compound, termed a heme, is hemoglobin; more than 60% of the iron in the body is used in hemoglobin metabolism. Iron is also essential for other heme compounds, such as myoglobin and cytochromes, and for a wide variety of nonheme enzymes, including many in the citric acid cycle.

Hemoglobin metabolism involves formation and breakdown. Formation is initiated by the process of absorption. Unlike most elements, iron has no specific mechanism for excretion so that absorption must be closely monitored to control body content and ensure replacement of the daily loss. Absorption occurs best from animal and plant hemes and less from inorganic ferric salts; different mechanisms are involved for the two types. Many factors influence absorption, especially gastric acid, which can solubilize iron salts and prevent their precipitation in the duodenum.

In the duodenum, iron rapidly enters the mucosal cells of the intestinal villi, where the iron is released from heme by the enzyme heme oxygenase. There, the ferrous iron destined for the formation of hemoglobin in the developing red cells of the marrow (the erythroblasts) is converted to ferric ions by ceruloplasmin and is attached to the transport glycoprotein transferrin. The nonassimilated iron remains in the intestinal cell and is combined with the storage protein apoferritin to form ferritin, which is lost by the body when the mucosal cells are shed after their 3–5-day life cycle. The mechanism by which the mucosal cell knows what to discard and what to assimilate is unknown.

Once ferric iron is attached to transferrin, it circulates in the blood until it attaches to transferrin receptors on immature red blood cells in the marrow. Once attached, the transferrin receptor complex is taken in by endocytosis, and the iron is released and reduced to ferrous ions. The transferrin receptor complex returns to the cell surface, and the transferrin reenters the blood plasma. The iron enters the mitochondria and is inserted into protoporphyrin by the enzyme ferrochetalase to form heme, which when combined with the protein globin forms the respiratory pigment hemoglobin.

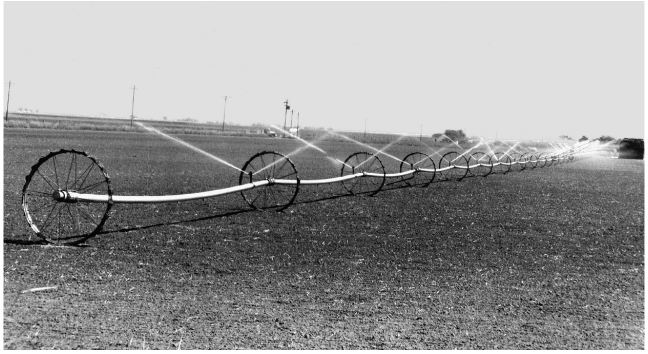
Mature red blood cells cannot take up iron; at the end of their 120-day life span they are engulfed by the monocyte-macrophage cells in liver and spleen, where the iron is released by the enzyme heme oxygenase. Sixty percent of this iron is rapidly returned to the marrow to produce red blood cells, while the remainder is stored as ferritin in the labile pool for release as needed. Iron excessively absorbed from the gut or released from the labile pool and not destined for the formation of red blood cells may enter the storage compartment as ferritin or hemosiderin. Apoferritin, the iron-free storage protein, exists in most living cells, and ferric ions can be stored in its hollow sphere to form a growing crystal of ferric oxyhydroxide (FeOOH). Hemosiderin occurs in the monocyte macrophages of the liver and spleen as FeOOH stripped of its apoferritin shell. *See* BLOOD; HEMOGLOBIN. [J.Mu.]

Iron metallurgy Extracting iron from ores and preparing it for use. Extraction involves the conversion of naturally occurring iron-bearing minerals into metallic iron. The term ironmaking is commonly used to include all of the industrial processes that convert raw materials into iron. The major process for the production of iron is the iron blast furnace. However, since 1970 the growth of alternative direct-reduction processes has been very significant. The principal difference between the blast furnace process and the direct-reduction processes is the temperature of operation. In the blast furnace, high operating temperatures enable the production of molten iron. At the lower operating temperatures of the direct-reduction processes, solid or sponge iron is produced. Most of the iron produced in the world is used in the production of steel. The remainder is converted to iron castings, ferroalloys, and iron powder. *See* FERROALLOY; IRON; PRESSURIZED BLAST FURNACE; PYROMETALLURGY; STEEL MANUFACTURE. [G.R.St.P.]

Ironwood The name given to any of at least 10 kinds of tree in the United States, including the American hornbeam (*Carpinus caroliniana*), eastern hophombeam (*Ostrya virginiana*), buckthorn bumelia (*Bumelia lycioides*), tough bumelia (*B. tenax*), buckwheat tree (*Cliftonia monophylla*), and swamp cyrilla or swamp ironwood (*Cyrilla racemiflora*). Leadwood (*Krugiodendron ferreum*), a native of southern Florida, has the highest specific gravity of all woods native to the United States and is also known as black ironwood. *See* HOPHORNBEAM; HORNBEAM. [A.H.G./K.P.D.]

Irregularia The name given by G. Cuvier in 1817 to an assemblage of echinoids in which the anus and periproct lie outside the apical system, the ambulacral plates remain simple, the primary radioles are hollow, and the rigid test shows more or less bilateral symmetry. The Irregularia are an artificial assemblage of similar but unrelated forms, and the name has no taxonomic validity. *See* DIADEMATACEA; ECHINOIDEA; PYGASTEROIDA; REGULARIA. [H.B.F.]

Irrigation (agriculture) The artificial application of water to the soil to produce plant growth. Irrigation also cools



A side-roll sprinkler system which uses the main supply line (often more than 1000 ft, or 300 m, long) to carry the sprinkler heads and as the axle for wheels.

the soil and atmosphere, making the environment favorable for plant growth. Water is applied to crops by surface, subsurface, sprinkler, and drip irrigation.

Surface irrigation includes furrow and flood methods. The furrow method is used for row crops. Corrugations or rills are small furrows used on close-growing crops. The flow, carried in furrows, percolates into the soil. Flow to the furrow is usually supplied by siphon tubes, spiles, gated pipe, or valves from buried pipe. In the flood method, controlled flooding is done with border strips, contour or bench borders, and basins.

Subirrigation is a type of irrigation accomplished by raising the water table to the root zone of the crop or by carrying moisture to the root zone by perforated underground pipe. Either method requires special soil conditions for successful operation.

A sprinkler system consists of pipelines which carry water under pressure from a pump or elevated source to lateral lines along which sprinkler heads are spaced at appropriate intervals. Laterals are moved from one location to another by hand or tractor, or they are moved automatically. The side-roll wheel system, which utilizes the lateral as an axle (see illustration), is very popular as a labor-saving method.

Drip irrigation is a method of providing water to plants almost continuously through small-diameter tubes and emitters. It has the advantage of maintaining high moisture levels at relatively low capital costs. It can be used on very steep, sandy, and rocky areas and can utilize saline waters better than most other systems. The system has been most popular in orchards and vineyards, but is also used for vegetables, ornamentals, and for landscape plantings. *See* Land drainage (agriculture); Terracing (agriculture). [M.A.H.]

Isentropic flow Compressible flow in which entropy remains constant throughout the flowfield. A slight distinction is sometimes made, especially in Europe, as follows. If the entropy of a fluid element moving along a streamline in a flow remains constant, the flow is isentropic along a streamline. However, the value of the entropy may be different along different streamlines, thus allowing entropy changes normal to the streamlines. An example is the flowfield behind a curved shock wave; here, streamlines that pass through different locations along the curved shock wave experience different increases in entropy. Hence, downstream from this shock, the entropy can be constant along a given streamline but differs from one streamline to another. This type of flow, with entropy constant along streamlines, is sometimes defined as isentropic. Flow with entropy constant everywhere is then called homentropic. *See* Compressible flow; Entropy; Isentropic process.

Because of the second law of thermodynamics, an isentropic flow does not strictly exist. From the definition of entropy, an isentropic flow is both adiabatic and reversible. However, all real flows experience to some extent the irreversible phenomena of friction, thermal conduction, and diffusion. Any nonequilibrium, chemically reacting flow is also irreversible. However, there are a large number of gas dynamic problems with entropy increase negligibly slight, which for the purpose of analysis are assumed to be isentropic. Examples are flow through subsonic and supersonic nozzles, as in wind tunnels and rocket engines; and shock-free flow over a wing, fuselage, or other aerodynamic shape. For these flows, except for the thin boundary-layer region adjacent to the surface where friction and thermal conduction effects can be strong, the outer inviscid flow can be considered isentropic. If shock waves exist in the flow, the entropy increase across these shocks destroys the assumption of isentropic flow, although the flow along streamlines between shocks may be isentropic. *See* Adiabatic process; Boundary-layer flow; Nozzle; Shock wave; Subsonic flight; Thermodynamic principles; Thermodynamic processes. [J.D.A.]

Isentropic process In thermodynamics, a process involving change without any increase or decrease of entropy. Since the entropy always increases in a spontaneous process, one must consider reversible or quasistatic processes. During a reversible process the quantity of heat transferred is directly proportional to the system's entropy change. Systems which are thermally insulated from their surroundings undergo processes without any heat transfer; such processes are called adiabatic. Thus during an isentropic process there are no dissipative effects and the system neither absorbs nor gives off heat. For this reason the isentropic process is sometimes called the reversible adiabatic process. *See* Adiabatic process; Entropy; Thermodynamic processes. [P.E.Bl.]

Isentropic surfaces Surfaces along which the entropy and potential temperature of air are constant. Potential temperature, in meteorological usage, is defined by the relationship

$$\Theta = T\left(\frac{1000}{P}\right)^{(c_p-c_v)/c_p}$$

in which T is the air temperature, P is atmospheric pressure expressed in millibars, C_P is the heat capacity of air at constant pressure, and C_V is the heat capacity at constant volume. Since the potential temperature of an air parcel does not change if the processes acting on it are adiabatic (no exchange of heat between the parcel and its environment), a surface of constant potential temperature is also a surface of constant entropy. The slope of isentropic surfaces in the atmosphere is of the order of 1/100 to 1/1000. An advantage of representing meteorological conditions on isentropic surfaces is that there is usually little air motion through such surfaces, since thermodynamic processes in the atmosphere are approximately adiabatic. *See* Adiabatic process; Atmospheric general circulation. [F.S.]

Ising model A model which consists of a lattice of "spin" variables with two characteristic properties: (1) each of the spin variables independently takes on either the value $+1$ or the value -1; and (2) only pairs of nearest neighboring spins can interact. The study of this model in two dimensions forms the basis of the modern theory of phase transitions and, more generally, of cooperative phenomena.

A macroscopic piece of material consists of a large number of atoms, the number being of the order of Avogadro's number (approximately 6×10^{23}). Thermodynamic phenomena all depend on the participation of such a large number of atoms. Even though the fundamental interaction between atoms is short-ranged, the presence of this large number of atoms can, under suitable conditions, lead to an effective interaction between widely separated atoms. Phenomena due to such effective long-range interactions are referred to as cooperative phenomena. The simplest examples of cooperative phenomena are phase transitions. The most familiar phase transition is either the condensation of steam into water or the freezing of water into ice. Only slightly less familiar is the ferromagnetic phase transition that takes place at the Curie temperature, which, for example, is roughly 1043 K for iron. *See* CURIE TEMPERATURE; FERROMAGNETISM; PHASE TRANSITIONS. [B.M.McC.; T.T.W.]

Island biogeography The distribution of plants and animals on islands. Islands harbor the greatest number of endemic species. The relative isolation of many islands has allowed populations to evolve in the absence of competitors and predators, leading to the evolution of unique species that can differ dramatically from their mainland ancestors.

Plant species produce seeds, spores, and fruits that are carried by wind or water currents, or by the feet, feathers, and digestive tracts of birds and other animals. The dispersal of animal species is more improbable, but animals can also be carried long distances by wind and water currents, or rafted on vegetation and oceanic debris. Long-distance dispersal acts as a selective filter that determines the initial composition of an island community. Many species of continental origin may never reach islands unless humans accidentally or deliberately introduce them. Consequently, although islands harbor the greatest number of unique species, the density of species on islands (number of species per area) is typically lower than the density of species in mainland areas of comparable habitat. *See* POPULATION DISPERSAL.

Once a species reaches an island and establishes a viable population, it may undergo evolutionary change because of genetic drift, climatic differences between the mainland and the island, or the absence of predators and competitors from the mainland. Consequently, body size, coloration, and morphology of island species often evolve rapidly, producing forms unlike any related species elsewhere. Examples include the giant land tortoises of the Galápagos, and the Komodo dragon, a species of monitor lizard from Indonesia. *See* POLYMORPHISM (GENETICS); POPULATION GENETICS; SQUAMATA.

If enough morphological change occurs, the island population becomes reproductively isolated from its mainland ancestor, and it is recognized as a unique species. Because long-distance dispersal is relatively infrequent, repeated speciation may occur as populations of the same species successively colonize an island and differentiate. The most celebrated example is Darwin's finches, a group of related species that inhabit the Galápagos Islands and were derived from South American ancestors. The island species have evolved different body and bill sizes, and in some cases occupy unique ecological niches that are normally filled by mainland bird species. The morphology of these finches was first studied by Charles Darwin and constituted important evidence for his theory of natural selection. *See* ANIMAL EVOLUTION; SPECIATION.

Island biogeography theory has been extended to describe the persistence of single-species metapopulations. A metapopulation is a set of connected local populations in a fragmented landscape that does not include a persistent source pool region. Instead, the fragments themselves serve as stepping stones for local colonization and extinction. The most successful application of the metapopulation model has been to spotted owl populations of old-growth forest fragments in the northwestern United States. *See* BIOGEOGRAPHY; ECOLOGICAL COMMUNITIES; ECOSYSTEM. [N.J.Go.]

Isoantigen An immunologically active protein or polysaccharide present in some but not all individuals in a particular species. These substances initiate the formation of antibodies when introduced into other individuals of the species that genetically lack the isoantigen. Like all antigens, they are also active in stimulating antibody production in heterologous species. The ABO, MN, and Rh blood factors in humans constitute important examples. Consequently, elaborate precautions for typing are required in blood transfusion. *See* ANTIBODY; ANTIGEN; BLOOD GROUPS. [M.J.Po.]

Isobar (meteorology) A curve along which pressure is constant. Leading examples of its uses are in weather forecasting and meteorology. The most common weather maps are charts of weather conditions at the Earth's surface and mean sea level, and they contain isobars as principal information. Areas of bad or unsettled weather are readily defined by roughly circular isobars around low-pressure centers at mean sea level. Likewise, closed isobars around high-pressure centers define areas of generally fair weather. *See* AIR PRESSURE.

A principal use of isobars stems from the so-called geostrophic wind, which approximates the actual wind on a large scale. The direction of the geostrophic wind is parallel to the isobars, in the sense that if an observer stands facing away from the wind, higher pressures are to the person's right if in the Northern Hemisphere and to the left if in the Southern. Thus, in the Northern Hemisphere, flow is counterclockwise about low-pressure centers and clockwise about high-pressure centers, with the direction of the flow reversed in the Southern Hemisphere. *See* GEOSTROPHIC WIND; WEATHER MAP. [F.B.Sh.]

Isobar (nuclear physics) One of two or more atoms which have a common mass number *A* but which differ in atomic number *Z*. Thus, although isobars possess approximately equal masses, they differ in chemical properties; they are atoms of different elements. Isobars whose atomic numbers differ by unity cannot both be stable; one will inevitably decay into the other. *See* ELECTRON CAPTURE; RADIOACTIVITY. [H.E.D.]

Isobaric process A thermodynamic process during which the pressure remains constant. When heat is transferred to or from a gaseous system, a volume change occurs at constant pressure. This thermodynamic process can be illustrated by the expansion of a substance when it is heated. The system is then capable of doing an amount of work on its surroundings. The maximum work is done when the external pressure of the surroundings on the system is equal to the pressure of the system. *See* ISOMETRIC PROCESS; POLYTROPIC PROCESS; THERMODYNAMIC PROCESS. [P.E.Bl.]

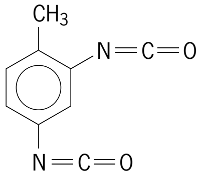
Isobryales An order of the true mosses (subclass Bryidae). This order is difficult to define precisely, but includes plants that generally grow from a creeping primary stem with leaves reduced or essentially lacking and plants that have spreading to ascending secondary stems which may be pinnately branched. The leaves may have single or double and sometimes short costae. The sporophytes are lateral, usually with elongate setae and capsules. The double peristome, sometimes reduced, consists of 16 teeth which are papillose on the outer surface, or less often cross-striate at the base, and an endostome with narrow segments and a low basal membrane or none at all. The calyptrae are cucullate and naked, or mitrate and hairy.

The order is heterogeneous in composition. It consists of about 19 families and 124 genera, some of which may be better placed in the Hypnales. *See* BRYIDAE; BRYOPHYTA; BRYOPSIDA; HYPNALES. [H.Cr.]

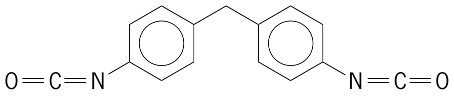
Isocyanate A derivative of isocyanic acid. Isocyanates are represented by the general formula $R{-}N{=}C{=}O$, where R is predominantly alkyl or aryl; however, stable isocyanates in which the $N{=}C{=}O$ group is linked to elements such as sulfur, silicon, phosphorus, nitrogen, or the halogens have also been prepared. Most members of this class of compounds are liquids that are sensitive to hydrolysis and are strong lacrimators. Isocyanates are extremely reactive, especially toward substrates containing active hydrogen. They have found wide use in the commercial manufacture of polyurethanes, which are used in making rigid and flexible foam, elastomers, coatings, and adhesives.

Diisocyanates react with difunctional reagents, such as diols, to form addition polymers with a wide variety of properties. The flexibility in the choice of starting materials (diisocyanate, diol, diamine, diacid, and so forth) and consequently in the multitude of possible adducts makes this product group unique in the field of polymeric materials.

Two aromatic diisocyantes, tolylene diisocyanate [TDI; reaction (**1**)] and di(4-isocyanatophenyl)methane [MDI; reaction (**2**)], have become the major starting materials for a family



(1)



(2)

of polymeric products, such as flexible and rigid polyurethane foams used in construction and appliance insulation, automotive seating, and furniture. Elastomers based on MDI, polyols, and polyamines are widely used in the automotive industry, where reaction injection molding technology is used for the manufacture of exterior parts such as body panels and bumpers. *See* POLYOL.

Thermoplastic polyurethane elastomers (TPU) are used in the molding and extrusion of many industrial and consumer products with superior abrasion resistance and toughness. *See* POLYURETHANE RESINS.

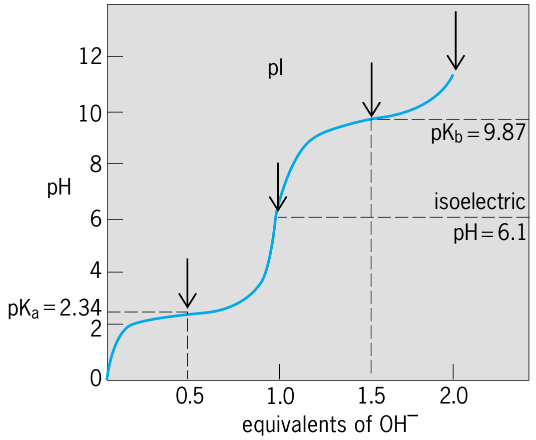
The trimerization to polyisocyanurates and the formation of polyamides from dicarboxylic acids have been used to synthesize polymers with excellent thermal properties. Aliphatic diisocyanates, notably 1,6-diisocyanatohexane (HDI), fully hydrogenated MDI (H_{12}MDI), and isophorone diisocyanate (IPDI) have become building blocks for color-stable polyurethane coatings and elastomers with high abrasion resistance. *See* POLYAMIDE RESINS; POLYMER. [R.H.Ri.]

Isoelectric point

The pH of a dispersion medium of a colloidal suspension or an ampholyte at which the solute does not move in an electrophoretic field. The term isoelectric point is abbreviated pI.

Ampholytes are molecules with acid as well as basic functional groups. When dissolved in a suitable medium, ampholytes may acquire positive and negative charges by dissociation or by accepting or losing protons, thereby becoming bipolar ions (zwitterions). Ampholytes may be as small as glycine and carry just one chargeable group each; or as large as polyampholytes (polyelectrolytes that carry positive charges, negative charges, or both). They may possess molecular weights in the hundreds of thousands like proteins or in the millions like nucleic acids, and carry many hundreds of chargeable groups. *See* ION; NUCLEIC ACID; PH; PROTEIN.

An example of establishing the isoelectric point is shown by the course of the pH changes during the titration of alanine [$NH_2CH(CH_3)COOH$], a 1:1 ampholyte, meaning a molecule that carries one positively and one negatively ionizable group. Starting from acid solution (see illustration), relatively small pH changes (with alkali as the titrant) are observed between pH 2 and 3 (acidic), and again between pH 9.5 and 10.5 (alkaline), caused by the buffering capacity of the carboxyl (—COOH) and amine (—NH_2) groups as weak electrolytes. The pH for $^1/_2$ equivalence corresponds to the pK of the acid function (a value related to the equilibrium constant), where one-half of the alanine molecules still carry only a positive charge ($-NH_3^+$), while the other half are also negatively charged ($-COO^-$). Thus alanine exists in the form of zwitterions. *See* PK.



Titration of alanine with sodium hydroxide (NaOH), showing the course of pH with added fractional equivalents. The four arrows show, from left to right, the pK_a [$^1/_2$ cations: $NH_3^+(CH_3)COOH$, and $^1/_2$ zwitterions: $NH_3^+(CH_3)CHCOO^-$]; the pI (all zwitterions); the pK_b ($^1/_2$ zwitterions, $^1/_2$ anions); and the end of titration, when all alanine molecules are in the anionic form: $NH_2(CH_3)CHOO^-$.

For molecules that carry four or more chargeable groups, that is, for polyelectrolytes, the courses of the overall titration curves may no longer reflect the individual dissociation steps clearly, as the dissociation areas usually overlap. The isoelectric point then becomes an isoelectric range, such as for pigskin (parent) gelatin, a protein that exhibits an electrically neutral isoelectric range from pH 7 to pH 9.

Since ampholytes in an electric field migrate according to their pI with a specific velocity to the cathode or anode, the blood proteins, for example, can be separated by the techniques of gel or capillary-zone electrophoresis. *See* ELECTROPHORESIS; TITRATION.

The notion that some ampholytes may pass with changing pH through a state of zero charge (zero zeta potential) on their way from the positively to the negatively charged state has become so useful for specifying and handling polyampholytes that it was extended to all kinds of colloids, and to solid surfaces that are chargeable in contact with aqueous solutions. Practically all metal oxides, hydroxides, or hydroxy-oxides become charged by the adsorption of hydrogen ions (H^+) or hydroxide ions (OH^-), while remaining neutral at a specific pH. Strictly speaking, the isoelectric point of electrophoretically moving entities is given by the pH at which the zeta potential at the shear plane of the moving particles becomes zero. The point of zero charge at the particle (solid or surface) is somewhat different but often is not distinguished from the isoelectric point. It is determined by solubility minima or, for solid surfaces, is found by the rate of slowest adsorption of colloids (for example, latexes) of well-defined charge.

The important separation technique of ion-exchange chromatography is based on the selective adsorption of ampholytes on the resins with which the column is filled, at a given pH. For example, the larger the net positive charge of an ampholyte, the more strongly will it be bound to a negative ion-exchange resin and the slower will it move through the column. By rinsing with solutions of gradually increasing pH, the ampholytes of a mixture can be eluted and made to emerge separately from the column and be collected. Automated amino acid analyzers are built on this principle. *See* AMINO ACIDS; COLLOID; ELECTROKINETIC PHENOMENA; ION EXCHANGE; ION-SELECTIVE MEMBRANES AND ELECTRODES. [F.R.E.]

Isoelectronic sequence

A term used in spectroscopy to designate the set of spectra produced by different chemical elements ionized in such a way that their atoms or ions contain the same number of electrons. The sequence in the table is an

Example of isoelectronic sequence

Designation of spectrum	Emitting atom or ion	Atomic number, Z
CaI	Ca	20
ScII	Sc^+	21
TiIII	Ti^{2+}	22
VIV	V^{3+}	23
CrV	Cr^{4+}	24
MnVI	Mn^{5+}	25

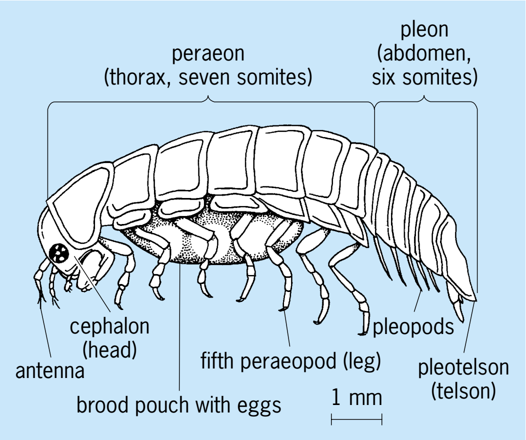
example. Since the neutral atoms of these elements each contain Z electrons, removal of one electron from scandium, two from titanium, and so forth, yields a series of ions all of which have 20 electrons. Isoelectronic sequences are useful in predicting unknown spectra of ions belonging to a sequence in which other spectra are known. *See* Atomic structure and spectra. [F.A.J./W.W.W.]

Isoetales An order in the class Lycopsida that diverged from the Lepidodendrales in the Late Devonian. These two groups have several characters that are not found in other lycopsids, notably a centralized, shootlike rooting structure (rhizomorph) that allows finite growth, wood production, and tree-sized dimensions. Isoetaleans evolved from trees as an increasingly specialized and reduced lineage; all but the earliest are small-bodied shrubs and pseudoherbs. A reduced morphology characterizes the only living isoetalean genus, *Isoetes*, which is globally distributed and contains approximately 150 species. *See* Lepidodendrales; Lycophyta; Lycopsida. [R.A.Ba.; W.A.DiM.]

Isolaimida An order of nematodes comprising the single superfamily Isolaimoidea. The order consists of one family and one genus. They are rather large for free-living soil nematodes (0.1–0.2 in. or 3–6 mm) and are found in seldom-cultivated sandy soils. Some forms have anterior annulations, while others have posterior transverse rows of punctations. The diagnostic characteristics of this superfamily are the presence of six hollow tubes around the oral opening and two whorls of six circumoral sensilla. Amphids are apparently absent, though some authors speculate that their function is taken over by the dorsolateral papillae of the second whorl. The triradiate stoma is elongate and has thickened walls anteriorly. The esophagus is clavate. Paired caudal papillae are large in males, small in females. *See* Nemata. [A.R.M.]

Isomerization Rearrangement of the atoms within hydrocarbon molecules. Isomerization processes of practical significance in petroleum chemistry are (1) migration of alkyl groups, (2) shift of a single-carbon bond in naphthenes, and (3) double-bond shift in olefins. *See* Alkylation; Aromatization; Cracking; Molecular isomerism. [G.E.L.]

Isometric process A constant-volume thermodynamic process in which the system is confined by mechanically rigid boundaries. No direct mechanical work can be done on the surroundings by a system with rigid boundaries; therefore the heat transferred into or out of the system equals the change of internal energy stored in the system. This change in the internal energy, in turn, is a function of the specific heat and the temperature change in the system. *See* Polytropic process. [P.E.Bl.]



***Limnoria*, female. (After R. J. Menzies, *The comparative biology of the wood-boring isopod crustacean Limnoria*, Museum of Comparative Zoology, Harvard Coll. Bull., 112(5):363–388, 1954)**

Isopoda An order of malacostracan crustaceans characterized by a cephalon, or head, bearing one pair of maxillipeds in addition to the antennae, mandibles, and maxillae (see illustration). A carapace is lacking. The peraeon, or thorax, consists of seven distinct somites each bearing a pair of peraeopods, the legs. The pleon, or abdomen, has six somites. The first five pairs of pleonal appendages are foliaceous. The last pair is modified into hardened appendages called uropods and the last somite is fused with the telson into a pleotelson.

The most familiar isopods are the terrestrial sow bugs or pill bugs. Many of the animals roll up into a compact ball when disturbed. Land isopods are usually found in moist environments, under decaying leaves and wood, and under rocks. The destructive marine wood-boring isopod *Limnoria*, the gribble, causes extensive damage to wharf piling in the United States, and one species is reported to attack treated timbers.

About 3000 species of isopods are known today, but it may be estimated that only one-half of the existing species have been described. *See* Crustacea. [R.J.Me.]

Isoptera An order of the Insecta, commonly called termites, with the general characteristics and stages of other exopterygote insects. Some authorities consider them a suborder of the Dictyoptera, or cockroaches, and they are certainly closely related to that group.

Approximately 2000 species of termites have been described and these are placed in six or seven families: Mastotermitidae, Hodotermitidae, Termopsidae (sometimes included in the Hodotermitidae), Kalotermitidae, Rhinotermitidae, Serritermitidae and the Termitidae. The latter family represents the higher termites and includes over 80% of all known termite species. *See* Exopterygota; Orthoptera.

The termite group is typically a tropical one, but certain genera do occur outside the tropics and may be found as far north in North America as British Columbia and Ontario. The group is distinguished by the fact that all species are eusocial and all feed on cellulose. The castes, apart from the imagos and primary reproductives, are drawn from the larval forms. In this respect they differ from the Hymenoptera where the castes are all variants of adults. Termites live in nests of varying degrees of complexity, ranging from large exigeous mounds to diffuse or temporary galleries in wood or soil. *See* Hymenoptera.

The mature termite (alate or imago) has membranous wings which extend beyond the end of the abdomen. There is a pair of compound eyes, and a pair of ocelli is present in most groups. The wings are superimposed flat on the abdomen when the insect is not in flight. Flight is weak and fluttering and is usually short. When the alate alights, the wings are shed along a basal suture with the base of each wing (the wing scale) being retained. The alates vary in color from yellow, through brown, to coal black.

In almost all termite species a second type of individual is produced in the colony. This is the soldier, which lacks wings, is nonreproductive, and is variously modified for defense. There are four rather distinct types of soldiers: mandibulate, phragmotic, nasutoid, and nasute.

In the more advanced termites there is a third caste, the worker. True workers usually have some pigmentation as opposed to the immature termites, which are generally white. Workers lack wings, are nonreproductive, and have mandibles which resemble those of the imagos; they are usually blind.

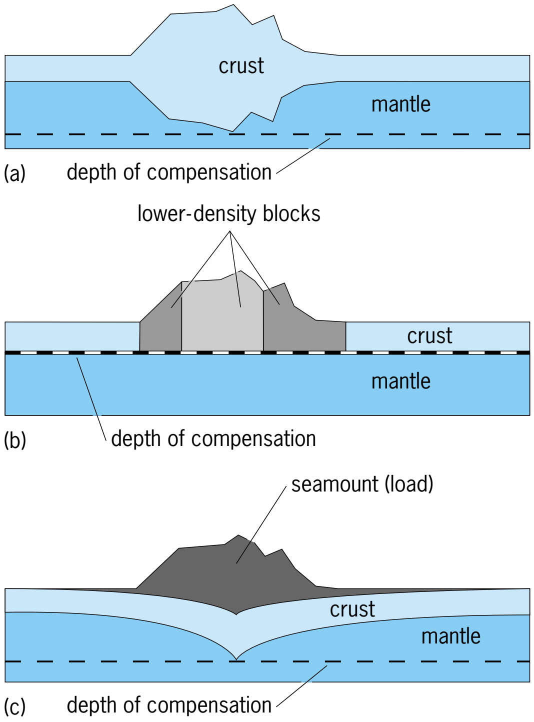
In addition to the definitive castes (alate, soldier, and worker) another type of individual may occur in the colony under certain circumstances. These individuals are the supplementary or replacement reproductives. Although the original pair (king and queen) may live for two or three decades, the life of the colony itself is not limited by their survival. If one or both are lost, other individuals in the colony become reproductive. If these new reproductives have wing buds, they are termed nymphoid (or brachypterous or second-form) reproductives. If they lack wing buds, they are termed ergatoid (or apterous or third-form) reproductives. *See* INSECTA; SOCIAL INSECTS. [A.M.S.]

Isopycnic The line of intersection of an atmospheric isopycnic surface with some other surface, for instance, a surface of constant elevation or pressure. An isopycnic surface is a surface in which the density of the air is constant. Since specific volume is the reciprocal of density, isosteric surfaces coincide with isopycnic surfaces. On a surface of constant pressure, isopycnics coincide with isotherms, because on such a surface, density is a function solely of temperature. On a constant-pressure surface, isopycnics lie close together when the field is strongly baroclinic and are absent when the field is barotropic. *See* BAROCLINIC FIELD; BAROTROPIC FIELD; SOLENOID (METEOROLOGY). [F.S.; H.B.B.]

Isostasy The application of Archimedes' principle to the layered structure of the Earth. The elevated topography of Earth is roughly equivalent to an iceberg that floats in the surrounding, denser water. Just as an iceberg extends beneath the exposed ice, the concept of isostasy proposes that topography is supported, or compensated, by a deep root. The buoyant outer shell of the Earth, the crust, displaces the denser, viscous mantle in proportion to the surface elevation. Isostasy implies the existence of a level surface of constant pressure within the mantle, the depth of compensation. Above this surface the mass of any vertical column is equal. Equal pressure at depth can also be achieved by varying density structure or by the regional deflection of the lithosphere. *See* ARCHIMEDES' PRINCIPLE; EARTH CRUST.

Local isostasy achieves equilibrium directly beneath a load by varying either the density or thickness of that mass column. This model attributes no inherent strength to the crust and assumes that the mantle is a simple fluid, redistributing mass to minimize pressure differences at depth. From studies of seamounts, oceanic trenches, foreland basins, and glacial rebound, it has become known that the outer shell of the Earth is rigid, responding to loads over a region broader than the load itself, and that the mantle is a viscous fluid with a time-dependent response to loads.

The simplest method of examining the response of the Earth is to study an area influenced by a discrete load such as a seamount or a continental glacier. If local isostasy (illus. *a*, *b*) is applicable, the region surrounding the load will be horizontal, unaffected by the load. In contrast, if the lithosphere has finite strength and regional or flexural isostasy (illus. *c*) is applicable, the surrounding regions will be deflected down toward the load. Gravity, bathymetry, and seismic studies of the crust surrounding Hawaii and other seamounts have demonstrated that the crust is downwarped beneath seamounts. The implication of this regional response is that the oceanic lithosphere has some strength and that the Earth's outer shell behaves elastically. *See* EARTH; EARTH, GRAVITY FIELD OF; GEODESY; LITHOSPHERE. [R.E.Bel.; B.J.C.]



Three major modes of isostatic compensation. (*a*) Airy isostasy, where the crustal density is constant beneath both the elevated topography and the level region; a large root extends beneath the elevated topography, and the depth of compensation is at the base of the crust where the pressure is constant. (*b*) Pratt isostasy, where the density of the crust varies inversely with the height of the topography; the depth of compensation is at the base of the horizontal crust-mantle boundary. (*c*) Flexural or regional isostasy, where the crust has some strength and is deflected beneath the elevated topography; the depth of compensation is a horizontal surface beneath the lowest extent of the crust.

Isotach A line along which the speed of the wind is constant. Isotachs are customarily represented on surfaces of constant elevation or atmospheric pressure, or in vertical cross sections. The closeness of spacing of the isotachs is indicative of the intensity of the wind shear on such surfaces. In the region of a jet stream the isotachs are approximately parallel to the streamlines of wind direction and are closely spaced on either side of the core of maximum speed. *See* JET STREAM; WIND. [F.S.; H.B.B.]

Isothermal chart A map showing the distribution of air temperature (or sometimes sea surface or soil temperature) over a portion of the Earth's surface, or at some level in the atmosphere. On it, isotherms are lines connecting places of equal temperature. The temperatures thus displayed may all refer to the same instant, may be averages for a day, month, season, or year, or may be the hottest or coldest temperatures reported during some interval.

Isothermal charts are drawn daily in major weather forecasting centers; 5-day, 2-week, and monthly charts are used regularly in long-range forecasting; mean monthly and mean annual charts are compiled and published by most national weather services, and are presented in standard books on, for example, climate, geography, and agriculture. *See* AIR TEMPERATURE; WEATHER MAP. [A.Cou.]

Isothermal process A thermodynamic process which occurs with a heat addition or removal rate just adequate to maintain constant temperature. The change in the internal energy per mole U accompanying a change in volume in an isothermal process is given by the equation below, where$T$ is the

$$U_2 - U_1 = \int_{V_1}^{V_2} \left[T \left(\frac{\partial P}{\partial T} \right)_V - P \right] dV$$

temperature, P is the pressure, and V is the volume per mole. The integral in the equation is zero for an ideal gas, and approximately zero for a condensed phase (solid or liquid) for which the volume changes vary little with pressure. Thus, in both these cases, $U_2 = U_1$. For real gases, the integral is nonzero, and the internal energy change is computed using the equation of state of the gas in the equation. *See* Chemical thermodynamics; Thermodynamic processes. [S.I.S.]

Isotone One of two or more atoms which display a constant difference $A - Z$ between their mass number A and their atomic number Z. Thus, despite differences in the total number of nuclear constituents, the numbers of neutrons in the nuclei of isotones are the same. The numbers of naturally occurring isotones provide useful evidence concerning the stability of particular neutron configurations. For example, the relatively large number (six and seven, respectively) of naturally occurring 50- and 82-neutron isotones suggests that these nuclear configurations are especially stable. On the other hand, from the fact that most atoms with odd numbers of neutrons are anisotonic, one may conclude that odd-neutron configurations are relatively unstable. *See* Nuclear structure. [H.E.D.]

Isotope One member of a (chemical-element) family of atomic species which has two or more nuclides with the same number of protons (Z) but a different number of neutrons (N). Because the atomic mass is determined by the sum of the number of protons and neutrons contained in the nucleus, isotopes differ in mass. Since they contain the same number of protons (and hence electrons), isotopes have the same chemical properties. However, the nuclear and atomic properties of isotopes can be different. The electronic energy levels of an atom depend upon the nuclear mass. Thus, corresponding atomic levels of isotopes are slightly shifted relative to each other. A nucleus can have a magnetic moment which can interact with the magnetic field generated by the electrons and lead to a splitting of the electronic levels. The number of resulting states of nearly the same energy depends upon the spin of the nucleus and the characteristics of the specific electronic level. *See* Atomic structure and spectra; Hyperfine structure; Isotope shift.

Of the 12 elements onfirmed thus far, 81 have at least one stable isotope whereas the others exist only in the form of radioactive nuclides. Some radioactive nuclides (for example, ^{115}In, ^{232}Th, ^{235}U, ^{238}U) have survived from the time of formation of the elements. Several thousand radioactive nuclides produced through natural or artificial means have been identified. *See* Radioisotope.

Of the 83 elements which occur naturally in significant quantities on Earth, 20 are found as a single isotope (mononuclidic), and the others as admixtures containing from 2 to 10 isotopes. Isotopic composition is mainly determined by mass spectroscopy. *See* Mass spectroscope.

Nuclides with identical mass number (that is, $A = N + Z$) but differing in the number of protons in the nucleus are called isobars. Nuclides having different mass number but the same number of neutrons are called isotones. *See* Isobar (nuclear physics); Isotone.

Isotopic abundance refers to the isotopic composition of an element found in its natural terrestrial state. The isotopic composition for most elements does not vary much from sample to sample. This is true even for samples of extraterrestrial origin such as meteorites and lunar materials brought back to Earth by space missions. However, there are a few exceptional cases for which variations of up to several percent have been observed. There are several phenomena that can account for such variations, the most likely being some type of nuclear process which changes the abundance of one isotope relative to the others. For some of the lighter elements, the processes of distillation or chemical exchange between different chemical compounds could be responsible for isotopic differences. *See* Nuclear reaction; Radioactivity.

The areas in which separated (or enriched) isotopes are utilized have become fairly extensive, and a partial list includes nuclear research, nuclear power generation, nuclear weapons, nuclear medicine, and agricultural research. For many applications there is a need for separated radioactive isotopes. These are usually obtained through chemical separations of the desired element following production by means of a suitable nuclear reaction. Separated radioactive isotopes are used for a number of diagnostic studies in nuclear medicine, including the technique of positron tomography. *See* Isotope separation; Nuclear medicine.

Studies of metabolism, drug utilization, and other reactions in living organisms can be done with stable isotopes such as ^{13}C, ^{15}N, ^{18}O, and ^{2}H. Molecular compounds are "spiked" with these isotopes, and the metabolized products are analyzed by using a mass spectrometer to measure the altered isotopic ratios. *See* Isotope dilution techniques; Radioisotope (biology). [D.J.Ho.]

Isotope dilution techniques Analytical techniques that involve the addition to a sample of an isotopically labeled compound. Soon after the discovery of the stable heavy isotopes of hydrogen, carbon, nitrogen, and oxygen, their value in analytical chemistry was recognized. Stable isotopes were particularly useful in the analysis of complex mixtures of organic compounds where the isolation of the desired compound with satisfactory purity was difficult and effected only with low or uncertain yields. The addition of a known concentration of an isotopically labeled compound to a sample immediately produces isotope dilution if the particular compound is present in the sample. After thorough mixing of the isotopically labeled compound with the sample, any technique that determines the extent of the isotopic dilution suffices to establish the original concentration of the compound in the mixture. Isotope dilution techniques exploit the difficulty in the separation of isotopes, with the isotopically labeled "spike" following the analytically targeted compound through a variety of separation procedures prior to isotopic analysis. *See* Isotope.

The technique depends on the availability of a stable or radioisotope diluent with isotope abundance ratios differing markedly from those of the naturally occurring elements. With monoisotopic elements, such as sodium or cesium, radioactive elements of sufficiently long life can be used in isotope dilution techniques.

The original applications of isotope dilution were by biochemists interested in complex mixtures of organic compounds. In these studies care had to be taken to ensure the stability of the labeled compound and its resistance to isotopic exchange reactions. Nitrogen-15–labeled glycine for example, could be used to determine glycine in a mixture of amino acids obtained from a protein. Deuterium-labeled glycine could not be used reliably if the deuterium isotopes were attached to the glycine amino or carboxyl group, because in these locations deuterium is known to undergo exchange reactions with hydrogens in the solvent or in other amino acids. Deuterium is very useful in elemental isotopic analysis where total hydrogen or exchangeable hydrogen concentrations are desired. *See* Biochemistry; Deuterium.

Applications of isotope dilution techniques have also been found in geology, nuclear science, and materials science. These applications generally focus on the very high sensitivity attainable with these techniques. Isotopes of argon, uranium, lead, thorium, strontium, and rubidium have been used in geologic age determinations of minerals and meteorites. Taking the estimated error as a measurement of sensitivity, isotopic dilution analyses of uranium have been done down to 4 parts in 10^{12} and on thorium to 8 parts in 10^{9}. Studies in geology and nuclear science require the determination of trace amounts of radiogenic products. If the half-life and decay scheme of the parent nuclide is known, then isotopic dilution determinations of parent and daughter isotopes provide a basis for the calculation of the age of the sample. If the age or history of the sample is known, then determination of the trace concentrations of isotopes provides information on pathways of nuclear reactions. *See* Radioactivity; Rock age determination. [L.Fr.]

Isotope separation The physical separation of different isotopes of an element from one another. The different isotopes of an element as it occurs in nature may have similar chemical properties but completely different nuclear reaction properties. Therefore, nuclear physics and nuclear energy applications often require that the different isotopes be separated. However, similar physical and chemical properties make isotope separation by conventional techniques unusually difficult. Fortunately, the slight mass difference of isotopes of the same element makes separation possible by using especially developed processes, some of which involve chemical industry distillation concepts. *See* Isotope.

Isotope separation depends on the element involved and its industrial application. Uranium isotope separation has by far the greatest industrial importance, because uranium is used as a fuel for nuclear power reactors. The two main isotopes found in nature are ^{235}U and ^{238}U, which are present in weight percentages (w/o) of 0.711 and 99.283, respectively. In order to be useful as a fuel the weight percentage of ^{235}U must be increased to between 2 and 5. The process of increasing the ^{235}U content is known as uranium enrichment, and the process of enriching is referred to as performing separative work. *See* Nuclear fuels; Nuclear reactor; Uranium.

The production of heavy water is another example of isotope separation. Heavy water is obtained by isotope separation of light hydrogen (^{1}H) and heavy hydrogen (^{2}H) in natural water. Heavy hydrogen is usually referred to as deuterium (D). All natural waters contain ^{1}H and ^{2}H, in concentrations of 99.985 and 0.015 w/o, respectively, in the form of H_2O and D_2O (deuterium oxide). Isotope separation increases the concentration of the D_2O, and thus the purity of the heavy water. *See* Deuterium; Heavy water.

The development of laser isotope separation technology provided a range of potential applications from space-flight power sources (^{238}Pu) to medical magnetic resonance imaging (^{13}C) and medical research (^{15}O).

The isotope separation process that is best suited to a particular application depends on the state of technology development as well as on the mass of the subject element and the quantities of material involved. Processes such as electromagnetic separation, thermal diffusion, and the Becker Process which are suited to research quantities of material are generally not suited to industrial separation quantities. However, the industrial processes that are used, gaseous diffusion, gas centrifugation, and chemical exchange, are not suited to separating small quantities of material. *See* Centrifugation; Diffusion.

Three experimental laser isotope separation technologies for uranium are the atomic vapor laser isotope separation (AVLIS) process, the uranium hexafluoride molecular laser isotope separation (MLIS) process, and the separation of isotopes by laser excitation (SILEX) process. The AVLIS process, which is more experimentally advanced than the MLIS and SILEX processes, exploits the fact that the different electron energies of ^{235}U and ^{238}U absorb different colors of light (that is, different wavelengths). AVLIS technology is inherently more efficient than either the gaseous diffusion or gas centrifuge processes. It can enrich natural uranium to ^{235}U in a single step. In the United States, the AVLIS process is being developed to eventually replace the gaseous diffusion process for commercially enriching uranium. *See* Laser; Photoionization. [J.J.St.]

Isotope shift A small difference between the different isotopes of an element in the transition energies corresponding to a given spectral line transition. For a spectral line transition between two energy levels a and b in an atom or ion with atomic number Z, the small difference $\Delta E_{ab} = E_{ab}(A') - E_{ab}(A)$ in the transition energy between isotopes with mass numbers A', and A is the isotope shift. It consists largely of the sum of two contributions, the mass shift (MS) and the field shift, also called the volume shift. The mass shift is customarily divided into a normal mass shift and a specific mass shift; each is proportional to the fractional mass difference $(A' - A)/A'A$. The normal mass shift is a reduced mass correction that is easily calculated for all transitions. The specific mass shift is produced by the correlated motion of different pairs of atomic electrons and is, therefore, absent in one-electron systems. The field shift is produced by the change in the finite size and shape of the nuclear charge distribution when neutrons are added to the nucleus. *See* Atomic structure and spectra; Nuclear structure. [P.M.K.]

Isotopic irradiation The uses of the radiation emitted by radioactive isotopes (radioisotopes), principally in industry and medicine. The radiation from radioisotopes produces essentially the same effect as the radiation from electron linear accelerators and other high-voltage particle accelerators, and the choice of which to use is based primarily on convenience and cost. Although the radioisotope radiation source does not require the extensive and complex circuitry necessary for a high-voltage radiation source, its radiation is always present and requires elaborate shielding for health protection and specialized mechanisms for bringing the irradiated objects into and out of the radiation beam. Further, the radiation output decreases with time according to the half-life of the radioisotope, which must therefore be replaced periodically. *See* Particle accelerator.

The two main radioisotopes for industrial processing are cobalt-60 with a half-life of 5.271 years and an average gamma-ray energy of 1.25 MeV, and cesium-137 with a half-life of 30.07 years and a gamma-ray energy of 0.662 MeV. The application of industrial irradiation is increasing, with sterilization of medical disposables using cobalt-60 gamma rays being the most common. A promising application is food preservation, including the reduction of postharvest losses by the elimination of pests with irradiation. The biocidal effect of the gamma-irradiation process is effective for the control of microbiological contamination in many raw materials used by the pharmaceutical and cosmetic industries. Other applications include irradiation of male insects for pest control, sterilization of corks, sterilization of laboratory animal bedding, preparation of vaccines, degradation of Teflon scraps used in lubricants, cross-linking of polyethylene for shrink films, and production of wood-polymer and concrete-polymer composites.

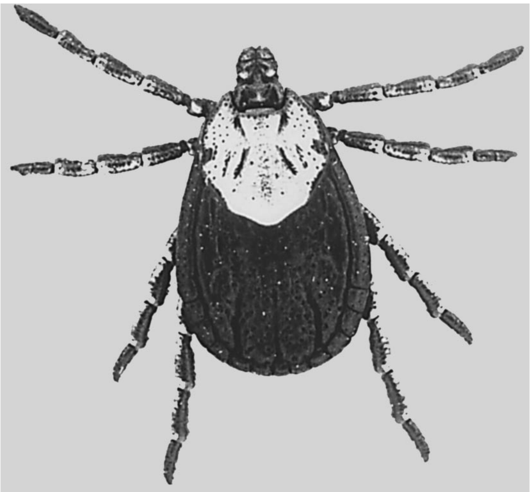
Radioisotopes are used in the treatment of cancer by radiation. Encapsulated sources are used in two ways: the radioisotopes may be external to the body and the radiation allowed to impinge upon and pass through the patient (teletherapy), or the radiation sources may be placed within the body (brachytherapy). For teletherapy purposes cobalt-60 is the most commonly used isotope. Some cesium-137 irradiators have been built, but cesium-137 radiation is not as penetrating as that from cobalt-60. Radium-226 is now being replaced with cesium-137 sources as a brachytherapy encapsulated source. Iridium-192 is also being used for brachytherapy applications. Iodine-125 or gold-198 seeds are put directly in a tumor and permanently left in place.

For some medical applications the radioisotope is dispersed in the body; the most commonly used is iodine-131. When the radioisotope is administered either orally or intravenously in a highly purified form, it goes to the thyroid, where certain forms of thyroid disorders and cancers can be treated by the radiation. *See* RADIOACTIVITY AND RADIATION APPLICATIONS; RADIOISOTOPE; RADIOLOGY. [P.R.A.]

Ixodides A suborder of the Acarina comprising the ticks. Ticks differ from mites, their nearest relatives, in their larger size and in having a pair of breathing pores, or spiracles, behind the third or fourth pair of legs. They have a gnathosoma, or head, which consists of a base, a pair of palps, and a rigid, elongated, ventrally toothed hypostome which anchors the parasite to its host. They also have a pair of protrusible cutting organs, or chelicerae, which permit the insertion of the hypostome. The 600 or so known species are all bloodsucking, external parasites of vertebrates including amphibians, reptiles, birds, and mammals. Ticks are divided into three families, Argasidae, Ixodidae (see illustration), and Nuttalliellidae.

In contrast to argasids, Ixodidae have a scutum covering most of the dorsal surface of the male but only the anterior portion of females, nymphs, and larvae. They are known as the hard ticks. The sexes are thus markedly dissimilar.

The numerous tick-borne diseases of animals cause vast economic losses, especially in tropical and subtropical regions. Aside from carrying disease, several species are extremely important pests of humans and animals. Heavy infestations of ticks produce severe anemia in livestock, and even death, from loss of blood alone. *See* ACARI; TICK PARALYSIS. [G.M.K.]



Ixodid tick, *Dermacentor andersonl*, female, enlarged to about 18 times natural size.

J

J/psi particle An elementary particle with an unusually long lifetime or, from the Heisenberg uncertainty principle, with an extremely narrow width $\Gamma = 91.0 \pm 3.2$ keV, and a large mass $m = 3096.916 \pm 0.011$ MeV. It is a bound state containing a charm quark and an anticharm quark. The discovery of the J/psi particle is one of the cornerstones of the standard model.

Since its discovery in 1974, more than 10^9 J/psi particles have been produced. More than 100 different decay modes and new particles radiating from the J/psi particle have been observed. The J/psi particle has been shown to be a bound state of charm quarks. The long lifetime of the J/psi results from its mass being less than the masses of particles which separately contain a charm and an anticharm quark. This situation permits the J/psi to decay only into noncharm quarks, and empirically this restriction was found to lead to a suppression of the decay rate resulting in a long lifetime and narrow width. The subsequent discovery of the *b* quark and the intermediate vector bosons Z^0 and $W^{\pm}$, and studies of Z^0 decays into charm, *b*, and other quarks, show that the theory of the standard model is in complete agreement with experimental data to an accuracy of better than 1%. *See* CHARM; ELEMENTARY PARTICLE; INTERMEDIATE VECTOR BOSON; QUARKS; STANDARD MODEL; UPSILON PARTICLES. [S.C.C.T.]

Jade A name that may be applied correctly to two distinct minerals. The two true jades are jadeite and nephrite. In addition, a variety of other minerals are incorrectly called jade. Idocrase is called California jade, dyed calcite is called Mexican jade, and green grossularite garnet is called Transvaal or South African jade. The most commonly encountered jade substitute is the mineral serpentine. It is often called "new jade" or "Korean jade." The most widely distributed and earliest known true type is nephrite, the less valuable of the two. Jadeite, the most precious of gemstones to the Chinese, is much rarer and more expensive. *See* JADEITE. [R.T.L.]

Jadeite The monoclinic sodium aluminum pyroxene, $NaAlSi_2O_6$. Free crystals are rare. Jadeite usually occurs as dense, felted masses of elongated blades or as fine-grained granular aggregates. It has a Mohs hardness of 6.5 and a density of 3.25–3.35. It has a vitreous or waxy luster, and is commonly green but may also be white, violet, or brown.

Jadeite is always found in metamorphic rocks. It is associated with serpentine at Tawmaw, Burma; Kotaki, Japan; and San Benito County, California. It occurs in metasedimentary rocks of the Franciscan group in California and in Celebes. It is found in Tibet; Yunan Province, China; and Guatemala.

Jadeite is the more cherished of the two jade minerals, because of the more intense colors it displays. It is best known in the lovely intense green color resembling that of emerald. *See* JADE; PYROXENE. [L.Gr.]

Jahn-Teller effect A distortion of a highly symmetrical molecule, which reduces its symmetry and lowers its energy. The effect occurs for all nonlinear molecules in degenerate electronic states, the degeneracy of the state being removed by the effect. It was first predicted in 1937 by H. A. Jahn and E. Teller. In early experimental work, the effect often "disappeared" or was masked by other molecular interactions. This has surrounded the Jahn-Teller effect with a certain mystery and allure, rarely found in science today. However, there are now a number of clear-cut experimental examples which correlate well with theoretical predictions. These examples range from the excited states of the most simple polyatomic molecule, H_3, through moderate-sized organic molecules, like the ions of substituted benzene, to complex solid state phenomena involving crystals or localized impurity centers. *See* CRYSTAL DEFECTS; DEGENERACY (QUANTUM MECHANICS); MOLECULAR STRUCTURE AND SPECTRA; QUANTUM MECHANICS.

With the exception of linear molecules which suffer Renner-Teller effects, all polyatomic molecules of sufficiently high symmetry to possess orbitally degenerate electronic states will be subject to the Jahn-Teller instability. However, in cases other than molecules with fourfold symmetry, the proof is somewhat involved and requires the use of the principles of group theory. *See* GROUP THEORY; RENNER-TELLER EFFECT. [V.E.B.; T.A.M.]

Jamming Intentional generation of interfering signals by powerful transmitters as a countermeasure intended to block a communication or radar system or to impair its effectiveness appreciably. For example, radio broadcasts or radio messages can be jammed by beaming a more powerful signal on the same frequency at the area in which reception is to be impaired, using carefully selected noise modulation to give maximum impairment of intelligibility of reception. *See* ELECTRONIC WARFARE. [J.Mar.]

Jasper An opaque, impure type of massive fine-grained quartz that typically has a tile-red, dark-brownish-red, brown, or brownish-yellow color. Jasper has been used since ancient times as an ornamental stone, chiefly of inlay work, and as a semiprecious gem material. *See* GEM; QUARTZ.

Jasper has a smooth conchoidal fracture with a dull luster. The specific gravity and hardness are variable; both values approach those of quartz. The color of jasper often is variegated in banded, spotted, or orbicular types. [C.Fr.]

Jaundice The yellow staining of the skin and mucous membranes associated with the accumulation of bile pigments, such as bilirubin, in the blood plasma. Bile pigments are the normal result of the metabolism of blood pigments, and are normally excreted from the blood into the bile by the liver. An increase in circulating bile pigments can, therefore, come about through increased breakdown of blood (hemolytic jaundice), through lack of patency of the bile ducts (obstructive jaundice), through inability or failure of the liver to clear the plasma (parenchymal jaundice), or through combinations of these. Jaundice occurs when the level of these circulating pigments becomes so high that they are visible in the skin and mucous membranes. *See* GALLBLADDER; LIVER.

Hemolytic jaundice results from certain morbid states that include various hemolytic anemias, hemolysis resulting from incompatible blood transfusion, severe thermal or electric injuries, or introduction of hemolytic agents into the blood-stream. Similar jaundice occurs in pulmonary infarction.

Chronic obstructive jaundice may be brought about through a variety of means. In the infant there may be a severe maldevelopment of the bile ducts, while in the adult obstructive jaundice is most commonly caused by impaction of a gallstone in the ducts, or benign and malignant tumors of the gallbladder, bile ducts, pancreas, or lymph nodes.

A wide variety of diseases exists in which part of the jaundice can be accounted for by actual damage to liver cells. This group comprises such conditions as inflammations of the liver, including viral hepatitis, Weil's disease, syphilis, parasitic infestations, and bacterial infections; toxic conditions, including poisoning and in a broader sense the toxemias associated with severe systemic diseases; tumorous conditions; and other miscellaneous conditions, the most common of which is congestive heart failure. [R.B.H.]

Jawless vertebrates Jawless vertebrates (Agnatha) include the modern Cyclostomata (lampreys and hagfishes) as well as extinct armored fishes known colloquially as ostracoderms ("bony-skinned"). They lived in the Ordovician, Silurian, and Devonian periods. Agnathans have pouchlike gills opening through small pores, rather than slits as in jawed vertebrates (Gnathostomata). Primitively, agnathans lack jaws, they show a persistent notochord, and most have no paired fins.

Lampreys (Petromyzontiformes; 42 species) and hagfishes (Myxiniformes; 43 species) are scaleless, eel-shaped fishes with round mouths, inside which there are keratinized teeth carried upon a complex tongue. Most species of lampreys live as adults in the sea, where they attach to host fishes by a sucker and use the tongue to rasp away flesh and blood. Hagfishes are exclusively marine, are blind, and live most of their lives buried in mud, emerging to eat polychaete worms or the abdominal contents of dead or dying fishes. Lampreys and hagfishes show a bipolar distribution and prefer cool waters.

Ostracoderms were very variable in shape and were covered with a superficial bony armor made up of solid shields or scales. One of the best known was the osteostracans (cephalaspids) of Europe and North America, with a solid semicircular head shield pierced by dorsally placed eyes and a small circular mouth on the undersurface. The head shield is also marked by sensory fields (lacunae filled with small plates) which were specialized parts of the lateral line system. Osteostracans probably lived on, or partly buried in, mud and sand, where they sucked in small food particles.

Modern ideas of the interrelationships of agnathan fishes suggest that they are not a natural group; that is, some such as the osteostracans and galeaspids are more closely related to jawed vertebrates than to other agnathans. Similarly, lampreys share many specializations with jawed vertebrates not seen in hagfishes, such as neural arches along the notochord, eye muscles, nervous control of heartbeat, and the capability to osmoregulate and adapt to fresh water. These attributes suggest that lampreys are more closely related to jawed vertebrates than to hagfishes and that the Cyclostomata is not a natural group.

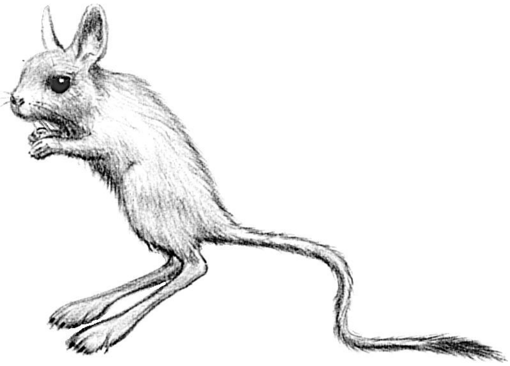
Members of the Conodonta may be jawless vertebrates, but their classification is still under discussion. *See* CEPHALASPIDOMORPHA; FOSSIL; PTERASPIDOMORPHA.

A classification of jawless vertebrates is given below.

Subphylum Craniata (complex brain and sensory organs)
Class Hyperotreti
Order Myxiniformes
Class Vertebrata (with neural arches in backbone)
Order: Petromyzontifomes
Anaspida
Thelodonti
Heterostraci (pteraspids)
Galeaspida
Osteostraci (cephalaspids)
Class incertae sedis Conodonta

See MYXINIFORMES; PETROMYZONTIDA. [P.L.F.]

Jerboa The common name for 25 species of rodents which make up the family Dipodidae. All species occur in desert or semiarid regions of Asia; three species extend into North Africa. All of these animals are adapted for jumping, and the hindlegs and feet are extremely long (see illustration). The most common species is *Jaculus jaculus*, the lesser Egyptian jerboa. *See* RODENTIA. [C.B.C.]



Typical jerboa, with long hindlegs and a tail that terminates in a tuft of hair.

Jet (gemology) A black, opaque material that takes a high polish. Jet has been used for many centuries for ornamental purposes. It is a compact variety of lignite coal. It has a refractive index of 1.66, a hardness of 3–4 on Mohs scale, and a specific gravity of 1.30–1.35. Jet is compact and durable, and can be carved or even turned on a lathe. The main source is Whitby, England, in hard shales. *See* GEM; LIGNITE. [R.T.L.]

Jet flow A fluid flow in which a stream of one fluid mixes with a surrounding medium, at rest or in motion. Such flows occur in a wide variety of situations, and the geometries, sizes, and flow conditions cover a large range. Jet flows vary greatly, depending on the values of two numbers. The first is the Reynolds number, defined in Eq. (1), where ρ is the density,

$$\mathrm{Re} \equiv \frac{\rho V L}{\mu} \qquad (1)$$

V is a characteristic velocity (for example, the jet exit velocity), L is a characteristic length (for example, the jet diameter), and μ is the viscosity. The second is the Mach number, defined in Eq. (2), where a is the speed of sound.

$$\mathrm{M} \equiv \frac{V}{a} \qquad (2)$$

See MACH NUMBER; REYNOLDS NUMBER.

For conditions where $\mathrm{Re} < 2300$ and $\mathrm{M} \ll 1$, jet flows take on a simple character. An example is the water jet formed by a household tap when the valve is partially opened to produce a low flow. If the flow or the diameter is increased or the viscosity is decreased so that $\mathrm{Re} > 2300$, the jet will change dramatically. For example, a water jet exiting into water at rest with $\mathrm{Re} \approx 2300$ is initially in the simple laminar state, but at this Reynolds number that state is unstable and the flow undergoes a transition to the more chaotic turbulent state. Turbulent structures called eddies are formed with a large range of sizes. The large-scale structures are responsible for capturing fluid from the surroundings and entraining it into the jet. However, the jet and external fluids are not thoroughly mixed until diffusion is completed by the small-scale structures. *See* DIFFUSION; LAMINAR FLOW; TURBULENT FLOW.

When the velocities in the jet are greater than the speed of sound ($M > 1$) the flow is said to be supersonic, and important qualitative changes in the flow occur. The most prominent change is the occurrence of shock waves. For example, a supersonic air jet exhausting from a nozzle at low pressure into higher-pressure air at rest is said to be overexpanded. As the jet leaves the nozzle, it senses the higher pressure around it and adjusts through oblique shock waves emanating from the edges of the nozzle. *See* SHOCK WAVE; SUPERSONIC FLOW.

Another class of jet flows is identified by the fact that the motion of the jet is induced primarily by buoyancy forces. A common example is a hot gas exhaust rising in the atmosphere. Such jet flows are called buoyant plumes, or simply plumes, as distinct from the momentum jets, or simply jets, discussed above. *See* FLUID FLOW. [J.A.Sc.]

Jet fuel Fuel blended from the light distillates fractionated from crude petroleum. All jet fuels must meet the stringent requirements of aircraft turbine engines and fuel systems, which demand extreme cleanliness and freedom from oxidation deposits in high-temperature zones. Combustors require fuels that atomize and ignite at low temperatures, burn with adequate heat release and controlled radiation, and neither produce smoke nor attack hot turbine parts. The operation of the aircraft in long-duration flights at high altitude imposes a special requirement of good low-temperature flow behavior. [W.G.D.]

Jet propulsion Propulsion of a body by means of force resulting from discharge of a fluid jet. This fluid jet issues from a nozzle and produces a reaction (Newton's third law) to the force exerted against the working fluid in giving it momentum in the jet stream. Turbojets, ramjets, and rockets are the most widely used jet-propulsion engines. *See* RAMJET; TURBOJET.

In each of these propulsion engines a jet nozzle converts potential energy of the working fluid into kinetic energy. Hot high-pressure gas escapes through the nozzle, expanding in volume as it drops in pressure and temperature, thus gaining rearward velocity and momentum. This process is governed by the laws of conservation of mass, energy, and momentum and by the pressure-volume-temperature relationships of the gas-state equation. *See* JET FLOW; NOZZLE. [J.W.Bl.]

Jet stream A relatively narrow, fast-moving wind current flanked by more slowly moving currents. Jet streams are observed principally in the zone of prevailing westerlies above the lower troposphere and in most cases reach maximum intensity, with regard both to speed and to concentration, near the tropopause. At a given time, the position and intensity of the jet stream may significantly influence aircraft operations because of the great speed of the wind at the jet core and the rapid spatial variation of wind speed in its vicinity. Lying in the zone of maximum temperature contrast between cold air masses to the north and warm air masses to the south, the position of the jet stream on a given day usually coincides in part with the regions of greatest storminess in the lower troposphere, though portions of the jet stream occur over regions which are entirely devoid of cloud. The jet stream is often called the polar jet, because of the importance of cold, polar air. The subtropical jet is not associated with surface temperature contrasts, like the polar jet. Maxima in wind speed within the jet stream are called jet streaks. *See* ATMOSPHERIC GENERAL CIRCULATION. [F.S.; H.B.B.]

Jet velocity The velocity of the engine exhaust gases relative to the exhaust nozzle. In ideal air-breathing cycles, it is assumed that the exhaust gas mass rate equals the inlet air mass rate, the mass of fuel burned being neglected, and that the exhaust gases are expanded to ambient pressure in the nozzle. Under these conditions the thrust of an engine is directly proportional to the airflow rate and to the difference between the jet and vehicle velocities; thrust is greatest at zero flight speed and becomes zero when the flight speed is the same as the jet velocity.

In the non-air-breathing rocket cycle, thrust of a rocket is independent of flight speed. Rather, at constant mass flow, thrust is directly proportional to nozzle exhaust velocity plus a pressure-times-area term. *See* PROPULSION; ROCKET PROPULSION. [R.R.H.]

Jewel bearing A bearing used in quality timekeeping devices, gyros, and instruments, usually made of synthetic corundum (crystallized Al_2O_3) which is more commonly known as ruby or sapphire. The extensive use of such bearings in the design of precision devices is mainly due to the outstanding qualities of the material. Sapphire's extreme hardness imparts to the bearing excellent wear resistance, as well as the ability to withstand heavy loads without deformation of shape or structure. The crystalline nature of sapphire lends itself to very fine polishing and this, combined with the excellent oil- and lubricant-retention ability of the surface, adds to the natural low-friction characteristics of the material. Ruby has the same properties as sapphire. *See* ANTIFRICTION BEARING; GEM; GYROSCOPE; WATCH. [R.M.Sch.]

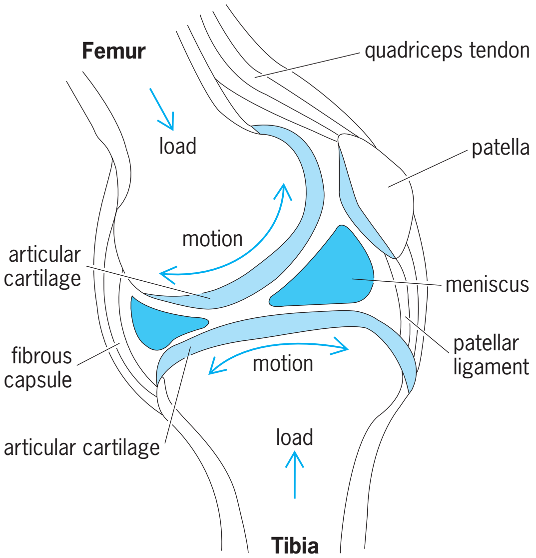
Johne's disease Chronic inflammation of the mucosa of the ileocecal valve and adjacent tissues of the gastrointestinal tract of cattle, sheep, goats, and captive wild ruminants, caused by the bacterium *Mycobacterium paratuberculosis*. Transmission of *M. paratuberculosis* is primarily by ingestion of feces from animals shedding the organism. The incubation period varies from 2 to 3 years or more. Diseased animals in advanced stages have intermittent or persistent diarrhea without fever and often become emaciated.

Johne's disease is diagnosed by serologic tests and mycobacteriologic examinations conducted on feces or tissues collected by biopsy or at necropsy. To confirm a diagnosis of Johne's disease, it is necessary to isolate and identify the etiologic agent.

Therapeutic drugs are not available for routine treatment of animals. A killed whole-cell vaccine is available for use in calves 1–35 days of age. Live attenuated strains of *M. paratuberculosis* have been used for vaccinating cattle in a few countries, but are not approved for use in the United States or Canada. *Mycobacterium paratuberculosis* has not been shown to cause disease in humans; however, a *M. paratuberculosis*-like organism has been isolated from a few individuals with Crohn's disease. *See* MYCOBACTERIAL DISEASES. [C.O.T.]

Joint (anatomy) The structural component of an animal skeleton where two or more skeletal elements meet, including the supporting structures within and surrounding it. The relative range of motion between the skeletal elements of a joint depends on the type of material between these elements, the shapes of the contacting surfaces, and the configuration of the supporting structures.

In bony skeletal systems, there are three general classes of joints: synarthroses, amphiarthroses, and diarthroses. Synarthroses are joints where bony surfaces are directly connected with fibrous tissue, allowing very little if any motion. Synarthroses may be further classified as sutures, syndesmoses, and gomphoses. Sutures are joined with fibrous tissue, as in the coronal suture where the parietal and frontal bones of the human skull meet. Syndesmoses are connected with ligaments, as are the shafts of the tibia and fibula. The roots of a tooth that are anchored in the jaw bone with fibrous tissue form a gomphosis. Amphiarthroses are joints where bones are directly connected with fibrocartilage or hyaline cartilage and allow only limited motion. An amphiarthrosis joined with fibrocartilage, as found



Cross section of the human knee showing its major components. This diarthrodial joint contains contacting surfaces on the tibia, femur, meniscus, and patella (knee cap). The patella protects the joint and also serves to redirect the force exerted by the quadriceps muscles to the tibia. (*After R. Skalak and S. Chien, eds., Handbook of Bioengineering, McGraw-Hill, 1987*)

between the two pubic bones of the pelvis, is known as a symphysis; but when hyaline cartilage joins the bones, a synchondrosis is formed, an example being the first sternocostal joint. The greatest range of motion is found in diarthrodial joints, where the articulating surfaces slide and to varying degrees roll against each other. *See* LIGAMENT.

The contacting surfaces of the bones of a diarthrodial joint are covered with articular cartilage, an avascular, highly durable hydrated soft tissue that provides shock absorption and lubrication functions to the joint (see illustration). Articular cartilage is composed mainly of water, proteoglycans, and collagen. The joint is surrounded by a fibrous joint capsule lined with synovium, which produces lubricating synovial fluid and nutrients required by the tissues within the joint. Joint motion is provided by the muscles that are attached to the bone with tendons. Strong flexible ligaments connected across the bones stabilize the joint and may constrain its motion. Different ranges of motion result from several basic types of diarthrodial joints: pivot, gliding, hinge, saddle, condyloid, and ball-and-socket. *See* COLLAGEN; SKELETAL SYSTEM. [V.C.M.; R.J.F.]

Joint (structures) The surface at which two or more mechanical or structural components are united. Whenever parts of a machine or structure are brought together and fastened into position, a joint is formed. *See* STRUCTURAL CONNECTIONS.

Mechanical joints can be fabricated by a great variety of methods, but all can be classified into two general types, temporary (screw, snap, or clamp, for example), and permanent (brazed, welded, or riveted, for example). [W.H.Cr.]

Jojoba *Simmondsia chinensis*, the only plant known to produce and store a liquid wax in its seed. The jojoba plant is native to the southwestern United States and Mexico. It is tolerant of some of the highest temperatures and most arid regions, and is being domesticated as a crop for hot low-rainfall regions around the world. A broadleaf evergreen shrub that is typically 3–10 ft (1–3 m) in height, it can grow as tall as 20 ft (6 m).

The seed-storage lipid of jojoba is a straight-chain ester. A majority of the wax molecules of jojoba are formed from acids and alcohols with 20 or 22 carbon atoms and one double bond. Many modifications can be made at the double bond, which results in the plant's versatility as an ingredient in a wide range of chemical products. Jojoba wax, used in cosmetics and lubricants, has the potential to serve as a basic feedstock if seed production costs are reduced. Jojoba is being developed simultaneously in many places around the world, and cultivation methods are variable and change rapidly. *See* FAT AND OIL (FOOD); WAX, ANIMAL AND VEGETABLE. [D.A.P.]

Josephson effect The passage of paired electrons (Cooper pairs) through a weak connection (Josephson junction) between superconductors, as in the tunnel passage of paired electrons through a thin dielectric layer separating two superconductors.

Quantum-mechanical tunneling of Cooper pairs through a thin insulating barrier (on the order of a few nanometers thick) between two superconductors was theoretically predicted by Brian D. Josephson in 1962. Josephson found that a current of paired electrons (supercurrent) would flow in addition to the usual current that results from the tunneling of single electrons. Josephson predicted that if the current did not exceed a limiting value (the critical current), there would be no voltage drop across the tunnel barrier. This zero-voltage current flow is known as the dc Josephson effect. Josephson also predicted that if a constant nonzero voltage were maintained across the tunnel barrier, an alternating supercurrent would flow through the barrier in addition to the dc current produced by the tunneling of unpaired electrons. This phenomenon is known as the ac Josephson effect. *See* TUNNELING IN SOLIDS.

Josephson pointed out that the magnitude of the maximum zero-voltage supercurrent would be reduced by a magnetic field. In fact, the magnetic field dependence of the magnitude of the critical current is one of the more striking features of the Josephson effect. Circulating supercurrents flow through the tunnel barrier to screen an applied magnetic field from the interior of the Josephson junction just as if the tunnel barrier itself were weakly superconducting. The screening effect produces a spatial variation of the transport current, and the critical current goes through a series of maxima and minima as the field is increased.

Josephson junctions, and instruments incorporating Josephson junctions, are used in applications for metrology at dc and microwave frequencies, frequency metrology, magnetometry, measurement of absolute temperatures below about 1 K, detection and amplification of electromagnetic signals, and other superconducting electronics such as high-speed analog-to-digital converters and computers. A Josephson junction, like a vacuum tube or a transistor, is capable of switching signals from one circuit to another; a Josephson tunnel junction is the fastest switch known. Josephson junction circuits are capable of storing information. Finally, because a Josephson junction is a superconducting device, its power dissipation is extremely small, so that Josephson junction circuits can be packed together as tightly as fabrication techniques permit. All the basic circuit elements required for a Josephson junction computer have been developed. *See* LOW-TEMPERATURE THERMOMETRY; SUPERCONDUCTING DEVICES; SUPERCONDUCTIVITY. [L.B.H.]

Joule's law A quantitative relationship between the quantity of heat produced in a conductor and an electric current flowing through it. As experimentally determined and announced by J. P. Joule, the law states that when a current of voltaic electricity is propagated along a metallic conductor, the heat evolved in a given time is proportional to the resistance of the conductor multiplied by the square of the electric intensity. Today the law would be stated as $H = RI^2$, where H is rate of evolution of heat in watts, the unit of heat being the joule; R is resistance in ohms; and I is current in amperes. This statement is more general than the one sometimes given that specifies that R be independent of I. Also, it is now known that the application of the law is not limited to metallic conductors. *See* ELECTRIC HEATING. [L.G.H./J.W.St.]

Juglandales An order of flowering plants, division Magnoliophyta (Angiospermae), in the subclass Hamamelidae of the class Magnoliopsida (dicotyledons). The order consists of 2 families: the Juglandaceae with a little over 50 species and the Rhoipteleaceae with only 1 species. Within its subclass the order is sharply set off by its compound leaves. *Juglans* (walnut and butternut) and *Carya* (hickory, including the pecan, *C. illinoensis*) are familiar genera of the Juglandaceae. *See* HAMAMELIDAE; HICKORY; MAGNOLIOPHYTA; MAGNOLIOPSIDA; PLANT KINGDOM. [A.Cr.; T.M.B.]

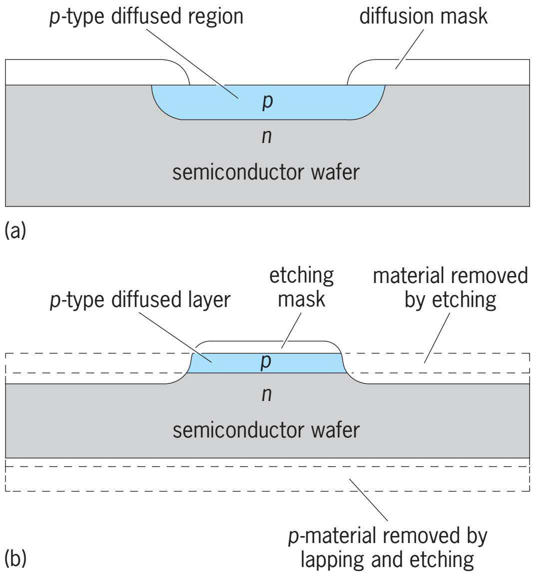
Juncales An order of flowering plants, division Magnoliophyta (Angiospermae), in the subclass Commelinidae of the class Liliopsida (monocotyledons). The order consists of the family Juncaceae, with about 300 species, and the family Thurniaceae, with only 3. Within its subclass the order is marked by its reduced, mostly wind-pollinated flowers and capsular fruits with one to many anatropous ovules per carpel. The flowers have six sepals arranged in two more or less similar whorls, both sets chaffy and usually brown or green. *See* COMMELINIDAE; FLOWER; LILIOPSIDA. [A.Cr.]

Junction detector A device in which detection of radiation takes place in or near the depletion region of a reverse-biased semiconductor junction. The electrical output pulse is linearly proportional to the energy deposited in the junction depletion layer by the incident ionizing radiation. *See* IONIZATION CHAMBER.

Introduced into nuclear studies in 1958, the junction detector, or more generally, the nuclear semiconductor detector, revolutionized the field. In the detection of both charged particles and gamma radiation, these devices typically improved experimentally attainable energy resolutions by about two orders of magnitude over that previously attainable. To this they added unprecedented flexibility of utilization, speed of response, miniaturization, freedom from deleterious effects of extraneous electromagnetic (and often nuclear) radiation fields, low-voltage requirements, and effectively perfect linearity of output response. They are now used for a wide variety of diverse applications. They are used for general analytical applications, giving both qualitative and quantitative analysis in the microprobe and the scanning transmission electron microscopes. They are used in medicine, biology, environmental studies, and the space program. In the last category they continue to play a very fundamental role, ranging from studies of the radiation fields in the solar system to the composition of extraterrestrial surfaces. *See* PARTICLE DETECTOR; SEMICONDUCTOR. [J.M.McK.]

Junction diode A semiconductor rectifying device in which the barrier between two regions of opposite conductivity type produces the rectification. Junction diodes are used in computers, radio and television, brushless generators, battery chargers, and electrochemical processes requiring high direct current and low voltage. Lower-power units are usually called semiconductor diodes, and the higher-power units are usually called semiconductor rectifiers. *See* SEMICONDUCTOR.

Junction diodes are classified by the method of preparation of the junction, the semiconductor material, and the general category of use of the finished device. By far the great majority of modern junction diodes use silicon as the basic semiconductor material. Germanium material was used in the first decade of semiconductor diode technology, but has given way to the all-pervasive silicon technology, which allows wider temperature limits of operation and produces stable characteristics more easily. Other materials are the group III–V compounds, the most common being gallium arsenide, which is used where its relatively large band-gap energy is needed.



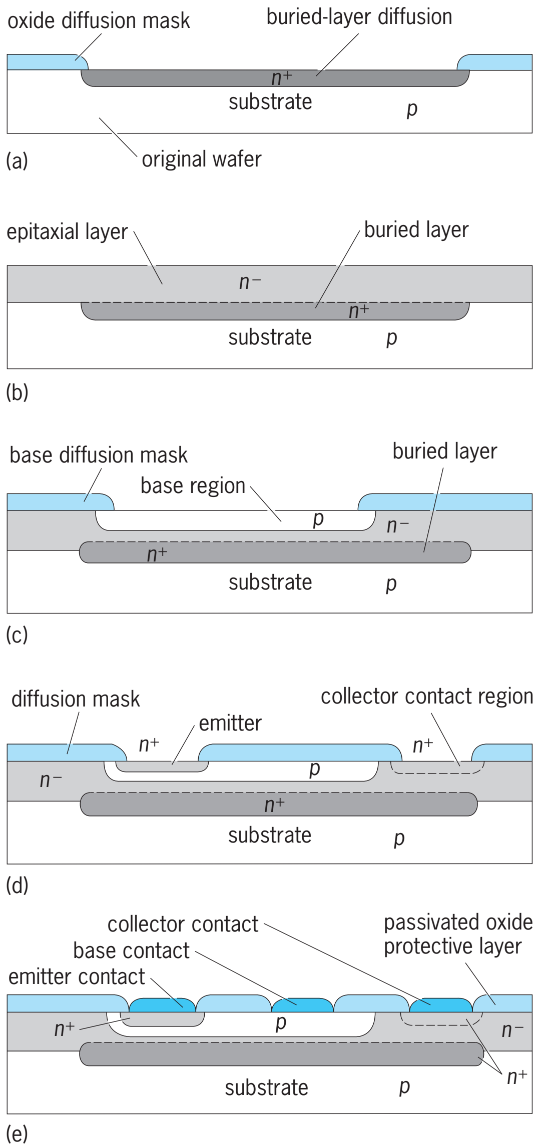
High-speed diffused silicon diodes. (*a*) Mesaless structure. (*b*) Mesa structure.

In silicon units nearly all categories of diodes are made by self-masked diffusion, as shown in illus. *a*. Exceptions are diodes where special control of the doping profile is necessary. In such cases, a variety of doping techniques may be used, including ion implantation, alloying with variable recrystallization rate, silicon transmutation by neutron absorption, and variable-impurity epitaxial growth. The mesa structure shown in illus. *b* is used for some varactor and switching diodes if close control of capacitance and voltage breakdown is required. *See* ELECTRONIC SWITCH; ION IMPLANTATION; RECTIFIER. [L.P.H.]

Junction transistor A transistor in which emitter and collector barriers are formed by *pn* junctions between semiconductor regions of opposite conductivity type. These junctions are separated by a distance considerably less than a minority-carrier diffusion length, so that minority carriers injected at the emitter junction will not recombine before reaching the collector barrier and therefore be effective in modulating the collector-barrier impedance. Junction transistors are widely used both as discrete devices and in integrated circuits. The discrete devices are found in the high-power and high-frequency applications. Silicon is the most widely used semiconductor material, although germanium is still used for some applications. *See* TRANSISTOR.

Most modern transistors are fabricated by the silicon self-masked planar double-diffusion technique. The structure of a planar diffused epitaxial transistor is shown in section in the illustration. In this structure both collector and emitter junctions are formed by diffusion of impurities from the top surface. In modern technology the base and emitter diffusions are carried out in two steps: a predeposition step, in which a very thin layer of heavily doped oxide is chemically deposited over the open surface of the silicon in the hole opened in the masking oxide; and a drive-in diffusion step, in which the deposited dopant is diffused into the silicon at a higher temperature than that used for the predeposition. The chemical predeposition step is being replaced by ion implantation directly through the oxide. *See* ION IMPLANTATION.

Silicon planar technology is used in fabricating integrated circuit chips. The general form of the transistor structure displayed in the illustration is used in integrated circuits. Such a structure



Double-diffused planar epitaxial transistor structure and method of fabrication. (*a*) Buried layer. (*b*) Epitaxial layer. (*c*) Collector junction formation. (*d*) Emitter junction. (*e*) Contact stripe placement.

is used for diodes as well as transistors since, for example, it is necessary only to connect the base and collector contacts to use the collector junction as a diode. *See* INTEGRATED CIRCUITS. [L.P.H.]

Jungermanniales The largest order of liverworts, often called the leafy liverworts; it consists of 43 families. The leaves are in three rows, with the underleaves usually reduced or lacking. Other distinctive features include a perianth formed by a fusion of modified leaves, a short-lived seta, and a four-valved capsule. The leaves have an embryonic bilobed phase which may be lost on further development.

The plants of this order are dorsiventrally organized and leafy. They grow by means of an apical cell with three cutting faces, resulting in two rows of lateral leaves and a third row of underleaves which are generally reduced, and sometimes lacking. The stems lack a central strand. Rhizoids are usually present, all smooth. The leaves pass through a primordial two-lobed stage but may become two- to several-lobed, or unlobed (owing to obliteration of one primordial lobe). A midrib is lacking. Asexual reproduction by gemmae is common. Antheridia occur in leaf axils, sometimes also in axils of underleaves. Archegonia are terminal. The sporophyte is usually protected by a perianth (in addition to a calyptra) formed by the fusion of leaves. The seta, usually long, consists of delicate, hyaline cells. The capsule is four-valved. *See* BRYOPHYTA; JUNGERMANNIIDAE. [H.Cr.]

Jungermanniidae One of the two subclasses of liverworts (class Hepaticopsida). The plants may be thallose, with little or no tissue differentiation, or they may be organized into erect or prostrate stems with leafy appendages. The leaves, generally one cell in thickness, are mostly arranged in three rows, with the third row of underleaves commonly reduced or even lacking. Oil bodies are usually present in all cells. The rhizoids are smooth. The capsules, generally dehiscing by four valves, are usually elevated on a long, delicate, short-lived seta. The spore mother cells are deeply lobed.

The subclass consists of the orders Takakiales, Calobryales, and Jungermanniales, which are leafy, and the Metzgeriales, which are mostly thallose. *See* BRYOPHYTA; CALOBRYALES; JUNGERMANNIALES; METZGERIALES; TAKAKIALES. [H.Cr.]

Jupiter The largest planet in the solar system, and the fifth in the order of distance from the Sun. It is visible to the naked eye, except for short periods when in near conjunction with the Sun. Usually it is the second brightest planet in the sky; only Mars at its maximum luminosity and Venus appear brighter.

Telescopic appearance. Through an optical telescope Jupiter appears as an elliptical disk, strongly darkened near the limb and crossed by a series of bands parallel to the equator (Fig. 1). Even fairly small telescopes show a great deal of complex structure in the bands and disclose the rapid rotation of the planet. The period of rotation is very short, about 9 h 55 m, the shortest of any planet. The features observed, however, do not correspond to the solid body of a planet but to clouds in its atmosphere, and the rotation period varies markedly with latitude.

Red Spot. Apart from the constantly changing details of the belts, some permanent or semipermanent markings have been observed to last for decades or even centuries, with some fluctuations in visibility. The most conspicuous and permanent marking is the great Red Spot (Fig. 2), intermittently recorded since the seventeenth century and observed continually since

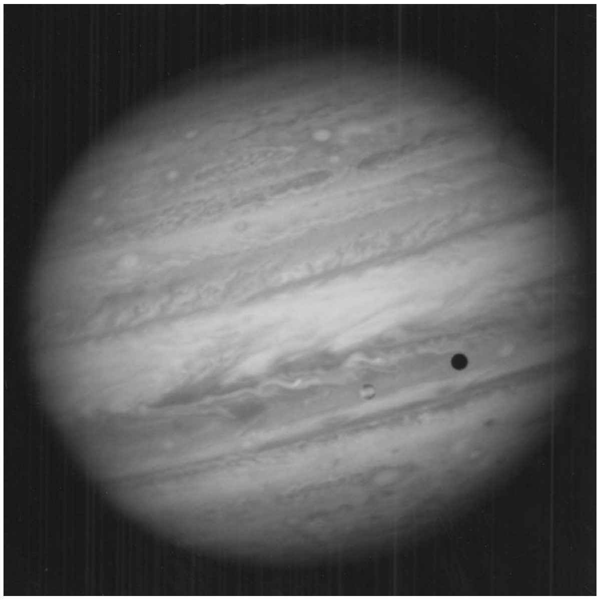


Fig. 1. Telescopic appearance of Jupiter from the Hubble Space Telescope (*Space Telescope Science Institute: Jet Propulsion Laboratory; NASA*).

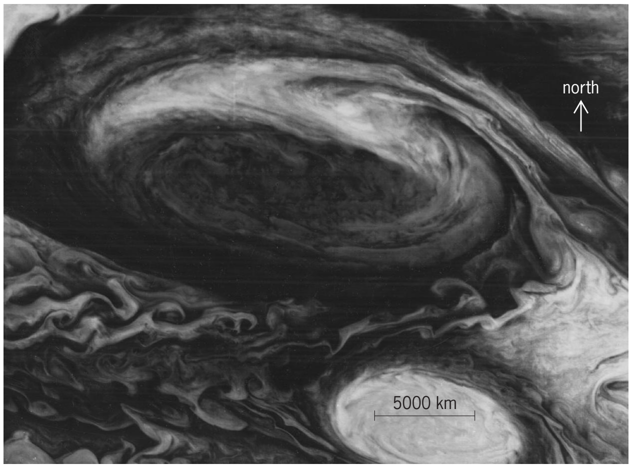

Fig. 2. Details of the Red Spot as seen by the *Voyager 1* flyby. 5000 km = 3000 mi. (*NASA*)

1878. At times it has been conspicuous and strongly colored; at other times it has been faint and only slightly colored. The Spot's distinctive coloration is probably due to chemical compounds (perhaps containing phosphorus) transported from deep within the atmosphere. The origin and longevity of the Great Red Spot remain difficult to explain.

Atmosphere. Jupiter's visible belts and zones reflect the complicated vertical atmospheric structure. The atmosphere consists primarily of hydrogen (H_2), helium (He), ammonia (NH_3), methane (CH_4), water (H_2O), hydrogen sulfide (H_2S), and other trace compounds. In the simplest model, the deepest cloud layer consists of water vapor and ammonia cumulus clouds. These form a cloud bank about 16 mi (25 km) thick which is overlain by a 6-mi-thick (10-km) clear region probably saturated with gaseous ammonia. Above this are ammonium hydrosulfide (NH_4SH) clouds, the tops of which perhaps receive a constant liquid ammonia rain from a higher level of ammonia clouds nearly 12 mi (20 km) in vertical extent. A high-altitude smog layer obscures the entire planet.

The belts and zones represent regions of differing cloud altitudes and compositions. The atmosphere is divided by a series of prograding and retrograding jet streams. Convection is strong since the bright zones are cooler and higher by 9–12 mi (15–20 km) than the dark belts, with their higher albedos arising from solid ammonia crystals.

Individual vortices form within the zones and belts, some persisting for decades. The major white ovals are hot-spot regions of strong infrared emission and are consistent with convective motion from the deep water-cloud layers, while other features such as the plumes observed in the equatorial region may be surface phenomena.

During July 16–22, 1994, 21 observable fragments of Comet Shoemaker-Levy 9 impacted the Jovian atmosphere at nearly 120,000 mi/h (200,000 km/h), the first time such an event had been witnessed. Though occurring on Jupiter's nonvisible side, each strike was clearly visible as a dark area in the south temperate zone as the planet's rapid rotation brought it into view. In addition, ejecta and impact plumes were seen to rise approximately 1860 mi (3000 km) above the planetary limb. The event provided a first probe into the Jovian atmosphere. *See* COMET.

Interior composition and structure. Jupiter primarily consists of liquid and metallic hydrogen. Early measures of the ratios of helium, carbon, and nitrogen to hydrogen gave values resembling those of the Sun, and therefore, the primordial composition of the solar system. However, later analyses of the methane spectrum showed a two- to threefold overabundance of carbon as compared to solar values, a result confirmed by gravity analyses of the rocky core. Still in a late phase of its gravitational contraction, the planet converts the released gravitational energy into heat, emitting 1.668 times as much thermal energy as it receives from the Sun.

The cloud zone thickness actually extends only 0.1–0.3% of the Jovian radius. Beneath that, the atmosphere is clear and gradually metamorphoses into the liquid hydrogen molecular fluid envelope which makes up approximately the outer 20% of the radius. The transition at lower depths to metallic hydrogen is abrupt. *See* HYDROGEN.

Observations suggest that the planet could be homogeneous (that is, it has no core) or else it has a dense central core with a mass less than or equal to 12 earth masses. The large abundance of carbon suggests that gases other than those from the solar nebula contributed to the composition of Jovian volatile gases. Probably the entire planet holds 11–45 earth masses of elements other than hydrogen and helium.

Jovian magnetosphere. Jupiter possesses the strongest magnetic field and most complex magnetosphere of any planet in the solar system. This field rotates with the rotational period of the planet and contains an embedded plasma trapped in the field. At the distance of the satellite Io, the field revolves faster than the satellite, and so numerous collisions occur with the atmospheric gas of that body, resulting in the stripping away of 10^{28}–10^{29} ions per second. The energy involved slows the magnetic field, and so, beyond Io, the magnetic field no longer rotates synchronously with the planet. The ions removed from Io spiral around the magnetic lines of force, oscillating above and below the plane of Io's orbit. This ring of ions is known as the Io plasma torus and emits strongly in the ultraviolet. The motion of Io through the magnetosphere creates a 400,000-V, 2×10^{12} W circuit, sufficient to cause pronounced aurorae in both the equatorial and polar regions of the satellite.

Jovian ring. V*oyager 1* and *2* detected a faint ring encircling Jupiter. It appears to have three parts, which interact in a complicated, dynamic way with the planet's magnetic field and several embedded satellites.

Satellites. Jupiter has 63 known satellites of which the four largest, I Io, II Europa, III Ganymede, and IV Callisto, discovered by Galileo in 1610, are by far the most important.

The four Galilean satellites are of fifth and sixth stellar magnitudes and would be visible to the naked eyeif they were not so close to the much brighter parent planet. They are easily visible in binoculars. All the others are faint telescopic objects.

The close approaches of the *Voyager* and *Galileo* spacecraft as well as the superior imaging capabilities of the Hubble Space Telescope have shown the four galilean satellites to be very different. I Io is probably the most geologically active body in the solar system. Its surface landforms include active shield volcanoes, calderas, mountains, plateaus, flows, grabens, and scarps. Spacecraft have shown that Io possesses over 80 separate volcanoes. The source of this volcanism is thought to be the transformation of tidal energy into heat as Jupiter's gravity deforms the satellite surface by several hundred feet.

Europa, primarily a rocky body, may be rich in silicates and lightweight water ices. The surface displays a satellite-wide system of cracks, and ridges, running for thousands of miles, about 10–25 mi (16–40 km) in width. There are few elevations, and the surface is remarkably free from craters. The ice surface makes the satellite one of the most reflective bodies in the solar system. Geologic activity is thought to heat the ice under the surface to near-liquid state, allowing it to gush through in volcanoes of slush and water.

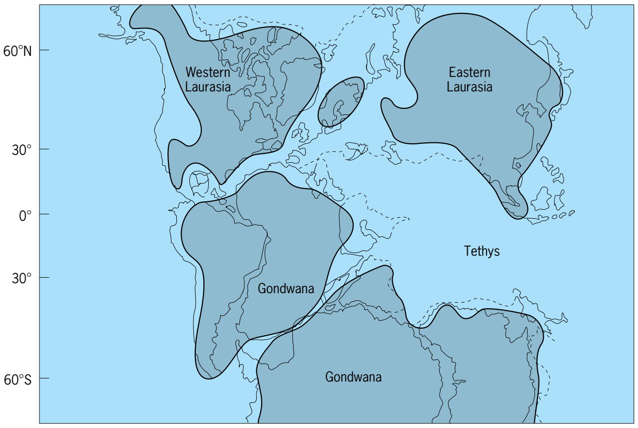
It is likely that liquid oceans exist on Europa at depths more than 6 mi (10 km) below the surface, kept liquid by geothermal activity and tidal action. This is suggested by the variable Europan magnetic field observed by the *Galileo* spacecraft. It is not inconceivable that simple life may exist in the Europan oceans, much in the same way as in Earth's oceans lifeforms congregate near thermal vents.

The density of III Ganymede suggests that it is composed largely of ice. It has a metallic core approximately the size of Io, surrounded by a 500-mi (800-km) shell of rock and a similarly sized overmantle of ice. The surface formed recently since there are few large impact craters, but those that exist may have crater caps of frost.

Since it is similar in radius and density, IV Callisto should have a geological history resembling that of Ganymede, but does not. In fact, it seems to have been geologically dead for millions of years. It is the most heavily cratered of the galilean satellites and has not undergone extensive resurfacing since the time of impacts. [E.M.Ha.]

Jurassic The system of rocks deposited during the middle part of the Mesozoic Era, and encompassing an interval of time between about 208 and 145 million years ago, based on radiometric dating. It takes its name from the Jura Mountains, which run along the border of France and Switzerland.

The main continental masses were grouped together as the supercontinent Pangaea, with a northern component, Laurasia, separated from a southern component, Gondwana, by a major seaway, Tethys, which expanded in width eastward (see illustration). From about Middle Jurassic times onward, this supercontinent began to split up, with a narrow ocean being created between eastern North America and northwestern Africa, corresponding to the central sector of the present Atlantic Ocean. At about the same time, and continuing into the Late Jurassic, separation began between the continents that now surround the Indian Ocean, namely Africa, India, Australia, and Antarctica. As North America moved westward, it collided with a number of oceanic islands in the eastern part of the Paleo-Pacific.



Approximate distribution of land and sea in the Oxfordian stage, the first stage of the late Jurassic. Small islands are excluded, but boundaries of modern continents are included as a reference.

The climate of Jurassic times was clearly more equable than at present. A number of ferns whose living relatives cannot tolerate frost are distributed over a wide range of paleolatitudes, sometimes as far as 60° N and S. Similarly, coral reefs, which are at present confined to the tropics, occur in Jurassic strata in western and central Europe, beyond the paleotropical zone. Many other groups of organisms had wide latitudinal distribution, and there was much less endemism (restriction to a particular area) with respect to latitude than there is today. In addition, there is a lack of evidence for polar icecaps.

The vertebrate terrestrial life of the Jurassic Period was dominated by the reptiles. The dinosaurs had first appeared late in the Triassic from a thecodont stock, which also gave rise to pterosaurs and, later, birds. From small bipedal animals such as *Coelophysis*, there evolved huge, spectacular creatures. These include the herbivorous *Apatosaurus*, *Brontosaurus*, *Brachiosaurus*, *Diplodocus*, and *Stegosaurus* as well as the carnivorous, bipedal *Allosaurus*. *See* Dinosaur.

Flying animals include the truly reptilian pterosaurs and the first animals that could be called birds as distinct from reptiles, as represented by the pigeon-sized *Archaeopteryx*. There were two important groups of reptiles that lived in the sea, the dolphin-like ichthyosaurs and the long-necked plesiosaurs. Both of these groups had streamlined bodies and limbs beautifully adapted to marine life. Turtles and crocodiles are also found as fossils in Jurassic deposits. *See* Archaeornithes; Pterosauria.

Jurassic mammals, known mainly from their teeth alone, were small and obviously did not compete directly with the dinosaurs. The fish faunas were dominated by the holosteans, characterized by heavy rhombic scales. Their evolutionary successors, the teleosts, probably appeared shortly before the end of the period. *See* Holostei; Teleostei.

Because they are far more abundant, the invertebrate fossil faunas of the sea are of more importance to stratigraphers and paleoecologists than are the vertebrates. By far the most useful for stratigraphic correlation are the ammonites, a group of fossil mollusks related to squids. They were swimmers that lived in the open sea, only rarely braving the fluctuating salinity and temperature of inshore waters. They are characteristically more abundant in marine shales and associated fine-grained limestones. From a solitary family that recovered from near extinction at the close of the Triassic, there radiated an enormous diversity of genera. Many of these were worldwide in distribution, but increasingly throughout the period these was a geographic differentiation into two major realms. The Boreal Realm occupied a northern region embracing the Arctic, northern Europe, and northern North America. The Tethyan Realm, with more diverse faunas, occupied the rest of the world. *See* Limestone; Shale.

With regard to the plant kingdom, the Jurassic might well be called the age of gymnosperms, the nonflowering “naked seed” plants, forests of which covered much of the land. They included the conifers, gingkos, and their relatives, the cycads. Ferns and horsetails made up much of the remainder of the land flora. These and others of the Jurassic flora are still extant in much the same forms. *See* Cycadales; Ginkgoales.

Jurassic source rocks in the form of organic-rich marine shale and associated rocks contain a significant proportion of the world’s petroleum reserves. A familiar example is the Upper Jurassic Kimmeridge Clay of the North Sea, and its stratigraphic equivalents in western Siberia. Some of the source rocks of the greatest petroleum field of all, in the Middle East, are also of Late Jurassic age. *See* Mesozoic; Petroleum geology. [A.Ha.]

Jute A natural fiber obtained from two Asiatic species, *Corchorus capsularis* and *C. olitorius*, of the plant family Tiliaceae. These are tall, slender, half-shrubby annuals, 8–12 ft (2.5–3.5 m) tall. The fibers are not very strong and deteriorate quickly in the presence of moisture, especially salt water. Despite these weaknesses, jute is much used. It is inexpensive and easily spun and converted into coarse fabrics. It is made into gunny, burlap bags, sacks for wool, potato sacks, covers for cotton bales, twine, carpets, rug cushions, curtains, and a linoleum base. It is also used in making coarse, cheap fabrics, such as novelty dress goods. Most of the commercial supply comes from plants grown in the Ganges and Brahmaputra valleys in Bangladesh and India. *See* Fiber crops; Malvales; Natural fiber.

A number of diseases that affect jute cause losses in yield and reduce fiber quality. “Runner” and “specky” fiber are primarily due to disease-producing organisms. The fungus *Macrophomina phaseolina* is believed to cause the most serious disease of the two species of jute. *See* Plant pathology. [E.G.N.; T.E.S.]

K

Kale Either of two cool-season biennial crucifers, *Brassica oleracea* var. *acephala* and *B. fimbriata*, of Mediterranean origin and belonging to the plant order Capparales. Kale is grown for its nutritious green curled leaves which are cooked as a vegetable. Distinct varieties (cultivars) are produced in Europe for stock feed. Kale is a minor vegetable in the United States. Virginia is an important producing state. *See* Capparales. [H.J.C.]

Kaliophilite A rare mineral tectosilicate found in volcanic rocks high in potassium and low in silica. Kaliophilite is one of three polymorphic forms of $KAlSiO_4$. It crystallizes in the hexagonal system in prismatic crystals. The hardness is 6 on Mohs scale, and the specific gravity is 2.61. The principal occurrence of kaliophilite is at Monte Somma, Italy. *See* Kalsilite; Silicate minerals. [C.S.Hu.]

Kalsilite A rare mineral found in volcanic rocks at Mafuru, in southwest Uganda. It is one of the three polymorphic forms of $KAlSiO_4$. The mineral is hexagonal. The specific gravity is 2.59. In index of refraction and general appearance in thin section it resembles nepheline and is difficult to distinguish from it. *See* Kaliophilite; Silicate minerals. [C.S.Hu.]

Kame A round hill or small knoll of sand and gravel, a few meters to more than 100 m high (330 ft). It is one of a family of stratified glacial sediments formed by meltwater in contact with a disintegrating ice sheet. Melting stagnant ice produces large volumes of water carrying boulders, sand, silt, and clay into holes melted in the wasting glacier. When the ice melts completely, the sediment is left standing as small hills. Mixtures of loose rock debris (till) carried above in the melting ice may be lowered onto the kame. Kames are common wherever ice sheets melted, as in New England, New York, the midwestern United States, the British Isles, and Sweden. [S.E.Wh.]

Kangaroo The name for a number of Australian marsupials that are members of the family Macropodidae. This family also includes the wallabies. The kangaroos and their relatives occur principally in Australia, but are found in Tasmania and New Guinea as well.

Kangaroos have a long, thick tail that is used as a balancing organ, and enlarged hindlegs that are adapted for jumping in many species. The forelimbs are quite short, except in arboreal species such as the blacktree kangaroo (*Dendrolagus ursinus*) and its relatives, in which all four limbs are about the same length. The two largest species are the red kangaroo (*Macropus rufus*) and the great gray kangaroo (*M. giganteus*).

Kangaroos usually have one offspring each year. After the uterine gestation period of about 6 weeks, the very immature young is born and crawls into the marsupium. After an uninterrupted period of 2 months, it ventures out to find food and then returns to the safety of the marsupium. It may seek the protection of the pouch for up to 9 months. *See* Marsupialia. [C.B.C.]

Kaolinite A common hydrous aluminum silicate mineral found in sediments, soils, hydrothermal deposits, and sedimentary rocks. It is a member of a group of clay minerals called the kaolin group minerals, which include dickite, halloysite, nacrite, ordered kaolinite, and disordered kaolinite. These minerals have a theoretical chemical composition of 39.8% alumina, 46.3% silica, and 13.9% water [$Al_2Si_2O_5(OH)_4$], and they generally do not deviate from this ideal composition. They are sheet silicates comprising a single silica tetrahedral layer joined to a single alumina octahedral layer. Although the kaolin group minerals are chemically the same, each is structurally unique as a result of how these layers are stacked on top of one another. Kaolinite is the most common kaolin group mineral and is an important industrial commodity used in ceramics, paper coating and filler, paint, plastics, fiberglass, catalysts, and other specialty applications. *See* Clay minerals; Silicate minerals. [J.E.K.]

Kapitza resistance A resistance to the flow of heat across the interface between liquid helium and a solid. A temperature difference is required to drive heat from a solid into liquid helium, or vice versa; the temperature discontinuity occurs right at the interface. The Kapitza resistance, discovered by P. L. Kapitza, is defined in the equation below, where T_S and T_H

$$R_K = \frac{T_S - T_H}{\dot{Q}/A}$$

are the solid and helium temperatures and $\dot{Q}/A$ is the heat flow per unit area across the interface. *See* Conduction (heat).

In principle, the measured Kapitza resistance should be easily understood. In liquid helium and solids (such as copper), heat is carried by phonons, which are thermal-equilibrium sound waves with frequencies in the gigahertz to terahertz region. The acoustic impedance of helium and solids can differ by up to 1000 times, which means that the phonons mostly reflect at the boundary, like an echo from a cliff face. This property together with the fact that the number of phonons dies away very rapidly at low temperatures means that at about 1 K there are few phonons to carry heat and even fewer get across the interface. The prediction is that the Kapitza resistance at the interface is comparable to the thermal resistance of a 10-m (30-ft) length of copper with the same cross section. *See* Acoustic impedance; Phonon; Quantum acoustics.

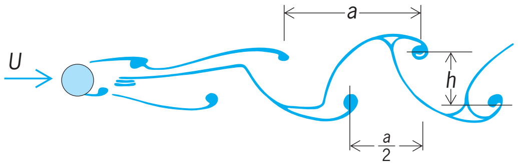
The reality is that above 0.1 K and below 0.01 K (10 mK) more heat is driven by a temperature difference than is predicted. Above 0.1 K this is now understood to be a result of imperfections such as defects and impurities at the interface, which scatter the phonons and allow greater transmission. *See* Crystal defects.

The enormous interest in ultralow-temperature (below 10 mK) research generated by the invention of the dilution refrigerator and the discovery of superfluidity in liquid helium-3 (^3He) below 0.9 mK also regenerated interest in Kapitza resistance, because heat exchange between liquid helium and solids was important for both the dilution refrigerator and superfluidity research. An ingenious technique was invented to overcome the enormous Kapitza resistance at 1 mK: The solid is powdered, and the powder is packed and sintered to a spongelike structure to enhance the surface area. In this way a 1-cm^3 (0.06-$in.^3$) chamber can contain up to 1 m^2 (10 ft^2) of interface area between the solid and the liquid helium.

It was found that at 1 mK the Kapitza resistance is 100 times smaller than predicted by the phonon model. There have been two explanations for the anomaly, and probably both are relevant. One is that energy is transferred by magnetic coupling between the magnetic ^{3}He atoms and magnetic impurities in the solid or at the surface of the solid; the other is that the spongelike structure has quite different, and many more, phonons than a bulk solid and that these can transfer heat directly to the ^{3}He atoms. Whatever its cause, this anomaly has had a major impact on ultralow-temperature physics. *See* Adiabatic demagnetization; Liquid helium; Low-temperature physics; Superfluidity. [J.P.Ha.]

Kapok tree Also called the silk-cotton tree (*Ceiba pentandra*), a member of the bombax family (Bombacaceae). The tree has a bizarre growth habit and produces pods containing seeds covered with silky hairs called silk cotton. It occurs in the American tropics, and has been introduced into Java, Philippine Islands, and Ceylon. The silk cotton is the commercial kapok used for stuffing cushions, mattresses, and pillows. *See* Malvales. [P.D.St./E.L.C.]

Kármán vortex street A double row of line vortices in a fluid. Under certain conditions a Kármán vortex street is shed in the wake of bluff cylindrical bodies when the relative fluid velocity is perpendicular to the generators of the cylinder, as illustrated.



Kármán vortex street. *U* = stream speed; *a* = spacing between vortices; *h* = distance between two rows of vortices.

This periodic shedding of eddies occurs first from one side of the body and then from the other, an unusual phenomenon because the oncoming flow may be perfectly steady. Vortex streets can often be seen, for example, in rivers downstream of the columns supporting a bridge. They can be created by steady winds blowing past smokestacks, transmission lines, bridges, missiles about to be launched vertically, and pipelines aboveground in the desert. *See* Vortex. [A.E.Br.]

Karst topography Distinctive associations of third-order, erosional landforms indented into second-order structural forms such as plains and plateaus. They are produced by aqueous dissolution, either acting alone or in conjunction with (and as the trigger for) other erosion processes. Karst is largely restricted to the most soluble rocks, which are salt, gypsum and anhydrite, and limestone and dolostone. *See* Dolomite rock; Gypsum; Limestone.

The essence of the karst dynamic system is that meteoric water (rain or snow) is routed underground, because the rocks are soluble, rather than flowing off in surface river channels. It follows that dissolutional caves develop in fracture systems, resurging as springs at the margins of the soluble rocks or in the lowest places. A consequence is that most karst topography is “swallowing topography,” assemblages of landforms created to deliver meteoric water down to the caves.

Karst landforms develop at small, intermediate, and large scales. Karren is the general name given to small-scale forms—varieties of dissolutional pits, grooves, and runnels. Individuals are rarely greater than 10 m (30 ft) in length or depth, but assemblages of them can cover hundreds of square kilometers. On bare rock, karren display sharp edges; circular pits or runnels extending downslope predominate. Beneath soil, edges are rounded and forms more varied and intricate.

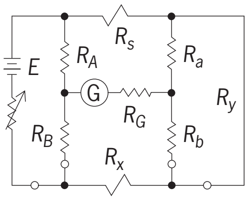
Sinkholes, also known as dolines or closed depressions, are the diagnostic karst (and pseudokarst) landform. They range from shallow, bowllike forms, through steep-sided funnels, to vertical-walled cylinders. Asymmetry is common. Individual sinkholes range from about 1 to 1000 m (3 to 3300 ft) in diameter and are up to 300 m (1000 ft) deep. Many may become partly or largely merged.

Dry valleys and gorges are carved by normal rivers, but progressively lose their water underground (via sinkholes) as the floors become entrenched into karst strata. Many gradations exist, from valleys that dry up only during dry seasons (initial stage) to those that are without any surface channel flow even in the greatest flood periods (paleo-valleys). They are found in most plateau and mountain karst terrains and are greatest where river water can collect on insoluble rocks before penetrating the karst (allogenic rivers).

Poljes, a Serbo-Croatian term for a field, is the generic name adopted for the largest individual karst landform. This is a topographically closed depression with a floor of alluvium masking an underlying limestone floor beveled flat by planar corrosion.

Karst plains and towers are the end stage of karst topographic development in some regions, produced by long-sustained dissolution or by tectonic lowering. The plains are of alluvium, with residual hills (unconsumed intersinkhole limestone) protruding through. Where strata are massively bedded and the hills are vigorously undercut by seasonal floods or allogenic rivers, they may be steepened into vertical towers. [D.Fo.]

Kelvin bridge A specialized version of the Wheatstone bridge network designed to eliminate, or greatly reduce, the effect of lead and contact resistance and thus permit accurate measurement of low resistance. The circuit shown in the illustration accomplishes this by effectively placing relatively high-resistance-ratio arms in series with the potential leads and contacts of the low-resistance standards and the unknown resistance. In this circuit R_A and R_B are the main ratio resistors, R_a and R_b the auxiliary ratio, R_x the unknown, R_s the standard, and R_y a heavy copper yoke of low resistance connected between the unknown and standard resistors.



A Kelvin bridge used to measure an unknown low resistance.

As with the Wheatstone bridge, the Kelvin bridge for routine engineering measurements is constructed using both adjustable-ratio arms and adjustable standards. However, the ratio is usually continuously adjustable, over a short span, and the standard is adjustable in appropriate steps to cover the required range. *See* Bridge circuit; Resistance measurement; Wheatstone bridge. [C.E.A.]

Kelvin’s circulation theorem A theorem in fluid dynamics that pertains to the dynamics of vortices and the use of ideal-fluid potential-flow equations. The theorem states that the circulation (defined as the line integral of the component of velocity tangential to the closed contour) in an inviscid and incompressible fluid subject to only conservative forces is constant. By using Stokes’ theorem of integral calculus, it may be shown that the circulation is also related to the flux of vorticity (defined as the curl of the velocity field) normal to the area transcribed by the contour. *See* Calculus of vectors; Stokes’ theorem.

The principal use of Kelvin's theorem is in the study of incompressible, inviscid fluid flows. If a body is moving through such a fluid, the vorticity far from the body is, by definition, zero. Then according to Kelvin's theorem, the vorticity in the fluid will everywhere be zero and the flow will be irrotational. This permits the reduction of the governing equations from the Euler equations to the Laplace equation and presents the many mathematical techniques of potential theory for solving fluid-flow problems. *See* LAPLACE'S IRROTATIONAL MOTION; VORTEX. [E.Pa.; F.Ste.]

Kelvin's minimum-energy theorem A theorem in fluid dynamics that pertains to the kinetic energy of an ideal fluid (that is, inviscid, incompressible, and irrotational) and provides uniqueness statements concerning the solution of potential-flow problems. The theorem states that the irrotational motion of a liquid occupying a simply connected region has less kinetic energy than any other motion consistent with the same normal motion of the boundary S. *See* GREEN'S THEOREM; POTENTIALS.

The implications of the minimum-energy of irrotational motion are: (1) irrotational motion is impossible in a simply connected region bounded by fixed walls since in this case the normal derivative of the velocity potential vanishes at all points on the boundary, and therefore, according to the energy theorem, the kinetic energy is zero, or the system is at rest; (2) irrotational motion is impossible in a fluid in which the velocity at infinity vanishes if the internal boundaries are also at rest; (3) if the velocity at infinity vanishes, then the irrotational motion due to prescribed motion of an internal boundary is unique; and (4) if a fluid is in motion with uniform velocity at infinity, then the irrotational motion due to prescribed motion of an internal boundary is unique. *See* FLUID-FLOW PRINCIPLES; LAPLACE'S IRROTATIONAL MOTION. [E.Pa.; F.Ste.]

Kenaf An annual, short-day, herbaceous plant (*Hibiscus cannabinus*) of the Malvaceae family, cultivated for its stem fibers. The genus *Hibiscus* has approximately 200 species, of which one, roselle (*H. sabdariffa* var. *altissima*), also is occasionally referred to as kenaf.

Kenaf usually grows up to 15 ft (5 m) in height, and is cylindrical and either branched or unbranched. The stem is composed of two fibers, bast and core. The bast fibers, located in the bark, are long compared to the core fibers, produced in the stem interior. The leaves either are entirely heart shaped or display radiating lobes. Flowers are typically yellow with deep red centers. Wild forms of kenaf are found in east and central Africa, where for several centuries kenaf has been used for both fiber and food. Selection and breeding have developed varieties with higher fiber yields, improved disease resistance, and reduced branching.

Kenaf is grown commercially for fiber production in many areas of the world, with the largest producer being the People's Republic of China. In the United States, kenaf production is located in Texas, Louisiana, Mississippi, and California. Kenaf is used in the manufacturing of various paper and pulp products, and as poultry litter, potting soil amendments, chemical- and oil-spill absorbents, animal and horse bedding, and packing materials. Potential uses include the manufacturing of filters, particle boards, and insulation boards. Kenaf leaves, which contain 20–30% crude protein, also may have potential as a livestock feed source.

Kenaf can adapt to a wide range of climates and soils. However, because it cannot tolerate frost, planting should not occur at temperatures below 32°F (0°C). Optimum yields are generally obtained on well-drained soils with fertility levels to meet the nutritional requirements. Most varieties of kenaf are photoperiod sensitive, and vegetative growth increases until the daylight period becomes less than 12 h 30 min. Flowering is then initiated and the vegetative growth rate declines. Early planting maximizes yields by increasing the growing season. Kenaf is propagated by seed and must be replanted annually. Dense plant populations generally produce greater total and bast fiber yields, reduce weed populations, and improve harvesting efficiency. [C.G.C.]

Kennel cough A common, highly contagious respiratory disease of dogs, also known as canine infectious tracheobronchitis. Several different bacteria and viruses are usually associated with the disease. Symptoms are generally mild but may vary widely depending on the agent, the host, and environmental factors. The main feature of the disease is sudden onset of violent coughing in dogs that had a recent exposure to other, infected dogs. The disease is easily transmitted between dogs by droplets in the air or direct contact, and often occurs as outbreaks or as a seasonal infection. Most dogs completely recover within 2 weeks; however, chronic and severe forms of the disease sometimes occur.

Infectious agents commonly associated with the disease are the bacterium *Bordetella bronchiseptica* and canine parainfluenza virus. Each agent is capable of producing a mild form of the disease; however, most single-agent infections probably show no symptoms of disease. Several species of mycoplasmas have been isolated from the lower respiratory tract of dogs with kennel cough, but always in combination with another agent (for example, bordetella or canine parainfluenza virus). These mycoplasmas are normally found in the upper respiratory tract of healthy dogs. *See* BORDETELLA; MYCOPLASMAS.

Close contact with other dogs is usually required for transmission of kennel cough. Each of the viral agents of the disease, and possibly some of the mycoplasmas, has host ranges restricted to dogs. Because infections that show no symptoms of disease are also common, it is sometimes difficult to determine the source of the infection. Canine parainfluenza virus and *B. bronchiseptica* do not usually persist longer than a few weeks or a few months, respectively, in an individual dog.

Treatment of kennel cough is often unwarranted. However, antitussives, bronchodilators, and corticosteroids are used to relieve coughing, and antimicrobials are used to treat or prevent bronchopneumonia. The risk of acquiring kennel cough can be reduced by minimizing exposure to infectious agents. [D.A.Be.]

Kepler's laws The three laws of planetary motion discovered by Johannes Kepler during the early years of the seventeenth century.

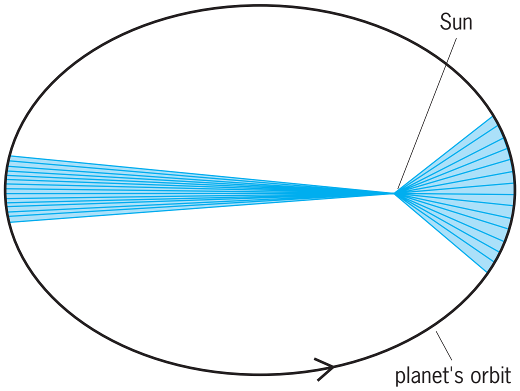
First law. The first law of Kepler states that a planet moves in an elliptical orbit around the Sun that is located at one of the two foci of the ellipse. An ellipse is one of the conic curves originally studied by Greek geometers. *See* CONIC SECTION; ELLIPSE.

In 1687, Isaac Newton demonstrated that any body, moving in an orbit around another body that attracts it with a force that varies inversely as the square of the distance between them, must move in a conic section. This path will be an ellipse when the velocity is below a certain limit in relation to the attracting force. Thus the first law is a general law that applies to all satellites held in orbit by an inverse-square force.

Second law. Kepler needed some method by which to predict the locations of planets at given times, and this he provided with his second law. It states that the radius vector of the ellipse (the imaginary line between the planet and the Sun) sweeps out areas that are proportional to time (see illustration). A planet moves more swiftly when it is closer to the Sun and more slowly when it is farther removed.

Again Newton demonstrated the dynamic cause behind Kepler's second law. In this case, it is not restricted to forces that vary inversely as the square of the distance; rather it is valid for all forces of attraction between the two bodies. The second law expresses the principle of the conservation of angular momentum. *See* ANGULAR MOMENTUM.

Third law. Kepler's third law defines the relations that hold within the system of planets. It states that the ratio between the square of a planet's period (the time required to complete one orbit) to the cube of the mean radius (the average distance from



Demonstration of Kepler's first and second laws. The planet moves along an elliptical orbit at a nonuniform rate, so that the radius vector drawn to the Sun, which is located at one focus of the ellipse, sweeps out areas that are proportional to time. Thus, the planet would take equal times (corresponding to the equal areas) to traverse the unequal distances along the ellipse that correspond to the two shaded areas. The diagram greatly exaggerates the eccentricity of any orbital ellipse in the solar system.

the Sun during one orbit) is a constant. The four satellites that Galileo had discovered around Jupiter were found to obey the third law, as did the satellites later found around Saturn. Newton demonstrated once again that the third law is valid for every system of satellites around a central body that attracts them, as the Sun attracts the planets, with a force that varies inversely as the square of the distance. *See* GRAVITATION; ORBITAL MOTION. [R.S.We.]

Kernite A hydrated borate mineral with chemical composition $Na_2B_4O_6(OH)_2 \cdot 3H_2O$. It occurs only very rarely in crystals but is found most commonly in coarse, cleavable masses and aggregates. It is colorless to white; colorless and transparent specimens tend to become chalky white on exposure to air.

Boron compounds are used in the manufacture of glass, especially in glass wool used for insulation purposes. They are also used in soap, in porcelain enamels for coating metal surfaces, and in the preparation of fertilizers and herbicides. *See* BORATE MINERALS. [C.K.]

Kerogen The complex, disseminated organic matter present in sedimentary rocks that remains undissolved by sequential treatment with common organic solvents followed by treatment with nonoxidizing mineral hydrochloric acid and hydrofluoric acid. *See* SEDIMENTARY ROCKS.

Kerogen is considered to be the major starting material for most oil and gas generation as sediments are subjected to geothermal heating in the subsurface. It is the most abundant form of organic carbon on Earth—about 1000 times more abundant than coal, which forms primarily from terrigenous remains of higher plants. Kerogen is formed from the remains of marine and lacustrine microorganisms, plants and animals, and variable amounts of terrigenous debris in sediments. The terrestrial portions of kerogen have elemental compositions similar to coal. *See* COAL.

Kerogens are classified according to their atomic ratios of hydrogen to carbon (H/C) and oxygen to carbon (O/C), with oil-prone kerogens being generally higher in H/C and lower in O/C than the gas-prone kerogens. With increasing length of exposure to subsurface temperatures, all kerogens show decreases in the O/C and H/C ratios as they generate preferentially carbon dioxide and water, then oil, and finally only gas (methane) at progressively higher subsurface depths and temperatures. *See* NATURAL GAS; PETROLEUM. [J.K.W.]

Kerosine A refined petroleum fraction used as a fuel for heating and cooking, jet engines, lamps, and as a base for insecticides. Kerosine, known also as lamp oil, is recovered from crude oil by distillation. Specifications are established for specific grades of kerosine by government agencies and by refiners. For use in lamps, for example, a highly paraffinic oil is desired because aromatics and naphthenes give a smoky flame. In order to avoid atmospheric pollution, sulfur content must be low; and a minimum flash point of 100°F (38°C) is desirable to reduce explosion hazards. *See* JET FUEL. [H.C.R.]

Kerr effect Electrically induced birefringence that is proportional to the square of the electric field. When a substance (especially a liquid or a gas) is placed in an electric field, its molecules may become partly oriented. This renders the substance anisotropic and gives it birefringence, that is, the ability to refract light differently in two directions. This effect, which was discovered in 1875 by John Kerr, is called the electrooptical Kerr effect, or simply the Kerr effect.

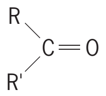
When a liquid is placed in an electric field, it behaves optically like a uniaxial crystal with the optical axis parallel to the electric lines of force. The Kerr effect is usually observed by passing light between two capacitor plates inserted in a glass cell containing the liquid. Such a device is known as a Kerr cell or optical Kerr shutter. Light passing through the medium normal to the electric lines of force (that is, parallel to the capacitor plates) is split into two linearly polarized waves.

In certain crystals there may be an electrically induced birefringence that is proportional to the first power of the electric field. This is called the Pockels effect. In these crystals the Pockels effect usually overshadows the Kerr effect, which is nonetheless present. In crystals of cubic symmetry and in isotropic solids (such as glass) only the Kerr effect is present. *See* ELECTROOPTICS. [M.A.D.]

Ketene A member of a class of organic compounds with the C=C=O group as a common structural element. Ketenes are derivatives of carboxylic acids, from which they are (hypothetically) formed by abstraction of water; they can therefore be considered to be inner anhydrides of acids, as opposed to the common carboxylic acid anhydrides formed from two molecules of a carboxylic acid.

Like real anhydrides, ketenes are acylating agents which readily undergo reactions with many compounds containing active hydrogens. They are relatively labile compounds, and only a limited number have been prepared and isolated. Many ketenes have been prepared in place and reacted immediately. *See* ACID ANHYDRIDE. [R.H.Ri.]

Ketone One of a class of chemical compounds of the general formula



R and R′ are alkyl, aryl, or heterocyclic radicals. The groups R and R′ may be the same or different or incorporated into a ring as in cyclopentanone:

$$\underbrace{CH_2CH_2CH_2CH_2C}=O$$

The ketones acetone and methyl ethyl ketone are used as solvents. Ketones are important intermediates in the syntheses of organic compounds.

By common nomenclature rules, the R and R′ groups are named, followed by the word ketone—for example, $CH_3CH_2COCH_2CH_3$ (diethyl ketone), $CH_3COCH(CH_3)_2$ (methyl isopropyl ketone), and $C_6H_5COC_6H_5$ (diphenyl ketone). The nomenclature of the International Union of Pure and Applied Chemistry uses the hydrocarbon name corresponding to the maximum number of carbon atoms in a continuous chain in the ketone molecule, followed by "-one," and preceded by a number designating the position of the carbonyl group in the carbon chain. The first two ketones above are named 3-pentanone and 3-methyl-3-butanone.

The lower-molecular-weight ketones are colorless liquids. Acetone and methyl ethyl ketone are miscible with water; the water solubility of the higher homologs decreases with increasing number of carbon atoms. Because of their characteristic odors, various ketones are of use in the flavoring and perfumery industry.

Addition to the carbonyl group is the most important type of ketone reaction. Ketones are generally less reactive than aldehydes in addition reactions. Methyl ketones are more reactive than the higher ketones because of steric group effects. [P.E.F.]

Key telephone system A communications system that allows users to access more than one central office line, answer or access a central office line from more than one telephone, and place a line on hold in order to answer or initiate calls on other lines. The system usually includes an intercom capability that allows users on different telephones in the system to communicate with one another. *See* INTERCOMMUNICATING SYSTEM.

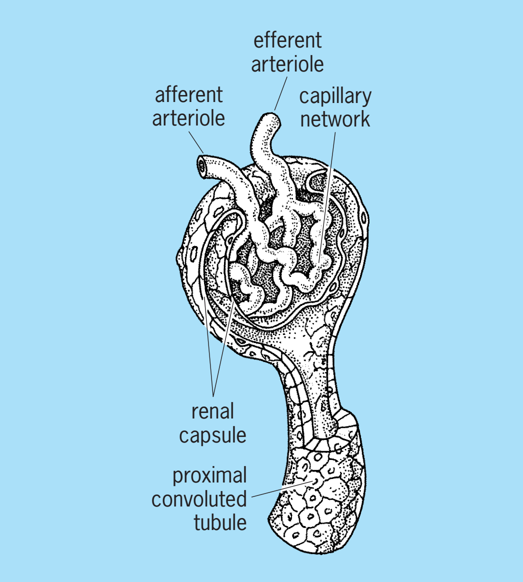
The main functional parts of a key telephone system are (1) the central service unit, also called the key service unit (KSU), which serves as an interface and switching center between incoming central office lines and system telephones; (2) station cabling to connect each telephone to the key service unit; (3) multibutton telephone sets, or key telephones, on which separate buttons provide access to the central office lines, intercom, and special features; and (4) a power supply, which converts available electrical power to the specifications required by the key telephone system.

The number of station lines and central office lines served by a key telephone system is limited by the size of the key service unit. On a typical key telephone system, each incoming central office line appears on a separate button on every key telephone set that is allowed to make or receive calls on that line. Usually, a visual indicator, such as a small incandescent lamp or light-emitting diode, allows the user to tell if the line is in use. The same lamp flashes at a certain rate when an incoming call is ringing on the line, and flashes at a different rate when a call is on hold. The number of lines that appear on every key telephone set varies with the capacity of buttons on each set. Such capacities vary from a low of 5 buttons to over 30 buttons, depending on the make and model of the key telephone system.

Key telephone systems are either electromechanical or electronic in design. Electronic key telephone systems use microprocessors and integrated circuits to accomplish the switching, voice amplification, and feature activation. *See* INTEGRATED CIRCUITS; MICROPROCESSOR; SWITCHING SYSTEMS (COMMUNICATIONS); TELEPHONE SERVICE. [S.R.R.; V.F.R.]

Kidney An organ involved with the elimination of water and waste products from the body. In vertebrates the kidneys are paired organs located close to the spine dorsally in the body cavity. They consist of a number of smaller functional units called urinary tubules or nephrons. The nephrons open to large ducts, the collecting ducts, which open into a ureter. The two ureters run backward to open into the cloaca or into a urinary bladder. In mammals, the kidneys are bean-shaped and found between the thorax and the pelvis. The number, structure, and function of the nephrons vary with evolution and, in certain significant ways, with the adaptation of the animals to their various habitats.

In its most primitive form, found only in invertebrates, the nephron has a funnel opening into the coelomic cavity followed by a urinary tubule leading to an excretory pore. In amphibians, some of the tubules have this funnel, but most of the tubules have a Bowman capsule (see illustration). In all higher vertebrates, the nephron has the Bowman capsule, which surrounds a tuft of capillary loops, called the glomerulus, constituting the closed end of the nephron. The inner epithelial wall of the Bowman capsule is in intimate contact with the endothelial wall of the capillaries. The wall of the capillaries, together with the inner wall of the Bowman capsule, forms a membrane ideally suited for filtration of the blood.



Nephron from frog kidney, dissected to show glomerulus within Bowman capsule.

The blood pressure in the capillaries of the glomerulus causes filtering of blood by forcing fluid, small molecules, and ions through the membrane into the lumen of Bowman's capsule. This filtrate contains some of the proteins and all of the smaller molecules in the blood. As the filtrate passes down through the tubule, the walls of the tubule extract those substances not destined for excretion and return them to the blood in adjacent capillaries. Many substances which are toxic to the organism are moved in the opposite direction from the blood into the tubules. The urine thus produced by each nephron is conveyed by the collecting duct and ureter to the cloaca or bladder from which it can be eliminated.

In all classes of vertebrates the renal arteries deliver blood to the glomeruli and through a second capillary net to the tubules. The major blood supply to the kidney tubules comes, however, from the renal portal vein, which is found in all vertebrates except mammals and cyclostomes. Waste products from the venous blood can thus be secreted directly into the urinary tubules. *See* URINARY SYSTEM. [B.S.N.]

Kidney disorders Disorders of the kidney are classified by both their etiology and their anatomic location along the nephron. Disorders other than those arising from tumors become evident when the kidney is unable to regulate the volume and composition of the extracellular fluids, resulting in edema and hypertension. Kidney disorders may be divided into the following categories: congenital, inflammatory, hereditary, infection-related, or associated with metabolic diseases (such as diabetes mellitus), toxins or drugs, circulatory collapse, and cancer.

The absence of kidneys at birth, which is quite rare, is incompatible with life. A slightly more common condition, however, is the presence of only one kidney or the presence of one kidney in an abnormal location. The most common congenital disorders are abnormalities in the peristaltic passage of urine, which normally flows from the kidneys into the ureters, where it is moved by a rhythmic peristaltic motion to the bladder. In many cases, diseases that inhibit the normal peristaltic flow of urine down the ureters because of a neuromuscular abnormality gradually run their course and do not require surgery. *See* CONGENITAL ANOMALIES.

The most common hereditary kidney disorder is adult polycystic kidney disease. It is an autosomal dominant disease that is found in all racial and ethnic groups and is characterized by the formation of cysts along the length of the nephron. As the cysts enlarge, the kidneys likewise enlarge—resulting in kidney failure in midadulthood. Alport's syndrome, a very rare genetic disease of the glomeruli, results in glomerular scarring and eventual renal failure within the second or third decade of life that cannot be reversed. *See* HUMAN GENETICS.

The kidneys are subject to infection from both local and remote sources and from a variety of causative organisms. The most common cause of pyelonephritis, a bacterial infection of the kidney, is obstruction of the bladder or ureters by a tumor or kidney stones that interrupt urine flow. The kidney may also be subject to infections originating at distant sites. Examples include bacterial products, such as endotoxins, that are released into the bloodstream and antibodies that are formed in response to bacterial invasion. *See* STREPTOCOCCUS.

The most common metabolic disorder to affect the kidney is diabetes mellitus. Of those persons with the insulin-dependent form of diabetes, 30–40% develop renal disease. Kidney dysfunction is one of the most life-threatening complications of diabetes. *See* DIABETES.

The two most common systemic diseases to affect the kidneys are systemic lupus erythematosus and vasculitis. Systemic lupus erythematosus is essentially a disease of young women and is characterized by the deposition of immunoglobulins and other immune substances in the glomeruli. Systemic vasculitis can affect either the medium-sized arteries or the arterioles. Involvement of the former leads to infarcts in various organs but seldom causes kidney failure. When the arterioles are affected, the lesions are diffuse, because the kidney is highly vascular and the arterioles, the smallest of the arteries, are abundant. Kidney failure often occurs.

The kidney is a major site for the excretion of waste products as well as heavy metals, the acids and alkalies of metabolism, and drugs. Because the urine becomes concentrated (100-fold) as it travels the length of the tubule, the concentration of otherwise-innocuous, or even therapeutic, substances may reach levels that are toxic to the kidneys. *See* TOXICOLOGY.

If systemic blood pressure drops to levels at which the kidneys are no longer perfused, the tubules become deprived of oxygen and suffer severe injury. The most common causes of underperfusion are blood loss and cardiac failure. If bloodflow to the kidneys is restored, epithelial cell damage is rapidly reversed and renal function returns to normal.

Cancer of the kidney occurs mainly in two age groups—the very young and those over 50 years of age. Tumors found in the young, the most common type being Wilms' tumor, are often bilateral, composed of fetal tissues, and may grow to a large size before detection. Some cancerous tumors of the kidney in children are responsive to radiation or chemotherapy. Tumors in the adult kidney, adenocarcinomas or hypernephromas, usually metastasize to the lungs and bones. *See* CANCER (MEDICINE); KIDNEY; URINARY SYSTEM. [G.S.]

Kiln A device or enclosure to provide thermal processing of an article or substance in a controlled temperature environment or atmosphere, often by direct firing, but occasionally by convection or radiation heat transfer. Kilns are used in many different industries, and the type of device called a kiln varies with the industry.

"Kiln" usually refers to an oven or furnace which operates at sufficiently high temperature to require that its walls be constructed of refractory materials. The distinction between a kiln and a furnace is often based more on the industry than on the design of the device. Generally the word "kiln" is used when referring to high-temperature treatment of nonmetallic materials such as in the ceramic, the cement, and the lime industries. When melting is involved as in steel manufacture, the term "furnace" is used, as in blast furnace and basic oxygen furnace. *See* FURNACE. [B.B.Cr.]

Kimberlite A variety of peridotite, an igneous rock containing at least 35% olivine. Kimberlite is richer in carbon dioxide than most peridotites, and has crystals larger in diameter than 0.5 mm of olivine, garnet, clinopyroxene, phlogopite, and orthopyroxene. All of these silicate minerals have high Mg/Fe ratios in kimberlites. Diamonds are the only economically significant mineral extracted from kimberlite. They form deeper than 150 km (93 mi) in the Earth's mantle and are carried upward as "accidental tourists" in kimberlite.

The magmatic liquid that forms kimberlite is generated by the melting of small amounts of the Earth's upper mantle containing water and carbonate. The liquid moves upward, gathering crystals (including diamond) and rock fragments along the way. During the violent injection of kimberlites into the upper crust, some detached fragments from the crust move downward and others from the lower crust and mantle move upward. Kimberlite bodies are important scientifically because they contain fragments of rocks that were once above the present-day erosion surface as well as fragments of the Earth's mantle.

Kimberlites usually occur in regions of thick and stable continental crust, in southern Africa (including the Kimberley district), India, Siberia, Canada, Colorado-Wyoming, Venezuela, and Brazil. Most kimberlite outcrops appear on the surface as small, roughly circular areas less than 1 km (0.6 mi) in diameter; they are usually not well exposed because kimberlite weathers rapidly. In three dimensions, kimberlite bodies are dikes or, more commonly, downward-tapering cylinders (pipes). *See* DIAMOND; IGNEOUS ROCKS; OLIVINE; PERIDOTITE. [D.S.Ba.]

Kinematics That branch of mechanics which deals with the motion of a system of material particles without reference to the forces which act on the system. Kinematics differs from dynamics in that the latter takes these forces into account. *See* DYNAMICS.

For a single particle moving in a straight line (rectilinear motion), the motion is prescribed when the position of the particle is known as a function of the time. Plane kinematics of a particle is concerned with the specification of the position of a particle moving in a plane by means of two independent variables. The kinematics of a particle in space is concerned with the ways in which three independent coordinates may be chosen to specify the position of the particle at a given time, and with the relations between the first and second time derivatives of these coordinates and the components of velocity and acceleration of the particle.

Among the coordinate systems studied in kinematics are those used by observers who are in relative motion. In nonrelativistic kinematics the time coordinate for each such observer is assumed to be the same, but in relativistic kinematics proper account must be taken of the fact that lengths and time intervals appear different to observers moving relative to each other. *See* RELATIVITY. [H.C.Co./B.G.]

Kinetic methods of analysis The measurement of reaction rates for the analytical determination of the initial concentrations of the species taking part in chemical reactions. This technique can be used since, in most cases, the rates or velocities of chemical reactions are directly proportional to the concentrations of the species taking part in the reactions.

The rate of a chemical reaction is measured by experimentally following the concentration of some reactant or product as a function of time as the mixture proceeds from a nonequilibrium to an equilibrium or static state (steady state). Kinetic techniques of analysis have the inherent problem of the difficulty of making measurements on a dynamic system. However, kinetic methods often have advantages over equilibrium techniques in spite of the increased experimental difficulty. For example, the equilibrium differentiations or distinctions attainable for the reactions of very closely related compounds are often very small and not sufficiently separated to resolve the individual concentrations of a mixture without prior separation. But the kinetic differentiations or distinctions obtained when such compounds are reacted with a common reagent are often quite large and permit simultaneous analysis. *See* CHEMICAL EQUILIBRIUM.

A further advantage of kinetic methods is that they permit a larger number of chemical reactions to be used analytically. Many reactions, both inorganic and organic, are not sufficiently well behaved to be employed analytically by equilibrium or thermodynamic techniques. Many reactions attain equilibrium too slowly; side reactions occur as the reactions proceed to completion, or the reactions are not sufficiently quantitative (do not go to completion) to be applicable. However, a kinetic-based technique can often be employed in these cases simply by measuring the reaction rate of these reactions during the early or initial portion of the reaction period. Also, the measurement of the rates of catalyzed reactions generally is a considerably more sensitive analytical method for the determination of trace amounts of a large number of species than equilibrium methods. *See* CATALYSIS. [H.B.Ma.]

Kinetic theory of matter A theory which states that the particles of matter in all states of aggregation are in vigorous motion. In computations involving kinetic theory, the methods of statistical mechanics are applied to specific physical systems. The atomistic or molecular structure of the system involved is assumed, and the system is then described in terms of appropriate distribution functions. The main purpose of kinetic theory is to deduce, from the statistical description, results valid for the whole system. The distinction between kinetic theory and statistical mechanics is thus of necessity arbitrary and vague. Historically, kinetic theory is the oldest statistical discipline.Today a kinetic calculation refers to any calculation in which probability methods, models, or distribution functions are involved. *See* STATISTICAL MECHANICS.

Kinetic calculations are not restricted to gases, but occur in chemical problems, solid-state problems, and problems in radiation theory. Even though the general procedures in these different areas are similar, there are a sufficient number of important differences to make a general classification useful.

In classical ideal equilibrium problems there are no interactions between the constituents of the system. The system is in equilibrium, and the mechanical laws governing the system are classical. The basic information is contained in the Boltzmann distribution f (also called Maxwell or Maxwell-Boltzmann distribution) which gives the number of particles in a given momentum and positional range ($d^3x = dx dy dz$, $d^3v = dv_x dv_y dv_z$, where x, y, and z are coordinates of position, and v_x, v_y, and v_z are coordinates of velocity). In Eq. (1) ϵ is the energy, $\beta = 1/kT$ (where k is the Boltzmann constant and T is the absolute temperature), and A is a constant determined from Eq. (2). The calculations of gas pressure, specific heat, and the classical equipartition theorem are all based on these relations. *See* BOLTZMANN STATISTICS.

$$f(xyz, v_x v_y v_z) = Ae^{-\beta\epsilon} \qquad (1)$$

$$\int\int d^3x\, d^3v f = N \qquad \text{total number of particles} \qquad (2)$$

Many important physical properties refer not to equilibrium but to nonequilibrium states. Phenomena such as thermal conductivity, viscosity, and electrical conductivity all require a discussion starting from the Boltzmann transport equation. If one deals with states that are near equilibrium, the exact Boltzmann equation need not be solved; then it is sufficient to describe the nonstationary situation as a small perturbation superimposed on an equilibrium state.

The basic classical procedure for arbitrary systems (systems with interactions taken into account) that allows the calculation of macroscopic entities is that using the partition function.

Classical nonideal nonequilibrium theory is the most general situation that classical statistics can describe. In general, very little is known about such systems.

There are quantum counterparts to the classifications just described. In a quantum treatment a distribution function is also used for an ideal system in equilibrium to describe its general properties. For systems of particles which must be described by symmetrical wave functions, such as helium atoms and photons, one has the Bose distribution, Eq. (3), where $\beta = 1/kT$, and A is determined by Eq. (2).

$$f(v_x v_y v_z) = \frac{1}{(1/A)e^{\beta\epsilon} - 1} \qquad (3)$$

See BOSE-EINSTEIN STATISTICS.

For systems of particles which must be described by antisymmetrical wave functions, such as electrons, protons, and neutrons, one has the Fermi distribution, Eq. (4). The application to electrons as an (ideal) Fermi-Dirac gas in a metal is the basis of the Sommerfeld theory of metals. *See* FERMI-DIRAC STATISTICS; FREE-ELECTRON THEORY OF METALS; QUANTUM STATISTICS. [M.Dr.]

$$f(v_x v_y v_z) = \frac{1}{(1/A)e^{\beta\epsilon} + 1} \qquad (4)$$

Kinetics (classical mechanics) That part of classical mechanics which deals with the relation between the motions of material bodies and the forces acting upon them. It is synonymous with dynamics of material bodies. *See* DYNAMICS.

Kinetics proceeds by adopting certain intuitively acceptable concepts which are associated with measurable quantities. These essential concepts and the measurable quantities used for their specification are as follows:

1. Space configuration refers to the positions and orientations of bodies in a reference frame adopted by the observer. It is expressed quantitatively by an arbitrarily chosen set of space coordinates, of which cartesian and polar coordinates are examples. All space coordinates rest on the notion of distance measurement.
2. Duration is expressed quantitatively by time measured by a clock or comparable mechanism.
3. Motion refers to change of configuration with time and is expressed by time rates of coordinate change called velocities and time rates of velocity change called accelerations. The classical assumption that coordinates behave as analytic functions of time permits representation of velocities and accelerations as first and second derivatives, respectively, of the space coordinates with respect to time.
4. Inertia is an attribute of bodies implying their capacity to resist changes of motion. A body's inertia with respect to linear motion is denoted by its mass.
5. Momentum is an attribute proportional to both the mass and velocity of a body. Momentum of linear motion is expressed as the product of mass and linear velocity.
6. Force serves to designate the influence exercised upon the motion of a particular body by other bodies, not necessarily specified. A quantitative connection between the motion of a body and the force applied to it is expressed by Newton's second law of motion, which is discussed later.

Distance, time, and mass are commonly regarded as fundamental, all other dynamical quantities being definable in terms of them.

A primary objective of classical kinetics is the prediction of the behavior of bodies which are subject to known forces when only initial values of the coordinates and momenta are available. This is accomplished by use of a principle first recognized by Isaac Newton. Newton's statement of the principle was restricted to the linear motion of an idealized body called a mass particle, having negligible extension in space.

The basic dynamical law set forth by Newton and known as his second law states that the time rate of change of a particle's linear momentum is proportional to and in the direction of the force applied to the particle. Stated analytically, Newton's second law becomes the differential equation, Eq. (1), in which m represents the particle's mass, v its velocity,

$$\frac{d(mv)}{dt} = F \tag{1}$$

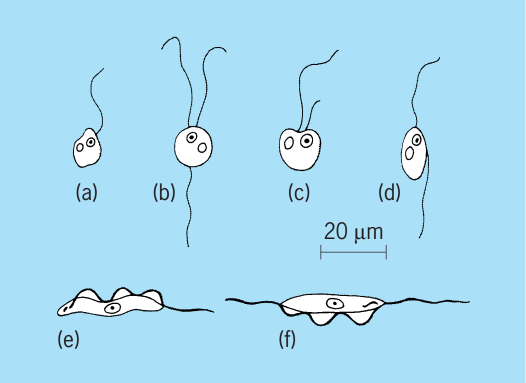
F the applied force, and t the time. Equation (1) provides a definition of force and of its units if units of mass, distance, and time have previously been adopted. The classical assumption of constancy of mass permits Eq. (1) to be expressed as Eq. (2), where a represents the linear acceleration.

$$ma = F \tag{2}$$

The behavior of systems composed of two or more interacting particles is treated by Newtonian dynamics augmented by Newton's third law of motion which states that when two bodies interact, the forces they exert on one another are equal and oppositely directed. The important laws of momentum and energy conservation are derivable for such systems (the latter only for forces of special type) and useful in solution of problems. *See* ACCELERATION; FORCE; GRAVITATION; HARMONIC MOTION; MASS; MOMENTUM; RIGID-BODY DYNAMICS; VELOCITY. [R.A.Fi.]

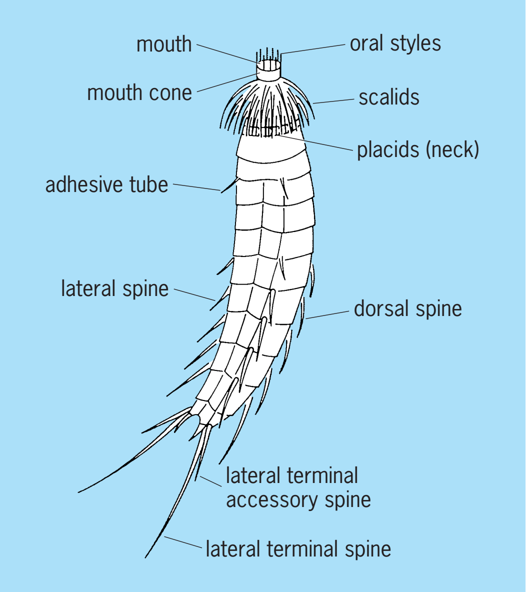
Kinetoplastida An order of the class Zoomastigophorea in the phylum Protozoa, also known as Protomastigida, containing a heterogeneous group of colorless flagellates possessing one or two flagella in some stage of their life cycle. These small organisms (5–89 μm in length) typically have pliable bodies. Some species are holozoic and ingest solid particles, while others are saprozoic and obtain their nutrition by absorption.

There is disagreement on the division of the order into families. However, the five or more families can be divided into two general groups (see illustration). The first group contains simple organisms with no distinctive features save one or two flagella of equal or unequal length (includes the families Oikomonadidae, Amphimonadidae, Monadidae, and Bodonidae). The second group contains organisms which have an undulating membrane in addition to one or two flagella (includes Trypanosomatidae and Cryptobiidae). The most important family is the Trypanosomatidae, since it includes several species that infect humans and domestic animals with serious diseases, such as African sleeping sickness. *See* CILIA AND FLAGELLA; TRYPANOSOMATIDAE. [M.M.B.]



Representative genera of families of order Kinetoplastida. (*a*) *Oikomonas* (family Oikomonadidae), one anterior flagellum. (*b*) *Amphimonas* (family Amphimonadidae), two equally long anterior flagella. (*c*) *Monas* (family Monadidae), two unequally long anterior flagella. (*d*) *Bodo* (family Bodonidae), two unequally long flagella, one of them trailing. (*e*) *Trypanosoma* (family Trypanosomatidae), one flagellum with undulating membrane. (*f*) *Cryptobia* (family Cryptobiidae), two flagella, one free and one with undulating membrane.

Kinorhyncha A phylum of free-living marine invertebrates less than 0.04 in. (1 mm) long. They are segmented and lack external ciliation (see illustration). Kinorhynchs are benthonic, so-called because they generally dwell in mud or sand from intertidal to deep-sea habitats. Two orders are generally recognized, Cyclorhagida and Homalorhagida.



***Echinoderes* sp., a cyclorhagid kinorhynch (ventrolateral view).**

The body is covered by a transparent cuticle secreted by an underlying epidermis. The cuticle is molted only in the process of juvenile growth. Three body regions are recognized: a head segment, a neck segment and an 11-segment trunk. The head is completely retractable. When everted, it extends its five to seven circles of recurved spines called scalids. The neck consists of plates called placids which function to close the anterior opening of the trunk when the head is retracted. Most kinorhynchs have a pair of adhesive tubes on the ventral surface of the third or fourth segment. [R.P.Hi.]

Kirchhoff's laws of electric circuits Fundamental natural laws dealing with the relation of currents at a junction and the voltages around a loop. These laws are commonly used in the analysis and solution of networks. They may be used directly to solve circuit problems, and they form the basis for network theorems used with more complex networks.

One way of stating Kirchhoff's voltage law is: "At each instant of time, the algebraic sum of the voltage rise is equal to the algebraic sum of the voltage drops, both being taken in the same direction around the closed loop."

Kirchhoff's current law may be expressed as follows: "At any given instant, the sum of the instantaneous values of all the currents flowing toward a point is equal to the sum of the instantaneous values of all the currents flowing away from the point." *See* CIRCUIT (ELECTRICITY). [K.Y.T./R.T.W.]

Kite A tethered flying device that supports itself and the cable that connects it to the ground by means of the aerodynamic forces created by the relative motion of the wind. This relative wind may arise merely from the natural motions of the air or may be caused by towing the kite through the agency of its connecting cable.

The lifting force of all kites is produced by deflecting the air downward, the resulting change in momentum producing an upward force. To be successful, a kite must have an extremely low wing loading (weight/area) so that it can fly even on days when the wind velocity is not high. It must be completely stable, since the only controls available to the operator are the length of cable and the rate at which it is taken in or let out. Efficient design requires that its lift-to-drag ratio be as high as possible. *See* AERODYNAMIC FORCE; AERODYNAMICS. [D.C.H.]

Kiwifruit A vigorous deciduous fruiting vine (family Actinidiceae) that is native to central China, where it commonly grows in moist and sheltered areas on the forest edges. Kiwifruit requires both the female cultivar and a male pollenizer for successful fruit production. The kiwifruit industry depends on a single female cultivar, Hayward, the fruit having a creamy-white central core, black-brown seeds, and a bright translucent green outer flesh surrounded by a light-brown fuzzy skin. It is adapted to moderate climates in the temperate zone and requires 600–850 h of winter chilling (temperatures between 32 and 45°F or 0 and 7°C) to ensure uniform bud-break. Kiwifruit wood is susceptible to winter injury at temperatures below 14°F (−10°C), and flower buds can be damaged by frost below 29°F (−1.5°C).

The kiwifruit (*Actinidia deliciosa*) was introduced into cultivation in New Zealand with seed brought from China in 1904, making it one of the most recently domesticated fruiting plants. It appears that all vines now in New Zealand descended from one male and two female plants. The principal kiwifruit-growing countries are Italy, New Zealand, Japan, Chile, France, Greece, United States (California), and Australia.

Kiwifruit is a source of vitamin C, minerals such as potassium, calcium, and phosphorus, and dietary fiber. The primary use is for the fresh market, although culled fruit is processed into canned and frozen fruit slices, wine, jam, juice, and dried products. *See* FRUIT; THEALES. [J.K.Ha]

Klebsiella A genus of gram-negative, nonmotile bacteria. Characteristic large mucoid colonies are due to production of a large amount of capsular material. Species of *Klebsiella* are commonly found in soil and water, on plants, and in animals and humans. Harmless strains of *Klebsiella* are beneficial because they fix nitrogen in soil. Pathogenic species include *K. pneumoniae, K. rhinoscleromatis*, and *K. ozaenae*, also known as *K. pneumoniae* subspecies *pneumoniae, rhinoscleromatis*, and *ozaenae*.

Klebsiella pneumoniae is the second most frequently isolated colon-related bacterium in clinical laboratories. The carbohydrate-containing capsule of *Klebsiella* promotes virulence by protecting the encased bacteria from ingestion by leukocytes; nonencapsulated variants of *Klebsiella* do not cause disease. Capsular types 1 and 2 cause pneumonia; types 8, 9, 10, and 24 are commonly associated with urinary tract infections. *See* ESCHERICHIA; PNEUMONIA.

Klebsiella accounts for a large percentage of hospital-acquired infections, mostly skin infections (in immunocompromised burn patients), bacteremia, and urinary tract infections. It is also the most common contaminant of intravenous fluids such as glucose solutions and other medical devices. *See* HOSPITAL INFECTIONS.

Klebsiella may produce *E. coli*-like enterotoxins and cause acute gastroenteritis in infants and young children. Enteric illnesses due to *Klebsiella* are more predominant where populations are more crowded and conditions less sanitary. Other virulence factors of *Klebsiella* include a relatively high ability to survive and multiply outside the host in a variety of environments, and its relatively simple growth requirements. *See* ENDOTOXIN.

Klebsiella rhinoscleromatis causes rhinoscleroma, a chronic destructive granulomatous disease of the upper respiratory tract that is most common in eastern Europe, central Africa, and tropical South America. *Klebsiella ozaenae* is one cause of chronic rhinitis (ozena), a destructive atrophy of the nasal mucosa, and is infrequently isolated from urinary tract infections and bacteremia. *See* MEDICAL BACTERIOLOGY. [D.J.Ev.]

Klystron An evacuated electron-beam tube in which an initial velocity modulation imparted to electrons in the beam results subsequently in density modulation of the beam. A klystron is used either as an amplifier in the microwave region or as an oscillator.

For use as an amplifier, a klystron receives microwave energy at an input cavity through which the electron beam passes. The microwave energy modulates the velocities of electrons in the beam, which then enters a drift space. Here the faster electrons overtake the slower to form bunches. In this manner, the uniform current density of the initial beam is converted to an alternating current. The bunched beam with its significant component of alternating current then passes through an output cavity to which the beam transfers its ac energy. *See* MICROWAVE.

Klystrons may be operated as oscillators by feeding some of the output back into the input circuit. More widely used is the reflex oscillator in which the electron beam itself provides the feedback. The beam is focused through a cavity and is velocity-modulated there, as in the amplifier. The cavity usually has grids to concentrate the electric field in a short space so that the field can interact with a slow, low-voltage electron beam. Leaving the cavity, the beam enters a region of dc electric field opposing its motion, produced by a reflector electrode operating at a potential negative with respect to the cathode. The electrons do not have enough energy to reach the electrode, but are reflected in space and return to pass through the cavity again. The points of reflection are determined by electron velocities, the faster electrons going farther against the field and hence taking longer to get back than the slower ones. Reflex oscillators are used as signal sources from 3 to 200 GHz. They are also used as the transmitter tubes in line-of-sight radio relay systems and in low-power radars. [R.B.N.]

Knudsen number In gas dynamics, the ratio of the molecular mean free path λ to some characteristic length L: $\mathrm{Kn} = \lambda/L$. The length chosen will depend on the problem under consideration. It may be, for example, the diameter of a pipe or an object immersed in a flow, or the thickness of a boundary layer or a shock wave. *See* MEAN FREE PATH.

The magnitude of the Knudsen number determines the appropriate gas dynamic regime. When the Knudsen number is small compared to unity, of the order of $\mathrm{Kn} \leq 0.1$, the fluid can be treated as a continuous medium and described in terms of the macroscopic variables: velocity, density, pressure, and temperature. In the transition flow regime, for Knudsen numbers of the order of unity or greater, a microscopic approach is required, wherein the trajectories of individual representative molecules are considered, and macroscopic variables are obtained from the statistical properties of their motions. In both internal and external flows, for $\mathrm{Kn} \geq 10$, intermolecular collisions in the region of interest are much less frequent than molecular interactions with solid boundaries, and can be ignored. Flows under such conditions are termed collisionless or free molecular. In the range $0.1 \leq \mathrm{Kn} \leq 1.0$, termed the slip flow regime, it is sometimes possible to obtain useful results by treating the gas as a continuum, but allowing for discontinuities in velocity and temperature at solid boundaries. *See* GAS DYNAMICS; KINETIC THEORY OF MATTER; RAREFIED GAS FLOW. [L.T.]

Koala A single species, *Phascolarctos cinereus*, which is a member of the family Phalangeridae in the mammalian order Marsupialia (pouch-bearing animals). It is a small animal that weighs from 11 to 17 lb (5 to 8 kg) when mature. They are restricted to eastern Australia. Not only do they have a specialized diet of eucalyptus leaves, but the leaves must be of a certain age from a specific species of tree, and the tree must grow upon a certain type of soil.

The koala breeds once each season, and the usual number of offspring is one. It remains in the pouch for 6 months; then it clings to the back of its mother and is carried around in this manner until 1 year old. *See* Mammalia; Marsupialia. [C.B.C.]

Kohlrabi

A cool-season biennial crucifer, *Brassica caulorapa* and *B. oleracea* var. *caulo-rapa*, of northern European origin belonging to the plant order Capparales. Kohlrabi is grown for its turniplike enlarged stem, which is usually eaten as a cooked vegetable (see illustration). A common cooked vegetable in Europe, especially Germany, kohlrabi is of minor importance in the United States. *See* Capparales; Turnip. [H.J.C.]

Kohlrabi (*Brassica caulorapa*), cultivar Early White Vienna. (*Joseph Harris Co., Rochester, New York.*)

Kondo effect

An unusual, temperature-dependent effect displayed in the thermal, electrical, and magnetic properties of nonmagnetic metals containing very small quantities of magnetic impurities. A striking example is the anomalous, logarithmic increase in the electrical resistivity with decreasing temperature. Other properties, such as heat capacity, magnetic susceptibility, and thermoelectric power, also display anomalous behavior because of the Kondo effect. For these properties, the temperature dependence of a typical dilute magnetic metal (Kondo alloy) differs greatly from the behavior expected of an ordinary metal containing no magnetic impurities.

The Kondo effect has been observed in a wide variety of dilute magnetic alloys. Usually these alloys are made from a nonmagnetic host such as copper, silver, gold, magnesium, or zinc and a small amount of a magnetic metal impurity such as chromium, manganese, iron, cobalt, nickel, vanadium, or titanium. Typical concentrations range from about one to a few hundred magnetic atoms per million host atoms. At higher concentrations, the dilute magnetic alloys may display spin-glass behavior. *See* Spin glass.

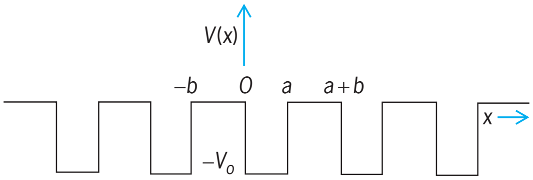
The Kondo effect is used in thermometry applications, especially thermocouple thermometers at very low temperatures (that is, millikelvin temperatures). In other applications where the properties of pure metals are studied, the Kondo effect serves as a useful indicator of the metal's magnetic-impurity level.

The problem of understanding the Kondo effect is considered important since it is recognized to be a simpler version of the more complex problem of understanding ferromagnetism in magnetic materials, which is one of the great challenges in physics. Basically the Kondo effect is an example of the most simple possible magnetic system—a single magnetic atom in a nonmagnetic environment. (The alloys used are so dilute that the interaction between different magnetic impurities can be safely ignored.) Although this involves a simple physical model, the problem has required some of the most sophisticated mathematical techniques known to advance its understanding.

An important step in this direction was the development of a partial mathematical solution of the Kondo problem using renormalization field theory techniques. Information gained in this step helped with the final development of a mathematically exact solution of the Kondo problem. The exact solution permits a systematic calculation of all properties (resistivity, thermal conductivity, thermopower, specific heat, magnetic susceptibility, neutron scattering behavior, and so forth) and provides a physical understanding of these properties. The theoretical work on the Kondo problem has been connected with new understanding in a variety of other scientific disciplines such as condensed-matter physics, surface physics, critical phenomena, elementary particle physics, magnetism, molecular physics, and chemistry, where parallels and analogs to the Kondo problem can be identified and utilized. *See* Critical phenomena; Ferromagnetism; Renormalization. [W.P.K.]

Kronig-Penney model

An idealized, one-dimensional model of a crystal which exhibits many of the basic features of the electronic structure of real crystals. Consider the potential energy $V(x)$ of an electron shown in the illustration with an infinite sequence of potential wells of depth $-V_0$ and width a, arranged with a spacing b. The width and the curvatures of the allowed bands increase with energy. The Kronig-Penney model has been extended to include the effects of impurity atoms. *See* Band theory of solids. [J.C.]



Potential energy which is assumed for the one-dimensional Kronig-Penney model.

Krypton

A gaseous chemical element, Kr, atomic number 36, and atomic weight 83.80. Krypton is one of the noble gases in group 18 of the periodic table. Krypton is a colorless, odorless, and tasteless gas. The table gives some physical properties of krypton. The principal use for krypton is in filling electric lamps and electronic devices of various types. Krypton-argon mixtures are widely used to fill fluorescent lamps. *See* Inert gases; Periodic table.

Physical properties of krypton

Property	Value
Atomic number	36
Atomic weight (atmospheric krypton only)	83.80
Melting point, triple point °C	−157.20
Boiling point at 1 atm pressure, °C	−153.35
Gas density at 0°C and 1 atm pressure, g/liter	3.749
Liquid density at its boiling point, g/ml	2.413
Solubility in water at 20°C, ml krypton (STP) per 1000 g water at 1 atm partial pressure krypton	59.4

The only commercial source of stable krypton is the air, although traces of krypton are found in minerals and meteorites.

A mixture of stable and radioactive isotopes of krypton is produced in nuclear reactors by the slow-neutron fission of uranium. It is estimated that about $2 \times 10^{-8}\%$ of the weight of the Earth is krypton. Krypton also occurs outside the Earth. [A.W.F.]

Kudzu A perennial vine legume, capable of rapid growth in a warm temperate, humid subtropical climate. The name kudzu has a Japanese origin. Kudzu (*Pueraria thunbergiana*) was introduced into the United States in 1876 and used as a shade plant until 1906, when a few enthusiastic growers in the southeastern United States began to use it as a forage crop, a practice that continued for 30 years. It was then promoted as a soil-conserving plant. However, much prejudice developed against its use because of its spread into forest borders, drainage ditches, and other areas.

Tropical kudzu (*P. phaseolides*) is one of the most important and widely planted cover and green manure crops of the tropics. It makes rapid vigorous growth, providing quick ground cover and suppressing most other vegetative growth. It is used as a forage crop although careful management is required to prevent complete domination of mixtures with grasses and other species. *See* LEGUME FORAGES; ROSALES. [P.T.]

Kuiper Belt A vast reservoir of icy bodies in the region of the solar system beyond the orbit of the planet Neptune. Until the discovery, in 1992, of the Kuiper Belt object 1992 QB_1 by David Jewitt and Jane Luu, the trans-Neptunian region of the solar system was thought to contain only the small planet Pluto and its satellite Charon. Members of the belt (Kuiper Belt objects) are the remnants of the original solid building blocks (planetesimals) that went into the formation of the outer planets. They were left behind because they were not incorporated into the planets and, owing to their location far beyond the giant planets, escaped being ejected from the solar system. They are thus relics from the solar nebula, the original disk of gas and dust that gave rise to everything in the solar system, and should preserve records of this early stage of the solar system's evolution. *See* NEPTUNE; PLANET; PLUTO.

In 1951 Gerard Kuiper proposed that perhaps distant planetesimals that did not agglomerate into planets might still exist beyond the planets. (This idea of a trans-Neptunian comet belt was actually first mentioned by K. E. Edgeworth in 1949, and then elaborated by Kuiper.) In the 1980s the concept of the Kuiper Belt was revived as a possible source for the short-period comets, which take less than 200 years to complete one orbit around the Sun. [The long-period comets, whose orbits take longer than 200 years, have long been recognized to come from the Oort Cloud, a large spherical cloud of comets at roughly 10,000 astronomical units (AU) from the Sun.]

Population. The Kuiper Belt starts just beyond Neptune and extends to some as yet unknown outer limit. These objects are not distributed uniformly throughout the belt, but lie in clumps separated by empty space. Based on their orbits, Kuiper Belt objects can be classified into resonance, classical, or scattered.

The Kuiper Belt contains several special areas called mean motion resonances, which are best explained by an example: Located at 39.4 AU, Pluto lies in the 3:2 resonance with Neptune. This means that every time Neptune completes three orbits around the Sun, Pluto completes two orbits around the sun. Resonances act as stable oases in space where members can survive for the age of the solar system. Just as the 3:2 resonance protects Pluto from close encounters with Neptune, it protects other members of the resonance, now called plutinos to highlight their dynamical similarity with Pluto.

The classical Kuiper Belt objects lie outside the resonances and are characterized by near-circular orbits almost in the ecliptic plane. These orbits are what would be expected from the first-generation planetesimals in the solar nebula, suggesting that the classical Kuiper Belt objects are indeed primordial planetesimals that have managed to preserve their original orbits.

The scattered Kuiper Belt objects stand out from the rest of the Kuiper Belt with their very large, very elliptical orbits. The origin of the scattered Kuiper Belt is unknown, but may be a by-product of the scattering process that produced the Oort Cloud.

Physical properties. The properties of Kuiper Belt objects are of intense interest since these bodies are primordial survivors from the early solar nebula. Unfortunately, most Kuiper Belt objects are so faint that detailed investigations of their properties are extremely difficult. Nothing is currently known besides their colors. *See* PLANETARY PHYSICS; SOLAR SYSTEM. [J.Lu.]

Kumquat Shrubs or small trees that are members of the genus *Fortunella*, which is one of the six genera in the group of true citrus fruits. Kumquats are believed to have originated in China and the Malay Peninsula, but are now widely grown in all citrus areas of the world. Of the several species the most common are *F. margarita*, which has oval-shaped fruit, and *F. japonica*, which has round fruit.

Kumquats, with their brilliant orange-colored fruits and dense green foliage, are highly ornamental and are most frequently grown for this reason. Kumquat fruits can be eaten whole without peeling; they are also used in marmalades and preserves and as candied fruits. *See* SAPINDALES. [F.E.G.]

Kuroshio A swift, intense current flowing northeastward off the coasts of China and Japan in the upper waters of the North Pacific Ocean. The Kuroshio is the western portion of a giant clockwise, horizontal circulation known as the North Pacific subtropical gyre. This circulation extends from 15° to 45°N across the entire width of the Pacific Ocean. It is driven by the large-scale winds—the trades in the south and the westerlies in the north. As with all other western boundary currents, such as the Gulf Stream, the effect of the Earth's rotation and its spherical shape is to concentrate the Kuroshio flow into a current that is only about 100 km (62 mi) wide with speeds up to 2 m/s (4 mi/h). *See* CORIOLIS ACCELERATION; GULF STREAM; PACIFIC OCEAN.

The Kuroshio (Japanese, meaning "Black Current") has an apparent blackness resulting from the water clarity, which is a consequence of the low biological productivity of seawater in the area. It originates off the southeast coast of Luzon, the main island of the Philippines. For the first 1000 km (620 mi), the Kuroshio flows northward along the east coasts of Luzon and Taiwan, until it enters the East China Sea. For the next 1000 km, it flows northeastward near the edge of the continental shelf off eastern China, until it exits the East China Sea through the Tokara Strait. During its final 1000 km, it flows east-northeastward off the southern coast of Japan (where it is sometimes called the Japan Current). Finally, it leaves the Asian coast near Tokyo and travels into the interior of the North Pacific Ocean as a slowly expanding jetlike current known as the Kuroshio Extension. Here it merges with the Oyashio, a cold current with high biological productivity, and becomes the North Pacific Current.

Like the Gulf Stream in the North Atlantic, the Kuroshio rapidly carries large quantities of warm water from the tropics into mid-latitude regions. It is consequently an important agent in redistributing global heat. North of 30°N, where prevailing winds are westerlies, the North American climate is strongly affected by the warmth of these waters. [M.Wi.]

Kutorginida An extinct order of brachiopods whose class assignment is uncertain. Members occur in rocks of Early Cambrian and questionably Middle Cambrian age. The shell has a primarily calcareous composition. The valves may have articulation of paired furrows or sockets and ridges, but these do not appear to be homologous to the teeth and sockets of articulate brachiopods. Both valves resemble articulate brachiopod valves in having the true hinge line coincident with the hinge axis, elongate muscle tracks, and well-defined interareas. *See* BRACHIOPODA. [M.W.F.]

Kyanite A nesosilicate mineral, Al_2SiO_5, crystallizing in the triclinic system and occurring in metamorphic rocks. It is essentially a pure phase, but minor amounts of iron (Fe^{3+}), chromium

(Cr^{3+}), and titanium (Ti^{4+}) may substitute for aluminum (Al). The structure of kyanite is based on cubic close-packed oxygens (O). Ten percent of the tetrahedral (fourfold) interstices are filled with silicon (Si), and 40 percent of the octahedral (sixfold) interstices are filled with Al. The Al, with O at the corners, occurs in zigzag edge-sharing chains of Al-O octahedra. Si-O tetrahedra share corners with Al-O octahedra along the sides. This structure is about 10 percent denser than that of the other two Al_2SiO_5 polymorphs, sillimanite and andalusite, making kyanite the high-pressure polymorph.

Kyanite occurs in well-formed bladed crystals and aggregates. Luster is vitreous to pearly. It is usually light blue because of minor Fe and Ti, and, rarely, light green because of Fe only. Kyanite may also be white or gray. Hardness is 5 (Mohs scale) along the length of crystals and 7 at right angles to the length. Kyanite has a single perfect cleavage parallel to the bladed face of crystals. *See* HARDNESS SCALES.

Kyanite is a source of material for the manufacture of highly refractory porcelains such as those used for spark plugs. *See* ANDALUSITE; MINERALOGY; SILICATE MINERALS; SILLIMANITE. [M.J.H.]

L

Labradorite A plagioclase feldspar with composition range $Ab_{50}An_{50}$ to $Ab_{30}An_{70}$ ($Ab = NaAlSi_3O_8$; $An = CaAl_2Si_2O_8$). In some labradorite samples brilliant colors, much like those seen in oil films on water, result from the interference of light reflected at successive lamellar interfaces. *See* Feldspar; Igneous rocks. [P.H.R.]

Labyrinthodontia An important subclass of fossil amphibians, first known in the Late Devonian, common in the Carboniferous and Permian, and persisting to the Late Triassic. They are named for infoldings of the enamel of their teeth, a primitive feature which is not universally present in labyrin-thodonts and which is shared with rhipidistean crossopterygian fishes. It is generally accepted that the labyrinthodonts are descended from rhipidisteans. Labyrinthodonts are usually fairly large (up to 6.5 ft or 2 m long). Some were totally aquatic (in fresh water). Most were probably semiaquatic, while some (especially the Dissorophidae) appeared to be terrestrial, at least as adults. *See* Amphibia. [R.E.DeM.]

Labyrinthulia Protozoa forming a subclass of Rhizopodea with obscure relationships to rest of the class. There is one order, Labyrinthulida. The mostly marine, ovoid to spindle-shaped, uninucleate organisms secrete a network of filaments (slime tubes) along which they glide, usually singly. This network inspired the name "net slime molds" sometimes applied to them. The mechanism of locomotion is unknown. *See* Rhizopodea. [R.P.H.]

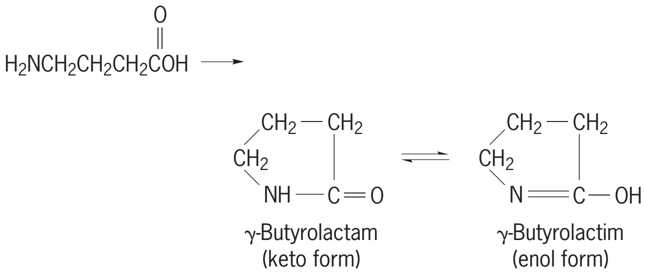
Lacquer A fast-drying, hard, high-gloss surface coating. Lacquers are made by dissolving a cellulose derivative and other modifying materials in a solvent and adding pigment if desired. The cellulose derivative most commonly used is nitrocellulose, but a cellulose ester such as cellulose acetate or cellulose butyrate, or a cellulose ether such as ethyl cellulose is often used in formulation. Lacquers dry by evaporation of the solvent. They usually are applied by spray because of their rapid drying properties.

Lacquers have been used extensively as fast-drying, weather-resistant finishes for automobiles and as coatings for furniture and other factory-finished items. Their use diminished, however, as less expensive coating materials with improved properties appeared on the market. *See* Surface coating. [C.R.Ma.; C.W.Si.]

Lacrimal gland A tubuloalveolar or acinous skin gland, also known as the tear gland. Two types occur among the vertebrates, the lacrimal proper and the Harderian. The eye glands drain into the nasal cavity by means of the lacrimal duct.

In land mammals the lacrimal gland proper is highly developed as a complex tubuloalveolar structure with several ducts which pour their copious fluid into the outer, upper part of the conjunctival sac or cavity. The tear substance washes across the eyeball and eventually passes through two small openings, one on the margin of each lid, into the lacrimal ducts. The latter converge to form the lacrimal sac, from which the nasolacrimal duct leads into the nasal passageway. Tears contain a considerable quantity of the common salt, sodium chloride. *See* Eye (vertebrate); Gland. [O.E.N.]

Lactam A cyclic amide that is the nitrogen analog of a lactone. For example, a γ-aminobutyric acid readily forms γ-butyrolactam (also known as 2-pyrrolidinone) upon heating, as in the reaction below. The tautomeric enol form of a lactam is known as a lactim.



The δ-amino acids similarly form δ (six-membered-ring) lactams upon heating, but larger- and smaller-ring lactams must be made by indirect methods.

Several lactams are of considerable industrial importance. 2-Pyrrolidinone and 1-methyl-2-pyrrolidinone are made by heating γ-butyrolactone with ammonia and methylamine, respectively. They are useful specialty solvents. Vinylation of 2-pyrrolidinone with acetylene gives 1-vinyl-2-pyrrolidinone, which is polymerized to a substance commonly used in aerosol hair sprays.

The ß-lactam antibiotics comprise two groups of clinically important therapeutic agents, the penicillins and the cephalosporins. In both cases they contain a four-membered or ß-lactam ring which has its nitrogen atom and a carbon atom in common with another ring. Such substances are derived commercially from fermentation processes, followed usually by chemical manipulation of the functional groups. *See* Amino acids; Antibiotic; Biochemical engineering; Lactone. [P.E.F.]

Lactase An enzyme found in mammals, honeybee larvae, and some plants. It is a ß-galactosidase which hydrolyzes lactose to galactose and glucose. In mammals, lactase appears in the intestinal secretion from the intestinal villi, and exerts its effect on lactose in chyme. *See* Enzyme; Glucose. [D.N.La.]

Lactate A salt or ester of lactic acid ($CH_3CHOHCOOH$). In lactates, the acidic hydrogen of the carboxyl group has been replaced by a metal or an organic radical. Lactates are optically active, with a chiral center at carbon 2. Commercial fermentation produces either the dextrorotatory (R) or the levorotatory (S) form, depending on the organism involved. *See* Optical activity.

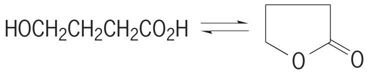
The R form of lactate occurs in blood and muscle as a product of glycolysis. Lack of sufficient oxygen during strenuous exercise causes enzymatic (lactate dehydrogenase) reduction of pyruvic acid to lactate, which causes tiredness, sore muscles, and even muscle cramps. During renewed oxygen supply (rest) the lactate is reoxidized to pyruvic acid and the fragments enter the Krebs (citric acid) cycle. The plasma membranes of muscle and liver are permeable to pyruvates and lactates, permitting the blood to transport them to the liver (Cori cycle). Lactates also increase during fasting and in diabetics. *See* Biological oxidation; Carbohydrate metabolism; Citric acid cycle.

Lactates are found in certain foods (sauerkraut), and may be used for flour conditioning and in food emulsification. Alkali-metal salts act as blood coagulants and are used in calcium therapy, while esters are used as plasticizers and as solvents for lacquers. *See* Ester; Salt (chemistry). [E.H.H.]

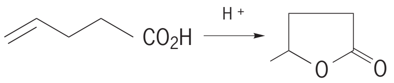
Lactation The function of the mammary gland providing milk nourishment to the newborn mammal. This process is under the control of the endocrine and nervous systems. It involves transformation of an inactive duct system to a lobuloalveolar glandular structure during pregnancy, cellular production of the components of milk (galactopoiesis), secretion into the ducts, and ejection under the stimulus of milking or suckling.

Lactation makes demands on the maternal regulation of calcium metabolism. Resorption of bone increases in lactating rats and women, and there is a marked increase in the absorption of calcium from the intestine. The elevated need for calcium results in an increased role for parathyroid hormone, calcitonin, and vitamin D in the regulation of the absorption and utilization of calcium. In humans a concomitant phenomenon frequently associated with lactation is amenorrhea. Consequently in some societies prolonged nursing is used as a birth control technique. *See* Mammary gland; Milk. [H.J.L.]

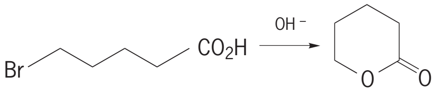
Lactone A cyclic, intramolecular ester derived from a hydroxy acid. Simple lactones are designated α, β, γ, δ and so forth. Five- and six-membered lactones are very readily obtained by cyclization of a hydroxy acid or precursor as shown in reactions (1)–(3). Lactones with three- and four-membered rings are also known. *See* Ester.



(1)

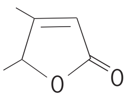


(2)

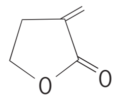


(3)

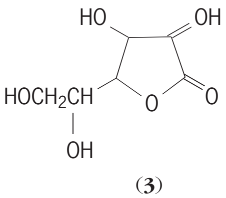
Lactones in various forms are found in numerous naturally occurring compounds. Unsaturated γ-lactone rings (**1** and **2**) are present in many components of essential oils. Ascorbic acid [vitamin C; (**3**)] is a carbohydrate lactone. *See* Ascorbic acid; Essential oils.



(**1**)



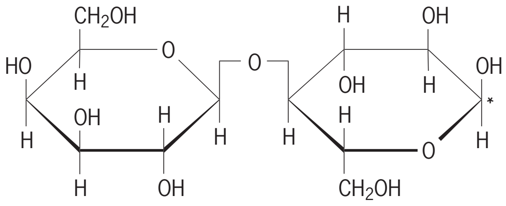
(**2**)



(**3**)

A major development in the chemistry of naturally occurring compounds has been the isolation from microorganisms of a number of macrocyclic lactones with rings containing from 12 to more than 30 atoms. These substances include immunosuppressive agents and antibiotics such as erythromycin. Although they represent some of the most complex organic compounds known, several of these macrocyclic lactones have been synthesized. *See* Antibiotic; Organic chemistry. [P.E.F.; J.A.Mo.]

Lactose Milk sugar or 4-*O*-β-D-galactopyranosyl-D-glucose. This reducing disaccharide is obtained as the α-D anomer (see formula, where the asterisk indicates a reducing group); the melting point is 202°C (396°F). Lactose is found in the milk of mammals to the extent of approximately 2–8%. It is usually prepared from whey, which is obtained by a by-product in the manufacture of cheese. Upon concentration of the whey, crystalline lactose is deposited. [W.Z.H.]



Laevicaudata An order of fresh-water branchiopod crustaceans formerly included in the order Conchostraca. The body is up to about 7 mm (0.3 in.) in length; females have 12 trunk segments, males have 10. The trunk terminates in a feebly developed telson that lacks claws and is covered ventrally by an opercular lamella. The head is free, articulated with the trunk, and can be swung forward. It is covered by a headshield and has paired, sessile eyes. It bears large antennae that are used for swimming. The mandibles, while of the rolling, crushing type, have narrow masticatory surfaces and stout teeth.

Clumps of small drought-resistant eggs are carried by the female and shed at the next molt. They hatch as a late nauplius of distinctive type. The Laevicaudata are inhabitants of temporary water bodies and are almost worldwide in distribution. Although they can swim, they are usually associated with the bottom. *See* Branchiopoda. [G.Fr.]

Lagomorpha The order of mammals including rabbits, hares, and pikas. Lagomorphs have two pairs of upper incisors (the second pair minute), and enamel surrounds the tooth, which does not form a sharp chisel. Motion of the jaw is vertical or transverse. Lagomorphs have three upper and two lower premolars, the earliest fossil rodents have one less of each. The tibia and fibula are fused, the fibula articulating with the calcaneum as in artiodactyls. There is a spiral valve in the cecum, and the scrotum is prepenial.

The order includes three families: Leporidae (rabbits and hares); Ochotonidae (pikas, whistling hares, or American coneys); and Eurymylidae, an extinct family from the Paleocene of Mongolia. *See* Mammalia.

Leporidae are the most familiar members of the order. There are, in general, two kinds: rabbits (such as the American cottontail), which are relatively small, with shorter hindlegs, shorter ears, and short tails; and hares, larger forms with longer legs, ears, and tails. Rapid locomotion is by leaps, using the hindlegs, combined (especially in rabbits) with abrupt changes of direction. Both types occur in the same region, with rabbits inhabiting brush, scrub, or woods and hares living in open grassland. In North America, hares are usually called jackrabbits. [A.E.Wo.]

Lagrange's equations Equations of motion of a mechanical system for which a classical (non-quantum-mechanical) description is suitable, and which relate the kinetic energy of the system to the generalized coordinates, the generalized forces, and the time. If the configuration of the system is specified by giving the values of f independent quantities $q_1, \ldots, q_f$, there are f such equations of motion.

In their usual form, these equations are equivalent to Newton's second law of motion and are differential equations of the second order for the q's as functions of the time t. [P.M.S.]

Lagrangian function A function of the generalized coordinates and velocities of a dynamical system from which the equations of motion in Lagrange's form can be derived. The Lagrangian function is denoted by $L(q_1, \ldots, q_f; \dot{q}_1, \ldots, \dot{q}_f; t)$. For systems in which the forces are derivable from a potential energy V, if the kinetic energy is T, the equation below holds.

$$L = T - V$$

See LAGRANGE'S EQUATIONS. [P.M.S.]

Lake An inland body of water, small to moderately large in size, with its surface exposed to the atmosphere. Most lakes fill depressions below the zone of saturation in the surrounding soil and rock materials. Generically speaking, all bodies of water of this type are lakes, although small lakes usually are called ponds, tarns (in mountains), and less frequently pools or meres. The great majority of lakes have a surface area of less than 100 mi^2 (259 km^2). More than 30 well-known lakes, however, exceed 1500 mi^2 (3885 km^2) in extent, and the largest freshwater body, Lake Superior, North America, covers 31,180 mi^2 (80,756 km^2). Most lakes are relatively shallow features of the Earth's surface. Because of their shallowness, lakes in general may be considered evanescent features of the Earth's surface, with a relatively short life in geological time.

Lakes differ as to the salt content of the water and as to whether they are intermittent or permanent. Most lakes are composed of fresh water, but some are more salty than the oceans. Generally speaking, a number of water bodies which are called seas are actually salt lakes; examples are the Dead, Caspian, and Aral seas. All salt lakes are found under desert or semiarid climates, where the rate of evaporation is high enough to prevent an outflow and therefore a discharge of salts into the sea.

Lakes with fresh waters also differ greatly in the composition of their waters. Because of the balance between inflow and outflow, fresh lake water composition tends to assume the composite dissolved solids characteristics of the waters of the inflowing streams—with the lake's age having very little influence. Under a few special situations, as crater lakes in volcanic areas, sulfur or other gases may be present in lake water, influencing color, taste, and chemical reaction of the water. *See* FRESH-WATER ECOSYSTEM; HYDROSPHERE; MEROMICTIC LAKE; SURFACE WATER.

Both natural and artificial lakes are economically significant for their storage of water, regulation of stream flow, adaptability to navigation, and recreational attractiveness. A few salt lakes are significant sources of minerals. *See* EUTROPHICATION. [E.A.A.]

Lamellibranchia The largest subclass of the class Bivalvia in the phylum Mollusca. Lamellibranchs are ciliary filter feeders with greatly enlarged ctenidia, in each of which the elongated gill filaments are held together in parallel series to form folded lamellae. The 30,000 living species constitute the most successful of molluscan groups, in terms both of individual numbers with their biomass and of ecological bioenergetics (calorie transfer in food chains).

There are several proposed systems of ordinal classification for the subclass Lamellibranchia, but little agreement on the best structural bases. One system frequently employed comprises six orders: Anisomyaria, Taxodonta, Heterodonta, Schizodonta, Anomalodesmata, and Adapedonta. There is more general acceptance of the (possibly 18) superfamilies of lamellibranchs, each with characteristic shell structure, hinge dentition, ligament, and degree of fusion of the mantle lobes involving the origin of the siphons. The more important superfamilies include Mytilacea (mussels), Ostreacea (true oysters), Cardiacea (true cockles), Unionacea and Corbiculacea (fresh-water clams), Myacea (including softshell clams), Mactracea (surf clams), Tellinacea, and Pholadacea (=Adesmacea). Within each larger superfamily there is a wide range of adaptive radiation, with different genera living as shallow or deep burrowers or as sessile attached forms. There can be considerable evolutionary convergence shown by genera from different superfamilies, and deep burrowers with massive fused siphons are found in five superfamilies. *See* BIVALVIA; BORING BIVALVES; MOLLUSCA. [W.D.R.H.]

Lamiales An order of flowering plants (Magnoliophyta, or angiosperms), in the subclass Asteridae (Eudicotyledons). The order consists of some 22 families with approximately 1100 genera and over 21,000 species. Seven families (Acanthaceae, Gesneriaceae, Lamiaceae, Orobanchaceae, Plantaginaceae, Scrophulariaceae, Verbenaceae) have more than 1000 species. Members of the Lamiales are distributed worldwide with some families being predominantly tropical and some being predominantly temperate. Lamiaceae, the largest family, is well represented in both tropical and temperate floras.

A basal split in the evolutionary relationships within the order sets off the family Oleaceae, with tetramerous flowers, which are radially symmetric, from the rest of the Lamiales. Pentamerous flowers with fewer stamens (two or four) than petals and bilateral symmetry predominate among the other families. Flowers of all families are characterized by petals fused into a tubular corolla, a single whorl of stamens (typically four), and ovaries consisting of two fused carpels. Iridoid compounds are found in most members of the Lamiales and are thought to function in deterring herbivory by insects. However, iridoids are not universal in the order and, for example, the large subfamily Nepetoideae in family Lamiaceae lacks iridoids but exhibits a diverse array of volatile oils that may serve a similar function.

The volatile oils in the Lamiaceae have made many species valuable as scents and herbs, including lavender (*Lavandula*), mint (*Mentha*), sage (*Salvia*), catnip (*Nepeta*), basil (*Ocimum*), and oregano (*Oreganum*). Additional economically important plants in the Lamiales include those grown for food: sesame (*Sesamum*, Pedaliaceae) and olives (*Olea*, Oleaceae); wood: teak (*Tectona*, Verbenaceae) and ash (*Fraxinus*, Oleaceae); houseplants: African violets and relatives (Gesneriaceae); and many ornamental plants from a wide variety of families. The order also contains some plants with specialized habits, including parasitic plants (Orobanchaceae), insectivorous plants (Byblidaceae, Lentibulariaceae), mangroves (Avicenniaceae), and aquatic plants, such as *Callitriche* and *Hippuris* (Plantaginaceae). *See* ASTERIDAE; MAGNOLIOPHYTA; MAGNOLIOPSIDA; PLANT KINGDOM. [R.Ol.]

Laminar flow A smooth, streamline type of viscous fluid motion characteristic of flow at low-to-moderate deformation rates. The name derives from the fluid's moving in orderly layers or laminae.

The chief criterion for laminar flow is a relatively small value for the Reynolds number, $\mathrm{Re} = \rho VL/\mu$, where ρ is fluid density, V is flow velocity, L is body size, and μ is fluid viscosity. Laminar flow may be achieved in many ways: low-density flows as in rarefied gases; low-velocity or "creeping" motions; small-size bodies such as microorganisms swimming in the ocean; or high-viscosity fluids such as lubricating oils. At higher values of the Reynolds number, the flow becomes disorderly or turbulent, with many small eddies, random fluctuations, and streamlines intertwining. *See* CREEPING FLOW; REYNOLDS NUMBER; TURBULENT FLOW; VISCOSITY.

Nearly all of the many known exact solutions of the equations of motion of a viscous fluid are for the case of laminar flow. These mathematically accurate descriptions can be used to give insight into the more complex turbulent and transitional flow patterns for which no exact analyses are known. *See* NAVIER-STOKES EQUATION.

The theory of viscous lubricating fluids in bearings is a highly developed area of laminar flow analysis. Even large Reynolds number flows, such as aircraft in flight, have regions of laminar flow near their leading edges, so that laminar flow analysis can be useful in a variety of practical and scientifically relevant flows. *See* ANTIFRICTION BEARING; BOUNDARY-LAYER FLOW; FLUID FLOW; LUBRICANT. [F.M.W.]

Laminariales An order of large brown algae (Phaeophyceae) commonly called kelps. Four families are recognized: Chordaceae, Laminariaceae, Alariaceae, and Lessoniaceae. Definitive features include a life history in which microscopic, filamentous, dioecious gametophytes alternate with a massive, parenchymatous sporophyte; growth of the sporophyte effected by meristems; and production of unilocular zoosporangia in extensive sori on blades of the sporophyte. *See* PHAEOPHYCEAE.

A mature sporophyte consists typically of a holdfast, stipe, and one or more blades. The holdfast usually comprises a cluster of rootlike structures (haptera); in a few species it is discoid or conical. The stipe, which varies in length from a few millimeters in *Hedophyllum* to more than 100 ft (30 m) in *Macrocystis* (giant kelp), may be branched or unbranched and may bear one or more blades.

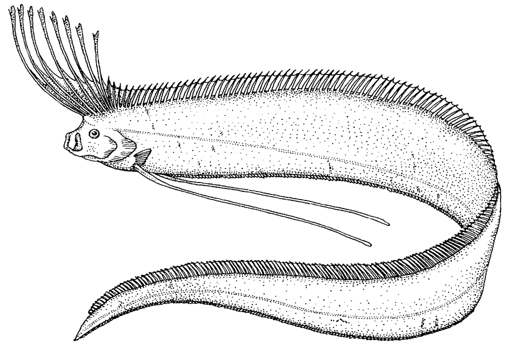
Kelps are largely confined to cold waters of both hemispheres, displaying a peak of diversity, abundance, and luxuriance all around the North Pacific. Only *Lessonia* and *Ecklonia* (both Lessoniaceae) are characteristic of the Southern Hemisphere, but *Macrocystis* is bipolar, occurring abundantly in subantarctic waters. Kelps are lacking in Antarctica, where their ecological niche is filled by members of the brown algal family Desmarestiaceae. Some kelps are found in the intertidal zone, usually on rocks exposed to heavy waves, but most are subtidal.

The principal use of kelps is in the alginate industry. Various kelps are used extensively for human food in Japan. In China *Laminaria japonica* has been established as an important maricultural crop plant. Ecologically, such kelps as *Macrocystis* and *Nereocystis* are particularly important because they form protective canopies harboring special communities of smaller seaweeds, invertebrates, fishes, and the sea otter. *See* ALGAE; ALGINATE. [P.C.Si.; R.L.Moe]

Lamp A generic term for a device designed to produce electromagnetic radiation in the form of light, heat, ultraviolet energy, or a combination of the three. The term lamp is applied to the entire range of sources, including flame sources (such as kerosine lamps or gas lamps with Welsbach mantles), incandescent sources, and electric arc discharge sources. Used with a modifier, such as ultraviolet, infrared, or sun, the term lamp is used to indicate sources that radiate energy in the ultraviolet or infrared portions of the electromagnetic spectrum (plus some radiation in the visible part of the spectrum).

Electric lamps are the most common and useful types of light-producing sources. These devices convert electrical energy into light (radiant energy in the visible portion of the spectrum). The most widely used lamps for lighting buildings and areas, such as parking lots, stadia, and streets, are incandescent lamps, fluorescent lamps, and high-intensity arc discharge lamps (HID lamps). *See* ARC LAMP; FLUORESCENT LAMP; INCANDESCENT LAMP; INFRARED LAMP; SUN; ULTRAVIOLET LAMP; VAPOR LAMP. [G.R.P.; R.L.Sm.]

Lampridiformes An order of teleost fishes including the ribbonfishes, oarfishes, opah, and their allies, also known as the Allotriognathi. Although these fishes are diverse in form, they share characters that define this order. In most, the body is notably compressed, often ribbonlike (see illustration). The fins are composed of soft rays, or the dorsal has one or two anterior spines; the pelvic fin, if present, is thoracic, with 1–17 spineless rays; the pelvic girdle is inserted between the coracoids, or attached to them, or is lost; scales are small and cycloid or, commonly, absent; and the swim bladder is without a duct. Most species are large and colorful. They are all oceanic. *See* ACTINOPTERYGII. [R.M.B.]



Oarfish (*Regalecus glesne*). (*After D. S. Jordan and B. W. Evermann, The Fishes of North and Middle America, U.S. Nat. Mus. Bull. no. 47, 1900*)

Lamprophyre Any of a heterogeneous group of gray to black, mafic igneous rocks characterized by a distinctive panidiomorphic and porphyritic texture in which abundant euhedral, dark-colored ferromagnesian (femic) minerals (dark mica, amphibole, pyroxene, olivine) occur in two generations—both early as phenocrysts and later in the matrix or groundmass— while felsic minerals (potassium feldspar, plagioclase, analcime, melilite) are restricted to the groundmass.

Many varieties of lamprophyre are known. Minettes, kersantites, vogesites, and spessartites are the most common and are sometimes collectively called calcalkaline lamprophyres. Camptonites and monchiquites are less common; alnoites are rare. These varieties, along with some others, are referred to as alkaline lamprophyres.

Lamprophyres are widespread but volumetrically minor rocks that apparently are restricted to the continents and are the last manifestation of igneous activity in a given area. They usually occur as subparallel or radial swarms of thin (~1.6–160 ft or ~0.5–50 m) dikes or, less commonly, sills, volcanic neck fillings, or diatremes, or, rarely, lava flows. *See* IGNEOUS ROCKS. [S.W.B.]

Land drainage (agriculture) The removal of water from the surface of the land and the control of the shallow groundwater table improves the soil as a medium for plant growth. The sources of excess water may be precipitation, snowmelt, irrigation water, overland flow or underground seepage from adjacent areas, artesian flow from deep aquifers, floodwater from channels, or water applied for such special purposes as leaching salts from the soil or for achieving temperature control.

The purpose of agricultural drainage can be summed up as the improvement of soil water conditions to enhance agricultural use of the land. Such enhancement may come about by direct effects on crop growth, by improving the efficiency of farming operations or, under irrigated conditions, by maintaining or establishing a favorable salt regime. Drainage systems are engineering structures that remove water according to the principles of soil physics and hydraulics. The consequences of drainage, however, may also include a change in the quality of the drainage water. Agricultural drainage is divided into two broad classes; surface and subsurface. Some installations serve both purposes. [J.N.Lu.]

Land reclamation The process by which seriously disturbed land surfaces are stabilized against the hazards of wind and water erosion. Surface mining for coal is responsible for almost one-half of the total land area disturbed in the United States. The drastic disturbance of the overburden severely changes the chemical and physical properties of the resulting spoils. These altered properties often create a hostile environment for seed germination and subsequent plant growth. Unless vegetative cover is established almost immediately, the denuded areas are subject to both wind and water erosion that pollute surrounding streams with sediment.

In the United States the Federal Strip Mine Law requires that topsoil be removed and reapplied on the spoil surface during regrading and reclamation. This practice alone has aided materially in reclamation of surface mine spoil areas throughout the United States. Even when topsoil is reapplied, the surface may contain coarse-textured materials and rock fragments, making it difficult to establish vegetative cover. Many of the eastern mine spoils are derived from sandstone and shales and have a low water-holding capacity. These spoils tend to form crusts and thus create a water-impermeable layer. Practically all of these topsoils have low fertility and thus require extensive fertilization for reclamation and seedling establishment. *See* SURFACE MINING. [O.L.B.]

Land-use planning

The long-term development or conservation of an area and the establishment of a relationship between local objectives and regional goals. Land-use planning is often guided by laws and regulations. The major instrument for current land-use planning is the establishment of zones that divide an area into districts which are subject to specified regulations. Although land-use planning is sometimes done by private property owners, the term usually refers to permitting by government agencies. Land-use planning is conducted at a variety of scales, from plans by local city governments to regulations by federal agencies. The United States has never developed a national land-use plan because land use is considered a local concern.

A major part of local planning is zoning, the division of areas into districts. Zones cover most potential uses, such as residential, commercial, light industry, heavy industry, open space, or transportation infrastructure (such as rail lines or highways). Detailed regulations guide how each zone can be used. As a result of pressures from rapid growth, some cities have begun to write growth management plans that limit the pace of growth. Comprehensive city plans aimed to limit the pace of growth have been accepted by the courts. *See* LANDSCAPE ARCHITECTURE.

Very few plans have been undertaken at a statewide scale. Each state plan differs by the needs and philosophy of the state. The state plans represent a balance of regional structures that address widespread growth with local powers that keep specific decision-making at the local level.

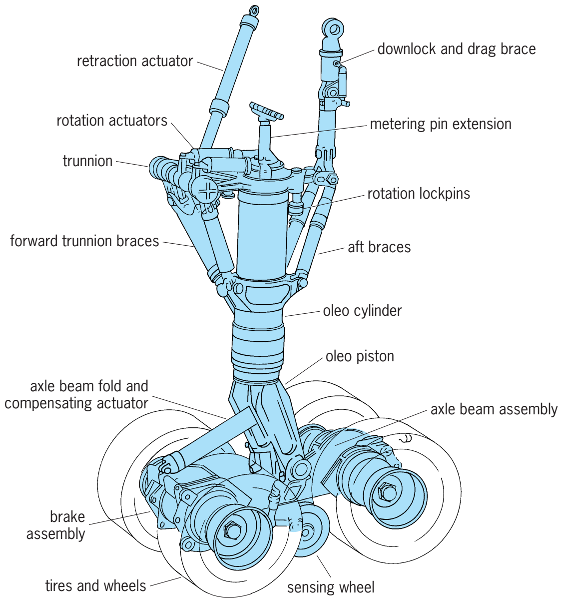
Environmental regulations are among the few national-level policies that have direct implications for land-use planning. Four of the major types of environmental laws that impact land-use planning are wetland laws, clean-air laws, clean-water laws, and laws for the protection of endangered species. *See* ENDANGERED SPECIES; WETLANDS.

Land-use planning, in large part, has focused on urban planning. Increasingly, land-use planning is done at larger scales and involves multiple issues. Awareness of environmental concerns, coupled with the wide availability of technical tools that include digital maps at all scales, has led to new approaches to land-use planning. These approaches often use ideas from landscape ecology, such as the concepts of patches; edges, boundaries, and fragmentation; buffer zones; and corridors and connectivity. *See* ECOLOGY, APPLIED; LANDSCAPE ECOLOGY. [C.Sc.]

Landing gear

That portion of an aircraft consisting of the wheels, tires, brakes, energy absorption mechanism, and drag brace. The landing gear is also referred to as the aircraft undercarriage. Additional components attached to and functioning with the landing gear may include retracting mechanisms, steering devices, shimmy dampers, and door panels.

The landing gear supports the aircraft on the ground and provides a means of moving it. It also serves as the primary means of absorbing the large amounts of energy developed in the transition from flight to ground roll during a landing approach. The brakes, normally located in the main wheels, are used to retard the forward motion of the aircraft on the ground and may provide some control in the steering of the aircraft. In most modern aircraft the landing gear is designed to retract into the aircraft so that it is out of the airstream and drag is thus reduced.



Main-wheel bogie for the XB-70A aircraft. (*After S. Pace, North American Valkyrie XB-70A, Aero Series vol. 30, Tab Books, 1984*)

Early aircraft and many small aircraft use a tail-wheel (or skid) in a conventional, or tail-dragger arrangement, in which the main landing gear is located ahead or forward of the center of gravity of the aircraft. The popular arrangement on modern aircraft is a tricycle landing gear, with the main gear located behind or aft of the center of gravity, and a nose gear located forward which carries about 20% of the static weight of the aircraft. Large aircraft such as the wide-body commercial aircraft and military aircraft like the C-5A employ multiple-wheeled bogies to support their huge weight and, in the case of the C-5A, to provide soft terrain landing and takeoff capability. *See* MILITARY AIRCRAFT.

The most accepted method of absorbing the energy due to landing is an air-oil strut called an oleo. The basic components are an outer cylinder which contains the air-oil mixture and an inner piston that compresses the oil through an orifice. The flow of oil through the orifice is metered by a variable-diameter pin that passes through the orifice as the gear strokes. The flow of oil in effect varies the stiffness of the compression of the gear. [R.R.De.]

Landscape architecture

The art and profession of designing and planning landscapes. Landscape architects are concerned with improving the ways in which people interact with the landscape, as well as with reducing the negative impacts that human use has upon sensitive landscapes. Landscape architects are involved in such diverse areas as landscape and urban design, community and regional planning, interior and exterior garden design, agricultural and rural land-use planning, parks and recreation, historic site and natural area preservation, landscape restoration and management, research and academic programs, energy and water conservation, and environmental planning.

Landscape architects are generalists in that their educational and professional experience is very broad. Many environmental and cultural factors affect landscape design and planning, and landscape architects have to know how these factors relate.

Design process is the main area of specialization for landscape architects, and decision-making related to design process is fundamental. *See* Civil engineering; Environmental engineering; Forestry, urban; Land-use planning. [K.J.D.]

Landscape ecology The study of the distribution and abundance of elements within landscapes, the origins of these elements, and their impacts on organisms and processes. A landscape may be thought of as a heterogeneous assemblage or mosaic of internally uniform elements or patches, such as blocks of forest, agricultural fields, and housing subdivisions. Biogeographers, land-use planners, hydrologists, and ecosystem ecologists are concerned with patterns and processes at large scale. Landscape ecologists bridge these disciplines in order to understand the interplay between the natural and human factors that influence the development of landscapes, and the impacts of landscape patterns on humans, other organisms, and the flows of materials and energy among patches. Much of landscape ecology is founded on the notion that many observations, such as the persistence of a small mammal population within a forest patch, may be fully understood only by accounting for regional as well as local factors.

Factors that lead to the development of a landscape pattern include a combination of human and nonhuman agents. The geology of a region, including the topography and soils along with the regional climate, is strongly linked to the distribution of surface water and the types of vegetation that can exist on a site. These factors influence the pattern of human settlement and the array of past and present uses of land and water. One prevalent effect of humans is habitat fragmentation, which arises because humans tend to reduce the size and increase the isolation among patches of native habitat.

The pattern of patches on a landscape can in turn have direct effects on many different processes. The structure and arrangement of patches can affect the physical movement of materials such as nutrients or pollutants and the fate of populations of plants and animals. Many of these impacts can be traced to two factors, the role of patch edges and the connectedness among patches.

The boundary between two patches often act as filters or barriers to the transport of biological and physical elements. As an example, leaving buffer strips of native vegetation along stream courses during logging activities can greatly reduce the amount of sediment and nutrients that reach the stream from the logged area. Edge effects can result when forests are logged and there is a flux of light and wind into areas formerly located in the interior of a forest. In this example, edges can be a less suitable habitat for plants and animals not able to cope with drier, high-light conditions. When habitats are fragmented, patches eventually can become so small that they are all edge. When this happens, forest interior dwellers may become extinct. When patch boundaries act as barriers to movement, they can have pronounced effects on the dynamics of populations within and among patches. In the extreme, low connectivity can result in regional extinction even when a suitable habitat remains. This can occur if populations depend on dispersal from neighboring populations. When a population becomes extinct within a patch, there is no way for a colonist to reach the vacant habitat and reestablish the population. This process is repeated until all of the populations within a region disappear. Landscape ecologists have promoted the use of corridors of native habitat between patches to preserve connectivity despite the fragmentation of a landscape. [D.Sk.]

Landslide The perceptible downward sliding, falling, or flowing of masses of soil, rock, and debris (mixtures of soil and weathered rock fragments). Landslides range in size from a few cubic meters to over 10^9 m^3 (3.5×10^{10} ft^3), their velocities range from a few centimeters per day to over 100 m/s (330 ft/s), and their displacements may be several centimeters to several kilometers. *See* Mass wasting.

The U.S. Highway Research Board classification divides landsliding of rock, soil, and debris, on the basis of the types of movement, into falls, slides, and flows. Other classifications consider flows, along with creep and other kinds of landslides, as general forms of mass wasting.

Falls occur when soil or rock masses free-fall through air. Falls are usually the result of collapse of cliff overhangs which result from undercutting by rivers or simply from differential erosion. Slides invariably involve shear displacement or failure along one or more narrow zones or planes. Internal deformation of the sliding mass after initial failure depends on the kinetic energy of the moving mass (size and velocity), the distance traveled, and the internal strength of the mass. Flows have internal displacement and a shape that resemble those of viscous fluids. Relatively weak and wet masses of shale, weathered rock, and soil may move in the form of debris flows and earthflows; water-soaked soils or weathered rock may displace as mudflows.

Mining and civil engineering works have induced myriads of landslides, a few of them of a catastrophic nature. Open-pitmines and road cuts create very high and steep slopes, often quite close to their stability limit. Local factors (weak joints, fault planes) or temporary ones (surges of water pressure inside the slopes, earthquake shocks) induce the failure of some of these slopes. The filling of reservoirs submerges the lower portion of natural, marginally stable slopes or old landslides. Water lowers slope stability by softening clays and by buoying the lowermost portion, or toe, of the slope.

Advances in soil and rock engineering have improved the knowledge of slope stability and the mechanics of landsliding. Small and medium-sized slopes in soil and rock can be made more stable. Remedial measures include lowering the slope angle, draining the slope, using retaining structures, compressing the slope with rock bolts or steel tendons, and grouting. *See* Engineering geology; Erosion; Soil mechanics. [A.S.N.]

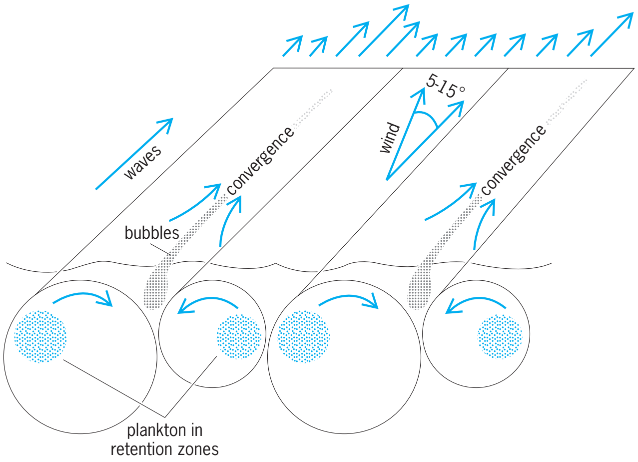
Langevin function A mathematical function which is important in the theory of paramagnetism and in the theory of the dielectric properties of insulators. The analytical expression for the Langevin function is shown in the equation below. If

$$L(x) = \coth x - l/x$$

$x \ll 1$, $L(x) \simeq x/3$. The paramagnetic susceptibility of a classical (non-quantum-mechanical) collection of magnetic dipoles is given by the Langevin function, as is the polarizability of molecules having a permanent electric dipole moment. *See* Paramagnetism. [E.A.; F.Ke.]

Langmuir circulation A form of motion found in the near-surface water of lakes and oceans under windy conditions. When the wind is stronger than 5–8 m/s (10–15 knots), streaks of bubbles, seaweed, or flotsam form lines running roughly parallel to the wind, called windrows. Windrows are seen at one time or another on all bodies of water, from ponds to oceans. In the 1920s, Irving Langmuir hypothesized that they are produced by convergences in the water rather than by a direct action of the wind. Langmuir proposed that as the surface water is blown downwind it moves in a spiral fashion, first angling toward the streaks along the surface, next sinking to some depth, then diverging out from under the streaks, and finally rising again in between the streaks (see illustration). In a series of observations and experiments conducted in the North Atlantic and on Lake George in New York, he was able to confirm this basic form of the circulation.

In the ocean, the downwelling under windrows can be strong enough to pull bubbles, seaweed, and other buoyant particles down tens to hundreds of meters below the surface. The downward motion is eventually halted by a subtle increase in the water density with depth, associated with colder temperatures and/or higher salinity. The mixed surface layer typically spans most or all of the depth that light penetrates (the euphotic zone). This



Langmuir circulation consists of a set of alternating rolls of water nearly aligned with the wind. Downwelling zones tend to be narrow and intense compared to the broader, gentler upwelling in between. The rolls may be asymmetric, with stronger flows to the right of the wind at the surface (in the Northern Hemisphere). Details of the lower part of the motion are not yet clear.

layer acts like the skin of the sea, through which heat, water vapor, oxygen, carbon dioxide, and all other materials must pass as they enter and leave the air and the sea. The mixing at the bottom of this layer also brings up nutrients and colder water from below. [J.A.Smi.]

Lanolin

A soft, waxy material derived from the greasy coating on raw wool. In the processing of wool, the fleece is scoured with an aqueous alkaline solution to remove debris, wax, water-soluble material, and free acids. The insoluble fraction, which constitutes about 15–20% of the weight of the original wool, is crude lanolin.

Lanolin is a very complex mixture of esters, similar to the skin lipids of birds and other animals. Analysis gives equal weights of acids and alcohols. The acids consist of 50–60% saturated fatty acids with chains up to C_{38}–C_{40}. Another group (30–35%) comprises α-hydroxy acids and a small amount of ω-hydroxy acids. *See* ESTER.

The major alcohol components are 35% cholesterol and 35–40% lanosterol. The latter is a key intermediate in the biosynthesis of steroids from squalene. *See* CHOLESTEROL; SQUALENE; STEROID.

A particularly useful property of lanolin is the formation of stable water-in-oil emulsions containing up to 25% water (hydrous lanolin). Major uses are as an emollient and skin moisturizer in lotions and cosmetic products, and in medicinal ointments. Unrefined lanolin has some use in inks and as a corrosion and rust preventative. *See* FAT AND OIL; WOOL. [J.A.Mo.]

Lanthanide contraction

The name given to an unusual phenomenon encountered in the rare-earth series of elements. The radii of the atoms of the members of this series decrease slightly as the atomic number increases. As the charge on the nucleus increases across the rare-earth series, all electrons are pulled in closer to the nucleus so that the radii of the rare-earth ions decrease slightly as the compounds go across the rare-earth series. Any given compound of the rare earths is very likely to crystallize with the same structure as any other rare earth. However, the lattice parameters become smaller and the crystal denser as the compounds proceed across the series. This contraction of the lattice parameters is known as the lanthanide contraction. *See* RARE-EARTH ELEMENTS. [F.H.Sp.]

Lanthanum

A chemical element, La, atomic number 57, atomic weight 138.91. Lanthanum, the second most abundant element in the rare-earth group, is a metal. The naturally occurring element is made up of the isotopes ^{138}La, 0.089%, and ^{139}La, 99.91%. ^{138}La is a radioactive positron emitter with a half-life of 1.1×10^{11} years. The element was discovered in 1839 by C. G. Mosander and occurs associated with other rare earths in monazite, bastnasite, and other minerals. It is one of the radioactive products of the fission of uranium, thorium, or plutonium. Lanthanum is the most basic of the rare earths and can be separated rapidly from other members of the rare-earth series by fractional crystallization. Considerable quantities of it are separated commercially, since it is an important ingredient in glass manufacture. Lanthanum imparts a high refractive index to the glass and is used in the manufacture of expensive lenses. The metal is readily attacked in air and is rapidly converted to a white powder. Lanthanum becomes a superconductor below about 6 K (-449°F) in both the hexagonal and face-centered crystal forms. *See* RARE-EARTH ELEMENTS. [F.J.Sp.]

Laplace transform

An integral transform extensively used by P. S. Laplace in the theory of probability. In simplest form it is expressed as the equation below. It is thought of as

$$f(s) = \int_0^\infty e^{-st}\phi(t)\,dt$$

transforming the determining function $\phi(t)$ into the generating function $f(s)$. The variable t is real, the variable s may be real or complex, $s = \sigma + i\tau$. As an example, if $\phi(t) = 1$ the integral converges for $\sigma > 0$, and $f(s) = 1/s$.

The Laplace transform is used for the solution of differential and difference equations, for the evaluation of definite integrals, and in many branches of abstract mathematics (functional analysis, operational calculus, and analytic number theory). *See* INTEGRAL TRANSFORM. [D.V.W.]

Laplace's differential equation

Laplace's equation in two independent variables x and y is given as Eq. (1) and

$$\frac{\partial^2 u(x,y)}{\partial x^2} = \frac{\partial^2 u(x,y)}{\partial y^2} = 0 \qquad (1)$$

is of central importance in both pure mathematics and mathematical physics. A function $u(x, y)$ having continuous first and second partial derivatives and satisfying Laplace's equation in a neighborhood of a point is called harmonic at that point. If a plane piece of tinfoil has its edges kept at a temperature which varies from point to point but does not change with time, and if the flow of heat in the tinfoil is steady (that is, independent of the time), the temperature $u(x, y)$ at interior points of the foil is harmonic. Likewise Laplace's equation dominates the flow of electricity (the potential is similarly harmonic) and the flow of any incompressible fluid.

Many properties of Laplace's equation with two independent variables apply also in three or more dimensions. Thus, in three dimensions, a point distribution of matter of masses m_k at points (x_k, y_k, z_k) has a potential defined by Eq. (2), which is harmonic

$$u(x,y,z) \equiv \sum m_k[(x-x_k)^2 + (y-y_k)^2 + (z-z_k)^2]^{-1/2} \qquad (2)$$

except in the points (x_k, y_k, z_k). Except at such points, the force (Newtonian law of gravitation) exerted by the distribution on a unit exploratory particle at (x, y, z) has the components $(\partial u/\partial x, \partial u/\partial y, \partial u/\partial z)$ and the component of the force in any direction is the directional derivative of $u(x, y)$ in that direction. *See* POTENTIALS; SPHERICAL HARMONICS. [J.L.W.]

Laplace's irrotational motion

Laplace's equation for irrotational motion of an inviscid, incompressible fluid is partial differential equation (1), where x_1, x_2, x_3 are rectangular caresian coordinates in an inertial reference frame, and Eq. (2) gives the velocity potential. The fluid velocity components, u_1, u_2, u_3 in the three respective rectangular coordinate directions are given by $u_i = \partial\phi/\partial x_i$, $i = 1, 2, 3$. More generally, in any inertial coordinate system, the equation is div (grad ϕ) = 0 and the velocity vector is $\mathbf{v} = \text{grad}\ \phi$. Irrotational motion implies that the fluid particles translate without rotation (like the cars on a ferris wheel). *See* FLUID FLOW. [A.E.Br.]

$$\partial^2\phi/\partial x_1{}^2 + \partial^2\phi/\partial x_2{}^2 + 2^2\phi/2x_3{}^2 = 0 \quad (1)$$

$$\phi = \phi(x_1,\ x_2,\ x_3,\ t) \quad (2)$$

Laplacian The differential operator $\partial^2/\partial x^2 + \partial^2/\partial y^2 + \partial^2/\partial z^2$, in which the symbols x, y, z denote the variables of a rectangular cartesian coordinate system. The laplacian is frequently denoted by the symbol ∇^2 (read del square) in accordance with the fact that the laplacian of a scalar function $S(x, y, z)$ is the divergence of the gradient of S, that is, the equation below applies.

$$\partial^2 S/\partial x^2 + \partial^2 S/\partial y^2 + \partial^2 S/\partial z^2 = \nabla \cdot (\nabla S)$$

The laplacian operator is involved in some of the most fundamental equations of mathematical physics, namely, Laplace's equation ($\nabla^2 u = 0$), Poisson's equation, various wave equations, and the heat flow and diffusivity equations. *See* CALCULUS OF VECTORS; GAUSS' THEOREM; GRADIENT OF A SCALAR; GREEN'S THEOREM; WAVE EQUATION. [H.V.C.]

Larch A genus, *Larix*, of the pine family, with deciduous needles and short spurlike branches, which annually bear a crown of needles. The cones are small and persistent, varying by species in size, number, and form of the cone scales. The tamarack (*L. laricina*), also called hackmatack, is a native species. It has an erect, narrowly pyramidal habit, and grows in the northeastern United States, west to the Lake states, and across Canada to Alaska. The tough resinous wood is durable in contact with the soil and is used for railroad ties, posts, sills, and boats. Other uses include the manufacture of excelsior, cabinet work, interior finish, and utility poles. *See* PINALES.

The western larch (*L. occidentalis*), the most important and largest of all the species, grows in the northwestern United States and southeastern British Columbia. [A.H.G./K.P.D.]

Large systems control theory A branch of control theory concerned with large-scale systems. The three commonly accepted definitions of a large-scale system are based on notions of decomposition, complexity, and centrality. A system is sometimes considered to be large-scale if it can be partitioned or decomposed into small-scale subsystems. Another definition is that a system is large-scale if it is complex; that is, conventional techniques of modeling, analysis, control, design, and computation do not give reasonable solutions with reasonable effort. A third definition is based on the notion of centrality. Until the advent of large-scale systems, almost all control systems analysis and design procedures were limited to components and information grouped in one geographical location or center. Thus, by another definition, a system in which the concept of centrality fails is large-scale. This can be due to a lack of either centralized computing capability or a centralized information structure. Large-scale systems appear in such diversified fields as sociology, management, the economy, the environment, computer networks, power systems, transportation, aerospace, robotics, manufacturing, and navigation. Some examples of large-scale systems are the United States economy, the global telephone communication network, and the electric power generation system for the western United States. *See* CONTROL SYSTEMS; SYSTEMS ENGINEERING. [M.Ja.]

Larmor precession A precession in a magnetic field of the motion of charged particles or of particles possessing magnetic moments.

The Larmor theorem states that, for electrons moving in a single central field of force, the motion in a uniform magnetic field H is, to first order in H, the same as a possible motion in the absence of H except for the superposition of a common precession of angular frequency given by Eq. (1). Here e/c is

$$\omega_L = \frac{eH}{2mc} \quad (1)$$

the magnitude of the electronic charge in electromagnetic units, and m is the electronic mass. The frequency ω_L is called the Larmor frequency and is numerically equal to 2π times 1.40 MHz per oersted or 2π times 111 MHz per SI unit of magnetic field strength (ampere-turn per meter). *See* PRECESSION.

In stating the Larmor theorem, use was made of the phrase "a possible motion." If H is applied sufficiently slowly, it can be proved that the motion is the same as in the absence of H, except for the superposition of the Larmor precession. However, a sudden application of H may change, for example, a circular orbit into an elliptical one.

According to elementary electromagnetic theory, a current loop of area A and of current I possesses a magnetic moment μ of magnitude IA and of direction normal to the loop. Thus an electron moving in a circular orbit has an orbital magnetic moment.

The electron also has orbital angular momentum, which by quantum theory must equal $\hbar J$, where J is an integer and $\hbar$ is Planck's constant h divided by 2π. In terms of the equivalent magnetic moment, Eq. (1) may be written in the form of Eq. (2).

$$\omega_L = -\frac{\mu}{\hbar J}H \quad (2)$$

In this form the Larmor precession is exhibited by any magnetic moment μ including magnetic moments associated with spin angular momentum as well as those associated with orbital angular momentum. In this form the Larmor precession applies to experiments in molecular beams, electron paramagnetic resonance (EPR), and nuclear magnetic resonance (NMR). *See* ANGULAR MOMENTUM; ELECTRON PARAMAGNETIC RESONANCE (EPR) SPECTROSCOPY; ELECTRON SPIN; MAGNETIC RESONANCE. [E.A.; F.Ke.]

Larnite The alpha polymorph of calcium silicate (Ca_2SiO_4). Larnite is a mineral which crystallizes at high temperature. Its occurrences are practically confined to limestone or chalk zones in contact with semimolten basalts. At room temperature, larnite is metastable and inverts to its low-temperature polymorph calcio-olivine through shock. This leads to "fall," or disintegration of slags with time, and presents problems in the cement industry. The mineral is very rare, known from its type locality at Scawt Hill, County Antrim, Ireland, and from Crestmore, near Riverside, California. *See* SILICATE MINERALS. [P.B.M.]

Larynx The complex of cartilages and related structures at the opening of the trachea, or windpipe, into the pharynx, or throat. In humans and most other mammals, the signet-shaped cricoid cartilage forms the base of the larynx and rests upon the trachea. The thyroid cartilage, which forms the prominent Adam's apple ventrally, lies anterior to the cricoid. Dorsally there are paired pivoting cartilages, the arytenoids. Each is pyramid-shaped and acts as the movable posterior attachment for the vocal cords and the laryngeal muscles that regulate the cords. Two other small paired cartilages, the cuneiform and the corniculate, also lie dorsal to the thyroid cartilage. The epiglottis, a leaf-shaped elastic cartilage with its stem inserted into the thyroid notch, forms a lid to the larynx. [T.S.P.]

Larynx disorders Diseases of the larynx manifest themselves by hoarseness and by stridor, a form of noisy breathing caused by localized narrowing in the larynx or trachea.

Laryngitis is an inflammation of the mucous membrane of the larynx always associated with hoarseness. It frequently occurs with common colds and as a complication of other inflammatory diseases of the upper respiratory system. In diphtheria, the formation of a membrane of fibrin, leukocytes, destroyed tissue, and bacteria can cause severe respiratory difficulties, which may demand tracheotomy. The development of chronic laryngitis is favored by a chronic irritation such as that caused by smoking.

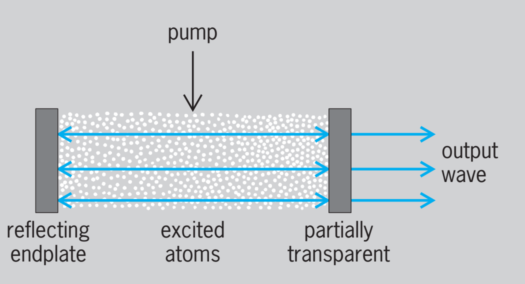
Hoarseness is also a manifestation of paralysis of the recurrent laryngeal nerve of the vagus, which is easily damaged upon surgical removal of a goiter.

Benign tumors of the larynx occur in the younger age group. A tumorlike formation of the vocal cord, known as singer's node, often accounts for the hoarseness of people who abuse the voice. Cancer of the larynx is not uncommon in humans, but is frequently of a slowly growing type and the outlook is often good. [E.R.W.]

Laser A device that uses the principle of amplification of electromagnetic waves by stimulated emission of radiation and operates in the infrared, visible, or ultraviolet region. The term laser is an acronym for light amplification by stimulated emission of radiation, or a light amplifier. However, just as an electronic amplifier can be made into an oscillator by feeding appropriately phased output back into the input, so the laser light amplifier can be made into a laser oscillator, which is really a light source. Laser oscillators are so much more common than laser amplifiers that the unmodified word "laser" has come to mean the oscillator, while the modifier "amplifier" is generally used when the oscillator is not intended. *See* AMPLIFIER; MASER; OSCILLATOR.

The process of stimulated emission can be described as follows: When atoms, ions, or molecules absorb energy, they can emit light spontaneously (as with an incandescent lamp) or they can be stimulated to emit by a light wave. This stimulated emission is the opposite of (stimulated) absorption, where unexcited matter is stimulated into an excited state by a light wave. If a collection of atoms is prepared (pumped) so that more are initially excited than unexcited (population inversion), then an incident light wave will stimulate more emission than absorption, and there is net amplification of the incident light beam. This is the way the laser amplifier works.

A laser amplifier can be made into a laser oscillator by arranging suitable mirrors on either end of the amplifier. These are called the resonator. Thus the essential parts of a laser oscillator are an amplifying medium, a source of pump power, and a resonator. Radiation that is directed straight along the axis bounces back and forth between the mirrors and can remain in the resonator long enough to build up a strong oscillation. (Waves oriented in other directions soon pass off the edge of the mirrors and are lost before they are much amplified.) Radiation may be coupled out by making one mirror partially transparent so that part of the amplified light can emerge through it (see illustration). The output wave, like most of the waves being amplified between the mirrors, travels along the axis and is thus very nearly a plane wave. *See* OPTICAL PUMPING.



Structure of a parallel-plate laser.

Continuous-wave gas lasers. Perhaps the best-known gas laser is the neutral-atom helium-neon (HeNe) laser, which is an electric-discharge-excited laser involving the noble gases helium and neon. The lasing atom is neon. The wavelength of the transition most used is 632.8 nanometers; however, many helium-neon lasers operate at longer and shorter wavelengths including 3390, 1152, 612, 594, and 543 nm. Output powers are mostly around 1 milliwatt.

A useful gas laser for the near-ultraviolet region is the helium-cadmium (HeCd) laser, where lasing takes place from singly ionized cadmium. Wavelengths are 325 and 442 nm, with powers up to 150 mW.

The argon ion laser provides continuous-wave (CW) powers up to about 50 W, with principal wavelengths of 514.5 and 488 nm, and a number of weaker transitions at nearby wavelengths. The argon laser is often used to pump other lasers, most importantly tunable dye lasers and titanium:sapphire lasers. For applications requiring continuous-wave power in the red, the krypton ion laser can provide continuous-wave lasing at 647.1 and 676.4 nm (as well as 521, 568, and other wavelengths), with powers somewhat less than those of the argon ion laser.

The carbon dioxide (CO_2) molecular laser has become the laser of choice for many industrial applications, such as cutting and welding.

Short-pulsed gas lasers. Some lasers can be made to operate only in a pulsed mode. Examples of self-terminating gas lasers are the nitrogen laser (337 nm) and excimer lasers (200–400 nm). The nitrogen laser pulse duration is limited because the lower level becomes populated because of stimulated transitions from the upper lasing level, thus introducing absorption at the lasing wavelength. Peak powers as large as 1 MW are possible with pulse durations of 1–10 nanoseconds. Excimer lasers are self-terminating because lasing transitions tear apart the excimer molecules and time is required for fresh molecules to replace them.

Solid-state lasers. The term solid-state laser should logically cover all lasers other than gaseous or liquid. Nevertheless, current terminology treats semiconductor (diode) lasers separately from solid-state lasers because the physical mechanisms are somewhat different. With that reservation, virtually all solid-state lasers are optically pumped.

Historically, the first laser was a single crystal of synthetic ruby, which is aluminum oxide (Al_2O_3 or sapphire), doped with about 0.05% (by weight) chromium oxide (Cr_2O_3). Three important rare-earth laser systems in current use are neodymium:YAG, that is, yttrium aluminum garnet ($Y_3Al_5O_{12}$) doped with neodymium; neodymium:glass; and erbium:glass. Other rare earths and other host materials also find application.

Semiconductor (diode) lasers. The semiconductor laser is the most important of all lasers, both by economic standards and by the degree of its applications. Its main features include rugged structure, small size, high efficiency, direct pumping by low-power electric current, ability to modulate its output by direct modulation of the pumping current at rates exceeding 20 GHz, compatibility of its output beam dimensions with those of optical fibers, feasibility of integrating it monolithically with other semiconductor optoelectronic devices to form integrated circuits, and a manufacturing technology that lends itself to mass production. *See* INTEGRATED OPTICS.

Most semiconductor lasers are based on III–V semiconductors. The laser can be a simple sandwich of *p*- and *n*-type material such as gallium arsenide (GaAs). The active region is at the junction of the *p* and *n* regions. Electrons and holes are injected into the active region from the *p* and *n* regions respectively. Light is amplified by stimulating electron-hole recombination. The mirrors comprise the cleaved end facets of the chip (either uncoated or with enhanced reflective coatings). *See* ELECTRON-HOLE RECOMBINATION; SEMICONDUCTOR; SEMICONDUCTOR DIODE.

Monochromaticity. When lasers were first developed, they were widely noted for their extreme monochromaticity. They provided far more optical power per spectral range (as well as per angular range) than was previously possible. It has since proven useful to relate laser frequencies to the international time standard (defined by an energy-level difference in the cesium atom), and this was done so precisely, through the use of optical heterodyne techniques, that the standard of length was redefined in such a way that the speed of light is fixed. In addition, extremely stable and monochromatic lasers have been developed, which can be used, for example, for optical communication between remote and moving frames, such as the Moon and the Earth. *See* FREQUENCY MEASUREMENT; HETERODYNE PRINCIPLE; LASER SPECTROSCOPY; LIGHT.

Tunable lasers. Having achieved lasers whose frequencies can be monochromatic, stable, and absolute (traceable to the time standard), the next goal is tunability. Most lasers allow modest tuning over the gain bandwidth of their amplifying medium. However, the laser most widely used for wide tunability has been the (liquid) dye laser. This laser must be optically pumped, either by a flash lamp or by another laser, such as the argon ion laser. Considerable engineering has gone into the development of systems to rapidly flow the dye and to provide wavelength tunability. About 20 different dyes are required to cover the region from 270 to 1000 nm.

Free-election lasers. The purpose of the free-electron laser is to convert the kinetic energy in an electron beam to electromagnetic radiation. Since it is relatively simple to generate electron beams with peak powers of 10^{10} W, the free-electron laser has the potential for providing high optical power, and since there are no prescribed energy levels, as in the conventional laser, the free-electron laser can operate over a broad spectral range.

[S.F.J.; A.L.S.; R.Pan.]

Laser alloying

A material processing method which utilizes the high power density available from focused laser sources to melt metal coatings and a portion of the underlying substrate. Since the melting occurs in a very short time and only at the surface, the bulk of the material remains cool, thus serving as an intimate heat sink. Large temperature gradients exist across the boundary between the melted surface region and the underlying solid substrate. The result is rapid selfquenching and resolidification.

For all laser sources, the exposure time (dwell time or pulse length) strongly influences the depth that will be melted. Longer exposure times result in deeper melting. Since deeper melting means a longer total time in the molten state, that means more time available for diffusion of the one or more alloying elements into the molten portion of the substrate. Deeper melting and longer melt times therefore result in more dilute surface alloys, while shallow melting and shorter melt times result in more concentrated surface alloys.

In making laser alloys, many other processing variables need to be considered. In addition to the exposure time, these include the laser power, the thickness of the film put down prior to laser melting, and in some instances the nature of the gaseous ambient during the laser processing. The processing variables are interrelated, and one variable cannot be freely changed without affecting another. Another consideration is that laser alloying is a liquid state–rapid quenching phenomenon. The near-surface region must be melted and yet vaporization avoided. Different minimum and maximum energy densities are thus defined for each laser exposure time. Laser alloying also involves very large temperature gradients and quenching from the liquid state. In this way it resembles other rapid-solidification technologies. The thermodynamic constraints which limit the conventional metallurgist do not necessarily apply. *See* ALLOY; LASER; METAL COATINGS.

[C.W.D.]

Laser cooling

Reducing the thermal motion of atoms with the force exerted by a laser beam. Typically, such cooling is used to reduce the temperature of a gas of atoms, or the velocity spread of atoms in an atomic beam.

Light affects atomic motion when the atoms absorb or emit photons, the particles or quanta that make up light. Photons carry momentum $p = h/\lambda$, where h is Planck's constant and λ is the light's wavelength. By conservation of momentum, when an atom absorbs or emits a photon, the atom's momentum must change by an amount equal to the photon momentum. Each absorption or emission thus gives the atom a tiny kick, changing its velocity. For most atoms this change is only a few millimeters to a few centimeters per second, while atoms in a gas at room temperature have velocities of a few hundred to a few thousand meters per second. Nevertheless, repeated absorption and emission of photons can have a significant effect on even hot atomic gases or beams. *See* CONSERVATION OF MOMENTUM; LIGHT; MOMENTUM; PHOTON.

The keys to using such repeated kicks to reduce the random, thermal motion of a gas of atoms are the monochromatic nature of laser light, the selectivity of absorption of light by atoms, and the Doppler effect. Light is an oscillating electromagnetic wave whose frequency of oscillation determines its color. The energy of each photon is $E = h\nu$, where ν is the frequency. Laser light can have nearly a single frequency or color, so that all the photons have almost identical energies. Atoms absorb only photons whose energy is equal, within a small range, to the difference in energy between two of its quantum states or energy levels. For sodium atoms this resonance frequency is $\nu_0 \equiv 5 \times 10^{14}$ Hz (wavelength $\lambda \equiv 589$ nanometers), but the absorption is efficient only over a range $\Delta\nu = 10^7$ Hz. Moving atoms, however, experience a Doppler shift so that, depending on their speed and whether they are moving along the direction of the laser beam or against it, the light appears to room-temperature atoms to have a frequency shifted up or down by a hundred or more times the natural absorption width $\Delta\nu$. *See* DOPPLER EFFECT; LASER.

If the frequency ν of the laser is tuned to be slightly lower than ν_0, those atoms moving against the laser beam see the laser upshifted, closer to ν_0. These atoms are more likely to absorb photons, receive kicks opposite to the direction of their velocity, and slow down. After absorbing a photon, the atoms are in an excited state and return to the original state by spontaneously emitting a photon. Such photons are radiated in random directions, so the effect of their kicks averages to zero. For atoms held in a trap, as ions generally are, any trapped atom will at some time be traveling against the laser beam and be cooled. Laser cooling was first demonstrated in 1978 with such trapped ions. For free atoms, another, similarly tuned laser beam is added, aimed in the opposite sense, to cool those atoms moving in the opposite direction. More generally, one uses three pairs of mutually perpendicular, counterpropagating laser beams, all tuned below ν_0. Then, no matter the direction of an atom's velocity, there are one or more laser beams that oppose the velocity and slow the atom.

Improving atomic clocks, where the thermal motion of atoms reduces the precision and accuracy, was a major motivation to developing laser cooling. Laser cooling is also used in atom optics, where well-collimated, monoenergetic atomic beams are more easily and effectively manipulated. In addition, laser cooling has been used to study collisions between very slow atoms. *See* ATOMIC CLOCK; SCATTERING EXPERIMENTS (ATOMS AND MOLECULES).

Laser cooling is intimately connected with trapping of atoms, because atoms must often be slowed down before they can be held in a trap and because atoms must often be trapped in order to observe laser cooling or its effects. Such effects include cold, trapped ions arranging themselves into a crystal because of the electric repulsion between the charged ions. Neutral atoms can become arrayed on an optical lattice of tiny traps formed by interference between the laser beams used to cool them. In both cases, the spacing between atoms is thousands of times larger than the spacing in solid crystals. Another effect is Bose-Einstein condensation, wherein a gas of atoms whose de Broglie wavelength is comparable to the spacing between atoms has a transition to a state where a significant fraction of the atoms are in the lowest kinetic energy state possible. *See* BOSE-EINSTEIN CONDENSATION; PARTICLE TRAP; QUANTUM MECHANICS. [W.D.P.]

Laser photobiology The interaction of laser light with biological molecules, and the applications to biology and medicine. *See* LASER.

Microirradiation is a useful technique for the study of cell function by alteration of a specific organelle or part of a cell. The laser beam is focused through the objective of a microscope onto the cell. Practically speaking, it is easy to obtain spots of about 1 micrometer in diameter. Ruby, neodymium, and argon lasers are used for this purpose.

Laser spectroscopy is used to probe biological processes in which very fast reactions are involved or to study structural changes of complex molecules. The two techniques used are flash photolysis (in the nanosecond and picosecond range) and Raman spectroscopy. *See* LASER SPECTROSCOPY; RAMAN EFFECT.

Continuous-wave lasers have been employed as a “light knife,” that is as a surgical cutting and coagulation tool. Generally, CO_2 lasers, emitting in the infrared, are used for this purpose. When the laser energy is focused onto a tissue surface, a small volume of tissue is heated, and thus only this area is “cut off.” An advantage of this procedure is that small capillaries are coagulated, preventing hemorrhage resulting from cut blood vessels. Argon lasers are the most commonly used for treating retinopathies, but also for glaucoma and cataract. Laser irradiation is used for removal of foreign pigments in the skin (tattoos), for treatment of vascular disorders (“wine marks”), and for removal of various pigmented skin lesions. [G.Mo.]

Laser photochemistry A branch of chemistry in which reactions are induced or altered by laser light. The initial part of any photochemical reaction involves an optical transition to some excited state of molecule. These excited states could involve electronic, vibrational, and rotational excitation. The particular photochemical product that results from the absorption of light depends on the specific excited state species created during the irradiation. Thus the properties of the light source often determine the photochemical product. Lasers have had an immense impact on the field of photochemistry by providing scientists with an intense, polarized, and nearly monochromatic source of light. There are lasers that extend from wavelengths of less than 110 nanometers (vacuum ultraviolet) to more than 100,000 nm (far-infrared); for comparison, the entire visible spectrum extends from only 400 nm (violet) to 700 nm (red).

Use of lasers in photochemical applications provides three main advantages over conventional light sources such as discharge or arc lamps. First, lasers are generally more powerful than conventional light sources. A continuous-wave argon ion laser can produce 10 W at 514.5 nm. Pulsed lasers, which compress the light energy into very short time periods (10^{-6} to 10^{-12} s), can generate correspondingly higher peak powers, typically from 10^3 to 10^9 W. These very short, intense pulses of light are used by the photochemist to monitor the time evolution of excited-state species or the appearance rate of products in a photochemical reaction.

Second, laser light can be collimated into a beam with a very small divergence angle, routinely less than 1/100 of a degree. The high degree of collimation of laser light permits efficient illumination at a chosen point within the sample, which could be far from the light source. This collimation permits the photochemist to confine the photochemical activation to some very small and precisely located area, such as in the fabrication and repair of microelectronic devices. In addition, the photochemical event, which has a very low absorption cross section, can be induced by photolyzing a very small region of the chemical sample with the total laser output power.

Third, laser light is exceptionally pure in color. The spectral purity of light can be described by a band width measured in wavenumbers (cm^{-1}), defined as the frequency width divided by the speed of light. While the full visible spectrum is 10,000 cm^{-1} wide, a typical laser may be as narrow as a few cm^{-1}. When conventional sources are used to irradiate molecules that have many possible excited-state transitions, a distribution of excited molecules results. These molecules may have been excited to several different electronic states with many possible vibrational or rotational energies. Under such conditions, it is often impossible to identify the excited electronic states that produced the various photochemical products. The high spectral purity of the laser obviates this problem, and the identity of the excited electronic state is almost always known to the laser photochemist.

The two general areas of laser-induced photochemistry are vibrational photochemistry and electronic photochemistry. In vibrational photochemistry the chemical reaction occurs entirely on the ground electronic state of the molecule, whereas electronic photochemistry occurs via some excited electronic state, usually involving the first excited singlet state (all electrons spin-paired) and possibly the lowest-lying triplet state (two electrons spin-unpaired) for most polyatomic molecules. Although electronic photochemistry has been profoundly affected by the advent of lasers, vibrational photochemistry, which requires intense light sources, is not even possible without lasers. *See* ELECTRON SPIN; TRIPLET STATE.

Because of the advantages of lasers, there is a constant demand for the development of lasers that will serve in new regions of the spectrum. In spite of the advantages of lasers, conventional light sources are still widely used in most photochemical investigations and commercial processes because of their simplicity and low cost. [D.Sn.]

Laser-solid interactions Interactions of laser light with solids. The term usually refers to the thermal effects of absorption of high-intensity laser beams. For nonthermal laser interactions with matter *see* LASER PHOTOCHEMISTRY; LASER SPECTROSCOPY; NONLINEAR OPTICS.

The high power densities attainable with lasers allow melting and even vaporization of any solid material that is sufficiently opaque at a given wavelength or photon energy. This has led to a number of applications involving cutting and drilling of ceramics and other brittle materials, even diamonds. Welding of components from the smallest wires to huge steel plates is done commercially with high-power lasers. Metal alloying in surface regions is also a domain of lasers. *See* LASER ALLOYING; LASER WELDING.

Ion implantation has become a dominant method of introducing controlled quantities of impurities near the surface of silicon and other semiconductors. The implanted layers need a heat treatment to repair the displacement damage caused by bombardment with energetic ions and to move the implanted impurity ions into lattice locations where they replace host atoms and become electrically active. Laser heating is particularly suitable for annealing since only the implanted regions are heated. *See* ION IMPLANTATION.

Thin films of single-crystalline silicon over an insulating substrate are very attractive for high-speed integrated circuits. An important approach to the formation of such films is the controlled melting of thin polycrystalline layers deposited over fused silica substrates or over oxidized silicon wafers. Through a careful control of temperature gradients around the molten spot, by shaping the laser beam or patterning the film, single-crystalline regions can be obtained. The formation of silicon-on-insulator structures will lead in the future to three-dimensional circuits, with several levels of transistors on the same chip. *See* INTEGRATED CIRCUITS; LASER. [G.K.C.]

Laser spectroscopy Spectroscopy with laser light or, more generally, studies of the interaction between laser radiation and matter. Lasers have led to a rejuvenescence of classical spectroscopy, because laser light can far surpass the light from other sources in brightness, spectral purity, and directionality, and if required, laser light can be produced in extremely intense and short pulses. The use of lasers can greatly increase the resolution and sensitivity of conventional spectroscopic techniques, such as absorption spectroscopy, fluorescence spectroscopy, or Raman spectroscopy. Moreover, interesting new phenomena have become observable in the resonant interaction of intense coherent laser light with matter. Laser spectroscopy has become a wide and diverse field, with applications in numerous areas of physics, chemistry, and biology. *See* LASER; SPECTROSCOPY. [T.W.Ha.]

Laser welding Welding with a laser beam. The primary apparatus is the continuous-wave, convectively cooled CO_2 laser with either oscillator/amplifier (gaussian output beam) or unstable resonator (hollows output beam) optics. These lasers, available in output powers ranging from approximately 1000 to 15,000 W, have been used to demonstrate specific welding accomplishments in a variety of metals and alloys. Substantial advances in laser technology made possible the production of fully automated multikilowatt industrial laser systems which can be operated on a continuous production basis. These systems can be used for a variety of development programs and on-line production applications. *See* LASER. [E.M.Br.]

Latent image An invisible image produced by a physical or chemical effect of light on the individual crystals (usually silver halide) of photographic emulsions. This image can be rendered visible by the process known as development. *See* PHOTOGRAPHY; PHOTOLYSIS. [R.H.N.]

Lateral line system A primitive vertebrate sensory system that is present in all larval and adult fishes, in larval amphibians (such as tadpoles), and in some adult amphibians that retain an aquatic lifestyle. The lateral line system consists of 100 or more sensory organs (neuromasts) that are typically arranged in lines on or just under the skin of the head and body. Neuromasts are composed of sensory hair cells, which are also found in the auditory system of all vertebrates. The lateral line system responds to water flowing past the skin surface and uses different flow patterns over the body to form hydrodynamic images of the animal's nearby surroundings, just as the visual system forms visual images of the environment using different light patterns on the retina.

Neuromasts are found just under the skin in fluid-filled canals that communicate with the skin surface through a series of pores (canal neuromasts, found in fishes only), or on the skin surface (superficial neuromasts, found in fishes and amphibians). A prominent canal that often forms a visible line along the trunk of most fishes is probably the origin of the term "lateral line," but in reality the lateral line system includes neuromasts that are distributed all over the head and body of the animal.

A neuromast contains up to hundreds of mechanosensory hair cells that are surrounded by support cells. Hair cells function as directional sensors that convey information to the brain about both the strength and direction of water currents. The ciliary bundle of each hair cell contains one long cilium (kinocilium) and a cluster of shorter cilia (stereocilia). The ciliary bundles of the hair cells are embedded in a gelatinous cupula. Hair cells are activated when water flows past the skin surface, causing the cupula to move, thus causing the cilia to bend. The neural response of each hair cell is proportional to both the degree of cilia displacement and the direction in which the stereocilia are displaced relative to the eccentrically placed kinocilium of each hair cell.

Information from neuromasts is transmitted to the brain by sensory (afferent) nerve fibers, which form five cranial nerves (the lateral line nerves) that terminate in distinct medullary regions of the brainstem (medulla oblongata). Distinct regions and pathways in the brain are dedicated to processing information from the lateral line system. These are similar in overall organization, and in proximity to regions of the brain dedicated to processing information from two other closely allied sensory systems, the auditory system and the electrosensory system. Information is also carried from the brain to the sense organs by efferent nerve fibers, which can modulate the sensitivity of the organs to certain stimuli (for example, to reduce sensitivity when water flows are produced by the animal's own movements). *See* AMPHIBIA.

The lateral line system is thought to have a function that is intermediate between touch and hearing, and is best described as a sense of touch-at-a-distance. In general, large-scale water movements such as oceanic currents, tides, and river flows that are strong enough to carry a fish with them are not by themselves very effective lateral line stimuli. Smaller-scale movements, such as those produced by a slowly moving (less than 8 cm or 0.25 ft/s) stream or by nearby animals (less than one or two body lengths away), can be effective lateral line stimuli.

Fishes can use different types of water flows to form hydrodynamic images of their surroundings. They can form images passively by remaining still and simply detecting the water currents created by other moving animals, or by detecting current distortions or turbulent wakes created by a stationary obstacle in moving water. Alternatively, fishes can actively form images by swimming past a stationary obstacle and then detecting the distortions in their own self-generated flows due to the presence of the obstacle.

Fishes and amphibians can also use their lateral line system to orient themselves relative to a water current (rheotaxis), hold a stationary position in a stream, capture prey, avoid predators, and communicate with intraspecifics. Many stream-dwelling fishes (such as trout and salmon) show rheotactic and station-holding behaviors by orienting their bodies upstream and holding positions behind stationary rocks or boulders. These behaviors are important for the upstream spawning migrations of these fishes and for capturing prey that are being carried downstream. *See* ELASMOBRANCHII; NERVOUS SYSTEM (VERTEBRATE). [S.Co.; J.F.Web.]

Lateral meristem Strips or cylinders of dividing cells located parallel to the long axis of the organ in which they occur. Radial enlargement of the cells derived from these meristems increases the diameter of the organ. The lateral meristem is concerned with secondary growth in the sense that its meristematic activity adds cells to the primary body which was derived from the apical meristems. *See* APICAL MERISTEM. [V.I.C.]

Laterite Originally the name for the iron-rich weathering product of basalt in southern India. The term is now used in a compositional sense for weathering products composed principally of the oxides and hydrous oxides of iron, aluminum, titanium, and manganese. Clay minerals of the kaolin group are typically associated with, and are genetically related to, laterite. Laterites range from soft, earthy, porous material to hard, dense rock. Concretionary forms of varying size and shape commonly are developed. The color depends on the content of iron oxides and ranges from white to dark red or brown, commonly variegated. *See* BAUXITE; CLAY MINERALS; KAOLINITE; WEATHERING PROCESSES.

Mature lateritic soils lack fertility for most systems of agriculture. Savannas or parklike grasslands are typical on laterite. Clay, not laterite, is found beneath rainforests and jungle vegetation. [S.S.G.]

Latitude and longitude The latitude of a location specifies the angle between an imaginary line directed generally toward the center of the Earth and the Equator. The longitude measures the angle between the meridian (the plane defined by the Earth's axis and this local reference direction) and the plane of the Greenwich meridian.

Astronomical (or astronomic) latitude and longitude use the direction of gravity for the reference direction. This direction, known as the astronomical vertical, is perpendicular to the equipotential surface of the Earth's gravitational field at the location of the observer.

A particular geopotential surface approximating mean sea level in the open ocean is called the geoid. A mathematical surface in the form of an oblate ellipsoid may be constructed to approximate the geoid. The direction perpendicular to this reference ellipsoid at the observer's location is used as the reference direction in defining geodetic latitude and longitude. *See* Geodesy.

Geocentric latitude and longitude are defined by a reference direction which passes precisely through the center of mass of the Earth. These coordinates are determined mathematically from the geodetic latitude and longitude, assuming a fixed relationship between the center of the geodetic datum and the center of mass and knowing the mathematical shape of the ellipsoid. [D.D.McC.]

Lattice (mathematics) Lattice theory deals with properties of order and inclusion, much as group theory treats symmetry. As a generalization of Boolean algebra, lattice theory was first applied to algebraic number theory; however, it was later recognized as a major branch of mathematics, unifying various aspects of algebra, geometry, and functional analysis, as well as of set theory, logic, and probability. *See* Boolean algebra; Group theory; Set theory.

The most basic concept of lattice theory is that of a partial ordering of a set S of elements $x, y, z, \ldots$. By this is meant a binary relation, usually denoted $\leqq$ (or $\geqq$), with the following properties:

(P1) $x \leqq x$ for all $x \in S$
(P2) If $x \leqq y$ and $y \leqq x$, then $x = y$
(P3) If $x \leqq y$ and $y \leqq z$, then $x \leqq z$

If $\leqq$ is any partial ordering of S, then its converse or dual $\geqq$ defined by statement (1), is also a partial ordering of S. This easily

$$x \geqq y \text{ if and only if } y \leqq x \qquad (1)$$

verified fact provides a fundamental Duality Principle, which is useful in many connections.

A lattice is defined as a partially ordered set in which any two elements x and y have a meet $x \cap y$ and a join $x \cup y$. These binary operations satisfy the four basic identities:

(L1) $x \cap x = x \cup x = x$
(L2) $x \cap y = y \cap x$ and $x \cup y = y \cup x$
(L3) $x \cap (y \cap z) = (x \cap y) \cap z$ and $x \cup (y \cup z) = (x \cup y) \cup z$
(L4) $x \cap (x \cup y) = x \cup (x \cap] y) = x$

The operations $\cap$ and $\cup$ are connected with the relation $\leqq$ by the condition that $x \leqq y$, $x \cap y = x$, and $x \cup y = y$ are three equivalent statements. Conversely, if L is an algebraic system with operations $\cap$ and $\cup$ satisfying (L1) to (L4) for all x, y, z, then the preceding condition defines $\leqq$ as a partial ordering of L, with respect to which $\cap$ and $\cup$ have the meanings defined above. [G.Bi.]

Lattice vibrations The oscillations of atoms in a solid about their equilibrium positions. In a crystal, these positions form a regular lattice. Because the atoms are bound not to their average positions but to the neighboring atoms, vibrations of neighbors are not independent of each other. In a regular lattice with harmonic forces between atoms, the normal modes of vibrations are lattice waves. These are progressive waves, and at low frequencies they are the elastic waves in the corresponding anisotropic continuum. The spectrum of lattice waves ranges from these low frequencies to frequencies of the order of 10^{13} Hz, and sometimes even higher. The wavelengths at these highest frequencies are of the order of interatomic spacings. *See* Crystal structure; Vibration; Wave motion.

At room temperature and above, most of the thermal energy resides in the waves of highest frequency. Because of the short wavelength, the motion of neighboring atoms is essentially uncorrelated, so that for many purposes the vibrations can be regarded as those of independently vibrating atoms, each moving about its average position in three dimensions with average vibrational energy of $3kT$, where k is the Boltzmann constant and T the absolute temperature. The wave character of the vibrations is needed, however, to describe heat transport by lattice waves. Also, lattice vibrations interact with free electrons in a conducting solid and give rise to electrical resistance. The temperature variation at low temperatures provides evidence that this interaction is with waves. *See* Electrical resistivity.

Scattering of lattice waves by defects increases with increasing frequency (f); its variation depends on the nature of the defect. Scattering by external and internal boundaries is almost independent of frequency, thus dominating at low frequencies and hence at low temperatures. A study of the thermal conductivity of nonmetallic crystals as function of temperature yields information about the defects present, and about the anharmonic nature of the interatomic forces in the crystal lattice. *See* Crystal defects; Thermal conduction in solids. [P.G.Kl.]

Launch complex The composite of facilities and support equipment needed to assemble, check out, and launch a rocket-propelled vehicle. The term usually is applied to the facilities and equipment required to launch larger vehicles for which a substantial amount of prelaunch preparation is needed. Small operational rockets may require similar but highly simplified resources on a much smaller scale. For these, the term launcher is usually used. *See* Space flight. [K.Kr.]

Laurales An order of flowering plants composed of seven eumagnoliid families of tropical tree species that are important ecologically; some are shrubs. They include in total about 2500 species. They are most closely related to Magnoliales, from which they differ in their partly inferior ovaries and their biaperturate or inaperturate pollen, and then to Winterales and Piperales. Lauraceae (the laurel or cinnamon family) are the best known and largest, but Monimiaceae and its segregates are also important. Nearly all species have aromatic oils, which are important spices, perfumes, and medicines; their flowers are for the most part small and often arranged in distinct whorls, but some such as those of Calycanthaceae are large and much like those of Magnoliales in that parts are arranged spirally and intergrade.

Many species are important as timbers. Cinnamon and camphor come from *Cinnamomum* species, sassafras tea was formerly made from the roots of *Sassafras albida* (now discouraged due to its suspected carcinogenic nature), and avocado comes from *Persea americana*; several genera are cultivated as ornamentals, such as *Calycanthus* (Carolina allspice) and *Chimonanthus* (wintersweet; both Calycanthaceae); and *Laurus* (bay laurel) and *Lindera* (spice bush; both Lauraceae). *See* Avocado; Camphor tree; Eumagnoliids; Magnoliales; Monocotyledons; Piperales; Sassafras. [M.Ch.]

Lava Molten rock material that is erupted by volcanoes through openings (volcanic vents) in the Earth's surface. Volcanic rock is formed by the cooling and solidification of erupted lava. Beneath the Earth's surface, molten rock material is called magma. All magmas and lavas consist mainly of a liquid, along with much smaller amounts of solid and gaseous matter. The liquid is molten rock that contains some dissolved gases or gas bubbles; the solids are suspended crystals of minerals or incorporated fragments of preexisting rock. Rapid cooling (quenching) of this liquid upon eruption forms a natural volcanic glass, whereas slower cooling allows more minerals to crystallize from the liquid and preexisting minerals to grow in size. The dissolved gases, a large proportion of which are lost on eruption, are mostly water vapor, together with lesser amounts of carbon, sulfur, chlorine, and fluorine gases. With very rare exception, the chemical composition of the liquid part of magmas and lavas is dominated by silicon and oxygen, which form polymers or compounds with other common rock-forming elements, such as aluminum, iron, magnesium, calcium, sodium, potassium, and titanium.

Viscosity is the principal property which determines the form of erupted lava. It is mainly dependent on chemical composition, temperature, gas content, and the amount of crystals in the magma. Liquid lava with basaltic composition (such as in Hawaii)—relatively low in silicon and aluminum and high in iron, magnesium, and calcium—has higher fluidity (lower viscosity) compared with lava of rhyolitic or dacitic composition (such as at Mount St. Helens, Washington), with higher abundance of silicon and aluminum but lower amounts of iron, magnesium, and calcium. High temperature and gas content of the liquid lava, combined with low crystal abundance, also contribute to increased lava fluidity. Measured maximum temperatures of basaltic lava (1150–1200°C; 2100–2190°F) are higher than those for andesitic and more silicic lavas (720–850°C; 1330–1560°F). Very fluid basaltic lavas can flow great distances, tens to hundreds of kilometers, from the eruptive vents; in contrast, more silicic lavas travel much shorter distances, forming stubby flows or piling up around the vent to form lava domes.

Volcanic products formed by erupted lava vary greatly in size and appearance, depending on volcano type, lava composition, and eruptive style. Most lava products are either lava flows, formed during nonexplosive eruptions by cooling and hardening of flowing lava; or fragmental (pyroclastic) products, formed during explosive eruptions by the shredding apart and ejection into the air of liquid lava. *See* ANDESITE; DACITE; MAGMA; PYROCLASTIC ROCKS; RHYOLITE; VISCOSITY; VOLCANIC GLASS; VOLCANO. [R.I.T.]

Lawrencium A chemical element, symbol Lr, atomic number 103. Lawrencium, named after E. O. Lawrence, is the eleventh transuranium element; it completes the actinide series of elements. *See* ACTINIDE ELEMENTS; PERIODIC TABLE; TRANSURANIUM ELEMENTS.

The nuclear properties of all the isotopes of lawrencium from mass 255 to mass 260 have been established. ^{260}Lr is an alpha emitter with a half-life of 3 min and consequently is the longest-lived isotope known. [A.Gh.]

Lawson criterion A necessary but not sufficient condition for the achievement of a net release of energy from nuclear fusion reactions in a fusion reactor. As originally formulated by J. D. Lawson, this condition simply stated that a minimum requirement for net energy release is that the fusion fuel charge must combust for at least enough time for the recovered fusion energy release to equal the sum of energy invested in heating that charge to fusion temperatures, plus other energy losses occurring during combustion. The Lawson criterion is to be thought of as only a rule of thumb for measuring fusion progress; detailed evaluation of all energy dissipative and energy recovery processes is required in order properly to evaluate any specific system. *See* NUCLEAR FUSION. [R.F.P.]

Lawsonite A metamorphic silicate mineral related chemically and structurally to the epidote group of minerals. Its composition is $CaAl_2(H_2O)(OH)_2[Si_2O_7]$. It possesses two perfect cleavages; crystals are orthorhombic prismatic to tabular, and colorless to pale blue; specific gravity is 3.1, and hardness is 6.5 on Mohs scale. *See* EPIDOTE; SILICATE MINERALS. [P.B.M.]

Layered intrusion In geology, an igneous rock body of large dimensions, 5–300 mi (8–480 km) across and as much as 23,000 ft (7000 m) thick, within which distinct subhorizontal stratification, or layering, is apparent and may be continuous over great distances, in some cases more than 60 mi (100 km). Although conspicuous layering may be found in other rocks of syenitic to granitic composition that are richer in silica, the great layered complexes of the world are, in an overall sense, of tholeiitic basaltic composition. (They may be viewed as intrusive analogs to continental flood basalts.) Indeed, their basaltic composition is of paramount significance to their origin. Only basaltic melts, originating in the mantle beneath the crust of the Earth, are both voluminous enough to occupy vast magma chambers and fluid enough for mineral layering to develop readily. The relatively low viscosity of basaltic melt is a consequence of its high temperature, 2100–2200°F (1150–1200°C), derived from the mantle source region, and its silica-poor, magnesium- and iron-rich (mafic) composition. *See* BASALT; EARTH; MAGMA.

Layered mafic complexes develop upon intrusion of large volumes of basaltic magma (120–24,000 mi^3 or 500–100,000 km^3) into more or less funnel-shaped (smaller complexes) or dish-shaped (larger complexes) chambers 3–5 mi (5–8 km) beneath the Earth's surface. It is widely held that such layering is dominantly produced by gravitational settling of early-formed (cumulus) crystals. These crystals begin to grow as the magma cools and, on reaching a critical size, begin to sink because of their greater density relative to that of the hot silicate melt. Although the sequential order of mineral crystallization can vary depending on subtle differences in magma chemistry, a classic sequence of crystallization from basaltic magma is olivine, $(Mg,Fe)SiO_4$; orthopyroxene, $(Mg,Fe)SiO_3$; clinopyroxene, $(Ca,Mg,Fe)SiO_3$; plagioclase $(Ca,Na)(Si,Al)_4O_8$.

While layers containing only one cumulus mineral may form under special circumstances, coprecipitation of two or three cumulus minerals—for example, olivine + orthopyroxene; orthopyroxene + plagioclase; or orthopyroxene + clinopyroxene + plagioclase—is more common. Under the influence of gravity and current movements in the cooling, tabular magma chamber, the cumulus minerals accumulate on the ever-rising floor of the chamber. The solid rock formed is known as a cumulate, a term that emphasizes its mode of origin and predominant content of cumulus minerals.

Lithologic layering within a complex is typically displayed on a variety of scales. On the broadest scale, a layered mafic complex may contain ultramafic cumulates rich in olivine and orthopyroxene at its base; mafic pyroxene- and plagioclase-rich cumulates at intermediate levels; and more evolved plagioclase-rich cumulates, or even granitic (granophyric) rocks, near its top.

Study of layered mafic complexes is of far more than academic interest because many of them host important deposits of chromium, copper, nickel, titanium, vanadium, and the platinum-group elements platinum, palladium, iridium, osmium, and rhodium. Each of these elements has a relatively high initial concentration in mafic magmas, but all must be dramatically concentrated within restricted layers to be recoverable economically. *See* IGNEOUS ROCKS. [G.K.Cz.]

Layout drawing A design drawing or graphical statement of the overall form of a component or device, which is usually prepared during the innovative stages of a design. Since it lacks detail and completeness, a layout drawing provides a faithful explanation of the device and its construction only to individuals such as designers and drafters who have been intimately involved in the conceptual stage. In a sense, the layout drawing is a running record of ideas and problems posed as the design evolves. In most cases the layout drawing ultimately becomes the primary source of information from which detail drawings and assembly drawings are prepared by other drafters under the guidance of the designer. *See* DRAFTING; ENGINEERING DRAWING. [R.W.M.]

Lazurite The chief mineral constituent in the ornamental stone lapis lazuli. Lazurite is a feldspathoid. It crystallizes in the isometric system, but well-formed crystals, usually dodecahedral, are rare. Most commonly, it is granular or in compact masses. The hardness is 5–5.5 on Mohs scale, and the specific gravity is 2.4–2.5. There is vitreous luster and the color is a deep azure, more rarely a greenish-blue. Lazurite is a tectosilicate, the composition of which is expressed by the formula $Na_4Al_3Si_3O_{12}S$.

Lapis lazuli is a mixture of lazurite with other silicates and calcite and usually contains disseminated pyrite. It has long been valued as an ornamental material. Localities of occurrence are in Afghanistan; Lake Baikal, Siberia; Chile; and San Bernardino County, California. *See* FELDSPATHOID; SILICATE MINERALS. [C.S.Hu.]

Leaching The removal of a soluble fraction, in the form of a solution, from an insoluble, permeable solid with which it is associated. The separation usually involves selective dissolving, with or without diffusion, but in the extreme case of simple washing it consists merely of the displacement (with some mixing) of one interstitial liquid by another with which it is miscible. The soluble constituent may be solid (as the metal leached from ore) or liquid (as the oil leached from soybeans).

Leaching is closely related to solvent extraction, in which a soluble substance is dissolved from one liquid by a second liquid immiscible with the first. Both leaching and solvent extraction are often called extraction. Because of its variety of applications and its importance to several ancient industries, leaching is known by a number of other names: solid-liquid extraction, lixiviation, percolation, infusion, washing, and decantation-settling. The liquid used to leach away the soluble material (the solute) is termed the solvent. The resulting solution is called the extract or sometimes the miscella.

Leaching processes fall into two principal classes: those in which the leaching is accomplished by percolation (seeping of solvent through a bed of solids), and those in which particulate solids are dispersed into the extracting liquid and subsequently separated from it. In either case, the operation may be a batch process or continuous. *See* EXTRACTION; FILTRATION; SOLVENT EXTRACTION. [S.A.M.]

Lead A chemical element, Pb, atomic number 82 and atomic weight 207.19. Lead is a heavy metal (specific gravity 11.34 at 16°C or 61°F), of bluish color, which tarnishes to dull gray. It is pliable, inelastic, easily fusible, melts at 327.4°C (621.3°F), and boils at 1740°C (3164°F). The normal chemical valences are 2 and 4. It is relatively resistant to attack by sulfuric and hydrochloric acids but dissolves slowly in nitric acid. Lead is amphoteric, forming lead salts of acids as well as metal salts of plumbic acid. Lead forms many salts, oxides, and organometallic compounds. *See* PERIODIC TABLE.

Industrially, the most important lead compounds are the lead oxides and tetraethyllead. Lead forms alloys with many metals and is generally employed in the form of alloys in most applications. Alloys formed with tin, copper, arsenic, antimony, bismuth, cadmium, and sodium are all of industrial importance. *See* LEAD ALLOYS.

Lead compounds are toxic and have resulted in poisoning of workers from misuse and overexposure. However, lead poisoning is presently rare because of the industrial application of modern hygienic and engineering controls. The greatest hazard arises from the inhalation of vapor or dust. In the case of organolead compounds, absorption through the skin may become significant. Some of the symptoms of lead poisoning are headaches, dizziness, and insomnia. In acute cases there is usually stupor, which progresses to coma and terminates in death. The medical control of employees engaged in lead usage involves precise clinical tests of lead levels in blood and urine. With such control and the proper application of engineering control, industrial lead poisoning may be entirely prevented.

Lead rarely occurs in its elemental state. The most common ore is the sulfide, galena. The other minerals of commercial importance are the carbonate, cerussite, and the sulfate, anglesite, which are much more rare. Lead also occurs in various uranium and thorium minerals, arising directly from radioactive decay. Commercial lead ores may contain as little as 3% lead, but a lead content of about 10% is most common. The ores are concentrated to 40% or greater lead content before smelting. *See* LEAD METALLURGY.

The largest single use of lead is for the manufacture of storage batteries. Other important applications are for the manufacture of tetraethyllead, cable covering, construction, pigments, solder, and ammunition.

Organolead compounds are being developed for applications such as catalysts for polyurethane foams, marine antifouling paint toxicants, biocidal agents against gram-positive bacteria, protection of wood against marine borers and fungal attack, preservatives for cotton against rot and mildew, molluscicidal agents, anthelmintic agents, wear-reducing agents in lubricants, and corrosion inhibitors for steel.

Because of its excellent resistance to corrosion, lead finds extensive use in construction, particularly in the chemical industry. It is resistant to attack by many acids because it forms its own protective oxide coating. Because of this advantageous characteristic, lead is used widely in the manufacture and handling of sulfuric acid.

Lead has long been used as protective shielding for x-ray machines. Because of the expanded applications of atomic energy, radiation-shielding applications of lead have become increasingly important.

Lead sheathing for telephone and television cables continues to be a sizable outlet for lead. The unique ductility of lead makes it particularly suitable for this application because it can be extruded in a continuous sheath around the internal conductors.

The use of lead in pigments has been a major outlet for lead but is decreasing in volume. White lead, $2PbCO_3 \cdot Pb(OH)_2$, is the most extensively used lead pigment. Other lead pigments of importance are basic lead sulfate and lead chromates.

A considerable variety of lead compounds, such as silicates, carbonates, and salts of organic acids, are used as heat and light stabilizers for polyvinyl chloride plastics. Lead silicates are used for the manufacture of glass and ceramic frits, which are useful in introducing lead into glass and ceramic finishes. Lead azide, $Pb(N_3)_2$ is the standard detonator for explosives. Lead arsenates are used in large quantities as insecticides for crop protection. Litharge (lead oxide) is widely employed to improve the magnetic properties of barium ferrite ceramic magnets. Also, a calcined mixture of lead zirconate and lead titanate, known as PZT, is finding increasing markets as a piezoelectric material. [H.S.; J.D.J.]

Lead alloys Substances formed by the addition of one or more elements, usually metals, to lead. Lead alloys may exhibit greatly improved mechanical or chemical properties as compared to pure lead. The major alloying additions to lead are antimony and tin. The solubilities of most other elements in lead are small, but even fractional weight percent additions of some of these elements, notably copper and arsenic, can alter properties appreciably.

Lead is used as a sheath over the electrical components to protect power and telephone cable from moisture. Lead alloy grids are used in the lead-acid storage battery (the type used in automobiles) to support the active material composing the plates. Chemical-resistant alloys are used extensively in many applications requiring resistance to water, atmosphere, or chemical corrosion. Lead bearing metals (babbitt metals) find frequent application in cast sleeve bearings, and are used extensively in freight-car journal bearings. Lead-base solder contains large amounts of tin with selected minor additions to provide specific benefits. *See* ALLOY; LEAD; LEAD METALLURGY; SOLDERING; TIN ALLOYS. [D.Wi.]

Lead isotopes (geochemistry) The study of the isotopic composition of stable and radioactive lead in geological and environmental materials to determine their ages or origins. *See* Lead.

Lead isotope geochemistry provides the principal method for determining the ages of old rocks and the Earth itself, as well as the sources of metals in mineral deposits and the evolution of the mantle. Lead (Pb) has four stable isotopes of mass 204, 206, 207, and 208. Three are produced by the radioactive decay of uranium (U) and thorium (Th) [reactions (1)–(3), where $t_{1/2}$ is

$$^{238}\mathrm{U}\,(t_{1/2} = 4.5 \times 10^{9}\ \mathrm{years}) \rightarrow {}^{206}\mathrm{Pb} + 8\alpha + 6\beta \qquad (1)$$

$$^{235}\mathrm{U}\,(t_{1/2} = 0.71 \times 10^{9}\ \mathrm{years}) \rightarrow {}^{207}\mathrm{Pb} + 7\alpha + 4\beta \qquad (2)$$

$$^{232}\mathrm{Th}\,(t_{1/2} = 13.9 \times 10^{9}\ \mathrm{years}) \rightarrow {}^{208}\mathrm{Pb} + 6\alpha + 4\beta \qquad (3)$$

the half-life of the isotope and α and β denote alpha and beta particles, respectively].

The lead produced by the decay of uranium and thorium is termed radiogenic. Since ^{204}Pb is not produced by the decay of any naturally occurring radionuclide, it can be used as a monitor of the amount of initial (nonradiogenic) lead in a system. This will include all of the ^{204}Pb and variable amounts of ^{206}Pb, ^{207}Pb, and ^{208}Pb. *See* Alpha particles; Beta particles; Radioactivity; Thorium; Uranium.

It is possible to calculate the isotopic composition of lead at any time t in the past by calculating and deducting the amount of radiogenic lead that will have accumulated, provided a mineral or rock represents a closed system. A closed system is one in which there has been no chemical transfer of uranium, thorium, or lead in or out of the mineral or rock since it formed. All calculations for uranium-lead dating should yield the same age; this is a unique and powerful property. The ratio of radiogenic ^{207}Pb to ^{206}Pb is simply a function of age, not the U/Pb ratio. Certain minerals such as zircon, monazite, and uraninite are particularly well suited for dating because of extremely high concentrations of uranium or thorium relative to initial lead. However, the degree to which they behave as closed systems can vary. *See* Rock age determination.

Even if a rock or mineral contains appreciable initial lead, it may still be dated by using isochron methods. Since the amount of radiogenic lead relative to nonradiogenic lead is a function of the U/Pb ratio and time, the slope on a plot of ^{206}Pb/^{204}Pb against ^{238}U/^{204}Pb is proportional to age. An isochron is a line on a graph defined by data for rocks of the same age with the same initial lead isotopic composition, the slope of which is proportional to the age. In practice, the ^{238}U/^{204}Pb ratio may well have been disturbed by recent alteration of the rock because uranium is highly mobile in near-surface environments. For this reason it is more common to combine the two uranium decay schemes and plot ^{207}Pb/^{204}Pb against ^{206}Pb/^{204}Pb; the slope of an isochron on this plot is a function of age.

Isochron dating has been used to determine an age of 4.55 billion years for the Earth and the solar system by dating iron and stony meteorites. The position of data along the isochron is a function of the U/Pb ratio. The iron meteorites are particularly important for defining the initial lead isotopic composition of the solar system since they contain negligible uranium. The meteorite isochron is commonly termed the geochron. *See* Earth, age of; Geochronometry; Meteorite.

Lead isotopes can serve as tracers in the lithosphere, atmosphere, and hydrosphere. Lead isotopes are commonly used to trace the sources of constituents in continental terranes, granites, ore deposits, and pollutants. For example, some granites such as those of the Isle of Skye in northwest Scotland have very unradiogenic lead, indicating that the magmas were derived by melting portions of the lower continental crust that were depleted in uranium about 3 billion years ago. *See* Ore and mineral deposits.

While there are at least 11 known radioactive isotopes of lead, only ^{212}Pb, ^{214}Pb, and especially ^{210}Pb have been of interest geochemically. Unlike their noble-gas parents, the radioactive lead isotopes as well as other daughter products have a strong affinity for atmospheric aerosols. Both ^{212}Pb and ^{214}Pb have been used to study the process of diffusion of ions in gases and the mechanism of attachment of small ions to aerosols. Measurement of the distribution of radon (Rn) daughter product activities with respect to aerosol size has been important in the development of theoretical models of ion-aerosol interactions. The short half-lives of ^{212}Pb and ^{214}Pb also make these isotopes suitable for studies of near-ground atmospheric transport processes. ^{210}Pb, because of its longer half-life, is removed mainly by precipitation and dry deposition. Its horizontal and vertical distributions are the result of the integrated effects of the distribution and intensity of sources, the large-scale motions of the atmosphere, and the distribution and intensity of removal processes. *See* Aerosol; Air mass; Atmospheric chemistry; Radon.

One of the most important uses of ^{210}Pb is for dating recent coastal marine and lake sediments. As the isotope is rapidly removed from water to underlying deposits, surface sediments often have a considerable excess of ^{210}Pb. The excess is defined as that present in addition to the amount produced by the decay of radium in the sediments. When the sedimentation rate is constant and the sediments are physically undisturbed, the excess ^{210}Pb decreases exponentially with sediment depth as a result of radioactive decay during burial. The reduction in activity at a given depth, compared with that at the surface, provides a measure of the age of the sediments at that depth. Typically, excess ^{210}Pb can be measured for up to about five half-lives or about 100 years, and it is therefore ideally suited for dating sediments that hold records of human impact on the environment. *See* Radioisotope (geochemistry); Sedimentology. [A.N.H.; J.A.R.]

Lead metallurgy The extraction of lead from ore, its subsequent purification and processing, and its alloying with other metals to achieve desired properties.

There are many types and several specifications for lead. Primary lead is lead which is extracted and refined from ore. Secondary lead, recycled mostly from old storage batteries, can be refined to meet the same specifications as the primary metal, but the remelting, drossing, and recasting involved may have a negative impact on composition.

In the United States most lead ore is smelted and refined to a minimum purity of 99.85%. At and above this level of purity, four different grades of lead are recognized by the American Society for Testing and Materials: corroding, chemical, acid-copper, and common desilverized lead. The major differences among these grades are the allowable concentrations of copper, silver, and bismuth. Even trace amounts of these elements can have a significant effect on the properties or cost of the lead and justify having the four grades.

The first step in the beneficiation of ores to raise the lead content and to separate the lead from the zinc and iron minerals is concentrating. The standard processing begins with crushing the raw ore, followed by wet grinding, and then by mixing with flotation chemicals that collect the lead minerals in a froth, which is thickened and filtrated. The lead concentrate produced in this first processing step has a lead metal content of around 70%.

Before smelting, lead concentrates are frequently blended with high-grade raw ores or returned intermediates (flue dusts, limerock, and so forth) drawn from proportioning bins. These materials are pelletized so that a homogeneous and carefully sized smelter feed is provided. The feed is then sintered. The sinter product is charged into the top of a blast furnace. As the charge descends in the furnace, the molten metal flows to the bottom, from where it is withdrawn for refining. *See* Lead. [A.L.P.]

Leaf A lateral appendage which is borne on a plant stem at a node (joint) and which usually has a bud in its axil. In most plants, leaves are flattened in form, although they may be nearly cylindrical with a sheathing base as in onion. Leaves usually contain chlorophyll and are the principal organs in which the important processes of photosynthesis and transpiration occur.

Morphology. A complete dicotyledon leaf consists of three parts: the expanded portion or blade; the petiole which supports the blades; and the leaf base. Stipules are small appendages that arise as outgrowths of the leaf base and are attached at the base of the petiole. The leaves of monocotyledons may have a petiole and a blade, or they may be linear in shape without differentiation into these parts; in either case the leaf base usually encircles the stem. The leaves of grasses consist of a linear blade attached to the stem by an encircling sheath.

Leaves are borne on a stem in a definite fixed order, or phyllotaxy, according to species (Fig. 1). For identification purposes, leaves are classified according to type (Fig. 2) and shape (Fig. 3), and types of margins (Fig. 4), tips, and bases (Fig. 5). The arrangement of the veins, or vascular bundles, of a leaf is called venation (Fig. 6). The main longitudinal veins are usually interconnected with small veins. Reticulate venation is most common in dicotyledons, parallel venation in monocotyledons.

Surfaces of leaves provide many characteristics that are used in identification. A surface is glabrous if it is smooth or free from hairs; glaucous if covered with a whitish, waxy material, or "bloom"; scabrous if rough or harsh to the touch; pubescent, a general term for surfaces that are hairy; puberulent if covered with very fine, downlike hairs; villous if covered with long, soft, shaggy hairs; hirsute if the hairs are short, erect, and stiff; and hispid if they are dense, bristly, and harshly stiff.

The texture may be described as succulent when the leaf is fleshy and juicy; hyaline if it is thin and almost wholly transparent; chartaceous if papery and opaque but thin; scarious if thin and dry, appearing shriveled; and coriaceous if tough, thickish, and leathery.

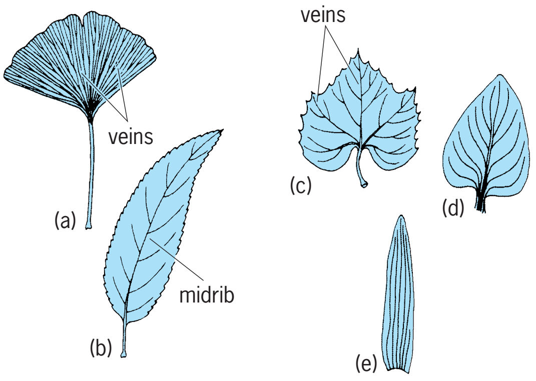

Fig. 6. Leaf venation. (*a*) Dichotomous. (*b*) Pinnate reticulate. (*c*) Palmate reticulate. (*d*) Parallel (expanded leaf). (*e*) Parallel (linear leaf).

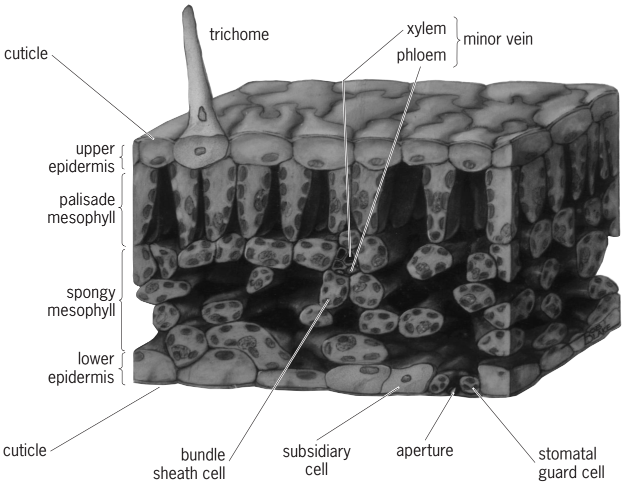

Fig. 7. Three-dimensional diagram of internal structure of a typical dicotyledon leaf.

Leaves may be fugacious, failing nearly as soon as formed; deciduous, failing at the end of the growing season; marcescent, withering at the end of the growing season but not falling until toward spring; or persistent, remaining on the stem for more than one season, the plant thus being evergreen. *See* DECIDUOUS PLANTS; EVERGREEN PLANTS.

Anatomy. The foliage leaf is the chief photosynthetic organ of most vascular plants. Although leaves vary greatly in size and form, they share the same basic organization of internal tissues and have similar developmental pathways. Like the stem and root, leaves consist of three basic tissue systems: the dermal tissue system, the vascular tissue system, and the ground tissue system. However, unlike stems and roots which usually have radial symmetry, the leaf blade usually shows dorsiventral symmetry, with vascular and other tissues being arranged in a flat plane.

Stems and roots have apical meristems and are thus characterized by indeterminate growth; leaves lack apical meristems, and therefore have determinate growth. Because leaves are more or less ephemeral organs and do not function in the structural support of the plant, they usually lack secondary growth and are composed largely of primary tissue only. *See* APICAL MERISTEM; ROOT (BOTANY); STEM.

The internal organization of the leaf is well adapted for its major functions of photosynthesis, gas exchange, and transpiration. The photosynthetic cells, or chlorenchyma tissue, are normally arranged in horizontal layers, which facilitates maximum interception of the Sun's radiation. The vascular tissues form an extensive network throughout the leaf so that no photosynthetic cell is far from a source of water, and carbohydrates produced by the chlorenchyma cells need travel only a short distance to reach the phloem in order to be transported out of the leaf (Fig. 7). The epidermal tissue forms a continuous covering over the leaf so that undue water loss is reduced, while at the same time the exchange of carbon dioxide and oxygen is controlled. *See* EPIDERMIS (PLANT); PARENCHYMA; PHLOEM; XYLEM.

[N.G.D.]

Least-action principle

Like Hamilton's principle, the principle of least action is a variational statement that forms a basis from which the equations of motion of a classical dynamical system may be deduced. Consider a mechanical system described by coordinates $q_1, \ldots, q_f$ and their canonically conjugate momenta $p_1, \ldots, p_f$. The action S associated with a segment of the trajectory of the system is defined by the equation below, where the integral is evaluated along the given

$$S = \int_c \sum_j p_j \, dq_j$$

segment c of the trajectory. The action is of interest only when the total energy E is conserved. The principle of least action states that the trajectory of the system is that path which makes the value of S stationary relative to nearby paths between the same configurations and for which the energy has the same constant value. The principle is misnamed, as only the stationary property is required. It is a minimum principle for sufficiently short but finite segments of the trajectory. *See* HAMILTON'S EQUATIONS OF MOTION; HAMILTON'S PRINCIPLE; MINIMAL PRINCIPLES.

[P.M.S.]

Least-squares method

A method of obtaining the best values (the ones with least error) of unknown quantities supposed to satisfy a system of linear equations of the form shown as notation (1), where $n > m$. Since there are more equations

$$\begin{aligned} M_{11}a_1 + M_{12}a_2 + \cdots + M_{1m}a_m &= b_1 \\ M_{21}a_1 + M_{22}a_2 + \cdots + M_{2m}a_m &= b_2 \\ \cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots \\ M_{n1}a_1 + M_{n2}a_2 + \cdots + M_{nm}a_m &= b_n \end{aligned} \tag{1}$$

than unknowns, the system is said to be overdetermined. In the physical situation, the b_i are measured quantities, the M_{ij} are known (or assumed) quantities, and the a_i are to be adjusted to their best values.

Consider a simple example. A quantity y of interest is supposed (perhaps for theoretical reasons) to be a linear function of an independent variable x. For a series of selected values $x_1, x_2, \ldots$ of x the values $y_1, y_2, \ldots$ of y are measured. The expected relation is shown as notation (2), and the problem is to find the best values

$$\begin{aligned} x_1\alpha + \text{ß} &= y_1 \\ x_2\alpha + \text{ß} &= y_2 \\ x_3\alpha + \text{ß} &= y_3 \\ \cdots\cdots\cdots \end{aligned} \tag{2}$$

of α and ß, that is, respectively, the slope and intercept of the line which graphically represents the function. The best values of α and ß, in the least squares sense, are obtained by writing Eq. (3) and asserting that term (4) shall be minimized with respect

$$\eta_i = y_i - (x_i\alpha + \text{ß}) \tag{3}$$

$$\sum_i^n = 1\eta_i^{\,2} \tag{4}$$

to α and β; that is, that Eqs. (5) hold. This leads to Eqs. (6) and (7), which may be solved for α and ß.

$$\begin{aligned} \frac{\partial}{\partial\alpha}\sum_{i=1}^n \eta_i^{\,2} &= 0 \\ \frac{\partial}{\partial\text{ß}}\sum_{i=1}^n \eta_i^{\,2} &= 0 \end{aligned} \tag{5}$$

$$\alpha\sum_{i=1}^n x_i + n\text{ß} - \sum_{i=1}^n y_i = 0 \tag{6}$$

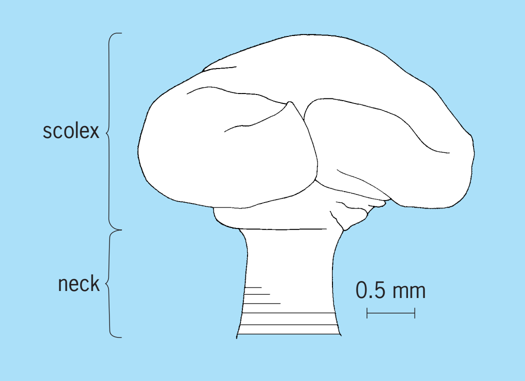
$$\alpha\sum_{i=1}^n x_i^2 + \text{ß}\sum_{i=1}^n x_i - \sum_{i=1}^n x_i y_i = 0 \tag{7}$$

See CURVE FITTING.

[McA.H.H.]

Lecanicephaloidea

An order of tapeworms of the subclass Cestoda. All species are intestinal parasites of elasmobranch fishes. These tapeworms are distinguished by having a peculiar



Anterior end of a lecanicephaloid tapeworm.

scolex divided into two portions. The lower portion is collarlike and bears four small suckers; the upper portion may be discoid or tentacle-bearing and is provided with glandular structures (see illustration). The scolex is usually buried in the intestinal wall of the host and may produce local pathology. The anatomy of the segments is very similar to that of the Proteocephaloidea. *See* CESTODA. [C.P.R.]

Lecanorales An order of the Ascolichenes, also known as the Discolichenes. Lecanorales is the largest and most typical order of lichens and parallels closely the fungal order Helotiales. The apothecia are open and discoid, with a typical hymenium and hypothecium. There are four growth forms—crustose, squamulose, foliose, and fruticose—all showing greater variability than any other order of lichens.

The Lecanorales is divided into 25 families, about 160 genera, and 8000–10,000 species. Family divisions are based on growth form of the thallus, structure of the apothecia, the species of symbiotic algae present, and spore characters. Species are separated by such characters as isidia, soredia, rhizines, and pores, and by chemistry. The larger families include: Cladoniaceae, Lecanoraceae, Lecideaceae, Parmeliaceae, Umbilicariaceae, and Usneaceae. [M.E.H.]

Le Chatelier's principle A description of the response of a system in equilibrium to a change in one of the variables determining the equilibrium.

For any chemical reaction equilibrium or phase equilibrium, an increase in temperature at constant pressure shifts the equilibrium in the direction in which heat is absorbed by the system. *See* CHEMICAL EQUILIBRIUM; PHASE EQUILIBRIUM.

For any reaction equilibrium or phase equilibrium, an increase in pressure at constant temperature shifts the equilibrium in the direction in which the volume of the system decreases.

For a reaction equilibrium in a dilute solution, addition of a small amount of a solute species that participates in the reaction will shift the equilibrium in the direction that uses up some of the added solute.

For an ideal-gas reaction equilibrium, addition at constant temperature and volume of a species that participates in the reaction will shift the equilibrium in the direction that consumes some of the added species. For an ideal-gas reaction equilibrium, addition at constant temperature and pressure of a species that participates in the reaction might shift the equilibrium to produce more of the added species or might shift the equilibrium to use up some of the added species; the direction of the shift depends on the reaction, on which species is added, and on the initial composition of the equilibrium mixture. [I.N.L.]

Lectins A class of proteins of nonimmune origin that bind carbohydrates reversibly and noncovalently without inducing any change in the carbohydrate. Lectins bind a variety of cells having cell-surface glycoproteins (carbohydrate bound proteins) or glycolipids (carbohydrate bound lipids). The presence of two or more binding sites for each lectin molecule allows the agglutination of many cell types, and the agglutination reaction has been used extensively to detect the presence of lectins in extracts from different organisms. Although lectins are ubiquitous in nature, their biological role is not well understood. *See* CARBOHYDRATE.

Hemagglutinating activity has been found in more than 1000 plant taxa. However, knowledge on distribution of well-characterized lectins covers only 4–5% of flowering plant families. Moreover, most of the best-characterized lectins come from a single family, Leguminosae.

Animal lectins have also been characterized in only a small number of species, but they have been found in almost all of the invertebrate and vertebrate phyla. Invertebrate lectins occur in body fluids or secretions, such as fish serum, snake venom, seminal and coelomic fluids, and hemolymph. Vertebrate lectins occur as soluble or integral membrane proteins in embryonic and adult fluids, organs, and tissues.

Microbial lectins have been isolated mainly from bacteria, but they are also found in viruses, slime molds, protozoa, green algae, and fungi.

From the few known examples, it seems clear that lectins are involved in recognition phenomena and their ability to bind particular carbohydrate structures is the key to their biological functions. These recognition functions include their involvement in interactions with cells or extracellular materials from the same organism (self-recognition) and interactions with foreign particles or cells (non-self recognition). Among the best-known examples of self-recognition mediated by lectins are the hepatic lectins involved in the recognition of glycoproteins that must be cleared from circulation. Specific lectins recognize and internalize the target proteins into lysosomes, where they are destroyed. *See* LYSOSOME.

Examples of lectin-mediated non-self-recognition are seen in the involvement of bacterial surface lectins in infection. Numerous bacterial strains produce surface lectins that recognize specific sugars in the surface of host cells and thus initiate the infection process. Another example is the symbiotic interaction between nitrogen-fixing bacteria and plant roots. The lectins present in the roots of legumes are localized at the surface of root hairs and in the root exudates, where they recognize the appropriate *Rhizobium* strain and account for part of the specificity in the initiation of nodulation.

Lectins are very useful reagents for the study of complex carbohydrates and cell surfaces, for the separation and identification of particular cells, and for the stimulation of cell proliferation. Lectins covalently attached to insoluble matrices are used to separate glycoproteins or glycopeptides that contain different carbohydrates. Labeled lectins are also used in histochemical and cytochemical studies to localize glyconjugates that carry particular sugars. This technique is particularly interesting, since changes in lectin-binding patterns occur during embryonic differentiation, malignant transformation, aging, and some pathological conditions. *See* PROTEIN. [R.P.Le.]

Lecythidales An order of flowering plants, division Magnoliophyta (Angiospermae), in the subclass Dilleniidae of the class Magnoliopsida (dicotyledons). The order consists of the single family Lecythidaceae, with about 400 species. They are tropical, woody plants with alternate, entire leaves, valvate sepals, separate petals, numerous centrifugal stamens, and a syncarpous, inferior ovary with axile placentation. Brazil nuts are the seeds of *Bertholletia excelsa*, a member of the Lecythidaceae. *See* BRAZIL NUT; DILLENIIDAE; MAGNOLIOPHYTA. [A.Cr.]

Legendre functions Solutions to the differential equation $(1 - x^2)y'' - 2xy' + \nu(\nu + 1)y = 0$.

The most elementary of the Legendre functions, the Legendre polynomial $P_n(x)$ Can be defined by the generating function in Eq. (1). More explicit representations are Eq. (2), and the hypergeometric function, Eq. (3). *See* HYPERGEOMETRIC FUNCTIONS.

$$(1 - 2xr + r^2)^{-1/2} = \sum_{n=0}^{\infty} P_n(x) r^n \qquad (1)$$

$$P_n(x) = \frac{(-1)^n}{2_n n!} \frac{d^n}{dx}^n (1 - x^2)^n \qquad (2)$$

$$P_n(x) = {}_2F_1[-n, n+1; 1; (1-x)/2] \qquad (3)$$

Generating function (1) implies Eq. (4). The function $(a^2 - 2ar \cos\theta + r^2)^{-1/2}$ represents the potential in an inverse square field at a point P of a source at A, where r and a are the

$$\begin{gathered}(a^2 - 2ar\cos\theta + r^2)^{-1/2} = \frac{1}{a}\sum_{n=0}^{\infty} P_n(\cos\theta)(r/a)^n \\ 0 < r < a\end{gathered} \qquad (4)$$

distances from P and A to a fixed point O, and θ is the angle between the segments PO and OA. *See* DIFFERENTIAL EQUATION; ORTHOGONAL POLYNOMIALS; POTENTIALS. [R.A.]

Legionnaires' disease A type of pneumonia usually caused by infection with the bacterium *Legionella pneumophila*, but occasionally with a related species (such as *L. micdadei* or *L. dumoffii*). The disease was first observed in an epidemic among those attending an American Legion convention in Philadelphia, Pennsylvania, in 1976. The initial symptoms are headache, fever, muscle aches, and a generalized feeling of discomfort. The fever rises rapidly, reaching 102–105°F (32–41°C), and is usually accompanied by cough, shortness of breath, and chest pains. Abdominal pain and diarrhea are often present. The mortality rate can be as high as 15% in untreated or improperly diagnosed cases. Erythromycin, new-generation fluroquinolones, and rifampicin are considered highly effective medications, whereas the penicillins and cephalosporins are ineffective.

While epidemics of Legionnaires' disease (also referred to as legionellosis) can often be traced to a common source (cooling tower, potable water, or hot tub), most cases seem to occur sporadically. It is estimated that *Legionella* spp. account for approximately 4% of all community- and hospital-acquired pneumonia. Legionnaires' disease is most fequently associated with persons of impaired immune status. *Legionella* bacteria are commonly found in fresh water and moist soils worldwide and are often spread to humans through inhalation of aerosols containing the bacteria. Legionnaires' disease is not a communicable disease, indicating that human infection is not part of the survival strategy of these bacteria. Therefore, the legionellae are considered opportunistic pathogens of humans. It is technology (air conditioning) and the ability to extend life through medical advances (such as transplantation and treatments for terminal diseases) that have brought these bacteria into proximity with a susceptible population.

For most humans exposed to *L. pneumophila*, infection is asymptomatic or short-lived. This is attributed to a potent cellular immune response in healthy individuals. Recovery from Legionnaires' disease often affords immunity against future infection. However, no vaccine exists at the present time. *See* MEDICAL BACTERIOLOGY; PNEUMONIA. [P.S.H.]

Legume A member of the plant family Leguminosae, and the name for the fruit produced by members of that family, as idealized in a bean or pea pod. The legume and grass families are by far the world's most important sources of food. Legumes, which include beans, soybeans, peas, and alfalfa, supply protein and fats. Through their root nodules, which are inhabited by *Rhizobium* bacteria, the legumes also preserve the nitrogen balance in the soil. Legumes comprise one of the largest plant families in the world, with perhaps 18,000 species. Most species are tropical and include trees, woody vines, and herbaceous plants. All legume plants bear the same type of fruit, the pod or legume, which is diversely modified within the family. Most have compound leaves, and many, particularly tropical legumes, have spectacular flowers, some of which are grown as ornamentals. *See* FABALES; GRASS CROPS; NITROGEN FIXATION.

The three major groups of Leguminosae differ in the appearance of their flowers, and some botanists consider them to be three separate families. Others, as here, regard them as a single diverse family because all have the same kind of fruit and because the groups intergrade. The first group is the Mimosoids, in which the flowers have reduced petals and usually have conspicuous, long stamens that give color to the flower clusters. The Mimosoid group, which is almost entirely tropical, includes the so-called sensitive plant and the silk tree, or mimosa, a widely planted ornamental in the southern United States. The second group, the Caesalpinioids, is characterized by well-developed petals and includes ornamentals such as the redbud and honey locust in temperate regions and the orchid trees of the tropics. The third and largest group is the Papilionoids, whose members bear a flower that resembles the sweet pea, with a big petal at the top, a wing on either side, and a "keel" of two fused petals that enclose the stamens at the bottom. Many important agricultural plants are members of the Papilionoid group, including peanuts, garden beans, soybeans, garden peas, lentils, chickpeas, cowpeas, clovers, and alfalfa. *See* ALFALFA; BEAN; CLOVER; COWPEA; LENTIL; PEA; PEANUT; SOYBEAN. [D.I.]

Legume forages Plants of the legume family used for livestock feed, grazing, hay, or silage. Legume forages are usually richer in protein, calcium, and phosphorus than other kinds of forages; such as grass. The production, preservation, and use of forage legumes require special skills on most soils. One important requirement is a supply of the needed symbiotic nitrogen-fixing bacteria if these are not already in the soil. Protection from weeds, injurious insects, diseases, and other harmful influences is often required. *See* LEGUME; NITROGEN FIXATION.

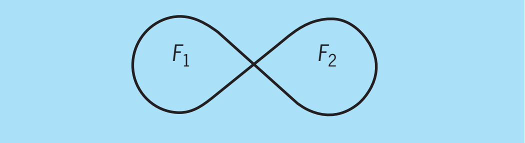
Alfalfa is the most important legume forage crop in the United States; it is used mainly for hay but is often grazed. White clover and the annual lespedezas are the most extensively grown legumes for grazing particularly in the southeastern United States. Red clover was an important crop prior to 1930 but is minor now. About a dozen other species of legumes are used for cultivated forage in the United States, and a large number are grown for range grazing. *See* ALFALFA; CLOVER; COVER CROPS; COWPEA. [P.T.]

Leitneriales An order of flowering plants, division Magnoliophyta (Angiospermae) in the subclass Hamamelidae of the class Magnoliopsida (dicotyledons). The order consists of a single family, genus, and species (*Leitneria floridana*) of the southeastern United States. The plants are simple-leaved, dioecious shrubs with the flowers in catkins. The ovary is superior and pseudomonomerous, with a single ovule ripening into a small drupe. *See* HAMAMELIDAE; MAGNOLIOPHYTA. [A.Cr.; T.M.Ba.]

Lemming The name applied to 11 species of rodents in the subfamily Microtinae, family Muridae. These animals have a northern circumpolar distribution.

The Norway lemming (*Lemmus lemmus*) is found in the mountainous wastelands of northern Norway and Lapland. It is usually nocturnal and timid in its habits, except when a population explosion occurs with its resultant migration, of which the causative factors are not known. Cyclic variations in fertility may be a factor. Usually there are two litters of five offspring each year, but often four litters of two to eight offspring occur. *See* RODENTIA. [C.B.C]

Lemniscate of Bernoulli A curve shaped like the figure eight (see illustration), referred to by Jacques Bernoulli in 1694. Let F_1, F_2 be points of a plane π with $F_1F_2 = 2a$, $a > 0$. The locus of a point P of π which moves so that $PF_1 \cdot PF_2 = b_2$, where b is a positive constant, is called an oval of Cassini. The lemniscate is obtained when $b = a$. Its equation in rectangular coordinates is $(x^2 + y^2)^2 = a^2(x^2 - y^2)$ and in polar coordinates $\rho^2 = a^2 \cos 2\theta$. *See* ANALYTIC GEOMETRY. [L.M.Bl.]



Curve known as lemniscate.

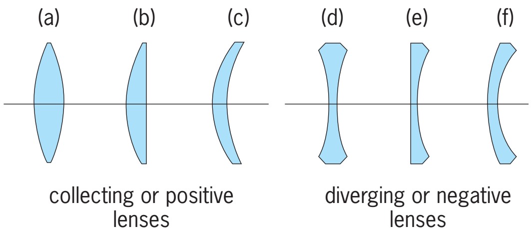
Lemon The fruit *Citrus limon*. The yellow fruits are medium-sized and elongate with a prominent nipple. The lemon is more sensitive to cold than other major citrus fruits, and thus its commercial culture is restricted to areas with mild winter temperatures.

The lemon is grown primarily for its acid flavor. Lemon juice, very high in vitamin C, is used in beverages and has many culinary uses. It is also used widely in proprietary soft drinks. The principal by-products are citric acid from the juice and lemon oil from the peel. *See* ASCORBIC ACID.

Commercial lemon production developed first in Italy, mainly in Sicily. Italy is the largest producer, followed by California. Spain, Greece, and Argentina are also significant producers. [R.K.So.]

Length A one-dimensional extension in space. Length is one of the three fundamental physical quantities, the others being mass and time. It can be measured by comparison with an arbitrary standard; the specific one in most common usage is the international meter. In 1983, at the meeting of the Conférence Général des Poids et Mésures, the meter was redefined in terms of time and the speed of light: "The meter is the length of the path traveled by light in vacuum during a time interval of 1/299 792 458 of a second." This definition defines the speed of light to be exactly 299 792 458 m/s, and defines the meter in terms of the most accurately known quantity, the second. *See* LIGHT; MASS; TIME. [D.A.J.]

Lens (optics) A curved piece of ground and polished or molded material, usually glass, used for the refraction of light. Its two surfaces have the same axis. Usually this is an axis of rotation symmetry for both surfaces; however, one or both of the surfaces can be toric, cylindrical, or a general surface with double symmetry (see illustration). The intersection points of the symmetry axis with the two surfaces are called the front and back vertices and their separation is called the thickness of the lens. There are three lens types, namely, compound, single, and cemented. A group of lenses used together is a lens system. Such systems may be divided into four classes: telescopes, oculars (eyepieces), photographic objectives, and enlarging lenses.



Common lenses. (*a*) Biconvex. (*b*) Plano-convex. (*c*) Positive meniscus. (*d*) Biconcave. (*e*) Plano-concave. (*f*) Negative meniscus. (*After F. A. Jenkins and H. E. White, Fundamentals of Optics, 4th ed., McGraw-Hill, 1976*)

Lens types. A compound lens is a combination of two or more lenses in which the second surface of one lens has the same radius as the first surface of the following lens and the two lenses are cemented together. Compound lenses are used instead of single lenses for color correction, or to introduce a surface which has no effect on the aperture rays but large effects on the principal rays, or vice versa. Sometimes the term compound lens is applied to any optical system consisting of more than one element, even when they are not in contact.

The diameter of a simple lens is called the linear aperture, and the ratio of this aperture to the focal length is called the relative aperture. This latter quantity is more often specified by its reciprocal, called the *f*-number. Thus, if the focal length is 50 mm and the linear aperture 25 mm, the relative aperture is 0.5 and the *f*-number is *f*/2. *See* FOCAL LENGTH.

A compound lens made of two or more simple thin lenses cemented together is called a cemented lens.

Lens systems. A lens system consisting of two systems combined so that the back focal point of the first (the objective) coincides with the front focal point of the second (the ocular) is called a telescope. Parallel entering rays leave the system as parallel rays. The magnification is equal to the ratio of the focal length of the first system to that of the second. *See* TELESCOPE.

A photographic objective images a distant object onto a photographic plate or film. The amount of light reaching the light-sensitive layer depends on the aperture of the optical system, which is equivalent to the ratio of the lens diameter to the focal length. The larger the aperture (the smaller the *f*-number), the less adequate may be the scene luminance required to expose the film. Therefore, if pictures of objects in dim light are desired, the *f*-number must be small. On the other hand, for a lens of given focal length, the depth of field is inversely proportional to the aperture.

In general, photographic objectives with large fields have small apertures; those with large apertures have small fields.

The basic type of enlarger lens is a holosymmetric system consisting of two systems of which one is symmetrical with the first system except that all the data are multiplied by the enlarging factor *m*. When the object is in the focus of the first system, the combination is free from all lateral errors even before correction. A magnifier in optics is a lens that enables an object to be viewed so that it appears larger than its natural size. The magnifying power is usually given as equal to one-quarter of the power of the lens expressed in diopters. *See* DIOPTER; MAGNIFICATION. [M.J.H.]

Lentil A semiviny annual legume with slender tufted and branched stems. The lentil plant (*Lens esculenta*) was one of the first plants brought under cultivation. The world's lentil production is centered in Asia, with nearly two-thirds of the production from India, Pakistan, Turkey, and Syria. Whitman and Spokane counties in Washington, and Latah, Benewah, and Nez Perce counties in Idaho grow about 95% of the lentils produced in the United States.

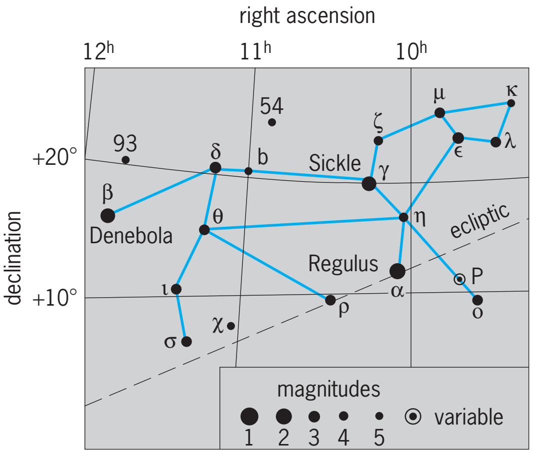
The seeds grow in short broad pods, each pod producing two or three thin lens-shaped seeds. Seed color varies from yellow to brown and may be mottled, although mottled seeds are not desirable for marketing.

Lentil seed is used primarily for soups but also in salads and casseroles. Lentils are more digestible than meat and are used as a meat substitute in many countries. *See* LEGUME. [K.J.M.]

Lenz's law A law of electromagnetism which states that, whenever there is an induced electromotive force (emf) in a conductor, it is always in such a direction that the current it would produce would oppose the change which causes the induced emf. If the change is the motion of a conductor through a magnetic field, the induced current must be in such a direction as to produce a force opposing the motion. If the change causing the emf is a change of flux threading a coil, the induced current must produce a flux in such a direction as to oppose the change.

Lenz's law is a form of the law of conservation of energy, since it states that a change cannot propagate itself. *See* CONSERVATION OF ENERGY; ELECTROMAGNETIC INDUCTION. [K.V.M.]

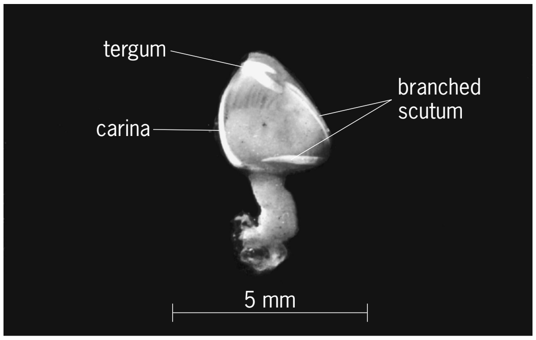
Leo The Lion, in astronomy, is a magnificent zodiacal constellation appearing during spring and early summer. It is the fifth sign of the zodiac. Leo is well defined and bears a close resemblance to the creature it represents (see illustration).



Line pattern of the constellation Leo. The grid lines represent the coordinates of the sky. Right ascension (E-W) in hours, and declination (N-S) in degrees, corresponding to the longitude and latitude of the Earth. The apparent brightness, or magnitudes, of the stars is shown by the sizes of the dots, which are graded by appropriate numbers as indicated.

Associated with this constellation are the famous Leonids shower of meteors, which can be seen radiating from Leo in November of each year and appearing especially brilliant at intervals of about 33 years. *See* CONSTELLATION. [C.-S.Y.]

Lepadomorpha A suborder of the Thoracica. These barnacles have a stalk or peduncle, which morphologically is the elongated, anterior, preoral region of the body, and a capitulum comprising the bivalved mantle enclosing the rest of the body (see illustration). The mantle folds are usually protected by a varying number of calcareous plates. The peduncle also may be protected by small calcareous scales or granules. Caudal furca and filamentary appendages are often present. These barnacles are hermaphroditic, or with separate sexes.



Morphology of *Octolasmis lowei*.

Several families are distinguished, the most primitive being Scalpellidae. *See* THORACICA. [H.G.St.]

Lepidodendrales An extinct order of the class Lycopsida which, together with Isoetales, forms the monophyletic rhizomorphaleans, the most derived and diverse group of clubmosses. The lepidodendraleans are best known as the scale trees that dominate most reconstructions of Upper Carboniferous swamps, where they were the main constituent of many coal-forming peats.

Lepidodendraleans are represented most frequently in the fossil record as characteristic "tire-track" bark fragments, which reflect the regular geometric arrangements of leaves, although taxonomic revisions have focused on the more complete information obtained from fossils preserved three-dimensionally in petrified peats. Reconstruction of the plants from their component organs has revealed that the classic trees possessed a wide range of growth architectures and shared lowland habitats with other smaller-bodied genera, reflecting a major radiation that occurred in the Late Devonian and perhaps Early Carboniferous.

Rhizomorphic lycopsids are distinguished by their centralized rootstock (rhizomorph), which permitted bipolar growth; both aerial and subterranean axes could branch, unlike the unipolar rhizomes of other, more primitive lycopsids. This trait and the newly acquired ability to produce wood allowed many rhizomorphic lycopsids to form large upright trees, with trunks up to 115 ft (35 m) tall and 3 ft (1 m) in diameter.

Unlike most seed plants, branches functioned primarily for reproduction and propagule dispersal rather than light capture; even when mature, they formed open canopies that cast little shade.

The warming and drying of the global climate toward the end of the Late Carboniferous greatly reduced the diversity of the rhizomorphic lycopsids, beginning with the most derived and specialized genera such as *Lepidophloios* and eventually leaving only the increasingly reduced and ecologically specialized isoetaleans to survive to present day. *See* ISOETALES; LYCOPHYTA; LYCOPSIDA. [R.M.Ba.; W.A.DiM.]

Lepidolite A mineral of variable composition which is also known as lithium mica and lithionite, $K_2(Li,Al)_{5-6}(Si_{6-7},Al_{2-1})O_{20-21}(F,OH)_{3-4}$. Rubidium (Rb) and cesium (Cs) may replace potassium (K); small amounts of Mn, Mg, Fe(II), and Fe(III) normally are present; and the OH/F ratio varies considerably. Polithionite is a silicon- and lithium-rich, and thus aluminum-poor, variety of lepidolite.

Lepidolite usually forms small scales or fine-grained aggregates. Its colors, pink, lilac, and gray, are a function of the Mn/Fe ratio. Hardness is 2.5–4.0 on Mohs scale; specific gravity is 2.8–3.0. *See* MICA; SILICATE MINERALS.

Lepidolite is uncommon, occurring almost exclusively in structurally complex granitic pegmatites, commonly in replacement units. Common associates are quartz, cleavelandite, alkali beryl, and alkali tourmaline. It is a commercial source of lithium, commonly used directly in lithium glasses and other ceramic products. [E.W.H.]

Lepidoptera The order of scaly-winged insects, including the butterflies, skippers, and moths. This is one of the largest orders in the class Insecta. It has more than 100,000 species, about 10,000 in North America, and between 125 and 175 families. The adults have a covering of hairs and scales on the wings, legs, and body, and are often beautifully colored. With minor exceptions, the adults are also characterized by two pairs of membranous wings and sucking mouthparts, featuring a prominent, coiled proboscis. Butterflies and skippers usually fly in the daytime, and most moths are nocturnal. The adults usually take liquid food, such as nectar and juices of fruits. The caterpillars are almost always herbivorous.

Morphology. The most unusual feature of the head of the adult animal is the form of the mouthparts. The proboscis is extended by blood pressure created by the retraction of the stipites of the maxillae. Diagonal muscles within each proboscis unit cause the proboscis to coil. The liquid food is sucked up by means of a muscular pump, formed from the pharynx, buccal cavity, and cibarium, a food pocket of the mouth cavity. Ocelli are absent in many groups. Antennae are quite variable in form.

The prothorax is well developed in some lower groups but it is considerably smaller than the pterothoracic, or wing-bearing, segments, and is largely membranous in most Lepidoptera. The most prominent feature of the dorsum of the prothorax, in most groups, is a pair of protuberant sclerotized lobes.

The scales are very variable in form. Generally, they are flat, thin, sclerotized sacks, with striated outer surfaces. The vast spectrum of colors seen in the Lepidoptera can be grouped into two categories, pigmentary and structural colors. Pigmentary colors result from pigments which are present in the scales. Structural colors are the result of either fine surface ridges on the scales or layers within the cuticle, which interfere with or diffract the light. The structural colors are generally metallic or iridescent.

In most moths, the wings are coupled by a single spine formed by fused setae which project forward from the base of the hindwing and are held by a clasp on the forewing. The spine is known as the frenulum and the clasp is the retinaculum. In the Homoneura, there is a lobe, the jugum, at the base of the forewing, which engages the hindwing, or the frenulum, when it is present.

The form of the external genitalia, especially that of the male, has been widely used in the separation of species.

Developmental stages. Metamorphosis is complete. The larvae, commonly called caterpillars, are mandibulate and cylindrical, with short thoracic legs and a variable number of abdominal prolegs. They have one pair of thoracic and eight pairs of abdominal spiracles. Pupae are variable in form and have appendages that are usually firmly cemented down (obtect), though they are sometimes partly or completely free (exarate). Pupae often are enclosed in a silken cocoon.

Classification. Unfortunately, the classification of the Lepidoptera is the subject of considerable controversy; much will doubtless be resolved when more is known of the anatomy and life history of many groups.

A rather conservative classification has been used here. In many superfamilies only the more important families are mentioned. The table lists the important families.

Homoneura (Jugatae). Fore- and hindwings are similar in shape and venation. They are connected by a jugum and, sometimes, also by a frenulum. Mouthparts are mandibulate, with mandibles vestigial or absent, and the galeae forms a rudimentary proboscis. The female has a single genital opening. The pupae are free or partially free.

This small suborder, including less than 1% of the species in the order, contains a diverse group of primitive forms showing certain features in common with the Trichoptera, or caddis flies.

The superfamily Micropterygoidea includes one small family, the Micropterygidae, minute moths possessing toothed, functional mandibles and lacking even the most rudimentary proboscis. The larvae, which feed on mosses, are unusual in having eight pairs of abdominal prolegs.

Superfamily Eriocranioidea is a group of tiny moths; the mandibles are greatly reduced and untoothed. Three families, the Eriocraniidae, Neopseustidae, and Mnesarchaeidea, have been recognized within the superfamily. The leaf-mining larva lacks legs. The adults reportedly do not feed. The females have a piercing ovipositor. Superfamily Hepialoidea contains medium- to large-sized moths which possess rudimentary mouth-parts. The larvae are borers. The rapid flying adults are mostly crepuscular, thus the common name swift, or ghost, moths. The only family of importance is the Hepialidae.

Heteroneura (Frenatae). Fore- and hindwings are markedly different in shape and venation. Usually they are connected by a frenulum and retinaculum. Mouthparts are formed for sucking or, rarely, are vestigial, Adults with functional mouthparts feed on nectar of flowers, juices of rotten fruits, and other liquids. The female usually has two genital openings. Pupae are usually obtect.

One family, the Incurvariidae, comprises the superfamily Incurvarioidea. The wings are covered with microscopic spines and the females have a single genital opening. The venation is almost complete.

Superfamily Nepticuloidea includes one family, the Nepticulidae. These tiny moths have wing spines and the females have a single genital opening, but they differ from the Incurvarioidea in having a reduced venation. The larvae are generally miners in leaves, bark, and rarely, in fruits.

Superfamily Cossoidea includes one family, the Cossidae, commonly called the carpenter or goat moths. These are heavy-bodied moths, with the abdomen extending well beyond the hindwings. Mouthparts are rudimentary except for labial palpi.

Superfamily Tineoidea contains 16–39 families; the number varies with the author. This is a very large group, of uncertain composition. These moths are of small size, usually with well-developed maxillary palpi. The labial palpi have a slender, pointed third segment. Venation may be reduced, and the wings may be divided into plumes.

The small, wide-winged moths of the superfamily Tortiicoidea belong to two families, the Olethreutidae and the Tortricidae. The maxillary palpi are vestigial or absent, and the third segment of the labial palpus is short and usually obtuse. The hair fringes of the wings are always shorter than the width of the wing.

The family contains a number of agriculturally undesirable species. Paramount among these is the codling moth (*Carpocapsa pomonella* L.), which is a very serious pest of apples and other fruits. The large genus *Laspeyresia* contains the interesting Mexican jumping bean moth (*L. saltitans* Westwood). The violent movements of the larvae of this moth are responsible for the action of the beans which they inhabit.

Tortricidae is a family which generally lacks the fringe of long hairs along the cubitus, characteristic of the Olethreutidae. The spruce budworm (*Choristoneura fumiferana* Clemens) is probably the most important injurious tortricid. In many places, especially in eastern Canada, it has defoliated vast areas of coniferous forest.

The superfamily Pyralidoidea is comprised of moths that are moderately small to medium-sized, long-legged, and slender-bodied. The maxillary palpi are usually well developed. Pyralididae is the second largest family of moths. They are small and medium-sized, and a wing expanse of 20–35 mm is not uncommon. The legs are usually long and slender. Pterophoridae is the family known as the plume moths. The wings are divided into featherlike plumes, of which there are usually two in the forewing and three in the hindwing. The moths lack maxillary palpi and have slender bodies and long legs. The larvae feed exposed or are borers.

Superfamily Zygaenoidea includes moderately small- to medium-sized moths that have complete venation, rudimentary palpi and, usually, a rudimentary proboscis. The wings are broad with short fringes. The larvae are short and more or less sluglike and are exposed feeders.

Superfamily Castnioidea includes one family, the Castniidae. They are large, diurnal, butterflylike moths with clubbed antennae, upright eggs, and boring larvae. A proboscis may be either

Size, distribution, and common names of some families of Lepidoptera

Classification	Common name	Distribution	No. of species*
Suborder Homoneura			
Micropterygidae	Micropterygids	Holarctic and Australia	3 (35)
Eriocraniidae	Ericocraniids	Holarctic	5 (20)
Mnesarchaeidae	Mnesarchaeids	New Zealand	
Hepialidae	Swift or ghost moths	Cosmopolitan	18 (200)
Suborder Heteroneura			
Incurvariidae	Yucca moths and relatives	Cosmopolitan	60
Nepticulidae	Serpentine leaf miners	Cosmopolitan	75
Cossidae	Goat or carpenter moths	Cosmopolitan	45
Aegeriidae	Clearwing moths	Cosmopolitan	120
Coleophoridae	Case bearers	Cosmopolitan	110 (900)
Gelechiidae	Gelechiids	Cosmopolitan	590 (3800)
Gracilariidae	Gracilariids	Cosmopolitan	235
Heliodinidae	Heliodinids	Cosmopolitan	21
Oecophoridae	Oecophorids	Cosmopolitan; largely Australian	225 (3000)
Orneodidae	Many-plume moths	Cosmopolitan	1
Psychidae	Bagworms	Cosmopolitan	25
Tineidae	Clothes moths and relatives	Cosmopolitan	135 (2500)
Yponomeutidae	Ermine moths	Cosmopolitan	65 (800)
Olethreutidae	Olethreutids	Cosmopolitan	715 (2500)
Tortricidae	Tortricids	Cosmopolitan	210 (1500)
Thyrididae	Window-winged moths	Tropical	10
Pyralididae	Pyralids; snout moths	Cosmopolitan	1135 (12,000)
Pterophoridae	Plume moths	Cosmopolitan	130
Eucleidae	Slug moths	Cosmopolitan	50 (900)
Megalopygidae	Flannel moths	Mostly American; a few African	11
Zygaenidae	Foresters and burnets	Palearctic, African, and Indo-Australian	—
Castniidae	Castniids	Neotropical and Indo-Australian	
Drepanidae	Hooktips	Holarctic	6
Geometridae	Measuring worms, loopers, cankerworms, carpets, waves, and pugs	Cosmopolitan	1200 (4000)
Uraniidae	Uraniids	Tropical	—
Sphingidae	Sphinx, hawk, or hummingbird moths	Cosmopolitan	106 (1000)
Lasiocampidae	Tent caterpillars, lappet moths	Cosmopolitan except New Zealand; mainly tropical	30 (1400)
Saturniidae	Giant silkworms	Cosmopolitan	60
Bombycidae	Silkworm and allies	Tropical	1 (introduced)
Arctiidae	Tiger moths	Cosmopolitan	200 (3600)
Lymantriidae	Tussock moths	Largely African and Indo-Malayan, but with important Holarctic species	27
Notodontidae	Prominents, puss moths	Cosmopolitan except New Zealand	120
Noctuidae	Noctuids, owlets, underwings, millers	Cosmopolitan	2700 (20,000)
Hesperiidae	Skippers, agave worms	Cosmopolitan	240 (3000)
Papilionidae	Swallowtails, bird-wings, parnassians	Cosmopolitan	27 (600)
Pieridae	Whites, sulfurs, orangetips	Cosmopolitan	61 (1000)
Nymphalidae	Four-footed butterflies	Cosmopolitan	211 (5000)
Libytheidae	Snout butterflies	Cosmopolitan	1 (17)
Lycaenidae	Blues, coppers, hairstreaks, metal marks	Cosmopolitan	138 (3500)

*The first figure is the number of described species in North America north of Mexico. This figure is reasonably accurate. The second figure, in parentheses, is a rough estimate of the number of described species in the world. It is difficult to postulate the actual total of Lepidoptera species from these figures since in some groups, such as the Papilionidae, probably more than 90% of the existing species have been described, while in others, such as many families of microlepidoptera, the figure may be well under 25%.

present or absent. These moths are considered by some to be distantly related to the butterflies, but the resemblances may very well be due to convergence.

Members of the superfamily Geometroidea are small to large moths with reduced maxillary palpi and tympanal organs at the base of the abdomen. The frenulum may be present or absent.

Geometridae includes the measuring worms, loopers, and cankerworms, which make up a very large family of small- and medium-sized moths with slender bodies and relatively broad wings. The females are occasionally apterous. The larvae have the anterior prolegs reduced or absent; usually only those on segments 6 and 10 are well developed. They proceed with a characteristic looping motion, which is the basis for the scientific name. The larvae ordinarily are exposed feeders.

Sphinx, hawk, or hummingbird moths constitute the one family Sphingidae of the superfamily Sphingoidea. These medium-sized to very large, heavy-bodied moths have extremely rapid flight. The adults are mostly crepuscular or nocturnal, but a few genera are diurnal. The antennae are thickened and have a pointed apex. The proboscis is well developed and often extremely long. The wings are narrow, with the hindwing much shorter than the forewing. The larvae are external feeders and usually have a characteristic caudal horn. The pupa is in a cell in the ground or in a loose cocoon at the surface, and its long proboscis is often in a projecting case resembling a pitcher's handle.

Moths of the superfamily Saturnioidea are medium-sized to very large moths with the frenulum almost always reduced or absent. There is no tympanum and the mouthparts are usually reduced. The antennae are ordinarily pectinate, especially in the males.

Noctuoidea is a large, rather uniform superfamily of more than 20,000 species. Most of them are moderately large moths with reduced maxillary palpi. Tympanal organs are present in the metathorax.

The superfamily Hesperioidea includes one rather large family, the Hesperiidae. The skippers are small to moderately large, heavy-bodied, mostly diurnal insects with a clubbed antenna, which is bent, curved, or reflexed at the tip. The larvae have a prominent constriction, or neck, behind the head, and often live in leaves drawn together by silk. Those of the giant skippers are borers in yucca and agave. The pupa is usually enclosed in a slight cocoon.

Butterflies of the superfamily Papilionoidea are small to large diurnal insects with clubbed antennae, which are rounded at the tip and not bent or reflexed. The forewings always have two or more veins, which are stalked.

Biological aspects. The Lepidoptera are a group of insects on which much biological research remains to be done. A great deal is still unknown about the genetics, physiology, and ecology of this group. Moreover, butterflies and moths have proved useful as experimental animals in genetical research. The larvae of many species are injurious to certain crops, causing severe economic losses. Lepidoptera of all stages are subject to the attacks of a large number of predators, including birds, mammals, lizards, frogs, spiders, and certain other insects.

The Lepidoptera penetrate almost every section of the globe, with the major exception of Antarctica. Arctic and alpine tundra areas normally support a lepidopteran fauna which, although relatively poor in species, is rich in numbers. After rains, deserts are often alive with butterflies and moths. Tropical areas are by far the richest in species. One of the strangest habitats occupied by a lepidopteran is the hair of the neotropical three-toed sloth, where the sloth moth (*Bradypodicola hahneli*), a pyralid, passes its entire life cycle presumably feeding on algae which grow in the hair.

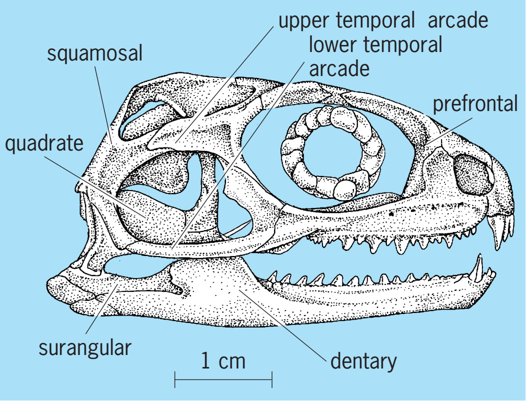
Migration is the most spectacular behavior occurring in the order. It is most frequent in the butterflies *Phoebis*, *Danaus*, *Libytheana*, and others, but is also known in moths such as *Chrysiridia*. Huge migratory swarms are frequently reported in many parts of the world, but this phenomenon, as well as the related communal roosting of adults, daily use of flyways, hilltopping, and so forth, is poorly understood.

Aggregations of butterflies at a mud puddle are a frequent sight, and moths have been observed “pumping,” an act which consists of sipping water steadily from a puddle and ejecting it as a stream of drops or fine spray from the anus.

The phenomena of mimicry and protective resemblance are widespread in the Lepidoptera. Eyespot patterns in certain species elicit escape responses in passerine birds. Thus, they are an effective protective device. The appearance of dark forms of various moths in heavily industrialized, and thus heavily sooted, areas is a widespread phenomenon. This “industrial melanism” is doubtless due to shifting selection pressures and is one of the best-known examples of evolution in action. *See* INSECTA; PROTECTIVE COLORATION. [P.R.E.]

Lepidosauria

Lepidosauria A subclass of reptiles, both living and extinct, in which the structure of the skull is characterized by two temporal openings (diapsid condition) on each side (see illustration). Lepidosauria differ from Archosauria, which are also diapsid, in that the bony arcades bordering their temporal openings may suffer reduction or loss, causing the apparent disappearance of one or both openings. They differ also in that no lepidosaur skull has any antorbital opening in front of the orbit, and in that their teeth are typically fused to the jaw (acrodont or pleurodont) rather than implanted in sockets (thecodont). *See* ARCHOSAURIA.



Skull of a living rhynchocephalian, *Sphenodon*, a typical diapsid. (*After A. S. Romer, Vertebrate Paleontology, 3d ed., University of Chicago Press, 1966*)

In the classification adopted here the Lepidosauria include three orders: Eosuchia, Rhynchocephalia, and Squamata. *See* EOSUCHIA; REPTILIA; SQUAMATA. [A.J.C.]

Lepospondyli

Lepospondyli A group of Paleozoic amphibians commonly recognized as one of the three amphibian subclasses, equivalent to its approximate contemporary, the Labyrinthodontia, and to the modern amphibians, the Lissamphibia. They include a diverse array of extinct aquatic, terrestrial and, possibly, subterranean species, all of which were only a few centimeters long or rarely as much as a meter. For most of the Carboniferous and much of the Permian periods (340–225 million years ago), they seem to have filled niches similar to those held by modern salamanders, apodans, and lizards. *See* LABYRINTHODONTIA.

The term lepospondyl refers to the single-piece, spoollike vertebral centra present in many forms, which contrasts with the typically multipiece centra in the Labyrinthodontia. Other lepospondyl skeletal features include the absence of labyrinthine infolding of dental enamel, of large teeth on the palatal bones, and of otic notches, all of which are generally present in labyrinthodonts. Exceptions exist within both the Lepospondyli and Labyrinthodontia. The absence of consistent patterns in lepospondyl skeletal anatomy has obscured relationships within the subclass and between the lepospondyls and other amphibians.

The orders Adelospondyli, Aistopoda, Lysorophia, Microsauria, and Nectridea are generally considered to compose the Lepospondyli. *See* AISTOPODA; AMPHIBIA; LYSOROPHIA; MICROSAURIA; NECTRIDEA. [C.F.W.]

Leprosy

Leprosy A chronic infectious disease caused by *Mycobacterium leprae* that primarily affects the skin and peripheral nerves and, to a lesser extent, the eyes and mucous membranes. Leprosy, or Hansen’s disease, has been known for more than 2000 years. It afflicts at least 3 million people worldwide and is most common in developing countries. There are about 200 new cases yearly in the United States. Its epidemiology is not fully understood, but transmission probably takes place by the respiratory route. The bacillus is very slow-growing, and the incubation period is usually 3–5 years. Less than 5% of any population is susceptible, and these individuals have a deficient cell-mediated immune response specifically to *M. leprae*, which may be genetic in origin. Epidemics have occurred, but are rare. *See* MYCOBACTERIAL DISEASES.

A skin rash and loss of feeling due to nerve damage by *M. leprae* are the hallmarks of leprosy. Usually the nerve damage is mild, but when severe the inability to feel, particularly in the hands and feet, predisposes the individuals to frequent injuries. Nerve involvement may also lead to a loss of muscle function that produces clawing of the fingers and toes as well as other neuromuscular dysfunctions. Manifestations of the disease depend upon the degree of the immune defect. Initially, most patients develop one or several depigmented areas of skin that may have decreased sensation, a stage referred to as indeterminate disease. The condition may self-heal. If treatment or self-healing does not halt the disease, it may progress to one of three advanced types. The mildest of these, tuberculoid disease, is usually manifested as a single large depigmented, scaly, numb area. The most severe type, lepromatous leprosy, usually involves most of the skin to varying degrees, with variously sized nodules or other changes. Between the two extremes immunologically is borderline disease, with skin changes of both types. The World Health Organization’s simplified classification labels indeterminate and tuberculoid patients paucibacillary (few bacilli) and borderline and lepromatous patients multibacillary.

Paucibacillary disease is treated with dapsone plus rifampin for 6–12 months. Clofazimine is added for multibacillary individuals and the treatment continued for 2 or more years. Isolation is unnecessary, since patients become noninfectious within days of starting treatment. *See* INFECTIOUS DISEASE. [R.R.J.]

Leptolepiformes An order of small ray-finned fishes of the Mesozoic that are important to the understanding of the early evolution of the Teleostei. The principal family included in this order, the Leptolepidae, has been reported from the Middle Triassic of Europe and ranges into the Cretaceous. Leptolepids represent the first teleosts as defined on the structure of the caudal skeleton. They were either derived from the earliest Pholidophoridae (known from the European Middle Triassic sediments) or shared a common ancestry with them. In size, body shape, fin position, structure of head and jaws, and general habitat, leptolepids are similar to the pholidophorids. In many ways these two families appear to parallel one another. *See* TELEOSTEI. [T.M.C.]

Lepton An elementary particle having no internal constituents which interacts through the electromagnetic, weak, and gravitational forces, but does not interact through the strong (nuclear) force. Leptons are very small, less than 10^{-18} m in size. This is less than 10^{-3} the size of a nucleus and less than 10^{-8} the size of an atom. Indeed, existing measurements are consistent with leptons being point particles.

These properties of the lepton family of particles are to be contrasted with the properties of the quark family of particles. Quarks interact through the strong force as well as through the electromagnetic, weak, and gravitational forces. By means of the strong force, quark-antiquark pairs bind together to form hadrons such as the π meson, and the quarks bind together to form hadrons such as the proton. In contrast, leptons act as individual particles and can be studied as isolated particles whereas, as far as is known, quarks are always inside hadrons and cannot be studied as isolated particles. *See* FUNDAMENTAL INTERACTIONS; HADRON; QUARKS.

Six leptons are known. There are three known charged leptons: the electron (e), muon (μ), and tau (τ). Associated with each charged lepton is a neutral lepton called a neutrino. A charged lepton and its associated neutrino is said to form a lepton generation. Thus there are three known lepton generations. *See* ELECTRON; NEUTRINO. [M.L.P.]

Leptospirosis An acute febrile disease of humans produced by spirochetes of many species of *Leptospira*. The incubation period is 6–15 days. Among the prominent features of the disease are fever, jaundice, muscle pains, headaches, hepatitis, albuminuria, and multiple small hemorrhages in the conjunctiva or skin. Meningeal involvement often occurs. The febrile illness subsides after 3–10 days. Fatal cases show hemorrhagic lesions in the kidney, liver, skin, muscles, and central nervous system.

Wild rodents are the principal reservoirs, although natural infection occurs in swine, cattle, horses, and dogs and may be transmitted to humans through these animals. Humans are infected either through contact with the urine or flesh of diseased animals, or indirectly by way of contaminated water or soil, the organisms entering the body through small breaks in the skin or mucous membrane. [T.B.T.]

Leptostraca The only extant order of the crustacean subclass Phyllocarida. The Leptostraca is represented by one fossil and a small number of living genera. These malacostracans are unique in having the carapace laterally compressed to such an extent that it forms a bivalvelike shell held together by a strong adductor muscle. The carapace covers only the thorax, leaving exposed the head, with its uniquely movable rostrum, stalked eyes, paired antennules, and antennae.

Leptostracans use the thoracopods to produce a feeding current and, in females, to form a brood pouch. That secondary brooding function suggests that egg-bearing females generally do not feed. Locomotion in leptostracans is accomplished by use of the first four pairs of pleopods. Most leptostracans are bottom dwellers, living on or slightly under the substrate, but one species is holopelagic, one inhabits hydrothermal vents, and still another is a marine cave dweller. *See* CRUSTACEA; PHYLLOCARIDA. [P.A.McL.]

Lespedeza A warm-season legume with trifoliate leaves, small purple pea-shaped blossoms, and one seed per pod. There are 15 American and more than 100 Asiatic species; two annual species and a perennial from Asia are grown as field crops in the United States. The American species are small shrubby perennials found in open woods and on idle land, rarely in dense stands; they are harmless weeds. *See* LEGUME. [P.T.]

Lethal dose 50 One special form of the effective dose 50, or median effective dose. The lethal dose 50, or median lethal dose (LD_{50}), is used when the response that is being investigated is the death of the experimental animal. The median lethal dose is therefore the dose which is fatal to 50% of the test animals. *See* EFFECTIVE DOSE 50. [C.W.]

Lethal gene A gene which brings about the death of the organism carrying it. Lethal genes constitute the most common class of mutations and are reflections of the fact that the fundamental function of genes is the control of processes essential to the growth and development of organisms. In higher diploid forms lethals are usually recessive and expressed only in homozygotes. Dominant lethals, expressed in heterozygotes, are rapidly eliminated and thus rarely detected. Recessive zygotic lethals are retained with considerable frequency in natural populations of cross-fertilizing organisms, while gametic lethals (those affecting normal functioning of eggs and sperm among animals, or the pollen and ovules of plants) are subject to stringent selection and are accordingly rare. *See* GENE; MOLECULAR BIOLOGY; MUTATION. [D.F.P.]

Lettuce A cool-season annual, *Lactuca sativa*, of Asian origin and belonging to the tribe Cichorium of the Compositae family. Lettuce is grown for its succulent leaves, which are eaten raw as a salad. Four varieties of this leading salad crop are head lettuce (*L. sativa* var. *capitata*), leaf or curled lettuce (*L. sativa* var. *crispa*) cos or romaine lettuce (*L. sativa* var. *longifolia*), and stem or asparagus lettuce (*L. sativa* var. *asparagina*). There are two types of head lettuce: butterhead, and crisphead or iceberg.

California raises more lettuce than any other state; Arizona, Florida, and Texas are next in importance. *See* ASTERALES. [R.G.Gr.]

Leucettida An order of the subclass Calcinea in the class Calcarea. These sponges have either a radiate arrangement of the flagellated chambers or a leuconoid structure. A distinct dermal membrane or cortex is present. The spongocoel is not lined with choanocytes; these cells are restricted to the flagellated chambers. Two families are recognized, the Leucascidae and Leucaltidae. *See* CALCAREA. [W.D.H.]

Leucite A framework structure silicate of the feldspathoidal mineral group with the chemical composition $(K,Na)AlSi_2O_6$. Leucite found in the natural environment is usually nearly pure $KAlSi_2O_6$. The crystals are typically white, and the luster varies from dull to vitreous. Mohs hardness lies between 5.5 and 6. Density ranges from 2.45 to 2.5.

Crystals are common in the lavas of Nyiragongo volcano, Zaire. Other well-known areas include: West Kimberley, Australia; Mount Vesuvius, Italy; Highwood Mountains and Bearpaw Mountains, Montana; and the Leucite Hills, Wyoming. *See* SILICATE MINERALS. [W.Lu.]

Leucite rock Igneous rocks rich in leucite but lacking or poor in alkali feldspar. Those types with essential alkali feldspar are classed as phonolites, feldspathoidal syenite, and feldspathoidal monzonite. The group includes an extremely wide assortment both chemically and mineralogically.

The rocks are generally dark-colored and aphanitic types of volcanic origin. They consist principally of pyroxene and leucite and may or may not contain calcic plagioclase or olivine. Leucite rocks are rare. They occur principally as lava flows and small intrusives (dikes and volcanic plugs). *See* IGNEOUS ROCKS; LEUCITE. [C.A.C.]

Leucosoleniida An order of the subclass Calcaronea in the class Calcarea. These sponges have an asconoid structure. A true dermal membrane or cortex does not develop in this order, and the spongocoel is lined with choanocytes. Leucosoleniidae is the one family recognized. *See* CALCAREA. [W.D.H.]

Leukemia A disease characterized by a progressive and abnormal accumulation of white blood cells, or leukocytes. Leukemic cells are malignant because they have three characteristics common to all cancers: (1) they exhibit uncontrolled growth that is frequently associated with an inability to mature normally; (2) they arise from a single precursor cell; and (3) they disregard anatomic boundaries and metastasize to organs or tissues where leukocytes are not normally found. The expanding clone of leukemic cells infiltrates organs and tissues, particularly the bloodstream and bone marrow, where they disrupt the production of normal cells. The resulting symptoms include fatigue, pallor, infections, bruising and bleeding, and discomfort caused by enlarged organs. In humans, the term leukemia encompasses more than 20 distinct malignancies. *See* BLOOD; HEMATOPOIESIS.

Normal leukocytes are grouped into two primary types or lineages, myeloid and lymphoid, and virtually any cell of either lineage can become leukemic. Leukemias are also divided into broad categories that are based on the cell involved (myeloid or lymphoid) and disease aggressiveness (either acute or chronic). Subclassifications are based on morphologic, cytochemical, immunologic, cytogenetic, and molecular criteria.

Although many agents are suspected of inducing leukemia, for the great majority of cases the etiology is unknown. It appears that no single factor is causative but a number of events must take place before leukemia occurs. The evidence for ionizing radiation as a leukemogenic cofactor is virtually irrefutable. Chronic exposure to high levels of benzene and perhaps related compounds is associated with a tenfold higher risk of developing myeloid leukemia. A clear, strong association has been demonstrated between pharmaceuticals (particularly alkylating agents) that are administered as therapy for a primary cancer and the subsequent development of secondary leukemia, virtually always acute myeloblastic leukemia. A strong association has been shown between the rare adult T-cell leukemia and a retrovirus called human T-cell leukemia virus I, or HTLV-I. Persons with the Down syndrome are 30 times more likely to develop acute, usually lymphoid, leukemia than the rest of the population. In the primary immunodeficiency states, malignancies develop 10,000 times faster than in unaffected persons, and each of the immunodeficiencies is associated with a distinct leukemia. The myelodysplastic syndromes are characterized by ineffective production of normal blood cells and result in low blood cell counts due to abnormal precursor cells in the bone marrow. The abnormal cells are clonal and manifest a spectrum of morphologic and cytogenetic abnormalities. Most have a tendency to evolve into acute leukemia, with the myeloid type predominating. *See* DOWN SYNDROME; RADIATION INJURY (BIOLOGY); TUMOR VIRUSES.

The two major types of leukemia usually differ in signs and symptoms. Acute leukemias have a relatively rapid onset, and those with the disease often experience problems immediately. Chronic leukemias have an insidious course and are frequently discovered during an examination for an unrelated problem. For both types, the most consistent symptoms are nonspecific and include weakness, fatigue, mild weight loss, and low-grade fever.

Practical therapeutic goals for the acute and chronic leukemias are distinct. Without prompt, intensive, in-hospital therapy, the acute leukemias usually cause death within a few months. In acute leukemia, the object of therapy is to totally obliterate the leukemic clone and allow normal bone marrow cells to recover. In the chronic leukemias, standard therapeutic principles are completely different. Many patients who initially require no therapy begin mild forms of outpatient treatment as the disease progresses. The intent is not to cure but to control the disease with minimal toxicity.

Many effective antileukemic agents have been synthesized. Combination therapy incorporates drugs that have different modes of action and different toxicities in order to increase cytotoxic potency, account for leukemic cells that may be resistant to a single agent, and lessen cumulative toxicity in any particular organ or tissue. Most antileukemic drugs act by perturbing enzymes or substrates that are related to deoxyribonucleic acid (DNA) or ribonucleic acid (RNA) synthesis and thus largely affect actively dividing cells. Any treatment must be repeated since the number of leukemic cells may exceed one trillion and a single course of antileukemic drugs will destroy only some of them. *See* CHEMOTHERAPY.

Perhaps the most dramatic and toxic treatment, bone marrow transplantation has had the most positive impact on the leukemia cure rate. Chemotherapy is administered alone or with radiation therapy in doses much higher than those used in standard antileukemic regimens to abolish the leukemic clone at the expense of the normal stem cells in the bone marrow. Patients would die following such treatment unless "rescued" with cryopreserved stem cells. The stem cells must come from a donor whose human leukocyte antigens match those of the patient's cells as closely as possible. Marrow transplantation is the therapy of choice for eligible patients with chronic myelocytic, relapsed acute lymphoid and acute myeloblastic, and other high-risk leukemias.

The search for therapies that are less toxic and more specific for leukemic cells has focused on substances that are derived from natural (biologic) sources or that affect biologic reactions, some of which are thought to be part of the body's natural defense against cancer. Examples include monoclonal antibodies, cell products manufactured by recombinant DNA technology, and the patient's own killer cells expanded and activated in the laboratory before reinfusion. Although such techniques have proved effective in other cancers, only alpha-interferon is commonly used in leukemia. *See* MONOCLONAL ANTIBODIES.

Despite the differences between the acute and chronic leukemias, and despite the fact that the great majority of patients can be brought into a remission or quiescent phase of the disease, leukemia is one of the most lethal malignancies. If cure is considered to be the absence of disease 3 to 5 years after cessation of therapy, only a small fraction of all leukemias are curable. An exception is acute lymphoid leukemia in children, where therapeutic advances have resulted in the attainment of a complete remission in almost all and cures in the majority. *See* CANCER (MEDICINE); ONCOLOGY. [L.V.; K.A.F.]

Level measurement The determination of the linear vertical distance between a reference point or datum plane and the surface of a liquid or the top of a pile of divided solids.

Liquid level measurement. Satisfactory measurements are possible only when the liquid is undisturbed by turbulence or wave action. When a liquid is too turbulent for the average level to be read, a baffle or stilling chamber is inserted in the tank or vessel to provide a satisfactory surface.

Stick, hook, and tape gages are used in open vessels where the surface of the liquid can readily be observed. The stick gage is a suitably divided vertical rod, or stick, anchored in the vessel so that the magnitude of the rise and fall of the liquid level may be observed directly. The hook gage provides a needle point, which is adjusted to produce a very tiny pimple in the liquid surface at the level reading, thereby minimizing the meniscus error. The tape gage reads the correct elevation when the point of a bob just touches the liquid surface.

Many forms of gage glass are available for the measurement of liquid level. Liquid in a tank or vessel is connected to the gage glass by a suitable fitting, and when the tank is under pressure the upper end of the glass must be connected to the tank vapor space. Thus the liquid rises to substantially the same height in the glass as in the tank, and this height is measured by suitable scale.

Various types of float mechanism are also used for liquid level measurement. The float, tape, and pulley gage provides an excellent method of measuring large changes in level with accuracy. It has the advantage that the scale can be placed for convenient reading at any point within a reasonable distance of the tank or vessel.

The change in buoyancy of a solid as its immersion in a liquid is varied is used to measure liquid level. This principle is used only when the densities of the liquid and vapor are substantially constant. Temperature changes will produce errors of greater magnitude than with the float mechanisms.

Hydrostatic head may also be used to measure liquid level. The pressure exerted by a column of liquid varies directly with its density as well as with its height, and thus this method of measurement requires that density be substantially constant. Densities of liquids vary with temperature; errors are therefore introduced with temperature changes, or the measuring element must be temperature compensated.

Electrode or probe systems are used in various forms for level indication and control. The number of electrodes and their design depend upon the characteristics of the liquid and the application. Fundamentally, a circuit through a relay coil is closed (or opened) when the liquid contacts a probe.

Capacitance-measuring devices can be used to measure levels of both dielectric (insulating) and conducting liquids. If the liquid being measured is a dielectric, one or two probes or rods, extending nearly to the bottom of the tank, are supported in an insulating mounting. The probes may be bare or covered with insulation. If the liquid is a conductor of electricity, only one probe is necessary but it must be covered with an insulating coating.

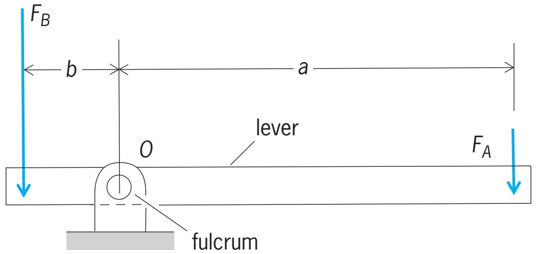
Nuclear level gages are used for difficult applications. Basically, all of the units involve a source of gamma (γ) radiation and a detector separated by the vessel or a portion of the vessel in which a liquid level varies. As the level rises, the detector receives less γ-radiation and thus the level is measured.

The sonic level detector is based on the time increment between the emission of a sound wave pulse and its reflection from liquid surface. The sound wave pulse is generated electronically, and its time in transit is measured very accurately by electronic means. If the speed of sound in the liquid or vapor is known accurately, the liquid level is known.

Solids level measurement. Solids level detectors are used to locate the top of a pile of divided solids in large vessels or processing equipment. The instruments are designed for the different solids handled, and the installation must be carefully made to ensure proper measurements. Because solids funnel, cone, and vary in average density with the particle size, shape, distribution, moisture content, and other factors, these detectors provide only an approximate indication of the volume present or the top of the pile. Solids level detectors are classified as continuous or fixed point. Continuous detectors provide a continuous measurement of the level over the range for which they were designed. Their output is an analog representation of the level of the solids. Fixed-point detectors indicate when a specific level has been reached and are used mainly for actuating alarm signals. By installing a number of these, however, at different points, the combined response can be made to approach that of a continuous detector.

[H.S.B.]

Lever A pivoted rigid bar used to multiply force or motion, sometimes called the lever and fulcrum (see illustration). The lever uses one of the two conditions for static equilibrium, which is that the summation of moments about any point equals zero. The other condition is that the summation of forces acting in any direction through a point equals zero. *See* INCLINED PLANE.



The lever pivots at the fulcrum.

If moments acting counterclockwise around the fulcrum of a lever are positive, then, for a frictionless lever, $F_B b - F_A a = 0$, which may be rearranged to give Eq. (1). If F_B represents the

$$F_B = \frac{a}{b} F_A \tag{1}$$

output and F_A represents the input, the mechanical advantage, MA, is then given by Eq. (2).

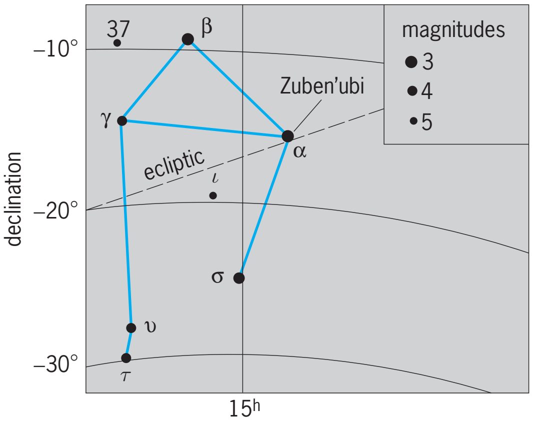
$$\mathrm{MA} = \frac{F_B}{F_A} = \frac{a}{b} \tag{2}$$

Applications of the lever range from the simple nutcracker and paper punch to complex multiple-lever systems found in scales and in testing machines used in the study of properties of materials. *See* SIMPLE MACHINE.

[R.M.Ph.]

Libra The Balance, in astronomy, appearing during the spring. It is the seventh sign of the zodiac. The constellation consists of faint stars and is not conspicuous. It lies just west of the claws of Scorpius. The principal stars, α, β, γ, and σ, outline a four-sided figure resembling a balance with beam and pans (see illustration). *See* CONSTELLATION.

[C.-S.Y.]



Line pattern of the constellation Libra. The grid lines represent the coordinates of the sky. The apparent brightness, or magnitude, of the stars is shown by the sizes of the dots, graded by appropriate numbers.

Lichens Symbiotic associations of fungi (mycobionts) and photosynthetic partners (photobionts). These associations always result in a distinct morphological body termed a thallus that may adhere tightly to the substrate or be leafy, stalked, or hanging. A thallus consists of layers, that is, a cortex and medulla made up of the fungus, and a photosynthetic layer of algal or cyanobacterial cells that are closely associated with fungal hyphae. Rhizoids anchor thalli to their substrates. *See* CYANOBACTERIA.

Lichens are formed from specialized groups of parasitic fungi; this association is one of a controlled parasitism rather than mutualism. Thus, the photobionts that lichen fungi slowly parasitize should be considered victims and not partners. Lichen-forming fungi share two characteristics with fungi that parasitize plants: concentric bodies and specialized branches of hyphae (haustoria) that penetrate host cells and absorb nutrients from them.

Lichens have a worldwide distribution and grow on almost any inanimate object. They are among the hardiest of organisms and thrive in some of the Earth's harshest environments, such as polar regions, deserts, and high mountains.

The name given to a lichen applies only to the mycobiont, while the photobiont has a separate name. Most of the 15,000 lichen-forming fungi are in the fungal class Ascomycotina (ascolichens). Approximately a dozen species of basidiomycetes form lichens. Lichens that do not have sexual reproduction (*Lepraria*) are placed in the Lichenes Imperfecti.

Photobionts of lichens are either green algae or cyanobacteria. The most common photobiont is *Trebouxia*. This unicellular green algae has never been found in the free-living state. It is believed that *Trebouxia* is a lichenized and highly modified form of the filamentous alga *Pleurastrum terrestre*.

The basic metabolic processes of lichens are photosynthesis, respiration, and nitrogen fixation. Lichens have adapted these processes to different conditions of light, temperature, day length, and water. The mycobiont causes the photobiont to excrete most of the carbon that it fixes during photosynthesis. Only a single type of compound is excreted. The mycobiont absorbs these compounds and converts them to mannitol, its own storage compound. *See* PLANT RESPIRATION.

Nitrogen-fixing lichens are common and contribute nitrogen to different ecosystems when they decay. In cyanolichens the mycobiont inhibits the nitrogen-assimilating enzymes of the cyanobiont, causing it to release most of the ammonia it produces. The ammonia is absorbed by the mycobiont and used to make proteins and nucleic acids. *See* NITROGEN FIXATION.

Lichens produce several hundred secondary compounds that accumulate as crystals in the thalli, often at high concentrations. These compounds may protect the slow-growing thalli from harmful bacteria, fungi, and insects and may play a regulatory role in the interactions between bionts. Lichen secondary compounds represent a new class of antibiotics in an age where standard antibiotics such as penicillin are becoming ineffective against antibiotic-resistant microbes. Secondary compounds are used extensively by taxonomists to characterize new taxa of lichens (chemotaxonomy). [V.Ah.]

Lidar The optical analog of radar. The term lidar is an acronym for light detection and ranging. Lidar systems employ intense pulses of light, typically generated by lasers, and large telescopes and sensitive optical detectors to receive the reflected pulses. They are most commonly used to measure the composition and structure of the atmosphere. The very narrow beamwidth, narrow linewidth, and ultrashort pulses of the laser make it possible to optically probe the atmosphere with exceptional sensitivity and resolution. When used to measure the range and velocity of hard targets, lidars are usually called laser ranging systems or laser radars. *See* LASER; OPTICAL DETECTORS; RADAR.

Ranging and altimeter systems. The most common lidar configuration is the monostatic system. The laser beam is either projected through the receiving telescope or propagates parallel to the optical axis of the telescope. If the system is designed for ranging or altimetry, the receiver measures the round-trip propagation time of the laser pulse between the lidar and the target.

The most sophisticated systems are used for ranging to retroreflector-equipped satellites and to the retroreflector arrays placed on the Moon by the Apollo astronauts. Accuracies of a few centimeters are achieved routinely. Data from these measurements are used to monitor geophysical phenomena such as continental drift, crustal dynamics, and the Earth's rotation rate. Airborne laser altimeters provide maps of surface topography, coastal water depth, forest canopies, sea ice distribution, volcanic landforms, impact craters, and ocean wave heights. *See* REMOTE SENSING.

Atmospheric lidars. The targets of atmospheric lidars are either suspended dust and aerosols or gas molecules which are continuously distributed in the atmosphere along the propagation path of the laser beam. Atmospheric lidar systems are used to measure density profiles of the scatterers. Profile measurements are accomplished by pulsing the laser and then periodically sampling the detector output. The sampling process is called range gating.

Atmospheric lidars are classified according to the type of scattering mechanism exploited to make the measurement. Aerosol lidars measure scattering from atmospheric dust and aerosols. Rayleigh lidars are designed to measure the molecular scattered signal, which is proportional to atmospheric density. Resonance fluorescence lidars are used to measure the density profiles of specific molecular species such as sodium in the upper atmosphere. The differential absorption lidar (DIAL) measures species concentrations in the lower atmosphere using two lasers, one tuned to an absorption line of the species of interest and the other tuned just off the absorption line. Raman lidars measure the scattered signal at the Raman shifted wavelength, and have provided excellent measurements of atmospheric density, temperature, and water vapor concentration at altitudes below 10 km (6 mi). Doppler lidars are used to measure tropospheric winds. *See* DOPPLER EFFECT; DOPPLER RADAR; RAMAN EFFECT; SCATTERING OF ELECTROMAGNETIC RADIATION. [C.S.G.]

Lie detector A device intended to detect an involuntary physiological response that all persons exhibit when lying but never when telling the truth. Because there is no such specific lie response, actual "lie detector" tests used in the United States record breathing movements, blood pressure changes, and electrodermal responses on a polygraph while the respondent answers "yes" or "no" to a series of questions. From the recordings, one can determine whether "relevant" questions had greater impact on the respondent than the interpolated "control" questions. *See* ELECTRODERMAL RESPONSE. [D.T.L.]

Lie group A topological group with only countably many connected components whose identity component is open and is an analytic group. An analytic group or connected Lie group is a topological group with the additional structure of a smooth manifold such that multiplication and inversion are smooth. Many groups that arise naturally as groups of symmetries of physical or mathematical systems are Lie groups. The study of Lie groups has applications to analytic function theory, differential equations, differential geometry, Fourier analysis, algebraic number theory, algebraic geometry, quantum mechanics, relativity, and elementary particle theory. *See* GROUP THEORY; TOPOLOGY. [A.W.K.]

Ligament A strong, flexible connective tissue band usually found between two bony prominences. Most ligaments are composed of dense fibrous tissue formed by parallel bundles of collagen fibers. They have a shining white appearance and are pliable, strong, and noncompliant. A second kind of ligament, composed either partly or almost entirely of yellow elastic fibers, is extensible or compliant, thereby allowing the connected bones to move apart. *See* CONNECTIVE TISSUE; JOINT (ANATOMY). [W.J.B.]

Ligand A molecule with an affinity to bind to a second atom or molecule. This affinity can be described in terms of noncovalent interactions, such as the type of binding that occurs in enzymes that are specific for certain substrates; or of a mode of binding where an atom or groups of atoms are covalently bound to a central atom, as in the case of coordination complexes and organometallic compounds. Ligands of the latter type can be further distinguished by the nature of the orbitals used in bond formation. *See* ENZYME.

When a protein binds to another molecule, that molecule may be referred to as a ligand. The site where the ligand is bound is known as the binding or active site of the protein. In order for a molecule to be classified as a ligand for a protein, several weak interactions such as hydrophobic, van der Waals, and hydrogen bonding must take place simultaneously. Therefore, the binding of a ligand by a protein is generally quite specific. *See* CHEMICAL BONDING; COORDINATION CHEMISTRY. [T.J.Me.]

Ligand field theory An essentially ionic approach to chemical bonding which is often used with coordination compounds. These compounds consist of a central transition-metal ion that is surrounded by a regular array of coordinated atoms or ligands. Accordingly, the ligands are assumed to be sources of negative charge which perturb the energy levels of the central metal ion. In this respect the ligands subject the metal ion to an electric field which is analogous to the electric or crystal field produced by the regular distribution of nearest neighbors within an ionic crystalline lattice. For example, the crystal field produced by the Cl ion ligand in octahedral $TiCl_6^{3-}$ is considered to be similar to that produced by the octahedral array of the six Cl ions about each Na ion in NaCl. The Na ion with its rare-gas configuration has an electronic charge distribution which is spherically symmetric both within and without the crystal field. The paramagnetic Ti(III) ion, which possesses one 3*d* electron (d^1), has a spherically symmetric charge distribution only in the absence of the crystal field produced by the ligands. The presence of the ligands destroys the spherical symmetry and produces a more complex set of energy levels within the central metal ion. The crystal field theory allows the energy levels to be calculated and related to experimental observation. *See* COORDINATION CHEMISTRY. [R.A.D.W.]

Light The term light, as commonly used, refers to the kind of radiant electromagnetic energy that is associated with vision. In a broader sense, light includes the entire range of radiation known as the electromagnetic spectrum. The branch of science dealing with light, its origin and propagation, its effects, and other phenomena associated with it is called optics. Spectroscopy is the branch of optics that pertains to the production and investigation of spectra. *See* OPTICS; SPECTROSCOPY.

Principal effects. The electromagnetic spectrum is a broad band of radiant energy that extends over a range of wavelengths running from trillionths of inches to hundreds of miles; wavelengths of visible light are measured in hundreds of thousandths of an inch. Arranged in order of increasing wavelength, the radiation making up the electromagnetic spectrum is termed gamma rays, x-rays, ultraviolet rays, visible light, infrared waves, microwaves, radio waves, and very long electromagnetic waves. *See* ELECTROMAGNETIC RADIATION.

The fact that light travels at a finite speed or velocity is well established. In round numbers, the speed of light in vacuum or air may be said to be 186,000 mi/s or 300,000 km/s. Measurements of the speed of light, *c*, which had attracted physicists for 308 years, came to an end in 1983 when the new definition of the meter fixed the value of the speed of light. Highly precise values of *c* were obtained by extending absolute frequency measurements into a region of the electromagnetic spectrum where wavelengths can be most accurately measured. These advances were facilitated by the use of stabilized lasers and high-speed tungsten-nickel diodes which were used to measure the lasers' frequencies. The measurements of the speed of light and of the frequency of lasers yielded a value of the speed of light limited only by the standard of length which was then in use. This permitted a redefinition of the meter in which the value of the speed of light assumed an exact value, 299,792,458 m/s. The meter is defined as the length of the path traveled by light in vacuum during a time interval of 1/299 792 458 of a second. *See* LASER. [K.M.E.]

One of the most easily observed facts about light is its tendency to travel in straight lines. Careful observation shows, however, that a light ray spreads slightly when passing the edges of an obstacle. This phenomenon is called diffraction. The reflection of light is also well known. Reflection of light from smooth optical surfaces occurs so that the angle of reflection equals the angle of incidence, a fact that is most readily observed with a plane mirror. When light is reflected irregularly and diffusely, the phenomenon is termed scattering. The scattering of light by gas particles in the atmosphere causes the blue color of the sky. *See* DIFFRACTION; REFLECTION OF ELECTROMAGNETIC RADIATION.

The type of bending of light rays called refraction is caused by the fact that light travels at different speeds in different media—faster, for example, in air than in either glass or water. Refraction occurs when light passes from one medium to another in which it moves at a different speed. Familiar examples include the change in direction of light rays in going through a prism, and the bent appearance of a slick partially immersed in water. *See* REFRACTION OF WAVES.

In the phenomenon called interference, rays of light emerging from two parallel slits combine on a screen to produce alternating light and dark bands. This effect can be obtained quite easily in the laboratory, and is observed in the colors produced by a thin film of oil on the surface of a pool of water. Polarization of light is usually shown with Polaroid disks. Such disks are quite transparent individually. When two of them are placed together, however, the degree of transparency of the combination depends upon the relative orientation of the disks. It can be varied from ready transmission of light to almost total opacity, simply by rotating one disk with respect to the other. *See* INTERFERENCE OF WAVES; POLARIZED LIGHT.

When light is absorbed by certain substances, chemical changes take place. This fact forms the basis for the science of photochemistry.

Theory. Phenomena involving light may be classed into three groups: electromagnetic wave phenomena, corpuscular or quantum phenomena, and relativistic effects. The relativistic effects appear to influence similarly the observation of both corpuscular and wave phenomena. *See* RELATIVITY.

Wave phenomena. Interference and diffraction are the most striking manifestations of the wave character of light. Their fundamental similarity can be demonstrated in a number of experiments. The wave aspect of the entire spectrum of electromagnetic radiation is most convincingly shown by the similarity of diffraction pictures produced on a photographic plate, placed at some distance behind a diffraction grating, by radiations of different frequencies, such as x-rays and visible light. The interference phenomena of light are, moreover, very similar to interference of electronically produced microwaves and radio waves.

Polarization demonstrates the transverse character of light waves. Further proof of the electromagnetic character of light is found in the possibility of inducing, in a transparent body that is being traversed by a beam of plane-polarized light, the property of rotating the plane of polarization of the beam when the body is placed in a magnetic field. *See* FARADAY EFFECT.

The fact that the velocity of light had been calculated from electric and magnetic parameters (permittivity and permeability) was at the root of Maxwell's conclusion in 1865 that "light, including heat and other radiations if any, is a disturbance in the form of waves propagated. . . according to electromagnetic laws." Finally, the observation that electrons and neutrons can give rise to diffraction patterns quite similar to those produced by visible light has made it necessary to ascribe a wave character to particles. *See* ELECTRON DIFFRACTION; NEUTRON DIFFRACTION.

Corpuscular phenomena. In its interactions with matter, light exchanges energy only in discrete amounts, called quanta. This fact is difficult to reconcile with the idea that light energy is spread out in a wave, but is easily visualized in terms of corpuscles, or photons, of light.

The radiation from theoretically perfect heat radiators, called blackbodies, involves the exchange of energy between radiation and matter in an enclosed cavity. The observed frequency distribution of the radiation emitted by the enclosure at a given temperature of the cavity can be correctly described by theory only if one assumes that light of frequency ν is absorbed in integral multiples of a quantum of energy equal to $h\nu$, where h is a fundamental physical constant called Planck's constant.

When a monochromatic beam of electromagnetic radiation illuminates the surface of a solid (or less commonly, a liquid), electrons are ejected from the surface in the phenomenon known as photoemission or the external photoelectric effect. It is found that the emission of these photoelectrons, as they are called, is immediate, and independent of the intensity of the light beam, even at very low light intensities. This fact excludes the possibility of accumulation of energy from the light beam until an amount corresponding to the kinetic energy of the ejected electron has been reached.

The scattering of x-rays of frequency ν_0 by the lighter elements is caused by the collision of x-ray photons with electrons. Under such circumstances, both a scattered x-ray photon and a scattered electron are observed, and the scattered x-ray has a lower frequency than the impinging x-ray. The kinetic energy of the impinging x-ray, the scattered x-ray, and the scattered electron, as well as their relative directions, are in agreement with calculations involving the conservation of energy and momentum. *See* COMPTON EFFECT; HEAT RADIATION; PHOTON.

Quantum theories. The need for reconciling Maxwell's theory of the electromagnetic field, which describes the electromagnetic wave character of light, with the particle nature of photons, which demonstrates the equally important corpuscular character of light, has resulted in the formulation of several theories which go a long way toward giving a satisfactory unified treatment of the wave and the corpuscular picture. These theories incorporate, on one hand, the theory of quantum electrodynamics, first set forth by P. A. M. Dirac, P. Jordan, W. Heisenberg, and W. Pauli, and on the other, the earlier quantum mechanics of L. de Broglie, Heisenberg, and E. Schrödinger. Unresolved theoretical difficulties persist, however, in the higher-than-first approximations of the interactions between light and elementary particles.

Dirac's synthesis of the wave and corpuscular theories of light is based on rewriting Maxwell's equations in a Hamiltonian form resembling the Hamiltonian equations of classical mechanics. Using the same formalism involved in the transformation of classical into wave-mechanical equations by the introduction of the quantum of action hν, Dirac obtained a new equation of the electromagnetic field. The solutions of this equation require quantized waves, corresponding to photons. The superposition of these solutions represents the electromagnetic field. The quantized waves are subject to Heisenberg's uncertainty principle. The quantized description of radiation cannot be taken literally in terms of either photons or waves, but rather is a description of the probability of occurrence in a given region of a given interaction or observation. *See* HAMILTON'S EQUATIONS OF MOTION; QUANTUM ELECTRODYNAMICS; QUANTUM FIELD THEORY; QUANTUM MECHANICS; RELATIVISTIC QUANTUM THEORY; UNCERTAINTY PRINCIPLE. [G.W.S.]

Light amplifier

In the broadest sense, a device which produces an enhanced light output when actuated by incident light. A simple photocell relay–light source combination would satisfy this definition. To make the term more meaningful, common usage has introduced two restrictions: (1) a light amplifier must be a device which, when actuated by a light image, reproduces a similar image of enhanced brightness; and (2) the device must be capable of operating at very low light levels without introducing spurious brightness variations (noise) into the reproduced image. The term is used synonymously with image intensifier. The light amplifier increases the brightness of an image which is below the visual threshold to a level where it can be readily seen with the unaided eye. It is, of course, impossible to see under conditions of complete darkness. Indeed, there is a fundamental lower limit of illumination under which an image of a given quality can be recognized. This limitation arises because of the corpuscular nature of light. *See* LIGHT; PHOTON.

In addition to their application for night vision, light amplifiers have been useful in many fields of science, such as astronomy, nuclear physics, and microbiology. [D.R.Co.]

Light curves

Graphs of the intensity of radiation from astronomical objects as they change with time. Variations may be caused by the changing perspective from the Earth of two stars in orbit around each other, by pulsations that change an individual star's size and surface temperature, by mass ejection or accretion, by explosions, by beams of radiation sweeping across the line of sight from the Earth, or by clouds of very high-energy electrons in powerful magnetic fields. The information contained in the light curve includes the timing of events, such as eclipses or pulses, and the amplitude of changes in the radiation received at Earth.

Each data point in a light curve is a photometric measurement, recorded at a particular time. These points represent measurements of the amount of radiation from the source received at Earth per second per area in a particular bandpass, for example, through a blue filter. In optical light, photometry is affected by the varying transparency of the atmosphere, so that light curves are often obtained as ratios to the intensities of nearby comparison stars. Simultaneous measurements can be made visually, with photometers that have two channels or with imagers, such as charge-coupled devices (CCDs) or photographic emulsions. These relative light curves are put on an absolute scale by means of calibrating measures of the comparison stars taken on clear nights. *See* ASTRONOMICAL PHOTOGRAPHY; CHARGE-COUPLED DEVICES; MAGNITUDE (ASTRONOMY); PHOTOMETRY. [R.F.Gr.]

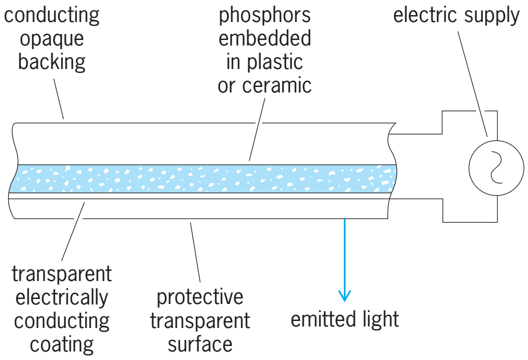
Light-emitting diode

A rectifying semiconductor device which converts electrical energy into electromagnetic radiation. The wavelength of the emitted radiation ranges from the near-ultraviolet to the near-infrared, that is, from about 400 to over 1500 nanometers.

Most commercial light-emitting diodes (LEDs), both visible and infrared, are fabricated from III–V semiconductors. These compounds contain elements such as gallium, indium, and aluminum from column III (or group 13) of the periodic table, as well as arsenic, phosphorus, and nitrogen from column V (or group 15) of the periodic table. There are also LED products made of II–VI (or group 12–16) semiconductors, for example ZnSe and related compounds. Taken together, these semiconductors possess the proper band-gap energies to produce radiation at all wavelengths of interest. Most of these compounds have direct band gaps and, as a consequence, are efficient in the conversion of electrical energy into radiation. With the addition of appropriate chemical impurities, called dopants, both III–V and II–VI compounds can be made *p*- or *n*-type, for the purpose of forming *pn* junctions. All modern-day LEDs contain *pn* junctions. Most of them also have heterostructures, in which the *pn* junctions are surrounded by semiconductor materials with larger band-gap energies. *See* ACCEPTOR ATOM; DONOR ATOM; ELECTROLUMINESCENCE; ELECTRON-HOLE RECOMBINATION; JUNCTION DIODE; JUNCTION TRANSISTOR; LASER; SEMICONDUCTOR; SEMICONDUCTOR DIODE.

Conventional low-power, visible LEDs are used as solid-state indicator lights in instrument panels, telephone dials, cameras, appliances, dashboards, and computer terminals, and as light sources for numeric and alphanumeric displays. Modern high-brightness, visible LED lamps are used in outdoor applications such as traffic signals, changeable message signs, large-area video displays, and automotive exterior lighting. General-purpose white lighting and multielement array printers are applications in which high-power visible LEDs may soon displace present-day technology. Infrared LEDs, when combined in a hybrid package with solid-state photodetectors, provide a unique electrically isolated optical interface in electronic circuits. Infrared LEDs are also used in optical-fiber communication systems as a low-cost, high-reliability alternative to semiconductor lasers. [J.M.Woo.; L.J.G.]

Light panel A surface-area light source that employs the principle of electroluminescence to produce light. Light panels are composed of two sheets of electrically conductive material, one a thin conducting backing and the other a transparent conductive film, placed on opposite sides of a plastic or ceramic sheet impregnated with a phosphor, such as zinc sulfide, and small amounts of compounds of copper or manganese. When an alternating voltage is applied to the conductive sheets, an electric field is applied to the phosphor. Each time the electric field changes, it dislodges electrons from the edges of the phosphor crystals. As these electrons fall back to their normal atomic state, they affect the atoms of the slight "impurities" of copper or manganese, and radiation of the wavelength of light is emitted. *See* ELECTROLUMINESCENCE.



Simplified diagram of an electroluminescent cell.

In contrast to incandescent, vapor-discharge, and fluorescent lamps, which are essentially point or line sources of light, the electroluminescent light panel is essentially a surface source of light. Complete freedom of size and shape is a fascinating aspect of luminescent cells (see illustration). *See* ILLUMINATION. [W.B.Bo.]

Light-scattering photometry Optical methods used to measure the extent of scattering of light by particles suspended in fluids or by macromolecules in solution. Two different approaches are employed. The photometric measurement of the extent of attenuation of an incident light beam as it passes through the scattering medium is known as turbidimetry. The measurement of the intensity of light scattered to a detector which is not in the path of the incident light (often at right angles to it) is known as nephelometry—literally, the measurement of cloudiness.

Nephelometry and turbidimetry are also used for quantitative analytical chemical measurements. These methods were formerly considered relatively nonprecise and were used only to obtain approximate concentration information. With the advent of microprocessor-based instrumentation, however, it has been possible to overcome such prior limitations as nonlinearity of response with concentration, and these methods have become increasingly popular, particularly in the field of clinical chemistry. *See* SCATTERING OF ELECTROMAGNETIC RADIATION.

Turbidimetric analysis involves measurement of the intensity of light that is transmitted through a solution or suspension. For strongly turbid samples containing many particles or particles that are large compared with the wavelength of visible light, turbidimetry is the method of choice, and it is most often performed on a colorimeter or spectrophotometer. For a limited range of particle concentrations in suspensions, this method of measurement gives fairly good precision. *See* COLORIMETRY; SPECTROSCOPY.

The relative ease of discriminating the presence of scattered light from the dark background present in the absence of scattering makes nephelometric measurement an extremely sensitive tool for analytical purposes. For a relatively clear solution, where the light is only weakly scattered because of a low concentration of particles or the presence of particles which are extremely small compared with the wavelength of the incident light, nephelometry is generally the tool best suited to measurement. In principle, nephelometric measurements can be made at the detection angle and with the wavelength of light most suitable for a particular application. The most notable analytical application of nephelometry is in the quantitative analysis of specific human serum proteins. *See* IMMUNOASSAY; PHOTOMETRY. [J.C.St.; A.F.-T.C.]

Light-year A unit of measurement of astronomical distance. A light-year is the distance light travels in 1 sidereal year. One light-year is equivalent to 9.461×10^{12} km, or 5.879×10^{12} mi. Distances to some of the nearer celestial objects, measured in units of light time, are shown in the table.

Distances from the Earth to some celestial objects

Object	Distance from Earth (in light time)
Moon (mean)	1.3 s
Sun (mean)	8.3 min
Mars (closest)	3.1 min
Jupiter (closest)	33 min
Pluto (closest)	5.3 h
Nearest star (Proxima Centauri)	4.3 years
Andromeda Nebula (M31)	2,300,000 years

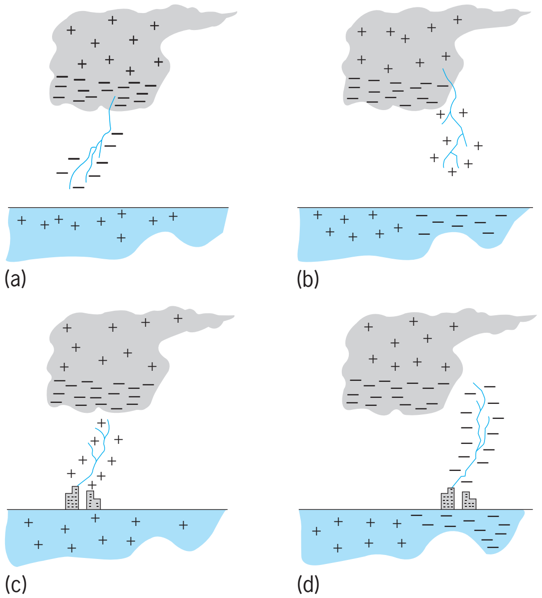
This unit, while useful for its graphic presentation of the enormous scale of stellar distances, is seldom used technically except in cosmology. *See* ASTRONOMICAL UNIT; PARALLAX (ASTRONOMY); PARSEC. [J.L.Gr.]

Lighthouse A distinctive structure, built on or near a shore, which exhibits a light of distinctive characteristics to serve as an aid to navigation. Lesser lights may be displayed from fixed structures called beacons or from floating buoys or lightships.

The characteristics of the lights displayed by lighthouses are given in light lists available to mariners and, in abbreviated form, on charts. Some lights have one or more sectors in which the light appears red, usually to warn of some danger in this sector. In other sectors most lights are white. *See* PILOTING. [A.B.M.]

Lightning An abrupt, high-current electric discharge that occurs in the atmospheres of the Earth and other planets and that has a path length ranging from hundreds of feet to tens of miles. Lightning occurs in thunderstorms because vertical air motions and interactions between cloud particles cause a separation of positive and negative charges. *See* ATMOSPHERIC ELECTRICITY.

The vast majority of lightning flashes between cloud and ground begin in the cloud with a process known as the preliminary breakdown. After perhaps a tenth of a second, a highly branched discharge, the stepped leader, appears below the cloud base and propagates downward in a succession of intermittent steps. The leader channel is usually negatively charged, and when the tip of a branch of the leader gets to within about 30 m (100 ft) of the ground, the electric field becomes large enough



Sketches of the different types of lightning between an idealized cloud and the ground: (*a*) type 1, (*b*) type 2, (*c*) type 3, and (*d*) type 4. Channel development within the cloud is not shown. Type 1 is the most common form of cloud-to-ground lightning, and type 4 is very rare. (*After M. A. Uman, The Lightning Discharge, Academic Press, 1987*)

to initiate one or more upward connecting discharges, usually from the tallest objects in the local vicinity of the leader. When contact occurs between an upward discharge and the stepped leader, the first return stroke begins. The return stroke is basically a very intense, positive wave of ionization that propagates up the partially ionized leader channel into the cloud at a speed close to the speed of light. After a pause of 40–80 milliseconds, another leader, the dart leader, forms in the cloud and propagates down the previous return-stroke channel without stepping. When the dart leader makes contact with the ground, a subsequent return stroke propagates back to the cloud. A typical cloud-to-ground flash lasts 0.2–0.3 s and contains about four return strokes; lightning often appears to flicker because the human eye is capable of just resolving the interval between these strokes.

Lightning between cloud and ground is usually classified according to the direction of propagation and polarity of the initial leader. For example, in the most frequent type of cloud-to-ground lightning a negative discharge is initiated by a downward propagating leader as described above (illus. *a*). In this case, the total discharge will effectively lower negative charge to ground or, equivalently, will deposit positive charge in the cloud.

A discharge can be initiated by a downward-propagating positive leader (illus. *b*). Positive discharges occur less frequently than negative ones, but positive discharges are often quite deleterious. Another type of lightning is a ground-to-cloud discharge that begins with a positive leader propagating upward (illus. *c*); this type is relatively rare and is usually initiated by a tall structure or a mountain peak. The rarest form of lightning is a discharge that begins with a negative leader propagating upward (illus. *d*).

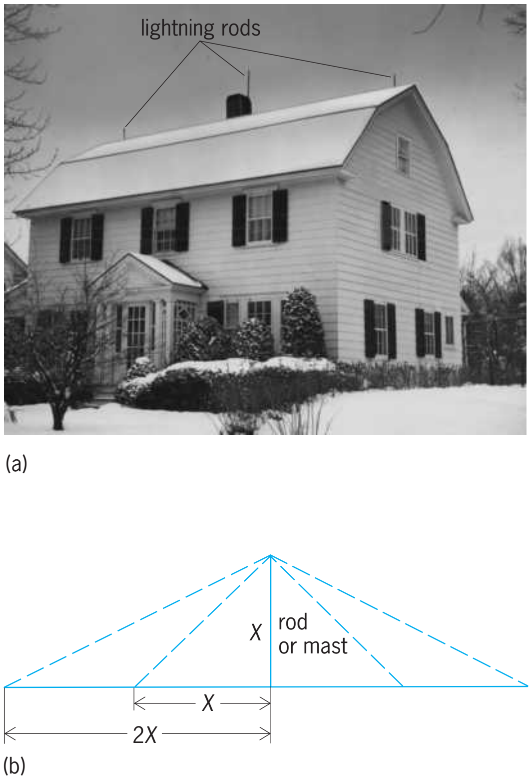
The electric currents that flow in return strokes have been measured during direct strikes to instrumented towers. The peak current in a negative first stroke is typically 30 kiloamperes, with a zero-to-peak rise time of just a few microseconds. This current decreases to half-peak value in about 50 microseconds, and then low-level currents of hundreds of amperes may flow for a few to hundreds of milliseconds. The long-continuing currents produce charge transfers on the order of tens of coulombs and are frequently the cause of fires. Subsequent return strokes have peak currents that are typically 10–15 kA, and somewhat faster current rise times. Five percent of the negative discharges to ground generate peak currents that exceed 80 kA, and 5% of the positive discharges exceed 250 kA. Positive flashes frequently produce very large charge transfers, with 50% exceeding 80 coulombs and 5% exceeding 350 coulombs. [E.P.K.]

Red sprites, elves, and blue jets are upper atmospheric optical phenomena associated with thunderstorms and have only recently been documented using low-light-level television technology. Sprites are massive but weak luminous flashes appearing directly above active thunderstorms coincident with cloud-to-ground or intracloud lightning. They extend from the cloud tops to about 95 km (59 mi) and are predominantly red. High-speed photometer measurements show that the duration of sprites is only a few milliseconds. Their brightness is comparable to a moderately bright auroral arc. Elves are associated with sprites. They are optical emissions of approximately 1 millisecond, with a fast lateral, horizontal expansion that emits more red than blue light. They occur at altitudes of 75–95 km (47–59 mi). Blue jets are optical ejections from the top of the electrically active core regions of thunderstorms. Following the emergence from the top of the thundercloud, they typically propagate upward in narrow cones of about 15° full width at vertical speeds of roughly 100 km/s (60 mi/s), fanning out and disappearing at heights of about 40–50 km (25–30 mi). [R.E.O.]

Lightning and surge protection

Means of protecting electrical systems, buildings, and other property from lightning and other high-voltage surges. From studies of lightning, two conclusions emerge: (1) Lightning will not strike an object if it is placed in a grounded metal cage. (2) Lightning tends to strike, in general, the highest objects on the horizon. *See* ATMOSPHERIC ELECTRICITY; LIGHTNING.

One practical approximation of the grounded metal cage is the well-known lightning rod or mast. The effectiveness of this device is evaluated on the cone-of-protection principle. The protected area is the space enclosed by a cone having the mast top as the apex of the cone and tapering out to the base. If the radius



Lightning rod cone of protection. (*a*) Configuration of rods on a house. (*b*) Geometry of the principle.

of the base of the cone is equal to the height *X* of the mast, equipment inside this cone will rarely be struck. A radius equal to twice the height of the mast (2*X*) gives a cone of shielding within which an object will be struck occasionally. The cone-of-protection principle is shown in the illustration.

The probability that an object will be struck by lightning is considerably less if it is located in a valley. Therefore, electric transmission lines which must cross mountain ranges often will be routed through the gaps to avoid the direct exposure of the ridges.

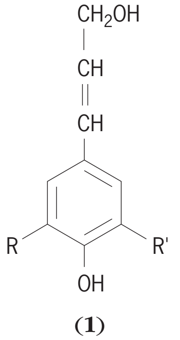
There are a number of protective devices to limit or prevent lightning damage to electric power systems and equipment. The word protective is used to connote either one of two functions: the prevention of trouble, or its elimination after it occurs. Various protective means have been devised either to prevent lightning from entering the system or to dissipate it harmlessly if it does. Overhead ground wires and lightning rods are used to prevent lightning from striking the electrical system. Lightning arresters are protective devices for reducing the transient system overvoltages to levels compatible with the terminal-apparatus insulation. *See* Surge suppressor.

Immediate reclosure is a practice for restoring service after the trouble occurs by immediately reclosing automatically the line power circuit breakers after they have been tripped by a short circuit. The protective devices involved are the power circuit breaker and the fault-detecting and reclosing relays. *See* Circuit breaker; Electric protective devices. [G.D.B.]

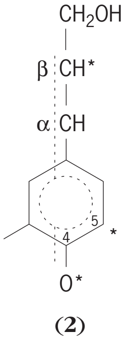
Lignin A polymer found extensively in the cell walls of all woody plants, Lignin, one of the most abundant natural polymers, constitutes one-fourth to one-third of the total dry weight of trees. It combines with hemicellulose materials to help bind the cells together and direct water flow. *See* Cell walls (plant); Hemicellulose; Polymer.

Several methods have been devised for isolating lignin from wood. Some isolation methods are based on acid treatments in which the carbohydrate components (cellulose and hemicelluloses) are hydrolyzed to water-soluble materials. However, with such procedures, serious doubts exist as to whether the isolated lignin is representative of the "native" lignin. Enzymatic digestion of the carbohydrate in wood meal is a lengthy, tedious procedure but offers the greatest promise of leaving lignin unaltered during isolation.

Structural studies on lignin have been hampered by the random, cross-linked nature of the polymer. The relative proportions of the monomers which make up lignin (**1** and **2**) vary with the plant species. Lignin is formed in the plant by an enzymatic dehydrogenation of the monomers. The * designations shown on the structure (**2**) indicate the principal sites for coupling monomers.



(**1**)



(**2**)

In general, the markets for lignin products are not large or attractive enough to compensate for the cost of isolation and the energy derived from its burning. An exception is lignosul-fonate, which is obtained during paper production either directly from sulfite pulping liquors or by sulfonation of acid-precipitated kraft lignin; its markets include a dispersant in carbon black slurries, clay products, dyes, cement, oil drilling muds, an asphalt emulsifier, a binder for animal feed pellets, a conditioner for boiler water or cooling water, and an additive to lead-acid storage battery plate expanders. *See* Paper; Wood chemicals. [D.R.D.]

Lignite A brownish-black, low-rank coal, with a heating value of less than 8300 Btu/lb (4611 kcal/kg) on a moist, mineral-matter-free basis. Lignite occurs in two subclasses: lignite A [8300–6300 Btu/lb (4611–3500 kcal/kg)] and lignite B [less than 6300 Btu/lb (3500 kcal/kg)]. Outside North America, low-rank coal is classified as brown coal, which includes lignite, subbituminous, and most high-volatile C bituminous coal of the North American classification system. Brown coal is divided into soft and hard coal; hard coal is subdivided into dull and bright coal. *See* Coal.

Because lignite has undergone less coalification than higher-rank coals, the organic precursor constituents are more easily recognized than those in high-rank coals, and lignite serves as an invaluable link between peat and high-rank coals in studying the coal origin. *See* Coal paleobotany; Peat.

Lignite is used primarily to generate electricity at mine-mouth power plants. Lignite has been successfully used as a feedstock for gasification, liquefaction, and pyrolysis. Minor uses of lignite are montan wax, activated carbon, firing kilns, and home heating. *See* Activated carbon; Coal chemicals. [W.B.A.]

Lignumvitae A tree, *Guaiacum sanctum*, also known as holywood lignumvitae, which is cultivated to some extent in southern California and tropical Florida. Lignumvitae is native in the Florida Keys, Bahamas, West Indies, and Central and South America. It is an evergreen tree of medium size with abruptly pinnate leaves. The tree yields a resin or gum known as gum guaiac or resin of guaiac which is used in medicine. The very heavy black heartwood is used in bowling balls, blocks and pulleys, and parts of instruments. *See* Sapindales. [A.H.G./K.P.D.]

Liliales An order of monocotyledons, the well-known lilies or family Liliaceae of many previous botanists, actually consisting of 9 families and about 1600 species. Liliales are clearly circumscribed in deoxyribonucleic acid (DNA) sequence analyses, but are difficult to define on the basis of morphological characters, resulting in varying family composition in different classifications. Nearly all features marking the families of Liliales are micromorphological (for example, perigonal nectaries, nuclear endosperm formation).

Many members of the order are herbaceous perennials, but there are also some vines. Many taxa are extremely poisonous. Most Colchicaceae, for example, possess colchicine-type alkaloids. *Lilium* (lilies), *Tulipa* (tulips), and *Fritillaria* (fritillaries) in Liliaceae, *Colchicum* (autumn crocuses, Colchicaceae), and *Alstroemeria* (Peruvian lilies, Alstroemeriaceae) are well-known horticultural plants. *See* Asparagus; Colchicine; Garlic; Liliidae; Liliopsida; Onion; Sisal. [M.F.F.; M.W.C.]

Liliidae A subclass of the class Liliopsida (monocotyledons) of the division Magnoliophyta (Angiospermae), the flowering plants, consisting of 2 orders (Liliales and Orchidales), 19 families, and about 25,000 species. The Liliidae are syncarpous monocotyledons with both the sepals and the petals usually petaloid. The flowers generally have well-developed nectaries, and pollination is usually by insects or other animals. *See* Liliales; Liliopsida; Magnoliophyta; Orchidales. [A.Cr.; T.M.Ba.]

Liliopsida One of the two classes which collectively make up the division Magnoliophyta (Angiospermae), the flowering plants. The Liliopsida, often known as Monocotyledoneae, or monocotyledons, embrace 5 subclasses (Alismatidae, Commelinidae, Arecidae, Zingiberidae, and Liliidae), 18 orders, 61 families, and about 55,000 species.

All of the characters which collectively distinguish the Liliopsida from the Magnoliopsida (dicotyledons) are subject to exception, but most of the Liliopsida have parallel-veined leaves, and when the embryo is differentiated into recognizable parts, there is only a single cotyledon. The vascular bundles are generally scattered or borne in two or more rings, so the stems and roots do not have a well-defined pith and cortex. Monocotyledons never have an intrafascicular cambium, and most of them have no secondary growth at all. The mature root system of monocots is wholly adventitious. The floral parts of monocots, when of definite number, are most often borne in sets of 3, seldom 4, never 5. The pollen is uniaperturate or of uniaperturate-derived type. *See* ALISMATIDAE; ARECIDAE; COMMELINIDAE; LILIIDAE; MAGNOLIOPHYTA; ZINGIBERIDAE. [A.Cr.; T.M.Ba.]

Lime (botany) An acid citrus fruit, *Citrus aurantifolia*, usually grown in tropical or subtropical regions because of its low resistance to cold. The two principal groups of limes are the West Indian or Mexican and the Tahiti or Bearss. The fruit of West Indian lime is very small (walnut size) and strongly acid, and drops when fully colored. The Tahiti lime is seedless and its aroma is less pronounced.

Except in the United States, the commercial lime industry is restricted to the West Indian group. The major producing areas are India, Mexico, Egypt, and the West Indies. Commercial production of the Tahiti lime is largely confined to the United States. It is grown mainly in Florida, with some plantings in the warmer areas of southern California. *See* FRUIT; FRUIT, TREE. [R.K.So.]

Lime (industry) A general term for burned (or calcined) limestone, also known as quicklime, hydrated lime, and unslaked or slaked lime. Its predominant usage (90%) is as a basic industrial chemical. It still enjoys its traditional building uses. In order of decreasing size uses are: steel fluxing, water treatment, nonferrous metals (alumina, magnesium, copper, and others), pulp and paper, refractories, soil stabilization, sewage and trade waste treatment, chemicals, and glass manufacture. *See* LIMESTONE.

Lime is not a mineral; it is manufactured from a mineral—limestone, coral, oystershell, all being sources of calcium carbonate. Dolomite, a calcium-magnesium carbonate, is used to produce dolomitic (magnesium) lime. Only the purest types of stone or shell are used for lime. [R.S.B.]

Limestone A common sedimentary rock composed predominantly of carbonates of calcium and magnesium. Limestones are the most voluminous of the nonsiliciclastic sedimentary rocks. In the strict sense, limestones refer to sedimentary rocks composed of the calcium carbonate mineral calcite ($CaCO_3$). Those rocks, dominated by the magnesium-calcium carbonate mineral dolomite [$CaMg(CO_3)_2$], are known as dolomites or dolostones. Although most limestones are similar in chemical and mineralogical composition, the complex organic and chemical origins of carbonate sediments lead to a wide range of textures and fabrics in the resulting limestones. These textures and fabrics share significant parallels with those found in siliciclastic rocks, and they are quite useful for the classification and determination of depositional environments for limestones. Limestones and dolomites are used commercially as building materials and as a source for industrial and agricultural lime. In addition, limestones and dolomites are important reservoirs for oil and gas and are the hosts for important mineral deposits, including lead, zinc, silver, and fluorite. *See* LIME (INDUSTRY); ORE AND MINERAL DEPOSITS; PETROLEUM GEOLOGY; STONE AND STONE PRODUCTS.

Most marine limestones (perhaps 90% or more) originate as calcium carbonate skeletal elements of various organisms, including both plants (marine algae such as *Lithothamnion* and phytoplankton such as coccoliths) and animals (such as corals, clams, snails, and oysters). The larger organisms are broken down into cobble-to-silt-sized sediments by biological processes, such as boring, browsing, and grazing, in the environment. Once formed, these sediments react to environmental processes as do their siliciclastic counterparts. *See* ALGAE; CHALK; DEPOSITIONAL SYSTEMS AND ENVIRONMENTS; MARINE SEDIMENTS; STRATIGRAPHY.

Some limestones and limestone components are formed by direct chemical precipitation from marine and meteoric waters. Most modern, tropical, marine surface water is supersaturated with respect to calcium carbonate. If carbon dioxide is removed from this water by warming, agitation, or photosynthesis, there is a tendency for calcium carbonate to be precipitated. This precipitation can take several forms: an aragonite or magnesian calcite cement, which lithifies carbonate sediment, such as the beach rock commonly found along tropical beaches; an aragonite precipitate on a moving nucleus in a high-energy environment, forming highly polished, round, sand-sized particles termed ooids; or clouds of spontaneously precipitated, clay-sized aragonite, forming on shallow carbonate platforms or in restricted bays. *See* OOLITE.

Finally, some limestones are formed in fresh-water environments associated with caves (speleothems, such as stalactites and stalagmites), springs (tufa and travertine), and lakes (almost always chemically precipitated fine muds of calcite, dolomite, or alkali-carbonates). *See* CAVE; STALACTITES AND STALAGMITES; TRAVERTINE; TUFA.

Textures and fabrics in limestones are much more difficult to interpret than in siliciclastics, because of the organic origin of most carbonate grains. While grain size distribution in siliciclastics is controlled by the flow velocity at the site of deposition, grain size distribution in carbonates may be controlled by the types of organisms present in the environment that furnishes the grains. As an example, an environment dominated by large mollusks will tend to produce a sediment characterized by coarse grain sizes, whereas a benthic foraminiferal community will tend to produce grain sizes that are much finer. Roundness in siliciclastic deposits may be used to infer transport and depositional processes. Roundness in the individual grains of a limestone, however, may reflect only the original shape of the organism or the architecture of its skeleton. [C.H.Mo.]

Limiter circuit A device whose purpose is to ensure that the amplitude of a sensed variable (referred to as a signal) is constrained or limited to lie within prescribed maximum and minimum values. It is more properly termed an amplitude limiter, although convention usually dispenses with the important modifier. Also, unless specified otherwise, the limiting is applied to voltage.

Strictly speaking, the limiter should behave as a perfectly linear device (such as an ideal amplifier or even a piece of wire) until the amplitude of the input signal reaches the upper or lower limit values. In other words, the output of an ideal limiter matches the input perfectly when the input is between the limit values. If the input is greater than the upper limit, the output equals the upper limit; if the input is less than the lower limit, the output equals the lower limit. If the upper and lower limits are equal in magnitude, the limiting is symmetrical. In the past, one or two stages of high-gain amplification would often precede a limiter in order to obtain clean limiting. *See* LINEARITY.

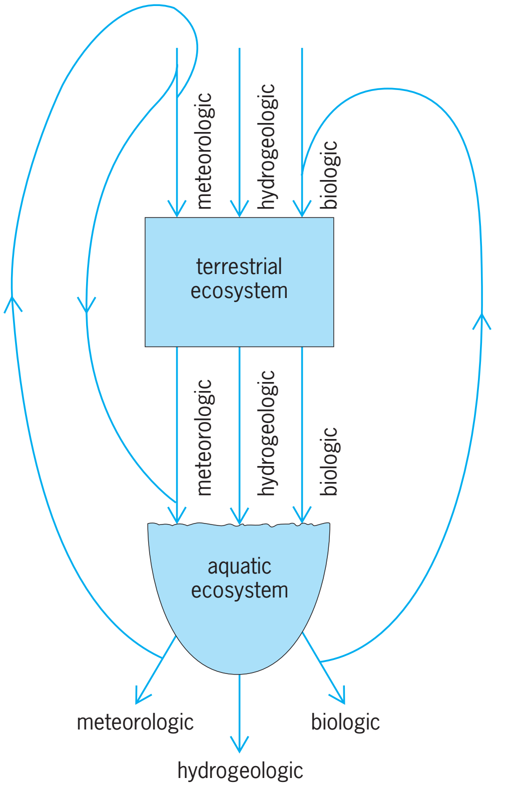
The term limiter is often used to mean sign detector, so that when the input is greater than zero, the output equals some fixed positive value; when the input is less than zero, the output is the negative of this value. This usage is sometimes employed in discussing frequency-modulation (FM) radio receivers.

Discrete-component limiters have become rare. The cost/performance ratio of integrated circuits makes them the only rational choice for commercial applications. Most often, integrated circuits now contain limit operations that are both functionally and physically integrated with companion operations to form a higher-level function. The isolated need for a limit-only function is almost never encountered. Limiting within an integrated circuit is usually obtained by designing an amplifier to be heavily overdriven and therefore to quickly enter the saturation (limiting) range. *See* AMPLIFIER; INTEGRATED CIRCUITS. [S.A.Wh.]

Limits and fits The extreme permissible values of a dimension are known as limits. The degree of tightness or looseness between two mating parts that are intended to act together is known as the fit of the parts. The character of the fit depends upon the use of the parts. Thus, the fit between members that move or rotate relative to each other, such as a shaft rotating in a bearing, is considerably different from the fit that is designed to prevent any relative motion between two parts, such as a wheel attached to an axle.

In selecting and specifying limits and fits for various applications, the interests of interchangeable manufacturing require that (1) standard definitions of terms relating to limits and fits be used; (2) preferred basic sizes be selected wherever possible to be reduce material and tool costs; (3) limits be based upon a series of preferred tolerances and allowances; and (4) a uniform system of applying tolerances (bilateral or unilateral) be used. *See* DESIGN STANDARDS; ENGINEERING DESIGN; MACHINE. [J.El]

Limnology The study of lakes, ponds, rivers, streams, swamps, and reservoirs that make up inland water systems. Each of these inland aquatic environments is physically and chemically connected with its surroundings by meteorologic and hydrogeologic processes (see illustration).

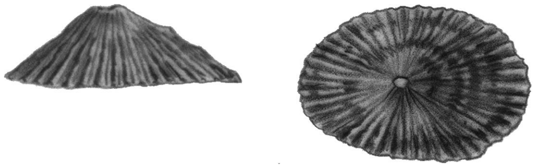


Diagrammatic model of the functional linkages between terrestrial and aquatic ecosystems. Vectors may be meteorologic, hydrogeologic, or biologic components moving nutrients or energy along the pathway shown.

Aquatic systems with excellent physical conditions for production of organisms and high nutrient levels may show signs of eutrophication. Eutrophic lakes are generally identified by large numbers of phytoplankton and aquatic macrophytes and by low oxygen concentrations in the profundal zone. *See* ECOLOGY; EUTROPHICATION; FRESH-WATER ECOSYSTEM; HYDROLOGY; LAKE; RIVER. [J.E.S.]

Limonite A field or generic term for natural hydrous iron oxides, the most common phase being the mineral goethite, α-FeO(OH). Limonite includes the so-called bog iron ores. It is the characteristic brown stain which coats rocks containing sulfide ores, such as pyrite and pyrrhotite, in the zone of weathering of these ores referred to as a gossan. It is formed by biogenic or inorganic precipitation in bog, spring, lacustrine, or marine deposits. [P.B.M.]

Limpet Name given to a variety of species of aquatic gastropod mollusks, all with a characteristic conical shell (see illustration) and a suckerlike foot. Limpets (like chitons) are well adapted for life on rocky surfaces exposed to wave action and, in the higher levels of the littoral zone, to alternating tidal submergence and aerial drying. All limpets move relatively slowly over rock or other hard surfaces, protecting themselves (against wave action or desiccation or predation) by clamping down the shell opening against the substrate by contraction of the enlarged shell muscles. There is never an operculum on the foot, and limpets are defenseless once detached.



***Diodora aspera*, the rough-keyhole limpet of the Pacific coast of North America, viewed from the side and top.**

Limpets usually graze slowly and continuously by radular scraping of attached algae and diatoms from rock surfaces. The structural and functional adaptations of the limpet form have arisen in many distinct groups of gastropods. *See* GASTROPODA; MOLLUSCA. [W.D.R.H.]

Linales An order of flowering plants, division Magnoliophyta (Angiospermae), in the subclass Rosidae of the class Magnoliopsida (dicotyledons). The order is a coherent group of 5 families and about 550 species. They are simple-leaved herbs or woody plants, with hypogynous, regular, syncarpous flowers that have five to many stamens which are connate at the base. The pollen is trinucleate. *Linum usitatissimum* (the source of flax fibers and linseed oil) and *Erythroxylon coca* (the source of cocaine) are well-known members of the Linales. *See* COCA; FLAX; MAGNOLIOPHYTA; MAGNOLIOPSIDA; ROSIDAE. [A.Cr.; T.M.Ba.]

Line integral The line integral of a vector function **F** of position over a path C is represented by Eq. (1), where F_x, F_y, F_z

$$\int \mathbf{F} \cdot d\mathbf{r} = \int_C F_x(x,y,z)\,dx + \int_C F_y(x,y,z)\,dy + \int_C F_z(x,y,z)\,dz \quad (1)$$

are the scalar components of **F** along the coordinate axes. The path C is supposed to be a curve, smooth at least in part, defined parametrically by equations of form (2) for each smooth

$$x = x(p) \quad y = y(p) \qquad z = z(p) \quad (2)$$

portion. The functions $F_x\,(x,y,z)$, etc., must be defined at all points of C.

When C is a closed curve, the line integral is called a circuit integral, and is written as notation (3).

$$\oint \mathbf{F} \cdot d\mathbf{r} \quad (3)$$

See INTEGRATION. [McA.H.H.]

Line spectrum A discontinuous spectrum characteristic of excited atoms, ions, and certain molecules in the gaseous phase at low pressures. If an electric arc or spark between metallic electrodes, or an electric discharge through a low-pressure gas, is viewed through a spectroscope, images of the spectroscope slit are seen in the characteristic colors emitted by the atoms or ions present. *See* ATOMIC STRUCTURE AND SPECTRA; SPECTROSCOPY. [G.R.H.]

Linear algebra That branch of mathematics which deals with solutions of systems of linear equations and the related geometric notions of vector spaces and linear transformations. It is fundamental in the theory of the calculus of functions of several variables and hence is of great importance in the application of mathematics to physical and biological sciences, economics, and so on.

The word linear is derived from the fact that the equation of a line in two-dimensional analytic geometry has the form shown in Eq. (1) and a system of linear equations has the corresponding form shown in Eq. (2), where $i = 1, 2, \ldots, m$. The a_{ij} and b_i are

$$ax + by = c \tag{1}$$

$$a_{i1}x_1 + a_{i2}x_2 + \cdots + a_{in}x_n = b_i \tag{2}$$

fixed quantities belonging to a specified field, for example, the field of real numbers, and solutions $(x_1, x_2, \ldots, x_n)$ are sought in the same field. [N.J.]

Linear programming An area of mathematics concerned with the minimization (or maximization) of a linear function of several variables subject to linear equations and inequalities. The subject in its present form was created in 1947, when G. B. Dantzig defined the general model and proposed the first, and still the most widely used, method for its solution: the simplex method.

Although the linearity assumptions are restrictive, many algorithms for extensions of linear programming, such as problems with nonlinear or integer restrictions, involve successively solving linear programming problems. With a result in 1979 giving a polynomially bounded ellipsoid method, an alternative to the simplex method, linear programming became the focus of work by computer scientists, and nonlinear methods have been refocused on solving the linear programming problem. Work by N. K. Karmarkar announced in 1984 attracted much attention because of claims of vastly improved performance of a new interior method. The relative merits of Kamarkar's method and the simplex method remain to be determined, but there seems to be a place for both methods. Karmarkar's work stimulated considerable activity in linear programming methodology. *See* NONLINEAR PROGRAMMING; OPTIMIZATION.

The linear programming problems is to minimize linear objective function (1) subject to restrictions (2). The variables x_1,

$$\begin{gathered} c_1x_1 + \cdots + c_nx_n \\ x_1 \geq 0, \ldots, x_n \geq 0 \end{gathered} \tag{1}$$

$$\begin{matrix} a_{11}x_1 + \cdots + a_{1n}x_n = b_1 \\ \vdots \qquad\qquad\qquad \vdots \\ a_{m1}x_1 + \cdots + a_{mn}x_n = b_m \end{matrix} \tag{2}$$

$\ldots, x_n$ are required to take on real values, and the coefficients a_{ij}, c_j, and b_i are real constants. The objective could be to maximize rather than minimize, and among constraints (2) the equations could be replaced by inequalities of the form less-than-or-equal-to or greater-than-or-equal-to. The set of x_j's satisfying constraints (2) form a convex polyhedron, and the optimum value of the objective function will always be assumed at a vertex of the polyhedron unless the objective function is unbounded. The simplex method works by moving from vertex to vertex until the vertex yielding the optimum value of the objective function is reached, while interior methods stay inside the polyhedron.

An important extension in practice is to integer programming, where some of the x_j's are required to take on integral values. The most common case in practice is where the integer x_j must be 0 or 1, representing decision choices such as to whether to switch from production of one product to another or whether to expand a warehouse to allow for larger throughput. Whereas linear programming solution times tend to be less than an hour, adding the constraint that some or all of the x_j's must be integral may cause the running time to be very long. *See* DECISION THEORY.

Early work on computer programs was done in the 1950s. Commercial computer codes implementing the simplex method have been used in industry since the mid-1960s. Efficient methods for handling the structures encountered have been developed. In particular, the matrices tend to be very sparse, that is, most (usually over 99%) of the a_{ij}'s are zeroes. In the 1980s, intense development in software was begun because of changed hardware and new algorithmic developments.

Following the early work on codes, the petroleum industry quickly became the major user of linear programming, and still is an important user, especially for blending models in petroleum refining. Commercial codes are used in industry and government for a variety of applications involving planning, scheduling, distribution, manufacturing, and so forth. In universities, linear programming is taught in most business schools, industrial engineering departments, and operations research departments, as well as some mathematics departments. The model is general enough to be useful in the physical and social sciences. The improved computational efficiency achieved in the 1980s has gone hand-in-hand with expanded applications, particularly in manufacturing, transportation, and finance. *See* OPERATIONS RESEARCH. [E.L.J.]

Linear system analysis The study of properties and behavior of a system using a body of mathematical techniques based on linear system theory. A system can be defined as a set or arrangement of things related in such a way as to form a whole. Linear system analysis is concerned with the study of equilibrium and change in dynamical systems, that is, in systems that contain variables that may change with time. These variables include system inputs (external causes of change or excitation), outputs (measurable results or effects of the behavior, response, or dynamics of the system), as well as variables describing internal states of the system. To perform the analysis, relationships between these variables are described by a set of equations known as the model. In order for linear system analysis to be applicable, the model must possess the linearity property: it must be a linear model. Linearity simplifies the analysis of systems significantly, and hence there is a large body of mathematical techniques and results, referred to as linear system theory, that can be used to study linear systems. *See* LINEARITY; SYSTEMS ENGINEERING.

Examples of systems studied include both natural (biological or environmental) systems and artificial or engineered systems, such as spacecraft, aircraft, and electronic circuits. Models describing such systems can be derived from the laws of physics or fitted empirically by using input and output data. The linearity property implies that the response of a system to the sum of several inputs is equal to the sum of its responses due to each of the individual inputs, and that the response of a system to an input multiplied by a scale factor is equal to the same scale factor times the response of the system to that input. Although most systems in reality are nonlinear, it is possible to study their behavior in a limited range of values of inputs and outputs around an operating point with the help of linear approximations. An electronic amplifier, for example, can be approximated by a linear model for analysis of response to small signals around an operating point defined by dc bias voltages. *See* AMPLIFIER. [H.K.E.]

A discrete-time system is one whose input and output responses evolve at discrete time instants rather than in continuous time. A discrete-time linear system is a discrete-time system that obeys the superposition property; that is, its response to a linear combination of two inputs is the same linear combination of the responses to the inputs applied separately. It is usually assumed that a discrete-time system is also a quantized system (not explicitly included in the definition), which means that the quantities, or signals, processed can take on only values from a finite set. In that case, a discrete-time system can be implemented by means of either finite-state processing components or a general-purpose or specialized signal-processing computer. One reason for the importance and increasing use of discrete-time (quantized) systems is the ease with which they can be realized and modified simply by programming a signal-processing computer. Other reasons are the great generality of functions that can be implemented, and the lower cost relative to implementation of continuous-time (or analog) processors for comparable signal-processing functions. Applications of discrete-time linear systems include control of a process, data manipulation, and signal processing such as filtering. [R.E.Z.]

Linear systems of equations Systems of mathematical equations of the form of system (1), where the a_{ij}, $i = 1, 2, \ldots, m$, $j = 1, 2, \ldots, n$, and the b_i, $i = 1, 2, \ldots, m$, are constants, or fixed numbers, and the x_i, $i = 1, 2, \ldots, n$ are called unknowns. System (1) is referred to as m linear equations in n unknowns. A solution of system (1) is a set of numbers $c_1, c_2, \ldots, c_n$ such that when x_1 is replaced by c_1, x_2 by $c_2, \ldots, x_n$ by c_n, every equation of system (1) becomes a true equality. The problem posed by such a system of equations is to find criteria for the existence of a solution and, when solutions exist, to obtain systematic methods for finding the solutions.

$$\begin{aligned} a_{11}x_1 + a_{12}x_2 + \cdots + a_{1n}x_n &= b_1 \\ a_{21}x_1 + a_{22}x_2 + \cdots + a_{2n}x_n &= b_2 \\ \cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots \\ a_{m1}x_1 + a_{m2}x_2 + \cdots + a_{mn}x_n &= b_m \end{aligned} \qquad (1)$$

Two linear systems of equations are equivalent if every solution of one of the systems is a solution of the other and vice versa.

If $m = n$ in system (1) and if the determinant $|A|$ of the matrix of the coefficients A, given by matrix (2), is not zero, then system (1) has a unique solution which can be obtained by Cramer's rule, which gives the values of the unknowns $x_1, x_2, \ldots, x_n$ as the ratio of two determinants. *See* Determinant.

$$A = \begin{pmatrix} a_{11} & a_{12} & \cdots & a_{1n} \\ a_{12} & a_{22} & \cdots & a_{2n} \\ \cdots & \cdots & \cdots & \cdots \\ a_{m1} & a_{m2} & \cdots & a_{mn} \end{pmatrix} \qquad (2)$$

Specifically, Cramer's rule gives

$$x_1 = \begin{vmatrix} b_1 & a_{12} & \cdots & a_{1n} \\ b_2 & a_{22} & \cdots & a_{2n} \\ \cdots & \cdots & \cdots & \cdots \\ b_n & a_{n2} & \cdots & a_{nn} \end{vmatrix} \Bigg/ |A|$$

$$x_2 = \begin{vmatrix} a_{11} & b_1 & a_{13} & \cdots & a_{1n} \\ a_{21} & b_2 & a_{23} & \cdots & a_{2n} \\ \cdots & \cdots & \cdots & \cdots & \cdots \\ a_{n1} & b_n & a_{n3} & \cdots & a_{nn} \end{vmatrix} \Bigg/ |A|$$

$$\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots$$

$$x_n = \begin{vmatrix} a_{11} & \cdots & a_{1n-1} & b_1 \\ a_{21} & \cdots & a_{2n-1} & b_2 \\ \cdots & \cdots & \cdots & \cdots \\ a_{n1} & \cdots & a_{nn-1} & b_n \end{vmatrix} \Bigg/ |A|$$

In every case the determinant in the denominator is $|A|$, and for the value of the unknown x_i, the determinant in the numerator is the determinant of the matrix obtained from A by replacing the ith column of A by $b_1, b_2, \ldots, b_n$. If $|A| = 0$ in this case of m equations in n unknowns, the system may either be inconsistent or it may have infinitely many solutions. *See* Equations, theory of; Polynomial systems of equations. [R.A.Be.]

Linearity A relationship between two or more quantities which can be expressed in terms of linear algebraic, differential, or integral equations. A system in which all quantities (or variables) can be described in terms of such equations is said to be a linear system. By definition, linear systems satisfy the principle of superposition. By this principle, the response of a linear system to multiple inputs is given simply by the sum of the responses due to each individual input. In addition, if all inputs are multiplied by a common constant factor, the resulting response is multiplied by the same factor. *See* Differential equation; Integral equation; Linear algebra.

As an example of a simple linear relationship, the voltage V across an ideal (ohmic) resistor is directly proportional to the current I through it, as given by the equation below, where R is the constant of proportionality. Here, the customary notation $V(I)$ is used to denote V as a function of I.

$$V(I) = IR$$

Linearity is a desirable characteristic of all systems where an output response is required to be a faithful reproduction (except for a constant scale factor) of one or more inputs. For example, electronic amplifiers used in measurement and signal transmission and reproduction systems are designed with linearity as a primary goal. Although physical systems are generally nonlinear to some degree, in practice the objective is to realize a good approximation to an ideal linear system by minimizing nonlinearities as far as possible. Any departure from linearity in these systems causes unwanted distortion of the original signal and results in a degraded and erroneous response. *See* Amplifier; Distortion (electronic circuits). [A.P.N.]

Lines of force Imaginary lines in fields of force whose tangents at any point give the direction of the field at that point and whose number through unit area perpendicular to the field represents the intensity of the field. The concept of lines of force is perhaps most common when dealing with electric or magnetic fields.

Electric lines of force are drawn to represent, or map, an electric field graphically in the space around a charged body. They are of great help in visualizing an electric field and in quantitative thinking about such a field. A magnetic field may also be represented by lines of force. Magnetic lines of force due to magnets originate on north poles and terminate on south poles, both inside and outside the magnet. *See* Electric field. [R.P.Wi.]

Linewidth A measure of the width of the band of frequencies of radiation emitted or absorbed in an atomic or molecular transition. One of the dominant sources of electromagnetic radiation of all frequencies is transitions between two energy levels of an atomic or molecular system. The frequency of the radiation is related to the difference in the energy of the two levels by the Bohr relation, Eq. (1), where ν_0, is the frequency of the radiation, h is Planck's constant, and E_1 and E_2 are the energies of the levels. This radiation is not monochromatic, but consists of a band of frequencies centered about ν_0 whose intensity $I(\nu)$ can be characterized by the linewidth. The linewidth is the full width at half height of the distribution function $I(\nu)$. The simplest case is for a transition from an excited state to the ground state for an atom or molecule at rest. For this case, the normalized distribution function is the lorentzian line profile given by Eq. (2). Here $\Delta\nu$ is the full width at half maximum (FWHM). The FWHM is

$$\nu_0 = (E_1 - E_2)/h \qquad (1)$$

$$I(\nu) = \frac{1}{\pi} \frac{\Delta\nu/2}{(\nu - \nu_0)^2 + (\Delta\nu/2)^2} \qquad (2)$$

related to the lifetime τ of the excited level through Eq. (3). This

$$(\Delta\nu)(\tau) = \frac{1}{2\pi} \qquad (3)$$

is a manifestation of the quantum-mechanical uncertainty principle, and the linewidth $\Delta\nu$ is referred to as the natural linewidth. *See* ENERGY LEVEL (QUANTUM MECHANICS); QUANTUM MECHANICS; UNCERTAINTY PRINCIPLE.

Another major source of line broadening for atomic and molecular transitions is the Doppler shift due to thermal motion. For most situations the Doppler width is greater than the natural linewidth. *See* DOPPLER EFFECT.

A third major source of line broadening is collisions of the radiating molecule with other molecules. This broadens the line, shifts the center of the line, and shortens the lifetime of the radiating state.

For radiating atoms in a liquid or solid the width is usually dominated by the strong interaction of the radiator with the surrounding molecules. The net result is a broad line profile with a complex structure. *See* BAND THEORY OF SOLIDS. [F.M.P.]

Linguistics The science, that is, the general and universal properties, of language. The middle of the twentieth century saw a shift in the principal direction of linguistic inquiry from one of data collection and classification to the formulation of a theory of generative grammar, which focuses on the biological basis for the acquisition and use of human language and the universal principles that constrain the class of all languages. Generative grammar distinguishes between the knowledge of language (linguistic competence), which is represented by mental grammar, and the production and comprehension of speech (linguistic performance).

If grammar is defined as the mental representation of linguistic knowledge, then a general theory of language is a theory of grammar. A grammar includes everything one knows about a language; its phonetics and phonology (the sounds and the sound system), its morphology (the structure of words), its lexicon (the words or vocabulary), its syntax (the structure of sentences and the constraints on well-formed sentences), and its semantics (the meaning of words and sentences). *See* PSYCHOACOUSTICS; SPEECH; SPEECH PERCEPTION.

Linguistics is not limited to grammatical theory. Descriptive linguistics analyzes the grammars of individual languages; anthropological linguistics, or ethnolinguistics, and sociolinguistics focus on languages in relation to culture, social class, race, and gender; dialectologists investigate how these factors fragment one language into many. In addition, sociolinguists and applied linguists examine language planning, literacy, bilingualism, and second-language acquisition. Computational linguistics encompasses automatic parsing, machine processing, and computer simulation of grammatical models for the generation and parsing of sentences. If viewed as a branch of artificial intelligence, computational linguistics has as its goal the modeling of human language as a cognitive system. A branch of linguistics concerned with the biological basis of language development is neurolinguistics. The form of language representation in the mind, that is, linguistic competence and the structure and components of the mental grammar, is the concern of theoretical linguistics. The branch of linguistics concerned with linguistic performance, that is, the production and comprehension of speech (or of sign language by the deaf), is called psycholinguistics. Psycholinguists also investigate how children acquire the complex grammar that underlies language use. *See* INFORMATION PROCESSING; PSYCHOLINGUISTICS. [V.A.F.]

Lingulida An order of inarticulated brachiopods consisting of a group of semisessile, suspension-feeding, marine, benthic, infaunal bivalves with representatives occurring throughout the Phanerozoic Era (from the Early Cambrian to the present). Most extant members of this group originated in the Ordovician Period, when the order achieved maximum diversity.

Shells are tongue shaped, equivalve, and slightly convex. The valves are separate and do not articulate about a hinge but possess a complex arrangement of muscles. Lingulids have a pair of anterior adductor muscles and one laterally placed posterior adductor muscle, two pairs of oblique muscles (three in *Lingula*), an elevator, and three pairs of minor muscles: the lophophore (tentacular feeding organ) protractors, retractors, and elevators. All extant members of this order have a relatively long, fleshy retractable pedicle and burrow in soft sediments.

Two superfamilies are recognized: Lingulacea, which have thin chitinophosphatic shell and no muscle platforms, and Trimerellacea, which have thick aragonite shells and muscle platforms. Important genera in this order include *Lingula*, "a living fossil" which appears to have changed little for 450 million years, and *Glottidia*. *See* BRACHIOPODA; INARTICULATA. [M.A.J.]

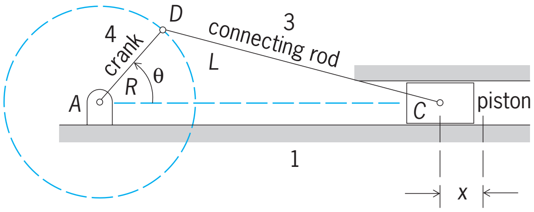
Link An element of a mechanical linkage. A link may be a straight bar or a disk, or it may have any other shape, simple or complex. It is assumed, for simple analysis, to be made of unyielding material; that is, its shape does not change. The frame, or fixed member, of a linkage is one of the links.

Two links of a kinematic chain meet in a joint, or pair, by which these links are held together. Just as each joint is a pair having two elements, one from each link, so a link in a kinematic chain is the rigid connector of two or more elements belonging to different pairs. *See* LINKAGE (MECHANISM); MECHANISM. [D.P.Ad.]

Linkage (genetics) Failure of two or more genes to recombine at random as a result of their location on the same chromosome pair. Among the haploid products of a cell which has gone through meiosis, two genes located in the same chromosome pair remain in their two original combinations of alleles ("parental") unless an odd number of exchanges of homologous segments occurred within the interval bounded by their loci. The incidence of exchanges of homologous segments at meiosis is roughly proportional to the length of the chromosome segment between two loci. The percentage of recombinants thus provides an estimate of this length and a basis for constructing gene maps on which linked loci are arranged in linear order and spaced out in proportion to the recombination percentages between them. *See* MEIOSIS. [G.Po.]

Linkage (mechanism) A set of rigid bodies, called links, joined together at pivots by means of pins or equivalent devices. A body is considered to be rigid if, for practical purposes, the distances between points on the body do not change. Linkages are used to transmit power and information. They may be employed to make a point on the linkage follow a prescribed curve, regardless of the input motions to the linkage. They are also used to produce angular or linear displacement. *See* LINK; MECHANISM.

If the links are bars the linkage is termed a bar linkage. A common form of bar linkage is one for which the bars are restricted to a given plane, such as a four-bar linkage. A commonly occurring variation of the four-bar linkage is the linkage used in reciprocating engines (see illustration). Slider *C* is the piston in a cylinder,



Slider crank mechanism.

link 3 is the connecting rod, and link 4 is the crank. (Link 1 is the fixed base, *A* and *D* are pivots, *R* is the length of the crank, *L* is the length of the connecting rod, and θ denotes the angle of the crank.) This mechanism transforms a linear into a circular motion, or vice versa. The straight slider in line with the crank center is equivalent to a pivot at the end of an infinitely long link. *See* FOUR-BAR LINKAGE; PANTOGRAPH; SLIDER CRANK MECHANISM. [R.O.]

Lipid One of a class of compounds which contains long-chain aliphatic hydrocarbons (cyclic or acyclic) and their derivatives, such as acids (fatty acids), alcohols, amines, amino alcohols, and aldehydes. The presence of the long aliphatic chain as the characteristic component of lipids confers distinct solubility properties on the simpler members of this class of naturally occurring compounds.

The lipids are generally classified into the following groups:

A. Simple lipids

1. Triglycerides or fats and oils are fatty acid esters of glycerol. Examples are lard, corn oil, cottonseed oil, and butter.
2. Waxes are fatty acid esters of long-chain alcohols. Examples are beeswax, spermaceti, and carnauba wax.
3. Steroids are lipids derived from partially or completely hydrogenated phenanthrene. Examples are cholesterol and ergosterol.

B. Complex lipids

1. Phosphatides or phospholipids are lipids which contain phosphorus and, in many instances, nitrogen. Examples are lecithin, cephalin, and phosphatidyl inositol.
2. Glycolipids are lipids which contain carbohydrate residues. Examples are sterol glycosides, cerebrosides, and plant phytoglycolipids.
3. Sphingolipids are lipids containing the long-chain amino alcohol sphingosine and its derivatives. Examples are sphingomyelins, ceramides, and cerebrosides.

Lipids are present in all living cells, but the proportion varies from tissue to tissue. The triglycerides accumulate in certain areas, such as adipose tissue in the human being and in the seeds of plants, where they represent a form of energy storage. The more complex lipids occur closely linked with protein in the membranes of cells and of subcellular particles. More active tissues generally have a higher complex lipid content; for example, the brain, liver, kidney, lung, and blood contain the highest concentration of phosphatides in the mammal. *See* FAT AND OIL; FAT AND OIL (FOOD); GLYCOLIPID ; SPHINGOLIPID; STEROID; TERPENE; TRIGLYCERIDE; VITAMIN; WAX, ANIMAL AND VEGETABLE. [R.H.G.]

Lipid metabolism The assimilation of dietary lipids and the synthesis and degradation of lipids; this article is restricted to mammals.

The principal dietary fat is triglyceride. This substance is not digested in the stomach and passes into the duodenum, where it causes the release of enterogastrone, a hormone which inhibits stomach motility. The amount of fat in the diet, therefore, regulates the rate at which enterogastrone is released into the intestinal tract. Fat, together with other partially digested foodstuffs, causes the release of hormones, secretin, pancreozymin, and cholecystokinin from the wall of the duodenum into the bloodstream.

Secretin causes the secretion of an alkaline pancreatic juice rich in bicarbonate ions, while pancreozymin causes secretion of pancreatic enzymes. One of these enzymes, important in the digestion of fat, is lipase. Cholecystokinin, which is a protein substance chemically inseparable from pancreozymin, stimulates the gallbladder to release bile into the duodenum. Bile is secreted by the liver and concentrated in the gallbladder and contains two bile salts, both derived from cholesterol: taurocholic and glycocholic acids. These act as detergents by emulsifying the triglycerides in the intestinal tract, thus making the fats more susceptible to attack by pancreatic lipase. In this reaction, which works best in the alkaline medium provided by the pancreatic juice, each triglyceride is split into three fatty acid chains, forming monoglycerides. The fatty acids pass across the membranes of the intestinal mucosal (lining) cells. Enzymes in the membranes split monoglyceride to glycerol and fatty acid, but triglycerides are reformed within the mucosal cells from glycerol and those fatty acids with a chain length greater than eight carbons: Short- and medium-chain fatty acids are absorbed directly into the bloodstream once they pass through the intestinal mucosa. *See* CHOLESTEROL; DIGESTIVE SYSTEM; GALLBLADDER; LIVER; PANCREAS; TRIGLYCERIDE.

Obesity is a condition in which excessive fat accumulates in the adipose tissue. One factor responsible for this condition is excessive caloric intake. In starvation, uncontrolled diabetes, and many generalized illnesses the opposite occurs and the adipose tissue becomes markedly depleted of lipid. *See* ADIPOSE TISSUE; DIABETES; LIPID; METABOLIC DISORDERS; OBESITY. [M.A.R.]

Lipoprotein Classes of conjugated proteins consisting of a protein combined with a lipid. The normal functioning of higher organisms requires movement of insoluble lipids, such as cholesterol, steroid hormones, bile, and triglycerides, between tissues. To accomplish this movement, lipids are incorporated into macromolecular complexes called lipoproteins.

All major types of lipoproteins share a general structure. The core of these spherical particles contains primarily cholesteryl ester and triglyceride. These insoluble molecules are surrounded by a coating of proteins and phospholipids that are amphipathic; that is, they have both polar and nonpolar regions. Lipoproteins vary by size and density. The largest lipoproteins, chylomicrons, are up to 500 nanometers in diameter, and since they contain primarily triglyceride they are so buoyant that they float in plasma. Very low density lipoproteins (VLDL) also primarily transport triglyceride. Low-density lipoproteins (LDL) and the smallest, most dense lipoproteins, high-density lipoproteins (HDL), transport cholesterol. The interactions of these particles with cell surface receptors and with metabolic enzymes are mediated by the protein components of the particles, termed apolipoproteins. *See* CHOLESTEROL; TRIGLYCERIDE.

Chylomicrons contain triglyceride (fat) from the diet. In addition, they carry fat-soluble vitamins, such as vitamin A and E, into the circulation. Chylomicrons are produced in the intestine, enter the body via the lymphatic system, and then enter the bloodstream.

Very low density lipoproteins are made in the liver and contain triglyceride that is synthesized either from excess carbohydrate sources of calories or from fatty acids that enter the liver and are reassembled into triglyceride. Lipoprotein lipase (LpL) is an enzyme found on the surface of blood vessels that is responsible for the breakdown of triglyceride in lipoproteins. The partially degraded lipoproteins are termed remnants. They are ultimately removed from the circulation by the liver.

Low-density lipoproteins result after triglyceride is removed from very low density lipoproteins. This leaves a smaller, denser particle that primarily contains cholesteryl ester as its core lipid and a single protein called apoB. Cells throughout the body contain an LDL receptor that recognizes apoB. This allows the uptake of low-density lipoproteins into cells, supplying them with cholesterol. When sufficient low-density lipoproteins and cholesterol are available, cells use them in preference to synthesizing new cholesterol from precursors. In contrast, high-density lipoproteins both deliver and remove cholesterol from tissues.

Blood levels of lipoproteins are major factors regulating risk for development of coronary artery atherosclerosis. Via unknown mechanisms, low-density lipoproteins and remnant lipoproteins infiltrate and then become attached to extracellular matrix molecules within the artery. Some of the lipoproteins are internalized by macrophages and smooth muscle cells. This might first require chemical modification such as oxidation of the lipids. The resulting pathological findings are deposition of cholesterol in cells and matrix within the vessel wall, leading to a decrease in the diameter of the artery.

In contrast, high-density lipoproteins appear to prevent atherosclerosis formation. The reasons are not entirely understood. Most likely, high-density lipoproteins remove excess cholesterol that accumulates in the artery, or prevent the oxidation of low-density lipoproteins. *See* ARTERIOSCLEROSIS. [I.J.Go.]

Liposomes Aqueous compartments enclosed by lipid bilayer membranes; liposomes are also known as lipid vesicles. Phospholipid molecules consist of an elongated nonpolar (hydrophobic) structure with a polar (hydrophilic) structure at one end. When dispersed in water, they spontaneously form bilayer membranes, also called lamellae, which are composed of two monolayer layer sheets of lipid molecules with their nonpolar (hydrophobic) surfaces facing each other and their polar (hydrophilic) surfaces facing the aqueous medium. The membranes enclose a portion of the aqueous phase much like the cell membrane which encloses the cell; in fact, the bilayer membrane is essentially a cell membrane without its protein components.

Liposomes are often used to study the characteristics of the lipid bilayer. Properties of liposomes have been characterized by a variety of techniques: molecular organization by x-ray diffraction, nuclear magnetic resonance, electron paramagnetic resonance, and Raman spectroscopy; melting behavior (that is, crystal to liquid-crystal transition) by calorimetry; net electric surface charge by microelectrophoresis; size by light scattering and electron microscopy. *See* LIPID.

Liposomes have numerous uses as biochemical and biophysical tools: (1) as vehicles for the delivery of both water- and of oil-soluble materials to the cell; (2) as immunological adjuvants; (3) as substrates for the study of membrane properties such as rotational or translational diffusion in the plane of the membrane; and (4) as intermediates in the construction of bilayers large enough for the study of electrical properties of membranes. *See* CELL MEMBRANES. [R.C.MacD.; R.I.MacD.]

Liquefaction of gases The process of refrigerating a gas to a temperature below its critical temperature so that liquid can be formed at some suitable pressure, also below the critical pressure.

Gas liquefaction is a special case of gas refrigeration. The gas is first compressed to an elevated pressure in an ambient-temperature compressor. This high-pressure gas is passed through a countercurrent heat exchanger to a throttling valve or expansion engine. Upon expanding to the lower pressure, cooling may take place, and some liquid may be formed. The cool, low-pressure gas returns to the compressor inlet to repeat the cycle. The purpose of the countercurrent heat exchanger is to warm the low-pressure gas prior to recompression, and simultaneously to cool the high-pressure gas to the lowest temperature possible prior to expansion. Both refrigerators and liquefiers operate on this same basic principle. *See* COMPRESSOR; CRITICAL PHENOMENA; GAS; HEAT EXCHANGER; REFRIGERATION.

An important distinction between refrigerators and liquefiers is that in a continuous refrigeration process, there is no accumulation of refrigerant in any part of the system. This contrasts with a gas-liquefying system, where liquid accumulates and is withdrawn. Thus, in a liquefying system, the total mass of gas that is warmed in the countercurrent heat exchanger is less than the gas to be cooled by the amount that is liquefied, creating an unbalanced flow in the heat exchanger. In a refrigerator, the warm and cool gas flows are equal in the heat exchanger. This results in balanced flow condition. The thermodynamic principles of refrigeration and liquefaction are identical. However, the analysis and design of the two systems are quite different due to the condition of balanced flow in the refrigerator and unbalanced flow in liquefier systems.

The prerequisite refrigeration for gas liquefaction is accomplished in a thermodynamic process when the process gas absorbs heat at temperatures below that of the environment. A process for producing refrigeration at liquefied gas temperatures usually involves equipment at ambient temperature in which the gas is compressed and heat is rejected to a coolant. During the ambient-temperature compression process, the enthalpy and entropy, but usually not the temperature of the gas, are decreased. The reduction in temperature of the gas is usually accomplished by heat exchange between the cooling and warming gas streams followed by an expansion of the high-pressure stream. This expansion may take place either through a throttling device (isenthalpic expansion) where there is a reduction in temperature only (when the Joule-Thomson coefficient is positive) or in a work-producing device (isentropic expansion) where both temperature and enthalpy are decreased. *See* ENTHALPY; ENTROPY; ISENTROPIC PROCESS; THERMODYNAMIC PRINCIPLES; THERMODYNAMIC PROCESSES. [T.M.F.]

Liquefied natural gas (LNG) A product of natural gas which consists primarily of methane. Its properties are those of liquid methane, slightly modified by minor constituents. One property which differentiates liquefied natural gas (LNG) from liquefied petroleum gas (LPG) is the low critical temperature, about −100°F (−73°C). This means that natural gas cannot be liquefied at ordinary temperatures simply by increasing the pressure, as is the case with LPG; instead, natural gas must be cooled to cryogenic temperatures to be liquefied and must be well insulated to be held in the liquid state. *See* LIQUEFACTION OF GASES; LIQUEFIED PETROLEUM GAS (LPG). [A.W.F.]

Liquefied petroleum gas (LPG) A product of petroleum gases, principally propane and butane, which must be stored under pressure to keep it in a liquid state. At atmospheric pressure and above freezing temperature, these substances would be gases. Large quantifies of propane and butane are now available from the gas and petroleum industries. These are often employed as fuel for tractors, trucks, and buses and mainly as a domestic fuel in remote areas. Because of the low boiling point (−47.2 to 32°F or −44 to 0°C) and high vapor pressure of these gases, their handling as liquids in pressure cylinders is necessary. Owing to demand from industry for butane derivations, LPG sold as fuel is made up largely of propane.

LPG has a high octane rating, making it useful in engines having compression ratios above 10:1. Another factor of importance in internal combustion engines is that LPG leaves little or no engine deposit in the cylinders when it bums. *See* INTERNAL COMBUSTION ENGINE; PETROLEUM PRODUCTS. [M.Sou.]

Liquid A state of matter intermediate between that of crystalline solids and gases. Macroscopically, liquids are distinguished from crystalline solids in their capacity to flow under the action of extremely small shear stresses and to conform to the shape of a confining vessel. Liquids differ from gases in possessing a free surface and in lacking the capacity to expand without limit. On the scale of molecular dimensions liquids lack the long-range order that characterizes the crystalline state, but nevertheless they possess a degree of structural regularity that extends over distances of a few molecular diameters. In this respect, liquids are wholly unlike gases, whose molecular organization is completely random.

Liquids possess important transport properties, notably their capacity to transmit heat (thermal conductivity), to transfer momentum under shear stresses (viscosity), and to attain a state of homogeneous composition when mixed with other miscible liquids (diffusion). These nonequilibrium properties of liquids are well understood in macroscopic terms arid are exploited in large-scale engineering and chemical-process operations. *See* GAS. [N.H.N.]

Liquid chromatography A method of chemical separation that involves passage of a liquid phase through a solid phase and relies on subtle chemical interactions to resolve complex mixtures into pure compounds. A small amount of the sample to be separated is injected onto the top of a column that is densely packed with spherical particles of small diameter, that is, the stationary phase. A liquid solvent, the mobile phase, flows through the column continuously to carry the sample from the top to the bottom of the column. During passage through the column, the components of the sample are transferred back and forth continuously between the two phases, and small thermodynamic differences in the chemical interactions of the various sample components with the mobile and stationary phases slow the passage of some solutes more than others and lead to their separation. The technique can be performed on very small scales for chemical analysis, dealing with micrograms or even nanograms of sample, or it can be performed on an industrial scale for purification of commercial products. The technique has great resolving power.

In the late 1960s, workers realized that to achieve maximum performance they needed to make the stationary-phase particles very small. As the stationary-phase particles became smaller, they packed too densely to permit gravity-driven flow of the mobile phase. It was necessary to force the mobile phase through the column under high pressure, and the technique was named high-pressure liquid chromatography (HPLC). The meaning of the acronym has been changed to high-performance liquid chromatography, for the elegant separations that are possible. Typical stationary-phase particles are monodisperse, macroporous silica particles either 3 or 5 micrometers in diameter, and the column lengths for analytical scale separations are on the order of 2–10 in. (5–25 cm), with inside diameters of about 0.16 in. (4 mm). The columns are made of stainless steel, which is relatively inert chemically and able to withstand the high pressures applied to the top of the column. Since these columns require pressures of a few hundred to a few thousand pounds per square inch, depending on the mobile-phase flow velocity desired, a high-pressure metering pump is an integral part of a modern liquid chromatograph. Most instruments include a means of performing gradient elution, that is, making a continuous change in the composition of the liquid mobile phase during the separation process. Gradient elution can be performed by using a separate pump for each solvent and changing the relative proportions during the separation, or by using a proportioning valve between the solvent reservoirs and the pump. An injector valve is used to introduce a small volume of sample, typically 5–100 microliters, onto the top of the column without interrupting the mobile-phase flow. These valves can be operated manually, or they can be programmed to perform injections from a tray of samples for routine analyses. After the sample traverses the column, a flow-through detector is employed to generate the chromatogram, which is the visual representation of the separation. Detectors can provide both quantitative and qualitative information about the separated components. Temperature control of the column and detector is important; they are generally operated at or near room temperature, and temperature fluctuations can adversely affect the reproducibility of the separation and detection steps.

Liquid chromatography very much depends on the highly selective chemical interactions that occur in both the mobile and stationary phases. Rapid separations have become possible for compounds whose difference in free energy of transfer between the two phases is only a few calories per mole. Columns exhibiting virtually every type of possible selectivity exist, including selectivity by shape, charge, size, and optical activity. Additional selectivity can be generated through manipulations of the mobile phase; additives that interact with the solute in the mobile phase can create unique selectivities in columns that do not normally show that type of selectivity.

In addition to facilitating chemical analysis, liquid chromatography can be used to obtain physicochemical information. Diffusion coefficients, kinetic parameters, critical micelle concentrations of surfactants, and other information have been estimated from chromatographic data. The most common application is the estimation of hydrophobic parameters, especially as models of biological or environmental partitioning processes (most frequently, of octanol-water partitioning). Bioavailability, bioaccumulation, soil sorption, and various other factors are estimated based on linear free-energy relationships. *See* CHROMATOGRAPHY. [J.G.D.]

Liquid crystals A state of matter that mixes the properties of both the liquid and solid states. Liquid crystals may be described as condensed fluid states with spontaneous anisotropy. They are categorized in two ways: thermotropic liquid crystals, prepared by heating the substance, and lyotropic liquid crystals, prepared by mixing two or more components, one of which is rather polar in character, for example, water. Thermotropic liquid crystals are divided, according to structural characteristics, into two classes, nematic and smectic.

Nematic structure. Nematic liquid crystals are subdivided into the ordinary nematic and the chiral-nematic (or cholesteric). The molecules in the ordinary nematic structure maintain a parallel or nearly parallel arrangement to each other along the long molecular axes (illus. *a*). They are mobile in three directions and can rotate about one axis. This structure is one-dimensional.

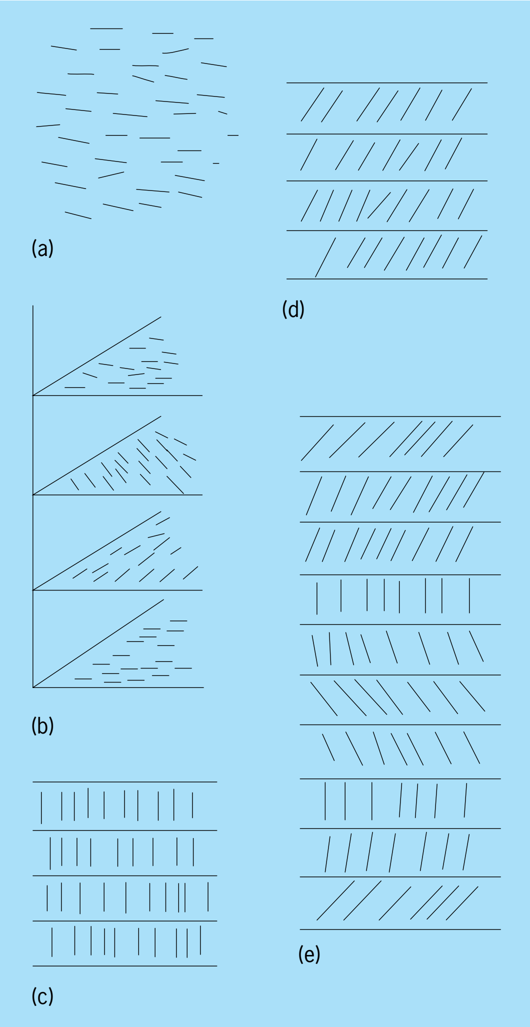
When the nematic structure is heated, it is generally transformed into the isotropic liquid where the completely disordered motion of the molecules produces a phase in which all directions are equivalent. The nematic structure is the highest-temperature mesophase in thermotropic liquid crystals. The energy required to deform a nematic liquid crystal is so small that even the slightest perturbation caused by a dust particle can distort the structure considerably.

In the chiral-nematic structure (illus. *b*), the direction of the long axis of the molecule in a given layer is slightly displaced from the direction of the molecular axes of the molecules in an adjacent layer. If a twist is applied to this molecular packing, a helical structure is formed. The helix has a pitch that is temperature-sensitive. The helical structure serves as a diffraction grating for visible light.

Smectic structure. The term smectic includes all thermotropic liquid crystals that are not nematics. In the smectic phase, not only is the small amount of orientational order of nematic liquid crystals present, but there is also a small amount of positional order. In most smectic structures, the molecules are free to bounce around randomly; but they tend to point along a specific direction and arrange themselves in layers, either in neat rows or randomly distributed. The molecules can move in two directions in the plane and rotate about one axis.

Smectic liquid crystals may have structured or unstructured strata. Structured smectic liquid crystals have long-range order in the arrangement of molecules in layers to form a regular two-dimensional lattice. The most common of the structured liquid crystals is smectic B. Molecular layers are in well-defined order, and the arrangement of the molecules within the strata is also well ordered. The long axes of the molecules lie perpendicular to the plane of the layers. In the smectic A (illus. *c*) structure, molecules are also packed in strata, but the molecules in a stratum are randomly arranged. The long axes of the molecules in the smectic A structure lie perpendicular to the plane of the layers. Molecular packing in a smectic C (illus. *d*) is the same as that in smectic A, except the molecules in the stratum are tilted at an angle to the plane of the stratum.

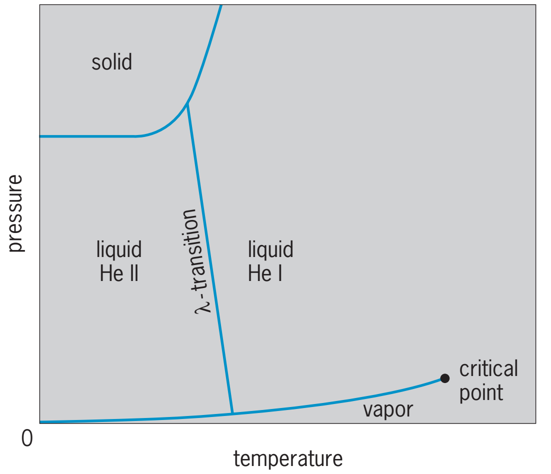
Applications. Liquid crystals are a state of matter that combines a kind of long-range order (in the sense of a solid) with the ability to form droplets and to pour (in the sense of waterlike



Molecular arrangement in liquid crystals. (*a*) Nematic. (*b*) Chiral-nematic. (*c*) Smectic A. (*d*) Smectic C. (*e*) Smectic C* ($S_c{}^+$). (*After R. Bline, Solid and liquid crystalline ferroelectrics and antiferroelectrics, Condensed Matter News 1(1):17–23, 1991*)

liquids). They also exhibit properties of their own such as the ability to form monocrystals with the application of a normal magnetic or electric field; an optical activity of a magnitude without parallel in either solids or liquids; and a temperature sensitivity that results in a color change in certain liquid crystals. As such, liquid crystals have many applications. They are used as displays in digital wristwatches, calculators, and panel meters. They can be used to record, store, and display images which can be projected onto a large screen. Direct and active-matrix liquid-crystal displays (LCDs) are used in several areas from laptop computers to communication equipment such as television teleconferencing systems, portable and high-definition television (HDTV), and video games. [G.H.B.; J.W.D.; D.Fi.]

Liquid helium Helium boils at a substantially lower temperature, 4.2 K (−452°F or −269°C), than any other substance; and below 2.172 K (−455.76°F) the liquid exhibits the extraordinary properties of superfluidity, notably the ability to flow through narrow channels with complete absence of friction. In addition to the common isotope of atomic weight 4, helium has a rare isotope of atomic weight 3 with a normal boiling point of 3.2 K (−454°F) and a superfluid transition at a very much lower temperature near 0.001 K. Both forms of helium remain in a liquid state at absolute zero. All of these characteristics are due to the weakness of the attractive force between two helium atoms and to the small atomic mass, which according to the laws of quantum mechanics makes the atoms difficult to localize.

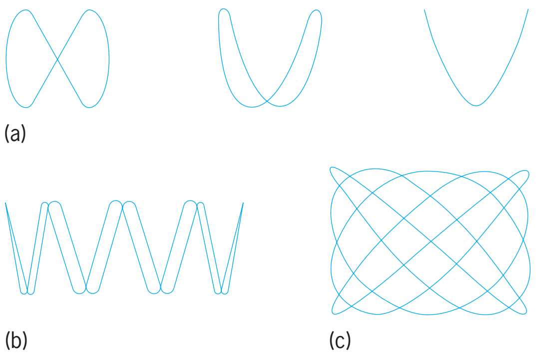


Phase diagram for ^{4}He. The critical point is at $T_c = 5.20$ K (−450.3°F), $P_c = 229$ kPa (2.26 atm or 33.2 lb/in.^{2}).

At 4.2 K (−452°F) liquid ^{4}He is colorless and of low refractive index ($n = 1.024$), with a density of 0.125 g/cm^3 (0.125 times that of water). The latent heat of vaporization, 5 cal/g (21 J/g), is very small, and so care must be taken to reduce the heat input by conduction and radiation into the storage container. The classical container consists of two vacuum-insulated vessels of silvered glass (Dewar flask) or metal, with the inner vessel containing the liquid helium immersed in a larger outer vessel filled with liquid nitrogen. Modern superinsulated Dewars are able to dispense with the liquid nitrogen.

The phase diagram of ^{4}He (see illustration) shows several remarkable characteristics. Helium remains a liquid down to absolute zero unless a pressure greater than 2.53 megapascals (25.0 atm or 367 lb/in.^{2}) is applied. A more subtle feature is a transition between two different liquid phases. This λ-transition is so named because the specific heat has a singularity resembling the Greek letter lambda. There is no latent heat; such a transition is called second-order. The high-temperature liquid phase, called helium I, is a rather ordinary liquid. The λ-transition at 2.172 K or −455.76°F (at vapor pressure) marks the onset of superfluidity, which is the characteristic property of the low-temperature phase, helium II. *See* HELIUM; SUPERFLUIDITY. [B.S.S.]

Lissajous figures Plane curves traced by a point which executes two independent harmonic motions in perpendicular



Typical Lissajous figures for ratios of vertical frequency to horizontal frequency. (*a*) 2:1, with various phase relations. (*b*) 8:1. (*c*) 5:4. (*After F. E. Terman, Radio Engineers' Handbook, McGraw-Hill, 1943*)

directions, the frequencies of the motion being in the ratio of two integers. Such figures are widely used in frequency and phase measurements (see illustration). *See* Harmonic motion.

The cathode-ray oscilloscope furnishes the most important and practical means for the generation of the figures. The x-deflection plates of the tube are supplied with one alternating voltage, and the y-deflection plates with another. If the frequencies are incommensurable, the figure is not a closed curve and, except for very low frequencies, will appear as a patch of light because of the persistence of the screen. On the other hand, if the frequencies are commensurable, the figure is closed and strictly periodic; it is a true Lissajous figure, stationary on the screen and, if the persistence is sufficient, visible continuously as a complete pattern. *See* Frequency measurement; Oscilloscope; Phase-angle measurement. [M.Gr.]

Lissamphibia The subclass of Amphibia including all living amphibians (frogs, toads, salamanders, and apodans). The other two subclasses are the Labyrinthodontia and the Lepospondyli. *See* Labyrinthodontia; Lepospondyli.

Living amphibians are grouped together by possession of a unique series of characters, the most important of which are (1) pedicellate teeth, consisting of two segments, a crown and a pedicel; (2) an operculum-plectrum complex of the middle ear; (3) the papilla amphibiorum, a special sensory area of the inner ear; (4) green rods in the retina of the eye; (5) similar skin glands; and (6) a highly vascular skin used in respiration (cutaneous respiration). *See* Amphibia; Anura; Urodela. [R.E.]

Listeriosis An infectious disease of humans and animals caused by the bacteria *Listeria monocytogenes* and *L. ivanovii*. Both humans and animals can be carriers, which excrete the bacterium in feces. Sheep, goats, and cattle can excrete the bacteria in milk, without clinical symptoms of mastitis. The most important pathway of infection is probably through food. *Listeria monocytogenes* has frequently been isolated from grass silage (fermented fodder), especially from silage of inferior quality, which is an important source of infection in ruminants. Relatively few animals develop clinical disease, but a high proportion can be latent carriers. Humans most likely ingest the bacteria with contaminated food, such as meat and meat products, raw milk and milk products, and unwashed vegetables. *See* Food microbiology.

Encephalitis is the most common form of disease in ruminants, and septicemia with involvement of several organs, including the pregnant uterus, occurs most commonly in monogastric animals, including very young sheep, goats, and calves.

Most human cases are sporadic, but food-borne epidemics occur. Abortions, perinatal disease, and disease in immunosuppressed individuals are most common. Perinatal disease is dominated by septicemia, widespread microscopic abscesses, and meningitis. In adults, meningitis is by far the most common manifestation, but in immunosuppressed individuals encephalitis occurs, possibly with a pathogenesis similar to encephalitis in ruminants.

Clinical diagnosis is based on symptoms, on isolation of *L. monocytogenes*, and on histopathological examination of affected tissue, especially brain tissue. *See* Medical bacteriology. [H.Gro.]

Lithium A chemical element, Li, atomic number 3, and atomic weight 6.939. Lithium heads the alkali metal family in the periodic table. In nature it is a mixture of the isotopes ^{6}Li and ^{7}Li. Lithium, the lightest solid element, is a soft, low-melting, reactive metal. In many physical and chemical properties it resembles the alkaline-earth metals as much as, or more than, it does the alkali metals. *See* Alkaline-earth metals; Periodic table.

The major industrial use of lithium is in the form of lithium stearate as a thickener for lubricating greases. Other important uses of lithium compounds are in ceramics, specifically in porcelain enamel formulation; as an additive to give longer life and higher output in alkaline storage batteries; and in welding and brazing fluxes.

Lithium is a moderately abundant element and is present in the Earth's crust to the extent of 65 parts per million (ppm). This places lithium a little below nickel, copper, and tungsten, and a little above cerium and tin in abundance.

Noteworthy among lithium's physical properties are the high specific heat (heat capacity), large temperature range of the liquid phase, high thermal conductivity, low viscosity, and very low density. Lithium metal is soluble in liquid ammonia and is slightly soluble in the lower aliphatic amines, such as ethylamine. It is insoluble in hydrocarbons.

Lithium undergoes a large number of reactions with both organic, and inorganic, reagents. It reacts with oxygen to form the monoxide, Li_2O, and the peroxide, Li_2O_2. Lithium is the only alkali metal that reacts with nitrogen at room temperature to form a nitride, Li_3N, which is black. Lithium reacts readily with hydrogen at about 930°F (500°C) to form lithium hydride, LiH. The reaction of lithium metal with water is exceedingly vigorous. Lithium reacts directly with carbon to form the carbide, Li_2C_2. Lithium combines readily with the halogens, forming halides with the emission of light. While lithium does not react with paraffin hydrocarbons, it does undergo addition reactions with arylated alkenes and with dienes. Lithium also reacts with acetylenic compounds, forming lithium acetylides, which are important in the synthesis of vitamin A.

The most important lithium compound is lithium hydroxide. It is a white powder, and the material of commerce is actually lithium hydroxide monohydrate, $LiOH \cdot H_2O$. Lithium carbonate, $LiCO_3$, finds application in the ceramic industries and in medicine as an antidepressant. Both lithium halides, lithium chloride and lithium bromide, form concentrated brines with ability to absorb moisture over a wide temperature range; these brines are used in commercial air conditioning systems. [M.Si.]

Lithosphere The rigid or mechanically strong outer layer of the Earth that can support stress. The lithosphere is divided into 12 major plates, the boundaries of which are zones of intense activity that produce many of the large-scale geological features that characterize the Earth. These plates move as coherent units with velocities of up to several centimeters per year, and their relative movement and interaction form the foundation for the theory of plate tectonics.

The lithosphere comprises the crust (either continental or oceanic) and a portion of the upper mantle that together overlie a zone of relative weakness termed the asthenosphere. The boundary between the crust and the mantle is known as the Mohorovičić discontinuity (Moho), and is compositional in origin—that is, the crust and mantle are distinguished by fundamental differences in rock chemistry. In contrast, the boundary between the lithosphere and the asthenosphere represents an isotherm that separates a conductively cooling lithosphere from a quasi-isothermal convecting asthenosphere. The asthenosphere differs from the overlying lithosphere principally in its ability to flow on geological time scales. These differences arise from the fact that temperature (and thus the fluid or flow properties of rocks) increases as a function of depth in the Earth. Whereas the lithosphere tends to be resistant to deformation, the asthenosphere deforms by flowing. The lithosphere is either oceanic or continental, each type being fundamentally different in terms of the formation and composition of the rocks that constitute the crust and upper mantle. While the most common definition of the lithosphere is in terms of its temperature structure, there exist a whole range of alternative definitions that consider the seismic, mechanical, rheological, and chemical characteristics of the crust and mantle. *See* Asthenosphere; Earth crust; Moho (Mohorovičić discontinuity); Plate tectonics.

The chemical lithosphere is defined as a chemical boundary layer between the surface of the Earth and the asthenosphere that cools by conduction and contains both the material differentiated or extracted from the mantle (for example, oceanic and continental crust) and mantle material modified by various degrees of depletion. [G.D.K.]

Litopterna Hoofed herbivores confined to the Cenozoic of South America. The order was well represented from the Paleocene to the Pleistocene, and apparently arose on that continent from a condylarth ancestry. By later Paleocene time two main lines of descent were clearly demarcated. The Proterotheriidae displayed a remarkable evolutionary convergence with the horses in their dentition and in reduction of the lateral digits of their feet. In one group the foot was reduced to a single median toe by early Miocene time. The members of the Macraucheniidae were proportioned much as in the camels and by late Tertiary time had similarly lost the vertebral arterial canal of the cervical vertebrae. *See* MAMMALIA. [R.H.T.]

Liver A large gland found in all vertebrates. It consists of a continuous parenchymal mass arranged to form a system of walls through which venous blood emanating from the gut must pass. This strategic localization between nutrient-laden capillary beds and the general circulation is associated with hepatic regulation of metabolite levels in the blood through storage and mobilization mechanisms controlled by liver enzymes.

Function. The large size of the liver is matched by its functional complexity and involvement in a diverse array of regulatory mechanisms. The liver plays a key role in assuring carbohydrate homeostasis (dynamic steady-state conditions) by removing simple sugars from the general circulation after ingestion of food and storing them as glycogen. In the intervals between ingestion of food, liver glycogen is broken down. This process tends to maintain blood sugar levels between 80 and 100 mg per 100 ml of blood. Under conditions of prolonged fast, where glycogen stores are exhausted, the liver is capable of converting noncarbohydrate metabolites such as amino acids and fats into glucose to maintain blood sugar levels. The complex steps involved in maintaining carbohydrate metabolism are subject to endocrine control, with the liver serving as a particularly sensitive target organ of hormone regulators such as insulin. *See* CARBOHYDRATE METABOLISM; GLUCOSE; GLYCOGEN; INSULIN.

The liver is key in the interconversion of many metabolites. It is a major site of production of fatty acids, triglycerides, phospholipids, ketone bodies, and cholesterol. Steroid hormones are degraded in the liver. *See* CHOLESTEROL; KETONE; LIPID; STEROID.

The liver is the sole source of such necessary constituents of the blood as fibrinogen, serum albumin, and cholinesterase. In the embryonic stage of most vertebrates the liver serves as the major manufacturing site of erythrocytes, a process known as erythropoiesis. The liver also removes toxins from the systemic circulation and degrades them, as well as excess hormones. Particulate material may be removed through a phagocytic action of specialized cells (Kupffer cells) lining the lumen of the hepatic "capillary spaces," or sinusoids. In addition to the products which the liver delivers directly to the general circulation (endocrine function), it secretes bile through a duct system which, involving the gallbladder as a storage chamber, eventually passes into the duodenum (exocrine function). Bile functions as an emulsifier of fats to facilitate their digestion by fat-splitting lipases, and may also activate the lipase directly. *See* GALLBLADDER.

Anatomy. The human liver is a massive wedge-shaped organ divided into a large right lobe and a smaller left lobe. Its anterior surface underlies the diaphragm. The upper portion of the liver is partially covered ventrally by the lungs, whereas the lower portion overhangs the stomach and intestine. The entire liver is covered by Glisson's capsule, an adherent membranous sheet of collagenous and elastic fibers.

Venous blood from the intestine, and to a lesser extent from spleen and stomach, converges upon a short broad vessel, called the hepatic portal vein, which enters the liver through a depression in the dorsocaudal surface termed the porta hepatis. There the hepatic portal vein divides into a short right branch and a longer left branch. These vessels then ramify into the small branches which actually penetrate the functional parenchymal mass as the inner tubes of the portal canals.

The hepatic artery also enters at the porta hepatis and ramifies into smaller branches, which flank the portal venules within the portal canals. The branches of the portal vein and hepatic artery then empty into sinusoids, which are major regions of hepatovascular exchange. They communicate with small branches of the hepatic veins and, through the hepatic vein, the blood is returned to the heart by way of the vena cava.

The tiny bile canaliculi, which lie between grooves in adjacent parenchymal cells, communicate with tiny intralobular bile ducts. These intralobular bile ducts empty into increasingly larger interlobular bile ducts which lie within the portal canals and make up the third element of the so-called portal triad. [G.H.F.]

Liver disorders A heterogeneous group of diseases that are of particular importance because of the many essential functions of the liver. Persons with liver disorders can develop a number of different signs and symptoms. One common symptom is fatigue, although some people are entirely asymptomatic. A striking sign of liver disease is jaundice (yellowing of the skin and eyes) due to abnormal production or transport of bile. The presence of liver disease can be confirmed by performing liver function tests on the blood. A needle biopsy can help determine the type of liver disorder and the extent of organ damage. *See* JAUNDICE; LIVER.

Fatty metamorphosis is a common condition characterized by accumulation of fat (lipid) within the liver cells. In the United States the most common cause of a fatty liver is excessive alcohol intake. In the developing areas of the world, malnutrition is the major cause of a fatty liver. Some obese persons also develop a fatty liver. *See* ALCOHOLISM; MALNUTRITION; OBESITY.

Hepatitis, an inflammation of the liver, has a variety of causes. The specific type of hepatitis present is usually determined by studies of serum, which identify the type of antibody directed against a component of the causative virus, or by liver biopsy. *See* HEPATITIS.

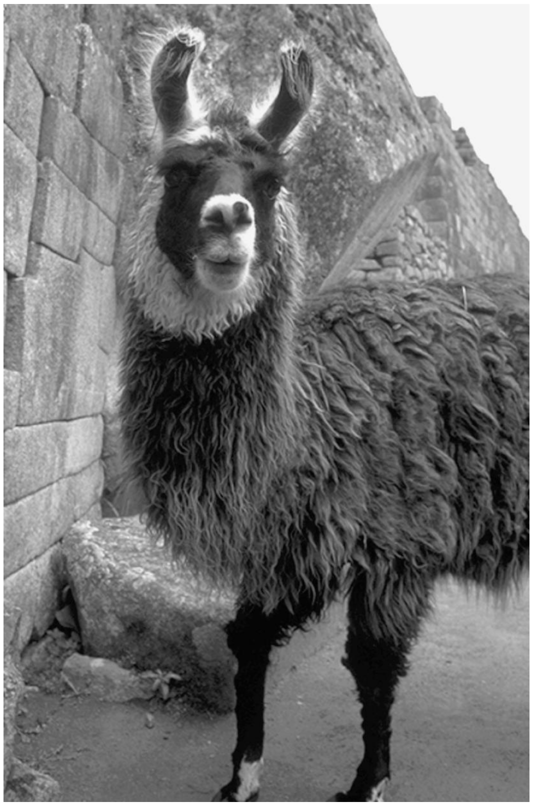
Cirrhosis is a disease in the liver characterized by scarring, which produces a marked nodularity of the liver. Cirrhosis has a variety of causes, although in the United States the most common by far is excessive alcohol intake. Cirrhosis may also result from almost any type of injury to the liver that does not heal but instead leads to progressive inflammation and scarring. *See* CIRRHOSIS.

Most neoplasms in the liver are malignant and are metastatic from a primary site. Usually their cause is unknown, but in the United States primary malignant tumors are most frequently associated with cirrhosis. Primary liver cancers are difficult to treat because they usually grow rapidly and involve other structures, preventing total surgical removal. *See* CANCER (MEDICINE); ONCOLOGY.

Reye's syndrome is a liver disorder that affects primarily infants and young children; it usually occurs during or after an episode of viral influenza and it has been causally related to the ingestion of aspirin for treatment of influenza. Wilson's disease, also called hepatolenticular degeneration, is a rare inherited disorder of copper metabolism in which cirrhosis of the liver is associated with degeneration of certain regions of the brain. Hemochromatosis, another hereditary disease, is marked by excessive deposition of iron in the liver because of faulty iron metabolism. It causes cirrhosis and is frequently associated with primary cancer of the liver. In alpha-1 antitrypsin deficiency, a disease characterized by an absence of an antienzyme in the blood, the liver can show extensive fibrosis and even cirrhosis. [S.P.H.]

Living fossils Living species very closely resembling fossil relatives in most anatomical details. The term is a relative one and, applied loosely, could embrace nearly all extant animals and plants. In its more restricted usage, the term applies to living species with four additional characteristics: (1) truly close anatomical similarity to (2) an ancient fossil species—generally at least 100,000,000 years old; (3) living members of the group are represented by only a single or at best a few species, which are (4) often found in a very limited geographic area. Examples are horseshoe crabs, ginkgo trees, and coelacanth fish. [N.E.]

Llama A member of the camel family (Camelidae) found only in South America. The llama is an artiodactyl, or even-toed ungulate, with two toes on each foot. The upper lip is cleft and prehensile. The animal has a long neck, and attains a maximum length of less than 8 ft (2.4 m) and a maximum weight of nearly 300 lb (135 kg; see illustration). A single young is born after a gestation period of about 11 months. The maximum life-span is about 20 years. Like other members of the family, the llama is herbivorous. It has 36 teeth with the dental formula I 1/3 C 1/1 Pm 3/3 M 3/3. These animals lack a gallbladder. Many interesting crosses have occurred among the different breeds in South America. *See* Artiodactyla.



The llama of South America.

Lama glama has been domesticated since the Inca civilization by the Peruvian Indians, who still keep large herds. While the fur provides material for rugs, rope, and cloth, the main use of this animal is as a beast of burden, especially in mining areas. Another race is the alpaca, which is more restricted in its distribution and is specialized in wool production.

There are two species of wild llama, the guanaco or huanaco (*L. guanicoe*) and the vicuña (*L. vicugna*). The most widespread is the guanaco, which stands about 4 ft (1.2 m) at the shoulder and just over 5 ft (1.5 m) at the top of the head. *See* Alpaca; Vicuña. [C.B.C.]

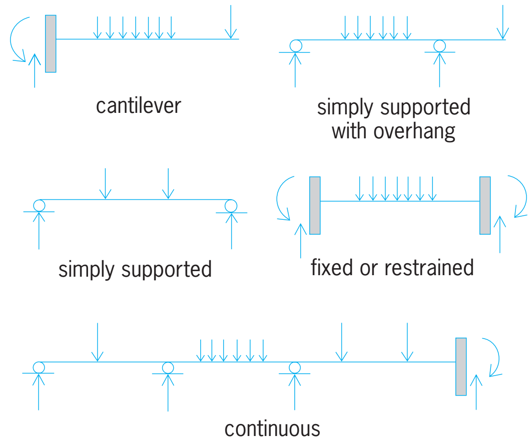
Loads, dynamic Forces which are derived from moving loads such as wind, earthquakes, machinery, vehicles, trains, cranes, and hoists. Analysis techniques which take into account the vibrations of the structures are required for loads which are repeated many times, such as machinery in motion, and produce harmonic motions of equal amplitude and constant frequency (cyclic loading); loads such as the motion produced by earthquakes (random motion); and varied loads, such as that of the wind, which produce gusts or short-duration impulses.

Repeated loads applied to a structural member can cause failure by fracture of the material. This fracture can occur at various stress levels depending upon the amplitude or acceleration of the motion, frequency, and duration. Often the stress level is below that of the design level for statically applied loads, and is referred to as the fatigue strength of the material for that application. *See* Stress and strain. [J.B.S.]

Loads, transverse Forces applied perpendicularly to the longitudinal axis of a member. Transverse loading causes the member to bend and deflect from its original position, with internal tensile and compressive strains accompanying change in curvature.

Concentrated loads are applied over areas or lengths which are relatively small compared with the dimensions of the supporting member. Examples are a heavy machine occupying limited floor area, wheel loads on a rail, or a tie rod attached locally. Loads may be stationary or they may be moving, as with the carriage of a crane hoist or with truck wheels.

Distributed loads are forces applied continuously over large areas with uniform or nonuniform intensity. Closely stacked contents on warehouse floors, snow, or wind pressures are considered to be uniform loads. Variably distributed load intensities include foundation soil pressures and hydrostatic pressures.



Types of beams.

Members subjected to bending by transverse loads are classed as beams. The span is the unsupported length. Beams may have single or multiple spans and are classified according to type of support, which may permit freedom of rotation or furnish restraint (*see* illustration). [J.B.S.]

Lobata An order of the phylum Ctenophora (comb jellies) comprising the families Bathocyroidae, Bolinopsidae, Eurhamphaeidae, Kiyohimeidae, Leucotheidae, and Ocyropsidae. Lobate ctenophores are characterized by large winglike lobes on the oral end of the body that are used for capturing food. All species are predators on zooplankton. Lobates are among the largest ctenophores; some epipelagic species attain an oral-aboral height of 8 in. (20 cm), and some deep-sea species have lobes nearly 39 in. (1 m) across. Most species are transparent, but some have conspicuous brown, blue, or purple spots on the lobes. Deep-sea forms often have red pigment surrounding the stomodeum. Lobates are bioluminescent, like other ctenophores. Bright blue-green light is produced in the meridional canals, and some species also release a cloud of luminous material into the water when disturbed, probably as part of an escape response.

The upper body is usually compressed in the tentacular plane. The comb (ctene) rows in this plane are short, but the substomodeal comb rows extend onto the outer surface of the lobes. Pendant structures called auricles extend from the oral end of the body into the space enclosed by the oral lobes. Locomotion is produced by the comb rows, but some genera (*Ocyropsis*, *Bathocyroe*) can also swim by flapping the oral lobes.

Except for the genus *Ocyropsis*, all lobate ctenophores are simultaneous hermaphrodites. Eggs develop into the cydippid larva typical of most ctenophores. After a variable length of time of swimming and feeding as a cydippid, the larva metamorphoses into the adult form, passing through intermediate larval stages in some species. Metamorphosis from the cydippid form involves loss of the primary tentacles, development of the oral lobes and auricles, and growth of secondary tentacles near the mouth. *See* CTENOPHORA. [L.P.M.]

Lobosia A subclass of Rhizopodea characterized by lobopodia predominantly, although certain of these protozoan species also may form slender pseudopodia, or even develop several different kinds. Lobosia are divided into two orders, Amoebida and Arcellinida, which differ in presence or absence of a test. Pseudopodia emerge through the aperture of the test. *See* AMOEBIDA; ARCELLINIDA; PROTOZOA; SARCODINA. [R.P.H.]

Local-area networks Computer networks that usually cover a limited range, say, within the boundary of a building. A computer network is two or more computers that communicate with each other through some medium. The primary usage of local-area networks (LANs) is the sharing of hardware, software, or information, such as data files, multimedia files, or electronic mail. Resource sharing provided by local-area networks improves efficiency and reduces overhead. *See* DIGITAL COMPUTER; ELECTRONIC MAIL; MULTIMEDIA TECHNOLOGY.

Four basic types of media are used in local-area networks: coaxial cable, twisted-pair wires, fiber-optic cable, and wireless. Each medium has its advantages and disadvantages relative to cost, speed, and expandability. Coaxial cables provide high speed and low error rates. Twisted-pair wires are cheaper than coaxial cables, can sustain the speeds common to most personal computers, and are easy to install. Fiber-optic cable is the medium of choice for high-speed local-area networks. Wireless local-area networks have the advantage of expandability. *See* COAXIAL CABLE; COMMUNICATIONS CABLE; FIBER-OPTIC CIRCUIT; OPTICAL COMMUNICATIONS; OPTICAL FIBERS.

The topology of a local-area networks is the physical layout of the network. For wired local-area networks, there are four basic topologies: bus, ring, star, and mesh. The most widely used local-area network topology is the bus, where the medium consists of a single wire or cable to which nodes are attached. A message transmitted over a bus propagates in both directions along the bus, passing each tap until it is finally absorbed at the ends.

There are a number of ways in which nodes can communicate over a network. The simplest is to establish a dedicated link between the transmitting and receiving stations. This technique is known as circuit switching. A better way of communicating is to use a technique known as packet switching, in which a dedicated path is not reserved between the source and the destination. Data are wrapped up in a packet and launched into the network. In this way, a node only has exclusive access to the medium while it is sending a packet. During its inactive period, other nodes can transmit. A typical packet is divided into preamble, address, control, data, and error-check fields. *See* PACKET SWITCHING.

An access protocol is a set of rules observed by all the nodes in a local-area network so that one node can get the attention of another and its data packet can be transferred. Two common protocols are carrier sense multiple access with collision detection (CSMA/CD) and token passing.

With the CSMA/CD protocol, a node that wants to transmit its data must first listen to the medium to hear if any other node is using the medium. If not, the node may transmit immediately. However, while the transmission is taking place, the transmitting node must continue listening to ascertain if anyone else has begun transmitting. If the transmitting node detects that someone else is also transmitting, the node aborts its own transmission, waits for a random amount of time, and then restarts the process until its data transmission succeeds.

With the token-passing protocol, the right to transmit is granted by a token, a predefined bit pattern that is recognized by each node. The token is passed for one node to another in a predetermined order. [W.Zh.]

Local Group The small cluster of galaxies that contains the Milky Way Galaxy. Galaxies exhibit a pronounced tendency to clump together on a variety of scales. It is assumed that gravitational attraction draws galaxies together. On a very large scale, this attractive process may still be at an early stage. On a smaller scale, the process has led to collapse. Galaxies have fallen together, though with enough angular momentum that they usually orbit each other rather than collide.

Collapsed structures that contain a few dozen to a few thousand substantial galaxies are called clusters; collapsed structures that contain a few but less than 10 or 20 big galaxies are called groups. The Milky Way Galaxy is a large but not exceptional spiral galaxy and one of two dominant members of a small assemblage referred to as the Local Group.

On successively larger scales, the Local Group is a member of the Coma-Sculptor Cloud and the Local Supercluster. The closest galaxies beyond the Local Group are at a distance of 7×10^6 light-years.

The Local Group has 36 known or suspected members. The only system larger than the Milky Way Galaxy is M31, the Andromeda Nebula. These two giant galaxies generate 80% of the light of the group. There are also two intermediate-scale galaxies: M33, the Triangulum Nebula near Andromeda, and the Large Magellanic Cloud, a close companion of the Milky Way and a conspicuous feature of the night sky in the Southern Hemisphere. Fainter than these are 32 small systems. The smallest among them are identified only because they are so close. Many would not be detected in even the nearest adjacent groups. The census of Local Group members may be very incomplete at the faint end and in the zones obscured by the plane of the Milky Way. *See* ANDROMEDA GALAXY; MAGELLANIC CLOUDS; MILKY WAY GALAXY. [R.B.T]

Location fit Mechanical sizes of mating parts such that, when assembled, they are accurately positioned in relation to each other. Locational fits are intended only to determine the orientation of the parts. For normally stationary parts that require ease of assembly or disassembly, for parts that fit snugly, and for parts that move yet fit closely as in spigots, slight clearance is provided between parts. Where accuracy of location is important, transition fits are used. In these fits the holes and shafts are normally nearly the same diameter. For greater accuracy of location, the shafts are made slightly larger than the holes; such fits are termed location interference fits. *See* ALLOWANCE. [P.H.B.]

Locomotive A machine mounted on flanged wheels which converts some form of potential energy into the mechanical work of propelling itself and other, nonpowered vehicles over a railroad track. The dimensions and weight of a locomotive are restricted by the presence of stationary structures adjacent to and above the track, such as overhead bridges and tunnels, and by the strength of the track and bridges that support it.

Economics demands that locomotives use an available and plentiful form of potential energy; that they convert it to useful work efficiently; that they be capable of applying sufficient force to overcome the resistance of the loaded vehicles they are to move, and they do so in the time allotted; and that they be durable, reliable, and relatively easy to maintain.

The first locomotives (around 1830) were steam propelled. Because of the many advantages of other forms of motive power, steam locomotives began to be replaced shortly after World War II and had virtually disappeared in the United States by the late 1950s. *See* STEAM ENGINE.

Electric locomotives draw electricity from a third rail set alongside the running rails of track through a sliding shoe that transmits electric power to the locomotive, or from a configuration of overhead wires known as a catenary by means of a pantograph that raises or lowers to compensate for wire height variations. The cost of these electric distribution systems has restricted the use of electric motive power to only very high traffic routes such as the Northeast Corridor of Amtrak in the United States, commuter lines, and some routes in Japan, Russia, England, and continental Europe.

Diesel-electric locomotive units are produced in a number of sizes, with corresponding power. Switching or shunting locomotives are of approximately 1000 hp and low maximum speed, while mainline passenger and freight units are being designed to produce 5000–6000 hp. Several diesel-electric units are most often coupled together to produce a single locomotive of as much as 15,000 hp or more. In such cases the entire locomotive assembly is controlled from the leading unit.

Diesel engines turn an alternator, which produces the electricity to power the traction motors. The traction motors are mounted in the truck assemblies with their armature shafts parallel to the locomotive's driving axles. A pinion gear on the armature shaft turns a bull gear on the axle to propel the locomotive. Traction motors are cooled by fan-driven air through ducts. There may be four or six such motor-driven axles per locomotive unit, and the gear ratio between pinion and bull gear teeth is varied according to the locomotive's intended use. *See* DIESEL ENGINE.

Both diesel-electric and straight electric locomotives can be equipped with dynamic brakes where traction motors act as generators resisting rotation, thus slowing the train. In the straight electric locomotive the current produced is fed back into the catenary, while in the diesel-electric the generated current is fed to high-resistance grids, which must be cooled by fan-driven air. Dynamic braking can be advantageous in reducing wear and tear on train brakes and wheels, but it must be used judiciously to avoid excessive longitudinal train forces. *See* BRAKE; DYNAMIC BRAKING; GAS TURBINE; RAILROAD ENGINEERING; TURBINE PROPULSION. [G.H.W.]

Loculoascomycetes A class in the phylum Ascomycota. The Loculoascomycetes form a well-developed mycelium which bears the sexual (ascus) and asexual (conidium) states, and are distinguished from other ascomycetes by their method of ascoma formation and their ascus structure. Ascoma formation is ascolocular, a type of development in which certain cells of the vegetative hyphae undergo numerous divisions to form a small mass of homogeneous tissue (stroma). As the stroma enlarges, internal differentiation occurs to form the ascogenous cells, from which the asci will form. As the asci develop, they dissolve or crush the internal tissues of the stroma (now an ascostroma), creating a cavity (locule). As the ascostroma matures, a neck with a canal for ascospore discharge usually forms. An ascostroma may have one or several locules with asci. Species with a single locule are termed pseudothecia, and they often resemble the perithecia of the Pyrenomycetes. The asci have a two-layered wall (bitunicate). The outer layer (ectotunica) is thin and rigid, whereas the inner layer (endotunica) is thicker and elastic. At maturity, the ectotunica splits, allowing the endotunica to expand and forcibly discharge the eight ascospores. The ascospores may be hyaline or brown, but they are usually multicelled.

Found primarily on living and dead plant tissues, the fungi in this class include a number of important plant disease fungi. *See* ASCOMYCOTA; EUMYCOTA; FUNGI; PLANT PATHOLOGY. [R.T.Ha.]

Locust (forestry) A name commonly applied to two trees, the black locust (*Robinia pseudoacacia*) and the honey locust (*Gleditsia triacanthos*). Both of these commercially important trees have podlike fruits similar to those of the pea or bean.

The black locust is native in the Appalachian and the Ozark regions and is now widely naturalized in the eastern United States, southern Canada, and Europe. The wood is hard and durable in the soil and is used for fence posts, mine timbers, poles, and railroad ties.

The honey locust is native in the Appalachian and the Mississippi Valley regions, but is also widely naturalized in the eastern United States and southern Canada. The reddish wood is hard, strong, and coarse-grained and takes a high polish. Because it is durable in contact with soil, it is used for fence posts and railroad ties; it is also used for construction, furniture, and interior finish. [A.H.G./K.P.D.]

Loess Silt-dominated sediment of eolian (windblown) origin. Loess is a common deposit in and near areas that were glaciated during the Quaternary Period, and most loess deposits are indirectly related to glaciation. *See* EOLIAN LANDFORMS; GLACIAL EPOCH; QUATERNARY.

Loess is a well-sorted clastic deposit which is unconsolidated, relatively homogeneous, seemingly nonstratified, and extremely porous. Colors range from buff to shades of pink, gray, yellow, or brown. Silt-sized particles, most of which are 0.0002– 0.002 in. (0.005–0.05 mm) in diameter, usually make up 60–90% of the deposit, with small amounts of fine sand and small to moderate amounts of clay-sized material. The particles are generally angular to subangular.

Quartz is the dominant mineral, with subordinate amounts of feldspar, calcite, dolomite, clay minerals, and small amounts of other minerals. Clay minerals are primarily smectite, illite, and chlorite. They occur as silt-sized aggregates and, along with calcite, as coatings or fillings on silt grains, in interstices, and in vertical tubes left from the decay of grass roots. These latter characteristics partially bind the particles together and give loess with relatively large dry strength. As a result, many loess deposits maintain near-vertical slopes in both natural and artificial cuts. *See* CALCITE; CLAY MINERALS; DOLOMITE; FELDSPAR; QUARTZ.

Loess occurs as a relatively thin (generally <90 ft or 30 m), blanket-type deposit which drapes over an irregular landscape. It is common in many areas of the world, but is particularly thick near valleys that served as meltwater drainageways during Quaternary glaciation. Loess also may be derived from desert areas, in which case the particles must be produced by either weathering processes or eolian abrasion. *See* SEDIMENTOLOGY; SOIL. [W.H.J.]

Logarithm An exponent of a suitably chosen positive number (base) larger than unity. Logarithms are of value in mathematical computation and in the equations and formulas used in expressing natural phenomena.

If $b^l = n$, where b is a positive number larger than unity, then l is called the logarithm of n to the base b and is written $l = \log_b n$. From this definition it follows at once that all positive numbers larger than unity have positive logarithms, all positive numbers smaller than unity have negative logarithms, and the logarithm of unity is equal to 0. Since $b^0 = 1$ irrespective of the value of b, it follows that the logarithm of unity is equal to 0. From the known properties of exponentials expressed by relations (1), it follows immediately that (1) the logarithm of a product of two or more

$$b^{l1} \cdot b^{l2} = b^{l1+l2} \qquad b^{l2} \div b^{l2} = b^{l1-l2}$$
$$(b^{l})^m = b^{lm} \qquad \sqrt[m]{b^{l}} = b^{l/m} \tag{1}$$

factors is equal to the sum of the logarithms of the factors; (2) the logarithm of the ratio of two numbers is equal to the difference between the logarithm of the numerator and the logarithm of the denominator; (3) the logarithm of the *m*th power of a number is the product of *m* and the logarithm of the number; and (4) the logarithm of the *m*th root of a number is equal to the logarithm of the number divided by *m*. *See* Exponent.

Although any positive number *b* larger than unity might have been chosen as the base of a system of logarithms, actually two numbers have been chosen in the construction of tables of logarithms, namely, the number $b = 10$ and the number $e = 2.718\ldots$ defined as the sum of infinite series (2). The system of logarithms

$$1 + \frac{1}{1} + \frac{1}{1 \cdot 2} + \frac{1}{1 \cdot 2 \cdot 3} + \cdots + \frac{1}{1 \cdot 2 \cdot 3 \cdots n} + \cdots \tag{2}$$

to the base 10 is usually referred to as common logarithms; the system of logarithms to the base *e* is called natural logarithms. *See* E (mathematics).

The integral part of the common logarithm of a number larger than unity is one unit less than the number of digits before the decimal point. This integral part is called the characteristic; the decimal part is called the mantissa. Similarly, because the common logarithms of 0. 1, 0.01, and 0.001 are −1, −2, and −3, it follows that the logarithm of a number smaller than unity having *p* zeros after the decimal point may be expressed as the sum of a negative characteristic equal to $-(p + 1)$ and a positive mantissa. [A.N.L./S.Bo.]

Logging Those processes required to bring all or a portion of a tree from the stump to the mill facilities. Logging (tree harvesting) processes are clustered into tree conversion, woods transport (off-road transportation), landing operations (wood transfer), transport from landing to mill facility (truck, water, or rail), and unloading at the mill facility (wood transfer). *See* Forest timber resources; Paper; Plywood; Wood products.

The start of harvesting is the cutting down of trees with hand tools, chain saws, or mechanized felling machines. The tree may be further cut into suitable lengths (bucking), or it may be transported whole or in tree-lengths. Tree products may be allocated during bucking with the aid of a computer on the felling and bucking machine or by a faller using a log order list or a hand-held computer to help decide the log products to make. The objective of the tree falling operation is to fell the tree with minimum damage, to avoid damaging surrounding trees, to minimize soil and water impacts, and to position the tree or logs for the next phase of harvesting. The goal of bucking is to produce the most valuable assortment of logs from the tree while considering the physical capability of the skidding (log-dragging), yarding (moving of logs to a landing), or forwarding (log-carrying) equipment.

Logs in lengths from about 1 to 10 m (3 to 33 ft) or other products must be transported from the stump to a place where they are further processed (often called a landing). In some cases, entire trees are pulled to the landing. Humans, animals, crawler tractors and wheeled skidders (machines that drag the logs), forwarders (machines that carry loads of logs), farm tractors with winches or trailers, cable logging systems, balloons, or even helicopters transport logs and tree products to landings.

At the landing, the logs or trees may be stored or directly processed for transport. They may be loaded onto trucks, trains, barges, or ships, or prepared for water transport. Whole trees brought to a landing may have limbs and bark removed, and then be chipped and loaded into chip vans for transport to a pulp mill. Tree-length segments may be delimbed and bucked into logs for different market destinations. Trees may be shredded, chunked, or processed through machines for use as fuel. The allocation process may include measurement by volume or weight of the products.

Because logs are heavy, they are normally loaded mechanically, although some regions still use manual or animal methods involving ramps. There are two general types of mechanical loaders used at roadside: swingboom loaders with grapples, and front-end loaders fitted with a log fork or grapple. Both are mobile, mounted on tracked or rubber-tired carriers. Forwarders usually unload themselves either into log decks for storage or onto setout trailers.

Trucks are most commonly used to transport log products to mill facilities. They vary from small vehicles hauling 5–8 tons on straight beds to large specialized off-highway vehicles hauling 50 tons or more. A variety of truck trailers are used depending upon the type of product. Trees or long logs may be loaded onto pole trailers. Short logs, 2.5 m (8 ft) and less, are often stacked sideways on flat-bed trailers with bunks. Chips or flakes are hauled in specially designed chip vans. Water transport in barges, as log rafts, and as free-floating logs is used in some areas.

Log products can be unloaded from truck trailers by lifting, rolling, or dumping over the side or end, depending upon the type of trailer. Trees and long logs are usually lifted from trailers by a grapple on mobile wheel loaders or overhead cranes (which can unload the entire truck in one pass). Shorter logs are often unloaded using slings. In some cases, short wood for pulp is swept directly off the trailer and fed into a debarking machine to eliminate rehandling. Chip trailers are often tilted and end-dumped on large hydraulic ramps. [J.Ses.; J.Ga.]

Logic The subject that investigates, formulates, and establishes principles of valid reasoning.

The first attempt to investigate systematically acceptable modes of reasoning was made by Aristotle, in whose *Organon* reasoning was recognized as the subject of a special science. He formulated three basic “laws of thought”: (1) the law of contradiction (no proposition is both true and false), (2) the law of excluded middle (each proposition is either true or false), and (3) the law of identity (each proposition implies itself). Advanced as his views of logic were, it seems doubtful that the idea of axiomatizing them ever occurred to him, despite the success of his contemporary Euclid in organizing geometry. That aspect of logic which enunciates or establishes valid reasoning (rather than merely investigating it) began with the publication in 1854 of George Boole’s *An Investigation of the Laws of Thought*. The partly abstract treatment of logic presented in this work initiated the completely abstract developments that were to follow. In it the laws of thought are regarded as mere conventions which, like the postulates of euclidean geometry, might be modified or even rejected to create new logics. The only requirement that a “new” logic must satisfy is the one demanded of every deductive system—consistency. Just as different geometries are useful for different purposes, a logic that is appropriate in one environment might not be so in another. There are a growing number of competent individuals, for example, who consider that any logic containing Aristotle’s law of excluded middle is not suitable for mathematics.

Propositional calculus. The unit of the propositional calculus is the proposition, which may be defined as the meaning of an indicative or declarative sentence, Each proposition has a truth-value; it is either true or false in the classical logic, but may assume other truth-values (for example, uncertain) in some of the new logics. It is convenient to use letters *p, q, r*, and so on to denote propositions. Propositions are combined by logical connectives to form other propositions. Chief among these are (1) negation (the negation of a proposition *p*, symbolized by p', may be formed verbally by writing “It is not the case that” before *p*); (2) conjunction (a binary operation symbolized by $\cdot$ or &, for example, $p \cdot q$, read “*p* and *q*”); (3) disjunction (a binary operation symbolized by $+$ or $\vee$; for example, $p \vee q$, read “*p* or

q"); (4) implication (a binary operation symbolized by $\supset$ or $\rightarrow$, for example, $p \rightarrow q$, read "p implies q"); and (5) equivalence (a binary operation denoted by $\equiv$; for example, $p \equiv q$, read "p is equivalent to q," means that each proposition implies the other). The proposition $p \cdot q$ asserts that both p and q are true. It is important to note that the disjunctive "or" is always used in the inclusive sense; that is, $p \vee q$ asserts that at least one, possibly both, of the propositions p and q is true. In addition, the meaning of "implication" in logic differs markedly from the ordinary sense of that term. The proposition $p \rightarrow q$ asserts merely that it is not the case that p is true and q is false; that is, in classical logic $p \rightarrow q$ means that either p is false or q is true. The logical connectives introduced above are examples of logical constants. They are not independent notions. Implication may be defined in terms of negation and conjunction, and this is true for all of the connectives. In fact, all the connectives can be defined in terms of one binary operation, the so-called Scheffer stroke function $p \mid q$, which may be read "p is false or q is false."

The logical connectives, the letters p, q, r, and so on that stand for propositions (propositional variables), and the parentheses, brackets, and braces needed for punctuation are formal concepts. A propositional function is a combination of concepts, formal or nonformal, involving at least one variable, which is not a proposition but becomes one when all the variables are given specified values. Examples are (1) p and q, (2) $x^2 + y^2 = 1$, and (3) x is president of the United States. Unlike a proposition, a propositional function has no truth-value. On the other hand, the statement "For every integer x, $x^2 + 1 = 0$" is a proposition (not a propositional function) even though it contains a (bound) variable. A formal function is a propositional function that contains only formal concepts—for example $[(p \vee q) \cdot r] \supset s$. A truth function is a propositional function in which only propositional variables occur, and such that the truth value of each proposition obtained from the function by substituting specific propositions for the variables depends only on the truth values of those propositions. Examples are (1) $(p \cdot q) \vee r'$, (2) Napoleon was a great general and p (where p is a propositional variable). On the other hand, "Jones stated that p" is not a truth function.

Tautologies are formal truth functions such that every proposition obtained from them by substituting specific values (propositions) for the variables they contain has the truth value T (true). A truth function is contingent provided it assumes both truth values T and F (false)—here only the classical two-valued (aristotelian logic) truth functions are considered—and self-inconsistent provided it has only the value F. The character of a truth function is determined when it is shown to be self-inconsistent, contingent, or a tautology.

A truth function may be analyzed by means of a truth table, or matrix. Such tables are made first for the elementary truth functions p' $p \vee q$, $p \cdot q$, $p \supset q$ as follows:

(I)

p	p'
T	F
F	T

(II)

p	q	$p \vee q$
T	T	T
T	F	T
F	T	T
F	F	F

(III)

p	q	$p \cdot q$
T	T	T
T	F	F
F	T	F
F	F	F

(IV)

p	q	$p \supset q$
T	T	T
T	F	F
F	T	T
F	F	T

In every table each row of the last column gives that truth value of the function which is determined by those truth values (assigned to the variables) that are entered in the preceding columns of that row.

All tautologies can be deduced from a set of just four of them:

P1 $(p \vee p) \supset p$
P2 $q \supset (p \vee q)$
P3 $(p \vee q) \supset (q \vee p)$
P4 $(q \supset r) \supset [(p \vee q) \supset (p \vee r)]$

These simple tautologies were selected by Alfred North Whitehead and Bertrand Russell in their monumental work *Principia Mathematica* as the basic set from which all tautologies can be derived. This is analogous to what is done in an axiomatic geometry in which all the theorems of the geometry are deduced from a selected set of axioms or postulates that are assumed to be true.

It was proved by E. L. Post that postulates P1–P4 are consistent; that is, it is impossible to deduce from them truth functions X and X'. He also proved that the four postulates form an independent set; that is, no one of the postulates can be deduced from the others.

In nonaristotelian logics the principle of the excluded middle (that is, each proposition is either true or false) is not valid. There are, then, at least three truth values possible for a proposition, and for this reason such logics are known as many-valued. If "true" be interpreted in mathematics to mean "provable," and a proposition be called false provided its negation is provable, then the law of excluded middle is demonstrably false, since it has been shown that mathematics contains proposition p such that neither p nor its negation p' is provable. *See* BOOLEAN ALGEBRA; EUCLIDEAN GEOMETRY; MATHEMATICS; SCIENCE. [L.M.Bl.]

Mathematical logic. Mathematical logic is an area of research that has emerged from the study of formal systems. It has its roots in work on the foundations of mathematics in the nineteenth and early twentieth centuries, showing that the customary forms of mathematical reasoning can be adequately expressed in formal (purely symbolic) systems. Mathematical logic contains four areas of research: proof theory, set theory, model theory, and recursion theory.

The original objective of work in the foundations of mathematics was the analysis and precise formulation of mathematical concepts, such as "limit," "function," and "differential manifold," as well as a complete and explicit determination of the valid forms of mathematical argument. This goal was achieved by the formalization of mathematics.

A formal system consists of a symbolic notation (or language) with rules for constructing expressions using the specified notation, axioms (expressions taken as given), and rules of inference used to derive additional expressions from a given set of expressions. To formalize an area of mathematics means to give a procedure for representing proofs in the specified area within a definite formal system. One formal system that is adequate for the formalization of all existing mathematics is the language of set theory, which can be set up in a variety of ways. There are various standard systems of axioms for set theory, notably the axiom system ZFC, consisting of axioms proposed by E. Zermelo and A. Fränkel, with the addition of the axiom of choice.

Proof theoretic research continues the study of formal systems that are adequate for the formalization of various parts of mathematics. Two basic results, due to K. Gödel, relate to the adequacy of formal systems in general: the so-called completeness and incompleteness theorems. The completeness theorem essentially states that the laws of inference are adequately mirrored in the usual formal systems in the sense that any law of inference that is in fact valid in all mathematical contexts is derivable in any of these systems. The incompleteness theorem, on the other hand, can be interpreted as stating that it is impossible to give a completely satisfactory axiom system for any theory that can serve as a formal foundation for mathematics. *See* GÖDEL'S THEOREM.

Axiomatic set theory was developed in part as a way of obtaining a formalism adequate for all of mathematics, and also for concrete mathematical reasons connected with the development of general topology and measure theory around 1900. Set theory is probably the most active research area within mathematical logic. It has been shown that a variety of problems in analysis, general topology, and algebra (especially homological algebra) cannot be settled within the framework of any of the standard set theoretic systems like ZFC. *See* SET THEORY.

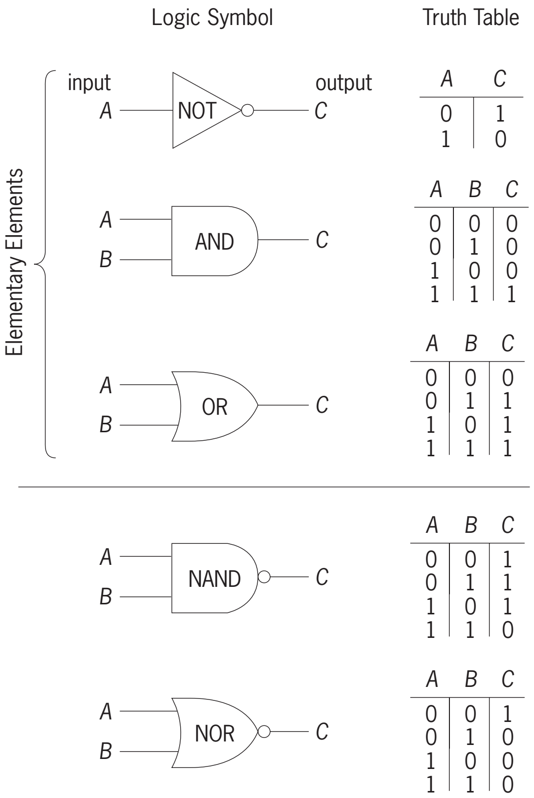
The development of formal systems in logic is related to the development of axiomatic systems in modern algebra, although the motivation is very different. Model theory combines the algebraic and logical points of view. In applied model theory, the tools of mathematical logic are applied to problems arising in algebra. In pure model theory, axiomatic systems are studied as if they were algebraic systems, and the class of all models of a given axiomatic system is investigated.

Given two functions, *f* and *g*, from the natural numbers to the natural numbers, *f* is said to be reducible to *g* if there is an algorithm that will compute *f* by using information about *g*. Two functions are equivalent if each can be reduced to the other. The equivalence classes are called degrees; they can be thought of as degrees of complexity. Modern recursion theory has produced a very detailed picture of the structure of the degrees and the reducibility relation. *See* MATHEMATICS; SCIENCE; SCIENTIFIC METHODS. [G.Ch.]

Logic circuits Electronic circuits which process information encoded as one of a limited set of voltage or current levels. Logic circuits are the basic building blocks used to realize consumer and industrial products that incorporate digital electronics. Such products include digital computers, video games, voice synthesizers, pocket calculators, and robot controls. *See* INTEGRATED CIRCUITS.

All logic circuits may be described in terms of three fundamental elements, shown graphically in the illustration. The NOT element has one input and one output; as the name suggests, the output generated is the opposite of the input in binary. In other words, a 0 input value causes a 1 to appear at the output; a 1 input results in a 0 output. (All signals are interpreted to be one of only two values, denoted as 0 and 1.)

The AND element has an arbitrary number of inputs and a single output. As the name suggests, the output becomes 1 if, and only if, all of the inputs are 1; otherwise the output is 0. The AND together with the NOT circuit therefore enables searching for a particular combination of binary signals.



Logic elements.

The third element is the OR function. As with the AND, an arbitrary number of inputs may exist and one output is generated. The OR output is 1 if one or more inputs are 1.

The operations of AND and OR have some analogies to the arithmetic operations of multiplication and addition, respectively. The collection of mathematical rules and properties of these operations is called boolean algebra. *See* BOOLEAN ALGEBRA.

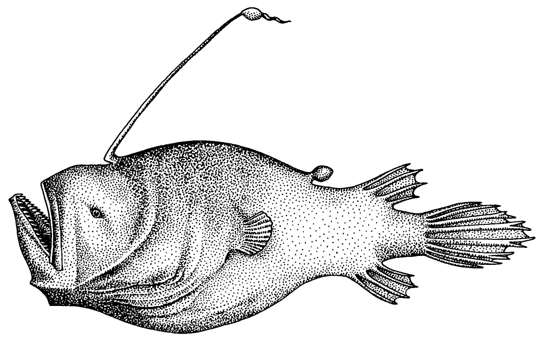
While the NOT, AND, and OR functions have been designed as individual circuits in many circuit families, by far the most common functions realized as individual circuits are the NAND and NOR circuits of the illustration. A NAND may be described as equivalent to an AND element driving a NOT element. Similarly, a NOR is equivalent to an OR element driving a NOT element.

As the names of the logic elements described suggest, logic circuits respond to combinations of input signals. Logic networks which are interconnected so that the current set of output signals is responsive only to the current set of input signals are appropriately termed combinational logic. An important further capability for processing information is memory, or the ability to store information. The logic circuits themselves must provide a memory function if information is to be manipulated at the speeds the logic is capable of. Logic circuit networks that include feedback paths to retain information are termed sequential logic networks, since outputs are in part dependent on the prior input signals applied and in particular on the sequence in which the signals were applied.

Several alternatives exist for the digital designer to create a digital system. Two common realizations are ready-made catalog-order devices, which can be combined as building blocks, and custom-designed devices. Gate-array devices comprise a two-dimensional array of logic cells, each equivalent to one or a few logic gates. Programmable logic arrays have the potential for realizing any of a large number of different sets of logic functions. In table look-up, the collection of input signals are grouped arbitrarily as address digits to a memory device. Finally, the last form of logic network embodiment is the microcomputer. *See* MICROCOMPUTER.

There are basically two logic circuit families in widespread use: bipolar and metal-oxide-semiconductor (MOS). *See* TRANSISTOR. [R.R.Sh; W.V.R.]

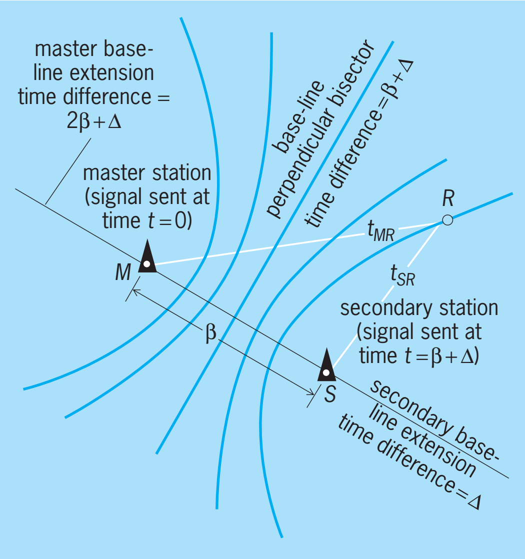
Lophiiformes The anglerfishes and their relatives. The first dorsal fin is reduced to a few flexible rays, of which the first is placed on top of the head and bears a terminal bulb or tassel and functions as a fishing lure (see illustration). Luminescent organs may be present, and in some deep-sea species the males are dwarfed and attached as ectoparasites on the females. There are 3 suborders, 15 families, nearly 60 genera, and about 195 known species. *See* ACTINOPTERYGII. [R.M.B.]



Anglerfish (*Cryptopsaras couesi*). (*After G. B. Goode and T. H. Bean, Oceanic Ichthyology, U.S. Nat. Mus. Spec. Bull. no. 2, 1895*)

Lophophore The crown of tentacles which surrounds the mouth in the Bryozoa, Phoronida, and Brachiopoda. The numerous ciliated tentacles arise from a circular or horseshoe-shaped fold of the body wall. The tentacles are hollow outgrowths of the body wall, each containing fluid-filled extensions of the body cavity and extended hydraulically. The primary function of the lophophore is to gather food. On the tentacles are ciliary tracts which drive a current of food-particle-bearing water through the lophophore. While the lophophore is primarily a feeding organ, it may also play a role in reproduction, respiration, and larval locomotion. *See* BRACHIOPODA; BRYOZOA; PHORONIDA. [J.E.Wi.]

Loran A navigation system from which hyperbolic lines of position are determined by measuring the difference in times of arrival of pulses from widely spaced, synchronized transmitting stations. Since radio waves travel at the speed of light, a line of position represents a constant range difference from two transmitters.



Principle of position fixing by hyperbolic navigation systems. (*After J. P. Van Etten, Navigation systems: Fundamentals of low and very-low-frequency hyperbolic techniques, Electr. Commun., 45(3):192–212, 1970*)

In the illustration, it is assumed that the master station *M* transmits a pulse signal at time $t = 0$, and that the secondary station *S* transmits a similar pulse signal Δ microseconds after receiving the master pulse signal. The secondary station receives the master signal at time $t = \beta$ microseconds, and therefore transmits its pulse at time $t = \beta + \Delta$ microseconds. A receiver at *R* measuring the difference in the times of arrival of the signals from the secondary and master stations measures the time difference $\mathrm{TD} = (\beta + \Delta) + t_{SR} - t_{MR}$. The locus of all points with this common time difference is a hyperbola through the receiver position R. Similarly, every hyperbolic line of position is uniquely defined by a time difference. The intersection of two such lines of position gives a navigational fix, or location. Loran is used by commercial and military ships and aircraft. The name is derived from "long range navigation." *See* HYPERBOLIC NAVIGATION SYSTEM. [J.P.V.E.]

Lorentz transformations The relationship in the special theory of relativity between the sets of coordinates (t, x, y, z) and (t', x', y', z') used to label events in spacetime by two inertial observers, *O* and *O′*, who are moving with respect to each other. Many of the effects predicted by special relativity can be derived in a direct manner from the Lorentz transformation formulas.

By definition, an event in spacetime is a point of space at an instant of time. It is an empirical fact that the collection of events in spacetime constitutes a four-dimensional continuum. This means that it takes four numbers to specify a particular event: one number to specify its "time" and three numbers to specify its spatial position.

In both prerelativity physics and in special relativity, an inertial observer, *O*, is one who is not acted upon by any external forces and thus undergoes straight-line motion. It is assumed in prerelativity physics and in special relativity that any inertial observer, *O*, can use a procedure involving the construction of a rigid cartesian grid of meter sticks and the synchronization of clocks placed at each point on the grid, to assign four numbers (t, x, y, z) to each event in spacetime. Another inertial observer, *O′*, who moves with respect to *O* at velocity v in the x direction, may also construct a global inertial coordinate system by using exactly the same procedure as *O*. The observer *O′* can thereby label events in spacetime by the numbers (t', x', y', z'). It is of interest to compare the way the same events are labeled by *O* and *O′*. For simplicity, it is assumed that *O* and *O′* meet at an event *A*, and that they adjust their clocks so that $t = t' = 0$ at this event. It is also assumed for simplicity that the axes of the grid of meter sticks carried by *O′* are aligned (that is, not rotated) with respect to the axes of *O* when they meet.

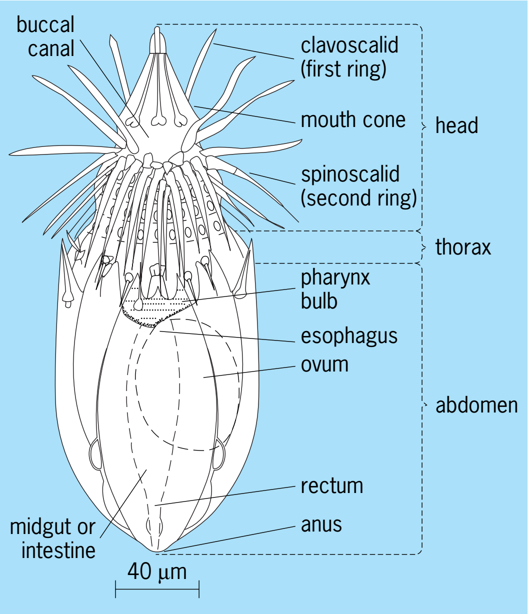
In prerelativistic physics, the relationship between the global inertial coordinate systems of *O* and *O′* is given by a galilean transformation defined by Eqs. (1). Equation (1*a*) states that *O* and *O′* agree on the time labeling of any two events. In particular, if two events are judged to be simultaneous by *O* (that is, if $t_1 = t_2$ for the two events), they also will be judged to be simultaneous by *O′* (that is, $t_1' = t_2'$). This reflects the fact that the notion of simultaneity is an absolute one in prerelativistic physics. The observers *O* and *O′* disagree only about the x-labeling of events, and this disagreement is readily understood as resulting from their relative motion.

$$t' = t \tag{1a}$$
$$x' = x - vt \tag{1b}$$
$$y' = y \tag{1c}$$
$$z' = z \tag{1d}$$

In special relativity the corresponding relationship between the global inertial coordinates of *O* and *O′* is a Lorentz transformation, defined by Eqs. (2). The Lorentz transformation differs dramatically from the galilean transformation in that *O* and *O′* disagree over the time labeling of events. In particular, two events judged by *O* to be simultaneous (that is, $t_1 = t_2$) will not, in general, be simultaneous according to *O′*. This reflects the fact that simultaneity is not an absolute notion in special relativity. *See* RELATIVITY. [R.M.Wal.]

$$t' = \frac{t - \dfrac{xv}{c^2}}{\sqrt{1 - \dfrac{v^2}{c^2}}} \tag{2a}$$
$$x' = \frac{x - vt}{\sqrt{1 - \dfrac{v^2}{c^2}}} \tag{2b}$$
$$y' = y \tag{2c}$$
$$z' = z \tag{2d}$$

Loricifera A phylum of multicellular invertebrates. These marine organisms are entirely meiobenthic; that is, they never exceed a maximum dimension of 400 micrometers and live in sediments ranging from deep-sea red clay to coarse sand or shell hash. They have some of the smallest known cells in the animal kingdom. Although they have been found throughout the world,



Ventral view of adult female loriciferan (*Nannaloricus mysticus*). (*After R. M. Kristensen, Loricifera, a new phylum with Aschelminthes characters from the meiobenthus, Z. Zool. Syst. Evolutionsforsch., 21(3):163–180, 1983*)

only 10 species representing three genera and two families have been described. Well over 50 species thought to represent several additional genera are known but remain undescribed.

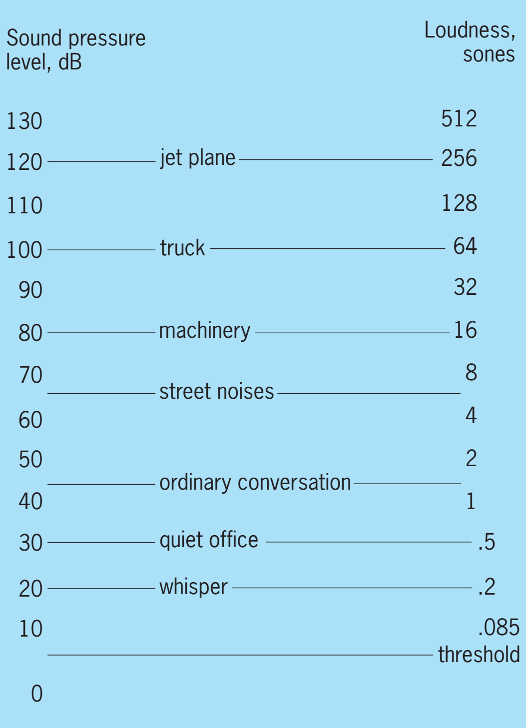
Adult loriciferans are bilaterally symmetrical. The body is regionated into a mouth cone which telescopically protrudes anteriorly from the center of a spherical, appendage-ringed (up to 400 rings may be present) head; a short, usually plated neck region; and a distinctively loricated (thick-cuticled) thorax-abdomen (see illustration). The head, along with its withdrawn mouth cone, may be inverted into the thorax-abdomen, which is then closed anteriorly by the cuticle of the neck region.

Loriciferans appear to be closely related to the Priapulida and perhaps less so to the Kinorhyncha. Certain structures of the mouth cone suggest affinities to the Tardigrada. Their presence may support the idea that proarthropods could have been developed from aschelminth ancestral stock. *See* ANIMAL KINGDOM; ARTHROPODA; KINORHYNCHA; PRIAPULIDA; TARDIGRADA. [R.P.H.]

Loudness The perceptual intensity of sound. Loudness depends importantly on the physical intensity of sound, increasing when physical intensity increases and decreasing when physical intensity decreases. But loudness also depends on other physical properties of sound, such as frequency and duration. Sound waves with frequencies between 1000 and 5000 hertz are louder than sound waves that have the same intensity but lower or higher frequencies. The physical level of sound is expressed in decibels. *See* DECIBEL.

Because loudness depends on sound frequency as well as sound intensity or pressure, different stimuli with the same sound pressure level (SPL) may not be equally loud. One type of decibel scale, called the phon scale, overcomes this deficiency. The level of a sound in phons is the SPL in decibels of an equally loud 1000-Hz tone. Thus a 1000-Hz tone at 40-dB SPL has a level of 40 phons, as do all other sounds that equal its loudness, even though these other sounds may have SPLs much greater than 40 dB.

The phon scale is often designated as a scale of loudness level. It is a scale of equal loudness, in that all equally loud sounds take the same level in phons, regardless of the SPL. Nevertheless, the phon scale is not a true scale of loudness, because it is a physical (decibel) scale. That is, a sound of 80 phons is not necessarily twice as loud as a sound of 40 phons. In order to determine a scale of perceived loudness, observers were asked to set the level of one sound to make it appear twice or half as loud as standard sounds. Observers were also asked to make numerical judgments of the degree of loudness. From such judgments a scale of loudness in sones was established. One sone is defined as the loudness of a 1000-Hz tone at 40-dB SPL heard with both ears. (When heard with one ear, loudness is half as great.) Above 40 dB, loudness in sones doubles with every 10-dB increase in the level of sound. Below 40 dB, loudness falls by half with decrements smaller than 10 dB (see illustration). *See* SOUND; SOUND PRESSURE. [L.E.M]



Decibel and loudness scales of common sounds.

Loudspeaker A device that converts an electrical signal from an amplifier into sound. A loudspeaker driver is an electromechanical-acoustic device with two electrical input terminals, to which an electrical signal is applied, and a diaphragm which vibrates and radiates sound. An electromechanical motor mechanism exerts a force on the diaphragm to cause it to vibrate. By far the most common type of motor mechanism, the electromagnetic-mechanical transducer employs a coil of wire immersed in a magnetic field; electric current flowing through the coil causes a force to be exerted on the coil which is mechanically coupled to the diaphragm. A less common type of motor mechanism is the electrostatic-mechanical transducer. It uses a capacitor to which an electric voltage is applied, causing a force to be exerted between the capacitor plates, which is mechanically coupled to the diaphragm. Two types of electrostatic transducers are used: the piezoelectric transducer and the condenser transducer. The piezoelectric transducer uses a piezoelectric crystal between the capacitor plates. The condenser transducer uses an air dielectric. One plate of the capacitor is a flexible membrane which serves as the diaphragm. *See* AUDIO AMPLIFIER.

A loudspeaker system employs one or more loudspeaker drivers in a common enclosure. A one-way loudspeaker system employs a full-range driver to cover the full audio spectrum. A two-way system employs a low-frequency driver called a woofer and a high-frequency driver called a tweeter. An electrical low-pass filter is used in series with the woofer and a high-pass filter is used in series with the tweeter. These filters are commonly referred to as the crossover networks. A three-way system adds a midfrequency driver called the midrange or squawker. The crossover network for this driver is a band-pass filter. In some systems, a driver called a supertweeter is used to reproduce audio frequencies into the ultrasonic range. A driver called a subwoofer is used to reproduce audio frequencies into the infrasonic range. *See* ELECTRIC FILTER; NETWORK THEORY.

Loudspeaker drivers can also be operated either as direct-radiator or horn-loaded. A direct-radiator driver is one whose diaphragm radiates directly into the external air load. A horn-loaded driver has an acoustic horn between the diaphragm and the air load. A horn can be used to improve the efficiency and to control the directional pattern of the radiated sound at the expense of frequency response. *See* DIRECTIVITY; SOUND-REINFORCEMENT SYSTEM. [W.M.L.]

Louping ill A viral disease of sheep, capable of producing central nervous system manifestations. It occurs chiefly in the British Isles. Infections have been reported, although rarely, among persons working with sheep. In sheep the disease is usually biphasic with a systemic influenzalike phase, which is followed by encephalitic signs. In infected humans the first phase is generally the extent of the illness. The virus is a member of the Russian tick-borne complex of the group B arboviruses. Characteristics, diagnosis, and epidemiology are similar to those of other viruses of this complex. *See* ANIMAL VIRUS; ARBOVIRAL ENCEPHALITIDES. [J.L.Me.]

Low-level counting The measurement of very small amounts of radioactivity. This can be achieved by measuring radioactivity in large samples or modifying conventional radiation-detection instruments for greater detection sensitivity, or both. All approaches must take into account the characteristics of the radiations, notably the very short range and intense energy deposition of alpha particles, intermediate range and energy deposition of beta particles, and high penetration of matter with low linear energy transfer by gamma rays. These techniques are important for measuring radionuclides from naturally occurring terrestrial and cosmic-ray-produced sources, and anthropogenic radionuclides to characterize the decay schemes of newly formed isotopes and analyze environmental and biological samples. *See* ALPHA PARTICLES; BETA PARTICLES; GAMMA RAYS.

Accurate measurements are defined by a small statistical error for the net sample count rate. Because the statistical error depends both on the net sample count rate and on the radiation background count rate, the value of the radiation background count rate must be kept as low as possible.

Commonly used radiation detectors are gas-ionization systems operating in the ionization, proportional, or Geiger-Müller regions; scintillation systems with scintillators that are inorganic solids, organic solids, or organic liquids; and solid-state systems with germanium or silicon detectors. *See* GEIGER-MÜLLER COUNTER; IONIZATION CHAMBER; JUNCTION DETECTOR; PARTICLE DETECTOR; SCINTILLATION COUNTER.

Radionuclides in very large samples may be measured directly by counting the energetic gamma rays they emit, for example in whole-body counting. If such samples emit only alpha particles, beta particles, or weak gamma rays (x-rays), then the radionuclides must be extracted and concentrated by chemical or physical processes. Radionuclides can be concentrated from water on ion-exchange resins or by precipitation, and from air by sorption on materials such as charcoal or molecular sieves. Filtering will collect radioactive solids from both media. Other processes include condensation of gases from air and volatilization from liquids or solids. The radionuclides must then be prepared for counting as thin solids, as solutes in a liquid scintillation cocktail, or as gases that are part of an ionization-detector filling. *See* ADSORPTION; CHARCOAL; FILTRATION; ION EXCHANGE; MOLECULAR SIEVE; PRECIPITATION (CHEMISTRY); VOLATILIZATION.

To maximize the detection efficiency, the intrinsic efficiency for recording the radiation should be near unity and the detector should view the sample from as large a solid angle as possible. Even relatively thin detectors have intrinsic efficiencies near unity for alpha particles, beta particles, and x-rays, but energetic gamma rays are detected with much lower intrinsic efficiency, except by very thick detectors. In general, the larger the sample, the smaller the angle subtended by the detector, although large detectors have been made for large samples. Relatively small samples can be surrounded more easily by a detector.

Achieving a low and stable radiation background is one basic aim in low-level counting. Stability is necessary because the detector background generally is determined by counting blanks between samples and subtracting these blank counts from the sample count on the assumption that the background is invariant. The counting facility must be situated to avoid fluctuating external radiation fields at nuclear facilities or near radiation sources. Airborne radon and progeny may have to be controlled by air-cleaning processes to avoid radiation background fluctuations. *See* RADON.

The detector background from ambient radiation is reduced by shielding and by anticoincidence systems. A typical shield consists of 2 in. (5 cm) of a heavy metal such as lead or mercury, or thicker iron, to surround a beta-particle detector, or at least twice that thickness for a gamma-ray detector. This shielding absorbs all beta particles and most gamma rays. Water or paraffin is added to shield against neutrons. For ultralow-level counting, the entire system can be shielded with massive amounts of iron and buried below ground to reduce the cosmic-ray background. *See* NEUTRON; RADIATION SHIELDING; RADIOACTIVITY. [B.Ka.]

Low-temperature acoustics The application of acoustics to research on the properties of condensed matter at low temperatures. Acoustic techniques are readily adaptable to the cryogenic environment and make possible many measurements of the structural and thermodynamic properties of materials at temperatures approaching absolute zero (0 K, which is -273°C). The study of sound propagation has also yielded major insights into the low-temperature phenomena of superconductivity in metals and superfluidity in liquid helium.

Solid materials. Acoustic measurements have been used to characterize the properties of a wide variety of solid-state materials, such as metals, dielectric crystals, amorphous solids, and magnetic materials. A measurement of the velocity of sound in a substance gives information on its elastic properties, while the attenuation of the sound characterizes the interaction of the lattice vibrations with the electronic and structural properties of the material. Ultrasonic frequencies, in the range from 20 kHz to 100 MHz and above, are commonly employed in these measurements because of the ease of generating and detecting the sound with piezoelectric quartz crystals.

Because the sound velocity effectively measures elastic constants, such measurements are used to characterize phase transitions in crystals where the structure of the lattice changes. The attenuation of sound in many crystals is due to defects and impurities in the crystal lattice and provides information on such structures. In a metal at very low temperatures, the dominant source of attenuation is the interaction of the sound with the conduction electrons. *See* CRYSTAL; LATTICE VIBRATIONS; PHASE TRANSITIONS; PHONON; SOUND ABSORPTION.

A large variety of magnetoacoustic effects are observed in metals and crystals. In these measurements, changes in the sound attenuation occur as the strength of a magnetic field applied to the sample is increased. One example is the phenomenon of nuclear acoustic resonance, resulting from the interaction of the nuclear spins in a crystal with vibrations of the lattice. There are also a number of other magnetoacoustic effects in metals which are useful in determining the orbits followed by the conduction electrons in the metal. *See* DE HAAS-VAN ALPHEN EFFECT.

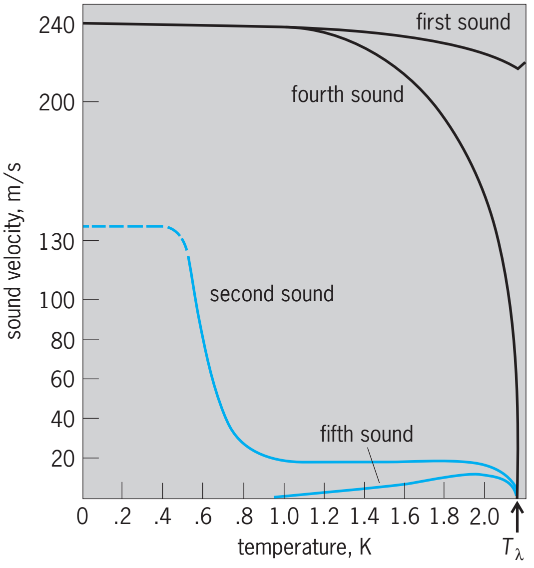
Sound propagation is useful for studying amorphous materials. In materials such as silica glass (amorphous silicon dioxide, SiO_2), only two quantum energy levels are found to be important at low temperatures. These levels correspond to two nearly equivalent arrangements of the atoms, with one arrangement having slightly higher energy. An imposed sound field can cause a transition from one arrangement to the other. If the relaxation rate back to the original configuration is comparable to the sound frequency, there will be a net absorption of energy from the sound wave. A peak in the attenuation in silica glass near 50 K (−370°F) has been identified as being due to this process, and measurements as a function of frequency allow a determination of the relaxation rate. *See* AMORPHOUS SOLID.

When a metal is cooled below its superconducting transition temperature, there are striking changes in the attenuation of sound. At the transition some of the electrons near the Fermi surface begin to pair together, due to the attractive electron-phonon coupling. Once this occurs, the electrons can no longer exchange momentum with the lattice, and hence have zero resistance. This also means that the paired electrons no longer absorb energy from the sound wave, and the attenuation is from the remaining unpaired normal electrons. As the temperature is lowered well below the transition, the density of the unpaired electrons drops rapidly, and the attenuation becomes very small. *See* SUPERCONDUCTIVITY.

Superfluid helium. Sound propagation has been extensively used to probe many of the unusual properties of superfluid helium. The novel features of the superfluid (zero viscosity and entropy) give rise to a rich variety of different types of sound which can propagate in the superfluid helium. Five distinct sound modes have been identified and observed experimentally. The sound velocities of a number of these modes are shown in the illustration as a function of temperature.

First sound is a pressure wave which propagates in the bulk liquid. It is quite similar to sound in ordinary fluids.

Second sound is an unusual type of wave: it is a temperature wave in the bulk superfluid. In this mode the normal fluid and superfluid move in opposite directions. This keeps the density constant, and hence there are no pressure oscillations in the wave (as in first sound); but because only the normal fluid carries entropy, there are oscillations in the entropy and thus in the temperature of the liquid. *See* SECOND SOUND.



Velocity of the various types of sound in superfluid ^{4}He as a function of temperature. 1 m/s = 3.28 ft/s. °F = (K × 1.8) − 459.67.

Third sound is a wave which propagates in very thin films of helium. The third sound is a wave in which the thickness of the film varies, somewhat like waves in a tank of water. Because the films are so thin, only the superfluid can move, the normal fluid being immobilized by its viscosity.

Fourth sound is a pressure wave which propagates in superfluid helium when it is confined in a porous material such as a tightly packed powder. In such a situation the normal fluid is immobilized, and only the superfluid can flow freely because of its zero viscosity (the porous materials are often called superleaks for this reason). The fourth sound is analogous to first sound because it involves density and pressure oscillations.

Fifth sound is a temperature wave which can propagate in helium confined in a superleak. It is analogous to second sound, except that again only the superfluid component can flow. *See* LIQUID HELIUM; SUPERFLUIDITY. [G.A.W.]

Low-temperature physics A branch of physics dealing with physical properties of matter at temperatures such that thermal fluctuations are greatly reduced and effects of interactions at the quantum-mechanical level can be observed. As the temperature is lowered, order sets in (either in space or in motion), and quantum-mechanical phenomena can be observed on a macroscopic scale.

Some of the most interesting manifestations of low temperatures have been investigated in the temperature range from 4 K (−452°F) down to less than a nanokelvin above absolute zero. (1 K is equal to 1.8°F above absolute zero, or −459.67°F.) Certain metals become superconducting, losing their electrical resistance entirely; hence persistent currents can flow indefinitely in a superconducting ring or coil, displaying quantum-mechanical coherence over large distances. The liquids helium-3 (^{3}He) and helium-4 (^{4}He) remain liquid down to absolute zero under their own vapor pressure due to the large zero-point energy of these light atoms. (To overcome the large zero-point energy in liquid ^{3}He and liquid ^{4}He, a large pressure, approximately 30 atm or 3 megapascals, must be applied to cause these systems to solidify.) Liquid ^{4}He becomes superfluid, exhibiting no resistance to flow under certain conditions; when set in circulation, the fluid current persists indefinitely. Liquid ^{3}He also becomes superfluid at a much lower temperature with interesting magnetic and orbital effects. At sufficiently low temperatures, nuclear magnetic ordering has been observed in solid ^{3}He, in magnetic insulators, and in metallic systems. Silver becomes a nuclear antiferromagnet in the nanokelvin range as a result of quantum-mechanical exchange interactions. Considerable attention has been addressed to the general problem of ordering in disordered systems leading to studies of spin glasses, localization, and lower dimensionality. Quantum statistics are investigated in atomic hydrogen and deuterium, stabilized in states known as spin-polarized hydrogen ($H\downarrow$) and spin-polarized deuterium ($D\downarrow$). Because of its light mass and weak interactions, spin-polarized hydrogen is expected to remain gaseous down to absolute zero, whereas spin-polarized deuterium might liquefy at low temperatures. *See* HYDROGEN; LIQUID HELIUM; SUPERFLUIDITY.

Low-temperature research also deals with problems of thermometry and heat transfer between systems and within systems. Many practical applications have emerged, including the use of superconductivity for large magnets, ultrafast electronics for computers, and low-noise and high-sensitivity instrumentation. This type of instrumentation has opened new areas of research in biophysics, and in fundamental problems such as the search for magnetic monopoles, gravity waves, and quarks. *See* LOW-TEMPERATURE THERMOMETRY; SUPERCONDUCTING DEVICES; SUPERCONDUCTIVITY.

The development of low-temperature techniques has revealed a wide range of other phenomena. The behavior of oriented nuclei is studied by observing the distribution of gamma-ray emission of radioactive nuclei oriented in a magnetic field. Other areas of study include surfaces of liquid ^{3}He and liquid ^{4}He,

^{3}He–^{4}He mixtures, cryogenics, acoustic microscopy, phonon spectroscopy, monolayer helium films, molecular hydrogen, determination of the voltage standard, and phase transitions. *See* ACOUSTIC MICROSCOPE; CRYOGENICS; ELECTRICAL UNITS AND STANDARDS; NUCLEAR ORIENTATION; PHASE TRANSITIONS. [O.G.S.]

Low-temperature thermometry The measurement of temperature below 32°F (0°C). Very few thermometers are truly wide-range, and hence most of the conventional methods of thermometry tend to fail the further one moves below room temperature (see table). The defining instrument for the lower regions of the International Practical Temperature Scale, the platinum resistance thermometer, rapidly loses sensitivity below −405°F (30 K), and its official limit is set at −434.81°F (13.81 K), the triple point of equilibrium hydrogen. This scale is based upon measurements of thermodynamic temperature made with the gas thermometer; the gas thermometer may be used down to about −456°F (2 K). *See* GAS THERMOMETRY.

The low-temperature region is unique in having available several different types of primary thermometers, all of which are quite practical. The least practical, perhaps, is the acoustic thermometer, which uses the property that, extrapolated to zero pressure, the speed of sound in a gas is proportional to $T^{1/2}$. This has been used in the range −456 to −424°F (2–20 K) as an alternative to, and check upon, the gas thermometer. The Johnson noise in a resistor can be used with particular advantage at low temperatures when allied with SQUID detector technology. *See* ELECTRICAL NOISE; SOUND.

Ranges and sensitivities of low-temperature thermometers

Thermometer	Temperature range, K
Thermocouples	
300 to 700 ppm Fe in Au/Ag + 0.37 at. % Au	1–25
Chromel/300 to 700 ppm Fe in Au	1–300
Chromel/Constantan	20–1100
Resistance thermometers	
Platinum (capsule)	4–500
Rhodium + 0.5 at. % Fe	0.5–300
Carbon	0.01–300
Germanium	0.01–30
Saturation vapor pressure thermometers	
Hydrogen	14–21
Helium-4	1.0–5.2
Helium-3	0.5–3.3
Noise thermometers*	0.002–0.1
Magnetic thermometers	
Gadolinium metaphosphate, $Gd(PO_3)_3$	2–100
Cerous magnesium nitrate (CMN), $Ce_2Mg_3(NO_3)_{12} \cdot 24H_2O$; single crystal	0.003–4
CMN powder sphere or cylinder	0.002–4
Copper (and other nuclear paramagnets)	0.001–0.01
Gamma-ray anisotropy thermometers*	0.002–0.05
^{60}Co in hexagonal close-packed cobalt single crystal	0.002–0.04
^{54}Mn in iron	0.003–0.03
^{54}Mn in nickel	0.004–0.045
^{3}He melting-curve thermometer	0.001–1
Nuclear resonance thermometer	310 nK–2K

*Primary thermometer.

In suitable systems it is possible to spatially orient atomic nuclei at very low temperatures, and if these nuclei are emitters of gamma rays, the emission pattern is anisotropic to a degree which is a measure of the thermodynamic temperature, Finally the magnetic susceptibility of suitable atomic nuclei may also be employed via the Curie law. Nuclear magnetic resonance or static SQUID-based techniques may be employed, but nuclear magnetic resonance is preferable in being unaffected by magnetic impurities, to which the second method falls hostage. *See* NUCLEAR MAGNETIC RESONANCE (NMR); SQUID; TEMPERATURE; TEMPERATURE MEASUREMENT; THERMOCOUPLE; THERMOMETER. [R.P.Hu.]

Lubricant A gas, liquid, or solid used to prevent contact of parts in relative motion, and thereby reduce friction and wear. In many machines, cooling by the lubricant is equally important. The lubricant may also be called upon to prevent rusting and the deposition of solids on close-fitting parts.

Crude petroleum is an excellent source of lubricants because a very wide range of suitable liquids, varying in molecular weight from 150 to over 1000 and in viscosity from light machine oils to heavy gear oils, can be produced by various refining processes (see table). In order to standardize on nomenclature for oils of differing viscosity, the Society of Automotive Engineers (SAE) has established viscosity ranges for the various SAE designations (see table).

Viscosity of oils for various applications

Application	Viscosity in centistokes at 25°C (77°F)	Primary function
Engine oils		
SAE 10W	60–90	Lubricate piston rings, cylinders, valve gear, bearings; cool piston; prevent deposition on metal surfaces
SAE 20	90–180	
SAE 30	180–280	
SAE 40	280–450	
SAE 50	450–800	
Gear oils		Prevent metal contact and wear of spur gears, hypoid gears, worm gears; cool gear cases
SAE 80	100–400	
SAE 90	400–1000	
SAE 140	1000–2200	
Aviation engine oils	220–700	Same as engine oils
Torque converter fluid	80–140	Lubricate, transmit power
Hydraulic brake fluid	35	Transmit power
Refrigerator oils	30–260	Lubricate compressor pump
Steam-turbine oil	55–300	Lubricate reduction gearing, cool
Steam cylinder oil	1500–3300	Lubricate in presence of steam at high temperatures

It is often desirable to add various chemicals to lubricating oils to improve their physical properties or to obtain some needed improvement in performance. These include viscosity-index improvers, pour-point depressants, antioxidants, anti-wear and friction-reducing additives, and dispersants.

Synthetic lubricants may be superior to mineral lubricants in some applications. The main advantage of synthetics is that they have a greater operating range than a mineral oil. Included in this class are esters, containing oxidation inhibitors and sometimes mild extreme pressure additives, silicones, and the polyglycols, such as polypropylene and ethylene oxides.

The most useful solid lubricants are those with a layer structure in which the molecular platelets will readily slide over each other. Graphite, molybdenum disulfide, talc, and boron nitride possess this property. A unique type of solid lubricant is provided by the plastic polytetrafluoroethylene (PTFE). The principal difficulty encountered with the use of solid lubricants is that of maintaining an adequate lubricant layer between the sliding metal surfaces.

A lubricating grease is a solid or semifluid lubricant comprising a thickening (or gelling) agent in a liquid lubricant. Other ingredients imparting special properties may be included. An important property of a grease is its solid nature; it has a yield value. This enables grease to retain itself in a bearing assembly without the aid of expensive seals, to provide its own seal against the ingress of moisture and dirt, and to remain on vertical surfaces and protect against moisture corrosion, especially during shut-down periods. [R.G.L.]

Lubrication

The use of lubricants to reduce friction and wear. Whenever two bodies in contact are made to slide relative to one another, a resistance to the motion is experienced. This resistance, called friction, is present in all machinery. Approximately 30% of the power of an automobile engine is consumed by friction. Friction and wear can be significantly reduced, and thus relative motion of machine parts made possible, by interposing a lubricant at the interface of the contacting surfaces; the machine elements designed to accomplish this are called bearings. Bearings can be lubricated by solids such as graphite or, more commonly, by liquids and gases. *See* ANTIFRICTION BEARING; FRICTION; GRAPHITE; LUBRICANT; SURFACE AND INTERFACIAL CHEMISTRY; WEAR.

Conventionally, lubrication has been divided into (1) fluid-film lubrication (hydrostatic, hydrodynamic, and elastohydrodynamic), where the sliding surfaces are separated by a relatively thick, continuous film of lubricant; and (2) boundary lubrication, where contact surface separation is but a few molecular layers and asperity contact is unavoidable.

Hydrostatic bearings. Hydrostatic films are created when a high-pressure lubricant is injected between opposing (parallel) surfaces (pad and runner), thereby separating them and preventing their coming into direct contact. Hydrostatic bearings require external pressurization. The film is 5–50 micrometers thick, depending on application. Though hydrostatic lubrication does not rely on relative motion of the surfaces, relative motion is permitted and can even be discontinuous. Figure 1 is a schematic of a hydrostatic bearing pad. To handle asymmetric loads, hydrostatic systems generally employ several evenly spaced pads. Hydrostatic bearings find application where relative positioning is of extreme importance. They are also applied where a low coefficient of friction at vanishing relative velocity is required.

Hydrodynamic bearings. Hydrodynamic bearings are self-acting. To create and maintain a load-carrying hydrodynamic film, it is necessary only that the bearing surfaces move relative to one another and ample lubricant is available. The surfaces must be inclined to form a clearance space in the shape of a wedge, which converges in the direction of relative motion. The lubricant film is then created as the lubricant is dragged into the clearance by the relative motion. This viscous action results in a pressure build-up within the film (Fig. 2). The fact that hydrodynamic bearings are self-generating and do not rely on auxiliary equipment makes these bearings very reliable. Hydrodynamic journal bearings and thrust bearings are designed to support radial and axial loads, respectively, on a rotating shaft.

Rolling contact bearings. Journal and thrust bearings are conformal bearings; that is, the opposing bearing surfaces conform in shape. Ball and roller bearings, also known as rolling contact bearings, are counterformal. Counterformal bearings always operate in the hydrodynamic mode, but because the contact area in these bearings is small the pressure attains high values, in the range of 1–3 gigapascals (10,000–30,000 atm). In consequence, the surfaces deform elastically and the lubricant viscosity increases by several orders of magnitude.

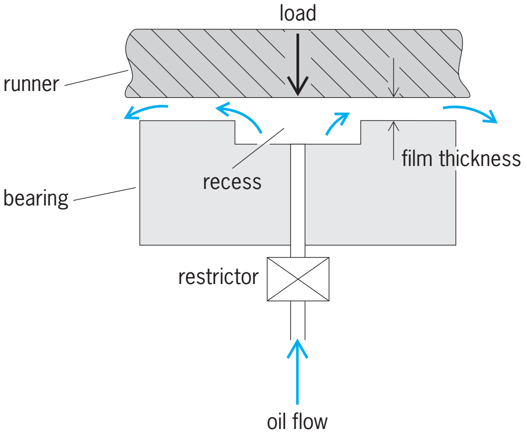


Fig. 1. Hydrostatic bearing pad.

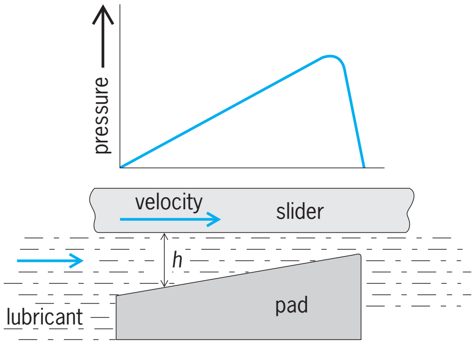

Fig. 2. Hydrodynamic film formation.

Lubricants. Today, mineral oils manufactured from petroleum are the most common liquid lubricants. The manufacturer of petroleum lubricants can choose from a wide variety of crude oils, and the choice is of great importance because the lubricating oil fraction of crude oils varies widely. *See* PETROLEUM; VISCOSITY. [A.Z.S.]

Lumber

Timber sawed or split into planks, boards, and similar products. Lumber can come in many forms, species, and types from a wide variety of commercial sources. Because most lumber is manufactured similarly and graded by standardized rules, it is fairly uniform throughout the United States. *See* WOOD PRODUCTS.

Lumber is manufactured from round logs primarily in rectangular shapes of different dimensions. Lumber length is recorded in actual dimensions. Width and thickness are traditionally recorded in nominal dimensions, which are somewhat more than actual dimensions. Lumber is classified by thickness into three categories: (1) board, lumber less than 38 mm (nominally 2 in.) thick; (2) dimension, lumber from 38 mm to, but not including, 114 mm (nominally 5 in.) thick; and (3) timber, lumber 114 mm (nominally 5 in.) or more in thickness in the least dimension. *See* LOGGING.

Lumber can be produced with either a rough or surfaced (dressed) finish. Rough-sawn lumber has surface imperfections caused by the primary sawing operations. Surfaced lumber is smoothed on either one or both sides and one or both edges.

In general, the grade of a piece of lumber is based on the number, character, and location of features that may lower the strength, durability, or utility value of the wood. Lumber grading can be divided into two main categories: remanufacture “shop grade” and structural “stress grade.” Sorting of lumber for remanufacture is based on visual inspection. The wood is designated shop grade on the proportion of defect-free or clear cuttings of a certain size that can be made from a piece of lumber. The larger volume and more frequent number of clear cuttings, the higher the grade. Pieces of lumber graded for structural uses are put into classes with similar mechanical properties called stress grades. Stress grades are characterized by (1) one or more sorting criteria, (2) a set of allowable properties for engineering design, and (3) a unique grade name. The allowable properties are inferred through visual grading criteria or are determined nondestructively by machine-grading criteria.

Visual grading is the oldest stress-grading method. It is based on the premise that mechanical properties of lumber differ from mechanical properties of clear wood. Growth characteristics, which affect properties and can be seen and judged by eye, are used to sort the lumber into stress grades. Typical visual sorting criteria include density, decay, proportion of heartwood and sapwood, slope of grain, knots, shake, checks and splits, wane, and pitch pockets.

Machine-graded lumber is evaluated by a machine using a nondestructive test followed by visual grading to evaluate certain characteristics that the machine cannot or may not properly evaluate. Machine-stress-rated (MSR), machine-evaluated (MEL), and E-rated lumber are three types of machine-graded lumber. Machine-graded lumber allows for better sorting of material for specific applications in engineered structures.

Clear, straight-grained lumber can be about 50% stronger when dry than when wet. For lumber containing knots, the increase in strength with decreasing moisture content is dependent on lumber quality. For timber, often no adjustment for moisture content is made because properties are assigned on the basis of wood in the green condition. *See* WOOD PRODUCTS; WOOD PROPERTIES. [D.E.Kr.]

Luminance The luminous intensity of any surface in a given direction per unit of projected area of the surface viewed from that direction. The International Commission on Illumination defines it as the quotient of the luminous intensity in the given direction of an infinitesimal element of the surface containing the point under consideration, by the orthogonally projected area of the element on a plane perpendicular to the given direction. Simply, it is the luminous intensity per unit area. Luminance is also called photometric brightness.

Since the candela is the unit of luminous intensity, the luminance, or photometric brightness, of a surface may be expressed in candelas/cm^2, candelas/in.^{2}, and so forth.

The stilb is a unit of luminance (photometric brightness) equal to 1 candela/cm^2. It is often used in Europe, but the practice in America is to use the term candela/cm^2 in its place.

The apostilb is another unit of luminance sometimes used in Europe. It is equal to the luminance of a perfectly diffusing surface emitting or diffusing light at the rate of 1 lumen/m^2. *See* LUMINOUS INTENSITY; PHOTOMETRY. [R.C.Pu.]

Luminescence Light emission that cannot be attributed merely to the temperature of the emitting body. Various types of luminescence are often distinguished according to the source of the energy which excites the emission. When the light energy emitted results from a chemical reaction, such as in the slow oxidation of phosphorus at ordinary temperatures, the emission is called chemiluminescence. When the luminescent chemical reaction occurs in a living system, such as in the glow of the firefly, the emission is called bioluminescence. In the foregoing two examples part of the energy of a chemical reaction is converted into light. There are also types of luminescence that are initiated by the flow of some form of energy into the body from the outside. According to the source of the exciting energy, these luminescences are designated as cathodoluminescence if the energy comes from electron bombardment; radioluminescence or roentgenoluminescence if the energy comes from x-rays or from γ-rays; photoluminescence if the energy comes from ultraviolet, visible, or infrared radiation; and electroluminescence if the energy comes from the application of an electric field. By attaching a suitable prefix to the word luminescence, similar designations may be coined to characterize luminescence excited by other agents. Since a given substance can frequently be made to luminesce by a number of different external exciting agents, and since the atomic and electronic phenomena that cause luminescence are basically the same regardless of the mode of excitation, the classification of luminescence phenomena into the foregoing categories is only a matter of convenience, not of fundamental distinction.

When a luminescent system provided with a special configuration is excited, or "pumped," with sufficient intensity of excitation to cause an excess of excited atoms over unexcited atoms (a so-called population inversion), it can produce laser action. (Laser is an acronym for light amplification by stimulated emission of radiation.) This laser emission is a coherent stimulated luminescence, in contrast to the incoherent spontaneous emission from most luminescent systems as they are ordinarily excited and used. *See* LASER; OPTICAL PUMPING.

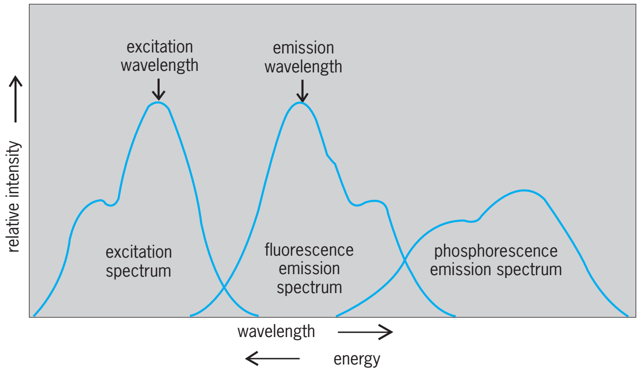
A second basis frequently used for characterizing luminescence is its persistence after the source of exciting energy is removed. Many substances continue to luminesce for extended periods after the exciting energy is shut off. The delayed light emission (afterglow) is generally called phosphorescence; the light emitted during the period of excitation is generally called fluorescence. In an exact sense, this classification, based on persistence of the afterglow, is not meaningful because it depends on the properties of the detector used to observe the luminescence. With appropriate instruments one can detect afterglows lasting on the order of a few thousandths of a microsecond, which would be imperceptible to the human eye. The characterization of such a luminescence, based on its persistence, as either fluorescence or phosphorescence would therefore depend upon whether the observation was made by eye or by instrumental means. These terms are nevertheless commonly used in the approximate sense defined here, and are convenient for many practical purposes. However, they can be given a more precise meaning. For example, fluorescence may be defined as a luminescence emission having an afterglow duration which is temperature-independent, while phosphorescence may be defined as a luminescence with an afterglow duration which becomes shorter with increasing temperature. *See* BIOLUMINESCENCE; CATHODOLUMINESCENCE; CHEMILUMINESCENCE; ELECTROLUMINESCENCE; FLUORESCENCE; PHOSPHORESCENCE; PHOTOLUMINESCENCE; THERMOLUMINESCENCE. [C.C.K.; J.H.S.]

Luminescence analysis Methods of chemical analysis in which analyte concentration is related to luminescence intensity or some other property of luminescence. Photoluminescence, particularly fluorescence, is the most widely used type of luminescence for chemical analysis. However, there are also important analytical applications of both chemiluminescence and bioluminescence.

Luminescence is light that accompanies the transition from an electronically excited atom or molecule to a lower energy state. The forms of luminescence are distinguished by the method used to produce the electronically excited species. When produced by absorption of incident radiation, the light emission is known as photoluminescence. Photoluminescence that is short-lived (10^{-8} s or less between excitation and emission) is known as fluorescence. Photoluminescence that is longer-lived (from 10^{-6} s all the way up to seconds) is known as phosphorescence. The reason for the difference in lifetime is that fluorescence involves an allowed, high-probability, transition while phosphorescence involves a forbidden, low-probability, transition. *See* FLUORESCENCE; LUMINESCENCE; PHOSPHORESCENCE; PHOTOLUMINESCENCE; SELECTION RULES (PHYSICS).

Chemiluminescence is observed when the electronically excited atom or molecule is formed as the product of a chemical reaction. If the light-producing reaction occurs in nature, such as the light emitted by fireflies, it is known as bioluminescence. *See* BIOLUMINESCENCE; CHEMILUMINESCENCE.

Photoluminescence excitation spectra are determined by measuring emission intensity at a fixed wavelength while varying the wavelength of the incident light used to produce the electronically excited species responsible for emission. The excitation spectrum is a measure of the efficiency of electronic excitation as a function of excitation wavelength. Photoluminescence emission spectra are determined by exciting at a fixed wavelength and varying the wavelength at which emission is observed. The illustration shows typical excitation and fluorescence and phosphorescence emission spectra for a molecule in solution. Between excitation and emission, electronically excited molecules normally lose some of their energy because of relaxation processes. As a consequence, the emission spectrum is at longer wavelengths,



Typical photoluminescence excitation and emission spectra for molecules in solution.

that is, at lower energy, than the excitation spectrum. Because the magnitude of the energy loss due to relaxation processes is greater for phosphorescence than for fluorescence, phosphorescence occurs at longer wavelengths than fluorescence. The spectra extend over a range of wavelengths, because in solution, molecules exist in a continuous distribution of vibrational and rotational energy levels. *See* ENERGY LEVEL (QUANTUM MECHANICS).

Observed luminescence intensities depend on three factors: (1) the number of electronically excited molecules or atoms produced by the excitation process; (2) the fraction of electronically excited molecules that emit light as they relax to a lower energy state; and (3) the fraction of the emitted luminescence that impinges on the detector and is measured. In the case of photoluminescence, the number of excited molecules is proportional to incident excitation intensity, the concentration of the luminescent species, and the efficiency with which the luminescence species absorbs the incident radiation. In the case of chemiluminescence and bioluminescence, the number of excited molecules depends on reactant concentrations and the efficiency with which the reaction pathway leads to production of the excited state. The dependence of intensity on concentration is the basis for chemical analysis based on luminescence.

By far the most important advantage of luminescence methods of chemical analysis is their ability to measure extremely low concentrations. This advantage arises because luminescence is measured relative to weak background signals. In contrast, methods based on the absorption of light require that a small difference between two large signals be measured. [W.R.Se.]

Luminous efficacy There are three ways this term can be used: (1) The luminous efficacy of a source of light is the quotient of the total luminous flux emitted divided by the total lamp power input. Light is visually evaluated radiant energy. Luminous flux is the time rate of flow of light. Luminous efficacy is expressed in lumens per watt. (2) The luminous efficacy of radiant power is the quotient of the total luminous flux emitted divided by the total radiant power emitted. This is always somewhat larger for a particular lamp than the previous measure, since not all the input power is transformed into radiant power. (3) The spectral luminous efficacy of radiant power is the quotient of the luminous flux at a given wavelength of light divided by the radiant power at that wavelength. A plot of this quotient versus wavelength displays the spectral response of the human visual system. It is, of course, zero for all wavelengths outside the range from 380 to 760 nanometers. It rises to a maximum near the center of this range. Both the value and the wavelength of this maximum depend on the degree of dark adaptation present. However, an accepted value of 683 lumens per watt maximum at 555 nanometers represents a standard observer in a light-adapted condition. *See* ILLUMINATION; LUMINOUS EFFICIENCY; LUMINOUS FLUX; PHOTOMETRY. [G.A.Ho.]

Luminous efficiency Visual efficacy of visible radiation, a function of the spectral distribution of the source radiation in accordance with the "spectral luminous efficiency curve," usually for the light-adapted eye or photopic vision, or in some instances for the dark-adapted eye or scotopic vision.

The spectral luminous efficiency of radiant flux is the ratio of luminous efficacy for a given wavelength to the value of maximum luminous efficacy. It is a dimensionless ratio. *See* ILLUMINATION; LUMINOUS EFFICACY; PHOTOMETRY. [G.A.Ho.]

Luminous energy The radiant energy in the visible region or quantity of light. It is in the form of electromagnetic waves, and since the visible region is commonly taken as extending 380–760 nanometers in wavelength, the luminous energy is contained within that region. It is equal to the time integral of the production of the luminous flux. *See* PHOTOMETRY. [R.C.Pu.]

Luminous flux The time rate of flow of light. It is radiant flux in the form of electromagnetic waves which affects the eye or, more strictly, the time rate of flow of radiant energy evaluated according to its capacity to produce visual sensation. The visible spectrum is ordinarily considered to extend from 380 to 760 nanometers in wavelength; therefore, luminous flux is radiant flux in that region of the electromagnetic spectrum. The unit of measure of luminous flux is the lumen. *See* PHOTOMETRY. [R.C.Pu.]

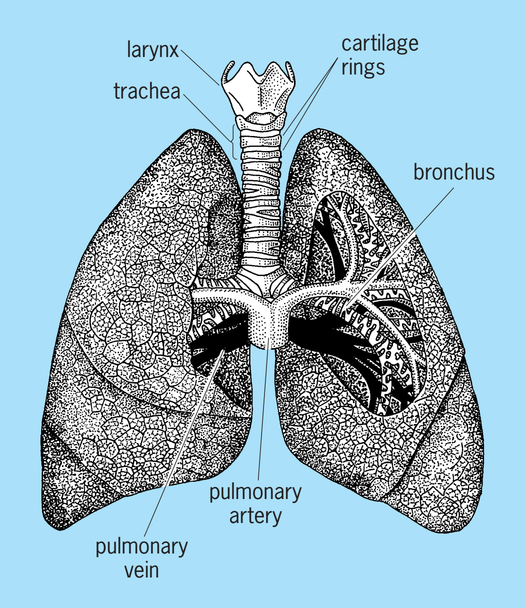
Luminous intensity The solid angular luminous flux density in a given direction from a light source. It may be considered as the luminous flux on a small surface normal to the given direction, divided by the solid angle (in steradians) which the surface subtends at the source of light. Since the apex of a solid angle is a point, this concept applies exactly only to a point source. The size of the source, however, is often extremely small when compared with the distance from which it is observed, so in practice the luminous flux coming from such a source may be taken as coming from a point. *See* CANDLEPOWER; PHOTOMETRY. [R.C.Pu.]

Luminous paint A type of paint that glows in the dark. Luminous paints may be either of the self-luminous type (energized by a radioactive salt) or of the type that requires preexcitation by an outside energy source such as light. Both types are made by incorporating luminescent material into the paint formulation. *See* LUMINESCENCE; PAINT. [C.C.K.; J.H.S.]

Lung Paired, air-filled respiratory sacs, usually in the anterior or anteroventral part of the trunk of most tetrapods. They lie within the coelom and are covered by peritoneum. In mammals they are within special chambers of the coelom known as pleural cavities and the peritoneum is termed pleura.

Amphibian lungs are often simple sacs, with only small ridges on the internal walls. In higher forms the lungs become more and more subdivided internally, thus increasing greatly the surface areas across which the respiratory exchange takes place. However, even in many reptiles the lungs may be quite simple. Birds have especially complex lungs with a highly differentiated system of tubes leading into and through them to the air sacs which are contained in many parts of the bird's body. Mammalian lungs are simpler, but in them the internal subdivision into tiny sacs or alveoli is extreme; there may be over 350,000,000 of them in one human lung.

In humans the two lungs lie within the chest, separated by the heart and mediastinum. The right lung has three lobes and the left lung two. A bronchus, an artery, and a vein enter each lung medially at the hilum; each branches again and again as it enters the lobules and smaller divisions of the lungs (see illustration). The terminal airways or bronchioles expand into small clusters of grapelike air cells, the alveoli. The alveolar walls consist of a single layer of epithelium and collectively present a huge surface.



The human lung. (*After T. I. Storer and R. L. Usinger, General Zoology, 4th ed., McGraw-Hill, 1965*)

A small network of blood capillaries in the walls of the alveoli affords surfaces for the actual exchange of gases. *See* RESPIRATION; RESPIRATORY SYSTEM. [T.S.P.]

Lupine A cool-season legume with an upright stem, leaves divided into several digitate leaflets, and terminal racemes of pea-shaped blossoms. Three species, yellow, blue, and white, each named for the color of its blossoms, are cultivated as field crops; several hybrids are grown as ornamentals; and many species occur as wild plants. The yellow crop varieties are usually the earliest and smallest, the whites latest and largest. Field crop lupines have been grown in Europe since early Roman times as a soil-improving crop. The older varieties could not be used as forage since the plants contained a bitter, water-soluble, toxic alkaloid. However, since 1912, plant breeders have developed "sweet" varieties with only traces of alkaloid. The ornamental lupines are perennials unsuited to areas with hot summers. *See* BREEDING (PLANT); COVER CROPS; LEGUME; LEGUME FORAGES. [P.T.]

Lutetium A chemical element, Lu, atomic number 71, atomic weight 174.97, a very rare metal and the heaviest member of the rare-earth group. The naturally occurring element is made up of the stable isotope ^{175}Lu, 97.41%, and the long-life β-emitter ^{176}Lu with a half-life of 2.1×10^{10} years. *See* PERIODIC TABLE.

Lutetium, along with yttrium and lanthanum, is of interest to scientists studying magnetism. All of these elements form trivalent ions with only subshells which have been completed, so they have no unpaired electrons to contribute to the magnetism. Their radii with regard to the other rare-earth ions or metals are very similar so they form at almost all compositions either solid solutions or mixed crystals with the strongly magnetic rare-earth elements. Therefore, the scientist can dilute the magnetically active rare earths in a continuous manner without changing appreciably the crystal environment. *See* MAGNETOCHEMISTRY; RARE-EARTH ELEMENTS. [F.H.Sp.]

Lychee The plant *Litchi chinensis*, also called litchi, a member of the soapberry family (Sapindaceae). The fruit is a one-seeded berry. The thin, leathery, rough shell or pericarp of the ripe fruit is bright red in most varieties. Beneath the shell, completely surrounding the seed, is the edible aril or pulp.

It is a native of southern China, where it has been cultivated for more than 2000 years. It is grown in India, Union of South Africa, Hawaii, Burma, Madagascar, West Indies, Brazil, Honduras, Japan, Australia, and the southern United States. *See* SAPINDALES. [P.D.St/E.L.C.]

Lychniscosa An order of the subclass Hexasterophora in the class Hexactinellida. The parenchymal megascleres of these sponges are united to form a rigid framework. Examples of this order are *Aulocystis* and *Dactylocalyx*. *See* HEXACTINELLIDA; HEXASTEROPHORA. [W.D.H.]

Lycophyta A division (formerly Lycopodiophyta) of the subkingdom Embryobionta which represents one of two main lineages that evolved during the Early Devonian from the earliest land plants to develop vascular tissue and multiple sporangia. Integration of living and fossil taxa has allowed tentative reconstruction of the evolutionary history of the lycophyte group, which is generally regarded as monophyletic (includes all the descendants of a single putative ancestor). The division Lycophyta contains two classes: the extinct Zosterophyllopsida (zosterophylls) and the Lycopsida (club-mosses), which contains 10 extant genera. *See* LYCOPSIDA; ZOSTEROPHYLLOPSIDA.

Living lycophytes are confined to the Lycopsida and are of far less phenotypic diversity and ecological significance than the fossils; most are small-bodied rhizomatous herbs or tuberous pseudoherbs occupying moist niches of low interspecific competition. Their economic significance is confined to various industrial applications of the abundant, small, and unusually uniformly sized spores of *Lycopodium*. The extant genera represent perhaps half of the major lycopsid groups known in the fossil record.

The lycophytes have a small gametophyte that is morphologically distinct from, and physically independent of, the larger sporophyte. Gametophytes are either supraterranean and photosynthetic or subterranean and saprophytic. The primitive growth habit is unipolar; rhizomes periodically generate adventitious roots and aerial branches. Vegetative branches are small, nonwoody, dichotomously branched, and either naked or, more commonly, scattered with cortical projections. The primary xylem undergoes external maturation. Other key features of the Lycophyta are unvascularized, kidney-shaped eusporangia that are positioned laterally rather than terminating axes. The spores are released through distal lateral dehiscence slits.

The evolutionary history of the lycophytes generally is documented by increases in body size, vegetative complexity, and reproductive sophistication. [R.M.Ba.; W.A.DiM.]

Lycopodiales An order of the class Lycopsida (club-mosses) that is evolutionarily positioned between two extinct orders. The Lycopodiales are more advanced than the Asteroxylales because their sporangia are unequivocally positioned on the upper surface of modified leaves, but less advanced than the Protolepidodendrales because they lack a uniquely lycopsid feature termed the ligule. All have steles with metaxylem toward the center of the axis, but otherwise show considerable variation. All are perennial nonwoody herbs. *See* ASTEROXYLALES; PROTOLEPIDODENDRALES.

The fossil record of lycopodialeans begins with *Baragwanathia*. Its earliest occurrence, in Australia, has been controversially dated as Late Silurian or Early Devonian. Unlike most other lycopsid orders, the range of variation observed among the fossils is well reflected by the extant genera. Eight genera (of approximately 350 extant species) are recognized: the widespread *Huperzia, Phlegmariurus, Lycopodium, Diphasiastrum, Pseudolycopodiella, Lycopodiella*, and *Palhinhaea*, together with the enigmatic antipodean endemic *Phylloglossum*.

Huperzia and *Phlegmariurus* are the most primitive of the living genera. They have non-rhizomatous aerial axes with undivided, star-shaped actinosteles. Sporangia are simple in construction and positioned on sporophylls that resemble leaves;

they do not form cones. In contrast, the remainder of the genera have rhizomatous growth and possess thin-walled sporangia and sporophylls that are aggregated into cones. *Lycopodium* and *Diphasiastrum* gametophytes share an annular meristem, and the stem vascular system is partially dissected into a plectostele. In *Pseudolycopodiella, Lycopodiella*, and *Palhinhaea*, the vascular system is further dissected into an annulus of apparently discrete but actually interconnected strands, and axial branching is more complex. Because gametophytes are lobed and occur on the soil surface, they are able to photosynthesize, thus reducing their dependence for nutrition on symbiotic mycorrhizal fungi. Also, the deciduous sporophytes of *Lycopodiella* and *Palhinhaea* develop from a protocorm and produce globose sporangia.

Phlegmariurus species grow hanging from other plants; *Pseudolycopodiella* and *Lycopodiella* are semiaquatics. The remaining genera are dominantly terrestrial. Lycopodialeans tend to prefer habitats where interspecific competition is low; few clubmoss species form a major proportion of the biomass in their preferred communities. Nonetheless, together they have a global distribution. Species-level diversity is greatest in the tropics, although a few species reach the Arctic Circle.

Lycopodialeans have a large and long-lived diploid sporophyte, which alternates with the wholly physiologically independent, smaller, and generally shorter-lived haploid gametophyte. The sporophyte produces spores that are released from the sporangium and germinate to produce gametophytes, which in most genera are subterranean and rely for nutrition on mycorrhizal fungi. *See* LYCOPHYTA; LYCOPSIDA. [R.M.Ba.; W.A.DiM.]

Lycopsida

A class (formerly Lycopodiopsida) of the division Lycophyta. It probably evolved in the Early Devonian from a zosterophyllopsid ancester; all six constituent taxonomic orders had probably evolved by the end of the Devonian. *See* LYCOPHYTA; ZOSTEROPHYLLOPSIDA.

Since this early and rapid radiation, lycopsids have always been globally distributed, with peak diversity in the tropics. In terms of both species diversity and biomass, lycophytes dominated many Devonian and Carboniferous plant communities, including the classic coal-swamp forests. Living lycopsids are of far less phenotypic diversity and ecological significance than the fossils; most are small-bodied rhizomatous perennial herbs or tuberous pseudoherbs occupying moist niches of low interspecific competition. Many are polyploids.

Extant genera are relatively evenly distributed from a phylogenetic viewpoint. Fourteen representative genera of lycopsids belong to six orders, which either lack living species (Asteroxylales, Protolepidodendrales, Lepidodendrales) or possess them (Lycopodiales, Selaginellales, Isoetales). *See* ASTEROXYLALES; ISOETALES; LEPIDODENDRALES; LYCOPODIALES; PROTOLEPIDODENDRALES; SELAGINELLALES. [R.M.Ba.; W.A.DiM.]

Lyme disease

A multisystem illness caused by the tick-borne spirochete *Borrelia burgdorferi*. The disease, also known as Lyme borreliosis, generally begins with a unique expanding skin lesion, erythema migrans, which is often accompanied by symptoms resembling those of influenza or meningitis. During the weeks or months following the tick bite, some individuals may develop cardiac and neurological abnormalities, particularly meningitis or inflammation of the cranial or peripheral nerves. If the disease is untreated, intermittent or chronic arthritis and progressive encephalomyelitis may develop months or years after primary infection. *See* NERVOUS SYSTEM DISORDERS.

The causative agent, *B. burgdorferi*, is a helically shaped bacterium with dimensions of 0.18–0.25 by 4–30 micrometers. Once thought to be limited to the European continent, Lyme borreliosis and related disorders are now known to occur also in North America, Russia, Japan, China, Australia, and Africa, where *B. burgdorferi* is maintained and transmitted by ticks of the genus *Ixodes*, namely *I. dammini, I. pacificus*, and possibly *I. scapularis* in the United States, *I. ricinus* in Europe, and *I. persulcatus* in Asia. Reports of Lyme disease in areas where neither *I. dammini* nor *I. pacificus* is present suggest that other species of ticks or possibly other bloodsucking arthropods such as biting flies or fleas may be involved in maintaining and transmitting the spirochetes. *See* IXODIDES.

All stages of Lyme borreliosis may respond to antibiotic therapy. Early treatment with oral tetracycline, doxycycline, penicillin, amoxicillin, or erythromycin can shorten the duration of symptoms and prevent later disease. *See* ANTIBIOTIC.

Prevention and control of Lyme borreliosis must be directed toward reduction of the tick population. This can be accomplished through reducing the population of animals that serve as hosts for the adult ticks, elimination of rodents that are not only the preferred hosts but also the source for infecting immature ticks with *B. burgdorferi*, and application of tick-killing agents to vegetation in infested areas. Personal use of effective tick repellents and toxins is also recommended. *See* INFECTIOUS DISEASE; INSECTICIDE.

Lyme disease affects not only humans but also domestic animals such as dogs, horses, and cattle that serve as hosts for the tick vectors. Animals affected show migratory, intermittent arthritis in some joints similar to that observed in humans. [W.Ba.; J.J.Ka.]

Lymphatic system

A system of vessels in the vertebrate body, beginning in a network of exceedingly thin-walled capillaries in almost all the organs and tissues except the brain and bones. This network is drained by larger channels, mostly coursing along the veins and eventually joining to form a large vessel, the thoracic duct, which runs beside the spinal column to enter the left subclavian vein at the base of the neck. The lymph fluid originates in the tissue spaces by filtration from the blood capillaries. While in the lymphatic capillaries it is clear and watery. However, at intervals along the larger lymphatic vessels, the lymph passes through spongelike lymph nodes, where it receives great numbers of cells, the lymphocytes, and becomes turbid.

The lymph nodes of mammals vary in number, size, form, and structure in different species. The amount of connective tissue of the lymph nodes, that is, the degree of development of the capsule and trabeculae, also varies in different mammals. Other lymphoid organs include the tonsils, thymus gland, and spleen, and in certain classes and groups of animals, structures which are confined to such groups, for instance, the bursa of Fabricius in the birds, a diverticulum from the lower end of the alimentary canal. *See* SPLEEN; THYMUS GLAND; TONSIL.

The functions of the lymphatics are to remove particulate materials such as molecular proteins and bacteria from the tissues; to transport fat from the intestine to the blood; to supply the blood with lymphocytes; to remove excess fluid; also to return to the bloodstream the protein which has escaped from the blood capillaries. Basically, the composition of lymph closely resembles that of the plasma; lymph contains all of the types of protein found in plasma, but in lower concentration. The composition of lymph varies to some extent from one part of the body to another. Thus, the lymph from the liver contains more protein than that from the skin.

The lymph nodes serve as filtering-out places for foreign particles, including microorganisms, because the lymph comes into intimate contact with the many phagocytic cells of the sinusoids. These macrophages are of both the fixed and free wandering types. In addition to the phagocytic function, lymphoid tissue produces antibodies, although the actual process of antibody formation is not well understood. *See* CELLULAR IMMUNOLOGY; PHAGOCYTOSIS. [W.An.]

Lymphoma

Any of a group of malignant neoplasms derived from cells endogenous to lymphoid tissue. Lymphomas are grouped into two major categories: Hodgkin's disease and non-Hodgkin's lymphomas. Lymphomas usually originate in the lymph nodes located throughout the body, but they can arise from lymphoid tissue that does not form distinct nodes, such as that in the gastrointestinal tract or lung. Determination of the specific variety of Hodgkin's disease or non-Hodgkin's lymphoma was formerly based on the appearance of the cells when examined under a light microscope. Identification now relies on the nature of the cells with respect to certain substances (antigens) that they have on their surface or within their cytoplasm. For clinical purposes, lymphomas are categorized into three grades, low, intermediate, and high, with low-grade lymphomas having the best prognosis. *See* Hodgkin's disease.

The etiology of most lymphomas is unknown. In experimental and domestic animals, viruses can cause lymphomas. Burkitt's lymphoma, a type of lymphoma that is rare in the United States but relatively common in children of central Africa, is thought to be caused by Epstein-Barr virus, a member of the herpes virus group. A form of T-cell lymphoma that has been identified in southern Japan has been attributed to a retrovirus referred to as human T-cell lymphoma-leukemia virus type 1 (HTLV-1). *See* Epstein-Barr virus; Retrovirus.

Patients with lymphomas may have painless swelling of various lymph nodes, such as those in the neck or near the armpit. Some patients, especially those with Hodgkin's disease, are referred to as B symptoms (fever, malaise, and weight loss). If the lymphoma originates in lymphoid tissue outside the lymph nodes, abdominal pain will signal lymphoma of the gastrointestinal tract and a cough will point to lymphoma of the lung.

Lymph nodes involved by lymphoma are characteristically enlarged. They may be firm and have a consistency resembling fish flesh. In rare cases they are rock hard and they may show areas of cellular death (necrosis).

By using modern immunologic techniques, most lymphomas can be identified as B-cell, T-cell, or M-cell type; about 90% of lymphomas are of B-lymphocyte origin. A T-cell lymphoma that occurs in the skin, referred to as mycosis fungoides, is a lymphoma of a specific subtype of lymphocyte labeled a T-helper/inducer lymphocyte. It is that subtype that is depleted in patients with acquired immune deficiency syndrome (AIDS). *See* Acquired immune deficiency syndrome (AIDS); Cellular immunology; Immunology.

Most diagnoses of lymphoma are made by surgical removal of a lymph node. Once a diagnosis of lymphoma is established, the patient usually must undergo a series of staging studies. These include a liver-spleen scan to determine if those organs are involved as well as a bone marrow biopsy to check for the presence of malignant cells. *See* Oncology.

The treatment of lymphomas depends on the type of lymphoma diagnosed. Lymphomas in the low-grade group are usually not treated, since treatment does not increase life expectancy. Patients who have Hodgkin's disease or who have intermediate or high-grade non-Hodgkin's lymphoma are usually treated with chemotherapy with or without concurrent radiation. Most cases of Hodgkin's disease and more than half the cases of intermediate and high-grade non-Hodgkin's lymphomas are potentially curable. Persons with low-grade non-Hodgkin's lymphomas usually have a life expectancy of 7–10 years, although some live considerably longer. Treatment protocols are now being developed for the low-grade lymphomas in the hope of increasing life expectancy. *See* Chemotherapy; Lymphatic system. [S.P.H.]

Lyophilization Solvent removal from the frozen state by sublimation; commonly referred to as freeze-drying. Lyophilization is accomplished by freezing the material to be dried below its eutectic point and then providing the latent heat of sublimation. Precise control of heat input permits drying from the frozen state without product melt-back. In practical application, the process is accelerated and more precisely controlled under reduced pressure conditions. [S.C.T.]

Lyra The Lyre, in astronomy, a summer constellation, small but important. Lyra has a first-magnitude star, Vega, a navigational star and the most brilliant star in this part of the sky. Vega forms, with two faint stars to the east, an almost perfect equilateral triangle. The southern one in turn forms, with three brighter stars to the south, an approximate parallelogram. The resulting overall figure resembles a tortoise more than a stringed musical instrument. However, according to legend, Mercury made the first lyre from a turtleshell by placing strings across it. Hence the two different representations are not incompatible. *See* Constellation. [C.-S.Y.]

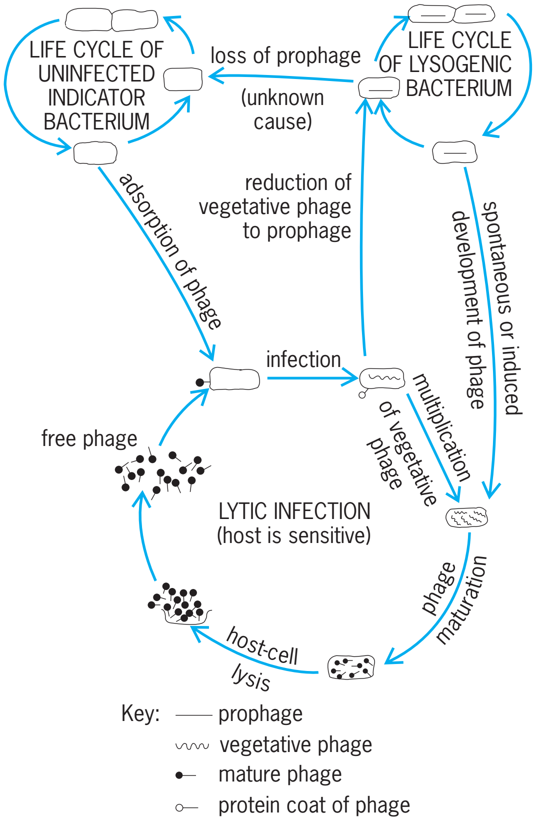
Lysenkoism A school of pseudoscience that flourished in the Soviet Union from the early 1930s to the mid-1960s, in violent opposition to traditional biology. The founder was T. D. Lysenko. He proclaimed a revolutionary fusion of agronomy and biological science, and therefore called his creation agrobiology, not Lysenkoism, the term that was used by his opponents.

A coherent outline of Lysenko's doctrines is hardly possible. The inheritance of acquired characters is often considered his central doctrine, though he came to it belatedly, as an offshoot of his original concept: "vernalization," or *iarovizatsiia*, a word that he coined. At first he used the word to describe the transformation of winter-habited wheat into spring habit as a result of moistening and chilling the seed before planting. He denounced the specialists who told him that the phenomenon had been observed and studied long before he put a new name on it, and he went on to extend the new term to almost any kind of seed treatment, and also to a stage in plant development that he claimed to have discovered. Lysenko came into conflict with scientific plant breeders and geneticists when he applied his concept of vernalization to hybridization and the selection of improved varieties. He came to endorse some of the crudest versions of the ancient belief in the inheritance of acquired characters. For example, he declared that domesticated plants are transformed into weeds by the hostile environment of poorly tended fields. *See* Genetics; Organic evolution; Vernalization. [D.J.]

Lysin A term used to describe substances that will disrupt a cell, with the release of some of its constituents. Unless the damage is minor, this action leads to the death of the cell. Lysins vary in the range of host species whose cells they will attack and in their requirements for accessory factors for lysis; the immune lysins are strictest in their requirements. Erythrocytes are lysed by a wide variety of chemicals, including water and hypertonic salt solutions, which displace the osmotic pressure from that of isotonicity. They are also susceptible to surface-active substances, such as saponin. Many bacteria, such as the staphylococcus and the streptococcus, elaborate one or more hemolysins that will lyse erythrocytes from certain, although not all, species of animals. *See* Lytic reaction. [H.P.T.]

Lysogeny Almost all strains of bacteria are lysogenic; that is, they have the capacity on rare occasions to lyse with the liberation of particles of bacteriophage (see illustration). Such particles can be detected by their ability to form plaques (colonies of bacteriophage) on lawns of sensitive (indicator) bacteria. The genetic determinant of the capacity of lysogenic bacteria to produce bacteriophage is a repressed phage genome (provirus) which exists in the bacterium in one of two states: (1) integrated into the bacterial chromosome (most cases), or (2) occupying some extra-chromosomal location (rare cases).

Bacteriophages which have the potential to exist as provirus are called temperate phages. When the provirus is integrated into the bacterial genome, it is called prophage. When the germinal substance (deoxyribonucleic acid or deoxyribonucleoprotein) of certain temperate phages enters a sensitive bacterium, the outcome may be death (lysis) for the bacterium as a result of phage multiplication, or it may result in the integration of the phage nucleic acid into the host genome (as a prophage), with the formation of a stable lysogenic bacterium. The lysogenic strain is designated by the name of the sensitive strain followed, in



Life cycles of phage and bacterial host. (*After E. Jawetz, J. L. Melnick, and E. A. Adelberg, Review of Medical Microbiology, 2d ed., Lange, 1956*)

parentheses, by the strain of lysogenizing phage, for example, *Escherichia coli* (λ). Such a bacterium differs from its nonlysogenic ancestor in one very special way: It is immune to lysis by phage homologous to its carried prophage. *See* BACTERIOPHAGE. [L.B.]

Lysorophia An order of elongated, swimming, and burrowing extinct lepospondylous amphibians. The single family Lysorophidae is best known from the upper Carboniferous and lower Permian genus *Lysorophus*. Fossils of this animal commonly are found in clusters of 100 or more individuals, which represent the burrowing, estivating, and possibly reproductive phases of the life cycle.

Body lengths of individuals found in these clusters range from about 3 to 30 in. (7.5 to 75 cm) and appear to represent different growth stages. The trunk consisted of about 100 vertebrae and was followed by a short flattened tail of about 15 more. Ribs were stout, long, and recurved, giving the trunk a robust snakelike appearance. Limbs were vestigial. The skull was small relative to the trunk. The jaws were set with a small number of sharp, conical teeth. Large branchial elements were present, suggesting the presence of external gills.

The closest living counterpart of *Lysorophus* is *Amphiuma*, a predaceous, aquatic urodele. Like *Amphiuma*, *Lysorophus* probably fed on small vertebrates and invertebrates, but the small gape of its mouth likely limited prey size severely. *Lysorophus* lived in areas subject to strong seasonality, to which its habit of estivation was an adaptation. *See* AMPHIBIA; LEPOSPONDYLI. [E.C.O.]

Lysosome A digestive structure found within virtually all types of animal cells. Lysosome sizes, microscopic appearances, and other properties vary among different cell types and circumstances owing, in part, to differences in their functions and states. Typical lysosomes are roughly spherical or elongate bodies with largest dimensions of 0.1–1 micrometer or greater; tens to hundreds are present in a single cell.

Each lysosome is bounded by a membrane and contains several dozen different species of digestive enzymes, each of which can sever particular chemical bonds found in natural materials. Most lysosomal enzymes function best in an acid environment. This acidification is accomplished by a proton pump, built into the membrane surrounding the lysosome, which effects the transport of hydrogen ions into the lysosomes. *See* CELL MEMBRANES; ENZYME; ION TRANSPORT.

Lysosomes digest materials taken into the cell from the outside (a process known as heterophagy) as well as other materials that originate in the cell's own cytoplasm (autophagy). The materials to be digested are ultimately incorporated into the same membrane-bounded compartments as the lysosomal enzymes. Selective degradative products can pass out of the lysosome by crossing the membrane, but the enzymes cannot. This sequestration, which protects the cell, persists because the admixture of the enzymes and the materials to digest takes place through fusion of membrane-bounded compartments.

In heterophagy, the cell takes up particles or molecules by the process of endocytosis, engulfing them in membrane-bounded vesicles or vacuoles that are formed at the cell surface. The endocytosed material enters lysosomes via intermediate membrane-bounded compartments known as endosomes. In higher animals, heterophagy is most prominently used by leukocytes and macrophages. These specialized cells endocytose invasive microorganisms and use endocytosis in clearing debris and disposing of dead or senescent cells. *See* CELL SENESCENCE AND DEATH; ENDOCYTOSIS; PHAGOCYTOSIS.

In autophagy, cells segregate regions of their own cytoplasm within compartments that come to be bounded by single membranes and to receive lysosomal enzymes. Autophagic lysosomes take part in the remodeling of cells as part of the processes of development and during stressful circumstances. They also participate, along with nonlysosomal enzymes and heterophagic lysosomes, in normal turnover of the body's constituents—the balanced synthesis and destruction through which most molecules of most cells are replaced by new molecules.

Genetic defects in lysosomal enzymes and related proteins are known to be associated with a large number of rare disorders in humans and animals (such as Tay-Sachs disease and Niemann-Pick disease type C). Defective lysosomal function leads to storage of particular classes of molecules that cannot be degraded and, in long-lived cells such as neurons, to complex pathogenic cascades with widespread impact on endosomal-lysosomal function, membrane trafficking, and signal transduction. Such disorders are most often fatal. Lysosomes or prelysosomal structures also have been "adopted" as intracellular homes by certain pathogenic microorganisms that avoid or survive the attacks of the lysosomal system. Some strains of viruses, and toxins such as the one responsible for diphtheria, may use endosomes as their route of entry into the cell, penetrating through the endosomal membrane into the surrounding cytoplasm. [E.Ho.; S.U.W.]

Lysozyme An enyme that was first identified and named by Alexander Fleming, who recognized its bacteriolytic properties. It has been designated muramidase, since it is known to facilitate the hydrolysis of a β-1-4-glycosidic bond between N-acetylglucosamine and N-acetylmuramic acid in bacterial cell walls; it also hydrolyzes similar glycosidic bonds in fragments of chitin. The most detailed studies have been performed on hen egg-white lysozyme, because this product is readily available. However, enzymes possessing lysozyme activity have been found in bacteria, bacteriophages, and plants and in human leukocytes, nasal secretions, saliva, and tears. The three-dimensional structure of the protein has been defined by x-ray crystallography. Additional data are available for the amino acid sequence of human lysozyme and also for a bacteriophage lysozyme. These results have given rise to speculation concerning the origin of the lysozyme gene during evolution.

Certain enzyme functions appear to be widely distributed in nature. The amino acid sequences of proteins possessing these functions reflect changes that have occurred in the course of evolution. The structures of lysozymes from three sources, distant in evolution, have been carefully examined. Hen egg lysozyme has no structural elements in common with bacteriophage lysozyme. Thus it must be concluded that these two enzymes emerged in evolution completely independent of each other. Preliminary studies of the structure of human lysozyme reveal considerable similarity to the structure of hen egg lysozyme. In fact, the resemblance is so great that it can be concluded that these proteins evolved from the same gene and have an essentially identical mechanism of action.

The amino acid composition of α-lactalbumin, a protein in cow's milk, is quite similar to that of hen egg lysozyme; nearly half of the amino acid positions in these two proteins are identical. It is postulated from a comparison of the amino acid sequences of hen egg lysozyme, human lysozyme, and α-lactalbumin that a "deletion" occurred during evolution in the α-lactalbumin gene with a resulting loss of information for two amino acids near position 13. In addition, positions 10, 12, and 19 in human lysozyme and α-lactalbumin are identical, so it is possible to see remnants of a common ancestral gene in all three proteins. These data illustrate the manner in which amino acid sequence information is being used as a molecular reflection of the paths of evolution. *See* ENZYME; PROTEINS, EVOLUTION OF.

[R.E.Ca.]

Lyssacinosa An order of the subclass Hexasterophora in the class Hexactinellida. In these sponges the parenchymal megascleres are typically free and unconnected but are sometimes secondarily united. Asconema, Euplectella, Rossella, and Rhabdocalyptus are examples of this order. *See* HEXACTINELLIDA; HEXASTEROPHORA.

[W.D.H.]

Lytic infection Infection of a bacterium by a bacteriophage with subsequent production of more phage particles and lysis, or dissolution, of the cell. The viruses responsible are commonly called virulent phages. Lytic infection is one of the two major bacteriophage-bacterium relationships, the other being lysogenic infection. *See* BACTERIOPHAGE; LYSOGENY.

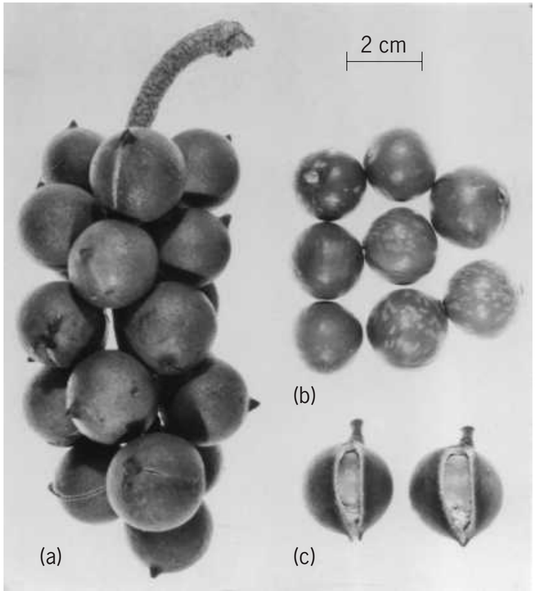
[P.B.C.]

Lytic reaction A term used in serology to describe a reaction that leads to the disruption or lysis of a cell. The best example is the lysis of sheep red blood cells by specific antibody and complement in the presence of Ca^{2+} by (calcium ion) and Mg^{2+} (magnesium ion), a reaction that forms the indicator system of the standard Wassermann test for syphilis, as well as other complement-fixation reactions. In this example lysis results in the release of cellular hemoglobin into the medium; the reaction may be followed by visual or instrumental estimation of the decreased cell turbidity or the increased color of the medium due to the free hemoglobin. The initiation of lysis by complement can apparently proceed after the attachment of only one molecule of IgM or two molecules of IgG antibody to the red blood cell. IgM and IgG are both immunoglobulins. *See* ANTIBODY; COMPLEMENT; COMPLEMENT-FIXATION TEST; SEROLOGY.

[H.P.T.]

M

Macadamia nut The fruit of a tropical evergreen tree, *Macadamia ternifolia*, native to Queensland and New South Wales and now grown commercially in Australia and Hawaii. The trees bear many small white or pinkish flowers in drooping racemes, each of which may mature from 1 to 20 fruits. These consist of a leathery outer husk (pericarp) which splits along one side at maturity, freeing the very hard-shelled, nearly round seed or nut. Two types of nuts are recognized, the most important commercially having a smooth shell and the other having a rough shell and sometimes referred to another species, *M. integrifolia* (see illustration). [L.H.MacD.]



Macadamia integrifolia. (*a*) Mature nuts. (*b*) Nuts without husks. (*c*) Nuts in husk showing method of dehiscence. (*After R. A. Jaynes, ed., Handbook of North American Nut Tress, Humphrey Press, 1969*)

Mach number In the flow of a fluid, the ratio of the flow velocity, V, at a given point in the flow to the local speed of sound, a, at that same point. That is, the Mach number, M, is defined as V/a. In a flowfield where the properties vary in time and/or space, the local value of M will also vary in time and/or space. In aeronautics, Mach number is frequently used to denote the ratio of the airspeed of an aircraft to the speed of sound in the freestream far ahead of the aircraft; this is called the freestream Mach number. The Mach number is a convenient index used to define the following flow regimes: (1) subsonic, where M is less than 1 everywhere throughout the flow; (2) supersonic, where M is greater than 1 everywhere throughout the flow; (3) transonic, where the flow is composed of mixed regions of locally subsonic and supersonic flows, all with local Mach numbers near 1, typically between 0.8 and 1.2; and (4) hypersonic, where (by arbitrary definition) M is 5 or greater.

Perhaps the most important physical aspect of Mach number is in the completely different ways that disturbances propagate in subsonic flow compared to that in a supersonic flow. Shock waves are a ubiquitous aspect of supersonic flows. *See* Compressible flow; Shock wave; Sonic boom; Supersonic flight. [J.D.A.]

Machine A combination of rigid or resistant bodies having definite motions and capable of performing useful work. The term mechanism is closely related but applies only to the physical arrangement that provides for the definite motions of the parts of a machine. For example, a wristwatch is a mechanism, but it does no useful work and thus is not a machine. Machines vary widely in appearance, function, and complexity from the simple hand-operated paper punch to the ocean liner, which is itself composed of many simple and complex machines. *See* Machinery; Simple machine. [R.M.Ph.]

Machine key Generally, a device used to prevent relative rotation of a shaft and the member to which it is connected, such as the hub of a gear, pulley, or crank. Many types of keys (see illustration) are available, and the choice in any installation depends on such factors as power requirements, tightness of fit, stability of connection, and cost.

Types of keys. (*After P. H. Black and O. E. Adams, Jr., Machine Design, McGraw-Hill, 3d ed., 1968*)

Square keys are common in general industrial machinery. Flat keys are used where added stability of the connection is desired, as in machine tools. Square or flat keys may be of uniform cross section or they may be tapered. In tapered keys the width is uniform and the height of the key tapers. Tapered keys may have gib heads to facilitate removal. Other types of keys have been developed for special applications. [P.H.B.]

Machinery A group of parts arranged to perform a useful function. Normally some of the parts are capable of motion; others are stationary and provide a frame for the moving parts. The terms machine and machinery are so closely related as to be almost synonymous; however, machinery has a plural implication, suggesting more than one machine. Common examples of machinery include automobiles, clothes washers, and airplanes; machinery differs greatly in number of parts and complexity.

Some machinery simply provides a mechanical advantage for human effort. Other machinery performs functions that no human being can do for long-sustained periods. *See* Machine; Mechanical engineering; Simple machine. [R.S.S.]

Machining An operation that changes the shape, surface finish, or mechanical properties of a material by the application of special tools and equipment. Machining almost always is a process where a cutting tool removes material to effect the desired change in the workpiece. Typically, powered machinery is required to operate the cutting tools. *See* PRODUCTION METHODS.

Although various machining operations may appear to be very different, most are very similar: they make chips. These chips vary in size from the long continuous ribbons produced on a lathe to the microfine sludge produced by lapping or grinding. These chips are formed by shearing away the workpiece material by the action of a cutting tool. Cylindrical holes can be produced in a workpiece by drilling, milling, reaming, turning, and electric discharge machining. Rectangular (or nonround) holes and slots may be produced by broaching, electric discharge machining, milling, grinding, and nibbling. Cylinders may be produced on lathes and grinders. Special geometries, such as threads and gears, are produced with special tooling and equipment utilizing the turning and grinding processes mentioned above. Polishing, lapping, and buffing are variants of grinding where a very small amount of stock is removed from the workpiece to produce a high-quality surface.

In almost every case, machining accuracy, economics, and production rates are controlled by the careful evaluation and selection of tooling and equipment. Speed of cut, depth of cut, cutting-tool material selection, and machine-tool selection have a tremendous impact on machining. In general, the more rigid and vibration-free a machining tool is, the better it will perform. Jigs and fixtures are often used to support the work-piece. Since it relies on the plastic deformation and shearing of the workpiece by the cutting tool, machining generates heat that must be dissipated before it damages the workpiece or tooling. Coolants, which also acts as lubricants, are often used.

To increase the life and speed of cutting tools, they are often coated with a thin layer of extremely hard material such as titanium nitride or zirconium nitride. These materials, which are applied over the cutting edges, provide excellent wear resistance. They are also brittle, so they rely on the toughness of the underlying cutting tool to support them. Coated tools are more expensive than conventional tools, but they can often cut at much higher rates and last significantly longer. When used properly on sufficiently rigid machine tools, they are far more economical than conventional tooling. *See* METAL COATINGS. [J.R.C.B]

Mackerel A fish which is a member of the order Perciformes, family Scombridae. There are about 50 carnivorous species found in the middle layer or near the surface of tropical and temperate seas. Mackerel are characterized by a long slender body, pointed head, and large mouth.

Scomber scombrus, the common mackerel, is an important fish commercially. It is a migratory species found on both sides of the North Atlantic. The Pacific mackerel (*Pneumatophorus diego*) is also an important commercial fish but differs from the common mackerel in having a swim bladder. The American Spanish mackerel (*Scomberomorus maculatus*) is a choice food fish. *See* PERCIFORMES. [C.B.C.]

Macrocyclic compound An organic compound that contains a large ring. In the organic chemistry of alicyclic compounds, a closed chain of 12 carbon (C) atoms is usually regarded as the minimum size for a large ring; crown ethers are similarly defined. Macrocyclic compounds may be a single, continuous thread of atoms, as in cyclododecane [$(CH_2)_{12}$], or they may incorporate more than one strand or other ring systems (subcyclic units) within the macrocycle or macroring. In addition, macrocycles may be composed of aromatic rings that confer considerable rigidity upon the cyclic system. These aromatic rings may be joined together or coupled by spacer units consisting of one or more carbon atoms. *See* AROMATIC HYDROCARBON.

Classes of macrocyclic polyethers. Crown ethers are generally composed of repeating ethylene (CH_2CH_2) units separated by noncarbon atoms such as oxygen (O), nitrogen (N), sulfur (S), phosphorus (P), or silicon (Si). By far, the most common heteroatom present in the macrorings of crowns [X in $(XCH_2CH_2)_n$] is oxygen; but as more intricate structures are prepared, nitrogen, sulfur, phosphorus, silicon, or siloxy residues are becoming much more common.

By adding a third strand to the simple macrocyclic polyethers, three-dimensional compounds based on the crown framework are formed. Typically, two of the oxygen atoms across the ring from each other are replaced by nitrogens, and a third ethyleneoxy chain is attached to them. Known as cryptands, these structures completely encapsulate cations smaller than their internal cavities and strongly bind the most similar in size.

Two crown ether rings may be held together by a crown-ether-like strand to give a bicyclic cryptand. These have sometimes been referred to as ditopic receptors because they possess two distinct binding sites.

Lariat ethers, spherands, calixarenes, cavitands, and carcerands are other types of macrocyclic compounds, all of which are capable of encapsulating “guest” molecules in their interior cavities.

Cyclophane is the name given to macrocyclic compounds that contain organic (usually aromatic) rings as part of a cavity-containing structure. The first such compound was [2.2]-paracyclophane. In it, two benzene rings are joined by ethylene (CH_2CH_2) chains in their para positions. *See* CYCLOPHANE.

Complexation phenomena. It is the ability of these macrocyclic host compounds to complex a variety of guest species that makes these structures interesting. A crown ether can be described as a doughnut with an electron-rich and polar hole and a greasy or lipophilic (hydrophobic) exterior. As a result, these compounds are usually quite soluble in organic solvents but accommodate positively charged species in their holes.

A variety of organic cations have been found to complex with crown ethers and related hosts. It has been suggested that for a host-guest interaction to occur, the host must have convergent binding sites and the guest must have divergent sites. This is illustrated by the interaction between optically active dibinaphtho-22-crown-6 and optically active phenethylammonium chloride. The crown ether oxygen atoms converge to the center of a hole and the ammonium hydrogens diverge from nitrogen. Three complementary O—H—N hydrogen bonds stabilize the complex. In this particular case, different steric interactions between the optically active crown and the enantiomers of the complex permit resolution of the salt.

Other organic cations have also been complexed, either by insertion of the charged function in the crown's polar hole or by less distinct interactions observed in the solid state. *See* COORDINATION CHEMISTRY; COORDINATION COMPLEXES.

Applications. The striking ability of neutral macrocyclic polyethers to complex with alkali and alkaline-earth cations as well as a variety of other species has proved of considerable interest to the chemistry community. Crown ethers may complex the cation associated with an organic salt and cause separation of the ions. In the absence of cations to neutralize them, many anions show considerably enhanced reactivity. *See* ORGANIC REACTION MECHANISM.

One of the important modern developments in synthetic chemistry was the use of the phase-transfer technique. Nucleophiles such as cyanide are often insoluble in media that dissolve organic compounds with which they react. Thus 1-bromooctane may be heated in the presence of sodium cyanide for days with no product formation. When a crown ether is added, two things change. First, solubility is enhanced because the crown wraps about the cation, making it more lipophilic. This, in turn, makes the entire salt more lipophilic. Second, by solvating the cation, the association between cation and anion and the interactions with solvent are weakened, thus activating the anion for reaction. This approach has been used to assist the dissolution of potassium permanganate ($KMnO_4$) in benzene in which solvent permanganate is a powerful oxidizing agent. One striking example of solubilization is the displacement of chloride (Cl^-) by fluoride (F^-) in dimethyl 2-chloroethylene-1,1-dicarboxylate by using the KF complex of dicyclohexano-18-crown-6. In this reaction, a crown provides solubility for an otherwise insoluble or marginally soluble salt. Use of crowns to transfer a salt from the solid phase into an organic phase is often referred to as solid-liquid phase-transfer catalysis. *See* CATALYSIS; PHASE-TRANSFER CATALYSIS.

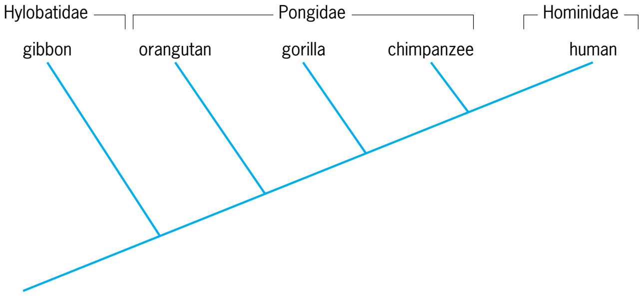
Since crown ethers and related species complex cations selectively, they can be used as sensors. Crowns have been incorporated into electrodes for this purpose, and crowns having various appended chromophores have been prepared. When a cation is bound within the macroring, a change in electron density is felt in the chromophore. The chromophores are often nitroaromatic residues and therefore highly colored. The color change that accompanies complexation can be easily detected and quantitated. *See* ION-SELECTIVE MEMBRANES AND ELECTRODES. [G.W.G.]

Macrodasyida An order of the phylum Gastrotricha. They inhabit marine or brackish waters, seldom fresh waters. Some do not exceed 0.5 mm (0.02 in.) in length, and most are not more than 1–1.5 mm (0.04–0.06 in.); these live in clean to detritus-rich marine sands of littoral or sublittoral areas. All have front and rear groups of adhesive tubes; most also have tubes along their sides. Some have cuticular thickenings or scales or hooks. *Turbanella* and *Tetranchyroderma* are the most common and most abundant of macrodasyids, with numbers of 50–100 per cubic centimeter of sand (800–1600 per cubic inch) not being unusual. *See* GASTROTRICHA. [W.D.Hu.]

Macroevolution Large-scale patterns and processes in the history of life, including the origins of novel organismal designs, evolutionary trends, adaptive radiations, and extinctions. Macroevolutionary research is based on phylogeny, the history of common descent among species. The formation of species and branching of evolutionary lineages mark the interface between macroevolution and microevolution, which addresses the dynamics of genetic variation within populations. Phylogenetic reconstruction, the developmental basis of evolutionary change, and long-term trends in patterns of speciation and extinction among lineages constitute major foci of macroevolutionary studies.

Phylogenetic reconstruction. Phylogenetic relationships are revealed by the sharing of evolutionarily derived characteristics among species, which provides evidence for common ancestry. Shared derived characteristics are termed synapomorphies, and are equated by many systematists with the older concept of homology. Characteristics of different organisms are homologous if they descend, with some modification, from an equivalent characteristic of their most recent common ancestor. Closely related species share more homologous characteristics than do species whose common ancestry is more distant. Species are grouped into clades according to patterns of shared homologies. The clades form a nested hierarchy in which large clades are subdivided into smaller, less inclusive ones, and are depicted by a branching diagram called a cladogram. A phylogenetic tree is a branching diagram, congruent with the cladogram, that represents real lineages of past evolutionary history.

A cladogram or phylogenetic tree is necessary for constructing a taxonomy, but the principles by which higher taxa are recognized remain controversial. The traditional evolutionary taxonomy of G. G. Simpson recognizes higher taxa as units of adaptive evolution called adaptive zones. Species of an adaptive zone share common ancestry, and distinctive morphological or behavioral characteristics associated with use of environmental resources. Higher taxa receive Linnean categorical ranks (genus, family, order, and so forth) reflecting the breadth and distinctness of their adaptive zones. All taxa must have a single evolutionary origin, which means that the taxon must include the most recent common ancestor of all included species. A taxon is monophyletic if it contains all descendants of the group's most recent common ancestor, or paraphyletic if some descendants of the group's most recent common ancestor are excluded because they have evolved a new adaptive zone. For example, evolutionary taxonomy of the anthropoid primates groups the orangutan, gorilla, and chimpanzee in the paraphyletic family Pongidae and the humans in the monophyletic family Hominidae. Although the humans and chimpanzees share more recent common ancestry than either does with the gorilla or orangutan, the chimpanzees are grouped with the latter species at the family level and the humans are placed in a different family because they are considered to have evolved a new adaptive zone. The Hominidae and Pongidae together form a monophyletic group at a higher level (see illustration). *See* ANIMAL SYSTEMATICS.



Phylogenetic relationships of anthropoid primates showing traditional family-level taxa. All apes and humans together form a monophyletic group. The family Pongidae is paraphyletic, and therefore considered invalid by cladistic taxonomists. (*After C. P. Hickman, Jr., L. S. Roberts, and A. Larson, Integrated Principles of Zoology, 9th ed., 1993*)

Cladistic taxonomy or phylogenetic systematics accepts only monophyletic taxa because these alone are considered natural units of common descent. Linnean rankings are considered unimportant. Taxa recognized using both the Simpsonian and cladistic taxonomies are standardly used in macroevolutionary analyses of extinction and patterns of diversity through time. The Simpsonian versus cladistic taxonomies often lead to fundamentally different interpretations, however. For example, extinction of a paraphyletic group, such as dinosaurs, would be considered pseudoextinction by cladists because some descendants of the group's most recent common ancestor survive. Birds are living descendants of the most recent common ancestor of all dinosaurs. The dinosaurs as traditionally recognized, therefore, do not form a valid cladistic taxon. *See* AVES; DINOSAUR; PHYLOGENY.

Developmental processes. Comparative studies of organismal ontogeny are used to find where in development the key features of higher taxa appear and how developmental processes differ between taxa. Evolutionary developmental biologists denote the characteristic body plans of taxa by the term Bauplan. The major characteristics of animal phyla and their developmental and molecular attributes appear to have arisen and stabilized early in the history of life, during the Cambrian Period. Subsequent evolutionary diversification builds upon the Bauplan established early in animal evolution. *See* CAMBRIAN.

Particularly important to the evolutionary diversification of life are historical processes that generate change by altering the timing of organismal development, a phenomenon called heterochrony. Heterochronic changes can produce either paedomorphic or paeramorphic results. Paedomorphosis denotes the retention of preadult characteristics of ancestors in the adult stages of descendants; peramorphosis is the opposite outcome, in which the descendant ontogeny transcends that of the ancestor, adding new features at the final stages. Heterochronic changes can be produced by changing the rates of developmental processes or the times of their onset or termination.

Developmental dissociation occurs when different kinds of heterochronic change alter the development of different parts of the organism independently. Extensive dissociation can fundamentally restructure organismal ontogeny, producing ontogenetic repatterning. However, it is rare that a single heterochronic transformation affects all parts of the organism simultaneously. For most taxa, novel morphologies are produced by a mosaic of different heterochronic processes and by changes in the physical location of developmental events within the organism.

Long-term trends. Traditional Darwinian theory emphasizes natural selection acting on varying organisms within populations as the main causal factor of evolutionary change. Over many generations, the accumulation of favorable variants by natural selection produces new adaptations and new species. Macroevolutionary theory postulates two additional processes analogous to natural selection that act above the species level and on much longer time scales. An evolving lineage ultimately experiences one of two fates, branching speciation or extinction. Lineages that have a high propensity to produce new species and an ability to withstand extinction will dominate evolutionary history.

The higher-level process of differential speciation and extinction caused by the varying characteristics of species or lineages has been called species selection. Because the precise meaning of the term species is controversial, the more neutral terms lineage selection and clade selection are sometimes substituted for species selection. Most species show an evolutionary duration from a few million to approximately 10 million years in the fossil record between geologically instantaneous events of branching speciation. Species selection therefore generally occurs on a time scale of millions of years, rather than the generational time scale of natural selection. Species selection may be the primary factor underlying morphological evolutionary trends at this scale if lineages evolve by punctuated equilibrium, in which most morphological evolutionary change accompanies branching speciation, and species remain morphologically stable between speciational events. *See* Speciation.

The fossil record reveals mass extinctions in which enormous numbers of species from many different taxa are lost within a relatively short interval of geological time. Some lineages may be better able to survive mass extinction events than others, and the characteristics that make a lineage prone to survive mass extinction may be very different from those that influence species selection between events of mass extinction. Catastrophic species selection denotes differential survival and extinction of lineages during events of mass extinction as determined by character variation among lineages. Prior to the Cretaceous mass extinction, dinosaur taxa dominated mammalian taxa, whereas mammals survived the mass extinction and then diversified extensively. The characteristics of the ancestral mammals may have permitted them to survive environmental challenges to which dinosaurs were susceptible. *See* Extinction (biology); Fossil; Mammalia; Paleontology; Permian.

Because natural selection, species selection, and catastrophic species selection can differ in the biological characteristics they promote, higher-level processes may undo or reverse evolutionary trends arising from lower-level processes. *See* Organic evolution. [A.Lar.]

Macroscelidea A mammalian order, the elephant shrews and their allies, which consists of a single African family, Macroscelididae. They are mostly hopping and scampering mammals, divided among several subfamilies, some of which resemble rodents and ungulates in certain features. Characteristic of all these animals is an intestinal cecum and the arrangement of bones in the ear region. The long proboscis of the first living macroscelidids to be discovered led to the name elephant shrews. *See* Mammalia. [M.C.McK.]

Madelung constant A numerical constant α_M in terms of which the electrostatic energy U of a three-dimensional periodic crystal lattice of positive and negative point charges q_+, $-q_-$, N in number, is given by the equation below, where d

$$U = -\frac{1}{2}\frac{Nq_+q_-}{d}\alpha_M$$

is the nearest-neighbor distance between positive and negative charges and N is large. Knowledge of such electrostatic energies as given by the Madelung constant is of importance in the calculation of the cohesive energies of ionic crystals and in many other problems in the physics of solids. *See* Ionic crystals.

Madelung constants for some common ionic crystals

Crystal structure	Madelung constant, α_M
Sodium chloride, NaCl	1.7476
Cesium chloride, CsCl	1.7627
Zinc blende, α-ZnS	1.6381
Wurtzite, β-ZnS	1.641
Fluorite, CaF_2	5.0388
Cuprite, CuO_2	4.1155
Rutile, TiO_2	4.816
Anatase, TiO_2	4.800
Corundum, Al_2O_3	25.0312

The Madelung constants for a number of common ionic crystal structures are given in the table. For these cases d is chosen as the nearest-neighbor distance. *See* Crystal. [B.G.D.]

Magellanic Clouds Two small, irregular galaxies that are close companions of the Milky Way Galaxy. Both are nearby galaxies that are located in the southern sky, not far from the south celestial pole. When viewed without a telescope, they resemble small sections of the Milky Way that might have drifted away from the main arc. The Large Magellanic Cloud (LMC) subtends an angular extent of about 5° in the sky, and the Small Magellanic Cloud (SMC) is about 3° across. Telescopic studies show, however, that each is really much larger than it appears. *See* Milky Way Galaxy.

The Magellanic Clouds are rather small irregular-type galaxies. The Large Magellanic Cloud is at a distance of 160,000 light-years (1.5×10^{18} km or 9×10^{17} mi), and the Small Cloud is about 10% farther away. The explosion of Supernova 1987A in the Large Magellanic Cloud was seen in February 1987. The galaxies are satellites of the Milky Way Galaxy. *See* Supernova.

It was shown in 1998, using Hubble Space Telescope measurements, that the oldest globular clusters in the Large Magellanic Cloud have the same ages as the oldest such clusters in the Milky Way Galaxy, indicating that both galaxies must have formed at nearly the same time. The Small Magellanic Cloud may have formed more recently, as no very old clusters have yet been identified among its several hundred star clusters. Both Magellanic Clouds have large numbers of very young stars, most of which are located in stellar associations, each of which contains several hundred recently formed stars in loose aggregates about 200 light-years (2×10^{15} km or 1.2×10^{15} mi) across. *See* Star clusters.

Both objects also are rich in gas, mostly neutral hydrogen gas. In certain areas the gas is heated by nearby bright stars, producing brilliant glowing nebulae. The brightest and biggest is the 30 Doradus nebula, one of the most remarkable objects of the nearby universe, which includes a “nursery” for the formation of supergiant stars. *See* Interstellar matter; Nebula; Supergiant star. [P.Hod.]

Magic numbers The number of neutrons or protons in nuclei which are required to fill major quantum shells. They occur at particle numbers 2, 8, 20, 50, and 82.

In atoms, the electrons that orbit the nucleus fill quantum electron shells at atomic numbers of 2 (helium), 10 (neon), 18 (argon), 36 (krypton), and 54 (xenon). These elements are chemically inert and difficult to ionize because the energies of orbits are grouped in bunches or shells with large gaps between them. In nuclei, an analogous behavior is found; quantum orbits completely filled with neutrons or protons result in extra stability. The neutrons and protons fill their quantum states independently, so that both full neutron and full proton shells can occur as magic nuclei. In a few cases, for example oxygen-16 ($^{16}_{8}O_8$) and calcium-40 ($^{40}_{20}Ca_{20}$), doubly magic nuclei have full neutron and proton shells. Between the major shell gaps, smaller subshell gaps cause some extra stabilization and semimagic behavior is found at particle numbers 14, 28, 40, and 64. *See* ATOMIC STRUCTURE AND SPECTRA; ELECTRON CONFIGURATION.

In very heavy nuclei the Coulomb repulsion between the protons results in a different sequence of states for neutrons and protons and different major shell gaps. For neutrons the magic sequence continues at $N = 126$; the next shell gap is predicted at $N = 184$. For protons the next major shell gap is anticipated at $Z = 114$. The latter shell gaps lie beyond the heaviest nuclei known, but calculations indicate that the extra stability gained by producing nuclei with these particle numbers may result in an island of long-lived superheavy nuclei.

The closing of nuclear quantum shells has many observable consequences. The nuclei are more tightly bound than average, and the extra stability leads to anomalously high abundances of magic nuclei in nature. The full shells require unusually high energies to remove the least bound neutron or proton, and the probability of capturing extra particles is lower than expected. Furthermore, the full shells are spherically symmetric, and the nuclei have very small electric quadrupole moments. Many of these properties were known before the nuclear shell model was developed to account for quantum-level ordering and gaps between major shells. The different shell closures for atomic and nuclear systems reflect the differences between the Coulomb force that binds electrons to nuclei and the strong force that holds the nucleus together. An important component of the strong force in nuclei is the spin-orbit term, which makes the energy of a state strongly dependent on the relative orientation of spin and orbital angular momentum. *See* ANGULAR MOMENTUM; ELEMENTS, COSMIC ABUNDANCE OF; ISOTOPE; NUCLEAR MOMENTS; NUCLEAR STRUCTURE; STRONG NUCLEAR INTERACTIONS. [C.J.Li.]

Magma The hot material, partly or wholly liquid, from which igneous rocks form. Besides liquids, solids and gas may be present in magma. Most observed magmas are silicate melts with associated crystals and gas, but some inferred magmas are carbonate, phosphate, oxide, sulfide, and sulfur melts.

Strictly, any natural material which contains a finite proportion of melt (hot liquid) is a magma. However, magmas which contain more than about 60% by volume of solids generally have finite strength and fracture like solids.

Hypothetical, wholly liquid magmas which develop by partial melting of previously solid rock and segregation of the liquid into a volume free of suspended solids and gas are called primary magmas. Hypothetical, wholly liquid magmas which develop by crystallization of a primary magma and isolation of rest liquid free of suspended solids are called parental (or secondary) magmas. Although no unquestioned natural examples of either primary or parental magmas are known, the concepts implied by the definitions are useful in discussing the origins of magmas.

Bodies of flowing lava and natural volcanic glass prove the existence of magmas. Such proven magmas include the silicate magmas corresponding to such rocks as basalt, andesite, dacite, and rhyolite as well as rare carbonate-rich magmas and sulfur melts. Oxide-rich and sulfide-rich magmas are inferred from textural and structural evidence of fluidity as well as mineralogical evidence of high temperature, together with the results of experiments on the equilibrium relations of melts and crystals. *See* IGNEOUS ROCKS; LAVA.

Magma is presumed to underlie regions of active volcanism and to occupy volumes comparable in size and shape to plutons of eroded igneous rocks. However, it is not certain that individual plutons existed wholly as magma at one time. Magma may underlie some regions where no volcanic activity exists, because many plutons appear not to have vented to the surface. *See* PLUTON.

Diverse origins are probable for various magmas. Basaltic magmas because of their high temperatures probably originate within the mantle several tens of kilometers beneath the surface of the Earth. Rhyolitic magmas may originate through crystallization of basaltic magmas or by melting of crustal rock. Intermediate magmas may originate within the mantle or by crystallization of basaltic magmas, by melting of appropriate crustal rock, and also by mixing of magmas or by assimilation of an appropriate rock by an appropriate magma. *See* IGNEOUS ROCKS; VOLCANO. [A.T.A.]

Magnesite A member of the calcite-type carbonates having the formula $MgCO_3$. It forms dolomite [$CaMg(CO_3)_2$] with calcite ($CaCO_3$) in the system $CaCO_3$—$MgCO_3$. Pure magnesite is not common in nature because there exists a complete series of solid solutions between $MgCO_3$ and $FeCO_3$, which is constantly present in magnesite in its natural occurrence. *See* CARBONATE MINERALS; MAGNESIUM.

Magnesite is usually white, but it may be light to dark brown if iron-bearing. The hardness of magnesite is 3½ to 4½ on the Mohs scale, and the specific gravity is 3.00. *See* HARDNESS SCALES.

Magnesite deposits are of two general types: massive and crystalline. Massive magnesite is an alteration product of serpentine which has been subjected to the action of carbonate waters. Crystalline magnesite is usually found in association with dolomite. It is generally thought to be a secondary replacement of magnesite in preexisting dolomite by magnesium-rich fluids.

Magnesite is an important industrial mineral. Various types of magnesite or magnesia (MgO) are produced by different thermal treatments. The caustic-calcined magnesite or magnesia is used in the chemical industry for the production of magnesium compounds, while dead-burned or sintered magnesite or magnesia is used in refractory materials. Fused magnesia is used as an insulating material in the electrical industry because of its high electrical resistance and high thermal conductivity. [L.L.Y.C.]

Magnesium A metallic chemical element, Mg, in group 2 of the periodic system, atomic number 12, atomic weight 24.312. Magnesium is silvery white and extremely light in weight. The specific gravity is 1.74, and the density is 1740 kg/m^3 (0.063 lb/in.^{3} or 108.6 lb/ft^3). Because of this lightness combined with alloy strength suitable for many structural uses, magnesium has long been known as industry's lightest structural metal. *See* PERIODIC TABLE.

With a density only two-thirds that of aluminum, magnesium is used in countless applications where weight saving is an important consideration. The metal also has, however, many desirable chemical and metallurgical properties which account for its extensive use in a variety of nonstructural applications.

Magnesium is very abundant in nature, occurring in substantial amounts in many rock-forming minerals such as dolomite, magnesite, olivine, and serpentine. In addition, magnesium is also found in sea water, subterranean brines, and salt beds. It is the third most abundant structural metal in the Earth's crust, exceeded only by aluminum and iron.

Some of the properties of magnesium in metallic form are listed in Table 1. Magnesium is very active chemically. It will actually displace hydrogen from boiling water, and a large number of metals can be prepared by thermal reduction of their salts and oxides with magnesium. The metal will combine with most nonmetals and with practically all acids. Magnesium reacts only slightly or not at all with most alkalies and many organic chemicals, including hydrocarbons, aldehydes, alcohols,

Table 1. Physical properties of primary magnesium (99.9% pure)

Property	Value
Atomic number	12
Atomic weight	24.312
Atomic volume, cm^3/g-atom	14.0
Crystal structure	Close-packed hexagonal
Electron arrangement in free atoms	(2) (8) 2
Mass numbers of the isotopes	24, 25, 26
Percent relative abundances of ^{24}Mg, ^{25}Mg, ^{26}Mg	77, 11.5, 11.5
Density, g/cm^3 at 20°C	1.738
Specific heat, cal/g/°C at 20°C (1 cal = 4.2 joules)	0.245
Melting point, °C	650
Boiling point, °C	1110 ±10

Table 2. Principal magnesium compounds and uses

Compound	Uses
Magnesium carbonte	Refractories, production of other magnesium compounds, water treatment, fertilizers
Magnesium chloride	Cell feed for production of metallic magnesium, oxychloride cement, refrigerating brines, catalyst in organic chemistry, production of other magnesium compounds, flocculating agent, treatment of foliage to prevent fire and resist fire, magnesium melting and welding fluxes
Magnesium hydroxide	Chemical intermediate, alkali, medicinal
Magnesium oxide	Insulation, refractories, oxychloride and oxysulfate cements, fertilizers, rayon-textile processing, water treatment, papermaking, household cleaners, alkali, pharmaceuticals, rubber filler catalyst
Magnesium sulfate	Leather tanning, paper sizing, oxychloride and oxysulfate cements, rayon delustrant, textile dyeing and printing, medicinal, fertilizer ingredient, livestock-food additive, ceramics, explosives, match manufacture

phenols, amines, esters, and most oils. As a catalyst, magnesium is useful for promoting organic condensation, reduction, addition, and dehalogenation reactions. It has long been used for the synthesis of complex and special organic compounds by the well-known Grignard reaction. Principal alloying ingredients include aluminum, manganese, zirconium, zinc, rare-earth metals, and thorium. *See* MAGNESIUM ALLOYS

Magnesium compounds are used extensively in industry and agriculture. Table 2 lists the major magnesium compounds and indicates some of their more significant applications. [W.H.Gr.; S.C.E.]

Magnesium alloys The most important alloying ingredients used in magnesium alloys are aluminum, zinc, manganese, silicon, zirconium, rare-earth metals, and thorium. The specific gravity of magnesium alloys ranges from 1.74 to 1.83. It has led to a great many structural applications in the aircraft, transportation, materials-handling, and portable-tool and -equipment industries. Magnesium alloys are commonly used in the form of die castings, which account for 75% of their usage in structural applications. *See* MAGNESIUM. [T.E.L.]

Magnet An object or device that produces a magnetic field. Magnets are essential for the generation of electric power and are used in motors, generators, labor-saving electromechanical devices, information storage, recording, and numerous specialized applications, for example, seals of refrigerator doors. The magnetic fields produced by magnets apply a force at a distance on other magnets, charged particles, electric currents, and magnetic materials. *See* GENERATOR; MAGNETIC RECORDING; MOTOR.

Magnets may be classified as either permanent or excited. Permanent magnets are composed of so-called hard magnetic material, which retains an alignment of the magnetization in the presence of ambient fields. Excited magnets use controllable energizing currents to generate magnetic fields in either electromagnets or air-cored magnets. *See* ELECTROMAGNET; FERROMAGNETISM; SUPERCONDUCTIVITY.

The essential characteristic of permanent-magnet materials is an inherent resistance to change in magnetization over a wide range of field strength. Resistance to change in magnetization in this type of material is due to two factors: (1) the material consists of particles smaller than the size of a domain, a circumstance which prevents the gradual change in magnetization which would otherwise take place through the movement of domain wall boundaries; and (2) the particles exhibit a marked magnetocrystalline anisotropy. During manufacture the particles are aligned in a magnetic field before being sintered or bonded in a soft metal or polyester resin. Compounds of neodymium, iron, and boron are used. *See* IRON ALLOYS.

Electromagnets rely on magnetically soft or permeable materials which are well annealed and homogeneous so as to allow easy motion of domain wall boundaries. Ideally the coercive force should be zero, permeability should be high, and the flux density saturation level should be high. Coincidentally the hysteresis energy loss represented by the area of the hysteresis curve is small. This property and high electrical resistance (for the reduction of eddy currents) are required where the magnetic field is to vary rapidly. This is accomplished by laminating the core and using iron alloyed with a few percent silicon that increases the resistivity.

Electromagnets usually have an energizing winding made of copper and a permeable iron core. Applications include relays, motors, generators, magnetic clutches, switches, scanning magnets for electron beams (for example, in television receivers), lifting magnets for handling scrap, and magnetic recording heads. *See* CATHODE-RAY TUBE; CLUTCH; ELECTRIC SWITCH; RELAY.

Special iron-cored electromagnets designed with highly homogeneous fields are used for special analytical applications in, for example, electron or nuclear magnetic resonance, or as bending magnets for particle accelerators. *See* MAGNETIC RESONANCE; PARTICLE ACCELERATOR.

Air-cored electromagnets are usually employed above the saturation flux density of iron (about 2 T); at lower fields, iron-cored magnets require much less power because the excitation currents needed then are required only to generate a small field to magnetize the iron. The air-cored magnets are usually in the form of a solenoid with an axial hole allowing access to the high field in the center. The conductor, usually copper or a copper alloy, must be cooled to dissipate the heat generated by resistive losses. In addition, the conductor and supporting structure must be sufficiently strong to support the forces generated in the magnet. *See* SOLENOID (ELECTRICITY).

In pulsed magnets, higher fields can be generated by limiting the excitation to short pulses (usually furnished by the energy stored in a capacitor bank) and cooling the magnet between pulses. The highest fields are generally achieved in small volumes. A field of 75 T has been generated for 120 microseconds.

Large-volume or high-field magnets are often fabricated with superconducting wire in order to avoid the large resistive power losses of normal conductors. The two commercially available superconducting wire materials are (1) alloys of niobium-titanium, a ductile material which is used for generating fields up to about 9 T; and (2) a brittle alloy of niobium and tin (Nb_3Sn) for fields above 9 T. Practical superconducting wires use complex structures of fine filaments of superconductor that are twisted together and embedded in a copper matrix. The conductors are supported against the electromagnetic forces and cooled by liquid helium at 4.2 K (−452°F). A surrounding thermal insulating enclosure such as a dewar minimizes the heat flow from the surroundings.

Superconducting magnets operating over 20 T have been made with niobium-titanium outer sections and niobium-tin inner sections. Niobium-titanium is used in whole-body nuclear magnetic resonance imaging magnets for medical diagnostics. Other applications of superconducting magnets include their use in nuclear magnetic resonance for chemical analysis, particle accelerators, containment of plasma in fusion reactors, magnetic separation, and magnetic levitation. *See* MAGNETIC LEVITATION; MAGNETIC SEPARATION METHODS; MEDICAL IMAGING; NUCLEAR FUSION; NUCLEAR MAGNETIC RESONANCE (NMR); SUPERCONDUCTING DEVICES.

The highest continuous fields are generated by hybrid magnets. A large-volume (lower-field) superconducting magnet that has no resistive power losses surrounds a water-cooled inner magnet that operates at the highest field. The fields of the two magnets add. Over 35 T has been generated continuously. [S.Fo.]

Magnet wire Insulated copper or aluminum wire used in the coils of all types of electromagnetic machines and devices. It is single-strand wire insulated with enamel, varnish, cotton, glass, asbestos, or combinations of these. To meet the immense variety of uses and to gain competitive advantage, a great number of kinds of enamel and fiber insulations are widely available. *See* ELECTRICAL INSULATION; MAGNET. [P.L.A.; C.J.Her.]

Magnetic compass A compass depending for its directive force upon the attraction of the Earth's magnetism for a magnet free to turn in any horizontal direction. A compass is an instrument used for determining horizontal direction.

The magnetic compass operates on the principle that like magnetic poles repel each other whereas unlike poles attract each other. The Earth has internal magnetism similar to that which would result from a short, powerful bar magnet at the center of the Earth. The lines of force connecting the two poles are vertical at two points on the surface of the Earth, called magnetic poles, and horizontal along the magnetic equator, a line approximating a great circle nearly midway between the magnetic poles. The horizontal component of the Earth's magnetic field varies from a maximum on or near the magnetic equator to zero at the magnetic poles.

A simple magnetic compass consists of a magnetized needle mounted so as to be free to align itself with the horizontal component of the Earth's field. A magnetic compass is unreliable or inoperative in the vicinities of the magnetic poles. [A.B.M.]

Magnetic ferroelectrics Materials that display both magnetic order and spontaneous electric polarization. Research on these materials has enabled considerable advances to be made in understanding the interplay between magnetism and ferroelectricity. The existence of both linear and higher-order coupling terms has been confirmed, and their consequences studied. They have given rise, in particular, to a number of magnetically induced polar anomalies and have even provided an example of a ferromagnet whose magnetic moment per unit volume is totally induced by its coupling via linear terms to a spontaneous electric dipole moment.

Most known ferromagnetic materials are metals or alloys. Ferroelectric materials, on the other hand, are nonmetals by definition. It therefore comes as no surprise to find that there are no known room-temperature ferromagnetic ferroelectrics. In fact, there are no well-characterized materials which are known to be both strongly ferromagnetic and ferroelectric at any temperature.

Somewhat unaccountably, antiferromagnetic ferroelectrics are also comparative rarities in nature. Nevertheless, a few are known, and among them the barium-transition-metal fluorides are virtually unique in providing a complete series of isostructural examples. They have the chemical composition $BaXF_4$ in which X is a divalent ion of one of the 3*d* transition metals, manganese, iron, cobalt, or nickel. These materials are orthorhombic and all spontaneously polar (that is, pyroelectric) at room temperature. For all except the iron and manganese materials, which have a higher electrical conductivity than the others, the polarization has been reversed by the application of an electric field, so that they are correctly classified as ferroelectric. Long-range antiferromagnetic ordering sets in at temperatures somewhat below 100 K (−280°F). Structurally the materials consist of XF_6 octahedra which share corners to form puckered *xy* sheets which are linked in the third dimension *z* by the barium atoms. *See* CRYSTAL.

The importance of these magnetic ferroelectrics is the opportunity they provide to study and to separate the effects of a variety of magnetic and nonmagnetic excitations upon the ferroelectric properties and particularly upon the spontaneous polarization. Measurements are often made via the pyroelectric effect, which is the variation of polarization with temperature. This effect is an extremely sensitive indicator of electronic and ionic charge perturbations in polar materials. Through these perturbations the effects of propagating lattice vibrations (phonons), magnetic excitations (magnons), electronic excitations (excitons), and even subtle structural transitions can all be probed with precision. *See* PYROELECTRICITY.

Of all the X ions present in the series $BaXF_4$, the largest is Mn^{2+}. As the temperature is reduced from room temperature, the fluorine cages contract and eventually the divalent manganous ion becomes too big for its cage, precipitating a complicated structural transition at 250 K (−10°F). One interesting effect of this phase transition is that it produces a lower-temperature phase with a crystal symmetry low enough to support the existence of the linear magnetoelectric effect, a linear coupling between magnetization and polarization. Below the antiferromagnetic transition at 26 K in $BaMnF_4$ this linear coupling produces a canting of the antiferromagnetic sublattices through a very small angle (of order 0.2 degree of arc). The result is a spontaneous, polarization-induced magnetic moment. At low temperatures $BaMnF_4$ is therefore technically a weak ferromagnet, although the resultant magnetic moment is extremely small, and it is more usually referred to as a canted antiferromagnet. This is the only well-categorized example of pyroelectrically driven ferromagnetism. *See* ANTIFERROMAGNETISM; FERROELECTRICS; FERROMAGNETISM; MAGNETISM. [M.E.L.]

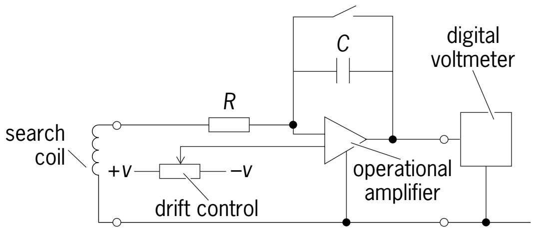
Magnetic instruments Instruments designed for the measurement of magnetic field strength or magnetic flux density, depending on their principle of operation.

Hall-effect instruments. Often called gaussmeters, these instruments measure magnetic field strength. They have a useful working range from 10 A/m to 2.4 MA/m (0.125 oersted to 30 kilooersteds). When a magnetic field, H_z, is applied in a direction at right angles to the current flowing in a conductor (or semiconductor), a voltage proportional to H_z is produced across the conductor in a direction mutually perpendicular to the current and the applied magnetic field. This phenomenon is called the Hall effect. The output voltage of the Hall probe is proportional to the Hall coefficient, which is a characteristic of the Hall-element material, and is inversely proportional to the thickness of this material. For a sensitive Hall probe, the material is thin with a large Hall coefficient. The semiconducting materials indium arsenide and indium antimonide are particularly suitable. *See* HALL EFFECT.

Fluxgate magnetometer. This instrument is used to measure low magnetic field strengths. It is usually calibrated as a gaussmeter with a useful range of 0.2 millitesla to 0.1 nanotesla (2 gauss to 1 microgauss).

Fluxmeter. This instrument is designed to measure magnetic flux. A fluxmeter is a form of galvanometer in which the torsional control is very small and heavy damping is produced by currents induced in the coil by its motion. This enables a fluxmeter to accurately integrate an emf produced in a search coil when the latter is withdrawn from a magnetic field, almost independently of the time taken for the search coil to be moved. *See* GALVANOMETER; MAGNETIC FLUX.

Electronic charge intergrators. Often termed an integrator or gaussmeter, an electronic charge integrator, in conjunction with a search coil of known effective area, is used for the measurement of magnetic flux density. Integrators have almost



Arrangement of an electronic charge integrator.

exclusively replaced fluxmeters because of their independence of level and vibration. The instrument (see illus.) consists of a high-open-loop-gain (10^7 or more) operational amplifier with a capacitive feedback and resistive input. *See* Operational amplifier.

Rotating-coil gaussmeter. This instrument measures low magnetic field strengths and flux densities. It comprises a coil mounted on a nonmagnetic shaft remote from a motor mounted at the other end. The motor causes the coil to rotate at a constant speed, and in the presence of a magnetic field or magnetic flux density a voltage is induced in the search coil. The magnitude of the voltage is proportional to the effective area of the search coil and the speed of rotation. *See* Magnetic field; Magnetic induction; Magnetometer. [A.E.D.]

Magnetic lens A magnetic field with axial symmetry capable of converging beams of charged particles of uniform velocity and of forming images of objects placed in the path of such beams. Magnetic lenses are employed as condensers, objectives, and projection lenses in magnetic electron microscopes, as final focusing lenses in the electron guns of cathode-ray tubes, and for the selection of groups of charged particles of specific velocity in velocity spectrographs.

Magnetic lenses may be formed by solenoids or helical coils of wire traversed by electric current, by axially symmetric pole pieces excited by a coil encased in a high-permeability material such as soft iron, or by similar pole pieces excited by permanent magnets. In the last two instances the armatures and pole pieces serve to concentrate the magnetic field in a narrow region about the axis.

Magnetic lenses are always converging lenses. Their action differs from that of electrostatic lenses and glass lenses in that they produce a rotation of the image in addition to the focusing action. For the simple uniform magnetic field within a long solenoid the image rotation is exactly 180°. Thus a uniform magnetic field forms an erect real image of an object on its axis. [E.G.R.]

Magnetic levitation A method of supporting and transporting objects or vehicles which is based on the physical property that the force between two magnetized bodies is inversely proportional to their distance. By using this magnetic force to counterbalance the gravitational pull, a stable and contactless suspension between a magnet (magnetic body) and a fixed guideway (magnetized body) may be obtained. In magnetic levitation (maglev), also known as magnetic suspension, this basic principle is used to suspend (or levitate) vehicles weighing 40 tons or more by generating a controlled magnetic force. By removing friction, these vehicles can travel at speeds higher than wheeled trains, with considerably improved propulsion efficiency (thrust energy/input energy) and reduced noise. In maglev vehicles, chassis-mounted magnets are either suspended underneath a ferromagnetic guideway (track) or levitated above an aluminum track. *See* Magnet; Magnetism.

In the attraction-type system, a magnet-guideway geometry is used to attract a direct-current electromagnet toward the track. This system, also known as the electromagnetic suspension (EMS) system, is suitable for low- and high-speed passenger-carrying vehicles and a wide range of magnetic bearings. The electromagnetic suspension system is inherently nonlinear and unstable, requiring an active feedback to maintain an upward lift force equal to the weight of the suspended magnet and its payload (vehicle).

In the repulsion-type system, also known as the electrodynamic levitation system (EDS or EDL), a superconducting coil operating in persistent-current mode is moved longitudinally along a conducting surface (an aluminum plate fixed on the ground and acting as the guideway) to induce circulating eddy currents in the aluminum plate. These eddy currents create a magnetic field which, by Lenz's law, oppose the magnetic field generated by the travelling coil. This interaction produces a repulsion force on the moving coil. At lower speeds, this vertical force is not sufficient to lift the coil (and its payload), so supporting auxiliary wheels are needed until the net repulsion force is positive. The speed at which the net upward lift force is positive (critical speed) is dependent on the magnetic field in the airgap and payload, and is typically around 80 km/h (50 mi/h). To produce high flux from the traveling coils, hard superconductors (type II) with relatively high values of the critical field (the magnetic field strength of the coil at 0 K) are used to yield airgap flux densities of over 4 tesla. With this choice, the strong eddy-current induced magnetic field is rejected by the superconducting field, giving a self-stabilizing levitation force at high speeds (though additional control circuitry is required for adequate damping and ride quality). *See* Eddy current.

Due to their contactless operation, linear motors are used to propel maglev vehicles: linear induction motors for low-speed vehicles and linear synchronous motors for high-speed systems. Operationally they are the unrolled versions of the conventional rotary motors. *See* Induction motor; Synchronous motor.

Suspending the rotating part of a machine in a magnetic field may eliminate the contact friction present in conventional mechanical bearings. Magnetic bearings may be based on either attractive or repulsive forces. Although well developed, radial magnetic bearings are relatively expensive and complex, and are used in specialized areas such as vibration dampers for large drive shafts for marine propellers. In contrast, the axial versions of magnetic bearings are in common use in heavy-duty applications, such as large pump shafts and industrial drums. *See* Antifriction bearing. [P.K.Si.]

Magnetic materials Materials exhibiting ferromagnetism. The magnetic properties of all materials make them respond in some way to a magnetic field, but most materials are diamagnetic or paramagnetic and show almost no response. The materials that are most important to magnetic technology are ferromagnetic and ferrimagnetic materials. Their response to a field H is to create an internal contribution to the magnetic induction B proportional to H, expressed as $B = \mu H$, where μ the permeability, varies with H for ferromagnetic materials. Ferromagnetic materials are the elements iron, cobalt, nickel, and their alloys, some manganese compounds, and some rare earths. Ferrimagnetic materials are spinels of the general composition MFe_2O_4, and garnets, $M_3Fe_5O_{12}$, where M represents a metal. *See* Ferrimagnetism; Ferromagnetism; Magnetism; Magnetization.

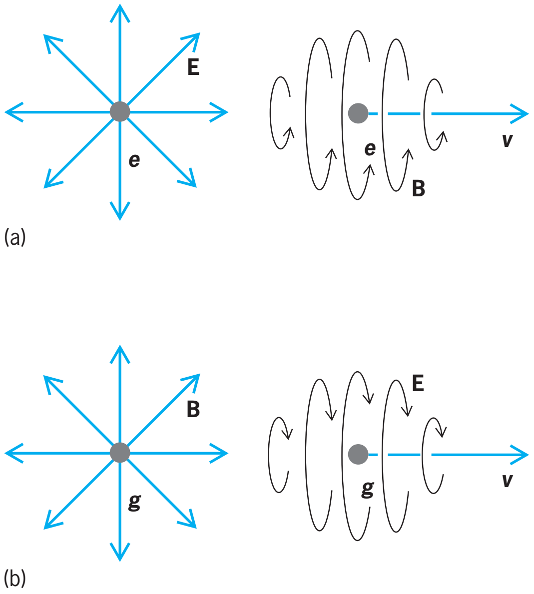
Ferromagnetic materials are characterized by a Curie temperature, above which thermal agitation destroys the magnetic coupling giving rise to the alignment of the elementary magnets (electron spins) of adjacent atoms in a crystal lattice. Below the Curie temperature, ferromagnetism appears spontaneously in small volumes called domains. In the absence of a magnetic field, the domain arrangement minimizes the external energy, and the bulk material appears unmagnetized. *See* Curie temperature.

Magnetic materials are further classified as soft or hard according to the ease of magnetization. Soft materials are used in devices in which change in the magnetization during operation is desirable, sometimes rapidly, as in ac generators and transformers. Hard materials are used to supply a fixed field either to act alone, as in a magnetic separator, or to interact with others, as in loudspeakers and instruments. *See* Electric rotating machinery; Electrical measurements; Generator; Inductor; Loudspeaker; Magnetic separation methods; Microphone; Transformer. [F.E.Lu.]

Magnetic monopoles

Magnetically charged particles. Such particles are predicted by various physical theories, but so far all experimental searches have failed to demonstrate their existence.

The fundamental laws governing electricity and magnetism become symmetric if particles exist that carry magnetic charge. Current understanding of electromagnetic physical phenomena is based on the existence of electric monopoles, which are sources or sinks of electric field lines (illus. *a*), and which when set into motion generate magnetic fields. The magnetic field lines produced by such a current have no beginning or end and form closed loops. All magnetic fields occurring in nature can be explained as arising from currents. However, theories of electromagnetism become symmetric if magnetic charges also exist. These would be sources or sinks of magnetic field and when set into motion would generate electric fields whose lines would be closed without ends (illus. *b*). *See* Electric field.



Electric (E) and magnetic (B) field lines generated by monopoles and by their motion with velocity *v*. (*a*) Electric monopole with electric charge *e*. (*b*) Magnetic monopole with magnetic charge *g*.

In 1931 P. A. M. Dirac found a more fundamental reason for hypothesizing magnetic charges, when he showed that this would explain the observed quantization of electric charge. He showed that all electric and magnetic charges e and g must obey Eq. (1), where k must be an integer and $\hbar$ is Planck's constant

$$eg = k({}^1\!/_2\hbar c) \qquad (1)$$

divided by 2π. Equation (1) can be satisfied only if all electric and magnetic charges are integer multiples of an elementary electric charge e_0 and an elementary magnetic charge g_0. Since the size of the elementary electric charge, the charge carried by an electron or proton, is known experimentally, Dirac's equation predicts the size of the elementary magnetic charge to be given by Eq. (2). Since the fine structure constant α is given by Eq. (3), the elementary magnetic charge g_0 is about 68.5 times larger than the elementary electric charge e_0. *See* Fine structure (spectral lines); Fundamental constants.

$$g_0 = \frac{1}{2}\frac{\hbar c}{e_0} \qquad (2)$$

$$\alpha = \frac{e_0^2}{\hbar c} \approx \frac{1}{137} \qquad (3)$$

In 1983 a successful theoretical unification of the electromagnetic and weak forces culminated in the detection of the W^+, the W^-, and the Z^0 particles predicted by the theory. This success has encouraged the search for a grand unification theory that would include the electroweak force and the nuclear or color force under one consistent description. In 1974 G. 't Hooft and independently A. M. Polyakov showed that magnetically charged particles are necessarily present in all true unification theories (those based on simple or semisimple compact groups). These theories predict the same long-range field and thus the same charge g_0 as the Dirac solution; now, however, the near field is also specified, leading to a calculable mass. The SU(5) model predicts a monopole mass of 10^{16} GeV/c^2, while theories based on supersymmetry or Kaluza-Klein models yield even higher masses up to the Planck mass of 10^{19} GeV/c^2. *See* Electroweak interaction; Fundamental interactions; Grand unification theories; Quantum gravitation; Supergravity; Supersymmetry.

There are two classes of magnetic monopole detectors, superconducting and conventional. On February 14, 1982, a prototype superconducting detector operating at Stanford University observed a single candidate event. Since then a number of groups have operated larger second- and third-generation detectors, and their combined data have placed a limit on the monopole flux more than 3000 times lower than the value from the data set that included the original event. Thus the possibility that this event was caused by the passage of a magnetic monopole has been largely discounted. [B.Ca.]

Magnetic reception (biology)

Sensitivity to magnetic stimuli, especially the very weak ones occurring naturally in the environment.

Evidence of magnetic detection has been found in a variety of invertebrates, including protozoa, flatworms, snails, and insects. In 1968 Martin Lindauer and Herman Martin first published extensive data showing that the Earth's geomagnetic field influences the orientation of the waggle-run dance by which a scout honeybee communicates the distance and direction of a food source to the forager bees. Later, Lindauer and Martin showed that fluctuations of less than 10^{-4} gauss (roughly 1/10,000 of the Earth's field) can influence these bees' behavior. Other investigators found evidence of magnetic detection in other kinds of insects, including termites, beetles, and fruit flies (*Drosophila*).

Most of the evidence for magnetic detection by birds has come from studies of their migratory and homing behavior. Results strongly suggest that birds possess a magnetic compass, that is, they can determine compass bearings from the geomagnetic field. Evidence indicates that birds' sensitivity to magnetic stimuli is roughly similar to the honeybees'. It appears that the tiny fluctuations in the Earth's magnetic field caused by solar flares and other solar disturbances have a detectable effect on birds' navigation. The detection system probably has a narrow range of sensitivity; magnetic fields much stronger or weaker than the Earth's probably cannot be detected. *See* Migratory behavior.

Although behavioral effects of magnetic stimuli have been found in many kinds of animals, no one has yet succeeded in conditioning an animal to a magnetic stimulus in the laboratory. There is abundant evidence that the detection process is not quick, usually taking 15 min or more; hence, the flash stimuli presented in most classical conditioning attempts may be undetectable.

The physical mechanism for magnetic detection by living organisms is unknown, though a variety of possibilities have been put forward. [W.T.K.]

Magnetic recording

The technique of storing information as a magnetic pattern on a moving magnetic medium. The medium may be a disk, either flexible (floppy) or rigid, or a tape.

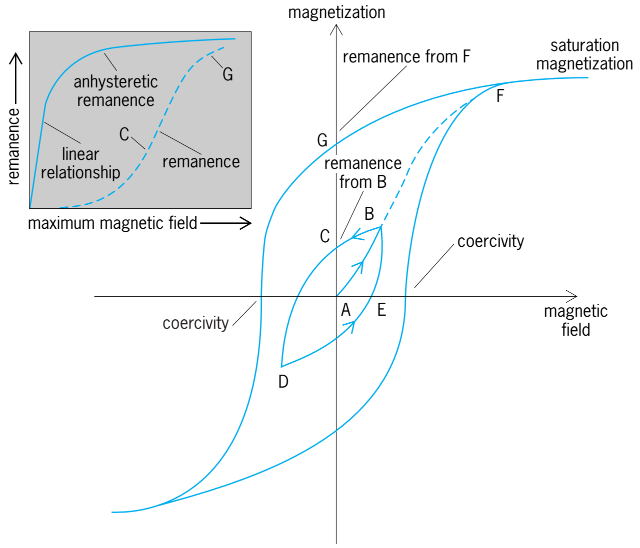


Fig. 1. Typical magnetization curves. At A, material is completely demagnetized. If the magnetic field is increased to B and then reversed, the minor loop BCDE is obtained. The inset shows remanence as a function of maximum field; points C and G correspond to the hysteresis loops shown.

All materials respond in some way to an applied magnetic field, but the term "magnetic material" generally means one that maintains a magnetic polarization in the absence of an applied field. This remanence depends upon the magnetic field history to which the material was exposed. This history can be plotted on a graph of magnetization versus magnetic field, giving rise to hysteresis loops (Fig. 1). If the material is initially completely demagnetized (A in Fig. 1, sometimes referred to as the ac erase state), and the applied field is increased to some intermediate value and then reversed, a minor loop (BCDE) is obtained. At zero magnetic field there is a remanence. If the field is increased to the point that further increases in the field result in no further increases in magnetization, the material is said to be saturated. The remanence, at zero magnetic field, is a function of the maximum magnetic field to which the material has been exposed. Also, it takes a finite field in the reverse direction to drive the magnetization to zero. This field is called the coercivity of the material, and is an important parameter in magnetic recording. *See* MAGNETIC HYSTERESIS; MAGNETIC MATERIALS; MAGNETIZATION.

The hysteretic behavior of magnetic materials, and in particular, the field dependence of the remanence, is the basis for recording sound. The basic idea is to use the electric current from a microphone to generate a magnetic field (Ampère's law) that magnetizes portions of a magnetic medium in proportion to this current. The resulting magnetic pattern along the medium can then be read back as a voltage induced in a pick-up coil (Faraday's induction law) as the fringing fields from the magnetic medium pass by. *See* AMPÈRE'S LAW; FARADAY'S LAW OF INDUCTION; MAGNETIC FIELD.

The writing field associated with a coil can be enhanced by filling the coil with a magnetic material. The reason is that the magnetic flux density generated by an electric current is proportional to the current through a constant of proportionality called the permeability. In free space, this quantity is usually denoted by μ_0. The permeability of a magnetic material, μ, however, is much larger. For example, the nickel-iron alloy permalloy has a relative permeability, μ/μ_0, of the order of 10,000. Therefore, the magnetic flux density inside a permalloy core would be 10,000 times that of an air core.

A high-permeability core also serves to confine the flux density. The field in a very narrow gap in the magnetic material can therefore be relatively large. Thus, recording generally employs an electromagnet with a narrow gap (Fig. 2). The writing and reading element is referred to as the head.

The relationship between the remanence and the field is very nonlinear (Fig. 1), which led to a good deal of distortion in early recorders. However, if an alternating current (ac) is added to the signal current, the resulting remanence, called the anhysteretic remanence, becomes linear at low fields. The amplitude of this bias must be sufficient to produce a field greater than the coercivity, and the bias frequency must be higher than the highest signal frequency. *See* SOUND RECORDING.

To extend magnetic recording to video recording with signals as high as 5 MHz requires increasing the speed between the tape and the recording head. Video recording is based on an approach in which a number of heads are mounted on the face of a drum that rotates rapidly in a direction transverse to the direction of the tape motion. *See* TELEVISION.

Magnetic recording was applied to the storage of data in the early 1950s. Data generally means information represented in a digital form, that is, a sequence of 0's and 1's. In the first tape system for data storage, the data were recorded longitudinally along seven tracks. In a disk system, data are stored along concentric tracks. The figure of merit is the areal bit density, which is the product of the linear density along a track and the track density. *See* COMPUTER STORAGE TECHNOLOGY.

Early tapes and disks utilized particulate media in which the magnetic ingredient consisted of microscopic particles of a magnetic oxide. These particles were immersed in a polymeric binder that served to separate the particles from one another and bind them to the substrate. The particles first used were the gamma form of iron oxide. Higher levels of magnetization and coercivity can be obtained in particles made of the ferromagnetic elements, iron and cobalt, and their alloys than is possible with oxide particles. However, metal particles tend to corrode in the atmosphere and to react with binders and so must be passivated at some cost in saturation magnetization. The particles are also difficult to disperse and are much more expensive than particles of iron oxide. Metal particles having coercivities in the range 700–1150 Oe

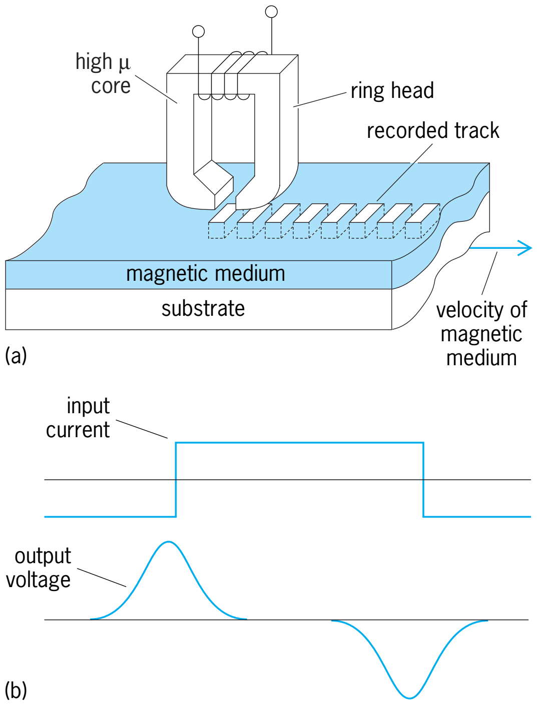

Fig. 2. Writing and reading process. (*a*) Motion of the magnetic medium past the electromagnet in the form of a ring head. (*b*) Variation with time of input current and output voltage.

(56–92 kA/m) are used in premium audio tapes, and particles with coercivities of 1350–1550 Oe (107–123 kA/m) are used in 8-mm video tapes.

Metallic films are used on magnetic disks to reduce the thickness of the magnetic medium and retain a large magnetization. Among the magnetic elements (iron, cobalt, and nickel), cobalt has a hexagonal crystalline structure that leads to a large coercivity. Therefore, many metallic media consist of cobalt with additional elements to stabilize the hexagonal phase, and also, for longitudinal recording, to ensure that the hexagonal axis lies in the plane of the film. [R.M.Wh.]

Magnetic relaxation The relaxation or approach of a magnetic system to an equilibrium or steady-state condition as the magnetic field is changed. This relaxation is not instantaneous but requires time. The characteristic times involved in magnetic relaxation are known as relaxation times. Relaxation has been studied for nuclear magnetism, electron paramagnetism, and ferromagnetism.

Magnetism is associated with angular momentum called spin, because it usually arises from spin of nuclei or electrons. The spins may interact with applied magnetic fields, the so-called Zeeman energy; with electric fields, usually atomic in origin; and with one another through magnetic dipole or exchange coupling, the so-called spin-spin energy. Relaxation which changes the total energy of these interactions is called spin-lattice relaxation; that which does not is called spin-spin relaxation. (As used here, the term lattice does not refer to an ordered crystal but rather signifies degrees of freedom other than spin orientation, for example, translational motion of molecules in a liquid.) Spin-lattice relaxation is associated with the approach of the spin system to thermal equilibrium with the host material; spin-spin relaxation is associated with an internal equilibrium of the spins among themselves. *See* MAGNETISM; SPIN (QUANTUM MECHANICS). [C.P.S.]

Magnetic resonance A phenomenon exhibited by the magnetic spin systems of certain atoms whereby the spin systems absorb energy at specific (resonant) frequencies when subjected to alternating magnetic fields. The magnetic fields must alternate in synchronism with natural frequencies of the magnetic system. In most cases the natural frequency is that of precession of the bulk magnetic moment of constituent atoms or nuclei about some magnetic field. Because the natural frequencies are highly specific as to their origin (nuclear magnetism, electron spin magnetism, and so on), the resonant method makes possible the selective study of particular features of interest. For example, it is possible to study weak nuclear magnetism unmasked by the much larger electronic paramagnetism or diamagnetism which usually accompanies it.

Nuclear magnetic resonance (that is, resonance exhibited by nuclei) reveals not only the presence of a nucleus such as hydrogen, which possesses a magnetic moment, but also its interaction with nearby nuclei. It has therefore become a most powerful method of determining molecular structure. The detection of resonance displayed by unpaired electrons, called electron paramagnetic resonance, is also an important application. *See* ELECTRON-NUCLEAR DOUBLE RESONANCE; MAGNETIC RESONANCE; MAGNETISM; NUCLEAR MEGNETIC RESONANCE (NMR). [C.P.S.]

Magnetic reversals The Earth's magnetic field has reversed polarity hundreds of times. That is, at different times in Earth's past, a compass would have pointed south instead of north. Recognition that the geomagnetic field has repeatedly reversed polarity played a key role in the revolution that transformed the geological sciences in the 1960s—the acceptance of the theory of plate tectonics. It is generally accepted that the geomagnetic field is generated by motion of electrically conducting molten metal in Earth's outer core. However, the mechanism by which the field decays and reverses polarity remains one of the great unknowns in geophysics. *See* GEODYNAMO; GEOMAGNETISM; PLATE TECTONICS.

The last magnetic field reversal occurred long before humans were aware of the geomagnetic field (780,000 years ago), so it is necessary to study geological records to understand the process by which the field reverses. The ability of rocks to act as fossilized compasses, which record a permanent "memory" of Earth's magnetic field at the time of rock formation, makes them suitable for detailed studies of ancient geomagnetic field behavior. *See* PALEOMAGNETISM; ROCK MAGNETISM. [A.P.R.]

Magnetic separation methods All materials possess magnetic properties. Substances that have a greater permeability than air are classified as paramagnetic; those with a lower permeability are called diamagnetic. Paramagnetic materials are attracted to a magnet; diamagnetic substances are repelled. Very strongly paramagnetic materials can be separated from weakly or nonmagnetic materials by the use of low-intensity magnetic separators. Minerals such as hematite, limonite, and garnet are weakly magnetic and can be separated from nonmagnetics by the use of high-intensity separators.

Magnetic separators are widely used to remove tramp iron from ores being crushed, to remove contaminating magnetics from food and industrial products, to recover magnetite and ferrosilicon in the float-sink methods of ore concentration, and to upgrade or concentrate ores. Magnetic separators are extensively used to concentrate ores, particularly iron ores, when one of the principal constituents is magnetic. *See* MECHANICAL SEPARATION TECHNIQUES; ORE DRESSING. [F.D.DeV.]

Magnetic susceptibility The magnetization of a material per unit applied field. It describes the magnetic response of a substance to an applied magnetic field. *See* MAGNETISM; MAGNETIZATION.

All ferromagnetic materials exhibit paramagnetic behavior above their ferromagnetic Curie points. The general behavior of the susceptibility of ferromagnetic materials at temperatures well above the ferromagnetic Curie temperature follows the Curie-Weiss law. The paramagnetic Curie temperature is usually slightly greater than the temperature of transition. *See* CURIE TEMPERATURE; CURIE-WEISS LAW; FERROMAGNETISM.

Most paramagnetic substances at room temperature have a static susceptibility which follows a Langevin-Debye law. Saturation of the paramagnetic susceptibility occurs when a further increase of the applied magnetic field fails to increase the magnetization, because practically all the magnetic dipoles are already oriented parallel to the field. *See* PARAMAGNETISM.

The susceptibility of diamagnetic materials is negative, since a diamagnetic substance is magnetized in a direction opposite to that of the applied magnetic field. The diamagnetic susceptibility is independent of temperature. Diamagnetic susceptibility depends upon the distribution of electronic charge in an atom and upon the energy levels. *See* DIAMAGNETISM.

The susceptibility of antiferromagnetic materials above the Néel point, which marks the transition from antiferromagnetic to paramagnetic behavior, follows a Curie-Weiss law with a negative paramagnetic Curie temperature. [E.A.; F.Ke.]

Magnetic thermometer A thermometer whose operation is based on Curie's law, which states that the magnetic susceptibility of noninteracting (that is, paramagnetic) dipole moments is inversely proportional to absolute temperature. Magnetic thermometers are typically used at temperatures below 1 K (−458°F). The magnetic moments in the thermometric material may be of either electronic or nuclear origin. Generally the magnetic thermometer must be calibrated at one (or more) reference temperatures. *See* ELECTRON; NUCLEAR MOMENTS; PARAMAGNETISM.

At temperatures from a few millikelvins upward, the thermometric material is preferably an electronic paramagnet, typically a nonconducting hydrous rare-earth salt. For higher temperatures, an ion is selected with a large magnetic moment in a crystalline environment with a high density of magnetic ions. In contrast, for low temperature use the magnetic exchange interactions between the magnetic ions should be small, which is accomplished by selecting an ion with a well-localized moment and by maintaining a large separation between the magnetic ions by means of diamagnetic atoms. This is the case in cerium magnesium nitrate (CMN) [$2Ce(NO_3)_3 \cdot 3Mg(NO_3)_3 \cdot 24H_2O$]. Here, the Ce^{3+} ion is responsible for the magnetic moment, which is well localized within the incompletely filled 4*f* shell relatively deep below the outer valence electrons. To reduce the magnetic interactions between the Ce^{3+} ions further, Ce^{3+} may be partly substituted with diamagnetic La^{3+} ions. Lanthanum-diluted CMN has been used for thermometry to below 1 mK. *See* EXCHANGE INTERACTION.

A mutual-inductance bridge, originally known as the Hartshorn bridge, has been the most widely employed measuring circuit for precision thermometry. The bridge is driven by a low-frequency alternating-current source. The inductance at low temperatures consists of two coils, which are as identical as possible. The voltages induced across them by the drive current are compared by means of a high-input-impedance ratio transformer. The output level of this voltage divider is adjusted to equal that of the midpoint between the two coils, using as null indicator a narrow-band preamplifier and a phase-sensitive (lock-in) detector. Thus, without a paramagnetic specimen, the bridge is balanced with the decade divider adjusted at its midpoint, while with the specimen inside one of the coils the change in the divider reading at bridge balance is proportional to the sample magnetization. For high-resolution thermometry it has become standard practice to replace the room-temperature zero detector with a SQUID magnetometer circuit. This also allows the mass of the sample to be reduced from several grams to the 1-mg level. *See* INDUCTANCE MEASUREMENT; SQUID.

Nuclear magnetic moments are smaller by a factor of 10^3 and are used for thermometry only in the ultralow-temperature region. For this the Curie-law behavior is generally sufficient down to the lowest temperatures. The nuclear paramagnetic thermometer loses adequate sensitivity for calibration purposes above 50–100 millikelvins, unless it is operated in a high polarizing field (H greater than 0.1 tesla). It can be utilized as a self-calibrating primary thermometer if the spin-lattice relaxation time is measured in parallel with the nuclear Curie susceptibility. Pulsed NMR measurement on the ^{195}Pt isotope in natural platinum metal provides presently the most widely used thermometry at temperatures below 1 mK. In the Curie-susceptibility measuring mode, it has been extended down to 10 μK. *See* LOW-TEMPERATURE THERMOMETRY; MAGNETIC RELAXATION; NUCLEAR MAGNETIC RESONANCE (NMR). [M.K.]

Magnetic thin films

Magnetic thin films Sheets of magnetic material with thicknesses of a few micrometers or less, used in the electronics industry. Magnetic films can be single-crystal, polycrystalline, amorphous, or multilayered in the arrangement of their atoms. Applications include magnetooptic storage, inductive recording media, magnetoresist sensors, and thin-film heads. *See* COMPUTER STORAGE TECHNOLOGY.

Both ferro- and ferrimagnetic films are used. The ferromagnetic films are usually transition-metal-based alloys. For example, permalloy is a nickel-iron alloy. The ferrimagnetic films, such as garnets or the amorphous films, contain transition metals such as iron or cobalt and rare earths. The ferrimagnetic properties are advantageous in magnetooptic applications where a low overall magnetic moment can be achieved without a significant change in the Curie temperature. *See* FERRIMAGNETISM; FERROMAGNETISM.

The change in electrical properties, such as the electrical resistance, with a magnetic field is used in sensor elements. The most notable of these in semiconductor technology is the magnetoresist head used in disk storage technology. Very large magnetoresist signals (called giant magnetoresistance) are observed in magnetic multilayers and composites containing a magnetic and nonmagnetic material. *See* MAGNETIC MATERIALS; MAGNETISM; MAGNETIZATION. [P.C.]

Magnetism

Magnetism The branch of science that describes the effects of the interactions between charges due to their motion and spin. These interactions may appear in various forms, including electric currents and permanent magnets. They are described in terms of the magnetic field, although the field hypothesis cannot be tested independently of the electrokinetic effects by which it is defined. The magnetic field complements the concept of the electrostatic field used to describe the potential energy between charges due to their relative positions. Special relativity theory relates the two, showing that magnetism is a relativistic modification of the electrostatic forces. The two together form the electromagnetic interactions which are propagated as electromagnetic waves, including light. They control the structure of materials at distances between the long-range gravitational actions and the short-range "strong" and "weak" forces most evident within the atomic nucleus. *See* ELECTROMAGNETIC RADIATION; RELATIVITY.

The magnetic field can be visualized as a set of lines (Fig. 1) illustrated by iron filings scattered on a suitable surface. The intensity of the field is indicated by the line spacing, and the direction by arrows pointing along the lines. The sign convention is chosen so that the Earth's magnetic field is directed from the north magnetic pole toward the south magnetic pole. The field can be defined and measured in various ways, including the forces on the equivalent magnetic poles, and on currents or moving charges. Bringing a coil of wire into the field, or removing it, induces an electromotive force (emf) which depends on the rate at which the number of field lines, referred to as lines of magnetic flux, linking the coil changes in time. This provides a definition of flux, Φ, in terms of the emf, e, given by Eq. (1) for a

$$e = -N\,d\Phi/dt \qquad \text{volts} \qquad (1)$$

coil of N turns wound sufficiently closely to make the number of lines linking each the same. The International System (SI) unit of Φ, the weber (Wb), is defined accordingly as the volt-second. The symbol B is used to denote the flux, or line, density, as in Eq. (2), when the area of the coil is sufficiently small to sample

$$B = \Phi/\text{area} \qquad (2)$$

conditions at a point, and the coil is oriented so that the induced emf is a maximum. The SI unit of B, the tesla (T), is the Wb/m^2. The sign of the emf, e, is measured positively in the direction of a right-hand screw pointing in the direction of the flux lines. It is often convenient, particularly when calculating induced emfs, to describe the field in terms of a magnetic vector potential function instead of flux.

Magnetic circuits. The magnetic circuit provides a useful method of analyzing devices with ferromagnetic parts, and

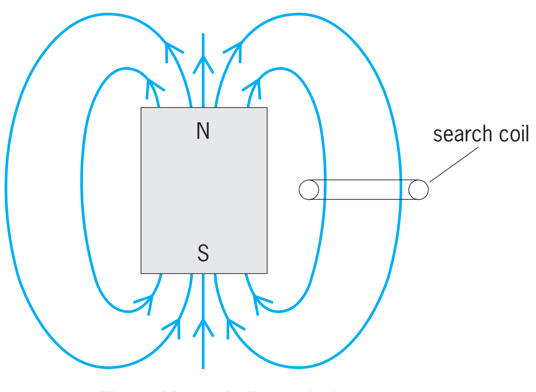

Fig. 1. Magnetic lines of a bar magnet.

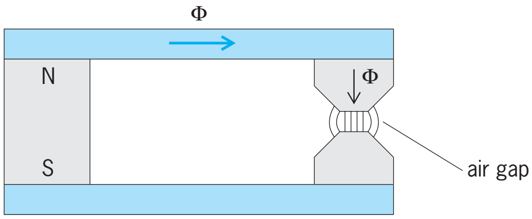

Fig. 2. **Magnetic circuit with an air gap.**

introduces various quantities used in magnetism. It describes the use of ferromagnetic materials to control the flux paths in a manner analogous to the role of conductors in carrying currents around electrical circuits. For example, pieces of iron may be used to guide the flux which is produced by a magnet along a path which includes an air gap (Fig. 2), giving an increase in the flux density, B, if the cross-sectional area of the gap is less than that of the magnet. *See* MAGNET; MAGNETIC MATERIALS.

The magnet may be replaced by a coil of N turns carrying a current, i, wound over a piece of iron, or ferromagnetic material, in the form of a ring of uniform cross section. The flux linking each turn of the coil, and each turn of a secondary coil wound separately from the first, is then approximately the same, giving the same induced emf per turn [according to Eq. (1)] when the supply current, i, and hence the flux, Φ, changes in time. The arrangement is typical of many different devices. It provides, for example, an electrical transformer whose input and output voltages are directly proportional to the numbers of turns in the windings. Emf's also appear within the iron, and tend to produce circulating currents and losses. These are commonly reduced by dividing the material into thin laminations. *See* EDDY CURRENT; TRANSFORMER.

The amount of flux produced by a given supply current is reduced by the presence of any air gaps which may be introduced to contribute constructional convenience or to allow a part to move. The effects of the gaps, and of different magnetic materials, can be predicted by utilizing the analogy between flux, Φ, and the flow of electric current through a circuit consisting of resistors connected in series (Fig. 3). Since Φ depends on the product, iN, of the winding current and number of turns, as in Eq. (3),

$$iN = \Phi \Re \qquad (3)$$

the ratio between them, termed the reluctance, $\Re$, is the analog of electrical resistance. It may be constant or may vary with Φ. The quantity iN is the magnetomotive force (mmf), analogous to voltage or emf in the equivalent electrical circuit. The relationship between the two exchanges the potential and flow quantities, since the magnetic mmf depends on current, i, and the electrical emf on $d\Phi/dt$. Electric and magnetic equivalent circuits are referred to as duals. *See* RELUCTANCE.

Any part of the magnetic circuit of length l, in which the cross section, a, and flux density, B, are uniform has a reluctance given by Eq. (4). This equation parallels Eq. (5) for the resistance, R,

$$\Re = l/(a\mu) \qquad (4)$$

$$R = l/(a\sigma) \qquad (5)$$

of a conduct of the same dimensions. The permeability, μ, is the magnetic equivalent of the conductivity, σ, of the conducting material. Using a magnet as a flux source (Fig. 2) gives an mmf which varies with the air gap reluctance. In the absence of any magnetizable materials, as in the air gaps, the permeability is given by Eq. (6) in SI units (Wb/A-m). The quantity μ_0 is

$$\mu = \mu_0 = 4\pi \times 10^{-7} \qquad (6)$$

sometimes referred to as the permeability of free space. Material properties are described by the relative permeability, μ_r in accordance with Eq. (7). The materials which are important in

$$\mu = \mu_r \mu_0 \qquad (7)$$

magnetic circuits are the ferromagnetics and ferrites characterized by large value of μ_r, sometimes in excess of 10,000 at low flux densities.

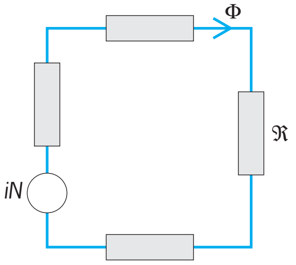

Fig. 3. **Circuit analogy. Components of a magnetic circuit carrying a flux Φ analogous to current. The reluctances of the components are analogous to resistance.**

Magnetic field strength. It is convenient to introduce two different measures of the magnetic field: the flux density, B, and the field strength, or field intensity, H. The field strength, H, can be defined as the mmf per meter. It provides a measure of the currents and other magnetic field sources, excluding those representing polarizable materials. It may also be defined in terms of the force on a unit pole.

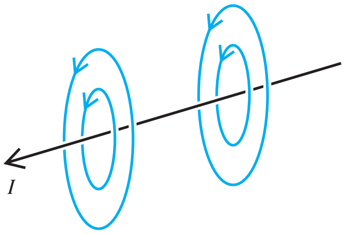

Fig. 4. **Magnetic field of a straight wire.**

A straight wire carrying a current I sets up a field (Fig. 4) whose intensity at a point at distance r is given by Eq. (8). The field

$$H = \frac{I}{2\pi r} \qquad (8)$$

strength, H, like B, is a vector quantity pointing in the direction of rotation of a right-hand screw advancing in the direction of current flow. The intensity of the field is shown by the number of field lines intersecting a unit area. The straight wire provides one example of the circuital law, known as Ampère's law, given by Eq. (9). Here, θ is the angle between H and the element dl

$$\oint H \cos\theta \, dl = I \qquad (9)$$

of any closed path of summation, or integration, and I is the current which links this path. Choosing a circular path, centered on a straight wire, reduces the integral to $H\,(2\pi r)$.

A long, straight, uniformly wound coil (Fig. 5), for example, produces a field which is uniform in the interior and zero outside. The interior magnetic field, H, points in the direction parallel to the coil axis. Applying Eq. (14) to the rectangle $pqrs$ of unit length in the axial direction shows that the only contribution is from pq, giving Eq. (10), where n is the number of turns, per unit length,

$$H = In \qquad (10)$$

carrying the current, I. The magnetic field strength, H, remains the same, by definition, whether the interior of the coil is empty or is filled with ferromagnetic material of uniform properties. The interior forms part of a magnetic circuit in which In is the mmf

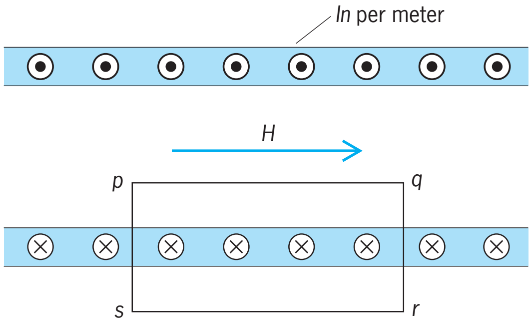

Fig. 5. Cross section of part of a long, straight uniformly wound coil. Black circles indicate current out of the plane of the page, and crosses indicate current into the plane of the page. Rectangle *pqrs* is used to calculate magnetic field strength, *H*, within the coil.

per unit length, where mmf is the magnetic analog of electric voltage, or scalar potential, in an electric circuit. The magnetic field strength, H, is the analog of the electric field vector, E, as a measure of potential gradient, pointing down the gradient. The flux density, B, describes the effect of the field, in the sense of the voltage which is induced in a search coil by changes in time [Eq. (1)]. The ratio of H to B is the reluctance of a volume element of unit length and unit cross section in which the field is uniform, so that, from Eq. (4), the two quantities are related by Eq. (11). The permeability, μ, is defined by Eq. (11). The

$$B = \mu H \tag{11}$$

relative permeability, μ_r, of polarizable materials is measured accordingly by subjecting a sample to a uniform field inside a long coil such as that shown in Fig. 5 and using the emf induced in a search coil wound around the specimen to observe the flux in it.

Magnetic flux and flux density. Magnetic flux is defined in terms of the forces exerted by the magnetic field on electric charge. The forces can be described in terms of changes in flux with time [Eq. (1)], caused either by motion relative to the source or by changes in the source current, describing the effect of charge acceleration.

Since the magnetic, or electrokinetic, energy of current flowing in parallel wires depends on their spacing, the wires are subject to forces tending to change the configuration. The force, dF, on an element of wire carrying a current, i, is given by Eq. (12),

$$dF = Bi\,dl \qquad \text{newtons} \tag{12}$$

and this provides a definition of the flux density, B, due to the wires which exert the force. The SI unit of B, called the tesla, or Wb/m^2, is the N/A-m. The flux density, B, equals $\mu_0 H$ in empty space, or in any material which is not magnetizable [Eq. (11)]. An example is the force, F, per meter (length) which is exerted by a long straight wire on another which is parallel to it, at distance r. From Eq. (8), this force is given by Eq. (13), when the wires carry

$$F = \frac{\mu_0 I i}{2\pi r} = 2 \times 10^{-7}\, Ii/r \qquad \text{newtons} \tag{13}$$

currents I and i. The force, F, is accounted for by the electrokinetic interactions between the conduction charges, and describes the relativistic modification of the electric forces between them due to their relative motion.

In general, any charge, q, moving at velocity u is subject to a force given by Eq. (14), where $\mathbf{u} \times \mathbf{B}$ denotes the cross-product

$$\mathbf{f} = q\,\mathbf{u} \times \mathbf{B} \qquad \text{newtons} \tag{14}$$

between vector quantities. That is, the magnitude of $\mathbf{f}$ depends on the sine of the angle θ between the vectors $\mathbf{u}$ and $\mathbf{B}$, of magnitudes u and B, according to Eq. (15). The force on a positive

$$f = quB \sin\theta \tag{15}$$

charge is at right angles to the plane containing $\mathbf{u}$ and $\mathbf{B}$ and points in the direction of a right-hand screw turned from $\mathbf{u}$ to $\mathbf{B}$.

The same force also acts in the axial direction on the conduction electrons in a wire moving in a magnetic field, and this force generates an emf in the wire. The emf in an element of wire of length dl is greatest when the wire is at right angles to the $\mathbf{B}$ vector, and the motion is at right angles to both. The emf is then given by Eq. (16). More generally, u is the component

$$\text{emf} = uB\,dl \tag{16}$$

of velocity normal to $\mathbf{B}$, and the emf depends on the sine of the angle between $\mathbf{dl}$ and the plane containing the velocity and the $\mathbf{B}$ vectors. The sign is given by the right-hand screw rule, as applied to Eq. (15).

Magnetic flux linkage. The magnetic flux linking any closed path is obtained by counting the number of flux lines passing through any surface, s, which is bounded by the path. Stated more formally, the linkage depends on the sum given in Eq. (17),

$$\Phi = \int\!\!\int B_n\, ds \qquad \text{webers} \tag{17}$$

where B_n denotes the component of B in the direction normal to the area element, ds. The rate of change of linkage gives the emf induced in any conducting wire which follows the path [Eq. (1)].

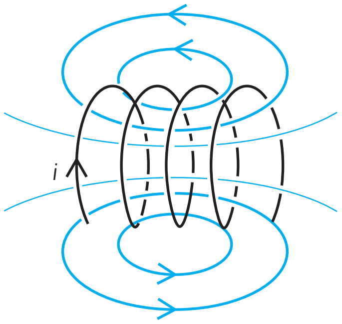

Fig. 6. *B* (magnetic flux) field of a short coil.

The flux linkage with a coil (Fig. 6) is usually calculated by assuming that each turn of the coil closes on itself, giving a flux pattern which likewise consists of a large number of separate closed loops. Each links some of the turns, so that the two cannot be separated without breaking, or "tearing," either the loop or the turn. The total linkage with the coil is then obtained by adding the contributions from each turn.

The inductance, L, is a property of a circuit defined by the emf which is induced by changes of current in time, as in Eq. (18).

$$e = -L\, di/dt \tag{18}$$

The SI unit of inductance is the henry (H), or V-s/A. The negative sign shows that e opposes an increase in current (Lenz's law). From Eq. (1) the inductance of a coil of N turns, each linking the same flux, Φ, is given by Eq. (19), so that the henry is also the

$$L = N\Phi/i \qquad \text{henrys} \tag{19}$$

Wb/A. When different turns, or different parts of a circuit, do not link the same flux, the product $N\Phi$ is replaced by the total flux linkage, Φ, with the circuit as a whole.

The mutual inductance, M, between any two coils, or circuit parts, is defined by emf which is induced in one by a change of current in the other. Using 1 and 2 to distinguish between them, the emf induced in coil 1 is given by Eq. (20a), where the

$$e_1 = -M_{12}\, di_2/dt \tag{20a}$$

$$e_2 = -M_{21}\, di_1/dt \tag{20b}$$

sign convention is consistent with that used for L, referred to as the self-inductance. Likewise, the emf induced in coil 2 when the roles of the windings are reversed is given by Eq. (20*b*). The interaction satisfies the reciprocity condition of Eq. (21), so that the suffixes may be omitted.

$$M_{21} = M_{12} \tag{21}$$

Magnetostatics. The term "magnetostatics" is usually interpreted as the magnet equivalent of the electrostatic interactions between electric charges. The equivalence is described most directly in terms of the magnetic pole, since the forces between poles, like those between charges, vary inversely with the square of the separation distance. Although no isolated poles, or monopoles, have yet been observed, the forces which act on both magnets and on coils are consistent with the assumption that the end surfaces are equivalent to magnetic poles.

Magnetic moment. The magnetic moment of a small current loop, or magnet, can be defined in terms of the torque which acts on it when placed in a magnetic flux density, B, which is sufficiently uniform in the region of the loop. For a rectangular loop with dimensions a and b and with N turns, carrying a current, i, equal but opposite forces act on the opposite sides of length a (Fig. 7). The force is $iNBa$ [Eq. (12)], and the torque, given by Eq. (22), depends on the effective distance, $b \sin\theta$, between

$$T = iNBab\sin\theta \qquad \text{N-m} \tag{22}$$

the wires. It is proportional to the area ab, and is a maximum when the angle θ between B and the axis of the loop is 90°. A current loop of any other shape can be replaced by a set of smaller rectangles placed edge to edge, and the torques of these added to give the total on the loop. The magnetic moment of any loop of area s is defined as the ratio of the maximum torque to the flux density, soits magnitude is given by Eq. (23). It is a

$$m = iNs \tag{23}$$

vector quantity pointing in the direction of a right-hand screw turned in the direction of current flow. It is expressed in vector cross-product notation by Eq. (24).

$$\mathbf{T} = \mathbf{m} \times \mathbf{B} \tag{24}$$

See TORQUE.

An electron orbiting at frequency f is the equivalent of a current $i = qf$, giving Eq. (25) for the moment, where s is the area

$$m_0 = qfs \tag{25}$$

of the orbit. The permissible values are determined by the quantum energy levels. The electron spin is a quantum state which can likewise be visualized as a small current loop. Atomic nuclei also possess magnetic moments. *See* ELECTRON SPIN; MAGNETON; NUCLEAR MOMENTS.

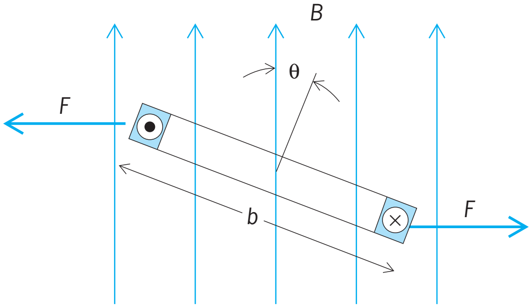

Fig. 7. Cross section of a rectangular current loop placed in magnetic flux density *B*. Equal but opposite forces, *F*, act on opposite sides of the loop carrying current into the plane of the page (indicated by a cross) and out of the plane of the page (indicated by black circle). These forces give rise to a torque on the loop.

Magnetic polarization. Materials are described as magnetic when their response to the magnetic field controls the ratio of B to H. The behavior is accounted for by the magnetic moments produced mainly by the electron spins and orbital motions. These respond to the field and contribute to it in a process referred to as magnetic polarization. The effects are greatest in ferromagnetics and in ferrites, in which the action is described as ferrimagnetic. *See* FERRIMAGNETISM; FERRITE; FERROMAGNETISM.

The sources are the equivalent of miniature "Ampèrean currents" whose sum, in any volume element, is equivalent to a loop of current flowing along the surface of the element. The flux density, B, depends on the field intensity, H, which is defined so that its value inside a long ferromagnetic rod of uniform cross section placed inside a long coil (Fig. 5) is the same as in the annular gap between the rod and the coil, in accordance with Eq. (10). If the field is not sufficiently uniform, H can be measured by using a search coil to observe the flux density, $\mu_0 H$, in the gap. The flux density inside the rod is given by Eq. (26), where B_0 denotes

$$B = \mu_r B_0 \tag{26}$$

$\mu_0 H$, and μ_r is the relative permeability [Eqs. (7) and (11)]. The same flux, B, is obtained by replacing the material by a coil in which the current in amperes per unit length is given by Eq. (27).

$$\begin{aligned} J_s &= (B - B_0)/\mu_0 \\ &= (1 - 1/\mu_r)B/\mu_0 \end{aligned} \tag{27}$$

The magnetic moment, dm, of a volume element of length dz is due to the current flowing over the surface enclosing the area, $dydz$; from Eq. (23), it is given by Eq. (28). The moment per unit volume defines the magnetic polarization, as in Eq. (29).

$$dm = (J_s\,dx)\,dy\,dz \tag{28}$$

$$M = dm/dx\,dy\,dz \tag{29}$$

The polarization, $\mathbf{M}$, is a vector pointing in the direction of $\mathbf{dm}$ with magnitude J_s. The surface current produces an $\mathbf{H}$-like, or

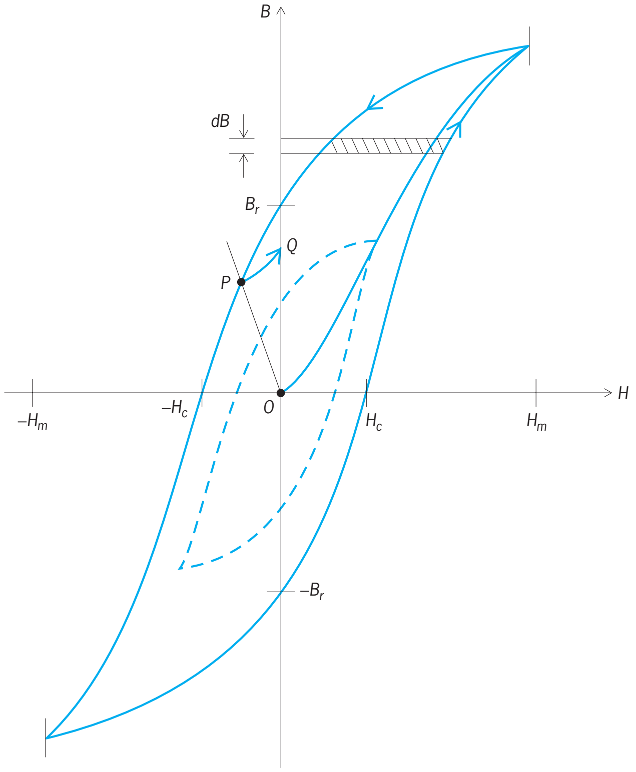

Fig. 8. Hysteresis behavior of a ferromagnetic material.

$\mathbf{B}/\mu_0$, field which is entirely different from $\mathbf{H}$ in the material. Substituting from Eq. (27) gives Eq. (30). This model of the material

$$\mathbf{H} = \frac{\mathbf{B}}{\mu_0} - \mathbf{M} \tag{30}$$

accounts for the flux field, $\mathbf{B}$, as observed by the voltage induced in a search coil wound around the specimen, and $\mathbf{H}$, becomes an auxiliary quantity representing the sum of the polarization, $\mathbf{M}$, and the magnetizing field, $\mathbf{B}\mu_0$, to which $\mathbf{M}$ responds. The polarization, $\mathbf{M}$, also makes the largest contribution to that field, since the equivalent surface current is in the same direction as the current in the magnetizing coil.

Magnetic hysteresis. The relationship between the flux density, B, and the field intensity, H, in ferromagnetic materials depends on the past history of magnetization. The effect is known as hysteresis. It is demonstrated by subjecting the material to a symmetrical cycle of change during which H is varied continuously between the positive and negative limits $+H_m$ and $-H_m$ (Fig. 8). The path that is traced by repeating the cycle a sufficient number of times is the hysteresis loop. The sequence is counterclockwise, so that B is larger when H is diminishing than when it is increasing, in the region of positive H. The flux density, B_r, which is left when H falls to zero is called the remanence, or retentivity. The magnetically "hard" materials used for permanent magnets are characterised by a high B_r, together with a high value of the field strength, $-H_c$, which is needed to reduce B to zero. The field strength, H_c, is known as the coercive force, or coercivity. Cycling the material over a reduced range in H gives the path in Fig. 12 traced by the broken line, lying inside the larger loop. The locus of the tips of such loops is known as the normal magnetization curve. The initial magnetization curve is the B-H relationship which is followed when H is progressively increased in one direction after the material has first been demagnetized ($B = H = 0$). [C.J.C.]

Magnetite

A cubic mineral and member of the spinel structure type with composition $[\mathrm{Fe}^{3+}]^{\mathrm{IV}}[\mathrm{Fe}^{2+}\mathrm{Fe}^{3+}]^{\mathrm{VI}}\mathrm{O}_4$. The color is opaque iron-black and streak black, the hardness is 6 (Mohs scale), and the specific gravity is 5.20. The habit is octahedral, but the mineral usually occurs in granular to massive form, sometimes of enormous dimensions. Magnetite is a natural ferrimagnet, but heated above 1072°F (578°C; the Curie temperature) it becomes paramagnetic.

The major magnetic ore of iron, magnetite may be economically important if it occurs in sufficient quantities. The most spectacular ore body occurs at Kiruna in northern Sweden. Other important occurrences are in Norway, Russia, and Canada. *See* IRON; SPINEL. [P.B.M.]

Magnetization

The process of becoming magnetized; also the property and in particular the extent of being magnetized. Magnetization has an effect on many of the physical properties of a substance. Among these are electrical resistance, specific heat, and elastic strain. *See* MAGNETOCALORIC EFFECT; MAGNETORESISTANCE; MAGNETOSTRICTION.

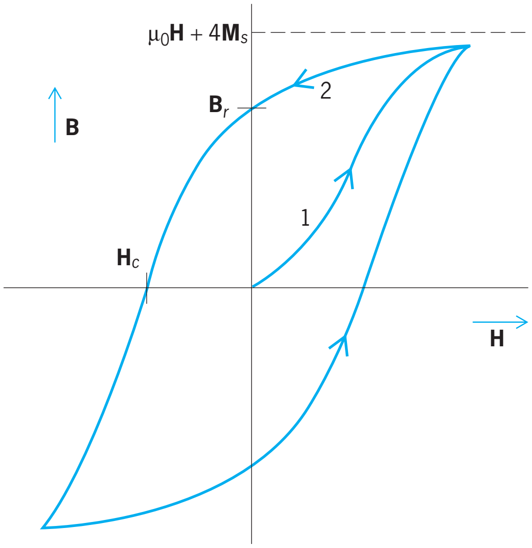
The magnetization $\mathbf{M}$ of a body is caused by circulating electric currents or by elementary atomic magnetic moments, and is defined as the magnetic moment per unit volume of such currents or moments. In the mks (SI) system of units, $\mathbf{M}$ is measured in webers per square meter. For $\mathbf{M}$, 1 weber/m$^2 = 10^4/4\pi$ gauss.

The magnetic induction or magnetic flux density $\mathbf{B}$ is given by the equation below, where $\mathbf{B}$ and $\mathbf{M}$ are in webers/m^2, $\mathbf{H}$, the

$$\mathbf{B} = \mu_0\mathbf{H} + \mathbf{M} \text{ (mks)}$$

applied magnetic field, is in ampere-turns/m, and μ_0, the permeability of free space, is defined as $4\pi \times 10^{-7}$ henry/m, that is, webers/(ampere-turn)(m). *See* ELECTRICAL UNITS AND STANDARDS.

The topic of magnetization is generally restricted to materials exhibiting spontaneous magnetization, that is, magnetization in the absence of $\mathbf{H}$. All such materials will be referred to as ferromagnets, including the special category of ferrimagnets. A ferromagnet is composed of an assemblage of spontaneously magnetized regions called domains. Within each domain, the elementary atomic magnetic moments are essentially aligned, that is, each domain may be envisioned as a small magnet. An unmagnetized ferromagnet is composed of numerous domains, oriented in some fashion.



Magnetization or *B-H* curves.

The process of magnetization in an applied field $\mathbf{H}$ consists of growth of those domains oriented most nearly in the direction of $\mathbf{H}$ at the expense of others, followed by rotation of the direction of magnetization against anisotropy forces. *See* FERROMAGNETISM.

On removal of the field $\mathbf{H}$, some magnetization will remain, called the remanence $\mathbf{M}_r$.

Curves, sometimes called B-H curves, are used to describe magnetic materials. They are plotted with $\mathbf{H}$ as abscissa and with either $\mathbf{M}$ or $\mathbf{B}$ as ordinate. In the illustration, $\mathbf{B}_r$ is the remanent induction ($\mathbf{B}_r = \mathbf{M}_r$); $\mathbf{H}_c$ is the coercive force, or reverse field required to bring the induction $\mathbf{B}$ back to zero; and $\mathbf{M}_s$ is the saturation magnetization, or magnetization when all domains are aligned. The saturation magnetization is equal to the spontaneous magnetization of a single domain, except that it is possible to increase this magnetization slightly by application of an extremely large field. Saturation magnetization is temperature dependent, and disappears completely above the Curie temperature T_c where a ferromagnet changes into a paramagnet. *See* CURIE TEMPERATURE.

The irreversible nature of magnetization is shown most strikingly by the fact that the path of demagnetization does not retrace the path of magnetization—path 2 of the illustration does not retrace path 1. There is a tendency for the magnetization to show hysteresis, that is, to lag behind the applied field, and the loop of the illustration is called a hysteresis loop. [E.A.; F.Ke.; K.V.M.]

Magneto

A type of permanent-magnet alternating-current generator frequently used as a source of ignition energy on tractor, marine, industrial, and aviation engines. *See* ALTERNATING-CURRENT GENERATOR.

Modern induction-type magnetos consist of a permanent-magnet rotor and stationary low- and high-tension windings, also called the primary and secondary windings. The energy output of a magneto is obtained as a result of a rapid rate of change of flux through the stationary windings. The primary winding has comparatively few turns and the secondary winding has many thousand turns of fine wire. One end of the secondary winding is connected to an end of the primary winding and grounded to the frame of the magneto. The primary winding is closed on itself through a breaker mechanism actuated by a cam on the magneto shaft. The breaker is mechanically set to interrupt the primary circuit each time the flux through the winding is changing at its greatest rate. The sudden collapse of the primary current induces a very high voltage in the secondary winding. *See* IGNITION SYSTEM; INTERNAL COMBUSTION ENGINE. [R.T.W.]

Magnetocaloric effect The reversible change of temperature accompanying the change of magnetization of a ferromagnetic or paramagnetic material. This change in temperature may be of the order of 1°C (2°F), and is not to be confused with the much smaller hysteresis heating effect, which is irreversible. *See* THERMAL HYSTERESIS. [E.A.; F.Ke.]

Magnetochemistry The branch of chemistry which studies the interrelationship between a magnetic held and atomic and molecular structures.

A substance in a magnetic field acquires an intensity of magnetization which may be either smaller or larger than that induced in a vacuum by the same field. In the first case, the substance is said to be diamagnetic. In the second case, the substance may be paramagnetic, ferromagnetic, or antiferromagnetic.

Diamagnetism, a universal property of matter, is usually of the order of magnitude 10^{-6} to 10^{-5}. Temperature-dependent paramagnetism, on the other hand, arises only when an atom, ion, or molecule possesses a permanent magnetic moment either in the ground state or in an excited state. A permanent magnetic moment is the result of the presence of one or more unpaired electrons. Paramagnetic susceptibilities are of the order of magnitude 10^{-4} to 10^{-3}.

A substance composed of atoms with permanent magnetic moments which are very near to one another (for example, iron metal) may display ferromagnetism. This phenomenon occurs when large numbers of the atoms with permanent magnetic moments interact so that their individual moments align in a parallel fashion, giving rise to a large resultant moment.

On the other hand, a similar substance (for example, manganese metal) may display antiferromagnetism. Here, the magnetic moments align in an antiparallel fashion, thus largely canceling the individual magnetic moments of the atoms. Parallel versus antiparallel alignment depends, among other factors, upon interatomic distances. *See* ANTIFERROMAGNETISM; ATOMIC STRUCTURE AND SPECTRA; ELECTRON PARAMAGNETIC RESONANCE (EPR) SPECTROSCOPY; MAGNETIC RESONANCE; MAGNETISM; MOLECULAR STRUCTURE AND SPECTRA. [D.M.Gr.]

Magnetohydrodynamic power generator A system for the generation of electrical power through the interaction of a flowing, electrically conducting fluid with a magnetic field. As in a conventional electrical generator, the Faraday principle of motional induction is employed, but solid conductors are replaced by an electrically conducting fluid. The interactions between this conducting fluid and the electromagnetic field system through which power is delivered to a circuit are determined by the magnetohydrodynamic (MHD) equations, while the properties of electrically conducting gases or plasmas are established from the appropriate relationships of plasma physics. Major emphasis has been placed on MHD systems utilizing an ionized gas, but an electrically conducting liquid or a two-phase flow can also be employed. *See* ELECTROMAGNETIC INDUCTION; GENERATOR; MAGNETOHYDRODYNAMICS; PLASMA (PHYSICS).

Electrical conductivity in an MHD generator can be achieved in a number of ways. At the heat-source operating temperatures of MHD systems (1300–5000°F or 1000–3000 K), the working fluids usually considered are gases derived from combustion, noble gases, and alkali metal vapors. In the case of combustion gases, a seed material such as potassium carbonate is added in small amounts, typically about 1% of the total mass flow. The seed material is thermally ionized and yields the electron number density required for adequate electrical conductivity above about 4000°F (2500 K). With monatomic gases, operation at temperatures down to about 2200°F (1500 K) is possible through the use of cesium as a seed material. In plasmas of this type, the electron temperature can be elevated above that of the gas (nonequilibrium ionization) to provide adequate electrical conductivity at lower temperatures than with thermal ionization. In so-called liquid metal, MHD electrical conductivity is obtained by injecting a liquid metal into a vapor or gas stream to obtain a continuous liquid phase.

The conversion process in the MHD generator itself occurs in a channel or duct in which a plasma flows usually above the speed of sound through a magnetic field. High power densities are one of the attractive features of MHD power generators.

Under the magnetic field strengths required for MHD generators, the plasma displays a pronounced Hall effect. To permit the basic Faraday motional induction interaction and simultaneously support the resulting Hall potential in the flow direction, a linear channel requires segmented walls comprising alternately electrodes (anode or cathode) and insulators. From an electrical machine viewpoint, both individual cells and the complete generator may be regarded as a gyrator. The optimum loading of the MHD channel is achieved by extracting power from both the Faraday and Hall terminals, and this is most readily accomplished through consolidation of the dc outputs of individual electrode pairs using power electronics. *See* GYRATOR; HALL EFFECT.

For most applications, a superconducting magnet system is needed to provide the 4–6-T field, which is at least twice the value utilized in conventional machines. *See* MAGNET; SUPERCONDUCTING DEVICES.

Improvement of the overall thermal efficiency of central station power plants has been the continuing objective of power engineers. Conventional plants based on steam turbine technology are limited to about 40% efficiency, imposed by a combination of working-fluid properties and limits on the operating temperatures of materials. When combined with a steam turbine system to serve as the high-temperature or topping stage of a binary cycle, an MHD generator has the potential for increasing the overall plant thermal efficiency to around 50%, and values higher than 60% have been predicted for advanced systems. *See* ELECTRIC POWER GENERATION; STEAM TURBINE.

MHD power generation also has important potential environmental advantages. These are of special significance when coal is the primary fuel, for it appears that MHD systems can utilize coal directly without the cost and loss of efficiency resulting from the processing of coal into a clean fuel required by competing systems. [W.D.J.]

Magnetohydrodynamics The interaction of electrically conducting fluids with magnetic fields. The fluids can be ionized gases (commonly called plasmas) or liquid metals. Magnetohydrodynamic (MHD) phenomena occur naturally in the Earth's interior, constituting the dynamo that produces the Earth's magnetic field; in the magnetosphere that surrounds the Earth; and in the Sun and throughout astrophysics. In the laboratory, magnetohydrodynamics is important in the magnetic confinement of plasmas in experiments on controlled thermonuclear fusion. Magnetohydrodynamic principles are also used in plasma accelerators for ion thrusters for spacecraft propulsion, for light-ion-beam powered inertial confinement, and for magnetohydrodynamic power generation. *See* COSMIC RAYS; GEOMAGNETISM; ION PROPULSION; MAGNETOHYDRODYNAMIC POWER GENERATOR; MAGNETOSPHERE; NUCLEAR FUSION; PLASMA (PHYSICS); SOLAR WIND; SUN.

The conducting fluid and magnetic field interact through electric currents that flow in the fluid. The currents are induced as the conducting fluid moves across the magnetic field lines. In turn, the currents influence both the magnetic field and the motion of the fluid. Qualitatively, the magnetohydrodynamic interactions tend to link the fluid and the field lines so as to make them move together. *See* Electric current; Magnetic field.

The generation of the currents and their subsequent effects are governed by the familiar laws of electricity and magnetism. The motion of a conductor across magnetic lines of force causes a voltage drop or electric field at right angles to the direction of the motion and the field lines; the induced voltage drop causes a current to flow as in the armature of a generator.

The currents themselves create magnetic fields which tend to loop around each current element. The currents heat the conductor and also give rise to mechanical ponderomotive forces when flowing across a magnetic field. (These are the forces which cause the armature of an electric motor to turn.) In a fluid, the ponderomotive forces combine with the pressure forces to determine the fluid motion. *See* Electricity; Generator; Magnetism; Motor.

Magnetohydrodynamic phenomena involve two well-known branches of physics, electrodynamics and hydrodynamics, with some modifications to account for their interplay. The basic laws of electrodynamics as formulated by J. C. Maxwell apply without any change. However, Ohm's law, which relates the current flow to the induced voltage, has to be modified for a moving conductor. *See* Electrodynamics; Hydrodynamics; Maxwell's equations; Ohm's law.

It is useful to consider first the extreme case of a fluid with a very large electrical conductivity. Maxwell's equations predict, according to H. Alfvén, that for a fluid of this kind the lines of the magnetic field move with the material. The picture of moving lines of force is convenient but must be used with care because such a motion is not observable. It may be defined, however, in terms of observable consequences by either of the following statements: (1) a line moving with the fluid, which is initially a line of force, will remain one; or (2) the magnetic flux through a closed loop moving with the fluid remains unchanged.

If the conductivity is low, this is not true and the fluid and the field lines slip across each other. This is similar to a diffusion of two gases across one another and is governed by similar mathematical laws.

As in ordinary hydrodynamics, the dynamics of the fluid obeys theorems expressing the conservation of mass, momentum, and energy. These theorems treat the fluid as a continuum. This is justified if the mean free path of the individual particles is much shorter than the distances that characterize the structure of the flow. Although this assumption does not generally hold for plasmas, one can gain much insight into magnetohydrodynamics from the continuum approximation. The ordinary laws of hydrodynamics can then easily be extended to cover the effect of magnetic and electric fields on the fluid by adding a magnetic force to the momentum-conservation equation and electric heating and work to the energy-conservation equation. [M.G.H.]

Magnetometer A device used to measure the intensity and direction of a magnetic field. Magnetometers may be classified as either scalar or vector instruments. A scalar magnetometer measures the strength of the total magnetic field, whereas a vector magnetometer measures one or more vector components of the magnetic field. Most magnetometers are relative instruments that must be calibrated with respect to a known magnetic field. A few magnetometers are absolute instruments that yield accurate magnetic field values without the need for calibration. Three modern devices in regular use are the nuclear magnetometer, fluxgate magnetometer, and SQUID magnetometer.

Two general classes of nuclear magnetometers are the proton precession magnetometer and the optically pumped magnetometer. Both are absolute instruments that measure total field strength without the need for calibration using a known magnetic field.

The fluxgate (saturable-core) magnetometer employs a sensor constructed from an identical pair of cores made from high-magnetic-permeability material. All fluxgate magnetometers are relative vector instruments that require calibration in a known magnetic field to produce accurate results. Orthogonal sets of fluxgate sensors can be used to measure all three field components and thereby the total field vector. Like proton magnetometers, fluxgate pairs can be configured as vector field gradiometers.

The cryogenic or SQUID magnetometer uses one or more Josephson junctions as a magnetic field sensor. A Josephson junction is a zone of weak magnetic coupling (a weak link) between two regions of superconducting material in which current will flow without resistance. A change in the magnetic field applied to the weak link produces a proportional change in magnetic flux within the Josephson junction. The SQUID is the most sensitive magnetometer in use, capable of measuring flux changes only a small fraction of a flux quantum Φ_0 (2.07×10^{-15} weber). *See* Josephson effect.

Two types of SQUID are in common use. The radio-frequency SQUID employs a single weak link, whereas the direct-current SQUID uses a pair of Josephson junctions. All SQUID magnetometers are relative, vector instruments. The principal advantages of the SQUID magnetometer over proton, optically pumped, and fluxgate magnetometers are sensitivity and frequency response. The principal disadvantage of the SQUID magnetometer is that it must be kept in a superconducting state. *See* SQUID. [M.O.McW.]

Magnetomotive force The magnetomotive force (mmf) around a magnetic circuit is the work per unit magnetic pole required to carry the pole once around the circuit. It is the analog of electromotive force.

It is expressed mathematically in the equation below, where

$$\text{mmf} = \oint H \cos\theta \, ds$$

$H \cos\theta$ is the component of magnetic field strength in the direction of a length of path ds. The line integral is taken around any closed path in the field. [K.V.M.]

Magneton A unit of magnetic moment used to describe atomic, molecular, or nuclear magnets. More precisely, one unit, the Bohr magneton, is used at the atomic and molecular levels, and another unit, the nuclear magneton, is used at the nuclear level. Still another unit (which might be called the muon magneton, but is usually not named) is used to describe the magnetic moment of the muon. *See* Magnetic moment.

The Bohr magneton μ_B is defined and its value given in Eq. (1), where $-e$ and m are the charge and mass of the elec-

$$\mu_B = \frac{e\hbar}{2m} = (9.274\ 009\ 49 \pm 0.000\ 000\ 80) \times 10^{-24}\ \text{joule/tesla}$$

tron respectively and $\hbar$ is Planck's constant divided by 2π. In Dirac's theory the magnetic moment of the electron is exactly $-\mu_B$, but according to the theory of quantum electrodynamics the electron has a small anomalous magnetic moment. The experimental value of the electron magnetic moment μ_e is given by Eq. (2), in agreement with the prediction of quantum electrodynamics within the errors.

$$\mu_e = -(1.001\ 159\ 652\ 1883 \pm 0.000\ 000\ 000\ 0042)\mu_B$$

The unit of magnetic moment to describe the muon is obtained from the Bohr magneton by replacing m in Eq. (1) by the muon mass m_μ. The experimental value of the muon magnetic moment is given in Eq. (3). The deviation of the muon magnetic moment

$$\mu_\mu = (1.001\ 165\ 9203 \pm 0.000\ 000\ 0007)\frac{e\hbar}{2m_\mu}$$

from its Dirac value can also be accounted for by the theory of quantum electrodynamics. *See* Lepton.

The nuclear magneton is obtained from the Bohr magneton by replacing m by the proton mass m_p. The value of the nuclear magneton is given in Eq. (4). The nuclear magneton is

$$\mu_N = (5.050\,783\,43 \pm 0.000\,000\,43) \times 10^{-27} \text{ joule/tesla}$$

used not only as the unit for the magnetic moment of the proton but also for the neutron and other hadrons and for atomic nuclei. If the proton and neutron were Dirac particles, the proton's magnetic moment would be one nuclear magneton (except for a small correction arising from quantum electrodynamics) and the neutron's magnetic moment would be zero (because the neutron is uncharged). However, the proton and neutron have large anomalous magnetic moments, given in Eqs. (5).

$$\begin{aligned}\mu_p &= (2.792\,847\,351 \pm 0.000\,000\,028)\mu_N \\ \mu_n &= (-1.913\,042\,73 \pm 0.000\,000\,45)\mu_N\end{aligned}$$

See NEUTRON; NUCLEAR MOMENTS; PROTON.

According to present theory, the proton, neutron, and other hadrons have large anomalous magnetic moments because these particles are not elementary but composite. In the theory of quantum chromodynamics, the principal constituents of a baryon, such as the proton or neutron, are three quarks. *See* BARYON; ELEMENTARY PARTICLE; FUNDAMENTAL CONSTANTS; QUANTUM CHROMODYNAMICS; QUARKS. [D.B.L.]

Magnetooptics That branch of physics which deals with the influence of a magnetic field on optical phenomena. Considering the fact that light is electromagnetic radiation, an interaction between light and a magnetic field would seem quite plausible. It is, however, not the direct interaction of the magnetic field and light that produces the known magnetooptic effects, but the influence of the magnetic field upon matter which is in the process of emitting or absorbing light. *See* COTTON-MOUTON EFFECT; FARADAY EFFECT; MAGNETOOPTIC KERR EFFECT; MAJORANA EFFECT; VOIGT EFFECT; ZEEMAN EFFECT. [G.H.Di.; W.W.W.]

Magnetoresistance The change of electrical resistance produced in a current-carrying conductor or semiconductor on application of a magnetic field H. Magnetoresistance is one of the galvanomagnetic effects. It is observed with H both parallel to and transverse to the current flow. The change of resistance usually is proportional to H^2 for small fields, but at high fields it can rise faster than H^2, increase linearly with H, or tend to a constant (that is, saturate), depending on the material. In most nonmagnetic solids the magnetoresistance is positive. *See* GALVANOMAGNETIC EFFECTS.

In semiconductors, the magnetoresistance is unusually large and is highly anisotropic with respect to the angle between the field direction and the current flow in single crystals. When the magnetoresistance is measured as a function of field, it is the basis for the Shubnikov–de Haas effect, much as the field dependence of the magnetization gives rise to the de Haas-van Alphen effect. Measurement of either effect as the field direction changes with respect to the crystal axes serves as a powerful probe of the Fermi surface. Magnetoresistance measurements also yield information about current carrier mobilities. Important to practical applications is the fact that the geometry of a semiconductor sample can generate very large magnetoresistance, as in the Corbino disk. *See* DE HAAS-VAN ALPHEN EFFECT; FERMI SURFACE; SEMICONDUCTOR.

Multilayered structures composed of alternating layers of magnetic and nonmagnetic metals, such as iron/chromium or cobalt/copper, can feature very large, negative values of magnetoresistance. This effect, called giant magnetoresistance, arises from the spin dependence of the electron scattering which causes resistance. When consecutive magnetic layers have their magnetizations antiparallel (antiferromagnetic alignment), the resistance of the structure is larger than when they are parallel (ferromagnetic alignment). Since the magnetic alignment can be changed with an applied magnetic field, the resistance of the structure is sensitive to the field. Giant magnetoresistance can also be observed in a simpler structure known as a spin valve, which consists of a nonmagnetic layer (for example, copper) sandwiched between two ferromagnetic layers (for example, cobalt). The magnetization direction in one of the ferromagnetic layers is fixed by an antiferromagnetic coating on the outside, while the magnetization direction in the other layer, and hence the resistance of the structure, can be changed by an external magnetic field. Films of nonmagnetic metals containing ferromagnetic granules, such as cobalt precipitates in copper, have been found to exhibit giant magnetoresistance as well. *See* ANTIFERROMAGNETISM; FERROMAGNETISM; MAGNETIC FIELD; MAGNETIZATION.

Magnetoresistors, especially those consisting of semiconductors such as indium antimonide or ferromagnets such as permalloy, are important to a variety of devices which detect magnetic fields. These include magnetic recording heads and position and speed sensors. *See* MAGNETIC MATERIALS; MAGNETIC RECORDING. [J.F.He.]

Magnetosphere A comet-shaped cavity or bubble around the Earth, carved in the solar wind. This cavity is formed because the Earth's magnetic field represents an obstacle to the solar wind, which is a supersonic flow of plasma blowing away from the Sun. As a result, the solar wind flows around the Earth, confining the Earth and its magnetic field into a long cylindrical cavity with a blunt nose. Since the solar wind is a supersonic flow, it also forms a bow shock a few earth radii away from the front of the cavity. The boundary of the cavity is called the magnetopause. The region between the bow shock and the magnetopause is called the magnetosheath. The Earth is located about 10 earth radii from the blunt-nosed front of the magnetopause. The long cylindrical section of the cavity is called the magnetotail, which is on the order of a few thousand earth radii in length, extending approximately radially away from the Sun. *See* SOLAR WIND; SUN.

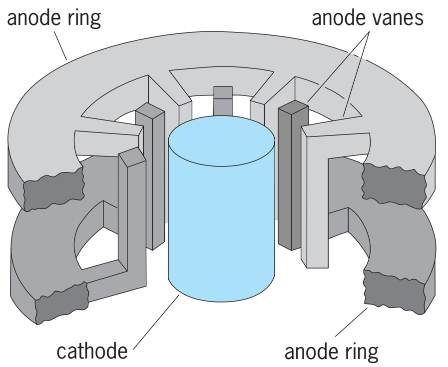
The magnetosphere has been extensively explored by a number of satellites carrying sophisticated instruments. The satellite observations have indicated that the cavity is not an empty one, but is filled with plasmas of different characteristics. The Earth's dipolar magnetic field is considerably deformed by these plasmas and the electric currents generated by them. *See* VAN ALLEN RADIATION.

All other magnetic planets, such as Mercury, Jupiter, and Saturn, have magnetospheres which are similar in many respects to the magnetosphere of the Earth. [S.-I.A.]

Magnetostriction The change of length of a ferromagnetic substance when it is magnetized. More generally, magnetostriction is the phenomenon that the state of strain of a ferromagnetic sample depends on the direction and extent of magnetization. The phenomenon has an important application in devices known as magnetostriction transducers. *See* FERROMAGNETISM.

The magnetostrictive effect is exploited in transducers used for the reception and transmission of high-frequency sound vibrations. Nickel is often used for this application. *See* SONAR; ULTRASONICS. [E.A.; F.Ke.]

Magnetron The oldest of a family of crossed-field microwave electron tubes wherein electrons, generated from a heated cathode, move under the combined force of a radial electric field and an axial magnetic field. By its structure a magnetron causes moving electrons to interact synchronously with traveling-wave components of a microwave standing-wave pattern in such a manner that electron potential energy is converted to microwave energy with high efficiency. Magnetrons have been used since the 1940s as pulsed microwave radiation sources for radar tracking. Because of their compactness and the high efficiency with which they can emit short bursts of megawatt peak



An interdigital-vane anode circuit and cathode, indicating the basic cylindrical geometry of the magnetron. (*After G. D. Sims and I. M. Stephenson, Microwave Tubes and Semiconductor Devices, Blackie and Son, London, 1963*)

output power, they have proved excellent for installation in aircraft as well as in ground radar stations. In continuous operation, a magnetron can produce a kilowatt of microwave power which is appropriate for rapid microwave cooking. *See* ELECTRON TUBE.

The magnetron is a device of essentially cylindrical symmetry (see illustration). On the central axis is a hollow cylindrical cathode. The outer surface of the cathode carries electronemitting materials, primarily barium and strontium oxides in a nickel matrix. Such a matrix is capable of emitting electrons when current flows through the heater inside the cathode cylinder. *See* VACUUM TUBE.

At a radius somewhat larger than the outer radius of the cathode is a concentric cylindrical anode. The anode serves two functions: (1) to collect electrons emitted by the cathode and (2) to store and guide microwave energy. The anode consists of a series of quarter-wavelength cavity resonators symmetrically arranged around the cathode.

A radial dc electric field (perpendicular to the cathode) is applied between cathode and anode. This electric field and the axial magnetic field (parallel and coaxial with the cathode) introduced by pole pieces at either end of the cathode provide the required crossed-field configuration. [R.J.Co.]

Magnification A measure of the effectiveness of an optical system in enlarging or reducing an image. For an optical system that forms a real image, such a measure is the lateral magnification *m*, which is the ratio of the size of the image to the size of the object. If the magnification is greater than unity, it is an enlargement; if less than unity, it is a reduction.

The angular magnification is the ratio of the angles formed by the image and the object at the eye. In telescopes the angular magnification (or, better, the ratio of the tangents of the angles under which the object is seen with and without the lens, respectively) can be taken as a measure of the effectiveness of the instrument.

Magnifying power is the measure of the effectiveness of an optical system used in connection with the eye. The magnifying power of a spectacle lens is the ratio of the tangents of the angles under which the object is seen with and without the lens, respectively. The magnifying power of a magnifier or an ocular is the ratio of the size under which an object would appear when seen through the instrument at a distance of 10 in. or 250 mm (the distance of distinct vision) divided by the object size. *See* LENS (OPTICS); OPTICAL IMAGE. [M.J.H.]

Magnitude (astronomy) The brightness of an astronomical object, expressed on a unique numerical scale. The stellar magnitude scale is logarithmic and is inverted in that fainter objects have numerically larger magnitudes. Although used primarily for stars, the stellar magnitude scale can also be used to express the brightness of the Sun, planets, asteroids, comets, nebulae, galaxies, and even background radiation.

Since the brightness of any object varies with wavelength, many different magnitude scales have been defined corresponding to different spectral regions, bandwidths, and methods of observation. Visual magnitudes, corresponding to the sensitivity of the human eye centered in the yellow part of the spectrum, are usually implied if the type is unspecified.

The star catalog of Hipparchus (about 150 B.C.) is thought to have contained approximately 850 naked-eye stars classified according to brightness. The 15 or so brightest stars were referred to as stars of the first magnitude, while second-magnitude stars were on the average two or three times fainter, and so on. The scale is logarithmic because intervals that are perceived as equal intervals are, in fact, equal brightness ratios.

Measurements of brightness ratios in the nineteenth century showed that, on average, stars of the sixth magnitude (near the limit of naked-eye vision) were about 100 times fainter than those of the first. On the scale introduced by N. R. Pogson in 1856 and universally adopted, an interval of 5 magnitudes corresponds to a factor of exactly 100, so that each magnitude corresponds to a factor of $100^5 \approx 2.512 \cdots$. The zero point of the Pogson scale was set so that most stars retained their customary magnitudes.

An attractive feature of the magnitude scale is the ease with which fractional magnitudes can be interpreted. Each change of 1% in the brightness of an object corresponds to a change of 0.01 in the magnitude, and this numerical correspondence holds to good accuracy for changes up to about 30%.

A distinction is made between the apparent magnitude of an object viewed from the Earth and its absolute magnitude, which measures the object's intrinsic luminosity by indicating its apparent magnitude as seen from a standard distance. The absolute magnitude may be defined as the apparent magnitude an object would have if viewed from a distance of 10 parsecs (1 pc = 3.26 light-years = 1.92×10^{13} mi = 3.09×10^{13} km). *See* PARSEC. [R.F.W.]

Magnolia A genus of trees with large, chiefly white flowers, and simple, entire, usually large alternate leaves. In the winter the twigs may be recognized by their aromatic odor when bruised.

The most important species commercially is *Magnolia acuminata*, commonly called cucumber tree, which grows in the Appalachian and Ozark mountains. The fruit is red when ripe and resembles a small cucumber in shape.

The wood of the magnolia is similar to that of the tulip tree and is rather soft, but it is of such wide natural dimensions that it is valued for furniture, cabinetwork, flooring, and interior finish.

Magnolia species occur naturally in a broad belt in the eastern United States and Central America, with a similar region in eastern Asia and the Himalayas. *See* MAGNOLIALES. [A.H.G./K.P.D.]

Magnoliales An order of flowering plants consisting of six families, the best known of which are Magnoliaceae (220 species) and Annonaceae (2200 species). The others contain some botanically interesting and peculiar plants (305 species), but none besides Myristicaceae (300 species) are commonly encountered. Previously, many authors have considered these families as among the most primitive of the flowering plants, but in all cases the plants exhibit some highly derived traits. Studies of sequences of deoxyribonucleic acid (DNA) demonstrate that Magnoliales are closely related to Laurales, Piperales, and Winterales, and then more distantly to the monocotyledons.

Some species are of minor economic importance in various parts of the tropics: Annonaceae contain the custard apple, soursop, and sweetsop (*Annona* species), ylang-ylang (an aromatic oil is produced by the flowers of *Canaga odorata*), and *Mkilua fragrans* is the source of a perfume. *Myristica fragrans* (Myristicaeae) is the source of nutmeg and mace, and seeds of several species in this family are used locally to produce consumable oils that are sometimes also used for candle making. Of Magnoliaceae, many species of *Magnolia* (tulip trees) are used as ornamental trees in the temperate and tropical zones, and *Liriodendron* (yellow poplar or green tulip tree) is a commonly planted shade tree throughout the north temperate region. The latter is also a valuable timber-producing genus. *See* LAURALES; PIPERALES; TULIP TREE. [M.W.C.]

Magnoliidae A subclass of the class Magnoliopsida (dicotyledons) in the division Magnoliophyta (Angiospermae), the flowering plants. The subclass consists of 8 orders, 39 families, and more than 12,000 species. The Magnoliidae are the most primitive subclass of flowering plants. In general, they have a well-developed perianth, which may or may not be numerous, centripetal stamens, and they are apocarpous. *See* ARISTOLOCHIALES; ILLICIALES; LAURALES; MAGNOLIALES; MAGNOLIOPHYTA; MAGNOLIOPSIDA; NYMPHAEALES; PAPAVERALES; PIPERALES; PLANT KINGDOM; RANUNCULALES. [A.Cr.; T.M.Ba.]

Magnoliophyta A division of seed plants consisting of about 250,000 species, which form the bulk and most conspicuous element of the land plants. Often called flowering plants or angiosperms, they have several unique characteristics, the most prominent of which are their reproductive structure, flowers, and covered seeds. The other obvious woody land plants are the gymnosperms, which have cones instead of flowers and have naked seeds. Another trait distinguishing the angiosperms is the presence of double fertilization, which results in the production of stored food (starch or oils) within their seeds. *See* FLOWER.

Angiosperms range from some of the smallest plants known to large forest trees, and they occur in all habitats, including the oceans, where they are only a minor element in most marine ecosystems. Some are capable of growing directly on rock surfaces as well as on the limbs of trees. The angiosperms are usually considered to be the most highly evolved division of the subkingdom Embryobionta. Their highly specialized and relatively efficient conducting tissues, combined with the protection of their ovules in an ovary, give them a competitive advantage over most other groups of land plants in most regions. *See* EMBRYOBIONTA.

The angiosperms may be characterized as vascular plants with roots, stems, and leaves, usually with well-developed vessels in the xylem and with companion cells in the phloem. The central cylinder has leaf gaps or scattered vascular bundles; the ovules are enclosed in an ovary; and the female gametophyte is reduced to a few-nucleate embryo sac without an archegonium. The male gametophyte is reduced to a tiny pollen grain that gives rise to a pollen tube containing a tube nucleus and two sperms; one sperm fuses with the egg in the embryo sac to form a zygote, and the other fuses with two nuclei of the embryo sac to form a triple fusion nucleus that is typically the forerunner of the endosperm of the seed. *See* LEAF; PHLOEM; POLLEN; REPRODUCTION (PLANT); ROOT (BOTANY); SEED; STEM; XYLEM. [M.W.C.]

Among plants with alternation of sporophyte and gametophyte generations, the angiosperms represent the most extreme stage in reduction of the gametophyte, which in effect is reduced to a mere stage in the reproduction of the sporophyte. The pollen grain, with its associated pollen tube, and the embryo sac represent the male and female gametophyte generations; the endosperm is a new structure not referable to either generation; and the remainder of the plant throughout its life cycle is the sporophyte. Many angiosperms can also propagate asexually by means of creeping stems or roots or by other specialized vegetative structures such as bulbils.

It is obvious to biologists that the angiosperms must have evolved from gymnosperms, but beyond this the facts are obscure. They appear in the fossil record early in the Cretaceous Period as obvious angiosperms, without any hint of a connection to any particular group of gymnosperms. Many believe that among the gymnosperms the seed ferns provide the most likely ancestors. *See* PALEOBOTANY; PINOPHYTA.

The Magnoliophyta consist of two large groups that have not been formally named: the eudicots and the magnoliids. The eudicots are characterized by flowers that are highly organized in terms of the number and orientation of parts whereas the magnoliids have many parts without any particular fixed patterns among the parts—except for the monocots, in which the most developed groups, like the eudicots, exhibit developed flowers with highly organized patterns. *See* LILIOPSIDA; MAGNOLIOPSIDA. [A.Cr.; T.M.Ba.; M.W.C.]

Magnoliopsida One of the two classes of flowering plants which collectively make up the division Magnoliophyta (Angiospermae). The Magnoliopsida, often known as Dicotyledoneae or dicotyledons, embrace 6 subclasses, 64 orders, 318 families, and about 165,000 species.

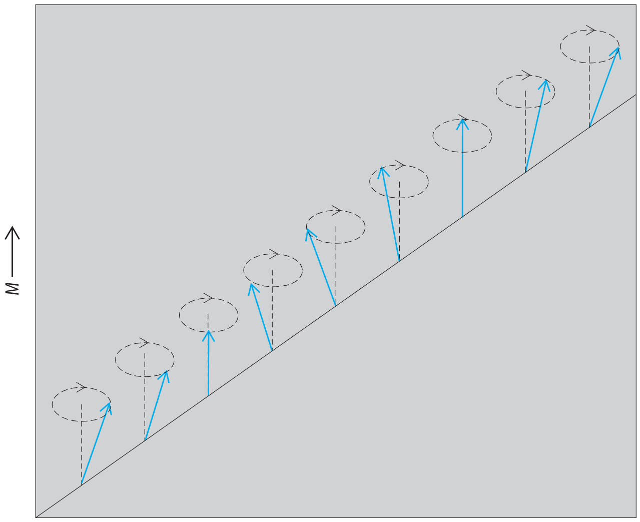
All of the characters which collectively distinguish the Magnoliopsida from the Liliopsida (monocotyledons) are subject to exception, but in general the Magnoliopsida have two cotyledons and net-veined leaves. The vascular bundles are typically borne in a ring (or cylinder) enclosing a pith. Increase in thickness of stems and roots, after the primary tissues have matured, results from meristematic activity of a cambial layer which passes through the vascular bundles. In about half of the species of the group, the cambium of the stem forms a continuous cylinder which produces a new layer of wood (secondary xylem) and bark (secondary phloem) each growing season for year after year. Such plants become trees or shrubs.

It is widely agreed that the most existing angiosperms belong to the dicotyledons (especially the order Magnoliales) and that most of the characters which distinguish the monocotyledons as a group are derived rather than primitive. *See* ASTERIDAE; CARYOPHYLLIDAE; DILLENIIDAE; HAMAMELIDAE; LILIOPSIDA; MAGNOLIALES; MAGNOLIIDAE; MAGNOLIOPHYTA; PLANT KINGDOM; ROSIDAE. [A.Cr.; T.M.Ba.]

Magnon A quantum of a spin wave; an elementary excitation of a magnetic system which is usually long-range-ordered, such as a ferromagnet. *See* ANTIFERROMAGNETISM; FERRIMAGNETISM; FERROMAGNETISM.

In the lowest energy state of a simple ferromagnet, all the magnetic moments of the individual atoms are parallel (say, to the z axis). Each atomic moment derives mainly from the electron spin angular momentum of the atom. In the next-to-lowest energy state (first excited state), the total z component of spin angular momentum, S_z, is reduced by one unit of $\hbar = h/2\pi$, where h is Planck's constant. In the case of a crystalline material, this unit is shared equally by all the spins, each of which lies on a cone (see illustration), precessing at an angular rate ω. These spins form a wave, known as a spin wave, having a repeat distance or wavelength, λ. The wave amplitude (that is, the cone angle) is extremely small, because of the sharing among all the spins whose number N is very large, roughly 10^{23}. Thus, each atom's share of the reduction in S_z, labeled Δ, is only $\hbar/N$, whereas the z component of the atomic spin in the fully aligned state is typically 1–10 times $\hbar$. It follows from simple geometry that the cone half-angle is of order 10^{-11} to 10^{-12} radian. The state with this value of the amplitude is said to be a one-magnon state with wave number $k = 1/\lambda$. If Δ is doubled to $2\hbar/N$, the state is a two-magnon state, and so forth. The integer values of $N\Delta/\hbar$ correspond to the possible changes in S_z being integral multiples of $\hbar$. *See* ELECTRON SPIN; WAVE MOTION.

While the spin waves associated with energy states, that is, stationary states, in crystals vary sinusoidally in space (see



Spin wave in a linear ferromagnetic array of precessing atomic spins of equal magnitude, represented as arrows (vectors) in perspective. The axis of precession is along the vertical direction of the total magnetization, *M*.

illustration), magnons can be associated, instead, with nonstationary states (wave packets) in some situations. Closely analogous to magnons are phonons and photons, quanta of mass-density waves and electromagnetic waves, respectively. *See* Electromagnetic wave; Phonon; Photon; Quantum mechanics. [T.A.K.]

Mahogany A hard, red or yellow-brown wood which takes a high polish and is extensively used for furniture and cabinetwork. The West Indies mahogany tree (*Swietenia mahagoni*), a native of tropical regions in North and South America, is a large evergreen tree with smooth pinnate leaves. Together with other species it yields the world's most valuable cabinet wood. In the United States it occurs naturally only in the extreme southern tip of Florida, but it is planted elsewhere in the state as an ornamental and shade tree. [A.H.G./K.P.D.]

Maillard reaction A nonenzymatic chemical reaction involving condensation of an amino group and a reducing group, resulting in the formation of intermediates which ultimately polymerize to form brown pigments (melanoidins). The reaction was named for the French biochemist Louis-Camille Maillard. It is of extreme importance to food chemistry, especially because of its ramifications in terms of food quality. *See* Amine; Reactive intermediates.

There are three major stages of the reaction. The first comprises glycosylamine formation and rearrangement *N*-substituted-1-amino-l-deoxy-2-ketose (Amadori compound). The second phase involves loss of the amine to form carbonyl intermediates, which upon dehydration or fission form highly reactive carbonyl compounds through several pathways. The third phase occurring upon subsequent heating involves the interaction of the carbonyl flavor compounds with other constituents to form brown nitrogen-containing pigments (melanoidins). These are highly desirous compounds in certain foods browned by heating in the presence of oxygen.

The Maillard reaction is considered undesirable in some biological and food systems. The interaction of carbonyl and amine compounds might damage the nutritional quality of proteins by reducing the availability of lysine and other essential amino acids and by forming inhibitory or antinutritional compounds. The reaction is also associated with undesirable flavors and colors in some foods, particularly dehydrated foods. *See* Amino acids; Carbonyl. [M.E.B.]

Malachite A bright-green, basic carbonate of copper $[Cu_2CO_3(OH)_2]$. Malachite is the most stable copper mineral in natural environments in contact with the atmosphere and hydrosphere. It occurs as an ore mineral in oxidized copper sulfide deposits; as a stain on fractures in rock outcrops; as a corrosion product of copper and its alloys (except in industrial-urban environments, where the basic copper sulfate dominates); as suspended particles in streams and in alluvial sediments; and as encrustations on bronze artifacts in seawater and on coccoliths floating in the oceans. It can be distinguished from other green copper minerals by its effervescence in acid. The combination of hardness (3.5–4 on Mohs scale) ideal for carving, color variation in concentric layers, and adamantine-to-silky luster has made malachite a highly prized ornamental stone. Its rare blocky-tabular crystals up to 5 mm (0.2 in.), its pseudomorphs after azurite crystals to 2 cm (0.8 in.), and its more common felty tufts perched on bright blue azurite are eagerly sought by mineral collectors. Malachite is an important copper ore mineral in supergene copper oxide deposits formed by weathering of primary copper sulfide deposits. *See* Azurite; Carbonate minerals; Copper. [M.T.E.]

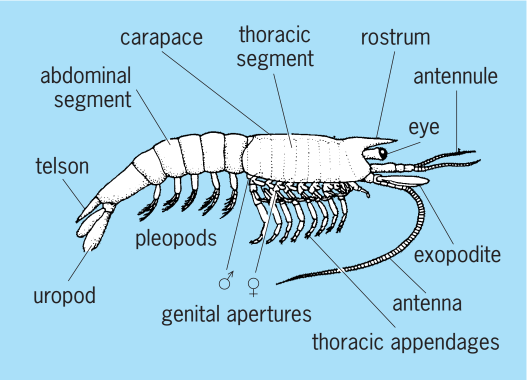
Maintenance, industrial and production The actions taken to preserve the operation of devices, particularly of electromechanical equipment, to ensure that the devices can perform their intended functions when needed. The field of maintenance science is an interdisciplinary research area that employs techniques from physics, engineering, and decision analysis. Traditionally, the focus of maintenance has been on equipment availability—the ratio of operating time less downtime to total available time. Modern maintenance practices focus on increasing equipment effectiveness, that is, making sure that the equipment is both available and capable of producing superior-quality products. *See* Systems engineering.

It has been estimated that up to 50% of all life-cycle equipment costs are attributable to operation and maintenance. Equipment buyers are now requiring better information on time to failure and repair. Suppliers have responded by including such things as failure mode and effects analysis, statistical information on failure times, cost-effective maintenance procedures, and better customer training with their products. Additionally, many companies emphasize design enhancements to improve maintainability, such as built-in diagnostics, greater standardization and modularity, and improved component accessibility. *See* Engineering design; Machine design.

Maintenance activities can be classified into several broad categories, depending on whether they respond to failures that have occurred or whether they attempt to prevent failures. The simplest and least sophisticated maintenance strategy still used by many companies is reactive maintenance or breakdown maintenance. Equipment is operated until it fails, then repaired or replaced. No effort is expended on activities that monitor the ongoing "health" of the equipment, and maintenance is focused on quick repairs that return the equipment to production as soon as possible. A slightly more sophisticated maintenance strategy is preventive maintenance, also known as calendar-based maintenance. This system involves detailed, planned maintenance activities on a periodic basis, usually monthly, quarterly, semiannually, or annually. As in reactive maintenance, preventive maintenance does not monitor information on equipment status. Rather, it attempts to avoid unplanned failures through planned repairs or replacements. Predictive maintenance is based on an ongoing (continuous or periodic) assessment of the actual operating condition of equipment. The equipment is monitored while in operation, and repair or replacement is scheduled only when measurements indicate that it is required. Predictive maintenance programs seek to control maintenance activities to avoid both unplanned equipment outages and unnecessary maintenance and overhauls. [G.A.K.]

Malacostraca The largest and most diversified class of the Crustacea; includes the shrimps, lobsters, crabs, sow bugs, beach hoppers, and their allies. The shell or carapace may be large, small, vestigial, or absent; the tail or abdomen is long or short; the eyes are generally set on movable stalks but may be sessile or even coalesced. Despite this diversity, the unity of the group is demonstrated by the following characteristics which all share. The maximum number of appendages is 19 pairs. The trunk limbs are sharply differentiated into a thoracic series of eight pairs and an abdominal series of six pairs. The female genital duct always opens at the level of the sixth thoracic segment, whereas those of the male open at the level of the eighth.

Malacostraca are divided into three subclasses, the Phyllocarida, Hoplocarida, and Eumalacostraca. Central to the classification of the Eumalacostraca has been the concept of the "caridoid facies" (see illustration). This term refers to a series of morphological attributes generally common to the four orders, Syncarida, Pancarida, Peracarida, and Eucarida. *See* EUCARIDA; EUMALACOSTRACA; HOPLOCARIDA; PERACARIDA; PHYLLOCARIDA; SYNCARIDA. [P.A.McL.]



Caridoid facies. (*After E. R. Lankester, ed., A Treatise on Zoology, pt. 7. fasc. 3, A. and C. Black, 1909*)

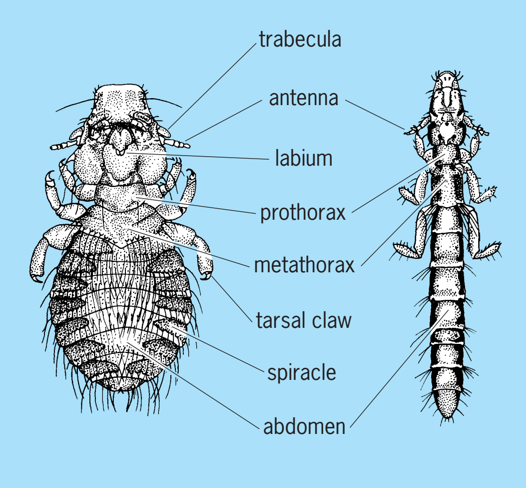
Malaria A disease caused by members of the protozoan genus *Plasmodium*, a widespread group of sporozoans that parasitize the human liver and red blood cells. Four species can infect humans: *P. vivax*, causing vivax or benign tertian malaria; *P. ovale,* a very similar form found chiefly in central Africa that causes ovale malaria; *P. malariae,* which causes malariae or quartan malaria; and *P. falciparum,* the highly pathogenic causative organism of falciparum or malignant tertian malaria. Malaria is characterized by periodic chills, fever, and sweats, often leading to severe anemia, an enlarged spleen, and other complications that may result in loss of life, especially among infants whose deaths are almost always attributed to falciparum malaria. The infective agents are inoculated into the human bloodstream by the bite of an infected female *Anopheles* mosquito, more than 60 species of which can carry the infection to humans. The disease is found in all tropical and some temperate regions, but it has been eradicated in North America, Europe, and Russia. Despite control efforts, malaria has probably been the greatest single killer disease throughout human history and continues to be a major infectious disease. *See* EPIDEMIC.

The vast reproductive capacity of *Plasmodium* parasites is illustrated by their life cycle, which begins as a series of asexual divisions in human liver and then red blood cells. Transfer of the parasites to the mosquito host depends on the rate of sexual multiplication that begins in the infected human red blood cells and is completed in the mosquito stomach, followed by asexual multiple division of the product of sexual fusion. Clinical malaria usually begins 7–18 days after infection with sporozoites. Red cell infections tend to follow a remarkably synchronous division cycle. The parasite progresses from merozoite to a vegetative phase (trophozoite) to a division stage (schizont), ending with the new generation of merozoites ready to break out in a burst of parasite releases and initiate the chills-fever-sweat phase of the disease. The sequence of chills, fever, and sweats is the result of simultaneous red cell destruction at 48- or 72-h intervals. *See* SPOROZOA.

Chloroquine remains the drug of choice for prevention as well as treatment of vivax, ovale, and malariae malaria. However, most strains of falciparum malaria have become strongly chloroquine-resistant. For prevention of chloroquine-resistant falciparum malaria (and in some areas vivax malaria is now chloroquine-resistant as well) a weekly dose of mefloquine beginning a week before, then during, and for 4 weeks after leaving the endemic area is recommended. Chloroquine-resistant malaria is chiefly treated with the oldest known malaricide, quinine, in the form of quinine sulfate, plus pyrimethamine-sulfadoxine. *See* DRUG RESISTANCE; QUININE.

Failure of earlier efforts to eradicate malaria and the rapid spread of resistant strains of both parasites and their mosquito vectors necessitated renewed interest in prevention of exposure by avoidance of mosquito bites using pyrethrin-treated bednets, coverage of exposed skin during active mosquito periods (usually dawn, dusk, and evening hours), and use of insect-repellent lotions. A balance between epidemiological and immunological approaches to prevention, and the continued development of new drugs for prophylaxis and treatment are recognized as the most effective means to combat one of the most dangerous and widespread threats to humankind from an infectious agent. *See* MEDICAL PARASITOLOGY. [D.He.]

Mallophaga A comparatively small order of insects numbering perhaps 3000 known species which are commonly called the bird lice or, more correctly, the biting lice. Most of them occur among the feathers of birds. Only a comparatively small number, perhaps 300 species, occur on mammals. The group can be distinguished from the sucking lice by the fact that they always possess mandibles. Unlike sucking lice, they never have claws enlarged or modified to close about a hair or a feather. The significant difference between biting and sucking lice is the fact that the Mallophaga rarely transmit any disease of their host, while the sucking lice are well-known vectors of organisms that cause certain diseases.



Morphology of two typical mallophagans.

The group may be technically defined as follows (see illustration): relatively small insects, much flattened and permanently without wings. The antennae are five-segmented; mandibles are distinctly developed and their apices cross. The prothorax is developed as a distinct segment, while the mesothorax and metathorax at times are closely fused. Legs possess either one or two terminal claws. The ovipositor is greatly reduced in size.

Like the sucking lice, the Mallophaga are closely adapted to life upon a single host species or, at most, upon a group of closely related hosts. The physical adaptation is not as close as in the sucking lice. There is enough adaptation, however, to preclude the ready passage of a mallophagan from one host species to another, particularly at times other than in the nest or when the hosts are in close bodily contact. The result is that they are usually passed from an animal to its offspring as a sort of racial inheritance, and the insects live as upon an "island" which is the host. Because of this, the classification of the Mallophaga reflects in a way the classification of their hosts. *See* Anoplura; Insecta. [D.M.DeL.]

Malnutrition Impaired health caused by a dietary deficiency, excess, or imbalance. To support human life, energy (from fat, carbohydrate, and protein), water, and more than 40 different food substances must be obtained from the diet in appropriate amounts. Malnutrition can result from the chronic intake of any of these substances at levels above, as well as below, ranges that are adequate and safe, but commonly the term refers only to deficient intake.

The number of people throughout the world who suffer from nutritional deficiencies as a result of inadequate dietary intake is uncertain, but even the most conservative estimates place that figure at hundreds of millions; many experts consider the actual number to approach 1 billion. Most malnourished people live in developing countries where income, education, and housing are inadequate to buy, transport, store, and prepare food and where nutritional deficiencies are almost always related to poverty. In industrialized countries, chronic conditions of deficient dietary intake occur far less frequently but are reported occasionally among people who are dieting to lose weight, fasting, or on an unusually restrictive ("fad") diet. Pregnant women, infants, and children are most at risk for inadequate dietary intake because their nutritional requirements are relatively high.

Nutritional deficiencies also occur as a result of illness, injury, or alcohol or drug abuse that interferes with appetite; the inability to eat; defective digestion, absorption, or metabolism of food molecules; or disease states that increase nutrient losses. Secondary malnutrition has been observed frequently among medical and surgical patients who are treated in hospitals for prolonged periods of time. Regardless of cause, the effects of malnutrition can range from minor symptoms to severe syndromes of starvation, protein-calorie malnutrition, or single-nutrient deficiencies. *See* Metabolic disorders.

The chronic intake of energy below the level of expenditure induces rapid losses in body weight and muscle mass accompanied by profound changes in physiology and behavior. Together, these effects cause a starving person to become weak, apathetic, depressed, and unable to work productively and to do whatever is necessary to reverse the malnutrition. The consequences of nutritional deficiencies are seen first in tissues that are growing rapidly. These changes are most evident in the gastrointestinal tract, skin, blood cells, and nervous system as indigestion, malabsorption, skin lesions, anemia, or neurologic and behavior changes. Of special concern is the loss of immune function that accompanies severe malnutrition.

The combined effects of malnutrition and infection in young children are referred to as protein-calorie malnutrition. It classified into two entities, marasmus and kwashiorkor, on the basis of physical appearance and the relative proportions of protein and calories in the diet. Children with the marasmus form appear generally wasted as a result of diets that are chronically deficient in calories as well as protein and other nutrients. Children with kwashiorkor are also very thin but have characteristically bloated bellies due to fluid retention and accumulation of fat in the liver, symptoms attributed to diets relatively deficient in protein. *See* Adipose tissue; Protein metabolism.

Deficiency conditions due to lack of a single vitamin or mineral occur rarely and usually reflect the lack of the most limiting nutrient in a generally deficient diet. In industrialized countries, single-nutrient deficiencies are most evident in individuals who abuse alcohol or drugs. Classic conditions of deficiency of niacin (pellagra), thiamine (beriberi), vitamin C (scurvy), and vitamin D (rickets) have virtually disappeared as a result of food fortification programs and the development of food distribution systems that provide fresh fruits and vegetables throughout the year. Iron-deficiency anemia also has declined in prevalence, although children in low-income families remain at risk. In developing countries, however, such conditions are still observed among people whose diets depend on one staple food as the major source of calories. A condition of substantial current public health importance is vitamin A deficiency, which is the principal cause of blindness and a major contributor to illness and death among children in developing countries. *See* Anemia; Vitamin. [M.N.]

Malpighiales One of the largest orders of the rosid eudicotyledons, comprising more than 30 families distributed worldwide. Recent analyses of deoxyribonucleic acid (DNA) sequences, both plastid and nuclear, led to its recognition, even though the group is highly heterogeneous and difficult to characterize. The largest families are Euphorbiaceae (8000 species), Clusiaceae (1400), Malpighiaceae (1100), Flacourtiaceae (900), and Violaceae (850). Most of the order is composed of woody species, many of regional importance as timber and medicines. Several of the smaller families are significant as well, including Salicaceae (used as coppice, and the original source of aspirin) and Rhizophoraceae (the ecologically significant mangroves). *See* Magnoliophyta. [M.W.C.]

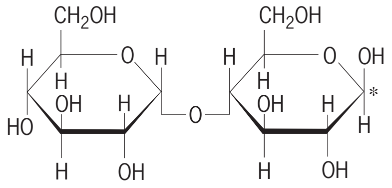
Malt beverage A fermented beverage produced from grain. Beer is a generic term used to describe alcoholic beverages made from cereal grains, especially barley, in the form of malt. Ale, lager, porter, and stout are different kinds of beer made by recognizably similar processes. The United States is the largest producer of beer in the world.

The manufacture of beer is a complex natural process of three general parts: the preparation of barley by germination, or the malting process; the actual digestion of barley (now malt) starch to produce a solution of sugars (called wort) and the adjustment of flavor with hops, which are the brewhouse processes; and the fermentation of these sugars by yeast to yield alcohol, carbon dioxide gas, and flavor compounds to produce beer. [M.J.L.]

Maltase An enzyme which breaks down (hydrolyzes) the disaccharide maltose into glucose. Maltase has been found in the pancreas, intestine, liver, kidney, and blood serum of animals. It has also been found in the bacteria, fungi, and monocotyledonous and dicotyledonous plants. *See* Carbohydrate metabolism; Enzyme. [D.N.La.]

Maltose An oligosaccharide, known as malt sugar, a reducing disaccharide (see illustration). It is fermentable by yeast in the presence of D-glucose.

The action of animal (salivary and pancreatic) as well as plant (germinating cereals, sweet potato) amylases on starch, dextrin,



Formula for maltose (α form; * indicates reducing group).

and glycogen produces maltose as the main end product. Maltose is hydrolyzed by acids and the enzyme maltase to two molecules of D-glucose. *See* Glucose; Maltase; Oligosaccharide. [W.Z.H.]

Malvales An order of flowering plants in the core eudicots. The order consists of 10 families and more than 5500 species. The circumscription of the order has been altered greatly in recent years, largely on the basis of deoxyribonucleic acid (DNA) sequence data. Of the five families in the traditional concept (Bombacaceae, Malvaceae, Sterculiaceae, Tiliaceae, and Elaeocarpaceae), the first four have been combined as Malvaceae, due to lack of monophyly of three of these families in their traditional circumscription; and Elaeocarpaceae are included in Oxalidales. In addition, other families have been transferred to Malvales, including Dipterocarpaceae and Thymelaeaceae. The expanded order is characterized by the presence of mucilage in epidermal cells and cavities; and of palmate leaves, stellate hairs, and numerous stamens with partially fused filaments occur frequently.

Malvaceae are cosmopolitan and include economic crops such as cotton (*Gossypium*), cocoa (*Theobroma*), and durian (*Durio*) and horticultural plants such as hollyhocks (*Althaea*) and rose of Sharon (*Hibiscus*). Dipterocarpaceae are important elements of tropical forests, especially in Southeast Asia, and provide hardwood timbers. Other horticultural genera in the order include *Cistus* and *Helianthemum* (Cistaceae) and *Daphne* (Thymelaeaceae). Several genera of Thymelaeaceae provide fibers used for making paper, and *Bixa* (Bixaceae) is the source of the orange dyestuff anatto. *See* Cacao; Cotton; Eudicotyledons. [M.W.C.]

Mammalia The class Mammalia has been the dominant group of vertebrates since the extinction of the dinosaurs 65 million years ago. There are over 4200 living species, classified into over 1000 genera, 140 families, and 18 orders. The number of extinct mammals is at least five times that. Most living mammals are terrestrial. However, many groups of mammals moved to the water from land-dwelling ancestors. These included manatees and dugongs (which are distantly related to elephants), otters (which are related to weasels), seals, sea lions, and walruses (which are distantly related to bears), and whales (which are distantly related to even-toed hoofed mammals), as well as numerous extinct groups. Mammals have also taken to the air, with over 920 living species of bats, as well as numerous gliding forms such as the flying squirrels, phalangerid marsupials, and flying lemurs or colugos. Mammals are even more successful at small body sizes, with hundreds of small species of rodents, rabbits, and insectivores.

Mammals are distinguished from all other animals by a number of unique characteristics. These include a body covered with hair or fur (secondarily reduced in some mammals, particularly aquatic forms); mammary glands in the female for nursing the young; a jaw composed of a single bone, the dentary; and three middle ear bones, the incus, malleus, and stapes. All mammals maintain a constant body temperature through metabolic heat. Their four-chambered heart (two ventricles and two atria) keeps the circulation of the lungs separate from that of the rest of the body, resulting in more efficient oxygen transport to the body tissues. They have many other adaptations for their active lifestyle, including specialized teeth (incisors, canines, molars, and premolars) for biting, tearing, and grinding up food for more efficient digestion. These teeth are replaced only once in the lifetime of the animal (rather than continuous replacement, found in other toothed vertebrates). Mammals have a unique set of muscles that allow the jaw to move in many directions for chewing and for stronger bite force. Their secondary palate encloses the internal nasal passage and allows breathing while they have food in the mouth. Ribs (found only in the thoracic region) are firmly attached to the breastbone (sternum), so that expansion of the lung cavity is accomplished by a muscular wall in the abdominal cavity called the diaphragm. *See* Cardiovascular system; Dentition; Ear (vertebrate); Hair; Lactation; Mammary gland; Thermoregulation; Tooth.

All mammals have large brains relative to their body size. Most mammals have excellent senses, and some have extraordinary senses of sight, smell, and hearing. To accommodate their large brains and more sophisticated development, mammals are born alive (except for the platypus and echidnas, which lay eggs), and may require considerable parental care before they are ready to fend for themselves. Juvenile mammals have separate bony caps (epiphyses) on the long bones, separated from the shaft of the bone by a layer of cartilage. This allows the long bones to grow rapidly while still having a strong, bony articulation at the end. When a mammal reaches maturity, these epiphyses fuse to the shaft, and the mammal stops growing (in contrast to other vertebrates, which grow continuously through their lives). *See* Brain; Nervous system (vertebrate); Skeletal system.

The living mammals are divided into three major groups: the monotremes (platypus and echidnas), which still lay eggs, retain a number of reptilian bones in their skeletons, and have other primitive features of their anatomy and physiology; the marsupials (opossums, kangaroos, koalas, wombats, and their relatives), which give birth to an immature embryo that must crawl into the mother's pouch (marsupium), where it finishes development; and the placentals (the rest of the living mammals), which carry the young through a long gestation until they give birth to relatively well-developed progeny. In addition to these three living groups, there were many other major groups, such as the rodentlike multituberculates, now extinct. The most recent classification of the mammals can be summarized as follows:

- Class Mammalia
  - Subclass Prototheria (monotremes)
  - Subclass Theriiformes
    - Infraclass Holotheria
      - Cohort Marsupialia (marsupials or pouched mammals)
      - Cohort Placentalia (placentals)
      - Magnorder Xenarthra (sloths, anteaters, armadillos)
      - Magnorder Epitheria
        - Grandorder Anagalida (= Glires) (rodents, rabbits, elephant shrews)
        - Grandorder Ferae (carnivores, pangolins, many extinct groups)
        - Grandorder Lipotyphla (hedgehogs, shrews, moles, tenreces, and kin)
        - Grandorder Archonta
          - Order Chiroptera (bats)
          - Order Primates (lemurs, monkeys, apes, humans)
          - Order Scandentia (tree shrews)
        - Grandorder Ungulata (hoofed mammals)
          - Order Tubulidentata (aardvarks)
          - Order Artiodactyla (even-toed hoofed mammals: pigs, hippos, camels, deer, antelopes, cattle, giraffes, pronghorns, and relatives)

Order Cete (whales and their extinct land relatives)
Order Perissodactyla (odd-toed hoofed mammals: horses, rhinos, tapirs, and extinct relatives)
Order Hyracoidea (hyraxes)
Order Tethytheria (elephants, manatees, and extinct relatives)

This classification does not list all the extinct groups, which include at least a dozen more ordinal-level taxa. See separate articles on each group. *See* REPRODUCTIVE SYSTEM.

Mammals evolved from the Synapsida, an early branch of the terrestrial amniotes that has been erroneously called the mammallike reptiles. (This name is inappropriate because synapsids were never related to reptiles.) The first undoubted mammals appeared in the Late Triassic (about 210 million years ago), and were tiny insectivorous forms much like living shrews. Through the rest of the age of dinosaurs, a number of different groups evolved over the next 145 million years of the Jurassic and Cretaceous. Most remained tiny, shrewlike animals, hiding from the dinosaurs in the underbrush and coming out mostly at night. The first two-thirds of mammalian history had passed before the dinosaurs became extinct 65 million years ago, and this allowed mammals to emerge from their shadow. Between 65 and 55 million years ago, a rapid adaptive radiation yielded all the living orders of placental mammals and many extinct forms as well. [D.R.Pr.]

Mammary gland A unique anatomical structure of mammals that secretes milk for the nourishment of the newborn. The mammary gland contains thousands of milk-producing units called alveoli, each of which consists of a unicellular layer of epithelial cells arranged in a spheroid structure. The alveolar epithelial cells take up a variety of nutrients from the blood that perfuses the outer surface of the alveolar structures. Some of the nutrients are then secreted directly into the alveolar lumen; other nutrients are used to synthesize the unique constituents of milk which are then secreted. Each alveolus is connected to a duct through which milk flows. The ducts from many alveoli are connected via a converging ductal system which opens externally by way of the lactiferous pore.

Surrounding each alveolus and its associated small ducts are smooth muscle cells called myoepithelial cells. These cells contract in response to the posterior pituitary hormone oxytocin; milk is thus forced out of the alveoli, through the ductal system, and out the lactiferous pore for the nourishment of the newborn. The release of oxytocin is a neuroendocrine reflex triggered by the stimulation of sensory receptors by the suckling of the newborn. *See* ENDOCRINE MECHANISMS.

Mammary glands are basically highly modified and specialized sebaceous glands which derive from ectoderm. In the embryo, mammary lines, formed on both sides of the midventral line, mark the location of future mammary glands. Along the mammary lines discrete ectodermal ingrowths, called mammary buds, produce a rudimentary branched system of ducts at birth. In all species (except the monotremes) a nipple or teat develops in concert with the mammary buds. In the most primitive mammal (the duckbill or platypus), which lacks nipples or teats, milk simply oozes out of the two mammary gland areas and is lapped up by the young.

From birth to sexual maturity the mammary gland consists of a nipple and a rudimentary ductal system in both males and females. At the onset of puberty in the female, the enhanced secretion of estrogen causes a further development of the mammary ductal system and an accumulation of lipids in fat cells. After puberty in women, the mammary gland consists of about 85% fat cells and a partially developed ductal system. *See* ESTROGEN.

During pregnancy the mammary gland comes under the influence of estrogen and progesterone which are derived from both the ovary and placenta. These hormones cause a further branching of the ductal system and the development of milk-secreting structures, the alveoli. In humans, approximately 200 alveoli are surrounded by a connective tissue sheath forming a structure called a lobule. About 26 lobules are packaged via another connective tissue sheath into a larger structure called a lobe. Each of 15–20 lobes is exteriorized into the nipple via separate lactiferous pores. *See* PROGESTERONE.

A complement of hormones maximizes the development of the ductal and lobuloalveolar elements in the mammary gland. Optimal ductal growth is attained with estrogen, a glucocorticoid, prolactin, and insulin. Maximal lobuloalveolar growth is obtained with estrogen, progesterone, growth hormone, prolactin, a glucocorticoid, and insulin. During pregnancy estrogen and progesterone stimulate mammary development but inhibit milk production.

During the final third of pregnancy, the alveolar epithelial cells begin secreting a fluid called colostrum. This fluid fills the alveoli and causes a gradual enlargement of the breast or udder. At parturition, the inhibitory influence of estrogen and progesterone is removed, and the gland can secrete milk under the influence of a further complement of hormones including prolactin, a glucocorticoid, insulin, and the thyroid hormones. *See* GLAND; LACTATION; MAMMALIA; MILK; PREGNANCY. [J.A.Ri.]

Mammography The radiological imaging of breast tissue. This procedure is used to identify cancer, preferably when still impalpable. Because of improved resolution in high-contrast film, only minor exposure of skin to x-rays is required, so that national screening programs have been set up in many western industrialized countries.

Mammography depends on the tumor being reflected as a dense focus in contrast to surrounding tissue or less dense glandular and ductal parts of the structure. Discrimination between benign and malignant lesions may sometimes be difficult, but may be aided by increased magnification of the image and by spot compression to confirm otherwise equivocally benign lesions. In addition, ultrasonography may be used to distinguish between cystic (mainly benign) and solid (possibly malignant) masses. Many women with impalpable cancers discovered through mammography have microcalcifications as the diagnostic feature; others are diagnosed by the presence of a distinct mass, architectural asymmetry of the glandular and ductal tissue, or tissue distortion.

Mammography has recognized limitations: the possibility exists that in some postmenopausal women it will fail to reveal cancer that is present. Similarly, in premenopausal women in whom the breast tissue is often dense, mammography can be falsely negative in some women with subsequently proven cancers. However, the ability of mammography to reflect breast changes over time and its value in the surveillance of women with breast cancer treated by conservation techniques (lumpectomy and radiation) has made mammography an invaluable clinical tool. *See* BREAST DISORDERS; CANCER (MEDICINE); MEDICAL ULTRASONIC TOMOGRAPHY; RADIOGRAPHY. [A.J.W.]

Mandarin A name used to designate a large group of citrus fruits in the species *Citrus reticulata* and some of its hybrids. This group is variable in the character of trees and fruits since the term is used in a general sense to include many different forms, such as tangerines, King oranges, Temple oranges, tangelos (hybrids between grapefruit and tangerine), Satsuma oranges, and Calamondin, presumably a hybrid between a mandarin and a kumquat. *See* KUMQUAT; ORANGE; TANGERINE.

Although tangerines are the most extensively planted of the mandarin group, others, particularly the Temple orange, the Murcott orange, and the tangelos, of which there are several varieties, are important commercial fruits in the United States. *See* FRUIT; FRUIT, TREE; SAPINDALES. [F.E.G.]

Mandibulata A subphylum of the phylum Arthropoda in the long-established classification scheme which comprises three groups at subphylum level; it is almost certainly not a natural assemblage. Mandibulata, defined as those arthropods possessing mandibles (lateral jaws) and antennae, includes the six classes Insecta, Chilopoda, Diplopoda, Symphyla, Pauropoda, and Crustacea. In fact, neither in their development nor in their functional morphology are the mandibles of crustaceans homologous with the mandibles of insects. The available fossil evidence for primitive crustaceans also supports a different phyletic origin for these appendages. In addition, insects have a single pair of antennae, while crustaceans have two pairs. *See* Arthropoda; Chilopoda; Crustacea; Diplopoda; Insecta; Pauropoda; Symphyla. [W.D.R.H.]

Manganese A metallic element, Mn, atomic number 25, and atomic weight 54.9380 g/mole. Manganese is one of the transition elements of the first long period of the periodic table, falling between chromium and iron. The principal properties of manganese are given in the table. It is the twelfth most abundant element in the Earth's crust (approximately 0.1%) and occurs naturally in several forms, primarily as the silicate ($MnSiO_3$) but also as the carbonate ($MnCO_3$) and a variety of oxides, including pyrolusite (MnO_2) and hausmannite (Mn_3O_4). Weathering of land deposits has led to large amounts of the oxide being washed out to sea, where they have aggregated into the so-called manganese nodules containing 15–30% Mn. Vast deposits, estimated at over 10^{12} metric tons, have been detected on the seabed, and a further 10^7 metric tons is deposited every year. The nodules also contain smaller amounts of the oxides of other metals such as iron (Fe), cobalt (Co), nickel (Ni), and copper (Cu). The economic importance of the nodules as a source of these important metals is enormous. *See* Hausmannite; Manganese nodules; Periodic table; Pyrolusite.

Properties of manganese

Property	Value
Atomic number	25
Atomic weight, g/mole	54.9380
Naturally occurring isotope	^{55}Mn (100%)
Electronic configuration	$[Ar]3d^54s^2$
Electronegativity	1.5
Metal radius, picometers	127
Melting point, °C (°F)	1244 ± 3 (2271 ± 5.4)
Boiling point. °C (°F)	1962 (3563)
Density (25 °C or 77°F), g/cm^3 (oz/in.^{3})	7.43 (4.30)
Electrical resistivity, ohm·cm	185×10^{-6}

Manganese is more electropositive than its near neighbors in the periodic table, and consequently more reactive. The bulk metal undergoes only surface oxidation when exposed to atmospheric oxygen, but finely divided metal is pyrophoric.

Manganese is a trace element essential to a variety of living systems, including bacteria, plants, and animals. In contrast to iron (Fe), its neighbor in the periodic table, the exact function of the manganese in many of these systems was determined only recently. The manganese superoxide dismutases have been isolated from bacteria, plants, and animals, and are relatively small enzymes with molecular weights of approximately 20,000. The function of the enzyme is believed to be protection of living tissue from the harmful effects of the superoxide ion (O_2^-), a radical formed from partial reduction of O_2 in the cells of respiring (O_2-utilizing) cells.

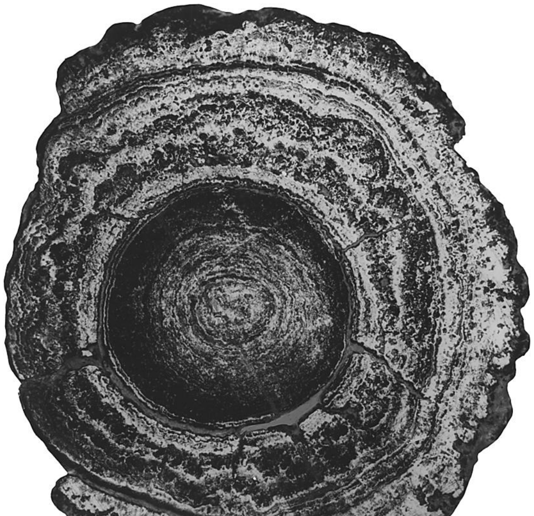
The most important biological role yet recognized for manganese is in the enzyme responsible for photosynthetic water oxidation to oxygen in plants and certain photosynthetic bacteria. This reaction represents the source of oxygen gas on the Earth and is therefore responsible for the development of the most common forms of life.

All steels contain some manganese, the major advantage being an increase in hardness, although it also serves as a scavenger of oxygen and sulfur impurities that would induce defects and consequent brittleness in the steel. Manganese even has some use in the electronics industry, where manganese dioxide, either natural or synthetic, is employed to produce manganese compounds possessing high electrical resistivity; among other applications, these are utilized as components in every television set. *See* Electrolysis; Glass; Metal; Transition elements. [G.Ch.]

Manganese nodules Concentrations of manganese and iron oxides found on the floors of many oceans. The origin of these potato-shaped metal-rich deposits has been elucidated; their complex growth histories are revealed by the textures of nodule interiors shown in the illustration.

Marine manganese nodules from certain regions are significantly enriched in nickel, copper, cobalt, zinc, molybdenum, and other elements so as to make them important reserves for these strategic metals.

Although manganiferous nodules and crusts have been sampled or observed on most sea floors, attention has focused on the nickel-plus-copper-rich nodules (2–3 wt% metals) from the north equatorial Pacific in a belt stretching from southeast Hawaii to Baja California, as well as the high-cobalt nodules from seamounts in the Pacific Ocean. Manganese nodules from the Atlantic Ocean and from higher latitudes in the Pacific Ocean have significantly lower concentrations of the minor strategic metals. However, surveys of the Indian Ocean have revealed metal-enrichment trends comparable to those found in the Pacific Ocean nodules; high Ni + Cu-bearing nodules are found adjacent to the Equator.



Reflected-light photograph of the polished surface of a sectioned manganese nodule showing the complex growth history of the concretionary deposit (diameter 1.6 in. or 4 cm).

Microchemical analyses have revealed that chemical differences exist between the outermost top (exposed to sea water) and bottom (immersed in sediment) layers of manganese nodules. Surfaces buried in underlying sediments are generally higher in Mn, Ni, and Cu contents, compared to the more Fe + Co-rich surfaces exposed to sea water. Episodic rolling-over of a nodule accounts for fluctuating concentrations of Mn, Fe, Ni, Cu, Co, and other metals across sectioned manganese nodules. [R.G.Bu.]

Manganese oxide minerals Minerals that contain manganese (Mn) and oxygen (O) or the hydroxyl ion (OH) as principal components. Over 20 manganese oxide minerals have been identified. They can be broadly categorized by the primary oxidation state of manganese in the mineral as tetravalent (Mn^{4+}), trivalent (Mn^{3+}), or divalent (Mn^{2-}) manganese oxides. Tetravalent and trivalent manganese oxides occur in widespread continental and marine environments. They are the primary constituents of manganese nodules and crusts that occur in vast quantities on the ocean floors. Manganese oxide minerals are of economic importance as a source of manganese for the manufacture of steel, and some are used as the cathodic material in dry-cell batteries. *See* Hydroxyl; Manganese.

The basic structural unit for many of the manganese oxide minerals is an octahedron formed from a manganese cation surrounded by six oxygens (MnO_6). Octahedra in these structures are linked to one another by sharing either corners (one oxygen atom) or edges (two oxygen atoms). The octahedra are then linked in some minerals to form chains of different widths, and in other minerals to form layers or sheets of octahedra. *See* Crystal.

The manganese oxides are black and opaque with the exception of manganosite (emerald green) and pyrochroite (colorless to pale green or blue). Both manganosite and pyrochroite become black on exposure to air. Most of the manganese oxides have a specific gravity of 4–5 and a hardness of 5–7 or less. Some of the minerals have a wide range of hardness. Many of the manganese oxides commonly are poorly crystalline and occur in irregular masses or grains. Many manganese oxides are intimately intergrown with other manganese oxides or other minerals on a fine scale. *See* Hausmannite; Manganite; Pyrolusite. [S.T.]

Manganite A mineral having composition MnO(OH) and crystallizing in the orthorhombic system in prismatic crystals with deep vertical striations. The hardness is 4 on Mohs scale, and the specific gravity is 4.3. The luster is metallic and the color iron black. Fine crystals have been found in the Harz Mountains; in Cornwall, England; and in the United States at Negaunee, Michigan. Manganite is a minor ore of manganese. *See* Manganese. [C.S.Hu.]

Mango A tree (*Mangifera indica*) of the family Anacardiaceae that originated in the Indo-Burma region and is now grown throughout the world. The mango is a medium to large evergreen tree; it produces a dense, round canopy, with leaves which are reddish brown when young and dark green when mature.

In the United States, mangoes are grown only in Florida and on a small scale in Hawaii, usually as backyard trees. Their greatest importance is in India, where almost 2,000,000 acres (800,000 hectares) are grown constituting 75% of the world area devoted to mango production. The ripe fruit is eaten raw as a dessert or used in the manufacture of juice, jams, jellies, and preserves. Unripe fruit can be made into pickles or chutneys. Mangoes are a good source of vitamins A and C. *See* Fruit, tree; Sapindales. [R.M.Wa.]

Mangrove A taxonomically diverse assemblage of trees and shrubs that form the dominant plant communities in tidal, saline wetlands along sheltered tropical and subtropical coasts. The development and composition of mangrove communities depend largely on temperature, soil type and salinity, duration and frequency of inundation, accretion of silt, tidal and wave energy, and cyclone or flood frequencies. Extensive mangrove communities seem to correlate with areas in which the water temperature of the warmest month exceeds 75°F (24°C), and they are absent from waters that never exceed 75°F (24°C) during the year. Intertidal, sheltered, low-energy, muddy sediments are the most suitable habitats for mangrove communities, and under optimal conditions, forests up to 148 ft (45 m) in height can develop. Where less favorable conditions are found, mangrove communities may reach maturity at heights of only 3 ft (1 m). *See* Ecosystem.

Plants of the mangrove community belong to many different genera and families, many of which are not closely related to one another phylogenetically. However, they do share a variety of morphological, physiological, and reproductive adaptations that enable them to grow in an unstable, harsh, and salty environment. Approximately 80 species of plants belonging to about 30 genera in over 20 families are recognized throughout the world as being indigenous to mangroves. About 60 species occur on the east coasts of Africa and Australasia, whereas about 20 species are found in the Western Hemisphere. At the generic level, *Avicennia* and *Rhizophora* are the dominant plants of mangrove communities throughout the world, with each genus having several closely related species in both hemispheres. At the species level, however, only a few species, such as the portia tree (*Thespesia populnea*), the mangrove fern (*Acrostichum aureum*), and the swamp hibiscus (*Hibiscus tiliaceus*), occur in both hemispheres.

The mangrove community is often strikingly zoned parallel to the shoreline, with a sequence of different species dominating from open water to the landward margins. These zones are the response of individual species to gradients of inundation frequency, waterlogging, nutrient availability, and soil salt concentrations across the intertidal area, rather than a reflection of ecological succession, as earlier studies had suggested. *See* Ecological succession.

Most plants of the mangrove community are halophytes, well adapted to salt water and fluctuations of tide level. Many species show modified root structures such as stilt or prop roots, which offer support on the semiliquid or shifting sediments, whereas others have erect root structures (pneumatophores) that facilitate oxygen penetration to the roots in a hypoxic environment. Salt glands, which allow excess salt to be extruded through the leaves, occur in several species; others show a range of physiological mechanisms that either exclude salt from the plants or minimize the damage excess salts can cause by separating the salt from the sensitive enzyme systems of the plant. Several species have well-developed vivipary of their seeds, whereby the hypocotyl develops while the fruit is still attached to the tree. The seedlings are generally buoyant, able to float over long distances in the sea and rapidly establish themselves once stranded in a suitable habitat. *See* Plants, saline environments of.

A mangrove may be considered either a sheltered, muddy, intertidal habitat or a forest community. The sediment surface of mangrove communities abounds with species that have marine affinities, including brightly colored fiddler crabs, mound-building mud lobsters, and a variety of mollusks and worms, as well as specialized gobiid fish (mudskippers). The waterways among the mangroves are important feeding and nursery areas for a variety of juvenile finfish as well as crustaceans. Animals with forest affinities that are associated with mangroves include snakes, lizards, deer, tigers, crab-eating monkeys, bats, and many species of birds.

Economically, mangroves are a major source of timber, poles, thatch, and fuel. The bark of some trees is used for tanning materials, whereas other species have food or medicinal value. *See* Ecological communities; Forest management. [P.Sae.]

Manifold (mathematics) A Hausdorff topological space with an n-dimensional atlas of charts for some integer n. The integer n is called the dimension of the manifold. If M is a Hausdorff space, an n-chart on M is a pair (U, φ) with U an open subset of M and φ a homeomorphism of U onto an open subset $\varphi(U)$ of n-dimensional euclidean space $\mathbf{R}^n$. An n-dimensional atlas for M is a system of n-charts (U, φ) such that the union of the sets U is all of M. *See* TOPOLOGY.

The terminology "charts" and "atlases" comes from the geographer's way of viewing the surface of the Earth. The manifold described in this case is the two-dimensional sphere $M = S^2$.

Many mathematicians include an additional restriction in the definition of manifold—sometimes the underlying topological space is connected, sometimes the topology is given by a metric, sometimes both.

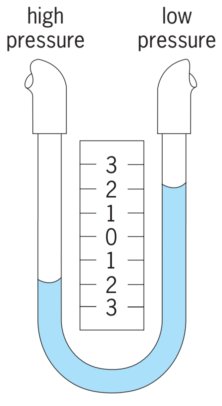
With an appropriate additional structure on a manifold, it is possible to speak of differentiability or smoothness of real-valued functions. In this setting, the notion of a smooth mapping between smooth manifolds can be defined, and the differential of a smooth mapping, which is a generalization of the derivative, can be introduced.

Two charts (U_1, φ_1) and (U_2, φ_2) in an atlas for an n-dimensional manifold M are compatible (for defining smoothness) if the mapping $\varphi_2 \circ \varphi_1{}^{-1}$ from the open set $\varphi_1(U_1 \cap U_2)$ in $\mathbf{R}^n$ to the open set $\varphi_2(U_1 \cap U_2)$ is infinitely differentiable and has an infinitely differentiable inverse function. If all the charts in an atlas are compatible with one another, the atlas is said to determine a differentiable structure on M, and M with its atlas is then called a smooth manifold. Two atlases determine the same differentiable structure if all the charts in question are compatible with one another. Smooth manifolds are called also differentiable manifolds, differential manifolds, and C^∞ manifolds.

Alternate definitions of compatibility of charts lead to other classes of manifolds. Thus a manifold with its atlas is said to be piecewise linear (PL) or real analytic if all the mappings $\varphi_2 \circ \varphi_1{}^{-1}$ have the corresponding property.

If the dimension n is even, say $2m$, then the open sets in $\mathbf{R}^n$ can be regarded as open sets in the complex space $\mathbf{C}^m$ The manifold with its atlas is called a complex manifold of dimension m if the mappings $\varphi_2 \circ \varphi_1{}^{-1}$ are analytic functions of several variables. Complex manifolds are used in studying varieties in algebraic geometry. *See* ALGEBRAIC GEOMETRY; COMPLEX NUMBERS AND COMPLEX VARIABLES; SERIES. [A.W.K.]

Manometer A double-leg liquid-column gage used to measure the difference between two fluid pressures. Micromanometers are precision instruments which typically measure from very low pressures to 50 mm of mercury (6.7 kilopascals). The barometer is a special case of manometer with one pressure at zero absolute. *See* BAROMETER.



U-tube manometer.

The various types of manometers have much in common with the U-tube manometer, which consists of a hollow tube, usually glass, a liquid partially filling the tube, and a scale to measure the height of one liquid surface with respect to the other (see illustration). If the legs of this manometer are connected to separate sources of pressure, the liquid will rise in the leg with the lower pressure and drop in the other leg. The difference between the levels is a function of the applied pressure and the specific gravity of the pressurizing and fill fluids.

A well-type manometer has one leg with a relatively small diameter, and the second leg is a reservoir. The cross-sectional area of the reservoir may be as much as 1500 times that of the vertical leg, so that the level of the reservoir does not change appreciably with a change of pressure. Mercurial barometers are commonly made as well-type manometers.

The inclined-tube manometer is used for gage pressures below 10 in. (250 mm) of water differential. The leg of the well-type manometer is inclined from the vertical to elongate the scale. Inclined double-leg U-tube manometers are also used to measure very low differential pressures. *See* PRESSURE MEASUREMENT. [J.H.Z.]

Manufactured fiber Any of a number of textile fibers produced from chemical substances of natural origin or synthetic origin; the latter are also known as synthetic fibers. Among the natural sources of manufactured fibers are plant cellulose and protein, rubber, metals, and nonmetallic inorganics. The synthetic fibers are produced from organic intermediates derived from petroleum, coal, and natural gas. *See* NATURAL FIBER; TEXTILE.

With the exceptions of glass and metal fibers, the manufactured fibers are made from very long chainlike molecules called linear polymers. These polymers may be naturally occurring (cellulose from cotton or wood pulp) or may be synthetic (polyester). Irrespective of their chemical nature, fiber-forming polymers must possess the following characteristics: (1) great length—at least 200 monomer units must be joined in a chain; (2) a high degree of intramolecular and intermolecular attraction, whether through primary chemical bonds or other attractive forces; (3) the ability to be oriented along the axis of the fiber; and (4) the ability to form well-ordered crystals or pseudocrystals. All of these parameters are sensitive to the chemical nature of the polymer and the processes of manufacture of the fiber. In turn, they establish the properties of the fiber, such as strength, flexibility, resilience, and abrasion resistance, which contribute to their usefulness in various end uses for apparel, home furnishings, and commercial and industrial applications. *See* POLYMER.

Only a fraction of those substances capable of forming fibers prove to have all of the characteristics necessary for commercial success. The fiber types of major importance in the United States are classified by composition as follows: cellulosic (composed of regenerated cellulose, cellulose diacetate, and cellulose triacetate); synthetic (composed of polyamide, polyester, polyacrylic, polyvinyl, and polyolefin resins); and inorganic (composed of glass and metal).

All of the manufactured fibers are produced according to the same principles: (1) the fiber-forming material must first be made fluid; (2) the fluid is forced under pressure (extruded) through tiny holes into a medium which causes it to solidify; and (3) the solid fibers are further processed to obtain their optimum properties.

Typically one of three procedures is used to produce fibers. In wet spinning, (for example, the production of rayon by the viscose process), the polymer is dissolved in an applicable reagent to form the fluid (dope). The fluid is then pumped through metal plates (spinnerets) containing many small holes into a liquid bath of appropriate composition. A chemical reaction between the spinning dope and the bath causes the fiber to solidify. In dry spinning, the polymer is again dissolved in an appropriate solvent and extruded through a spinneret. However, the liquid bath is replaced by a stream of warm gas (usually air) which evaporates the solvent and allows the polymer to solidify as a filament. Cellulose diacetate and triacetate are produced in this manner. In melt spinning, Nylon, polyester, and the other thermoplastic fibers are produced by melt spinning. No solvents or reagents are required since the polymer can be melted without appreciable decomposition. Thus, the fluid consists of hot molten polymer which, upon extrusion into a stream of cold air, solidifies into a filament. Depending upon the end use, filaments may be produced in various sizes ranging from finer than a human hair to thick bristles for toothbrushes. They may also be produced with different cross-sectional shapes, such as round, lobed, square, or dogbone.

After extrusion, filaments are usually stretched (drawn). Drawing causes an increase in order (crystallinity) by extending the molecules of the fiber so that they pack more closely together, and orients the molecules along the longitudinal axis of the fiber. Higher orientation and increased crystallinity raise the strength of the fiber, decrease its stretch, and improve its elasticity.

Often, the manufactured fibers are textured to improve their comfort properties. Fabrics made from smooth, straight filament yarns are not as comfortable as those made from yarns spun from the shorter natural fibers. Texturing introduces irregularities (crimp) along the length of the filament and leads to bulkier filament yarns which are closer to spun yarns in their performance.

Advances in polymer and fiber technology have led to the development of fibers with exceptionally high temperature resistance and extremely high strength. These properties are desirable in applications such as upholstery and floor coverings in aircraft and other mass-transit vehicles, protective clothing for fire fighters and other emergency personnel, body armor for soldiers and police officers, tire cords, and industrial belting.

Metallic fibers of silver and gold have been used for millennia to decorate fabrics. Today metallic fibers serve useful as well as decorative purposes. These fibers are formed by drawing metal wires through successively finer dies to achieve the desired diameter. Although gold and silver are the easiest to draw, modern methods have allowed the manufacture of steel, tantalum, and zirconium fibers. Because they are electrical conductors, metal fibers have been blended into fabrics to reduce the tendency to develop static electrical charges.

Glass fibers are prepared by the melt spinning of previously formed glass marbles, and the molten filaments are drawn down to very fine dimensions. It is the fineness of the fibers that gives them their flexibility and allows them to be used in textiles. Unfortunately, the fibers are so stiff that when broken they can penetrate human skin. Thus, they are not well suited to use in apparel or upholstery. Glass is widely used in curtains and drapery because of its total resistance to the degrading effects of sunlight, its low cost, and its flame resistance. It provides a nonrotting, nonsettling insulating material for homes and industrial uses. *See* GLASS.

Fiber properties include the physical, mechanical, chemical, biological, and geometrical characteristics of fibers. Some of the more important ones are tensile strength, elongation at break, modulus of elasticity or stiffness, fatigue under repeated stress, resilience or ability to recover from deformation, moisture absorption and wettability, electrostatic properties, friction, color, luster, density, and resistance to light, heat, weathering, abrasion, laundering, mildew, insects, chemicals, and solvents; and finally a number of geometric features, such as diameter, cross-sectional shape, and crimp. Such properties play an important part in determining whether or not the fiber can be made into a fabric that will be wrinkle-resistant, pleasing to the touch, comfortable, easy to clean, durable, and attractive in color, luster, drape, and general appearance. With a knowledge of the physical properties of the available fibers, the textile engineer can choose the best fiber or best blend of several fibers to fit the intended use. The final result, however, is also dependent upon the proper choice and control of additional factors such as the yarn and fabric structure, the weave pattern, and the finishing of the cloth. [I.Bl.]

Manufacturing engineering Engineering activities involved in the creation and operation of the technical and economic processes that convert raw materials, energy, and purchased items into components for sale to other manufacturers or into end products for sale to the public. Defined in this way, manufacturing engineering includes product design and manufacturing system design as well as operation of the factory. More specifically, manufacturing engineering involves the analysis and modification of product designs so as to assure manufacturability; the design, selection, specification, and optimization of the required equipment, tooling, processes, and operations; and the determination of other technical matters required to make a given product according to the desired volume, timetable, cost, quality level, and other specifications. *See* PROCESS ENGINEERING; PRODUCTION.

The formulation of a process plan for a given part has seven aspects: (1) a thorough understanding of processing techniques, their yield and their reliability, precedences, and constraints (both economic as well as technical); (2) the material and tolerances of the part; (3) proper definition of machinability or process data; (4) proper work-holding design of the stock or piece part during the fabrication process, a key consideration in generating piece parts of consistent quality; (5) proper tool selection for the task; (6) the capability of the equipment selected; and (7) personnel skills required and available.

Process planning aids based on computer programs that incorporate a type of spread sheet can be used to reduce significantly the time required to generate individual process plans. For example, systems have been developed that calculate the cycle time for each part as well as the number of tools used per part, the number of unique tools per part set, and the total time for cutting operations per tool type. *See* COMPUTER-AIDED DESIGN AND MANUFACTURING.

In parallel with the definition of process equipment, the manufacturing system designer must determine the most appropriate materials-handling techniques for the transfer of parts from machine to machine of each family of parts. During the manufacture of pieces, the parts are organized by the type of feature desired. The parts are then grouped and manufactured as a family, a method known as group technology. This includes the selection of storage devices appropriate for raw material, work in process, and finished-goods inventory as well as fixtures, gages, and tooling. Materials-handling equipment may be very different for each family, depending on part size and weight, aggregate production volume, part quality considerations during transfer, and ease of loading and unloading candidate machines. Different materials-handling approaches may also be appropriate within individual fabrication systems. *See* MATERIALS-HANDLING EQUIPMENT.

A quality assurance philosophy must be developed that emphasizes process control as the means to assure part conformance rather than emphasizing the detection of part nonconformance as a means of detecting an out-of-control process. The success of any fabrication process is based on rigid work-holding devices that are accurately referenced to the machine, accurate tool sizing, and tool position control. The basic way to determine if these three factors are functioning together acceptably is to measure a feature they produce as they produce it or as soon as possible after that feature is machined. The primary objective of this measurement is to determine that the combination is working within acceptable limits (statistical process control); the fact that the part feature is in conformance to print (conformance to tolerance specified on the print/drawing) is a by-product of a process that is in control. *See* QUALITY CONTROL.

In a modern manufacturing environment an organization's strategies for highly automated systems and the role for workers in these systems are generally based on one of two distinct philosophical approaches. One approach views workers within the plant as the greatest source of error. This approach uses computer-integrated manufacturing technology to reduce the workers' influence on the manufacturing process. The second approach uses computer-integrated manufacturing technology to help the workers make the best product possible. It implies that workers use the technology to control variance, detect and correct error, and adapt to a changing marketplace. *See* COMPUTER-INTEGRATED MANUFACTURING.

The best approach utilizes the attributes of employees in the factory to produce products in response to customer demand. This viewpoint enables the employees to exert some control over the system, rather than simply serving it. The employees can then use the system as a tool to achieve production goals.

As technology and automation have advanced, it has become necessary for manufacturing engineers to gain a much broader perspective. They must be able to function in an integrated activity involving product design, product manufacture, and product use. They also have to consider how the product will be destroyed as well as the efficient recovery of the materials used in its manufacture.

Manufacturing engineers must also be able to use an increasing array of computerized support tools, ranging from process planning and monitoring to total factory simulation—and in some cases, including models of the total enterprise. *See* SIMULATION. [J.L.N.]

Map design The systematic process of arranging and assigning meaning to elements on a map for the purpose of communicating geographic knowledge in a pleasing format. Careful design is crucial to map effectiveness to avoid distorted or inaccurately represented information.

The first design stage involves determining the type of map to be created for the problem at hand. Decisions must be made about the map's spatial format in terms of size and shape, the basic layout, and the data to be represented. In this step, the experience, cultural background, and educational attainment of the intended audience must be considered. The second stage involves the exploration of preliminary ideas through the manipulation of design parameters such as symbols, color, typography, and line weight. In the third step, alternatives are evaluated and may be accepted or rejected. Under some circumstances, prototype maps may be developed for sample readers as a means of evaluating design scenarios. The last step involves the selection of a final design.

Design considerations include the selection of scale (the relationship between the mapping media format and the area being mapped), symbols to represent geographic features, the system of projection (the method used to translate Earth coordinates to flat media), titles, legends, text, borders, and credits. The process of arranging each map element is referred to as map composition. Success in map composition is achieved when design principles are applied to create a pleasing image with a high degree of information content and readability.

Computers now duplicate all capabilities of manual map design. Design iterations can be explored and evaluated faster and with lower cost, compared to manual drafting methods. The digital environment facilitates the independent storage of map elements that can be combined to form composite images. Other computer innovations such as interactive mapping allow a map user to act as map creator in exploring geographic relationships by selecting and tailoring data sets available through software or the World Wide Web. In addition to its benefits to the design process, mapping software has brought challenges to the mapping sciences, including the proliferation of poorly designed maps constructed by persons untrained in cartography. *See* CARTOGRAPHY; COMPUTER GRAPHICS; MAP PROJECTIONS; MAP REPRODUCTION. [T.A.Wi.]

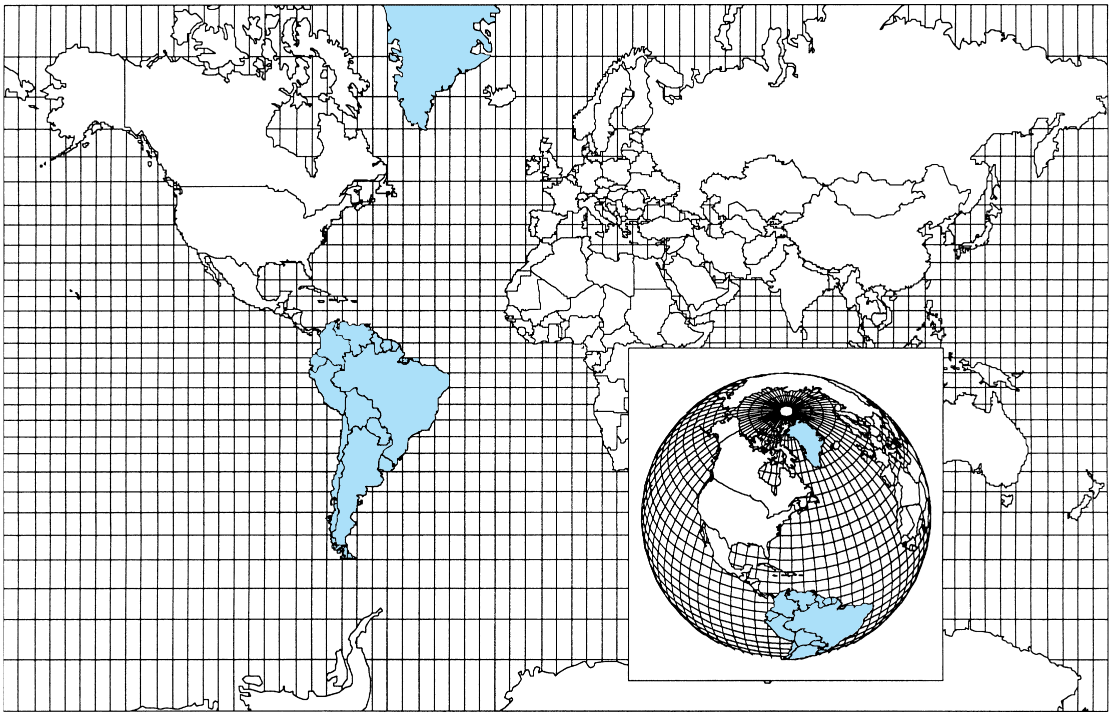
Map projections Systematic methods of transforming the spherical representation of parallels, meridians, and geographic features of the Earth's surface to a nonspherical surface, usually a plane. Map projections have been of concern to cartographers, mathematicians, and geographers for centuries because globes and curved-surface reproductions of the Earth are cumbersome, expensive, and difficult to use for making measurements. Although the term "projection" implies that transformation is accomplished by projecting surface features of a sphere to a flat piece of paper using a light source, most projections are devised mathematically and are drawn with computer assistance. The task can be complex because the sphere and plane are not applicable surfaces. As a result, each of the infinite number of possible projections deforms the geometric relationships among the points on a sphere in some way, with directions, distances, areas, and angular relationships on the Earth never being completely recreated on a flat map.

It is impossible to transfer spherical coordinates to a flat surface without distortion caused by compression, tearing, or shearing of the surface (see illustration). Conceptually, the transformation may be accomplished in two ways: (1) by geometric transfer to some other surface, such as a tangent or intersecting cylinder, cone, or plane, which can then be developed, that is, cut apart and laid out flat; or (2) by direct mathematical transfer to a plane of the directions and distances among points on the sphere. Patterns of deformation can be evaluated by looking at different projection families. Whether a projection is geometrically or mathematically derived, if its pattern of scale variation is like that which results from geometric transfer, it is classed as cylindrical, conic, or in the case of a plane, azimuthal or zenithal. *See* CARTOGRAPHY; TERRESTRIAL COORDINATE SYSTEM.

Cylindrical projections result from symmetrical transfer of the spherical surface to a tangent or intersecting cylinder. True or correct scale can be obtained along the great circle of tangency or the two homothetic small circles of intersection. If the axis of the cylinder is made parallel to the axis of the Earth, the parallels and meridians appear as perpendicular lines. Points on the Earth equally distant from the tangent great circle (Equator) or small circles of intersection (parallels equally spaced on either side of the Equator) have equal scale departure. The pattern of deformation therefore parallel the parallels, as change in scale occurs in a direction perpendicular to the parallels. A cylinder turned 90° with respect to the Earth's axis creates a transverse projection with a pattern of deformation that is symmetric with respect to a great circle through the Poles. Transverse projections based on the Universal Transverse Mercator grid system are commonly used to represent satellite images, topographic maps, and other digital databases requiring high levels of precision. If the turn of the cylinder is less than 90°, an oblique projection results. All cylindrical projections, whether geometrically or mathematically derived, have similar patterns of deformation. *See* GREAT CIRCLE, TERRESTRIAL.

Transfer to a tangent or intersecting cone is the basis of conic projections. For these projections, true scale can be found along one or two small circles in the same hemisphere. Conic projections are usually arranged with the axis of the cone parallel to the Earth's axis. Consequently, meridians appear as radiating straight lines and parallels as concentric angles. Conical patterns of deformation parallel the parallels; that is, scale departure is uniform along any parallel. Several important conical projections are not true conics in that their derivation either is based upon more than one cone (polyconic) or is based upon one cone with a subsequent rearrangement of scale variation. Because conic projections can be designed to have low levels of distortion in the midlatitudes, they are often preferred for representing countries such as the United States.

Azimuthal projections result from the transfer to a tangent or intersecting plane established perpendicular to a right line passing through the center of the Earth. All geometrically developed azimuthal projections are transferred from some point on this line. Points on the Earth equidistant from the point of tangency

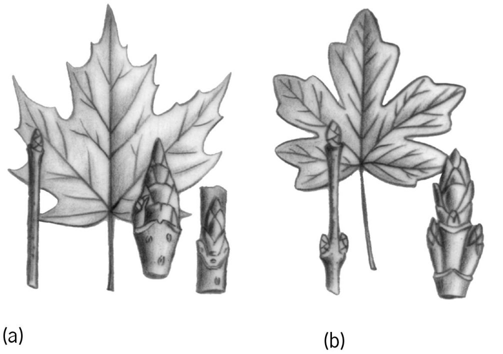


On this Mercator projection, (mathematically derived, cylindrical type), Greenland and South America appear similar in size. The inset map shows that South America is actually about 15 times larger than Greenland.

or the center of the circle of intersection have equal scale departure. Hence the pattern of deformation is circular and concentric to the Earth's center. All azimuthal projections, whether geometrically or mathematically derived, have two aspects in common: (1) all great circles that pass through the center of the projection appear as straight lines; and (2) all azimuths from the center are truly displayed. [A.H.Ro.; T.A.Wi.]

Maple A genus, *Acer*, of broad-leaved, deciduous trees including about 115 species in North America, Asia, Europe, and North Africa. This genus is characterized by simple, opposite, usually palmately lobed (rarely pinnate) leaves, generally inconspicuous flowers, and a fruit consisting of two longwinged samaras or keys (see illustration).

The most important commercial species is the sugar or rock maple (*A. saccharum*), called hard maple in the lumber market. This tree grows in the eastern half of the United States and adjacent Canada. It can be recognized by its gray furrowed bark, sharp-pointed scaly winter buds, and symmetrical oval outline of the crown.



Characteristic maple leaves, twigs, and buds. (*a*) Sugar maple (*Acer saccharum*). (*b*) Hedge maple (*A. campestre*).

Maples rank third in the production of hardwood lumber. Hard maple is used for flooring, furniture, boxes, crates, woodenware, spools, bobbins, motor vehicle parts, veneer, railroad ties, and pulpwood. It is the source of maple sugar and syrup and is planted as a shade tree. *See* SAPINDALES. [A.H.G./K.P.D.]

Marattiales An order (class Polypodiopsida) of primitive ferns that consists of about seven living genera and 150 species. They exist mostly in tropical regions. These large, coarse, sappy ferns usually have large, highly divided fronds. Stems of living genera (*Angiopteris* and *Marattia*) are short and bulbous, often a foot or more in diameter. Other genera have smaller, mostly horizontal, and somewhat more elongated stems. The internal vascular system (food and water conduction tissue) of the stems and fronds can be quite complex, apparently as a function of size. Marattialeans are included among the primitive ferns primarily because of the way that the sporangia (spore-bearing organs) arise from a mass of cells rather than from a single cell as in more highly evolved ferns. *See* PALEOBOTANY; POLYPODIOPHYTA. [B.M.St.]

Marble A term applied commercially to any limestone or dolomite taking polish. Marble is extensively used for building and ornamental purposes. *See* DOLOMITE; LIMESTONE.

In petrography the term marble is applied to metamorphic rocks composed of recrystallized calcite or dolomite. Schistosity, often controlled by the original bedding, is usually weak except in impure micaceous or tremolite-bearing types. Calcite (marble) deforms readily by plastic flow even at low temperatures. Therefore, granulation is rare, and instead of schistosity there develops a flow structure characterized by elongation and bending of the grains concomitant with a strong development of twin lamellae. *See* METAMORPHIC ROCKS; MINERALOGY; SCHIST.

Pure marbles attaining 99% calcium carbonate, $CaCO_3$, are often formed by simple recrystallization of sedimentary limestone. Dolomite marbles are usually formed by metasomatism. *See* CALCITE; DOLOMITE; METASOMATISM. [T.F.W.B.]

Marcasite A mineral having composition FeS_2 and crystallizing in the orthorhombic system. Marcasite frequently has a radiating structure and may be globular or stalactitic. There is poor prismatic cleavage. The hardness is 6–6.5 on Mohs scale and the specific gravity is 4.89. The luster is metallic and the color pale bronze-yellow to nearly white on a fresh fracture. Marcasite and pyrite are dimorphous; both have the composition FeS_2. Because marcasite is whiter, it is called white iron pyrite.

Marcasite is found in metalliferous deposits associated with lead and zinc ores, as replacement deposits in limestone, and in concretions in clays and shales. The nodular and lenticular masses in coal known as brasses are in part marcasite and in part pyrite. *See* PYRITE. [C.S.Hu.]

Marchantiales An order of the liverwort subclass Marchantiidae. Characteristic features include the differentiation of upper and lower tissues of the gametophyte, ventral scales, and rhizoids of two kinds. The sporophyte is considerably reduced, and the capsule dehisces irregularly. The archegonia, though dorsal, come to be pendant from an elevated receptacle because of differential growth resulting in decurved margins. The stalks of the receptacles are modified branches often with rhizoids in one, two, or rarely four furrows along their length. The order consists of 12 families grouped in two suborders, the more complex Marchantiineae and the simplified Ricciineae. *See* BRYOPHYTA; MARCHANTIIDAE. [H.Cr.]

Marchantiidae One of the two subclasses of liverworts (class Hepaticopsida). The gametophytes are ribbonlike or rosette-shaped thalli, usually showing considerable internal tissue differentiation. The rhizoids may be both smooth and internally pegged on the same thalli. Oil bodies, if present, are restricted to scattered cells that lack chloroplasts. The antheridia are usually ovoid, and the archegonia usually consist of six rows of cells. The sporophytes are generally reduced.

The subclass differs from the thallose Metzgeriales of the subclass Jungermanniidae in the internal differentiation of the thallose gametophytes, the smooth and pegged rhizoids, and the variation in the way the capsules dehisce. The subclass is divided into three orders, the Marchantiales, the Monocleales, and the Sphaerocarpales. *See* BRYOPHYTA; JUNGERMANNIIDAE; MARCHANTIALES; METZGERIALES; MONOCLEALES; SPHAEROCARPALES. [H.Cr.]

Margarine An emulsified fatty food product used as a spread and a baking and cooking fat, consisting of an aqueous phase dispersed in the fat as a continuous phase. Developed originally as a butter substitute, margarine is now considered a food in its own right and is manufactured in forms unknown to butter, such as plastic, soft, or fluid. However, margarine is colored, flavored, fortified with vitamins, and otherwise formulated to have the same or similar taste, appearance, and nutritional value as butter. *See* BUTTER.

Currently, margarine produced in the United States must contain not less than 80% fat. The fats and oils must be edible but may be from any vegetable or animal carcass source, natural or hydrogenated. The required aqueous phase may be water, milk, or solutions of dairy or vegetable protein, and must be pasteurized. Vitamin A must be added to yield a finished margarine with not less than 15,000 international units per pound (0.45 kg). Optional ingredients include salt or potassium chloride for low-sodium diets, nutritive sweeteners, fatty emulsifiers, antioxidants, preservatives, edible colors, flavors, vitamin D, acids, and alkalies. *See* FAT AND OIL (FOOD). [T.J.W.]

Marijuana The Spanish name for the dried leaves and flowering tops of the hemp plant, *Cannabis sativa* (Cannabinaceae). The narcotic ingredients allegedly have stimulating effects, and after smoking two or three cigarettes, the smoker often has a feeling of well-being and increased power and ability. After excessive amounts of the drug, illusions are often common, as well as pleasing, fanciful hallucinations. Sometimes the excessive user experiences disorientation and even delirium. *See* HEMP. [P.D.St./E.L.C.]

Marine biological sampling The collection and observation of living organisms in the sea, including the quantitative determination of their abundance in time and space. The biological survey of the ocean depends to a large extent on specially equipped vessels. Sampling in intertidal regions at low tide is one of the few instances where it is possible to observe and collect marine organisms without special apparatus.

A primary aim of marine biology is to discover how ocean phenomena control the distribution of organisms. Sampling is the means by which this aim is accomplished. Traditional techniques employ the use of samplers attached to wires lowered over the side of a ship by means of hydraulic winches. These samplers include bottles designed for enclosing seawater samples from particular depths, fine-meshed nets that are towed behind the ship to sieve out plankton and fish, and grabs or dredges that are used to collect animals inhabiting the ocean bottom. These types of gear are relied upon in many circumstances; however, they illustrate some of the problems common to all methods by which the ocean is sampled. First, sampling is never synoptic, which means that it is not possible to sample an area of ocean so that conditions can be considered equivalent at each point. Usually, it is assumed that this is so. Second, there are marine organisms for which there exists no sampling methodology. For example, knowledge of the larger species of squid is confined to the few animals that have been washed ashore. A third problem concerns the representativeness of the samples collected. The open ocean has no easily definable boundaries, and organisms are not uniformly distributed. The actual sampling is regularly done out of view of the observer; thus, sampling effectiveness is often difficult to determine. Furthermore, navigational systems are not error-free, and therefore the position of the sample is never precisely known. All developments in methods for sampling the ocean try to resolve one or more of these difficulties by improving synopticity, devising more efficient sampling gear, or devising methods for observation such that more meaningful samples can be obtained.

Direct and remote observation methods provide valuable information on the undersea environment and thus on the representativeness of various sampling techniques. Personnel-operated deep-submergence research vessels (DSRVs) are increasingly being employed to observe ocean life at depth and on the bottom, and for determining appropriate sampling schemes. The deep-submergence research vessels are used with cameras and television recording equipment and are also fitted with coring devices, seawater samplers, and sensors of various types. Cameras are deployed from surface ships on a wire. Other cameras are operated unattended at the bottom for months at a time, recording changes occurring there. Scuba diving is playing a larger role, especially in open-ocean areas, and is used to observe marine organisms in their natural habitat as well as to collect the more fragile marine planktonic forms such as foraminifera, radiolaria, and jellyfish. Remotely piloted vehicles (RPVs) will continue to assume greater importance in sampling programs since they can go to greater depths than can divers, and they overcome a limitation in diving in that remotely piloted vehicles can be operated at night. Optical sensors carried aboard Earth-orbiting satellites can provide images of ocean color over wide areas. Ocean color is related to the turbidity and also to the amount of plant material in the seawater. This thus establishes a means by which sampling programs carried out from ships can be optimized. *See* DIVING; SEAWATER FERTILITY; UNDERWATER PHOTOGRAPHY; UNDERWATER TELEVISION; UNDERWATER VEHICLE. [J.Marr.]

Marine boiler A steam boiler designed to suit the marine environment and generally arranged to supply steam to the main propulsion machinery, ship's service electric generators, feedpump drivers, and other auxiliary services.

Marine boilers are usually of the two-drum water-tube type with water-cooled furnaces, superheaters, desuperheaters, and heat recovery equipment of the economizer or air-heater type. The majority of ships are fitted with two boilers, although some large passenger ships may have three or more. Some cargo ships are fitted with only one boiler, and in some of these cases a smaller auxiliary boiler may be fitted for emergency or in-port steaming use.

Marine boilers are generally arranged for oil firing. Oil is used extensively because of its simplicity of handling and storing and the fact that it can be stored in spaces that often cannot be used for carrying cargo. *See* BOILER; MARINE MACHINERY; STEAM-GENERATING UNIT. [R.P.G.]

Marine conservation The management of marine species and ecosystems to prevent their decline and extinction. As in terrestrial conservation, the goal of marine conservation is to preserve and protect biodiversity and ecosystem function through the preservation of species, populations, and habitats. The importance of conserving marine species and ecosystems is growing as a consequence of human activities. Negative impacts on marine biological systems are caused by such actions as overfishing; overutilization, degradation, and loss of coastal and marine habitats; introduction of nonnative species; and intensification of global climate change, which alters oceanic circulation and disrupts existing trophic relationships. Marine conservation biologists seek to reduce the negative effects of all these actions by conducting directed research and helping to develop management strategies for particular species, communities, habitats, or ecosystems.

A variety of approaches and tools are used in marine conservation. These include population assessment; mitigation, recovery, and restoration efforts; establishment of marine protected areas; and monitoring programs. Many of these approaches overlap with those in terrestrial conservation. However, fundamental differences between terrestrial and marine environments in spatial dimension, habitat type, and organismal life history require that basic conservation techniques be modified for application to the marine environment. *See* BIODIVERSITY; ECOSYSTEM; MARINE ECOLOGY; OCEANOGRAPHY.

Effective management requires knowledge of the size and status of populations. Trends in abundance can be detected through stock assessment methods first developed for marine fisheries and subsequently modified for application to other marine organisms. These methods use estimates of population size, reproduction, survivorship, and immigration to determine whether populations are increasing, decreasing, or stable. Population viability analysis is a specialized statistical assessment in which demographic and environmental information is used to determine the probability that a population will persist in a particular environment for a specified period of time. This method can be used to guide management decisions, and has been used in efforts to manage marine mammals, turtles, seabirds, and other species. *See* ECOLOGICAL COMMUNITIES; ECOLOGICAL METHODS; POPULATION ECOLOGY.

Depleted, threatened, or endangered populations are often subject to mitigation or recovery efforts. The purpose of these efforts is to reduce the immediate threat of extinction or extirpation. This is typically achieved by direct human intervention to increase the size of a population or to prevent further decline in population size. Methods used to achieve recovery for fish and marine invertebrates include reducing fishing quotas, restricting the use of certain types of fishing gear, restricting the seasonal or annual distribution of a fishery, or closing fisheries altogether.

Recovery efforts can be most successful if they are based on multispecies or ecosystem-level management strategies. These strategies take into account positive and negative interactions between species, such as facilitation, competition, and predation. They further take into account interactions between species and their environment. Key to the success of assessment and recovery programs is identification of the appropriate biological unit for conservation (for example, population, subspecies, stock, or evolutionarily significant unit). Maintaining genetic diversity is an important goal of conservation biology, because genetic diversity confers evolutionary potential. Thus, conservation efforts often are aimed at populations that are genetically distinct from other populations of the same species.

Restoration efforts are aimed at returning habitats to an ecologically functional condition, usually consistent with some previous, more pristine condition. *See* ENDANGERED SPECIES; FISHERIES ECOLOGY; MARINE FISHERIES.

Marine protected areas are set aside for the protection or recovery of species, habitats, or ecosystems. They include marine parks, marine reserves, marine sancturaries, harvest refugia, and voluntary or legislated no-take areas. Some marine protected areas allow for consumptive use (such as fishing) or extraction of resources (for example, oil drilling), while others are closed to most human activities.

Monitoring programs are necessary to determine the outcome of specific conservation actions and to guide future conservation decisions. Monitoring programs vary according to the objectives of specific conservation projects but typically include such activities as long-term surveys of population size and status, and the development of mathematical models to help predict specific outcomes. [T.Kl.]

Marine containers Standardized rectangular boxes for the transport of marine cargo. Since 1960, the ocean transportation of general cargo or freight has undergone a revolutionary technological change. The innovation was containerization—the development of standard marine cargo containers for consolidating packages into units of interchange between ships, docks, trucks, and railcars, and the development of special ships and handling systems to transport these containers at sea. This innovation brought economies of scale to marine cargo-handling operations, introduced capital-intensive processes to the labor-oriented stevedoring tasks, reduced cargo theft and damage,

Container crane and straddle carrier.

reduced the time a ship spent in port, and provided the means for efficient intermodal transport of cargoes.

Basic to the change to containerization was a new approach to loading and unloading cargoes. Instead of using nets or slings to lift individual bales, boxes, sacks, or pallets of cargo in and out of the ship's holds, the new systems employ standard cargo containers and special handling equipment to place the containers aboard (see illustration). The containers are loaded or stuffed at an inland factory or terminal and usually are never opened until they reach their ultimate destination. The ship carrying these containers becomes an extension of a truckline or a railroad.

Intermodability, moving containerized cargo by more than one mode of transport without the need for intermediate reloading, is the essence of this technology. The containers can be moved to the ship via regular highway trailers or trailer chassis, or by flatbed railcar or rail piggyback. Once at the marine terminal, they can be lifted or rolled on the ships. Upon arrival at the discharge port, all land and water modes are again available to move them, with cargo undisturbed, to the consignee. [J.C.C.]

Marine ecology An integrative science that studies the basic structural and functional relationships within and among living populations and their physical-chemical environments in marine ecosystems. Marine ecology draws on all the major fields within the biological sciences as well as oceanography, physics, geology, and chemistry. Emphasis has evolved toward understanding the rates and controls on ecological processes that govern both short- and long-term events, including population growth and survival, primary and secondary productivity, and community dynamics and stability. Marine ecology focuses on specific organisms as well as on particular environments or physical settings. *See* ENVIRONMENT.

Marine environments. Classification of marine environments for ecological purposes is based very generally on two criteria, the dominant community or ecosystem type and the physical-geological setting. Those ecosystems identified by their dominant community type include mangrove forests, coastal salt marshes, submersed seagrasses and seaweeds, and tropical coral reefs. Marine environments identified by their physical-geological setting include estuaries, coastal marine and nearshore zones, and open-ocean-deep-sea regions. *See* DEEP-SEA FAUNA; ECOLOGICAL COMMUNITIES; HYDROTHERMAL VENT; PHYTOPLANKTON; ZOOPLANKTON.

An estuary is a semienclosed area or basin with an open outlet to the sea where fresh water from the land mixes with seawater. The ecological consequences of fresh-water input and mixing create strong gradients in physical-chemical characteristics, biological activity and diversity, and the potential for major adverse impacts associated with human activities. Because of the physical forces of tides, wind, waves, and fresh-water input, estuaries are perhaps the most ecologically complex marine environment. They are also the most productive of all marine ecosystems on an area basis and contain within their physical boundaries many of the principal marine ecosystems defined by community type. *See* ESTUARINE OCEANOGRAPHY; MANGROVE; SALT MARSH.

Coastal and nearshore marine ecosystems are generally considered to be marine environments bounded by the coastal land margin (seashore) and the continental shelf 300–600 ft (100–200 m) below sea level. The continental shelf, which occupies the greater area of the two and varies in width from a few to several hundred kilometers, is strongly influenced by physical oceanographic processes that govern general patterns of circulation and the energy associated with waves and currents. Ecologically, the coastal and nearshore zones grade from shallow water depths, influenced by the adjacent landmass and input from coastal rivers and estuaries, to the continental shelf break, where oceanic processes predominate. Biological productivity and species diversity and abundance tend to decrease in an offshore direction as the food web becomes supported only by planktonic production. Among the unique marine ecosystems associated with coastal and nearshore water bodies are seaweed-dominated communities (for example, kelp "forests"), coral reefs, and upwellings. *See* CONTINENTAL MARGIN; REEF; UPWELLING.

Approximately 70% of the Earth's surface is covered by oceans, and more than 80% of the ocean's surface overlies water depths greater than 600 ft (200 m), making open-ocean–deep-sea environments the largest, yet the least ecologically studied and understood, of all marine environments. The major oceans of the world differ in their extent of landmass influence, circulation patterns, and other physical-chemical properties. Other major water bodies included in open-ocean–deep-sea environments are the areas of the oceans that are referred to as seas. A sea is a water body that is smaller than an ocean and has unique physical oceanographic features defined by basin morphology. Because of their circulation patterns and geomorphology, seas are more strongly influenced by the continental landmass and island chain structures than are oceanic environments.

Within the major oceans, as well as seas, various oceanographic environments can be defined. A simple classification would include water column depths receiving sufficient light to support photosynthesis (photic zone); water depths at which light penetration cannot support photosynthesis and which for all ecological purposes are without light (aphotic zone); and the benthos or bottom-dwelling organisms. Classical oceanography defines four depth zones; epipelagic, 0–450 ft (0–150 m), which is variable; mesopelagic, 450–3000 ft (150–1000 m); bathypelagic, 3000–12,000 ft (1000–4000 m); and abyssopelagic, greater than 12,000 ft (4000 m). These depth strata correspond approximately to the depth of sufficient light penetration to support photosynthesis; the zone in which all light is attenuated; the truly aphotic zone; and the deepest oceanic environments.

Marine ecological processes. Fundamental to marine ecology is the discovery and understanding of the principles that underlie the organization of marine communities and govern their behavior, such as controls on population growth and stability, quantifying interactions among populations that lead to persistent communities, and coupling of communities to form viable ecosystems. The basis of this organization is the flow of energy and cycling of materials, beginning with the capture of radiant solar energy through the processes of photosynthesis and ending with the remineralization of organic matter and nutrients.

Photosynthesis in seawater is carried out by various marine organisms that range in size from the microscopic, single-celled marine algae to multicellular vascular plants. The rate of photosynthesis, and thus the growth and primary production of marine plants, is dependent on a number of factors, the more important of which are availability and uptake of nutrients, temperature, and intensity and quality of light. Of these three, the last probably is the single most important in governing primary production and the distribution and abundance of marine plants. Considering the high attenuation of light in water and the relationships between light intensity and photosynthesis, net autotrophic production is confined to relatively shallow water depths. The major primary producers in marine environments are intertidal salt marshes and mangroves, submersed seagrasses and seaweeds, phytoplankton, benthic and attached microalgae, and—for coral reefs—symbiotic algae (zooxanthellae). On an areal basis, estuaries and nearshore marine ecosystems have the highest annual rates of primary production. From a global perspective, the open oceans are the greatest contributors to total marine primary production because of their overwhelming size.

The two other principal factors that influence photosynthesis and primary production are temperature and nutrient supply. Temperature affects the rate of metabolic reactions, and marine plants show specific optima and tolerance ranges relative to photosynthesis. Nutrients, particularly nitrogen, phosphorus, and silica, are essential for marine plants and influence both the rate of photosynthesis and plant growth. For many phytoplankton-based marine ecosystems, dissolved inorganic nitrogen is considered the principal limiting nutrient for autotrophic production, both in its limiting behavior and in its role in the eutrophication of estuarine and coastal waters. *See* PHOTOSYNTHESIS.

Marine food webs and the processes leading to secondary production of marine populations can be divided into plankton-based and detritus-based food webs. They approximate phytoplankton-based systems and macrophyte-based systems. For planktonic food webs, current evidence suggests that primary production is partitioned among groups of variously sized organisms, with small organisms, such as cyanobacteria, playing an equal if not dominant role at times in aquatic productivity. The smaller autotrophs—both through excretion of dissolved organic compounds to provide a substrate for bacterial growth and by direct grazing by protozoa (microflagellates and ciliates)—create a microbially based food web in aquatic ecosystems, the major portion of autotrophic production and secondary utilization in marine food webs may be controlled, not by the larger organisms typically described as supporting marine food webs, but by microscopic populations.

Macrophyte-based food webs, such as those associated with salt marsh, mangrove, and seagrass ecosystems, are not supported by direct grazing of the dominant vascular plant but by the production of detrital matter through plant mortality. The classic example is the detritus-based food webs of coastal salt marsh ecosystems. These ecosystems, which have very high rates of primary production, enter the marine food web as decomposed and fragmented particulate organics. The particulate organics of vascular plant origin support a diverse microbial community that includes bacteria, flagellates, ciliates, and other protozoa. These organisms in turn support higher-level consumers.

Both pelagic (water column) and benthic food webs in deep ocean environments depend on primary production in the overlying water column. For benthic communities, organic matter must reach the bottom by sinking through a deep water column, a process that further reduces its energy content. Thus, in the open ocean, high rates of secondary production, such as fish yields, are associated with areas in which physical-chemical conditions permit and sustain high rates of primary production over long periods of time, as is found in upwelling regions.

Regardless of specific marine environment, microbial processes provide fundamental links in marine food webs that directly or indirectly govern flows of organic matter and nutrients that in turn control ecosystem productivity and stability. *See* BIOLOGICAL PRODUCTIVITY; ECOLOGY; ECOSYSTEM; SEAWATER FERTILITY. [R.We.]

Marine engine An engine that propels a waterborne vessel. In all except the smallest boats, the engine is but part of an integrated power plant, which includes auxiliary machinery for propulsion engine support, ship services, and cargo, trade, or mission services. Marine engines in common use are diesel engines, steam turbines, and gas turbines. Gasoline engines are widely used in pleasure craft. *See* BOAT PROPULSION; INTERNAL COMBUSTION ENGINE; MARINE MACHINERY.

Diesel engines of all types and power outputs are in use for propulsion of most merchant ships, most service and utility craft, most naval auxiliary vessels, and most smaller surface warships and shorter-range submarines. The diesel engines most commonly used fall into either a low-speed category or the medium- and high-speed category. Low-speed engines are generally intended for the direct drive of propellers without any speed reduction, and therefore are restricted to a range of rotative speeds for which efficient propellers can be designed, generally below 300 revolutions per minute (rpm). The largest engines are rated for power output of over 5000 kW (almost 7500 horsepower) per cylinder at about 100 rpm. Because of their higher rotative speeds, medium- and high-speed engines drive propellers through speed-reduction gears, but they are directly connected for driving generators in diesel-electric installations. Large medium-speed engines are capable of over 1500 kW (2000 hp) per cylinder at about 400 rpm. The upper limit of the medium-speed category, and the start of the high-speed category, is generally placed in the range of 900–1200 rpm. *See* DIESEL ENGINE.

While steam-turbine plants cannot achieve the thermal efficiency of diesel engines, steam turbines of moderately high power levels (above about 7500 kW or 10,000 hp) offer efficient energy conversion from steam, which can in turn be produced by combustion of low-quality fuel oil, coal, or natural gas in boilers, or from a nuclear reactor. For high efficiency, high turbine speeds are required, typically 3000–10,000 rpm, with reduction gearing or electric drive used to achieve low propeller rotative speeds. The combination of turbine and reduction gear or electric drive has usually proven robust and durable, so that most oil-fueled steamships currently in service are held over from an earlier era. Others, more recently built, are capitalizing on the availability, in their trade, of a fuel unsuitable for diesel engines. *See* STEAM TURBINE.

Aircraft-derivative gas turbines have become the dominant type of propulsion engine for medium-sized surface warships, including frigates, destroyers, cruisers, and small aircraft carriers. In all cases the turbines are multishaft, simple-cycle engines, with the power turbine geared to the propeller. In some installations, two to four turbines are the sole means of propulsion; in other cases, one or two turbines provide high-speed propulsion, while diesel engines or smaller gas turbines are used for cruising speeds. Factors favoring the aircraft-derivative gas turbine in this application are low weight, compact dimensions, high power, rapid start and response, standardization of components, and maintenance by replacement. *See* GAS TURBINE.

In the electric drive arrangement, the engine is directly coupled to a generator, and the electricity produced drives an electric motor, which is most often of sufficiently low rotative speed to be directly connected to the propeller shaft. Any number of engine-generator sets may be connected to drive one or more propulsion motors. Electric drive has been used with engines of all types, including low-speed diesels. Advantages of electric drive include flexibility of machinery arrangement, elimination of gear noise, high propeller torque at low speed, and inherent reversing capability. In ships with high electric requirements for cargo, mission, or trade services—for example, passenger ships, tankers with electric-motor-driven cargo pumps, or warships with laser weapons—there is an advantage in integrating propulsion and ship service support through a common electric distribution system. However, electric drive is usually heavier, higher in initial cost, and less efficient than direct or geared drive. [A.L.R.]

Marine engineering The engineering discipline concerned with the machinery and systems of ships and other marine vehicles and structures. Marine engineers are responsible for the design and selection of equipment and systems, for installation and commissioning, for operation, and for maintenance and repair. They must interface with naval architects, especially during design and construction.

Marine engineers are likely to have to deal with a wide range of systems, including diesel engines, gas turbines, boilers, steam turbines, heat exchangers, and pumps and compressors; electrical machinery; hydraulic machinery; refrigeration machinery; steam, water, fuel oil, lubricating oil, compressed gas, and electrical systems; equipment for automation and control; equipment for fire fighting and other forms of damage control; and systems for cargo handling. Many marine engineers become involved with structural issues, including inspection and surveying, corrosion protection, and repair.

Marine engineers are generally mechanical engineers or systems engineers who have acquired their marine orientation through professional experience, but programs leading to degrees in marine engineering are offered by colleges and universities in many countries. *See* BOAT PROPULSION; MARINE BOILER; MARINE ENGINE; MARINE MACHINERY; MARINE REFRIGERATION; NAVAL

Architecture; Propeller (marine craft); Ship design; Ship powering, maneuvering, and seakeeping. [A.L.R.]

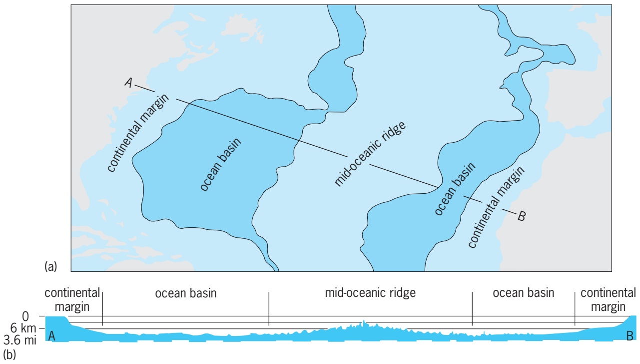
Marine fisheries The harvest of animals and plants from the ocean to provide food and recreation for people, food for animals, and a variety of organic materials for industry. It is now generally agreed that the world catch is approaching a maximum, which may be less than 100,000,000 metric tons per year. If methods can be devised to harvest smaller organisms not heretofore used because they have been too costly to catch and process, it has been estimated that the yield could perhaps be increased severalfold. Russia is said to have succeeded in developing an acceptable human food product from Antarctic krill. [J.L.McH.]

Marine geology The study of the portion of the Earth beneath the oceans. Approximately 70% of the Earth's surface is covered with water. Marine geology involves the study of the sea floor; of the sediments, rocks, and structures beneath the sea floor; and of the processes that are responsible for their formation. The average depth of the ocean is about 3800 m (12,500 ft), and the greatest depths are in excess of 11,000 m (36,000 ft; the Marianas Trench). Hence, the study of the sea floor necessitates employing a complex suite of techniques to measure the characteristic properties of the Earth's surface beneath the oceans. Contrary to popular views, only a minority of marine geological investigations involve the direct observation of the sea floor by scuba diving or in submersibles. Rather, most of the ocean floor has been investigated by surface ships using remote-sensing geophysical techniques, and more recently by the use of satellite observations.

The oceanic crust is relatively young, having been formed entirely within the last 200 million years (m.y.), a small fraction of the nearly 5-billion-year history of the Earth. The process of renewing or recycling the oceanic crust is the direct consequence of plate tectonics and sea-floor-spreading processes. It is therefore logical that the geologic history of the sea floor be outlined within the framework of plate tectonic tenets. Where plates move apart, molten lava reaches the surface to fill the voids, creating new oceanic crust. Where the plates come together, oceanic crust is thrust back within the interior of the Earth, creating the deep oceanic trenches. These trenches are located primarily around the rim of the Pacific Ocean. The material can be traced by using the distribution of earthquakes to depths of about 700 km (420 mi). At that level, the character of the subducted lithosphere is lost, and this material is presumably remelted and assimilated with the surrounding upper-mantle material. *See* Earthquake; Geodynamics; Lithosphere; Plate tectonics.

Mid-oceanic ridges. Most of the ocean floor can be classified into three broad physiographic regions, one grading into the other (see illustration). The approximate centers of the ocean basin are characterized by spectacular, globally encircling mountain ranges, the mid-oceanic ridge (MOR) system, which formed as the direct consequence of the splitting apart of oceanic lithosphere. The detailed morphologic characteristics of these mountain ranges depend somewhat upon the rate of separation of the plates involved. Abyssal hill relief, especially within 500 km (300 mi) of ridge crest, is noticeably rougher on the slow-spreading Mid-Atlantic Ridge than on the fast-spreading East Pacific Rise. The profile of the East Pacific Rise is also broader and shallower than for the Mid-Atlantic Ridge. If the entire mid-oceanic ridge system were spreading rapidly, the expanded volume of the ridge system would displace water from the ocean basins onto the continents.

The broad cross-sectional shape of this mid-ocean mountain range can be related directly and simply to its age. The depth of the mid-oceanic ridge at any place is a consequence of the steady conduction of heat to the surface and the associated cooling of the oceanic crust and lithosphere. As it cools, contracts, and becomes more dense, the oceanic crust plus the oceanic lithosphere sink isostatically (under its own weight) into the more fluid substrate (the asthenosphere). Hence, the depth to the top of the oceanic crust is a predictable function of the age of that crust; departures from such depth predictions represent oceanic depth anomalies. These depth anomalies are presumably formed as a consequence of processes other than lithospheric cooling, such as intraplate volcanism. The Hawaiian island chain and the Polynesian island groups are examples of this type of volcanism. *See* Asthenosphere; Mid-Oceanic Ridge; Oceanic islands; Volcanology.



Geology of the North Atlantic Ocean. (*a*) Physiographic divisions of the ocean floor. (*b*) Principal morphologic features along the profile between North America and Africa.

Basins. The deep ocean basins, which lie adjacent to the flanks of the mid-oceanic ridge, represent the older portions of the sea floor that were once the shallower flanks of the ridge (see illustration). The bulk of sediments found on the ocean floor can be broadly classified as terrigenous or biogenic. Terrigenous sediments are derived from adjacent landmasses and are brought to the sea through river systems. This sediment load is sometimes transported across the continental shelves, often utilizing, as pathways, submarine canyons that dissect the shelves, the continental slope, and the continental rise. Biogenic sediments are found in all parts of the ocean, either intermixed with terrigenous sediments or in near "pure form" in those areas inaccessible to terrigenous sedimentation.

Biogenic sediments are composed mostly of the undissolved tests of siliceous and calcareous microorganisms, which settle slowly to the sea floor. This steady so-called pelagic rain typically accumulates at rates of a few centimeters per thousand years. The composition and extent of the input to the biogenic sediment depend upon the composition and abundances of the organisms, which in turn are largely reflective of the water temperature and the available supply of nutrients. The Pacific equatorial zones and certain other regions of deep ocean upwelling are rich in nutrients and correspondingly rich in the microfauna and flora of the surface waters. Such regions are characterized by atypically high pelagic sediment rates. *See* Upwelling.

Continental margins. The continental margins lie at the transition zone between the continents and the ocean basins and mark a major change from deep water to shallow water and from thin oceanic crust to thick continental crust. Rifted margins are found bounding the Atlantic Ocean (see illustration). These margins represent sections of the South American and North American continents that were once contiguous to west Africa and northwest Africa, respectively. These supercontinents were rifted apart 160–200 m.y. ago as the initial stages of sea-floor spreading and the birth of the present Atlantic Ocean sea floor. *See* Continents, evolution of.

Continental margins are proximal to large sources of terrestrial sediments that are the products of continental erosion. The margins are also the regions of very large vertical motions through time. This vertical motion is a consequence of cooling of the rifted continental lithosphere and subsidence. During initial rifting of the continents, fault-bound rift basins are formed that serve as sites of deposition for large quantities of sediment. These sedimented basins constitute significant loads onto the underlying crust, giving rise to an additional component of margin subsidence. The continental margins are of particular importance also because, as sites of thick sediment accumulations (including organic detritus), they hold considerable potential for the eventual formation and concentration of hydrocarbons. As relatively shallow areas, they are also accessible to offshore exploratory drilling and oil and gas production wells. *See* OIL AND GAS, OFFSHORE.

Many sedimentary aprons or submarine fans are found seaward of prominent submarine canyons that incise the continental margins. Studies of these sedimentary deposits have revealed a number of unusual surface features that include a complex system of submarine distributary channels, some with levees. The channel systems control and influence sediment distribution by depositional or erosional interchannel flows. Fans are also effected by major instantaneous sediment inputs caused by large submarine mass slumping and extrachannel turbidity flows. *See* SUBMARINE CANYON.

In contrast to the rifted margins, the continental margins that typically surround the Pacific Ocean represent areas where plates are colliding. As a consequence of these collisions, the oceanic lithosphere is thrust back into the interior of the Earth; the loci of underthrusting are manifest as atypically deep ocean sites known as oceanic trenches. The processes of subducting the oceanic lithosphere give rise to a suite of tectonic and morphologic features characteristically found in association with the oceanic trenches. An upward bulge of the crust is created seaward of the trench that represents the flexing of the rigid oceanic crust as it is bent downward at the trench. The broad zone landward of most trenches is known as the accretionary prism and represents the accumulation of large quantities of sediment that was carried on the oceanic crust to the trench. Because the sediments have relatively little strength, they are not underthrust with the more rigid oceanic crust, but they are scraped off. In effect, they are plastered along the inner wall of the trench system, giving rise to a zone of highly deformed sediments. These sediments derived from the ocean floor are intermixed with sediments transported downslope from the adjacent landmass, thus creating a classic sedimentary melange. *See* CONTINENTAL MARGIN; SEDIMENTOLOGY.

Anomalous features. In addition to the major morphologic and sediment provinces, parts of the sea floor consist of anomalous features that obviously were not formed by fundamental processes of sea-floor spreading, plate collisions, or sedimentation. Examples are long, linear chains of seamounts and islands. Many of these chains are thought to reflect the motion of the oceanic plates over hot spots that are fixed within the mantle. *See* MAGMA; SEAMOUNT AND GUYOT.

The presence of large, anomalously shallow regions known as oceanic plateaus may also represent long periods of anomalous regional magmatic activity that may have occurred either near divergent plate boundaries or within the plate. Alternatively, many oceanic plateaus are thought to be small fragments of continental blocks that have been dispersed through the processes of rifting and spreading, and have subsequently subsided below sea level to become part of the submarine terrain.

Other important features of the ocean floor are the so-called scars represented by fracture zone traces that were formed as part of the mid-oceanic ridge system, where the ridge axis was initially offset. Oceanic crusts on opposite sides of such offsets have different ages and hence they have different crustal depths. A structural-tectonic discontinuity exists across this zone of ridge axis offset known as a transform zone. Although relative plate motion does not occur outside the transform zone, the contrasting properties represented by the crustal age differences create contrasting topographic and subsurface structural discontinuities, which can sometimes be traced for great distances. Fracture zone traces define the paths of relative motion between the two plates involved. Those mapped by conventional methods of marine survey have provided fundamental information that allows rough reconstructions of the relative positions of the continents and oceans throughout the last 150–200 m.y. The study that deals with the relative motions of the plates is known as plate kinematics. *See* TRANSFORM FAULT.

Marginal seas. The sea-floor features described so far are representative of the main ocean basins and reflect their evolution mostly through processes of plate tectonics. Other, more complicated oceanic regions, typically found in the western Pacific, include a variety of small, marginal seas (back-arc basins) that were formed by the same general processes as the main ocean basins. These regions define a number of small plates whose interaction is also more or less governed by the normal tenets of plate tectonics. One difficulty in studying these small basins is that they are typified by only short-lived phases of evolution. Frequent changes in plate motions interrupt the process, creating tectonic overprints and a new suite of ocean-floor features. Furthermore, conventional methods of analyzing rock magnetism or depths of the sea floor to date the underlying crust do not work well in these small regions. The small dimensions of these seas bring into play relatively large effects of nearby tectonic boundaries and render invalid key assumptions of these analytical techniques. The number of small plates that actually behave as rigid pieces is not well known, but it is probably only 10–20 for the entire world. [D.E.H.]

Marine machinery All machinery installed on waterborne craft, including engines, transmissions, shafting, propulsors, generators, motors, pumps, compressors, blowers, eductors, centrifuges, boilers and other heat exchangers, winches, cranes, steering gear, and associated piping, tanks, wiring, and controls, used for propulsion, for ship services, and for cargo, trade, or mission services.

Practically all marine machinery elements have nonmarine counterparts; in some cases, the latter were developed from marine applications, while in other cases specific equipment was "marinized." For marine service, machinery may have to meet higher standards of reliability and greater demands for weight and volume reduction and access for maintenance. Marine machinery must be capable of withstanding the marine environment, which tends toward extreme ambient conditions, high humidity, sea-water corrosion, vibration, sea motions, shock, variable demand, and fluctuating support services. Even higher standards may apply for warship machinery. To improve system reliability, essential equipment may be fitted in duplicate or provided with duplicated or alternative support or control systems, while nonessential equipment may be fitted with bypasses, to permit continued operation of a system following a component failure. Isolation valves or circuit breakers are common, enabling immediate repair.

Machinery on modern ships is highly automated, with propulsion usually directly controlled from the wheelhouse, and auxiliary machinery centrally controlled from an air-conditioned, sound-proofed control room, usually in the engine room. In the typical modern merchant ship (but not in passenger ships), the machinery operates automatically, and the controls are unattended at sea, with engineers called out by alarm in the event of malfunctions.

Propulsion machinery comprises an engine, usually a diesel engine, steam turbine, or gas turbine, with required gearing or other transmission system, and, for steam plants, steam generators. *See* BOAT PROPULSION; MARINE BOILER; MARINE ENGINE; PROPELLER (MARINE CRAFT); SHIP NUCLEAR PROPULSION. [A.L.R.]

Marine microbiology An independent discipline applying the principles and methods of general microbiology to research in marine biology and biogeochemistry. Marine microbiology focuses primarily on prokaryotic organisms, mainly bacteria. Because of their small size and easy dispersability, bacteria are virtually ubiquitous in the marine environment. Furthermore, natural populations of marine bacteria comprise a large variety of physiological types, can survive long periods of starvation, and are able to start their metabolic activity as soon as a substrate becomes available. As a result, the marine environment, similar to soil, possesses the potential of a large variety of microbial processes that degrade (heterotrophy) but also produce (autotrophy) organic matter. Considering the fact that the marine environment represents about 99% of the biosphere, marine microbial transformations are of tremendous global importance. *See* BIOSPHERE.

Heterotrophic transformations. Quantitatively, the most important role of microorganisms in the marine environment is heterotrophic decomposition and remineralization of organic matter. It is estimated that about 95% of the photosynthetically produced organic matter is recycled in the upper 300–400 m (1000–1300 ft) of water, while the remaining 5%, largely particulate matter, is further decomposed during sedimentation. Only about 1% of the total organic matter produced in surface waters arrives at the deep-sea floor in particulate form. In other words, the major source of energy and carbon for all marine heterotrophic organisms is distributed over the huge volume of pelagic water mass with an average depth of about 3800 m (2.5 mi). In this highly dilute medium, particulate organic matter is partly replenished from dissolved organic carbon by microbial growth, the so-called microbial loop.

Of the large variety of organic material decomposed by marine heterotrophic bacteria, oil and related hydrocarbons are of special interest. Other environmentally detrimental pollutants that are directly dumped or reach the ocean as the ultimate sink by land runoff are microbiologically degraded at varying rates. Techniques of molecular genetics are aimed at encoding genes of desirable enzymes into organisms for use as degraders of particular pollutants.

A specifically marine microbiological phenomenon is bacterial bioluminescence, which may function as a respiratory bypass of the electron transport chain. Free-living luminescent bacteria are distinguished from those that live in symbiotic fashion in light organelles of fishes or invertebrates. *See* BIOLUMINESCENCE.

Photoautotrophs and chemoautotrophs. The type of photosynthesis carried out by purple sulfur bacteria uses hydrogen sulfide (instead of water) as a source of electrons and thus produces sulfur, not oxygen. Photoautotrophic bacteria are therefore limited to environments where light and hydrogen sulfide occur simultaneously, mostly in lagoons and estuaries. In the presence of sufficient amounts of organic substrates, heterotrophic sulfate-reducing bacteria provide the necessary hydrogen sulfide where oxygen is depleted by decomposition processes. Anoxygenic photosynthesis is also carried out by some blue-green algae, which are now classified as cyanobacteria. *See* CYANOBACTERIA; PHOTOSYNTHESIS.

Chemoautotrophic bacteria are able to reduce inorganic carbon to organic carbon (chemosynthesis) by using the chemical energy liberated during the oxidation of inorganic compounds. Their occurrence, therefore, is not light-limited but depends on the availability of oxygen and the suitable inorganic electron source. Their role as producers of organic carbon is insignificant in comparison with that of photosynthetic producers (exempting the processes found at deep-sea hydrothermal vents). The oxidation of ammonia and nitrite to nitrate (nitrification) furnishes the chemically stable and biologically most available form of inorganic nitrogen for photosynthesis. *See* NITROGEN CYCLE.

The generation of methane and acetic acid from hydrogen and carbon dioxide stems from anaerobic bacterial chemosynthesis, and is common in anoxic marine sediments. *See* METHANOGENESIS (BACTERIA).

Marine microbial sulfur cycle. Sulfate is quantitatively the most prominent anion in seawater. Since it can be used by a number of heterotrophic bacteria as an electron acceptor in respiration following the depletion of dissolved oxygen, the resulting sulfate reduction and the further recycling of the reduced sulfur compounds make the marine environment microbiologically distinctly different from fresh water and most soils. The marine anaerobic, heterotrophic sulfate-reducing bacteria are classified in three genera; *Desulfovibrio, Desulfotomaculum*, and *Clostridium*.

The marine aerobic sulfur-oxidizing bacteria fall into two groups: the thiobacilli and the filamentous or unicellular organisms. While the former comprise a wide range from obligately to facultatively chemoautotrophic species (requiring none or some organic compounds), few of the latter have been isolated in pure culture, and chemoautotrophy has been demonstrated in only a few.

Hydrothermal vent bacteria. Two types of hydrothermal vents have been investigated: warm vents (8–25°C or 46–77°F) with flow rates of 1–2 cm (0.4–0.8 in.) per second, and hot vents (260–360°C or 500–600°F) with flow rates of 2 m (6.5 ft) per second. In their immediate vicinity, dense communities of benthic invertebrates are found with a biomass that is orders of magnitude higher than that normally found at these depths and dependent on photosynthetic food sources. This phenomenon has been explained by the bacterial primary production of organic carbon through the chemosynthetic oxidation of reduced inorganic compounds. The chemical energy required for this process is analogous to the light energy used in photosynthesis and is provided by the geothermal reduction of inorganic chemical species. The specific compounds contained in the emitted vent waters and suitable for bacterial chemosynthesis are mainly hydrogen sulfide, hydrogen, methane, and reduced iron and manganese. The extremely thermophilic microorganisms isolated from hydrothermal vents belong, with the exception of the genus *Thermotoga,* to the Archaebacteria. Of eight archaeal genera, growing within a temperature range of about 75–110°C (165–230°F), three are able to grow beyond the boiling point of water, if the necessary pressure is applied to prevent boiling. These organisms are strictly anaerobic. However, unlike mesophilic bacteria, hyperthermophilic marine isolates tolerate oxygen when cooled below their minimum growth temperature. *See* ARCHAEBACTERIA; HYDROTHERMAL VENT. [H.W.J.]

Marine mining The process of recovering mineral wealth from sea water and from deposits on and under the sea floor. While mineral resources to the value of trillions of dollars do exist in and under the oceans, their exploitation is not simple. Many environmental problems must be overcome and many technical advances must be made before the majority of these deposits can be mined in competition with existing land resources.

The mineral resources of the marine environment are of three basic types: the dissolved minerals of the ocean waters; the unconsolidated mineral deposits of marine beaches, continental shelf, and deep-sea floor; and the consolidated deposits contained within the bedrock underlying the seas. As with land deposits, the initial stages preceding the production of a marketable commodity include discovery, characterization of the deposit to assess its value and exploitability, and mining, including beneficiation of the material to a salable product. [M.J.Cru.]

Marine navigation The process of directing a watercraft to a destination in a safe and expeditious manner. From a known present position, a course is determined that avoids dangers, and on this course estimates are made of time schedules. The task is to periodically effect en route checks and to make required adjustments.

The method used will depend on the type of vessel and on its role or mission. The devices available range from a simple compass to a host of sophisticated electronic systems. In all cases, the navigator must plan and prepare by setting instruments in order and by checking for predictable current and tidal effects and hazards to navigation en route. This preparation includes having the latest correct charts and reviewing pertinent sections of sailing directions, light lists, and tide and current tables.

The methods used to fulfill the requirements of these phases come after one of the following broad categories of navigation: dead reckoning, piloting, celestial navigation, and electronic navigation. The first three categories have become somewhat standardized; the fourth category has been under constant and innovative development.

While the navigator is occupied primarily with courses, speeds, distances, and position determination, the safety of the craft is not to be neglected. Integrated navigation-conning systems have the basic function of helping reduce the number of accidents between ships by having the computer correlate most of the data available during crowded conditions and thus help unburden the navigator by presenting these data in more usable form for better and quicker decision making. The system generally includes a collision avoidance device plus a general-purpose computer. The computer receives inputs from navigation sensors and from ship propulsion and ship status stations. The integrated console is designed to optimize the human engineering aspects of ship control and navigation.

Collision avoidance systems (CAS), also known as automatic radar plotting aids (ARPA), of varying degrees of sophistication have been developed to reduce the work load of the navigator and eliminate human error. Typically, such a system consists of a digital computer that receives inputs from the ship's radar, compass, and log, and determines and displays collision threats, and in some installations provides a recommended avoiding action.

Vessel traffic services (VTS) have been established in a number of heavily trafficked ports throughout the world in an attempt to reduce the number of collisions and strandings and safeguard the environment. Generally the service provides marine traffic management of an advisory nature, but in an especially hazardous situation it may be necessary for the VTS to exercise emergency control of vessel movements. *See* VESSEL TRAFFIC SERVICE.

Traffic-separation schemes have been established in a number of high-traffic density areas throughout the world, primarily to decrease the risk of collision at sea. A typical scheme consists of the establishment of parallel traffic lanes separated by an intervening buffer zone, analogous to a divided freeway on land. [A.B.M.; R.Gre.]

An electronic chart displays on a video screen the same type of hydrographic information that mariners seek in a traditional nautical chart. Electronic charts integrated with a range of information, and with hardware and software that can process a hydrographic database to support decision making, are classified as electronic chart display and information systems (ECDIS). In addition to displaying a real-time picture of the vessel's position in the waterway, an ECDIS manages navigational and piloting information (typically, vessel-route-monitoring, track-keeping, and track-planning information) to support navigational decision making.

There are a variety of intelligent systems deployed aboard automated ship's bridges: piloting expert systems, engineering and vibration expert systems, neutral network systems for adaptive and intelligent steering control, and automated intelligent docking systems. *See* EXPERT SYSTEMS; NEURAL NETWORK.

Integrated bridge systems are designed to allow the wheelhouse to function as the operational center for navigational and supervisory tasks aboard the ship. These bridges in many cases become ship's operations centers, incorporating controls and monitors for all essential vessel functions, including navigation, engine control, and communications. *See* NAVIGATION. [M.R.Gr.]

Marine refrigeration Marine refrigerating equipment is used for shipboard refrigeration of products as well as for air conditioning the quarters of passengers and crew. Shipboard refrigeration is necessary for the preservation of perishables in transit and foodstuffs to be used by passengers and crew. Marine refrigeration is also used for maintaining certain cargo products in liquid form that would otherwise evaporate when stored at ambient conditions. *See* AIR CONDITIONING; REFRIGERATION.

The common refrigerants that have been in use for years, known as CFCs (chlorofluorocarbons) and HCFCs (hydrochlorofluorocarbons), are still being phased out because they contain chlorine, which depletes Earth's stratospheric ozone layer. Replacements for these refrigerants known as hydrofluorocarbons (HFCs), which are non-ozone-depleting, have been developed. These refrigerants contain fluorine in place of chlorine, and do not destroy the ozone layer. For some systems, the cargo itself is used as the refrigerant, such as when carrying ammonia or petroleum products such as propane or butane.

For refrigerating systems using insulated holds, liquid refrigerant is delivered to cooling coils, where the refrigerant is expanded, and enters the evaporator as a low-pressure liquid. There it evaporates by absorbing heat from the space being cooled. The refrigerant vapor is then drawn from the evaporator by a compressor, which delivers the refrigerant to a condenser as a high-pressure, high-temperature vapor. The condenser, normally a shell-and-tube heat exchanger cooled by seawater flowing through the tubes, removes the heat absorbed in the evaporator and the heat of compression from the refrigerant as it condenses to a high-pressure liquid. The refrigerating cycle is then repeated. For the container system, each container has its own refrigeration system consisting of a compressor, air-cooled condenser, cooling coil, and circulating fan. For liquid cargoes in insulated tanks, the latent heat of vaporization is released as the evaporating liquid changes state to a gas. [J.H.Me.]

Marine sediments The accumulation of minerals and organic remains on the sea floor. Marine sediments vary widely in composition and physical characteristics as a function of water depth, distance from land, variations in sediment source, and the physical, chemical, and biological characteristics of their environments. The study of marine sediments is an important phase of oceanographic research and, together with the study of sediments and sedimentation processes on land, constitutes the subdivision of geology known as sedimentology. *See* OCEANOGRAPHY.

Traditionally, marine sediments are subdivided on the basis of their depth of deposition into littoral 0–66 ft (0–20 m), neritic 66–660 ft (20–200 m), and bathyal 660–6600 ft (200–2000 m) deposits. This division overemphasizes depth. More meaningful, although less rigorous, is a distinction between sediments mainly composed of materials derived from land, and sediments composed of biological and mineral material originating in the sea. Moreover, there are significant and general differences between deposits formed along the margins of the continents and large islands, which are influenced strongly by the nearness of land and occur mostly in fairly shallow water, and the pelagic sediments of the deep ocean far from land.

Sediments of continental margins. These include the deposits of the coastal zone, the sediments of the continental shelf, conventionally limited by a maximum depth of 330–660 ft (100–200 m), and those of the continental slope. Because of large differences in sedimentation processes, a useful distinction can be made between the coastal deposits on one hand (littoral), and the open shelf and slope sediments on the other (neritic and bathyal). Furthermore, significant differences in sediment characteristics and sedimentation patterns exist between areas receiving substantial detrital material from land, and areas where most of the sediment is organic or chemical in origin.

Coastal sediments include the deposits of deltas, lagoons, and bays, barrier islands and beaches, and the surf zone. The zone of coastal sediments is limited on the seaward side by the depth to which normal wave action can stir and transport sand, which depends on the exposure of the coast to waves and does not usually exceed 66–100 ft (20–30 m); the width of this zone is normally a few miles. The sediments in the coastal zone are usually land-derived. The material supplied by streams is sorted in the surf zone; the sand fraction is transported along the shore in the surf zone, often over long distances, while the silt and clay fractions are carried offshore into deeper water by currents. Consequently, the beaches and barrier islands are constructed by wave action mainly from material from fairly far away, although local erosion may make a contribution, while the lagoons and bays behind them receive their sediment from local rivers.

The types and patterns of distribution of the sediments are controlled by three factors and their interaction: (1) the rate of continental runoff and sediment supply; (2) the intensity and direction of marine transporting agents, such as waves, tidal currents, and wind; and (3) the rate and direction of sea level changes. The balance between these three determines the types of sediment to be found. *See* DELTA; ESTUARINE OCEANOGRAPHY.

On most continental shelves, equilibrium has not yet been fully established and the sediments reflect to a large extent the recent rise of sea level. Only on narrow shelves with active sedimentation are present environmental conditions alone responsible for the sediment distribution. Sediments of the continental shelf and slope belong to one or more of the following types: (1) biogenic (derived from organisms and consisting mostly of calcareous material); (2) authigenic (precipitated from sea water or formed by chemical replacement of other particles, for example, glauconite, salt, and phosphorite); (3) residual (locally weathered from underlying rocks); (4) relict (remnants of earlier environments of deposition, for example, deposits formed during the transgression leading to the present high sea level stand); (5) detrital (products of weathering and erosion of land, supplied by streams and coastal erosion, such as gravels, sand, silt, and clay).

Much of the fine-grained sediment transported into the sea by rivers is not permanently deposited on the self but kept in suspension by waves. This material is slowly carried across the shelf by currents and by gravity flow down its gentle slope, and is finally deposited either on the continental slope or in the deep sea. If submarine canyons occur in the area, they may intercept these clouds, or suspended material, channel them, and transport them far into the deep ocean as turbidity currents. If the canyons intersect the nearshore zone where sand is transported, they can carry this material also out into deep water over great distances. *See* CONTINENTAL MARGIN; REEF. [T.H.V.A.]

Deep-sea sediments. In general, classifications are difficult to apply because so many deep-sea sediments are widely ranging mixtures of two or more end-member sediment types. However, they can be divided into biogenic and nonbiogenic sediments.

Biogenic sediments, those formed from the skeletal remains of various kinds of marine organisms, may be distinguished according to the composition of the skeletal material, principally either calcium carbonate or opaline silica. The most abundant contributors of calcium carbonate to the deep-sea sediments are the planktonic foraminiferids, coccolithophorids and pteropods. Organisms which extract silica from the sea water and whose hard parts eventually are added to the sediment are radiolaria, diatoms, and to a lesser degree, dilicoflagellates and sponges. The degree to which deep-sea sediments in any area are composed of one or more of these biogenic types depends on the organic productivity of the various organisms in the surface water, the degree to which the skeletal remains are redissolved by sea water while setting to the bottom, and the rate of sedimentation of other types of sediment material. Where sediments are composed largely of a single type of biogenic material, it is often referred to as an ooze, after its consistency in place on the ocean floor.

The nonbiogenic sediment constituents are principally silicate materials and, locally, certain oxides. These may be broadly divided into materials which originate on the continents and are transported to the deep sea (detrital constituents) and those which originate in place in the deep sea, either precipitating from solution (authigenic minerals) or forming from the alteration of volcanic or other materials. The coarser constituents of detrital sediments include quartz, feldspars, amphiboles, and a wide spectrum of other common rock-forming minerals. The finer-grained components also include some quartz and feldspars, but belong principally to a group of sheet-silicate minerals known as the clay minerals, the most common of which are illite, montmorillonite, kaolinite, and chlorite. The distributions of several of these clay minerals have yielded information about their origins on the continents and, in several cases, clues to their modes of transport to the oceans. [P.E.Bi.]

Maritime meteorology Those aspects of meteorology that occur over, or are influenced by, ocean areas. Maritime meteorology serves the practical needs of surface and air navigation over the oceans. Phenomena such as heavy weather, high seas, tropical storms, fog, ice accretion, sea ice, and icebergs are especially important because they seriously threaten the safety of ships and personnel. The weather and ocean conditions near the air-ocean interface are also influenced by the atmospheric planetary boundary layer, the ocean mixed layer, and ocean fronts and eddies.

To support the analysis and forecasting of many meteorological and oceanographic elements over the globe, observations are needed from a depth of roughly 1 km (0.6 mi) in the ocean to a height of 30 km (18 mi) in the atmosphere. In addition, the observations must be plentiful enough in space and time to keep track of the major features of interest, that is, tropical and extratropical weather systems in the atmosphere and fronts and eddies in the ocean. Over populated land areas, there is a fairly dense meteorological network; however, over oceans and uninhabited lands, meteorological observations are scarce and expensive to make, except over the major sea lanes and air routes. Direct observations in the ocean, especially below the sea surface, are insufficient to make a synoptic analysis of the ocean except in very limited regions. Fortunately, remotely sensed data from meteorological and oceanographic satellites are helping to fill in some of these gaps in data. Satellite data can provide useful information on the type and height of clouds, the temperature and humidity structure in the atmosphere, wind velocity at cloud level and at the sea surface, the ocean surface temperature, the height of the sea, and the location of sea ice. Although satellite-borne sensors cannot penetrate below the sea surface, the height of the sea can be used to infer useful information about the density structure of the ocean interior. *See* REMOTE SENSING.

The motion of the atmosphere and the ocean is governed by the laws of fluid dynamics and thermodynamics. These laws can be expressed in terms of mathematical equations that can be put on a computer in the form of a numerical model and used to help analyze the present state of the fluid system and to forecast its future state. This is the science of numerical prediction, and it plays a very central role in marine meteorology and physical oceanography.

The first step in numerical prediction is known as data assimilation. This is the procedure by which observations are combined with the most recent numerical prediction valid at the time that the observations are taken. This combination produces an analysis of the present state of the atmosphere and ocean that is better than can be obtained from the observations alone. Data assimilation with a numerical model increases the value of a piece of data, because it spreads the influence of the data in space and time in a dynamically consistent way.

The second step is the numerical forecast itself, in which the model is integrated forward in time to predict the state of the atmosphere and ocean at a future time. Models of the global atmosphere and world ocean, as well as regional models with higher spatial resolution covering limited geographical areas, are used for this purpose. In meteorology and oceanography the success of numerical prediction depends on collecting sufficient data to keep track of meteorological and oceanographic features of interest (including those in the earliest stages of development), having access to physically complete and accurate numerical models of the atmosphere and ocean, and having computer systems powerful enough to run the models and make timely forecasts. *See* WEATHER FORECASTING AND PREDICTION. [R.L.Han.]

Marjoram The aromatic herb *Majorana hortensis*, a common plant in Mediterranean areas. The spicy camphora-ceous odor of marjoram has long been cherished as an addition to a wide variety of foods; in the Middle Ages marjoram was used as an air freshener. Marjoram is in the mint family (Lamiaceae) and is a close relative of European or Greek oregano, with which it is often confused. There is still controversy concerning the proper taxonomic classification of this plant. Some authors place it in the genus *Origanum*, while others continue to separate it into its own genus *Majorana*. *See* OREGANO.

Marjoram is a small perennial (1–2 ft or 30–60 cm tall), and has ovate leaves to 1 in. (2.5 cm) long. The leaves are slightly hairy, as are the erect somewhat woody stems. Majoram flowers are white to very light lavender or pink in color but are very small and usually go unnoticed; the entire flower spike or inflorescence is, however, easily noticeable.

The dried and fresh leaves are used as flavoring for meats (sausage), vegetables, cheeses, poultry stuffing blends, and sauces, especially tomato-based sauces. *See* LAMIALES; SPICE AND FLAVORING. [S.Kir.]

Marl A sediment that consists of a mixture of calcium carbonate ($CaCO_3$) and any other constituents in varying proportions. Marls usually are fine-grained, so that most consist of $CaCO_3$ mixed with silt and clay. The dominant carbonate mineral in most marls is calcite ($CaCO_3$), but other carbonate minerals such as aragonite (another form of $CaCO_3$), dolomite [$Ca, Mg(CO_3)_2$], and siderite ($FeCO_3$) may be present. *See* ARAGONITE; CALCITE; CARBONATE MINERALS; DOLOMITE; SIDERITE.

In North America, the name marl may be limited to a lake deposit that is rich in $CaCO_3$, but usually the term is extended to include marine deposits. Deep-sea marls consist of mixtures of clay and the $CaCO_3$ skeletons of microscopic planktonic animals (foraminiferans) and plants (coccoliths and discoasters). Marls deposited in the deeper parts of lakes consist of fine-grained $CaCO_3$, but marls deposited in shallow water may contain $CaCO_3$ in the form of shells of mollusks and fragments of calcareous algae such as *Chara* (stonewort) mixed with fine-grained $CaCO_3$ that is precipitated on the leaves of rooted aquatic vegetation. The $CaCO_3$ from these various sources is then mixed with sand, silt, or clay brought in by streams from the surrounding drainage basin. *See* MARINE SEDIMENTS.

Although the term marl has been applied to sediments with a greatly variable content of $CaCO_3$, strictly speaking the $CaCO_3$ content should range between 30 and 70%. Because of the high $CaCO_3$ content, most marls are light to medium gray, although they can be almost any color. The high $CaCO_3$ content also tends to make dried marl earthy and crumbly.

The indurated rock equivalent of marl is marlstone. Equivalent terms range from calcareous claystone to argillaceous or impure limestone, depending on the amount of $CaCO_3$ that is present. Marlstone is common in marine sequences of all ages, and is particularly common in ancient lake sequences of Tertiary age in the western United States. For example, the famous "oil shale" of the Green River Formation of Wyoming, Colorado, and Utah is not a shale at all but a marlstone in which the dominant carbonate mineral is dolomite. *See* LIMESTONE; OIL SHALE; SEDIMENTARY ROCKS. [W.E.De.]

Marmot Several species of rodents of the genus *Marmota* which are members of the squirrel family, Sciuridae. These mammals are found in Europe, Asia, and North America.

One of the best-known marmots is the alpine marmot (*Marmota marmota*). It has a broad round head, a short furry tail, prominent eyes, and medium-sized ears; it is covered with thick, coarse, dull-colored fur. Other marmots are the red marmot (*M. caudata*) of Central Asia, the red-bellied marmot (*M. flaviventris*), ranging from New Mexico to British Columbia, and the woodchuck, or groundhog (*M. monax*), of North America. All species seem to prefer high altitudes except the woodchuck, which lives in woodlands and on farms. In many ways the marmots resemble the prairie dog. *See* PRAIRIE DOG; RODENTIA. [C.B.C.]

Mars The planet that is fourth outward from the Sun. Mars has a mean heliocentric distance (semimajor axis) of 1.524 astronomical units, equivalent to 141.6×10^6 mi (227.9×10^6 km). Its orbital eccentricity of 0.093, one of the largest of the major planets, causes the distance between Mars and the Sun to vary from 128×10^6 mi (207×10^6 km) at perihelion to 155×10^6 mi (249×10^6 km) at aphelion. The mean diameter of Mars is 4212 mi (6780 km), or about 53% that of the Earth. The planet has a mass of 7.08×10^{20} tons (6.42×10^{23} kg), about 11% of Earth's. The sidereal rotation period is 24h 37m 22.7s, corresponding to a mean solar day of 24h 39m 35.2s.

Mars appears to the unaided eye as a bright, slightly reddish star. Having a mean (synodic) period between oppositions of 780 days, Mars is in conjunction with the Sun every other year. Viewed through a telescope, Mars usually appears as a bright reddish disk marked by complex, semipermanent dark regions and variable white polar caps.

Interior. Accurate measurements of the planet's gravitational field made by orbiting spacecraft have shown that Mars has a dense core and thus is differentiated into a core, mantle, and crust. The crust, composed of silicate rocks, enriched in silicon and aluminum and deficient in magnesium, is believed to be about 30 mi (50 km) thick. Over geologic time, partial melting of the crust or upper mantle has caused lower-density materials to float to the surface, creating the observed lava plains and volcanic structures.

At present Mars does not have a global magnetic field of appreciable strength. However, early in its history Mars must have had a more substantial magnetic field, because its near-surface rocks exhibit strong remanent magnetism. *See* ROCK MAGNETISM.

Geology. The Martian surface has been modified extensively by the processes of impact cratering, volcanism, faulting, and fluvial erosion. The terrain in the southern hemisphere is very heavily cratered and thus quite old, having formed some 3.8×10^9 years ago. Much of it stands 1–2 mi (1–4 km) higher than the planet's mean radius. By contrast, the northern hemisphere is dominated by vast, lava-covered plains with relatively few impact craters and an average elevation of about 3 mi (5 km) below the mean radius.

The Tharsis rise, or bulge, is an uplifted portion of the surface that stands several kilometers above the mean elevation of the planet. Most of Mars's tectonic features are associated with Tharsis, which affects approximately one-quarter of the entire surface.

The Martian surface exhibits several enormous shield volcanoes. The largest and perhaps the youngest is Olympus Mons, which is nearly 370 mi (600 km) across at its base and stands approximately 16 mi (26 km) above the surrounding terrain. Three other large shield volcanoes, Ascraeus Mons, Pavonis Mons, and Arsia Mons, lie along the nearby Tharsis rise. In shape and structure the Martian shield volcanoes bear a strong resemblance to their Hawaiian counterparts. At the summit of each shield is a complex of calderas, collapsed craterlike features that were once vents for lava.

Perhaps the most spectacular features on the Martian surface are the huge canyons located primarily in the equatorial regions. Valles Marineris, actually a system of canyons, extends for over 3000 mi (5000 km) along the equatorial belt. In places, the canyon complex is as much as 300 mi (500 km) wide and drops to more than 4 mi (6 km) below the surrounding surface. Dwarfing the Earth's Grand Canyon, Valles Marineris is

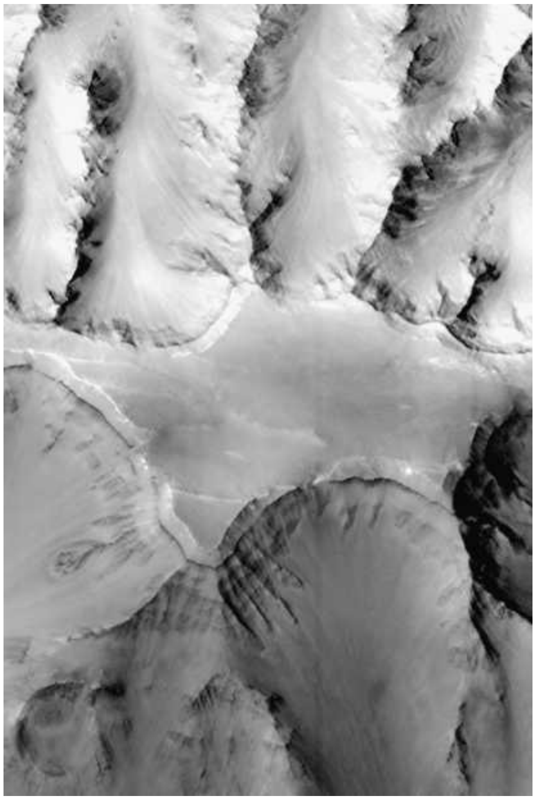


Fig. 1. An image from the *Mars Global Surveyor* resolves features as small as 20 ft (6 m) in a 10-km-wide portion of Coprates Chasma, which is located in the middle of Mars's vast Valles Marineris canyon complex. The high-standing plateau is underlain by multiple rock layers that may be volcanic or sedimentary in nature. (*NASA/Malin Space Science Systems*)

comparable in size to the great East African Rift Valley. In general, the walls of the canyon are precipitous, have well-defined edges, and show evidence of slumping and landslide activity (Fig. 1).

An astonishing class of features on the Martian surface is a widespread network of channels that bear a very strong resemblance to dry river beds. Ranging in size from broad, sinuous features nearly 40 mi (60 km) wide to small, narrow networks less than 300 ft (100 m) wide, the channels appear to have been created by water erosion. The largest channels must have been formed by enormous torrents of water, presumably released in some catastrophic manner (Fig. 2).

Surface exploration. Five spacecraft have landed safely on the Martian surface and returned significant scientific data about its properties. Two American *Viking* landers arrived in 1976. *Mars Pathfinder* which landed in 1997, carried a small, instrumented rover, *Sojourner*, which was directed from Earth via remote control to several rocks and fine-grained drifts in the lander's immediate vicinity. The *Mars Exploration Rovers*, *Spirit* and *Opportunity*, which landed in 2004, had far greater mobility.

Meteorites from Mars. A small number of meteorites have reached Earth after being violently ejected from the planet Mars during the collision of sizable asteroids or comets. The meteorites are thus samples from Mars itself. The first of these Martian meteorites was recognized in 1982, and 14 such samples were known by the end of 1999. They are sometimes collectively termed the SNC meteorites, representing the first letters of their three subclasses: shergottites, nakhlites, and chassignites. The Martian meteorites contain a distinctive ratio of the isotopes of oxygen found nowhere on Earth, on the Moon, or in other meteorites. With one exception, they crystallized from molten rock within the last 1.3×10^9 years, far more recently than the usual 4.6×10^9 years (the age of the solar system) found in all other meteorites. The lone exception to date, designated ALH 84001, crystallized 4.5×10^9 years ago during the planet's infancy. *See* METEORITE.

Atmosphere. The Martian atmosphere is very thin, with surface pressure averaging about 6.5 millibars (650 pascals), or less than 1% of the pressure at the Earth's surface. It is composed principally of carbon dioxide (95.3%), but contains nitrogen, argon, oxygen, and a trace of water vapor, totaling 4.7%. Both carbon dioxide and water form clouds in the Martian atmosphere.

Dust storms. Localized dust storms appear quite frequently on Mars. Because the Martian atmosphere is extremely thin, wind velocities greater than 90–110 mi/h (40– 50 m/s) are needed to set surface dust grains in motion. Some dust storms develop with such intensity that their total extent may be hemispheric or even global.

Water inventory. The seasonal cycle of growth and decay of the bright polar caps has long been taken as evidence of the presence of water on Mars. However, evidence from the *Mariner* spacecraft identified carbon dioxide as the principal constituent of the polar snow, with lesser amounts of water ice also present. Formed during autumn and winter by condensation and deposition of the icy mist covering the polar regions, the polar caps at the end of winter cover a vast area extending down to latitude 60° in the southern hemisphere and 70° in the northern hemisphere. The residual caps, which never completely disappear, are believed to be composed almost entirely of water ice. It is estimated that if all the water present in the polar caps were distributed uniformly over the surface of Mars, it would produce a layer 70–110 ft (22–33 m) deep. A far greater amount of water may exist as subsurface ice trapped elsewhere in areas of heavily cratered and fractured terrain.

Even though at present liquid water cannot exist on the Martian surface, the planet's numerous large flood channels suggest that vast amounts of water flowed on the surface early in Martian history. There is strong circumstantial evidence that much of the low-lying northern hemisphere was covered with an ocean roughly 4×10^9 years ago. Although unproven, this hypothesis suggests that 10^7 mi^2 (27×10^6 km^2) of the northern plains were also inundated.

Possibility of life. The ample evidence that early Mars had an abundance of liquid water, a thicker atmosphere, and a more clement environment has raised speculation that the planet may have once been, or may still be, an abode for primitive life forms. In 1976, the twin *Viking* landers conducted experiments on the Martian surface to test for the existence of life. One of the

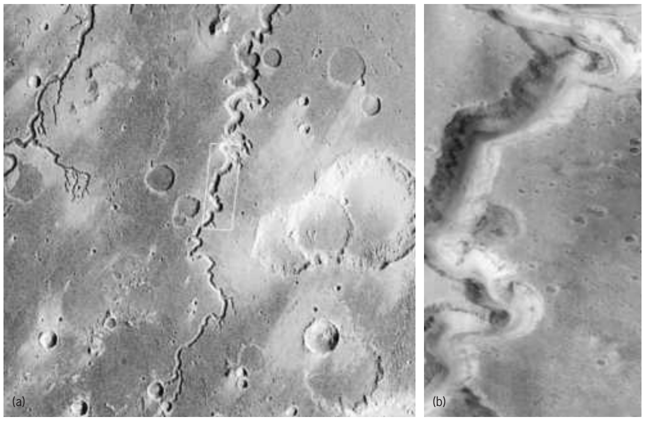

Fig. 2. Nanedi Vallis, a long, water-cut canyon on Mars, which is 1.5 mi (2.5 km) wide. (*a*) Canyon and surrounding terrain. (*b*) Detailed view of area in white rectangle in part *a*. Rocky outcrops jut from the canyon's walls, and a secondary rivulet is seen in its floor. (*NASA/Malin Space Science Systems*)

biological experiments gave a positive result—the release of oxygen from a soil sample when humidified—but there is no consensus as to the source of this reaction.

Twenty years later, a scientific team claimed that it had found evidence of fossilized microbes within a known Martian meteorite (ALH 84001). After years of intensive study, scientists have reached no consensus. The mineral associations within ALH 84001 and other Martian meteorites neither confirm the presence of once-living organisms nor exclude it.

Satellites. Mars has two small satellites, Phobos and Deimos. Neither satellite is massive enough to be gravitationally contracted to a spherical shape. Both satellites are saturated with impact craters. Both satellites have the same low albedo, approximately 0.05. This low reflectivity suggests that the Martian satellites may have originated in the asteroid belt. *See* ASTEROID. [J.K.B.]

Marsileales A small order of heterosporous, leptosporangiate ferns (division Polypodiophyta) which grow in water or wet places and are rooted to the substrate. The leaves arise on long stalks from the rhizome and typically have floating blades with four leaflets, suggesting a four-leaved clover. The order contains a single family and only 3 genera, about 50 species in all, most of them belonging to the widespread genus *Marsilea* (water clover). *See* POLYPODIOPHYTA. [A.Cr.]

Marsupialia An order of animals, long considered the only order of the mammalian infraclass Metatheria.

The marsupials are characterized by the presence of a pouch (marsupium) in the female, a skin pocket whose teat-bearing abdominal wall is supported by epipubic bones. The young are born in the embryonic state and crawl unaided to the marsupium, where they attach themselves to the teats and continue their development. In a few species the pouch is vestigial or has disappeared completely.

A wide variety of terrestrial adaptations are found among the 82 genera of living marsupials. Some spectacular examples of evolution convergent upon placental modes of life are exemplified by the Australian marsupial "moles" (*Notoryctes*), "wolves" (*Thylacinus*), and "flying squirrels" (*Petaurus*). For the most part, the adaptive radiation of the marsupials has paralleled that of the placentals, yielding many ecological analogs, such as kangaroos and wallabies, which are the counterparts of the placental deer and antelopes, although these groups differ widely in structure. *See* ANTEATER; EUTHERIA; KANGAROO; KOALA; MAMMALIA; METATHERIA; OPOSSUM. [R.H.T.]

Marten The name applied to seven species of carnivores which are members of the family Mustelidae. This family also includes the skunk, weasel, otter, badger, and wolverine.

The American marten (*Martes americana*) inhabits the cooler forests of North America. Its brown pelt, known as the American sable, is highly prized. It is small and has scent glands, as do most members of the family. Other species are the pine marten (*M. martes*), yellow-throated marten (*M. flavigula*), stone marten (*M. foina*), Japanese marten (*M. melampus*), and South Indian yellow-throated marten (*M. gwatkinsi*). These are all found in Asia; the pine and stone martens occur in Europe as well.

The adult weighs a maximum of 3 lb (1.4 kg), and for the size of the animal, the gestation period of about 38 weeks is unusually long. This is apparently because these species, as many other members of the family do, have delayed implantation of the fertilized egg; that is, after fertilization there is a lapse of several months before embryonic activation is initiated. Mating occurs in the summer and the litter of three or four is born the following spring. *See* BADGER; CARNIVORA; FISHER; MAMMALIA; OTTER; SABLE; SKUNK; WEASEL; WOLVERINE. [C.B.C.]

Maser A device for coherent amplification or generation of electromagnetic waves by use of excitation energy in resonant atomic or molecular systems. "Maser" is an acronym for microwave amplification by stimulated emission of radiation. The device uses an unstable ensemble of atoms or molecules that may be stimulated by an electromagnetic wave to radiate energy at the same frequency and phase as the stimulating wave, thus providing coherent amplification. Amplifiers and oscillators operating on the same principle as the maser exist in many regions of the electromagnetic spectrum. Those operating in the optical region were once called optical masers, but they are now universally called lasers (the "l" stands for "light"). Amplification by maser action is also observed arising naturally from interstellar gases. *See* COHERENCE; LASER.

Maser amplifiers can have exceptionally low internally generated noise, approaching the limiting effective input power of one-half quantum of energy per unit bandwidth. Their inherently low noise makes maser oscillators that use a narrow atomic or molecular resonance extremely monochromatic, providing a basis for frequency standards. The hydrogen maser, which uses a hyperfine resonance of a gas of hydrogen atoms as the amplification source, is the prime example of this use. Also because of their low noise and consequent high sensitivity, maser amplifiers are particularly useful for reception and detection of very weak signals in radio astronomy, microwave radiometry, and the like. A maser amplifier was used in the experiments that detected the cosmic microwave radiation left over from the big bang that created the universe. *See* COSMIC BACKGROUND RADIATION; ELECTRICAL NOISE; FREQUENCY MEASUREMENT; RADIO ASTRONOMY; UNCERTAINTY PRINCIPLE.

The quantum theory describes discrete particles such as atoms or molecules as existing in one or more members of a discrete set of energy levels, corresponding to the various possible internal motions of the particle (vibrations, rotations, and so forth). Thermal equilibrium of an ensemble of such particles requires that the number of particles n_1 in a lower energy level 1 be related to the number of particles n_2 in a higher energy level 2 by the Boltzmann distribution, given by the equation below, where E_1

$$\frac{n_1}{n_2} = \exp\frac{(E_2 - E_1)}{kT}$$

and E_2 are the respective energies of the two levels, k is Boltzmann's constant, and T is the absolute (Kelvin) temperature. *See* BOLTZMANN STATISTICS; NONRELATIVISTIC QUANTUM THEORY; QUANTUM MECHANICS.

Particles may be stimulated by an electromagnetic wave to make transitions from a lower energy level to a higher one, thereby absorbing energy from the wave and decreasing its amplitude, or from a higher energy level to a lower one, thereby giving energy to the wave and increasing its amplitude. These two processes are inverses of each other, and their effects on the stimulating wave add together. The upward and downward transition rates are the same, so that, for example, if the number of particles in the upper and lower energy states is the same, the stimulated emission and absorption processes just cancel. For any substance in thermal equilibrium at a positive (ordinary) temperature, the Boltzmann distribution requires that n_1 be greater than n_2 resulting in net absorption of the wave. If n_2 is greater than n_1, however, there are more particles that emit than those that absorb, so that the particles amplify the wave. In such a case, the ensemble of particles is said to have a negative temperature T, to be consistent with the Boltzmann condition. If there are not too many counterbalancing losses from other sources, this condition allows net amplification. This is the basic description of how a maser amplifies an electromagnetic wave. An energy source is required to create the negative temperature distribution of particles needed for a maser. This source is called the pump.

Gas masers. In the first known maser of any kind, the amplifying medium was a beam of ammonia (NH_3) molecules, and the molecular resonance used was the strongest of the rotation-inversion lines, at a frequency near 23.87 GHz (1.26-cm wavelength). Molecules from a pressurized tank of ammonia issued through an array of small orifices to form a molecular beam in a meter-long vacuum chamber. Spatially varying electric fields in the vacuum chamber created by a cylindrical array of electrodes formed a focusing device, which ejected from the beam the molecules in the lower energy level and directed the molecules in the upper energy level into a metal-walled electromagnetic cavity resonator. When the cavity resonator was tuned to the molecular transition frequency, the number of molecules was sufficiently large to produce net amplification and self-sustained oscillation. This type of maser is particularly useful as a frequency or time standard because of the relative sharpness and invariance of the resonance frequencies of molecules in a dilute gas. *See* CAVITY RESONATOR; MOLECULAR BEAMS.

Solid-state masers. Solid-state masers usually involve the electrons of paramagnetic ions in crystalline media immersed in a magnetic field. At least three energy levels are needed for continuous maser action. The energy levels are determined both by the interaction of the electrons with the internal electric fields of the crystal and by the interaction of the magnetic moments of the electrons with the externally applied magnetic field. The resonant frequencies of these materials can be tuned to a desired condition by changing the strength of the applied magnetic field and the orientation of the crystal in the field. An external oscillator, the pump, excites the transition between levels 1 and 3 [at the frequency $\nu_{31} = (E_3 - E_1)/h$], equalizing their populations. Then, depending on other conditions, the population of the intermediate level 2 may be greater or less than that of levels 1 and 3. If greater, maser amplification can occur at the frequency ν_{21}, or if less, at the frequency ν_{32}. Favorable conditions for this type of maser are obtained only at very low temperature, as in a liquid-helium cryostat. A typical material is synthetic ruby, which contains paramagnetic chromium ions (Cr^{3+}), and has four pertinent energy levels. The important feature of solid-state masers is their sensitivity when used as amplifiers. *See* PARAMAGNETISM.

Astronomical masers. Powerful, naturally occurring masers have probably existed since the earliest stages of the universe, though that was not realized until a few years after masers were invented and built on Earth. Their existence was first proven by discovery of rather intense 18-cm-wavelength microwave radiation of the free radical hydroxyl (OH) molecule coming from very localized regions of the Milky Way Galaxy.

Masers in astronomical objects differ from those generally used on Earth in that they involve no resonators or slow-wave structures to contain the radiation and so increase its interaction with the amplifying medium. Instead, the electromagnetic waves in astronomical masers simply travel a very long distance through astronomical clouds of gas, far enough to amplify the waves enormously even on a single pass through the cloud. It is believed that usually these clouds are large enough in all directions that a wave passing through them in any direction can be strongly amplified, and hence astronomical maser radiation emerges from them in all directions.

Naturally occurring masers have been important tools for obtaining information about astronomical objects. Since they are very intense localized sources of microwave radiation, their positions around stars or other objects can be determined very accurately with microwave antennas separated by long distances and used as interferometers. This provides information about the location of stars themselves as well as that of the masers often closely surrounding them. The masers' velocity of motion can also be determined by Doppler shifts in their wavelengths. The location and motion of masers surrounding black holes at the centers of galaxies have also provided information on the impressively large mass of these black holes. Astronomical masers often vary in power on time scales of days to years, indicating changing conditions in the regions where they are located. Such masers also give information on likely gas densities, temperature, motions, or other conditions in the rarefied gas of which they are a part. *See* BLACK HOLE; DOPPLER EFFECT. [C.H.T.; J.P.Go.]

Masking of sound Interference with the audibility of a sound caused by the presence of another sound. More specifically, the number of decibels (dB) by which the intensity level of a sound (signal) must be raised above its threshold of audibility, to be heard in the presence of a second sound (masker), is called the masking produced by the masker on the signal. The masker and the signal may be identical or may differ in frequency, complexity, or time.

When both the masker and signal are pure tones and the tonal signal and masker have the same frequency, a very low level masker is required to mask the signal, indicating significant masking. As the difference in the frequency between the signal and masker increases, the signal is easier to detect, requiring a higher-level masker to mask the signal. Results from these psychophysical tuning curve measures of masking agree very well with data obtained from single auditory neurons in the auditory periphery, suggesting that tonal masking is mediated by the activity of these peripheral neurons.

The most widely studied complex masking sound is random noise which has energy at all frequencies and is said to be flat if the level for each 1-Hz bandwidth of the noise is the same. When random-flat noise is used to mask a pure tone, only a narrow frequency band (critical band) of the noise centered at the tonal frequency causes masking. If the bandwidth of the noise is narrower than this critical bandwidth, the tone's intensity can be lowered before the tone is masked. If the bandwidth is wider than this critical bandwidth, further widening of the bandwidth causes no changes in the detectability of the signal. The width of the critical band increases proportionally to its center frequency, that is, to the signal frequency. When noise masks speech, either the detectability of speech or speech intelligibility can be measured. The level for speech intelligibility is about 10–14 dB higher than for speech detectability.

Masking can occur when the signal either precedes or follows the masker in time. In backward masking the signal precedes the masker, while in forward masking the signal follows the masker. The physiological basis for this effect, as well as its implications for auditory processing of complex stimuli, is of great interest to the auditory scientist. *See* ACOUSTIC NOISE; HEARING (HUMAN); SOUND. [W.A.Y.]

Masonry Construction of natural building stone or manufactured units such as brick, concrete block, adobe, glass block, or cast stone that is usually bonded with mortar. Masonry can be used structurally or as cladding or paving. It is strong in compression but requires the incorporation of reinforcing steel to resist tensile and flexural stresses. Masonry veneer cladding can be constructed with adhesive or mechanical bond over a variety of structural frame types and backing walls.

Masonry is noncombustible and can be used as both structural and protective elements in fire-resistive construction. It is durable against wear and abrasion, and most types weather well without protective coatings. The mass and density of masonry also provide efficient thermal and acoustical resistance.

Brick, concrete block, and stone are the most widely used masonry materials for both interior and exterior applications in bearing and nonbearing construction. Stone masonry can range from small rubble or units of ashlar (a hewn or squared stone) embedded in mortar, to mechanically anchored thin slabs, to ornately carved decorative elements. Granite, marble, and limestone are the most commonly used commercial building stones. Glass block can be used as security glazing or as elements to produce special daylighting effects. *See* BRICK; CONCRETE; GLASS; GRANITE; MARBLE; LIMESTONE; STONE AND STONE PRODUCTS.

Masonry mortar is made from cement, sand, lime, and water. Masonry grout, a more fluid mixture of similar ingredients, is used to fill hollow cores and cavities and to embed reinforcing steel. Anchors and ties are usually of galvanized or stainless steel. Flashing may be of stainless steel, coated copper, heavy rubber sheet, or rubberized asphalt. *See* GROUT; MORTAR. [C.Bea.]

Mass The quantitative or numerical measure of a body's inertia, that is, of its resistance to being accelerated.

Because it is often necessary to compare masses of such dissimilar bodies as a sample of sugar, a sample of air, an electron, and the Moon, it is necessary to define mass in terms of a property that not only is inherent and permanent but is also universal in that it is possessed by all known forms of matter. All matter possesses two properties, gravitation and inertia. The property of gravitation is that every material body attracts every other material body. The property of inertia is that every material body resists any attempt to change its motion. A body's motion is said to change if the body is accelerated, that is, if it increases or decreases its speed or changes the direction of its motion. Because of its inertia a body cannot be accelerated unless a force is exerted on it. The greater the inertia of a body, the less will be the acceleration produced by a given force. *See* GRAVITATION; INERTIA.

The present definition of mass is in terms of inertia. The masses of two bodies are compared by applying equal forces to the bodies and measuring their accelerations. For example, the two bodies may be allowed to collide. According to Newton's third law, each body will then experience an equally strong force. If there are no external forces, and if a_1 and a_2 are the measured accelerations of the two bodies, the ratio of the masses of the two bodies is by definition given by the equation

$$\frac{m_1}{m_2} = \frac{a_2}{a_1}$$

This equation gives only ratios of masses; it is therefore necessary to designate the mass of some one body as the standard mass to which the masses of all other bodies can be compared. The body that has been chosen for this purpose is a cylinder of platinum-iridium alloy. It is known as the international standard of mass; its mass is called 1 kilogram (kg), and it is kept at the International Bureau of Weights and Measures near Paris, France. Replicas of the standard mass, kept at various national laboratories, are periodically compared with this standard.

Einstein's special theory of relativity predicts that the inertia of a body should increase if the energy of the body increases. This prediction has been conclusively verified experimentally. It follows that the mass of a body will increase if, for example, the body gains speed (addition of kinetic energy), or its temperature rises (addition of heat energy), or the body is compressed (addition of elastic energy). *See* CONSERVATION OF MASS. [L.N.]

Mass defect The difference between the mass of an atom and the sum of the masses of its individual components in the free (unbound) state. The mass of an atom is always less than the total mass of its constituent particles; this means, according to Albert Einstein's well-known formula, that an energy of $E = mc^2$ has been released in the process of combination, where m is the difference between the total mass of the constituent particles and the mass of the atom, and c is the velocity of light.

The mass defect, when expressed in energy units, is called the binding energy, a term which is perhaps more commonly used. *See* NUCLEAR BINDING ENERGY. [W.W.W.]

Mass-luminosity relation The relation, observed or predicted by theory, between the quantity of matter a star contains (its mass) and the amount of energy generated in its interior (its luminosity). Because of the great sensitivity of the rate of energy production in a stellar interior to the mass of the star, the mass-luminosity relation provides an important test of theories of stellar interiors.

For a family of stars with different masses but with the same mixture of chemical elements uniformly distributed throughout the stellar volumes, there will be a unique mass-luminosity relation. Since most of the stars in the solar neighborhood have about the same chemical composition, the observed relation, obtained from binary stars for which masses and luminosities can be observationally evaluated, conforms reasonably well with theory. *See* BINARY STAR; STAR. [D.M.P.]

Mass number The mass number A of an atom is the total number of its nuclear constituents, or nucleons, as the protons and neutrons are collectively called. The mass number is placed before and above the elemental symbol, thus ^{238}U. The mass number gives a useful rough figure for the atomic mass; for example, $^1\text{H} = 1.00814$ atomic mass units (amu), $^{238}\text{U} = 238.124$ amu, and so on. *See* ATOMIC NUMBER. [H.E.D.]

Mass spectrometry An analytical technique for identification of chemical structures, determination of mixtures, and quantitative elemental analysis, based on application of the mass spectrometer. Determination of organic and inorganic molecular structure is based on the fragmentation pattern of the ion formed when the molecule is ionized; further, because such patterns are distinctive, reproducible, and additive, mixtures of known compounds may be analyzed quantitatively. Quantitative elemental analysis of organic compounds requires exact mass values from a high-resolution mass spectrometer; trace analysis of inorganic solids requires a measure of ion intensity as well. *See* MASS SPECTROSCOPE.

For analysis of organic compounds the principal methods are electron impact, chemical ionization, field ionization, field desorption, particle bombardment, laser desorption, and electrospray.

In electron impact, when a gaseous sample of a molecular compound is ionized with a beam of energetic (commonly 70-V) electrons, part of the energy is transferred to the ion formed by the collision, as shown in the reaction below.

$$\text{A—B—C} + e \longrightarrow \text{A—B—C}^+ + e + e$$

For most molecules the production of cations is favored over the production of anions by a factor of about 10^4, and the following discussion pertains to cations. The ion corresponding to the simple removal of the electron is commonly called the molecular ion and normally will be the ion of greatest m/e ratio in the spectrum. In the ratio, m is the mass of the ion in atomic mass units (daltons) and e is the charge of the ion measured in terms of the number of electrons removed (or added) during ionization. Occasionally the ion is of vanishing intensity, and sometimes it collides with another molecule to abstract a hydrogen or another group. In these cases an incorrect assignment of the molecular ion may be made unless further tests are applied. Proper identification gives the molecular weight of the sample.

The remaining techniques were devised generally to circumvent the problem of the weak or vanishingly small intensity of a molecular ion.

In chemical ionization the ions to be analyzed are produced by transfer of a heavy particle (H^+, H^-, or heavier) to the sample from ions produced from a reactant gas.

Field ionization and field desorption is used for less volatile material. The sample is ionized when it is in a very high field gradient (several volts per angstrom) near an electrode surface. The molecular potential well is distorted so that an electron tunnels from the molecule to the anode. The ion thus formed is repelled by the anode. Typically, the lifetime of the ion in the mass spectrometer source is much less (10^{-12} to 10^{-9} s) than in electron impact. Because little energy is transferred as internal energy and the ion is removed rapidly, little fragmentation occurs, and the molecular weight is more easily determined.

In electrohydrodynamic ionization, a high electric-field gradient induces ion emission from a droplet of a liquid solution, that is, the sample and a salt dissolved in a solvent of low volatility. An example is the sample plus sodium iodide (NaI) dissolved in glycerol. The spectra include peaks due to cationized molecules of MNa^+, $\text{MNa}(\text{C}_3\text{H}_8\text{O}_3)_n{}^+$, and $\text{Na}(\text{C}_3\text{H}_8\text{O}_3)_n{}^+$.

A sample heated very rapidly may vaporize before it pyrolyzes. Techniques for heating by raising the temperature of a source probe on which the sample is coated by 200 K (360°F)/s have been developed. Irradiation of an organic sample with laser radiation can move ions of mass up to 1500 daltons into the gas phase for analysis. This technique is the most compatible with analyzers that require particularly low pressures such as ion cyclotron resonance. Time-resolved spectra of surface ejecta are proving to be the most useful kinds of laser desorption spectra available.

A solid sample or a sample in a viscous solvent such as glycerol may have ions sputtered from its surface by bombardment with accelerated electrons, ions, or neutrals. Bombardment by electrons is achieved simply by inserting a probe with the sample directly into the electron beam of an electron impact source (in-beam electron ionization).

In laser desorption, the energy of laser photons may be used to remove an analyte from a surface and ionize it for mass-spectrometric analysis. In virtually all cases involving polar compounds of high molecular weight, the analyte is prepared in or on an organic matrix that is coated on the surface to be irradiated. The matrix material assists in the ionization process; the technique is known as matrix-assisted laser desorption ionization (MALDI). Numerous organic materials have been investigated. Molecular weights in excess of 700,000 have been measured with this technique, and the technique is particularly suited for the molecular-weight determination of large polar biological molecules; for example, enzymes and intact antibodies have been analyzed.

In electrospray ionization, a solution sprayed through a nozzle of very small diameter into a vacuum with an electric field having a gradient of several hundred to a thousand volts per centimeter produces gaseous ions from solutes effectively. Electrospray ionization is the only mass-spectrometric technique that produces a large fraction of multiply charged ions from an organic or biological analyte. Since mass spectrometers measure mass-to-charge ratios of ions, not simply their mass, electrospray ionization has the advantage of permitting ions of very high mass to be analyzed without special mass-analysis instrumentation; for example, an ion of mass 120,000 daltons carrying 60 positive charges appears at mass-to-charge 2000, within the range of many mass analyzers. This technique has been used to measure the masses of ions from molecules of masses up to about 200,000 daltons. Since the distribution of charged species reflects to some extent the degree of protonation in solution, a signal that reflects the folding of a protein, there is evidence that solution conformations of proteins can be studied by electrospray ionization mass spectrometry.

Measurement using a mass spectrometer takes advantage of the mass dependency in the equations of motion of an ion in an electric or magnetic field. Three common mass analyzers are magnetic-sector, quadrupole, and time-of-flight. An ion traversing the magnetic field of a sector instrument successfully reaches the detector when its mass, m, corresponds to $m/z = r^2B^2/2V$, where z is the charge of the ion, r is the radius of the flight tube, B is the magnetic field strength, and V is the acceleration voltage. A mass spectrum can be recorded by varying B or V. A quadrupole is an array of four parallel rods electronically connected such that a radio frequency (RF) is applied to opposing rods, and the waveforms applied to adjacent rods are out of phase. In addition, a direct-current (DC) component is added to the rods such that one opposing pair has +DC and the other −DC. Ions entering the quadrupole follow complex sinusoidal paths. An ion successfully traversing the rods to the detector is mass-selected by the amplitude of the applied radio frequency and the amount of resolution from adjacent masses by the DC/RF ratio. A spectrum is detected by scanning the RF amplitude and the DC voltage in a fixed ratio. The time-of-flight analyzer is a tube with an acceleration field at one end and a detector at the other. Ions are pulsed and accelerated down the tube, starting a clock. Arrival times at the detector are converted to mass by solving the equation $m/z = 2V(t/L)^2$, where V is the acceleration potential, t is the arrival time, and L is the flight tube length.

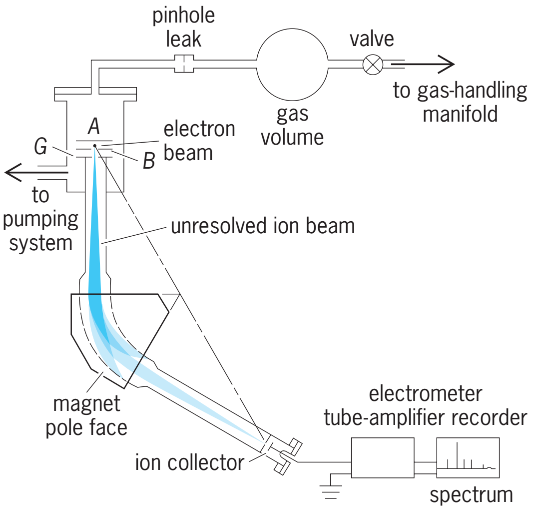
The mass analyzers are characterized by their mass resolving power (RP), scan or acquisition rate, and mass range. Sector instruments are usually assembled with an additional energy filter and can be operated up to 100,000 RP. Resolving power is defined as $M/\Delta M$, where M is the mass number of the observed mass and ΔM is the mass difference in two signals with a 10% valley between them. Increased resolution in sectors comes at the sacrifice of sensitivity. To increase resolution, the slits are narrowed on the ion beam. It is typical to lose 90% of the signal going from 1000 to 10,000 RP. Magnetic instruments are available with mass ranges up to 10,000 atomic mass units (amu) for singly charged ions at full acceleration potential. To obtain good quality, data sectors are scanned relatively slowly—a practical rate is 5 s per decade (1000–100 amu). Quadrupoles are usually operated at unit resolution. For example, 100 is resolved from 101, or 1000 from 1001. Quadrupoles can be scanned at 2000 amu/s and are available with mass range up to 4000 amu. Fast scanning and high-gas-pressure tolerance make quadrupoles popular for mass spectrometer–chromatographic hybrid systems. Modern time-of-flight analyzers are capable of 10,000 RP, 50% valley definition of ΔM. Acquisition rates can be 100 spectra per second. The time-of-flight mass range is theoretically unlimited, and singly charged ions over 100,000 amu have been observed. *See* ATOMIC NUMBER; MASS NUMBER. [T.D.Wi.]

The analysis of solid inorganic samples can be made either by vaporization in a Knudsen cell arrangement at very high temperatures or by volatilization of the sample surface so that particles are atomized and ionized with a high-energy spark (for example, 20,000 eV). The wide range of energies given to the particles requires a double-focusing mass spectrometer for analysis. Detection in such instruments is by photographic plate; exposures for different lengths of time are recorded sequentially, and the darkening of the lines on the plate is related empirically to quantitative composition by calibration charts. The method is useful for trace analysis (parts per billion) with accuracy ranging from 10% at higher concentration levels to 50% at trace levels. Methods for improving accuracy, including interruption and sampling of the ion beam, are under development.

Secondary ion mass spectrometry is most commonly used for surface analysis. A primary beam of ions accelerated through a few kilovolts is focused on a surface; ions are among the products sputtered from this surface, and they may be directly analyzed in a quadrupole filter. Sputtered material may also be analyzed by ionization of the neutrals in an inductively coupled plasma and subsequent mass analysis. This method produces ions with a lower energy spread than spark source mass spectrometry and, since detection then becomes less of a problem, has been supplanting spark source methods. *See* LASER SPECTROSCOPY; SECONDARY ION MASS SPECTROMETRY (SIMS); SPECTROSCOPY. [M.M.Bu.]

Mass spectroscope An instrument used for determining the masses of atoms or molecules found in a sample of gas, liquid, or solid. It is analogous to the optical spectroscope, in which a beam of light containing various colors (white light) is sent through a prism to separate it into the spectrum of colors present. In a mass spectroscope, a beam of ions (electrically charged atoms or molecules) is sent through a combination of electric and magnetic fields so arranged that a mass spectrum is produced (see illustration). If the ions fall on a photographic plate which after development shows the mass spectrum, the instrument is called a mass spectrograph; if the spectrum is allowed to sweep across a slit in front of an electrical detector which records the current, it is called a mass spectrometer.

Mass spectroscopes are used in both pure and applied science. Atomic masses can be measured very precisely. Because of the equivalence of mass and energy, knowledge of nuclear structure



Schematic drawing of mass spectrometer tube. Ion currents are in the range 10^{-10} to 10^{-15} ampere and require special electrometer tube amplifiers for their detection. In actual instruments the radius of curvature of ions in a magnetic field is 4–6 in. (10–15 cm).

and binding energy of nuclei is thus gained. The relative abundances of the isotopes in naturally occurring or artificially produced elements can be determined.

Empirical and theoretical studies have led to an understanding of the relation between molecular structure and the relative abundances of the fragments observed when a complex molecule, such as a heavy organic compound, is ionized. When a high-resolution instrument is employed, the masses of the molecular or fragment ions can be determined so accurately that identification of the ion can frequently be made from the mass alone.

Because chemical compounds may have mass spectra as unique as fingerprints, mass spectroscopes are widely used in industries such as oil refineries, where analyses of complex hydrocarbon mixtures are required. *See* Beta particles. [A.O.N.]

Mass wasting A generic term for downslope movement of soil and rock, primarily in response to gravitational body forces. Mass wasting is distinct from other erosive processes in which particles or fragments are carried down by the internal energy of wind, running water, or moving ice and snow.

The stability of slope-making materials is lost when their shear strength (or sometimes their tensile strength) is overcome by shear (or tensile) stresses, or when individual particles, fragments, and blocks are induced to topple or tumble. The shear and tensile strength of earth materials depends on their mineralogy and structure. Processes that generally decrease the strength of earth materials include one or more of the following: structural changes, weathering, groundwater, and meteorological changes. Stresses in slopes are increased by steepening, heightening, and external loading due to static and dynamic forces. Processes that increase stresses can be natural or result from human activities. Although other classifications exist, these movements can be conveniently classified according to their velocity into two types: creep and landsliding. *See* Soil mechanics.

Geologically, creep is the imperceptible downslope movement at rates as slow as a fraction of millimeter per year; its cumulative effects are ubiquitously expressed in slopes as the downhill bending of bedded and foliated rock, bent tree trunks, broken retaining walls, and tilted structures. There are two varieties of geologic creep. Seasonal creep is the slow, episodic movement of the uppermost several centimeters of soil, or fractured and weathered rock. It is especially important in regions of permanently frozen ground. Rheologic creep, sometimes called continuous creep, is a time-dependent deformation at relatively constant shear stresses of masses of rock, soil, ice, and snow. This type of creep affects rock slopes down to depths of a few hundred meters, as well as the surficial layer disturbed by seasonal creep. Continuous creep is most conspicuous in weak rocks and in regions where high horizontal stresses (several tens of bars or several megapascals) are known to exist in rock masses at depths of 330 to 660 ft (100 to 200 m).

Landsliding includes all perceptible mass movements. Three types are generally recognized on the basis of the type of movement: falls, slides, and flows. Falls involve free-falling material; in slides the moving mass displaces along one or more narrow shear zones; and in flows the distribution of velocities within the moving mass resembles that of a viscous flow. *See* Landslide.

Mass wasting is an important consideration in the interaction between humans and the environment. Deforestation accelerates soil creep. Engineering activities such as damming and open-pit mining are known to increase landsliding. On the other hand, enormous natural rock avalanches have buried entire villages and claimed tens of thousands of lives. [A.S.N.]

Massif A block of the Earth's crust commonly consisting of crystalline gneisses and schists, the textural appearance of which is generally markedly different from that of the surrounding rocks. Common usage indicates that a massif has limited areal extent and considerable topographic relief. Structurally, a massif may form the core of an anticline or may be a block bounded by faults or even unconformities. In any case, during the final stages of its development a massif acts as a relatively homogeneous tectonic unit which to some extent controls the structures that surround it. Numerous complex internal structures may be present; many of these are not related to its development as a massif but are the mark of previous deformations. [P.H.O.]

Mastigomycotina A subdivision of true fungi (Division Eumycota of the Kingdom Fungi), comprising three classes: Chytridiomycetes, Hyphochytriomycetes, and Oomycetes. It is an artificial grouping of zoosporic fungi with all members, except a few advanced ones, able to produce free-living zoospores in some part of their life cycle. The thallus may be unicellular, multicellular, or mycelial. The thallus has a chitinaceous or cellulosic wall. In a few endoparasitic species the thallus is naked (lacks a wall). Forms of sexual reproduction are many and varied. Distribution is cosmopolitan; many are aquatic, occurring in fresh water or brackish water, and a few are marine. They are also abundant in soils, and some have part of their life cycles on vascular plants. Many are saprobes, but some are parasitic on insects or fish, and some are destructive plant pathogens. *See* Chytridiomycetes; Eumycota; Fungi; Hyphochytriomycetes; Oomycetes. [D.J.S.B.]

Mastigophora A superclass of the Protozoa also known as the Flagellata. The common morphological flagellate type is spherical to cylindrical on an anteroposterior axis. Despite their common morphological plan, based on the flagellum as a means of locomotion, Flagellata are very diverse in shape, colony formation, internal structure, external shell or test, color, physiology, reproduction, and choice of environment.

The Mastigophora exhibit marked plantlike characteristics, so that texts and references in botany always treat at least some of them. Some workers include all colorless flagellates in the algae; however, flagellates display many distinctly animal features and sometimes are treated as Protozoa. Thus, flagellates are regarded as a link between the plant and animal kingdoms. *See* Phytamastigophorea; Zoomastigophorea.

Mastigophora possess one common feature, locomotion by means of one or more whiplike protoplasmic extrusions termed flagella. The flagellate body is typically monaxial and elongate to some degree. Cells are practically spherical in *Monas*, but ovoid, cordiform, pyriform, fusiform, acicular, tubular, or flattened cells are more common. Flattened species typically glide along a surface rather than swim. A particular shape is normally maintained by *Ochromonas*, whereas *Mastigamoeba* and some others form pseudopodia, and certain species (*Euglena agilis*) undergo frequent distortions termed euglenoid or metabolic changes of shape.

Structurally the flagellate cell is not simple. The cytoplasm is sometimes quite vacuolated (*Collodictyon or Trepomonas*) and occasionally colored, although color is generally confined to chromatophores when these are present. One or more contractile vacuoles may be located near the flagellar base.

Most flagellates are single-celled but colony formation is frequent. Cells may be naked (*Oicomonas*), enclosed in a thick cellulose cell wall or pellicle (*Euglena spirogyra*), or in a chitinous, calcareous, or silicious test, the lorica or shell (*Trachelomonas, Distephanus speculum*).

Flagellates adjust to wide ranges of pH, osmotic pressure, light, and temperature but optima are found upon investigation. Some flagellate species occur in both fresh and sea water, but cannot be transferred directly from fresh to sea water. Almost any aqueous ecological niche contains Flagellata.

Flagellata are near the base of the food pyramid, probably next to bacteria. Their varied synthetic abilities, fast reproductive rate, and huge numbers in both fresh and salt water compensate for their usual small size. The oceanic blooms which kill fish and other animals are principally flagellates, but green flagellates reaerate polluted water. They often cause tastes and odors in potable water, but they readily attack organic matter in natural water as do bacteria, They include many parasites dangerous to humans and animals and are themselves frequently parasitized. *See* PROTOZOA. [J.B.L.]

Mastitis Inflammation of the mammary gland. This condition is most frequently caused by infection of the gland with bacteria that are pathogenic for this organ. It has been described in humans, cows, sheep, goats, pigs, horses, and rabbits. Mastitis causes lactating women to experience pain when nursing the child, it damages mammary tissue, and the formation of scar tissue in the breast may cause disfigurement.

The mammary gland is composed of a teat and a glandular portion. The gland has defensive mechanisms to prevent and overcome infection with bacteria. Nonspecific defense mechanisms include teat duct keratin, lactoferrin, lactoperoxidase, and complement. Specific defense mechanisms are mediated by antibodies and include opsonization, direct lysis of pathogens, and toxin neutralization. Milk contains epithelial cells, macrophages, neutrophils, and lymphocytes. To induce mastitis, a pathogen must first pass through the teat duct to enter the gland, survive the bacteriostatic and bactericidal mechanisms, and multiply. Bacteria possess virulence factors such as capsules and toxins which enable them to withstand these protective mechanisms. *See* LACTATION.

When bacteria multiply within the gland, there is a release of inflammatory mediators and an influx of neutrophils. The severity of mammary infection is classified according to the clinical signs. In humans, infection occurs during lactation, with clinical episodes most frequent during the first 2 months of lactation. In acute puerperal mastitis the tissue becomes hot, swollen, red, and painful, and a fever may be present. In the absence of treatment, this may progress to a pus-forming mastitis, with the development of breast abscesses.

In acute puerperal mastitis of humans, suitable antibiotics are administered by the intravenous or intramuscular route, while in the abscess form surgical drainage is provided in addition to antibacterial therapy. Penicillins, cephalosporins, and erythromycin are administered locally into the infected gland after milking for 1–2 days. Additional antibiotics are given systemically, that is, intravenously or intramuscularly, in severe cases of mastitis, and also to improve bacteriologic cure rates. *See* ANTIBIOTIC. [N.L.N.]

Matched-field processing A signal-processing technique based on comparison of measured data with predictions for the data that are calculated from a propagation model. Signal-processing techniques have always been of interest for squeezing information out of various kinds of data. In the past, the processing of sonar signals has often been based on beamforming, in which data are examined relative to a variety of plane waves coming from different directions, thereby calculating "beams" of energy. Matched-field processing encompasses conventional plane-wave beamforming but goes beyond it by considering far more accurate and appropriate models for complicated signal behavior.

Some signal-processing methods such as matched filtering can be applied to received data to transform what appears to be nearly random, unpatterned noise into meaningful signals. Other signal-processing methods, such as matched-field processing, can be applied to strong signals to reveal details about the original direction of a signal (to locate the source) or about source characterization (for example, to determine whether the source is a living organism or a particular type of military threat). Matched-field processing has been used to extract environmental information from acoustic data in an effort (1) to address concerns such as global warming (to determine whether the oceans are showing deep, that is, below-surface, changes in temperature patterns) or (2) to search for buried minerals or oil in the ocean bottom. Electromagnetic signals passing through the ionosphere or elastic waves transmitted through the earth also contain a wealth of information about the media through which those signals pass, and those signals can be used in a similar fashion to obtain information about ionospheric or terrestrial parameters. Thus, all types of signals (acoustic, electromagnetic, seismic) can be analyzed via matched-field processing to learn about environments and sources.

Matched-field processing has been studied extensively in underwater acoustics. The process was first suggested by M. J. Hinich in 1973 and H. P. Bucker in 1976. Matched-field processing is usually a passive rather than an active approach; that is, it uses the sound generated by the target itself rather than ensonifying (the acoustic equivalent to illuminating with light) that target from some other source. [A.Tol.]

Material resource planning A formal computerized approach to inventory planning, manufacturing scheduling, supplier scheduling, and overall corporate planning. The material requirements planning (MRP) system provides the user with information about timing (when to order) and quantity (how much to order), generates new orders, and reschedules existing orders as necessary to meet the changing requirements of customers and manufacturing. The system is driven by change and constantly recalculates material requirements based on actual forecast orders. It makes adjustments for possible problems prior to their occurrence, as opposed to traditional control systems which looked at more historical demand and reacted to existing problems. *See* MANUFACTURING ENGINEERING.

The logic of the material requirements planning system is based on the principle of dependent demand, a term describing the direct relationship between demand for one item and demand for a higher-level assembly part or component. For example, the demand for the number of wheel assemblies on a bicycle is directly related to the number of bicycles planned for production; further, the demand for tires is directly dependent on the demand for wheel assemblies. In most manufacturing businesses, the bulk of the raw material and in-process inventories are subject to dependent demand. Dependent demand quantities are calculated, while independent demand items are forecast. Independent demand is unrelated to a higher-level item which the company manufactures or stocks. Generally, independent demand items are carried in finished goods inventory and subject to uncertain end customer demand. Spare parts or replacement requirements for a drill press are an example of an independent demand item.

By use of the computer, material requirements planning is able to manipulate massive amounts of data to keep schedules up to date and priorities in order. The technological advances in computing and processing power, the benefits of on-line capabilities, and reduction in computing cost make computerized manufacturing planning and control systems such as material requirements planning powerful tools in operating modern manufacturing systems productively. *See* INDUSTRIAL ENGINEERING; INVENTORY CONTROL; SYSTEMS ENGINEERING. [L.C.G.]

Materials handling The loading, moving, and unloading of materials. The hundreds of different ways of handling materials are generally classified according to the type of equipment used. For example, the International Materials Management Society has classified equipment as (1) conveyor, (2) cranes, elevators, and hoists, (3) positioning, weighing, and control equipment, (4) industrial vehicles, (5) motor vehicles, (6) railroad cars, (7) marine carriers, (8) aircraft, and (9) containers and supports. *See* MATERIALS-HANDLING EQUIPMENT. [R.Mu.]

Materials-handling equipment Devices used for handling materials in an industrial distribution activity. The equipment moves products as discrete articles, in suitable containers, or as solid bulk materials which are relatively free-flowing.

Many different types of machines result from combinations and permutations of the following factors: (1) The route over which the product is moved may be fixed or variable; (2) the path of travel may be horizontal, inclined, declined, or vertical; (3) motion may be imparted to the product manually, by the force of gravity, by air pressure, by vacuum, by vibration, or by power-actuated components of the machine; (4) the motion may be continuous or intermittent (reciprocating); and (5) the product may be supported or carried suspended during the handling operation. Based upon their most common characteristics, materials-handling machines can be grouped into six broad categories, listed in the following cross references. *See* BULK-HANDLING MACHINES; ELEVATING MACHINES; HOISTING MACHINES; INDUSTRIAL TRUCKS; MONORAIL. [A.M.P.]

Materials science and engineering A multidisciplinary field concerned with the generation and application of knowledge relating to the composition, structure, and processing of materials to their properties and uses. The field encompasses the complete knowledge spectrum for materials ranging from the basic end (materials science) to the applied end (materials engineering). It forms a bridge of knowledge from the basic sciences (and mathematics) to various engineering disciplines.

The study of metallic materials constitutes a major division of the materials science and engineering field. Most metals have a crystalline structure of closely packed atoms arranged in an orderly manner. In general they are good electrical and thermal conductors. Many are relatively strong at room temperature and retain good strength at elevated temperatures. Metals and alloys are often cast into the nearly final shape in which they will be used (castings). Ferrous metals and alloys contain iron as their major metallic element; nonferrous metals and alloys contain elements other than iron as their major metallic element. *See* ALLOY; ALUMINUM ALLOYS; CAST IRON; COPPER ALLOYS; IRON ALLOYS; METAL; METAL CASTING; NICKEL ALLOYS; STAINLESS STEEL; STEEL; ZINC ALLOYS.

The study of ceramic materials forms a second major division of the field of materials science and engineering. Ceramics are inorganic materials consisting of metallic and nonmetallic elements chemically bonded together. Most ceramic materials have high hardness, high-temperature strength, and good chemical resistance; however, they tend to be brittle. Ceramics in general have low electrical and thermal conductivities, which makes them useful for electrical and thermal insulative applications. Most ceramic materials can be classified into three groups: traditional ceramics, technical ceramics, and glasses. *See* CERAMICS; GLASS; PORCELAIN.

The study of polymeric materials forms a third major division of materials science and engineering. Most of these materials consist of carbon-containing long molecular chains or networks. Structurally, most of them are noncrystalline, but some are partly crystalline. The strength and ductility of polymeric materials vary greatly. Most polymers have low densities and relatively low softening or decomposition temperatures. Many are good thermal and electrical insulators. Polymeric materials have replaced metals and glasses for many applications. *See* POLYMER.

A fourth major division of materials science and engineering comprises the study of composite materials. A composite material is a mixture of two or more materials that differ in form and chemical composition and are essentially insoluble in each other, and most are produced synthetically by combining various types of fibers with different matrices to increase strength, toughness, and other properties. Three important types of composite materials have polymeric, metallic, or ceramic matrices. *See* COMPOSITE MATERIAL.

In addition to metallic, ceramic, polymeric, and composite materials, materials science and engineering is also concerned with the research and development of other special classes of materials that are based on applications. Some major types of these materials are electronic materials, optical materials, magnetic materials, superconducting materials, dielectric materials, nuclear materials, biomedical materials, and building materials. *See* INTEGRATED CIRCUITS; MAGNETIC MATERIALS; OPTICAL FIBERS; SUPERCONDUCTING DEVICES; SUPERCONDUCTIVITY. [W.F.S.]

Maternal behavior The pattern of care given an offspring by its mother. Many species reproduce generation after generation without receiving or providing any parental care. Insects and fish commonly produce vast numbers of offspring that they neither feed nor defend, resulting in the loss of many offspring to predators and to other hazards. Their great numbers, however, ensure that some will survive and reproduce. Also, if the young of a species are self-sufficient at birth or if they mature very rapidly after birth, they can often survive and reproduce with little parental care.

Parental behavior is most highly developed in species that produce only a few offspring at once, mature slowly, and have complex behavior patterns that can be learned only through extended practice. Parental behavior can involve as little as hiding the young and never seeing them again or it can involve years of feeding, defending, and teaching. In most species that care for their young after birth, the female does most or all of the work. The biological explanation for this arises from the fact that a male can father vast numbers of offspring, whereas a female can bear only a few. Each offspring that fails to survive or reproduce can represent a significant proportion of the female's lifetime reproductive output. Thus, the females that pass their genes on to subsequent generations in greatest numbers are not those that bear the most young but those that invest more in caring for the few young they produce. Active care of the young by the male is most common when males of a species limit themselves to one or a few female partners. *See* REPRODUCTIVE BEHAVIOR.

Factors that influence the onset of maternal behavior include physiological and psychological factors related to pregnancy, hormonal influences associated with childbirth, the behavior of the newborn, and cultural factors such as learning and social traditions. Although hormones play necessary roles in recovery from pregnancy and in milk production, there is no evidence that they play a critical role in any other aspect of human maternal behavior. Cultural factors and the behavior of the newborn are the primary cues that prompt human mothers to care for their young. [E.Wa.; G.Pos.]

Mathematical biology The application of mathematics to biological systems. Mathematical biology spans all levels of biological organization and biological function, from the configuration of biological macromolecules to the entire ecosphere over the course of evolutionary time.

The influence of physics on mathematical biology has been twofold. On the one hand, organisms simply are material systems, and presumably can be analyzed in the same terms as any other material system. Reductionism, the theory that biological processes find their resolution in the particularities of physics, finds its practical embodiment in biophysics. Thus, one of the roots of mathematical biology is what was originally called mathematical biophysics. On the other hand, other early investigations in mathematical biology, such as population dynamics (mathematical ecology), exploited the form of such analyses, such as using differential rate equations, but they expressed their analyses in strictly biological terms. Such approaches were guided by analogy with mathematical physics rather than by reduction to physics and so rest on the form rather than the substance of physics. *See* BIOPHYSICS; PHYSICS.

Both of these approaches are important, especially since organisms possess characteristics that have no obvious counterpart in inorganic systems. As a result, mathematical biology has acquired an independent and unique character. In several important cases, these characteristics have required a reconsideration of physics itself, as in the impact of open systems on classical thermodynamics.

Surrogacy and models. The idea that something can be learned about a system by studying a different system, or surrogate, is central to all science. The relation between a system and its surrogates is embodied in the concept of a model. The basic idea of mathematical biology is that an appropriate formal or mathematical system may similarly be used as a surrogate for a biological system. The use of mathematical models offers possibilities that transcend what can be done on the basis of observation and experiment alone. *See* MODEL THEORY.

For example, morphological differences between related species can be made to disappear by means of relatively simple coordinate transformations of the space in which the forms are embedded. Surrogacy explicitly becomes a matter of intertransformability, or similarity, and what is true for morphology also holds true for other functional relationships that are characteristic of organisms, whether they be chemical, physical, or evolutionary. These assertions of surrogacy and modeling can be restated: closely related implies similar. This is a nontrivial assertion: “closely related” is a metric relation pertaining to genotypes, whereas “similar” is an equivalence relation based on phenotypes. It is the similarity relation between phenotypes that provides the basis for surrogacy. Thus the question immediately arises: given a genotype, how far can it be varied or changed or mutated, and still preserve similarity?

Such questions fall mathematically into the province of stability theory, particularly structural stability. Under very general conditions, there exist many genomes that are unstable (bifurcation points) in the sense that however high a degree of metric approximation is chosen, the associated phenotypes may be dissimilar, that is, not intertransformable. That observation by R. Thom provides the basis for his theory of catastrophes and demonstrates the complexity of the surrogacy relationship. The fundamental importance of such ideas for phenomena of development, for evolution (particularly for macroevolution), and for the extrapolation of data from one species to another, or the relation between health and disease, is evident. *See* CATASTROPHE THEORY; MACROEVOLUTION.

Metaphor. A closely related group of ideas that are characteristic of mathematical biology may be described as metaphoric. One example of a metaphoric approach is the study of brain activities through the application of the properties of neural networks, that is, networks of interconnected boolean (binary-state) switches. Appropriately configured switching networks are known to exhibit behaviors that are analogous to those that characterize the brain, such as learning, memory, and discrimination. That is, networks of neuronlike units can automatically manifest brainlike behaviors and can be regarded as metaphorical brains. Such boolean neural nets also underlie digital computation, a relationship which is explored in the hybrid area of artificial intelligence. The same mathematical formulation of switching networks arises in genetic and developmental phenomena, such as the concept of operon, and in other physiological systems, such as the immune system. *See* ARTIFICIAL INTELLIGENCE; NEURAL NETWORK; OPERON.

Another important example of metaphor in biology is morphogenesis, or pattern generation, through the coupling of chemical reactions with physical diffusion. Chemical reactions tend to make systems heterogeneous, diffusion tends to smooth them out, and combining the two can lead to highly complex behaviors. Since reactions and diffusions typically occur together in biological systems, exploring the general properties of such systems can illuminate pattern generation in general.

Such ideas turn out to be closely related to those of bifurcation and catastrophe and have a profound impact on physics itself, since they are inherently associated with systems that are thermodynamically open and hence completely outside the realm of classical thermodynamics. The behavior of such open systems can be infinitely more complicated than those that are commonly explored in physics. Open systems may possess large numbers of stable and unstable steady states of various types, as well as more complicated oscillatory steady-state behaviors (limit cycles) and still more general behaviors collectively called chaotic. Changes in initial conditions or in environmental circumstances can result in dramatic switching (bifurcations) between these modes of behavior. *See* CHAOS.

Applications. Perhaps the biotechnology that has affected everyone most directly is medicine. Medicine can be regarded as a branch of control theory, geared to the maintenance or restoration of a state of health. It is unique in that the systems needed for control are themselves control systems that are far more intricate and complex than any that can be fabricated. In addition to the light it sheds on the processes needed for control, mathematical biology is indispensable for designing the controls themselves and for assessing their costs, benefits, safety, and efficacy.

In general, the object of any theory of control is to produce an algorithm, or protocol, that will achieve optimal results. Mathematical biology allows one to relate systems of different characters through the exploitation of their mathematical commonalities. Biology has many optimal designs and optimal controls, which are the products of biological evolution through natural selection. The design of optimal therapies in medicine is analogous to the generation of optimal organisms. Thus the mathematical theory appropriate for analyzing one discipline of biology, such as evolution, itself becomes transmuted into a theory of control in an entirely different realm. The same holds true for other biotechnologies, such as the efficient exploitation of biological populations. *See* MATHEMATICAL ECOLOGY. [R.Ro.]

Mathematical ecology The application of mathematical theory and technique to ecology. The earliest studies in ecology were by naturalists interested in organisms and their relationships to the environment. Such investigations continue to this day as a central part of the subject, and have focused attention on understanding the ecological and evolutionary relationships among species. For the most part, such approaches are retrospective, designed to help in understanding how current ecological relationships developed, and to place that development within appropriate evolutionary context. The second major branch is applied ecology, and derives from the need to manage the environment and its resources. Here the necessity for rigorous mathematical treatments is obvious, but the goals are quite different from those in evolutionary ecology. Management and control are the objectives, and the relevant time horizon lies in the future. The focus is no longer simply to derive understanding and explanation; rather, one seeks methods for prediction and algorithms for control.

There has been a dramatic increase in mathematical activity concerning the modeling and control of epidemics, and an increasing recognition of the need to view such problems in their proper ecological context as host-parasite interactions. Researchers are using mathematical models to help to understand the factors underlying disease outbreaks, and to develop methods for control such as vaccination strategies. *See* EPIDEMIOLOGY.

Finally, the need for environmental protection in the face of threats from such competing stresses as toxic substances, acid precipitation, and power generation has led to the development of more sophisticated models that address the responses to stress of community and ecosystem characteristics, for example, succession, productivity, and nutrient cycling. *See* ECOLOGY; ECOLOGY, APPLIED; ENVIRONMENTAL ENGINEERING. [S.A.L.]

Mathematical geography The branch of geography that examines human and physical activities on the Earth's surface using models and statistical analysis. The primary areas in which mathematical methods are used include the analysis of spatial patterns, the processes that are responsible for creating and modifying these patterns, and the interactions among spatially separated entities.

What sets geographic methods apart from other quantitative disciplines is geography's focus on place and relative location. Latitude and longitude provide an absolute system of recording spatial data, but geographic databases also typically contain large amounts of relative and relational data about places. Thus, geographers have devoted much effort to accounting for spatial interrelations while maintaining consistency with the assumptions of mathematical models and statistical theory. *See* GEOGRAPHY; MODEL THEORY; STATISTICS.

Spatial pattern methodologies attempt to describe the arrangement of phenomena over space. In most cases these phenomena are either point or area features, though computers now allow for advanced three-dimensional modeling as well. Point and area analyses use randomness (or lack of pattern) as a dividing point between two opposite pattern types—dispersed or clustered.

An important innovation in geographic modeling has been the development of spatial autocorrelation techniques. Unlike conventional statistics, in which many tests assume that observations are independent and unrelated, very little spatial data can truly be considered independent. Soil moisture or acidity in one location, for example, is a function of many factors, including the moisture or acidity of nearby points. Because most physical and human phenomena exhibit some form of spatial interrelationships, several statistical methods, primarily based on the Moran Index, have been developed to measure this spatial autocorrelation. Once identified, the presence and extent of spatial autocorrelation can be built into the specification of geographical models to more accurately reflect the behavior of spatial phenomena. [J.C.Co.]

Mathematical physics An area of science concerned with the application of mathematical concepts to the physical sciences and the development of mathematical ideas in response to the needs of physics. Historically, the concept of mathematical physics was synonymous with that of theoretical physics. In present-day terminology, however, a distinction is made between the two. Whereas most of theoretical physics uses a large amount of mathematics as a tool and as a language, mathematical physics places greater emphasis on mathematical rigor, and devotes attention to the development of areas of mathematics that are, or show promise to be, useful to physics. The results obtained by pure mathematicians, with no thought to applications, are almost always found to be both useful and effective in formulating physical theories.

Mathematical physics forms the bridge between physics as the description of nature and its structure on the one hand, and mathematics as a construction of pure logical thought on the other. This bridge between the two disciplines benefits and strengthens both fields enormously. *See* MATHEMATICS; PHYSICS; THEORETICAL PHYSICS.

The methods employed in mathematical physics range over most of mathematics, the areas of analysis and algebra being the most commonly used. Partial differential equations and differential geometry, with heavy use of vector and tensor methods, are of particular importance in the formulation of field theories, and functional analysis as well as operator theory in quantum mechanics. Group theory has become an especially valuable tool in the construction of quantum field theories and in elementary-particle physics. There has also been an increase in the use of general geometrical approaches and of topology. For solution methods and the calculation of quantities that are amenable to experimental tests, of particular prominence are Fourier analysis, complex analysis, variational methods, the theory of integral equations, and perturbation theory. *See* ABSTRACT ALGEBRA; COMPLEX NUMBERS AND COMPLEX VARIABLES; DIFFERENTIAL GEOMETRY; FOURIER SERIES AND TRANSFORMS; GROUP THEORY; INTEGRAL EQUATION; OPERATOR THEORY; TOPOLOGY; VARIATIONAL METHODS (PHYSICS); VECTOR METHODS (PHYSICS). [R.G.Ne.]

Mathematical software The collection of computer programs that can solve equations or perform mathematical manipulations. The developing of mathematical equations that describe a process is called mathematical modeling. Once these equations are developed, they must be solved, and the solutions to the equations are then analyzed to determine what information they give about the process. Many discoveries have been made by studying how to solve the equations that model a process and by studying the solutions that are obtained.

Before computers, these mathematical equations were usually solved by mathematical manipulation. Frequently, new mathematical techniques had to be discovered in order to solve the equations. In other cases, only the properties of the solutions could be determined. In those cases where solutions could not be obtained, the solutions had to be approximated by using numerical calculations involving only addition, subtraction, multiplication, and division. These methods are called numerical algorithms. These algorithms are often straightforward, but they are usually tedious and require a large number of calculations, usually too many for a human to perform. There are also many cases where there are too many equations to write down. *See* ALGORITHM; NUMERICAL ANALYSIS.

The advent of computers and high-level computer languages has allowed many of the tedious calculations to be performed by a machine. In the cases where there are too many equations, computer programs have been written to manipulate the equations. A numerical algorithm carried out by a computer program can then be applied to these equations to approximate their solutions. Mathematical software is usually divided into two categories: the numerical computation environment and the symbolic computation environment. However, many software packages exist that can perform both numerical and symbolic computation.

Mathematical software that does numerical computations must be accurate, fast, and robust. Accuracy depends on both the algorithm and the machine on which the software is run. Most mathematical software uses the most advanced numerical algorithms. Robustness means that the software checks to make sure that the user is inputting reasonable data, and provides information during the performance of the algorithm on the convergence of the calculated numbers to an answer. Mathematical software packages can approximate solutions to a large range of problems in mathematics, including matrix equations, nonlinear equations, ordinary and partial differential equations, integration, and optimization. Mathematical software libraries contain large collections of subroutines that can solve problems in a wide range of mathematics. These subroutines can easily be incorporated into larger programs.

Early computers were used mainly to perform numerical calculations, while the mathematical symbolic manipulations were still done by humans. Now software is available to perform these mathematical manipulations. Most of the mathematical software packages that perform symbolic manipulations can also perform numerical calculations. Software can be written in the package to perform the numerical calculations, or the calculations can be performed after the symbolic manipulations by putting numbers into the symbolic formulas. Mathematical software that is written to solve a specific problem using a numerical algorithm is usually computationally more efficient than these software environments. However, these software environments can perform almost all the commonly used numerical and symbolic mathematical manipulations. *See* SYMBOLIC COMPUTING.

Parallel computers have more than one processor that can work on the same problem at the same time. Parallel computing allows a large problem to be distributed over the processors. This allows the problem to be solved in a smaller period of time. Many numerical algorithms have been converted to run on parallel computers. *See* COMPUTER PROGRAMMING; CONCURRENT PROCESSING; DIGITAL COMPUTER; DISTRIBUTED SYSTEMS (COMPUTERS); MULTIPROCESSING; SOFTWARE. [J.So.]

Mathematics Mathematics is frequently encountered in association and interaction with astronomy, physics, and other branches of natural science, and it also has deep-rooted affinities to the humanities. It is a realm of knowledge entirely unto itself, and one of considerable scope.

Relation to science. Mathematics is not a branch of natural science itself. It does not deal with phenomena and objects of the external world and their relations to each other but, strictly speaking, only with objects and relations of its own imagery. One can practice meaningful mathematics without being concerned with science at all, and philosophical attempts to reduce all origin of mathematics to utilitarian motives are wholly unconvincing. However, mathematics is the language of science in a deep sense. Mathematics is an indispensable medium by which and within which science expresses, formulates, continues, and communicates itself. And just as the language of true literacy not only specifies and expresses thoughts and processes of thinking but also creates them in turn, so does mathematics not only specify, clarify, and make rigorously workable concepts and laws of science, but also at certain crucial instances becomes an indispensable constituent of their creation and emergence as well.

Creative formulas. A formula is a string of mathematical symbols subject only to certain general rules of composition. To a working mathematician a string of symbols is a formula if it is something worth remembering. Much mathematics is concentrated in and propelled by certain formulas of unusual import.

Foundations—mathematical logic. A prime demand on mathematics is that it be deductively rigorous, and a traditional model for intended rigor is Euclid's presentation of mathematical assertions in theorems. A theorem is a proposition which has been proved, excepting certain first theorems called axioms, which are admitted without proof; and to prove a theorem means to obtain it from other theorems by certain procedures of deduction or inference. It had long been commonplace that each branch of mathematics was based on its own axioms, but during the 19th century, mathematicians arrived at the insight that even the same branch might have alternate axioms. Specifically, there were envisaged alternate versions of two- and three-dimensional geometry, the axiom varied being the axiom on parallels. It was also recognized that a set of axioms becomes mathematically possible if it is logically consistent, that is, if one cannot deduce from the axioms to theorems one of which, as a proposition, is the negation of the other. *See* EUCLIDEAN GEOMETRY.

At the same time certain developments led to the realization that not only the axioms but the rules of inference themselves might be, and even ought to be, subjected to variations. Now if axioms and rules of inferences are both viewed as subject to change, it is customary to speak of a mathematical system or also a formal system, and, of course, an irreducible first requirement is that the system be consistent after the manner just stated. Consistency alone is a somewhat negative property. There is a further property, called completeness, which is more positive, and which, if present, is very welcome. A system is complete if for any proposition which can be formulated it either can be proved that it holds or that its negation holds.

Some of the developments that led to doubt as to whether the traditional rules of inference are inviolate were the following.

1. G. Boole had found in 1854 that the classical Aristotelian connectives "and," "or," "negation of" for propositions follow rules similar to those which the operations addition, multiplication, "the negative of" obey in ordinary algebra (Boole's algebra of propositions); his conclusions took from rules of inference the status of untouchability.

2. G. Cantor, the founder of the theory of sets and operations between them, defined a set (intuitively or naively) as the collection of all objects having a certain property which is verbally expressible. Especially, "the set of all sets" is again a set and it has the peculiarity of being a set which contains itself as one of its elements. But this leads to the following contradictory situation (Russell's paradox): Divide the totality of all possible sets into two categories. A set shall belong to category I if it does not contain itself as an element, and to category II if it does contain itself as an element. Now form the set M whose elements are the sets of category I. It can now be reasoned by deductive steps admissible in Cantor's own theory that the set M cannot belong to either of the two categories, although the original division into categories did assign each set to one of them.

3. In 1904 E. Zermelo formulated the following axiom of choice: Given any family of nonvacuous sets $\{S\}$, no matter how (infinitely) large the family may be, it is possible to choose simultaneously an element $x = x_s$ from each given set S and thus to consider the set M consisting of precisely these elements. By the use of this axiom some striking theorems in classical mathematics could be proved which, without the use of the axiom, seemed to be logically out of reach entirely. Mathematicians began to wonder whether a theorem based on the axiom of choice is indeed valid or, at any rate, whether it has the same level of validity as one without it, and as a consequence, theorems employing the axiom of choice were frequently labeled as such. *See* SET THEORY.

Some of the doubts were resolved eventually; the most striking results are the following ones of K. Gödel. (1) Any consistent mathematical system which is sufficient for classical arithmetic must be incomplete. (2) Any such system remains consistent if one adds to it the axiom of choice, so that working mathematics cannot disprove the axiom of choice. In 1963 P. Cohen showed that the axiom cannot be proved, either. *See* LOGIC.

Constructiveness. Some mathematicians object to mere existence proofs, and they demand that any proof also be constructive. The interpretations of this demand differ widely. Some proofs closely approach what a practical mathematician welcomes; if, for instance, a theorem asserts the existence of a number or a function, then the proof must also embody a procedure for actual computation of the solution, approximately, at least. Other versions are little more than the negative requirement that certain combinations of inference be avoided. There are also views which combine both; the best known among the last is the intuitionist view. It firmly demands a certain kind of constructiveness, which, however, does not necessarily guarantee the calculation by present-day computing machines. However, the actual stricture by which intuitionism became widely known is that proof by contradiction is not admissible. Proof by contradiction is also called proof by double negation, and it is equivalent to the Aristotelian law of the excluded middle. It assumes tentatively that the proposition to be proved is false and from this assumption deduces a contradiction to a previously established theorem.

Space in mathematics. If geometry is the mathematics of space, then, in a superficial sense, all mathematics began with geometry, because apparently it began with measurements of figures: length, area, volume, and size of angles. It did not concern itself with questions of shape but with clarifying and deciding when figures are equal or substantially equal with regard to form. The first true theory of geometry was that of the Greeks, whose primary concern was study of the basic concept of equality of figures—their congruence and similarity—and the Greeks were so determined to dissociate their theory from the preceding phase of merely making measurements that Euclid's extensive work, for instance, avoids to a fault any kind of actual measurements. But, for all its lofty purposes, Greek geometry was too rigid and circumscribed to be able really to cope with the mathematical problem of space. Geometry did not progress further until, with the advent of coordinate systems, introduced by Descartes and his predecessors, a better mathematics of space could be initiated.

If a cartesian coordinate system is etched into two- or three-dimensional euclidean space, then the space becomes a point set, each point being a pair (x^1, x^2) or a triple (x^1, x^2, x^3) of real numbers, and any figure a suitable subset of it. This is a deliberate process of arithmetization of space which unifies space and number at the base. It does not hamper geometry in its task of pursuing problems of shape but instead aids it. In the cartesian plane, two figures are similar if the points of one can be obtained from the points of the other by means of a transformation, Eqs. (1), where Eq. (2) applies and where, for some $\rho < 0$, Eq. (3) can

$$\begin{aligned} y^1 &= a^1 + \alpha_1{}^1 x^1 + \alpha_2{}^1 x^2 \\ y^2 &= a^2 + \alpha_1{}^2 x^1 + \alpha_2{}^2 x^2 \end{aligned} \tag{1}$$

$$\alpha_1{}^1 \cdot \alpha_1{}^2 + \alpha_2{}^1 \cdot \alpha_2{}^2 = 0 \tag{2}$$

$$\left(\alpha_1{}^1\right)^2 + \left(\alpha_2{}^1\right)^2 = \left(\alpha_1{}^2\right)^2 + \left(\alpha_2{}^2\right)^2 = \rho^2 \tag{3}$$

be written. The similarity is a congruence if, and only if, $\rho = 1$ (orthogonal transformation). Now this analytic representation of congruence and similarity suggests a geometric examination of the most general linear transformations, Eqs. (1), which are nonsingular, that is, for which the determinant $|\alpha_q{}^p| \neq 0$. They were virtually unknown to the Greeks, although they highlight the axiom of parallels of Euclid's geometry. A one-to-one transformation of the cartesian plane is such a linear transformation if, and only if, it carries a straight line onto a straight line and parallel straight lines into parallel straight lines.

The family of all linear transformations constitutes a transitive group, and the subfamily of orthogonal transformations is already a transitive group. F. Klein made the pronouncement, which is generally accepted, that there arises a geometry on a space if on the space there is given a transitive group of transformations; two figures are considered equal whenever one figure can be carried into the other figure by one of the transformations.

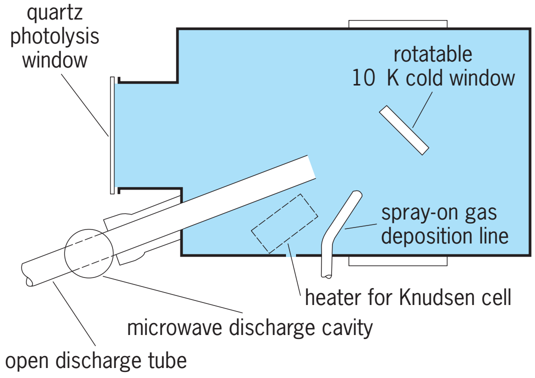
The arithmetization of space led to a purely mathematical creation of n-dimensional space, euclidean and other, for any integer dimension n, by defining its points generally as n-tuples of real numbers $(x^1, \ldots, x^n)$ with suitable definitions for various geometrical relations between such points. The best-known application of this was the four-dimensional space of the theory of relativity, but actually multidimensional geometry had been playing a part in physics before that. If a mechanical system involves M mass points, it was customary in effect to introduce the space of dimension $n = 3M$, whose points are the states of the system, that is, the n-tuples of coordinates $\{x_m{}^1, x_m{}^2, x_m{}^3\}$, $m = 1, \ldots, M$, at any one time point. Also, if there are restraints operative in the system, then the Lagrange-Hamilton theory suitably reduced the dimension of the space by the use of the free parameters of the system instead of the original n coordinates themselves. The use of free parameters spread from mechanical systems to other systems in physics and chemistry, and all so-called equations of state are geared to this. Finally, in quantum theory a state of a system has infinitely many coordinates and the infinitely dimensional space representing it is a Hilbert space. Also, partly under the influence of Hilbert space, mathematicians have become fascinated with infinitely dimensional spaces in general. They are being studied intensively, and large parts of mathematics are being pressed into these new frames of reference.

The arithmetization of space is also reflected in the ever-widening use of graphs and charts. *See* ALGEBRA; CALCULUS OF VECTORS; GEOMETRY; TOPOLOGY. [S.Bo.]

Matrix isolation

Matrix isolation A technique for providing a means of maintaining molecules at low temperature for spectroscopic study. This method is particularly well suited for preserving reactive species in a solid, inert environment. Elusive molecular fragments, such as free radicals that may be postulated as important controlling intermediates for chemical transformations used in industrial reactions, high-temperature molecules that are in equilibrium with solids at very high temperatures, and molecular ions that are produced in plasma discharges or by high-energy radiation all can be examined by using absorption (infrared, visible, and ultraviolet), electron-spin resonance, and laser-excitation spectroscopes.

The experimental apparatus for matrix isolation experiments is designed with the method of generating the molecular transient and performing the spectroscopy in mind. The illustration shows the cross section of a vacuum vessel used for absorption spectroscopic measurements. The matrix sample is introduced through the spray-on line; argon is the most widely used matrix gas, although neon, krypton, xenon, and nitrogen are also used. The reactive species can be generated in a number of ways: mercury-arc photolysis of a trapped precursor molecule through the quartz window, evaporation from a Knudsen cell in the heater, chemical reaction of atoms evaporated from the Knudsen cell with molecules deposited through the spray-on line, and vacuum-ultraviolet photolysis of molecules deposited from the spray-on line by radiation from discharge-excited atoms flowing through the tube. For laser excitation studies, the sample is deposited on a tilted copper wedge which is grazed by the laser beam, and light emitted or scattered at approximately 90° is examined by a spectrograph. In electronspin resonance studies, the sample is condensed on a sapphire rod that can be lowered into the necessary waveguide and magnet.



Vacuum-vessel base cross section for matrix photoionisation experiments.

The matrix isolation technique enables spectroscopic data to be obtained for reactive molecular fragments, many of which cannot be studied in the gas phase. [L.A.]

Matrix mechanics A formulation of quantum theory in which the operators are represented by time-dependent matrices. *See* MATRIX THEORY.

Matrix mechanics is not useful for obtaining quantitative solutions to actual problems; on the other hand, because it is concisely expressed in a form independent of special coordinate systems, matrix mechanics is useful for proving general theorems. [E.G.]

Matrix theory The study of matrices and their properties, and of linear transformations on vector spaces, which can be represented by matrices.

A matrix is a rectangular array of numbers, with the numbers that appear in the matrix being called entries. For example, A, given by Eq. (1), is a 2 × 3 matrix (that is, it has 2 rows and 3 columns). The entry in the ith row and jth column of a matrix is denoted by a_{ij}. For example, in the matrix A, $a_{21} = 4$ and $a_{12} = 2$.

$$A = \begin{bmatrix} 1 & 2 & 3 \\ 4 & 5 & 6 \end{bmatrix} \qquad (1)$$

In general, if X is an $m \times n$ matrix and Y is an $n \times q$ matrix, then the product $P = XY$ is an $m \times q$ matrix whose entry in row i and column j is given by Eq. (2) for $i, \ldots, m$ and $j = 1, \ldots, q$.

$$p_{ij} = x_{i1}y_{1j} + x_{i2}y_{2j} + \cdots + x_{in}y_{nj} \qquad (2)$$

The number of columns of X must be the same as the number of rows of Y in order that the product matrix P can be defined. In general, XY and YX need not be the same matrix; that is, matrix multiplication is not always commutative. Multiplication of a matrix X by the $n \times n$ matrix with 1 in row i and column i for $i = 1, \ldots, n$, and 0 elsewhere, does not change the matrix X. Finally, the product of two matrices can have every entry 0 without this being the case for either factor.

Vectors in the plane can be added and multiplied (scaled) by constants. For example, if the vectors u and v and the number c are given by Eq. (3), then $u + v$ is given by Eq. (4) and cu is given by Eq. (5).

$$u = \begin{bmatrix} 1 \\ 2 \end{bmatrix} \qquad v = \begin{bmatrix} 3 \\ 4 \end{bmatrix} \qquad c = -3 \qquad (3)$$

$$u + v = \begin{bmatrix} 1+3 \\ 2+4 \end{bmatrix} = \begin{bmatrix} 4 \\ 6 \end{bmatrix} \qquad (4)$$

$$cu = \begin{bmatrix} -3 \cdot 1 \\ -3 \cdot 2 \end{bmatrix} = \begin{bmatrix} -3 \\ -6 \end{bmatrix} \qquad (5)$$

There are a number of simple axioms that are satisfied by vector addition and scalar multiplication. A set of vectors V together with a set of numbers F that satisfy these rules is called a vector space over F. The set of numbers F is a field. This means that F has many of the properties associated with rational numbers (fractions), real numbers (decimals), or complex numbers. There are many important mathematical systems that satisfy the axioms for a vector space. Some examples are the two-dimensional space of plane geometry, the three-dimensional space of solid geometry, and polynomials with coefficients from F. *See* FIELD THEORY (MATHEMATICS); LINEAR ALGEBRA.

If V and W are vector spaces over F, then a linear transformation T on V to W is a function that assigns to each vector v in V a unique vector w in W, as in Eq. (6). Moreover, if u and v are any vectors in V, and c and d are any scalars in F, then T satisfies Eq. (7).

$$Tv = w \qquad (6)$$

$$T(cu + dv) = cTu + dTv \qquad (7)$$

A basis of the vector space V is an ordered sequence of vectors $v_1, \ldots, v_n$ in V such that any vector v in V can be written in only one way as in Eq. (8) for appropriate scalars $c_1, \ldots, c_n$.

$$v = c_1v_1 + c_2v_2 + \cdots + c_nv_n \qquad (8)$$

Once bases $v_1, \ldots, v_n$ and $w_1, \ldots, w_m$ for V and W respectively have been chosen, any linear transformation T on V to W can be completely and uniquely described in terms of the entries in an $m \times n$ matrix A by Eq. (9). In other words, each Tv_j, as a vector in W, can be expressed uniquely as a sum of scalar multiples of the basis $w_1, \ldots, w_m$. The scalars $a_{1j}, \ldots, a_{mj}$ are the entries in column j of A. This observation is fundamental because it shows that the study of linear transformations is coextensive with the study of matrices.

$$\begin{gathered} Tv_j = a_{1j}w_1 + a_{2j}w_2 + \cdots + a_{mj}w_m \\ j = 1, 2, \ldots, n \end{gathered} \qquad (9)$$

There are a number of important questions about linear transformations that have been studied extensively. In particular:

1. Given w in W, the problem of determining all vectors v in V (if any) for which Eq. (10) is satisfied.

$$Tv = w \qquad (10)$$

2. If $V = W$, the problem of determining all scalars λ and nonzero vectors v for which Eq. (11) is satisfied.

$$Tv = \lambda v \qquad (11)$$

The set of all vectors Tv obtained as v varies over V is called the range of T. The range of T is always a vector space. Thus the first problem above is equivalent to determining the range of a linear transformation T. Once bases of V and W have been selected, Eq. (10) is readily seen to be equivalent to solving a system of linear equations of the form of Eqs. (12) for the determination of the numbers $x_1, \ldots, x_n$.

$$\begin{gathered} a_{11}x_1 + \cdots + a_{1n}x_n = b_1 \\ a_{21}x_1 + \cdots + a_{2n}x_n = b_2 \\ \vdots \\ a_{m1}x_1 + \cdots + a_{mn}x_n = b_m \end{gathered} \qquad (12)$$

Finding the numbers λ and vectors v that satisfy Eq. (11) is called the eigenvalue problem; the number λ in (11) is called an eigenvalue of T, and the corresponding vector v in Eq. (11) is called an eigenvector of T. Equation (11) leads to a system similar to Eqs. (12), but $m = n$ and each b_i must be replaced by λx_i for $i = 1, \ldots, n$. Moreover, both the eigenvalue λ and $x_1, \ldots, x_n$ must be determined. Because of the importance of Eqs. (10) and (11) in many areas of applied mathematics, special-purpose computer programs have been developed to deal with them. *See* EIGENFUNCTION; EIGENVALUE (QUANTUM MECHANICS).

Because of their applications in the physical and social sciences, certain special classes of linear transformations and matrices have been studied extensively. If A is an $m \times n$ matrix, then the transpose of A is the $n \times m$ matrix whose rows, in succession, are columns of A written as rows. The transpose of A is denoted by A^T. If A has complex number entries, then A^* is the matrix obtained from A^T by replacing each entry by its complex conjugate. An $n \times n$ matrix A is said to be nonsingular (or invertible) if there is a unique $n \times n$ matrix A^{-1} for which $AA^{-1} = A^{-1}A = I_n$; the matrix I_n is the identity matrix: $a_{ii} = 1$ for $i = 1, \ldots, n$, and $a_{ij} = 0$ if $i \neq j$. If $A^* = A$, then A is hermitian; if $A^* = A^{-1}$, then A is unitary; if $A^*A = AA^*$, then A is normal.

The singular-value decomposition theorem states that any $m \times n$ matrix A can be factored into a product $A = UDV$, in which U is $m \times m$ unitary, V is $n \times n$ unitary, and D is an

$m \times n$ matrix whose only (possibly) nonzero entries are $d_{11} \geq \cdots > d_{pp} \geq 0$, where p is the smaller of m and n. The numbers $d_{11}, \ldots, d_{pp}$ are called the singular values of A. The singular-value decomposition theorem is used extensively in solving least-squares problems.

Matrices whose entries are nonnegative real numbers are important in many applications of matrix theory to problems in the social sciences. Matrices with polynomial entries have been studied extensively because of their importance in control theory, systems theory, and other areas of applied mathematics and engineering. [M.Ma.]

Matter (physics) A term that traditionally refers to the substance of which all bodies consist. Matter in classical mechanics is closely identified with mass. Modern analyses distinguish two types of mass: inertial mass, by which matter retains its state of rest or uniform rectilinear motion in the absence of external forces; and gravitational mass, by which a body exerts forces of attraction on other bodies, and by which it reacts to those forces. Expressed in appropriate units, these two properties are numerically equal—a purely experimental fact, unexplained by theory. Albert Einstein made the equality of inertial and gravitational mass a fundamental principle (principle of equivalence), as one of the two postulates of the theory of general relativity. *See* Gravitation; Inertia; Mass; Relativity; Weight.

In quantum mechanics, mass is only one among many properties (quantum numbers) that a particle can have, for example, electric charge, spin, and parity. The nearest quantum-mechanical analogs of traditional matter are fermions, having half-integral values of spin. Forces are mediated by exchange of bosons, particles having integral spins. Fermions correspond to classical matter in exhibiting impenetrability (a consequence of the exclusion principle), but the correspondence is only rough. For example, fermions can also be exchanged in interactions (a photon and an electron can exchange an electron), and they also exhibit wavelike (nonlocalized) behavior. States of classical matter-particles were given by their positions and momenta, but in quantum mechanics it is impossible to assign simultaneous precise positions and momenta to particles. *See* Exclusion principle; Nonrelativistic quantum theory; Quantum electrodynamics; Quantum mechanics; Quantum statistics.

The primary constituents of ordinary matter are baryonic, consisting of quarks. However it is possible that as much as 99% (by mass) of the matter in the universe consists of nonbaryonic "dark matter" whose nature is yet to be discovered. *See* Baryon; Big bang theory; Cosmology; Inflationary universe cosmology; Quarks; Universe. [D.Sha.]

Matthiessen's rule An empirical rule which states that the total resistivity of a crystalline metallic specimen is the sum of the resistivity due to thermal agitation of the metal ions of the lattice and the resistivity due to the presence of imperfections in the crystal. This rule is a basis for understanding the resistivity behavior of metals and alloys at low temperatures.

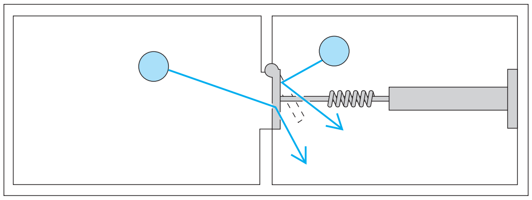
The resistivity of a metal results from the scattering of conduction electrons. Lattice vibrations scatter electrons because the vibrations distort the crystal. Imperfections such as impurity atoms, interstitials, dislocations, and grain boundaries scatter conduction electrons because in their immediate vicinity the electrostatic potential differs from that of the perfect crystal. [F.J.B.]

Maxillopoda A class of Crustacea whose application is gaining moderately widespread use, despite the fact that its validity is not universally accepted by researchers. The constituent subclasses of the Maxillopoda also remain unsettled.

The class Maxillopoda was proposed for those taxa with six thoracic somites (with some exceptions), a well-developed mandibular palp in adults, well-developed maxillules and maxillae adapted for filtering in filter feeders, and the lack of gnathobases on the appendages of the thorax. The Recent taxa included were the Copepoda, Branchiura, Mystacocarida, and provisionally, the Cirripedia. Subsequently the Cirripedia (subdivided into Cirripedia sensu stricto and Ascothoracida) were unequivocally incorporated. The Ostracoda are now included by some but excluded by others. More recent suggestions have included the Tantulocarida, and even the probably noncrustacean Pentastomida, within the Maxillopoda. *See* Branchiura; Cirripedia; Copepoda; Crustacea; Ostracoda; Pentastomida; Tantulocarida. [P.A.McL.]

Maxwell's demon An imaginary being whose action appears to contradict the second law of thermodynamics, which identifies the natural direction of change with the direction of increasing entropy. There has always been a certain degree of discomfort associated with the acceptance of the law, particularly in relation to the time reversibility of physical laws and the role of molecular fluctuations. In 1867, J. C. Maxwell considered, in this connection, the action of "a finite being who knows the paths and velocities of all the molecules by inspection." This being was later referred to as a demon by Lord Kelvin, and the usage has been generally adopted. *See* Entropy; Thermodynamic principles; Time, arrow of.

The activity of Maxwell's demon can be modeled by a trapdoor in a partition between two regions full of gas at the same pressure and temperature. The trapdoor needs to be restrained by a light spring to ensure that it is closed unless it is struck by molecules traveling from the left (see illustration). Its hinging is such that molecules traveling from the right cannot open it. The essential point of Maxwell's vision was that molecules striking the trapdoor from the left would be able to penetrate into the right-hand region but those present on the right would not be able to escape back into the left-hand region. Therefore, the initial equilibrium state of the two regions, that of equal pressures, would be slowly replaced by a state in which the two regions acquired different pressures as molecules accumulated in the right-hand region at the expense of the left-hand region. Only a slightly more elaborate mechanical arrangement is needed to change the apparatus to one in which the temperatures of the two regions move apart. In each case, the demonic trapdoor appears to be contriving a change that is contrary to the second law, for an implication of that law is that systems in either mechanical equilibrium (at the same pressure) or thermal equilibrium (at the same temperature) cannot spontaneously diverge from equilibrium.



Type of device that emulates mechanically the actions of Maxwell's demon. Molecules traveling to the right can open the trapdoor and enter the right-hand compartment, but those striking it from the right cannot open it, so do not move into the left-hand compartment.

As frequently occurs in science, the resolution of a paradox or the elimination of an apparent conflict with a firmly based law depends on a detailed analysis of the proposed arrangement. Numerous analyses of this kind have shown that the activities of Maxwell's demon do not in fact result in the overthrow of the second law. [P.W.A.]

Maxwell's equations Four differential equations proposed by James Clerk Maxwell in 1864 as the basis of the theory of electromagnetic waves. They may be written, in vector notation, as Eqs. (1)–(4), where **D** is the electric displacement, **B** the

$$\nabla \cdot \mathbf{D} = \rho \tag{1}$$

$$\nabla \cdot \mathbf{B} = 0 \tag{2}$$

$$\nabla \times \mathbf{E} = -\frac{\delta \mathbf{B}}{\delta t} \tag{3}$$

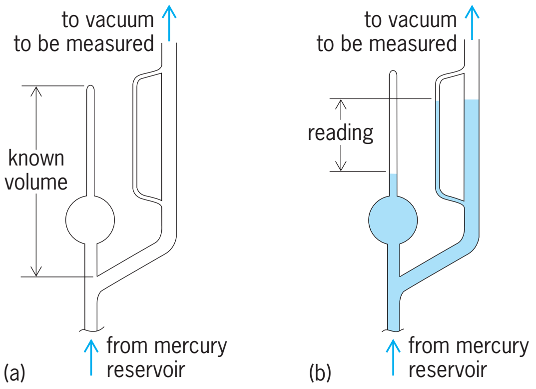
$$\nabla \times \mathbf{H} = \mathbf{i} + \frac{\delta \mathbf{D}}{\delta t} \tag{4}$$

magnetic flux density, **E** the electric field strength or intensity, **H** the magnetic field strength or intensity, ρ the charge density, and **i** the current density.

The first equation states that electric flux lines, if they end at all, will do so on electric charges. The second states that magnetic flux lines never terminate. The third is a form of Faraday's law of induction, which states that the rate of change of the magnetic flux threading a circuit equals the electromotive force or line integral of **E** around the circuit. The fourth integral is based partially on A. M. Ampère's experiments on steady currents which show that the line integral of the magnetic intensity **H** (or $\mathbf{B}/\mu$, where μ is the permeability) around a closed curve equals the current encircled. *See* DISPLACEMENT CURRENT; EQUATION OF CONTINUITY; STOKES' THEOREM. [W.R.Sm.]

McLeod gage

McLeod gage A type of instrument used to measure vacuum by application of the principle of Boyle's law. A known volume of a gas whose pressure is to be measured is trapped by raising the level of a fluid (mercury or oil) by means of a plunger, by lifting a reservoir, by using pressure, or by tipping the apparatus. As the fluid level is further raised, the gas is compressed into the capillary tube (see illustration). Obeying Boyle's law, the compressed gas now exerts enough pressure to support a column of fluid high enough to read. Readings are somewhat independent of the composition of the gas under pressure. *See* VACUUM MEASUREMENT. [R.C.]



McLeod gage. (*a*) Filling (charging) position. (*b*) Measuring position.

Mean effective pressure

Mean effective pressure A term commonly used in the evaluation for positive displacement machinery performance which expresses the average net pressure difference in pounds per square inch (psi) on the two sides of the piston in engines, pumps, and compressors. It is also known as mean pressure and is abbreviated as mep or mp.

In an engine (prime mover) it is the average pressure which urges the piston forward on its stroke. In a pump or compressor it is the average pressure which must be overcome, through the driver, to move the piston against the fluid resistance.

The criterion of mep is a vitally convenient device for the evaluation of a reciprocating engine, pump, or compressor design as judged by initial cost, space occupied, and deadweight. *See* COMPRESSOR; DIESEL CYCLE; THERMODYNAMIC CYCLE; VAPOR CYCLE. [T.Ba.]

Mean free path

Mean free path The average distance traveled between two similar events. The concept of mean free path is met in all fields of science and is classified by the events which take place. The concept is most useful in systems which can be treated statistically, and is most frequently used in the theoretical interpretation of transport phenomena in gases and solids, such as diffusion, viscosity, heat conduction, and electrical conduction. The types of mean free paths which are used most frequently are for elastic collisions of molecules in a gas, of electrons in a crystal, of phonons in a crystal, and of neutrons in a moderator. *See* KINETIC THEORY OF MATTER. [W.D.W.]

Measles

Measles An acute, highly infectious viral disease with cough, fever, and maculopapular rash. It is of worldwide endemicity.

The virus enters the body via the respiratory system, multiplies there, and circulates in the blood. Cough, sneezing, conjunctivitis, photophobia, and fever occur, with Koplik's spots (small red spots containing a bluish-white speck in the center) in the mouth.

A rash appears after 14 days' incubation and persists 5–10 days. Serious complications may occur in 1 out of 15 persons; these are mostly respiratory (bronchitis, pneumonia), but neurological complications are also found. Encephalomyelitis occurs rarely. Permanent disabilities may ensue for a significant number of persons. Measles is one of the leading causes of death among children in the world, particularly in the developing countries.

In unvaccinated populations, immunizing infections occur in early childhood during epidemics which recur after 2–3 years' accumulation of susceptible children. Transmission is by coughing or sneezing. Measles is infectious from the onset of symptoms until a few days after the rash has appeared. Second attacks of measles are very rare. Treatment is symptomatic.

Killed virus vaccine should not be used, as certain vaccinees become sensitized and develop local reactions when revaccinated with live attenuated virus, or develop a severe illness upon contracting natural measles. Live attenuated virus vaccine effectively prevents measles; vaccine-induced antibodies persist for years. *See* BIOLOGICALS; HYPERSENSITIVITY; SKIN TEST. [J.L.Me.]

Measure

Measure A reference sample used in comparing lengths, areas, volumes, masses, and the like. The measures employed in scientific work are based on the international units of length, mass, and time—the meter, the kilogram, and the second—but decimal multiples and submultiples are commonly employed. Prior to the development of the international metric system, many special-purpose systems of measures had evolved and many still survive, especially in the United Kingdom and the United States. *See* METRIC SYSTEM; PHYSICAL MEASUREMENT; TIME; UNITS OF MEASUREMENT; WEIGHT. [D.Wi.]

Measure theory

Measure theory A branch of mathematical analysis connected with the theory of integration. In order to discuss this subject, a formal definition of the term measure must be given.

Let X be an arbitrary set. Let m be a fixed collection of subsets of X satisfying the following conditions:

1. $\phi \in m$. (ϕ is the empty set. The symbol $\in$ indicates that ϕ is an element of m).

2. If $A \in m$, then $A^c \in m$. (A^c is the complement of A. It consists of those elements of X which do not belong to A.)

3. If $A_1, A_2, \ldots \in m$, then (1) is valid. (This set is the union of

$$\bigcup_{k=1}^{\infty} A_k \in m \tag{1}$$

$A_1, A_2, \ldots$. It consists of those elements of X which belong to at least one of the sets $A_1, A_2, \ldots$.)

In this situation the collection m is called a σ-algebra. Here the term algebra refers to the various set operations (complementation, union, intersection), and the prefix σ to the fact that countably many such operations can be performed with sets in m and still result in sets in m. For example, the three properties mentioned above imply another property:

4. If $A_1, A_2, \ldots \in m$, then (2) is valid. (This set is the intersection of $A_1, A_2, \ldots$. It consists of those elements of X which belong to all of the sets $A_1, A_2, \ldots$.)

$$\bigcap_{k=1}^{\infty} A_k \in m \qquad (2)$$

Now suppose that X is a set and m is a particular σ-algebra of subsets of X. A measure μ is a function which assigns to each set in m a certain nonnegative real number (or $+\infty$) and which satisfies the following conditions:

1. $\mu(\phi) = 0$.
2. If A and $B \in m$ and are disjoint ($A \cap B = \phi$), then Eq. (3) holds.

$$\mu(A \cup B) = \mu(A) + \mu(B) \qquad (3)$$

3. If $A_1, A_2, \ldots \in m$, then Eq. (4) holds.

$$\mu\left(\bigcup_{k=1}^{\infty} A_k\right) \le \sum_{k=1}^{\infty} \mu(A_k) \qquad (4)$$

Various other properties can be derived from these conditions, such as:

4. If A and $B \in m$ and $A \subset B$ (that is, A is a subset of B), then $[\mu](A) \le \mu(B)$.
5. If $A_1, A_2, \ldots \in m$ and are mutually disjoint ($A_i \cap A_j = \phi$ if $i \ne j$), then Eq. (5) holds.

$$\mu\left(\bigcup_{k=1}^{\infty} A_k\right) = \sum_{k=1}^{\infty} \mu(A_k) \qquad (5)$$

The last property is of crucial importance and is called the countable additivity property of the measure μ.

Measure theory has a great number of important applications. Undoubtedly, the most important is the application to integration. *See* Integration. [B.F.J.]

Measured daywork A tool used primarily in manufacturing facilities as a control device to measure productive output in relation to labor input within a specific time period. The measurement of the work content is accomplished through the use of time standards which are usually the result of a stopwatch time study, predetermined time standards (methods-time measurement, the work-factor system), or some other form of work-measurement technique designed to measure tasks of labor under normal and average conditions.

A measured daywork plan is similar to incentive pay plans inasmuch as in both plans, time standards are used as a device to measure operator performance and also for various forms of management planning. However, in a measured daywork plan, worker income is based on a fixed hourly rate established by management, and is usually affected only by job classification, shift premiums, and overtime adjustments. Because of the fixed hourly rate in a measured daywork plan, there is little incentive for a worker to exceed a normal or standard level of performance or productivity. On the other hand, time standards are more readily acceptable, and become less an item of contention to the employee and bargaining unit (union).

The term daywork as used in industry denotes a fixed hourly rate that is not raised or lowered by varying worker performance levels. The hourly rate for a particular job should be a fair one relative to other jobs in the shop, and should also be comparable to rates of pay for similar jobs in the industrial community.

Once measured labor time standards have been established for shop operations, in addition to evaluating operator performance and identifying labor costs, new-product costs can also be determined prior to release to production, worker-power planning and scheduling can be done, equipment capacity requirements can be identified, and planning and make/buy decisions can be facilitated. *See* Performance rating; Productivity; Wage incentives; Work measurement. [D.S.]

Mechanical advantage Ratio of the force exerted by a machine (the output) to the force exerted on the machine, usually by an operator (the input). The term is useful in discussing a simple machine, where it becomes a figure of merit. It is not particularly useful, however, when applied to more complicated machines, where other considerations become more important than a simple ratio of forces. *See* Efficiency; Simple machine. (R.M.Ph.)

Mechanical alloying A materials-processing method that involves the repeated welding, fracturing, and rewelding of a mixture of powder particles, generally in a high-energy ball mill, to produce a controlled, extremely fine microstructure. The mechanical alloying technique allows alloying of elements that are difficult or impossible to combine by conventional melting methods. In general, the process can be viewed as a means of assembling metal constituents with a controlled microstructure. If two metals will form a solid solution, mechanical alloying can be used to achieve this state without the need for a high-temperature excursion. Conversely, if the two metals are insoluble in the liquid or solid state, an extremely fine dispersion of one of the metals in the other can be accomplished. The process of mechanical alloying was originally developed as a means of overcoming the disadvantages associated with using powder metallurgy to alloy elements that are difficult to combine. *See* Crushing and pulverizing; Powder metallurgy; Solid solution.

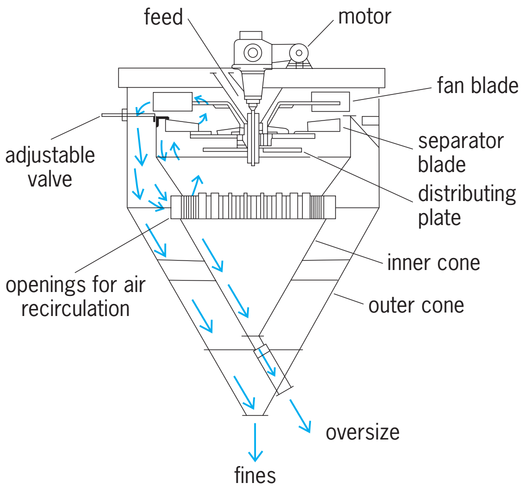
Some oxides are insoluble in molten metals. Mechanical alloying provides a means of dispersing these oxides in the metals. Examples are nickel-based superalloys strengthened with dispersed thorium oxide or yttrium oxide (Y_2O_3). These superalloys have excellent strength and corrosion resistance at elevated temperatures, making them attractive candidate materials for use in applications such as jet-engine turbine blades, vanes, and combustors. A number of other potential applications for mechanical alloying material are being explored, including powders for coating applications, alloys of immiscible systems, amorphous alloys, intermetallics, cermets, and organic-ceramic-metallic material systems in general. *See* Amorphous solid; Cermet; High-temperature materials; Intermetallic compounds; Metal coatings.

Liquids or solid immiscible systems are difficult to process by conventional pyrometallurgy; mechanical alloying provides a route to obtain a homogeneous distribution in the solid phase. *See* Pyrometallurgy. [F.H.Fr.]

Mechanical classification A sorting operation in which mixtures of particles of mixed sizes, and often of different specific gravities, are separated into fractions by the action of a stream of fluid. Water is ordinarily used as the sorting fluid, but other liquids or air or other gases may be used (see illustration).

The main objective of classification is to separate the particles according to size. This function is identical to that of screening, but classification is applicable to smaller particles, especially those that are undersize. For small particles it is more economical than screening. In classification the oversize and undersize are called sands and slimes, respectively.

Material also may be mechanically classified by specific gravity, a method that separates substances differing in chemical composition. This is called hydraulic separation. Such classification is based on the fact that, in a fluid, particles of the same specific gravity but of different size or shape settle at different constant speeds. Large, heavy, round particles settle faster than



The double-cone air separator. (*After W. L. McCabe and J. C. Smith, Unit Operations of Chemical Engineering, McGraw-Hill, 3rd ed., 1975*)

small, light, needlelike ones. If the particles also differ in specific gravity, the speed of settling is further affected. This is the basis for the separation of particles by kind rather than by size alone. *See* Flotation; Mechanical separation techniques; Unit operations. [W.L.McC.]

Mechanical engineering One of several recognized fields of engineering. To grasp the meaning of mechanical engineering, it is desirable to take a close look at what engineering really is. The Engineers' Council for Professional Development has defined engineering as the profession in which a knowledge of the mathematical and physical sciences gained by study, experience, and practice is applied with judgment to develop ways to utilize economically the materials and forces of nature for the progressive well-being of mankind. It is a profession in which study in mathematics and science is blended with experience and judgment for the production of useful things.

Formal training of a mechanical engineer includes mastery of mathematics through the level of differential equations. Training in physical science embraces chemistry, physics, mechanics of materials, fluid mechanics, thermodynamics, statics, and dynamics. *See* Engineering; Machinery; Technology. [R.S.S.]

Mechanical impedance For a system executing simple harmonic motion, the mechanical impedance is the ratio of force to particle velocity. If the force is that which drives the system and the velocity is that of the point of application of the force, the ratio is the input or driving-point impedance. If the velocity is that at some other point, the ratio is the transfer impedance corresponding to the two points.

Mechanical impedance is a complex quantity. The real part, the mechanical resistance, is independent of frequency if the dissipative forces are proportional to velocity; the imaginary part, the mechanical reactance, varies with frequency, becoming zero at the resonant and infinite at the antiresonant frequencies of the system. *See* Forced oscillation; Harmonic motion. [M.Gr.]

Mechanical rectifier A device which uses a synchronously operated mechanical switch to convert a single-phase or polyphase alternating voltage to a direct voltage. Single-phase mechanical rectifiers are made for small current output and are normally called vibrators. For large values of power where low voltages (less than 600 volts) are desired, the polyphase mechanical rectifier is used. This low-voltage device has higher efficiency than electronic rectifiers, which have appreciable voltage drop across the arc. These devices are not commonly used in power system applications. *See* Rectifier. [A.G.C.]

Mechanical separation techniques A group of laboratory and production operations whereby the components of a polyphase mixture are separated by mechanical methods into two or more fractions of different mechanical characteristics. The separated fractions may be homogeneous or heterogeneous, particulate or nonparticulate.

Types of mechanical separator

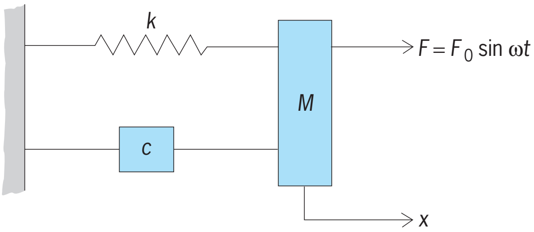
Materials separated	Separators
Liquid from liquid	Settling tanks, liquid cyclones, centrifugal decanters, coalescers
Gas from liquid	Still tanks, deaerators, foam breakers
Liquid from gas	Settling chambers, cyclones, electrostatic precipitators, impingement separators
Solid from liquid	Filters, centrifugal filters, clarifiers, thickeners, sedimentation centrifuges, liquid cyclones, wet screens, magnetic separators
Liquid from solid	Presses, centrifugal extractors
Solid from gas	Settling chambers, air filters, bag filters, cyclones, impingement separators, electrostatic and high-tension precipitators
Solid from solid	
By size	Screens, air and wet classifiers, centrifugal classifiers
By other characteristics	Air and wet classifiers, centrifugal classifiers, jigs, tables, spiral concentrators, flotation cells, dense-medium separators, magnetic separators, electrostatic separators

The techniques of mechanical separation are based on differences in phase density, in phase fluidity, and in such mechanical properties of particles-as size, shape, and density; and on such particle characteristics as wettability, surface charge, and magnetic susceptibility. Obviously, such techniques are applicable only to the separation of phases in a heterogeneous mixture. They may be applied, however, to all kinds of mixtures containing two or more phases, whether they are liquid-liquid, liquid-gas, liquid-solid, gas-solid, solid-solid, or gas-liquid-solid.

Methods of mechanical separations fall into four general classes: (1) those employing a selective barrier such as a screen or filter cloth; (2) those depending on difference in phase density alone (hydrostatic separators); (3) those depending on fluid and particle mechanics; and (4) those depending on surface or electrical characteristics of particles. A wide variety of separation devices have been devised and are in use. The more important kinds of equipment are listed in the table, grouped according to the phases involved. *See* Centrifugation; Clarification; Dust and mist collection; Filtration; Flotation; Magnetic separation methods; Mechanical classification; Screening; Sedimentation (industry); Thickening. [S.A.M.]

Mechanical vibration The continuing motion, repetitive and often periodic, of a solid or liquid body within certain spatial limits. Vibration occurs frequently in a variety of natural phenomena such as the tidal motion of the oceans, in rotating and stationary machinery, in structures as varied in nature as buildings and ships, in vehicles, and in combinations of these various elements in larger systems. The sources of vibration and the types of vibratory motion and their propagation are subjects that are complicated and depend a great deal on the particular characteristics of the systems being examined. Further, there is strong coupling between the notions of mechanical vibration and the propagation of vibration and acoustic signals through both the ground and the air so as to create possible sources of discomfort, annoyance, and even physical damage to people and structures adjacent to a source of vibration.

Mass-spring-damper system. Although vibrational phenomena are complex, some basic principles can be recognized in a very simple linear model of a mass-spring-damper system (see illustration). Such a system contains a mass M, a spring with spring constant k that serves to restore the mass to a neutral position, and a damping element which opposes the motion of



Vibrating linear system (mass-spring-damper) with one degree of freedom.

the vibratory response with a force proportional to the velocity of the system, the constant of proportionality being the damping constant *c*. This damping force is dissipative in nature, and without its presence a response of this mass-spring system would be completely periodic. *See* DAMPING.

Complex systems. The foregoing model of the linear spring-mass-damper system contains within it a number of simplifications that do not reflect conditions of the real world in any obvious way. These simplifications include the periodicity of both the input and, to some extent, the response; the discrete nature of the input, that is, the assumption that it is temporal in nature with no reference to spatial distribution; and the assumption that only a single resonant frequency and a single set of parameters are required to describe the mass, the stiffness, and the damping. The real world is far more complex. Many sources of vibration are not periodic. These include impulsive forces and shock loading, wherein a force is suddenly applied for a very short time to a system; random excitations, wherein the signal fluctuates in time in such a way that its amplitude at any given instant can be expressed only in terms of a probabilistic expectation; and aperiodic motions, wherein the fluctuation in time may be some prescribed nonperiodic function or some other function that is not readily seen to be periodic.

Sources of vibration. There are many sources of mechanical and structural vibration that the engineer must contend with in both the analysis and the design of engineering systems. The most common form of mechanical vibration problem is motion induced by machinery of varying types, often but not always of the rotating variety. Other sources of vibration include: groundborne propagation due to construction; vibration from heavy vehicles on conventional pavement as well as vibratory signals from the rail systems common in many metropolitan areas; and vibrations induced by natural phenomena, such as earthquakes and wind forces. Wave motion is a source of vibration in mechanical and structural systems associated with offshore structures.

Effect of vibrations. The most serious effect of vibration, especially in the case of machinery, is that sufficiently high alternating stresses can produce fatigue failure in machine and structural parts. Less serious effects include increased wear of parts, general malfunctioning of apparatus, and the propagation of vibration through foundations and buildings to locations where the vibration of its acoustic realization is intolerable either for human comfort or for the successful operation of sensitive measuring equipment. *See* ACOUSTIC NOISE; SOUND; VIBRATION; WEAR. [C.L.D.; J.P.D.H.]

Mechanics

In its original sense, mechanics refers to the study of the behavior of systems under the action of forces. Mechanics is subdivided according to the types of systems and phenomena involved.

An important distinction is based on the size of the system. Those systems that are large enough can be adequately described by the newtonian laws of classical mechanics; in this category, for example, are celestial mechanics and fluid mechanics. On the other hand, the behavior of microscopic systems such as molecules, atoms, and nuclei can be interpreted only by the concepts and mathematical methods of quantum mechanics.

Mechanics may also be classified as nonrelativistic or relativistic mechanics, the latter applying to systems with material velocities comparable to the velocity of light. This distinction pertains to both classical and quantum mechanics.

Finally, statistical mechanics uses the methods of statistics for both classical and quantum systems containing very large numbers of similar subsystems to obtain their large-scale properties. *See* CLASSICAL FIELD THEORY; CLASSICAL MECHANICS; DYNAMICS; FLUID MECHANICS; QUANTUM MECHANICS; STATICS; STATISTICAL MECHANICS. [B.G.]

Mechanism

Classically, a mechanical means for the conversion of motion, the transmission of power, or the control of these. Mechanisms are at the core of the workings of many machines and mechanical devices. In modern usage, mechanisms are not always limited to mechanical means. In addition to mechanical elements, they may include pneumatic, hydraulic, electrical, and electronic elements. In this article, the discussion of mechanism is limited to its classical meaning. *See* MACHINE.

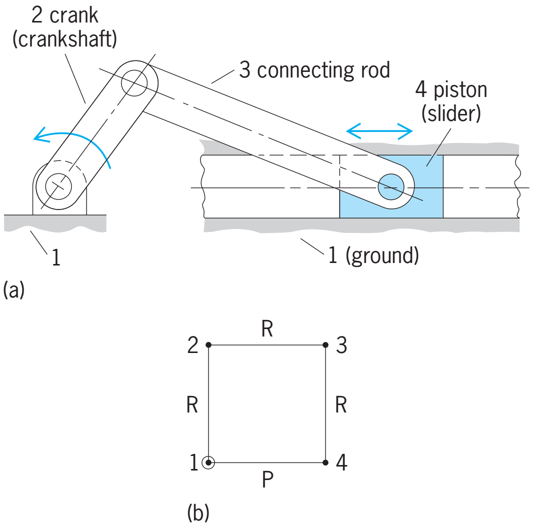
Most mechanisms consist of combinations of a relatively small number of basic components. Of these, the most important are cams, gears, links, belts, chains, and logical mechanical elements. The last include such devices as ratchets, trips, detents, and interlocks. In order to understand how any mechanism works, their degree of freedom, structure, and kinematics must be considered. *See* BELT DRIVE; CAM MECHANISM; CHAIN DRIVE; ESCAPEMENT; GEAR; LINKAGE (MECHANISM); RATCHET.

Degree of freedom is conveniently illustrated for mechanisms with rigid links. The discussion is limited to mechanisms which obey the general degree-of-freedom equation,

$$F = \lambda(l - j - 1) + \sum f_i$$

where F = degree of freedom of mechanism, l = number of links of mechanism, j = number of joints of mechanism, f_i = degree of freedom of relative motion at ith joint, σ = summation symbol (summation over all joints), and λ = mobility number (the most common cases are $\lambda = 3$ for plane mechanisms and $\lambda = 6$ for spatial mechanisms). *See* DEGREE OF FREEDOM (MECHANICS).

The kinematic structure of a mechanism refers to the identification of the joint connection between its links. Just as chemical compounds can be represented by an abstract formula and electric circuits by schematic diagrams, the kinematic structure of mechanisms can be usefully represented by abstract diagrams. The structure of mechanisms for which each joint connects two links can be represented by a structural diagram, or graph, in



Slider-crank mechanism, (*a*) Mechanism, (*b*) Graph of mechanism. *R* = pin joint; *P* = sliding joint.

which links are denoted by vertices, joints by edges, and in which the edge connection of vertices corresponds to the joint connection of links; edges are labeled according to joint type, and the fixed link is identified as well. Thus the graph of the slider-crank mechanism of illustration *a* is as shown in illustration *b*. In this figure the circle around vertex 1 signifies that link 1 is fixed.

Kinematics is divided into kinematic analysis (analysis of a mechanism of given dimensions) and synthesis (determination of the proportions of a mechanism for given motion requirements). It includes the investigation of finite as well as infinitesimal displacements, velocities, accelerations and higher accelerations, and curvatures and higher curvatures in plane and three-dimensional motions. *See* KINEMATICS.

The design of mechanisms involves many factors. These include their structure, kinematics, dynamics, stress analysis, materials, lubrication, wear, tolerances, production considerations, control and actuation, vibrations, critical speeds, reliability, costs, and environmental considerations. Modern trends in the design of mechanisms emphasize economical design analysis by means of computer-aided design techniques. [F.F.]

Mechanoreceptors

Mechanoreceptors Sensory receptors that provide the organism with information about such mechanical changes in the environment as movement, tension, and pressure. In higher animals receptors are actually the only means by which information of the surroundings is gained and by which reactions to environmental changes are started. *See* SENSATION.

Mechanoreceptors are excited by mechanical disturbances of their surroundings through deformation of their structure, through pressure or tension, or through a combination of these. In general, little energy is required for mechanical stimuli to cause a detectable excitation in mechanoreceptors.

From a physical point of view, mechanoreceptors are energy transducers; they convert mechanical into electrical energy, which in turn triggers the nerve impulse. Deformation leads to a sequence of events which may be summarized by the following scheme:

$$\begin{matrix}\text{Mechanical}\\ \text{stimulus}\end{matrix} \rightarrow \begin{matrix}\text{Generator}\\ \text{current}\end{matrix} \rightarrow \begin{matrix}\text{Nerve impulse}\\ \text{(action potential)}\end{matrix}$$

The generator current is the earliest detectable sign of excitation. The most salient characteristic of the generator current is its graded nature; its amplitude increases continuously, without visible steps, if the stimulus strength is progressively increased. When the generator current reaches a certain critical amplitude, an all-or-nothing potential is discharged in the sense organ which may then propagate as an all-or-nothing nerve impulse along the afferent axon of the receptor. *See* NERVOUS SYSTEM (INVERTEBRATE); NERVOUS SYSTEM (VERTEBRATE). [W.R.L.]

Mecoptera

Mecoptera A small order of insects called the scorpion flies. Characteristic of the adult insect is the peculiar prolongation of the head into a beak, which bears chewing mouthparts. They are small to medium in size. The insects either have two pairs of large, net-veined wings of equal size, often with dark areas, or have short and aborted wings. The legs are long and slender. In some species, the male abdomen has a terminal enlargement which is held recurved over the back so that he resembles a scorpion, thus the common name. The Mecoptera are found in moist habitats within densely wooded areas. The adults are omnivorous but feed chiefly on small insects. *See* INSECTA. [B.E.R.]

Medical bacteriology

Medical bacteriology The study of bacteria that cause human disease. The field encompasses the detection and identification of bacterial pathogens, determination of the sensitivity and mechanisms of resistance of bacteria to antibiotics, the mechanisms of virulence, and some aspects of immunity to infection. *See* VIRULENCE.

The clinical bacteriology laboratory identifies bacterial pathogens present in specimens such as sputum, pus, blood, and spinal fluid, or from swabs of skin, throat, rectal, or urogenital surfaces. Identification involves direct staining and microscopic examination of these materials, and isolation of bacteria present in the material by growth in appropriate media. The laboratory must differentiate bacterial pathogens from harmless bacteria that colonize humans. Species and virulent strains of bacteria can be identified on the basis of growth properties, metabolic and biochemical tests, and reactivity with specific antibodies.

Recent advances in the field of diagnostic bacteriology have involved automation of biochemical testing; the development of rapid antibody-based detection methods; and the application of molecular biology techniques. Once a bacterial pathogen has been identified, a major responsibility of the diagnostic bacteriology laboratory is the determination of the sensitivity of the pathogen to antibiotics. This involves observation of the growth of the bacteria in the presence of various concentrations of antibiotics. The process has been made more efficient by the development of automated instrumentation.

An increasingly serious problem in the therapy of infectious diseases is the emergence of antibiotic-resistant strains of bacteria. An important area of research is the mechanisms of acquisition of antibiotic resistance and the application of this knowledge to the development of more effective antibiotics. *See* ANTIBIOTIC; ANTIGEN-ANTIBODY REACTION; BACTERIAL PHYSIOLOGY AND METABOLISM; BACTERIAL TAXONOMY; IMMUNOCHEMISTRY.

The study of bacterial pathogenesis involves the fields of molecular genetics, biochemistry, cell biology, and immunology. In cases where the disease is not serious and easily treated, research may involve the deliberate infection of human volunteers. Otherwise, various models of human disease must be utilized. These involve experimental infection of animals and the use of tissue cell culture systems. Modern molecular approaches to the study of bacterial pathogenesis frequently involve the specific mutation or elimination of a bacterial gene thought to encode a virulence property, followed by observation of the mutant bacteria in a model system of human disease. In this way, relative contributions of specific bacterial traits to different stages of the disease process can be determined. This knowledge permits the design of effective strategies for intervention that will prevent or cure the disease. *See* BACTERIAL GENETICS.

The presence of specific antibodies is frequently useful in the diagnosis of bacterial diseases in which the pathogen is otherwise difficult to detect. An example is the sexually transmitted disease syphilis; the diagnosis must be confirmed by the demonstration of antibodies specific for *T. pallidum*. *See* ANTIBODY; BIOLOGICALS.

Immunity to some bacteria that survive intracellularly is not mediated by antibodies but by immune effector cells, known as T cells, that activate infected cells to kill the bacteria that they contain. An active area of research is how bacterial components are presented to the immune system in a way that will induce effective cell-mediated immunity. This research may lead to the development of T-cell vaccines effective against intracellular bacterial pathogens.

For disease entities caused by specific bacteria *see* ANTHRAX; BOTULISM; BRUCELLOSIS; CHOLERA; DIPHTHERIA; GANGRENE, GAS; GLANDERS; GONORRHEA; GRANULOMA INGUINALE; JOHNE'S DISEASE; LEPROSY; LISTERIOSIS; PLAGUE; PSEUDOTUBERCULOSIS; TETANUS; TUBERCULOSIS; TULAREMIA. For disease entities caused by more than one microorganism *see* FOOD POISONING; INFANT DIARRHEA; MENINGITIS; PNEUMONIA. For groups of disease-producing bacteria *see* GANGRENE, GAS; HAEMOPHILUS; IMMUNOLOGY; MEDICAL BACTERIOLOGY; PNEUMOCOCCUS; SEPTICEMIA; SPIROCHETE; STREPTOCOCCUS. [S.L.M.]

Medical control systems

Medical control systems Physiological and artificial systems that control one or more physiological variables or functions of the human body. Regulation, control processes, and system stability are at the heart of the survival of living organisms, both unicellular and multicellular. In the nineteenth century,

C. Bernard concluded that the higher animals, far from being indifferent to their surroundings, must be in close and intimate relation to them. The equilibrium they maintain is the result of compensation established as continually and exactly as if by a very sensitive balance. W. B. Cannon (1929) differentiated the stability properties of biological systems from those of physical systems, and introduced the term homeostasis to describe the steady states in the body that are maintained by complex, coordinated physiological reactions. The condition of homeostasis is achieved either by regulation of supplies (for example, control of blood sugar level) or by regulation of processes (for example, control of body temperature and control of voluntary movements). *See* HOMEOSTASIS.

Medical control systems may be classified into two groups: (1) the physiological control systems in normal or pathological conditions (for example, control of electrolytes, arterial pressure, respiration, body temperature, blood sugar, endocrinal functions, neuromuscular and motor activity, and sensory functions), and (2) the external (artificial) control systems that interface with physiological systems (for example, artificial kidneys or hemodialyzers, blood oxygenators or heart-lung machines used during open-heart surgery, external prosthetics and orthotics, cardiac pacemakers, ventilators, implantable defibrillators, and implantable pumps for drug delivery). For the development and proper functioning of artificial devices, the underlying control mechanisms of the normal and of the disabled physiological systems with which the external devices must interface must be adequately understood. Thus, in its broadest sense, the area of medical control systems encompasses all branches of engineering, mathematical biology, biophysics, physiology, and medicine. *See* BIOMECHANICS; BIOMEDICAL CHEMICAL ENGINEERING; BIOMEDICAL ENGINEERING; CONTROL SYSTEMS; MATHEMATICAL BIOLOGY.

The importance of control systems engineering in medical applications has grown because of the inherent complexity of medical control systems. H. A. Simon's concept of complexity is very appropriate for medical control systems: complex systems are composed of subsystems that in turn have their own subsystems, and so on; and the large number of parts interact in a complicated way so that it is sometimes impossible to infer the properties of the whole from the properties of the parts and their laws of interaction. Indeed, the analytical models developed, using control systems engineering, of the components of a medical system have had limited success in predicting the behavior of the overall system.

Examples of medical control systems include myoelectric prostheses, which are replacement devices for lost limbs; external orthoses, which are used for rehabilitation of patients with acquired disabilities; and implantable devices such as defibrillators and pumps for drug delivery. Numerous other devices, such as cardiac pacemakers, artificial kidneys, heart-lung machines, and artificial ventilators, have been in routine clinical use for many years. [G.C.A.]

Medical imaging A medical specialty that uses x-rays, gamma rays, high-frequency sound waves, and magnetic fields to produce images of organs and other internal structures of the body. In diagnostic radiology the purpose is to detect and diagnose disease, while in interventional radiology, imaging procedures are combined with other techniques to treat certain diseases and abnormalities. *See* RADIOLOGY.

Film x-ray studies, the most common radiologic procedures, are made up of still pictures of the various organs and tissues in the body. In these procedures, x-rays are passed through the body to expose the photographic film that is placed on the opposite side of the body. The changes in film density that result from exposure allow the radiologist to distinguish between normal and abnormal tissue and to diagnose many different disease types. *See* X-RAYS.

Fluoroscopy is a dynamic x-ray imaging technique that produces a moving image over time. It is essential for evaluating organ movement such as the beating of the heart or movement of the diaphragm. The gastrointestinal series and the barium enema are the most common fluoroscopic studies. These procedures begin with the administration of a barium mixture either by ingestion or by an enema that fills the stomach or large intestine. The barium mixture, known as a contrast medium, like dense tissues, blocks the x-ray beam. Fluoroscopy then reveals the location of the barium-coated lining of the stomach and intestine and enables the radiologist to observe as they contract and distend.

Angiography is the radiologic study of blood vessels. Because arteries and veins are not normally visible in conventional x-ray studies, an iodinated compound, which is opaque to the x-ray, must be injected into the bloodstream. An arteri-ogram is an x-ray study of the arteries; a venogram is an x-ray study of the veins. Arteriography is most often used to show the presence and extent that arteries have become clogged and narrowed by arteriosclerosis, which can lead to strokes and heart attacks.

Computed tomography (CT), also called computed axial tomography (CAT), is a scanning technique that combines computer and x-ray technologies. The computer constructs a two-dimensional anatomic image that represents a cross-sectional slice through the body. Three-dimensional images can be generated by using special computer software. These are especially useful in planning reconstructive orthopedic or plastic surgery. *See* COMPUTERIZED TOMOGRAPHY.

Ultrasound imaging, or sonography, is a diagnostic imaging procedure that uses high frequency sound waves instead of ionizing radiation. During an ultrasound examination, a lightweight transducer is placed on the patient's skin over the part to be imaged. The transducer produces sound waves that penetrate the skin to reach tissues and organs. When the sound waves strike specific tissue surface, echoes are produced. The echoes are detected by the transducer and are then electronically converted into an anatomic image that is displayed on a video screen. The image can also be recorded on film or videotape. Ultrasound imaging is commonly used in obstetrics to monitor the position and development of the fetus and also to detect any fetal abnormalities or problems in the pregnancy. Ultrasound is also used to show problems in other internal structures, including the gallbladder, kidney, and heart. Doppler ultrasound can monitor blood flow through veins and arteries. It is commonly used to study kidney transplants and blood flow to the brain and also to diagnose blocked arteries. *See* MEDICAL ULTRASONIC TOMOGRAPHY.

Magnetic resonance imaging (MRI) is a diagnostic procedure that uses a large, high-strength magnet, radio-frequency signals, and a computer to produce images. The technique of MRI is extremely useful in evaluating diseases of the brain and spine. It is also used to evaluate joints, bone and soft tissue abnormalities, as well as abnormalities of the chest, abdomen, and pelvis. *See* NUCLEAR MAGNETIC RESONANCE (NMR).

Nuclear medicine imaging studies use radioactive compounds called radionuclides of radiopharmaceuticals that emit gamma rays, or some emit beta particles. The chemicals are formulated so that they collect temporarily in the parts of the body to be studied. For most nuclear imaging studies, the radionuclide is injected into the patient and the images are taken with a gamma camera suspended above the patient who lies on a table. The camera detects the gamma rays emitted from the radionuclide in the patient's body and uses this information to produce an image that shows the distribution of the radionuclide within the body. The image is recorded on film and is called a scintigram or scan. Scintigrams of the heart and bone are the two most common nuclear medicine examinations.

The single-photon emission computed tomography (SPECT) examination uses a computer to obtain two-dimensional images that are thin slices of internal organs such as the heart, brain, and liver. The SPECT images can display organs with much greater detail than conventional scintigrams.

Positron emission tomography (PET) is a more refined radiologic technique that is used to study the metabolic activity inside an organ. The technique has been shown to be useful in the study of brain-related disorders, such as epilepsy and Alzheimer's disease, and of the vitality of heart tissue.

Interventional radiology combines imaging procedures with various injection and catheter techniques to treat tumors, blockages, bleeding vessels, and other abnormalities without extensive surgery. Among the more common interventional procedures is angioplasty, which is used to treat blocked or narrowed arteries. *See* RADIOGRAPHY. [M.Lo.; R.DelF.]

Medical mycology The study of fungi (molds and yeasts) that cause human disease. Fungal infections are classified according to the site of infection on the body or whether an opportunistic setting is necessary to establish disease. Fungal infections that occur in an opportunistic setting have become more common due to conditions that compromise host defenses, especially cell-mediated immunity. Such conditions include acquired immunodeficiency syndrome (AIDS), cancer, and immunosuppressive therapy to prevent transplant rejection or to control inflammatory syndromes. Additionally, opportunistic fungal infections have become more significant as severely debilitated individuals live longer because of advances in modern medicine, and nosocomial (hospital-acquired) fungal infections are an increasing problem. Early diagnosis with treatment of the fungal infection and control of the predisposing cause are essential. *See* OPPORTUNISTIC INFECTIONS.

Antifungal drug therapy is extremely challenging since fungi are eukaryotes, as are their human hosts, leading to problems with toxicity or cross-reactivity with host molecules. Most antifungal drugs target the fungal cell membrane or wall. The "gold standard" for therapy of most severe fungal infections is amphotericin B, which binds to ergosterol, a membrane lipid found in most fungi and some other organisms but not in mammals. Unfortunately, minor cross-reactive binding of amphotericin B to cholesterol in mammalian cell membranes can lead to serious toxicity, especially in the kidney where the drug is concentrated. Recent advances in antifungal therapy include the use of liposomal amphotericin B and newer azoles such as fluconazole and itraconazole, which show reduced toxicity or greater specificity. Conversely, drug resistance in pathogenic fungi is an increasing problem, as it is in bacteria.

Candidiasis is the most common opportunistic fungal infection, and it has also become a major nosocomial infection in hospitalized patients. *Candida albicans* is a dimorphic fungus with a yeast form that is a member of the normal flora of the surface of mucous membranes. In an opportunistic setting, the fungus may proliferate and convert to a hyphal form that invades these tissues, the blood, and other organs. The disease may extend to the blood or other organs from various infected sites in patients who are suffering from a grave underlying disease or who are immunocompromised. Other important opportunistic fungal diseases include aspergillosis, mucormycosis, and cryptococcus.

Healthy persons can acquire disease from certain pathogenic fungi following inhalation of their fungal spores. The so-called deep or systemic mycoses are all caused by different species of soil molds; most infections are unrecognized and produce no or few symptoms. However, in some individuals infection may spread to all parts of the body from the lung, and treatment with amphotericin B or an antifungal azole drug is essential.

Other fungal infections develop when certain species of soil molds are inoculated deep into the subcutaneous tissue, such as by a deep thorn prick or other trauma. A specific type of lesion develops with each fungus as it grows within the tissue. Proper wound hygiene will prevent these infections.

Ringworm, also known as dermatophytosis or tinea, is the most common of all fungal infections. Some species of pathogenic molds can grow in the stratum corneum, the dead outermost layer of the skin. Disease results from host hypersensitivity to the metabolic products of the infecting mold as well as from the actual fungal invasion. Tinea corporis, ringworm of the body, appears as a lesion on smooth skin and has a red, circular margin that contains vesicles. The lesion heals with central clearing as the margin advances. On thick stratum corneum, such as the interdigital spaces of the feet, the red, itching lesions, known as athlete's foot or tinea pedis, become more serious if secondary bacterial infection develops. The ringworm fungi may also invade the hair shaft (tinea capitis) or the nail (onychomycosis). Many pharmaceutical agents are available to treat or arrest such infections, but control of transmission to others is important. *See* FUNGAL INFECTIONS; FUNGI; YEAST. [C.Ha.; J.P.W.]

Medical parasitology The study of diseases of humans caused by parasitic agents. It is commonly limited to parasitic worms (helminths) and the protozoa. Current usage places the various nonprotozoan microbes in distinct disciplines, such as virology, rickettsiology, and bacteriology.

Nematodes. The roundworms form an extremely large yet fairly homogeneous assemblage, most of which are free-living (nonparasitic). Some parasitic nematodes, however, may cause disease in humans (zoonosis), and others cause disease limited to human hosts (anthroponosis). Among the latter, several are enormously abundant and widespread. *See* NEMATA.

The giant roundworm (*Ascaris lumbricoides*) parasitizes the small intestine, probably affecting over a billion people; and the whipworm (*Trichuris trichiura*) infects the human colon, probably affecting a half billion people throughout the tropics. Similarly, the hookworms of humans, *Necator americanus* in the Americas and the tropical regions of Africa and Asia, and *Ancylostoma duodenale* in temperate Asia, the Mediterranean, and Middle East, suck blood from the small intestine and cause major debilitation, especially among the undernourished. The human pinworm (*Enterobius vermicularis*) infects the large intestine of millions of urban dwellers. Most intestinal nematodes, which require a period of egg maturation outside the human host before they are infective, are associated with fecal contamination of soil or food crops and are primarily rural in distribution.

The nonintestinal nematodes are spread by complex life cycles that usually involve bloodsucking insects. One exception is the guinea worm (*Dracunculus medinensis*), a skin-infecting 2–3-ft (0.6–1-m) worm transmitted by aquatic microcrustaceans that are ingested in drinking water that has been contaminated by larvae that escape from the skin sores of infected humans. Such bizarre life cycles are typical of many helminths. Other nematodes of humans include (1) the filarial worms, which are transmitted by mosquitoes and may induce enormously enlarged fibrous masses in legs, arms, or genitalia (elephantiasis), and (2) *Onchocerca volvulus*, which is transmitted by blackflies (genus *Simulium*) and forms microscopic embryos (microfilariae) in the eyes causing high incidence of blindness in Africa and parts of central and northern South America.

A more familiar tissue-infecting nematode of temperate regions is *Trichinella spiralis*, the pork or trichina worm, which is the agent of trichinosis. The tiny spiraled larvae encyst in muscle and can carry the infection to humans and other carnivorous mammals who eat raw or undercooked infected meat.

Trematodes. Parasites of the class Trematoda vary greatly in size, form, location in the human host, and disease produced, but all go through an initial developmental period in specific kinds of fresh-water snails, where they multiply as highly modified larvae of different types. Ultimately, an infective larval stage (cercaria) escapes in large numbers from the snail and continues the life cycle. Each trematode species follows a highly specific pathway from snail to human host, usually by means of another host or transport mechanism. These include the intestinal, liver, blood, and lung flukes. *See* SCHISTOSOMIASIS; TREMATODA.

Cestodes. Tapeworms, the other great assemblage of parasitic flatworms, parasitize most vertebrates, with eight or more species found in humans. Their flat ribbonlike body form consists of a chain of hermaphroditic segments. Like the trematodes, their life cycles are complex, although not dependent on a snail host. The enormous beef tapeworm of humans, *Taenia saginata*, is transmitted by infected beef ("measly beef") from cattle that grazed where human feces containing egg-filled tapeworm segments contaminated the soil. Other tapeworms include the pork, dog, and broad (or fish) tapeworms. *See* CESTODA.

Protozoa. Of the many protozoa that can reside in the human gut, only the invasive strain of *Entamoeba histolytica* causes serious disease. This parasite, ingested in water contaminated with human feces containing viable cysts of *E. histolytica*, can cause the disease amebiasis, which in its most severe form is known as amebic dysentery. Another common waterborne intestinal protozoon is the flagellate *Giardia lamblia*, which causes giardiasis, a mild to occasionally serious or long-lasting diarrhea. *See* GIARDIASIS; PROTOZOA.

Other flagellate parasites infect the human skin, bloodstream, brain, and viscera. The tsetse fly of Africa carries to humans the blood-infecting agents of trypanosomiasis, or African sleeping sickness, *Trypanosoma brucei gambiense* and *T. brucei rhodesiense*. The infection can be fatal if the parasites cross the blood-brain barrier. In Latin America, the flagellate *T. cruzi* is the agent of Chagas' disease, a major cause of debilitation and premature heart disease among those who are poorly housed. The infection is transmitted in the liquid feces of a conenose bug (genus *Triatoma*) and related insects. The infective material is thought to be scratched into the skin or rubbed in the eye, especially by sleeping children. *See* TRYPANOSOMATIDAE.

Another group of parasitic flagellates includes the macrophage-infecting members of the genus *Leishmania*, which are transmitted by blood-sucking midges or sand flies. Cutaneous leishmaniasis is characterized by masses of infected macrophages in the skin, which induce long-lasting dermal lesions of varying form and severity. The broad spectrum of host-parasite interactions is well exemplified by leishmaniases. The various manifestations of the disease are the result of the particular species of agent and vector, the immunological status of the host, the presence or absence of reservoir hosts, and the pattern of exposure.

Two remaining major groups of protozoa are the ciliates and the sporozoans. The former group is largely free-living, with only a single species, *Balantidium coli*, parasitic in humans (and pigs). This large protozoon is found in the large intestine, where it can cause balantidiasis, an ulcerative disease. The sporozoans, on the other hand, are all parasitic and include many parasites of humans. The most important are the agents of malaria. Other disease agents are included in the genera *Isospora, Sarcocystis, Cryptosporidium*, and *Toxoplasma. Pneumocystis*, a major cause of death among persons with acquired immune deficiency syndrome (AIDS), was formerly considered a protozoon of uncertain relationship, but now it is thought to be a member of the Fungi. *See* ACQUIRED IMMUNE DEFICIENCY SYNDROME (AIDS); MALARIA; SPOROZOA.

Toxoplasma gondii, the agent of toxoplasmosis, infects as many as 20% of the world's population. It can penetrate the placenta and infect the fetus if the mother has not been previously infected and has no antibodies. As with most medically important parasites, the great majority of *Toxoplasma* infections remain undetected and nonpathogenic. The parasite primarily affects individuals lacking immune competence—the very young, the very old, and the immunosuppressed. *See* MEDICAL BACTERIOLOGY; MEDICAL MYCOLOGY; PARASITOLOGY; ZOONOSES. [D.He.]

Medical ultrasonic tomography A mapping or imaging technique, used to obtain clinically useful information about the structure and functioning of tissues and organs, in which acoustic pulses are emitted from an acoustoelectric transducer, and echoes are received from acoustic impedance discontinuities along the assumed line-of-sight axial propagation path. A number of different modes of operation have emerged, each having areas of usefulness.

The A (amplitude) mode uses acoustic pulse emissions and echo reception along a single line-of-sight axial propagation path, and thus provides a one-dimensional mapping. This mode of operation cannot provide identification of structural features. It is, however, a most accurate method of measuring time delays and, therefore, distances between echo-producing structures or distances of structures from transducers, provided the speed of sound propagation in the medium is known.

The M mode of operation is used to display the movement of time-varying, echo-producing structures by intensity-modulating the trace as it is swept slowly across the oscilloscope screen in a direction at right angles to the fast time-base sweep. This mode of operation is used extensively in diagnosing disorders of the heart. *See* ECHOCARDIOGRAPHY; HEART DISORDERS.

For a two-dimensional picture to be obtained, the line-of-sight propagation path must be scanned and the position and direction of the path monitored and used to form a two-dimensional picture. Typically, the B-mode display is formed by moving the transducer so that the line-of-sight path remains in a single plane. The time-base trace of the cathode-ray oscilloscope screen is moved to correspond, in position and direction, to the ultrasonic line-of-sight propagation path, and echoes are displayed as intensity modulations of the trace.

The C (constant-range) mode provides a two-dimensional image display at constant time delay, and presumed constant distance, from the ultrasonic transducer. The scanning is arranged so that the point at constant depth along the propagation path (beam axis) traverses a plane. *See* MEDICAL IMAGING; ULTRASONICS. [F.Du.]

Medical waste Any solid waste that is generated in the diagnosis, treatment, or immunization of human beings or animals, in research pertaining thereto, or in the production or testing of biologicals. Since the development of disposable medical products in the early 1960s, the issue of medical waste has confronted hospitals and regulators. Previously, reusable products included items such as linen, syringes, and bandages; they were sterilized or disinfected prior to reuse, and the principal waste product was limited to human pathological tissue.

Most hazardous substances are described by their relevant properties, such as corrosive, poison, or flammable. Medical waste was originally defined in terms of its infectious properties, and thus it was called infectious waste. However, given the difficulty of identifying pathogenic organisms in waste that might cause disease, it has become standard practice to define medical waste by types or categories. While definitions differ somewhat under different regulations, in the United States the Centers for Disease Control and Prevention (CDC) cite four categories of infective wastes that should require special handling and treatment: laboratory cultures and stocks, pathology wastes, blood, and items that possess sharp points such as needles and syringes (sharps). These categories require that the generator of these wastes exercise judgment in identifying the material to be included.

The waste category that has generated a great deal of interest is sharps. Needles and syringes, in particular, pose risks, since the instruments can penetrate into the body, increasing the potential for disease transmission. Improper disposal of these items in the past has been the catalyst for increased regulation and tighter management control.

Treatment of medical waste constitutes a method for rendering it noninfectious prior to disposal in a landfill or other solid-waste site. The treatment technologies currently used for medical waste include incineration, sterilization, chemical disinfection, and microwave, as well as others under development. *See* HAZARDOUS WASTE. [R.A.Sp.]

Medicine The field of science devoted to healing. Many subdivisions exist and more ramifications appear almost daily. Included in the area of medicine are the clinical specialties of surgery, pediatrics, psychiatry, obstetrics, and others. Internal medicine is the specialization which deals with internal diseases of a nonsurgical nature.

Related to the clinical specialties, particularly in regard to medical education and research, are the basic medical sciences. These include, among others, anatomy, physiology, psychology, pharmacology, biochemistry, and microbiology. Midway between the basic and the clinical sciences lies pathology, the study of the structural and functional alterations caused by diseases or abnormal states.

An important area in all specialties is preventive medicine and public health. This form of medicine supplies a necessary link with the community, state, or large geographic region in matters of prevention, mass treatment, and statistical appraisals of health matters. It is also concerned with socioeconomic factors related to physical and mental well-being. *See* PUBLIC HEALTH.

Socialized medicine is that form which exists under the direct control and financing of the state. The National Health Service of Great Britain is the best-known example, and other systems exist.

Other subdivisions of medicine, with names that are largely self-explanatory, include veterinary, legal, tropical, and military medicine. *See* FORENSIC MEDICINE.

Although medicine is based primarily upon scientific information and method, an important feature is the relationship between the physician and the patient. It is at this point that the necessary scientific background of medicine gives way to the art of healing. *See* SURGERY. [E.G.St./N.K.M.]

Mediterranean Sea The Mediterranean Sea lies between Europe, Asia Minor, and Africa. It is completely landlocked except for the Strait of Gibraltar, the Bosporus, and the Suez Canal. The Mediterranean is conveniently divided into an eastern basin and a western basin, which are joined by the Strait of Sicily and the Strait of Messina.

The total water area of the Mediterranean is 965,900 mi^2 (2,501,000 km^2), and its average depth is 5040 ft (1536 m). The greatest depth in the western basin is 12,200 ft (3719 m), in the Tyrrhenian Sea. The eastern basin is deeper, with a greatest depth of 18,140 ft (5530 m) in the Ionian Sea about 34 mi (55 km) off the Greek mainland. The Atlantic tide disappears in the Strait of Gibraltar. The tides of the Mediterranean are predominantly semidiurnal. [J.Ly.]

Meiosis The set of two successive cell divisions that serve to separate homologous chromosome pairs prior to the formation of gametes (sperm and eggs). The major purpose of meiosis is the precise reduction in the number of chromosomes by one-half, so that a diploid cell can create haploid gametes. Meiosis is therefore a critical component of sexual reproduction. *See* GAMETOGENESIS.

The basic events of meiosis are actually quite simple. As the cell begins meiosis, each chromosome has already duplicated its deoxyribonucleic acid (DNA) and carries two identical copies of the DNA molecule. These are visible as two lateral parts, called sister chromatids, which are connected by a centromere. Homologous pairs of chromosomes are first identified and matched. This process, which occurs only in the first of the two meiotic divisions, is called pairing. The matched pairs are then physically interlocked by recombination, which is also known as exchange or crossing-over. After recombination, the homologous chromosomes separate from each other, and at the first meiotic division are partitioned into different nuclei. As a consequence, the second meiotic division begins with half of the original number of chromosomes. During this second meiotic division, the sister chromatids of each chromosome separate and migrate to different daughter cells. *See* CHROMOSOME.

The patterns by which genes are inherited are determined by the movement of the chromosomes during the two meiotic divisions. It is a fundamental tenet of mendelian inheritance that each individual carries two copies of each gene, one derived from its father and one derived from its mother. Moreover, each of that individual's gametes will carry only one copy of that gene, which is chosen at random. The process by which the two copies of a given gene are distributed into separate gametes is referred to as segregation. Thus, if an individual is heterozygous at the *A* gene for two different alleles, *A* and *a*, his or her gametes will be equally likely to carry the *A* allele or the *a* allele, but never both or neither. The fact that homologous chromosomes, and thus homologous genes, segregate to opposite poles at the first meiotic division explains this principle of inheritance. *See* CELL CYCLE.

Meiotic divisions. The two meiotic divisions may be divided into a number of distinct stages. Meiotic prophase refers to the period after the last cycle of DNA replication, during which time homologous chromosomes pair and recombine. The end of prophase is signaled by the breakdown of the nuclear envelope, and the association of the paired chromosomes with the meiotic spindle. The spindle is made up of microtubules that, with associated motor proteins, mediate chromosome movement. In some cases (such as human sperm formation), the spindle is already formed at the point of nuclear envelope breakdown, and the chromosomes then attach to it. In other systems (such as human female meiosis), the chromosomes themselves organize the spindle.

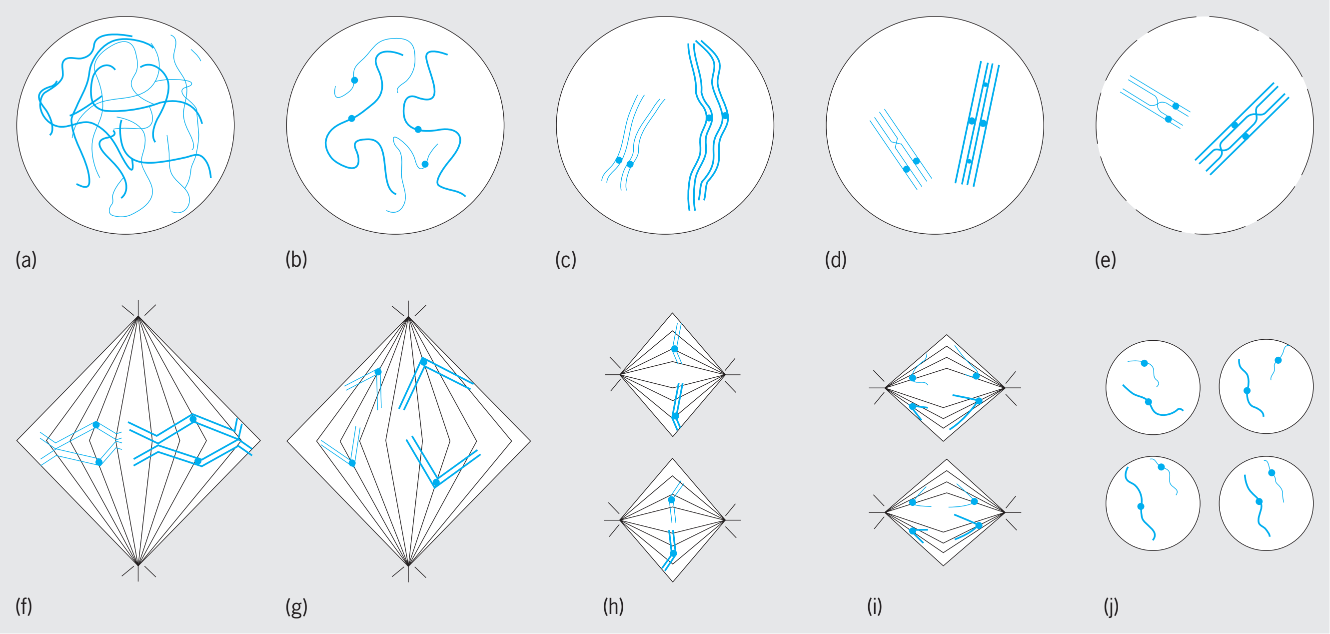
Metaphase I is the period before the first division during which pairs of interlocked homologous chromosomes, called bivalents, line up on the middle of the meiotic spindle. The chromosomes are primarily (but not exclusively) attached to the spindle by their centromeres such that the centromere of one homolog is attached to spindle fibers emanating from one pole, and the centromere of its partner is attached to spindle fibers from the other pole (see illustration). The bivalents are physically held together by structures referred to as chiasmata that are the result of meiotic recombination events. In most meiotic systems, meiosis will not continue until all of the homolog pairs are properly oriented at the middle of the spindle, the metaphase plate. The orientation of each pair of homologs on the spindle occurs in a random fashion, such that the paternally derived homolog of one bivalent may point toward one pole of the spindle, while in the adjacent bivalent the maternally derived homolog is oriented toward the same pole.

Anaphase I refers to the point at which homologous chromosome pairs separate and move to opposite poles. Depending on the organism, there may or may not be a true telophase, or a time in which nuclei reform. In most organisms, the first cell division occurs after the completion of anaphase I.

Following the completion of the first meiotic division, the chromosomes recondense and align themselves on a new pair of spindles, with their sister chromatids oriented toward opposite poles. The stage at which each chromosome is so aligned is referred to as metaphase II. In some, but not all, organisms, metaphase II is preceded by a brief prophase II. DNA replication does not occur during prophase II; each chromosome still consists of the two sister chromatids. Nor are there opportunities for pairing or recombination at this stage due to the prior separation of homologs at anaphase I.

The start of anaphase II is signaled by the separation of sister centromeres, and the movement of the two sister chromatids to opposite poles. At telophase II, the sisters have reached opposite poles and the nuclei begin to reform. The second cell division usually occurs at this time. Thus, at the end of the second meiotic division, there will be four daughter cells, each with a single copy of each chromosome.

Details of meiotic prophase. Because pairing and recombination occur during the first meiotic prophase, much attention has been focused on this stage of the process. The prophase of the first meiotic division is subdivided into five stages: leptotene,



Stages of meiosis. (*a*) Pre-meiotic interphase. (*b*) Leptotene. (*c*) Zygotene. (*d*) Pachytene. (*e*) Diplotene/ diakinesis. (*f*) Metaphase I. (*g*) Anaphase I. (*h*) Metaphase II. (*i*) Anaphase II. (*j*) Telophase II.

zygotene, pachytene, diplotene, and diakinesis (see illustration). Homolog recognition, alignment, and synapsis occur during leptotene and zygotene. In the leptotene, initial homolog alignments are made. By zygotene, homologous chromosomes have become associated at various points along their length. These associations facilitate a more intimate pairing that results in the homologous chromosomes lying abreast of a tracklike structure called the synaptonemal complex. The beginning of pachytene is signaled by the completion of a continuous synaptonemal complex running the full length of each bivalent. During diplotene, the attractive forces that mediated homologous pairing disappear, and the homologs begin to repel each other. However, homologs virtually always recombine, and those recombination events can be seen as chiasmata that tether the homologs together. The final stage in meiotic prophase is diakinesis, during which the homologs shorten and condense in preparation for nuclear division.

Recombination. Meiotic recombination involves the physical interchange of DNA molecules between the two homologous chromosomes, thus allowing the creation of new combinations of alleles for genes located on that pair of chromosomes. Recombination involves the precise breakage and rejoining of two nonsister chromatids. The result is the formation of two recombinant chromatids, each of which carries information from both of the original homologs. The number and position of recombination events is very precisely controlled. Exchange occurs only in the gene-rich euchromatin that makes up most of the chromosome arms, never in the heterochromatin that surrounds the centromeres. Moreover, as a result of a process known as interference, the occurrence of one exchange in a given chromosomal region greatly decreases the probability of a second exchange in that region. *See* RECOMBINATION (GENETICS).

Errors of meiosis. The failure of two chromosomes to segregate properly is called nondisjunction. Nondisjunction occurs either because two homologs failed to pair and/or recombine or because of a failure of the cell to properly move the segregating chromosomes on the meiotic spindle. The result of nondisjunction is the production of gametes that are aneuploid, carrying the wrong number of chromosomes. When such a gamete is involved in a fertilization event, the resulting zygote is also aneuploid. Those cases where the embryo carries an extra copy of a given chromosome are said to be trisomic, while those that carry but one copy are said to be monosomic for that chromosome. Most aneuploid zygotes are not viable and result in early spontaneous abortion. There are no viable monosomies for the human autosomes; however, a few types of trisomic zygotes are capable of survival. These are trisomies for the sex chromosomes (XXX, XXY, XYY), trisomy 21 (Down syndrome), trisomy 18, and trisomy 13. *See* CROSSING-OVER (GENETICS).

Meiosis versus mitosis. The fundamental difference between meiosis and mitosis is that at the first meiotic division, sister chromatids do not separate; rather, homologous chromosomes separate from each other with their sister chromatids still attached to each other. Recombination is frequent in most meiotic cells; however, it occurs only rarely in mitotic cells, usually as part of DNA repair events. Most critically, DNA synthesis occurs only once within the two meiotic divisions, while there is a complete replication before every mitotic division. This allows mitosis to produce two genetically identical daughter cells, while meiosis produces four daughter cells, each of which have only one-half the number of chromosomes present prior to meiosis. *See* CELL DIVISION; GENE; MITOSIS. [M.Y.W.; R.S.H.]

Meissner effect

The expulsion of magnetic flux from the interior of a superconducting metal when it is cooled in a magnetic field to below the critical temperature, near absolute zero, at which the transition to superconductivity takes place. It was discovered by Walther Meissner in 1933, when he measured the magnetic field surrounding two adjacent long cylindrical single crystals of tin and observed that at −452.97°F (3.72 K) the Earth's magnetic field was expelled from their interior. This indicated that at the onset of superconductivity they became perfect diamagnets. This discovery showed that the transition to superconductivity is reversible, and that the laws of thermodynamics apply to it. The Meissner effect forms one of the cornerstones in the understanding of superconductivity, and its discovery led F. London and H. London to develop their phenomenological electrodynamics of superconductivity. *See* DIAMAGNETISM; THERMODYNAMIC PRINCIPLES.

The magnetic field is actually not completely expelled, but penetrates a very thin surface layer where currents flow, screening the interior from the magnetic field.

The Meissner effect is subject to limitations. Full diamagnetism is not observed in polycrystalline samples, and the effect is not observed in impure samples or samples with certain geometrics, such as a round flat disk, with the magnetic field parallel to the axis of rotation. *See* Superconductivity. [H.W.M.]

Meitnerium The seventeenth of the synthetic transuranium elements. Element 109 falls in column 9 of the periodic table under the elements cobalt, rhodium, and iridium. It is expected to have chemical properties similar to those of iridium. *See* Iridium; Periodic table; Transuranium elements.

Element 109 was discovered in 1982 by a team under P. Armbruster and G. Münzenberg at the Gesellschaft für Schwerionenforschung (GSI) at Darmstadt, Germany. In a sequence of bombardments of bismuth-209 targets with beams of ions of titanium-50, chromium-54, and iron-58, the compound systems $^{259}105$, $^{263}107$, and $^{267}109$ were produced. The decay analysis of the isotopes produced showed in the case of elements 105 and 107 the production of $^{258}105$ and $^{262}107$ by reaction channels in which one neutron is emitted. These isotopes have odd neutron and proton numbers and possess a special stability against spontaneous fission. It was shown that alpha-particle decay dominated the decay chains. Spontaneous fission occurs through a 30% electron capture branch of $^{256}105$ in $^{258}104$. Three decay chains were observed for the three reactions ending by fission of $^{258}104$, and the decay of the first atom of element 109 was observed. *See* Alpha particles; Dubnium; Nuclear fission; Nuclear reaction; Radioactivity; Rutherfordium.

The single atom of element 109 was produced at a bombarding energy of 299 MeV in the reaction between iron-58 and bismuth-209. A total dose of 7×10^{17} ions was used to bombard thin layers of bismuth during a 250-h irradiation time. [P.Ar.]

Melanterite A mineral having composition $FeSO_4 \cdot 7H_2O$. Melanterite occurs mainly in green, fibrous or concretionary masses, or in short, monoclinic, prismatic crystals. Luster is vitreous, hardness is 2 on Mohs scale, and specific gravity is 1.90.

Melanterite is a common secondary mineral derived from oxidation and hydration of iron sulfide minerals such as pyrite and marcasite. Its occurrence is widespread. It is not an ore mineral. *See* Marcasite. [E.C.T.C.]

Melilite A complete solid solution series ranging from gehlenite, $Ca_2Al_2SiO_7$, to akermanite, $Ca_2MgSi_2O_7$, often containing appreciable Na and Fe. The Mohs hardness is 5–6, and the density increases progressively from 2.94 for akermanite to 3.05 for gehlenite. The luster is vitreous to resinous, and the color is white, yellow, greenish, reddish, or brown. Akermanite-rich varieties occur in thermally metamorphosed siliceous limestones and dolomites, but more gehlenite-rich ones result if Al is present. Melilites are found instead of plagioclase in silica-deficient, feldspathoid-bearing basalts. *See* Silicate minerals. [L.Gr.]

Melting point The temperature at which a solid changes to a liquid. For pure substances, the melting or fusion process occurs at a single temperature, the temperature rise with addition of heat being arrested until melting is complete.

Melting points reported in the literature, unless specifically stated otherwise, have been measured under an applied pressure of 1 atm (10^5 pascals), usually 1 atm of air. (The solubility of air in the liquid is a complicating factor in precision measurements.) Upon melting, all substances absorb heat, and most substances expand; consequently an increase in pressure normally raises the melting point. A few substances, of which water is the most notable example, contract upon melting; thus, the application of pressure to ice at 32°F (0°C) causes it to melt. Large changes in pressure are required to produce significant shifts in the melting point.

For solutions of two or more components, the melting process normally occurs over a range of temperatures, and a distinction is made between the melting point, the temperature at which the first trace of liquid appears, and the freezing point, the higher temperature at which the last trace of solid disappears, or equivalently, if one is cooling rather than heating, the temperature at which the first trace of solid appears. *See* Phase equilibrium; Solution; Sublimation; Triple point. [R.L.S.]

Membrane distillation A separation method in which a nonwetting, microporous membrane is used with a liquid feed phase on one side of the membrane and a condensing, permeate phase on the other side. Separation by membrane distillation is based on the relative volatility of various components in the feed solution. The driving force for transport is the partial pressure difference across the membrane. Separation occurs when vapor from components of higher volatility passes through the membrane pores by a convective or diffusive mechanism. *See* Convection (heat).

Membrane distillation shares some characteristics with another membrane-based separation known as pervaporation, but there also are some vital differences. Both methods involve direct contact of the membrane with a liquid feed and evaporation of the permeating components. However, while membrane distillation uses porous membranes, pervaporation uses nonporous membranes.

Membrane distillation systems can be classified broadly into two categories: direct-contact distillation and gas-gap distillation. These terms refer to the permeate or condensing side of the membrane; in both cases the feed is in direct contact with the membrane. In direct-contact membrane distillation, both sides of the membrane contact a liquid phase; the liquid on the permeate side is used as the condensing medium for the vapors leaving the hot feed solution. In gas-gap membrane distillation, the condensed permeate is not in direct contact with the membrane.

Potential advantages of membrane distillation over traditional evaporation processes include operation at ambient pressures and lower temperatures as well as ease of process scale-up. *See* Chemical separation techniques; Membrane separations. [S.S.K.; N.N.L.]

Membrane mimetic chemistry The study of processes and reactions whose developments have been inspired by the biological membrane. Faithful modeling of the biomembrane is not an objective of membrane mimetic chemistry. Rather, only the essential components of natural systems are recreated from relatively simple, synthesized molecules. (The term membrane mimetic is more restrictive than the term biomimetic. Biomimetic chemistry is directed at the mechanistic elucidation of biochemical reactions and at the development of new compounds modeled on specific biological systems.) *See* Cell membranes.

Various surfactant aggregate systems have been used in membrane mimetics.

Surfactants (detergents) contain distinct hydrophobic (apolar) and hydrophilic (polar) regions. Depending on the chemical structure of their hydrophilic polar head groups, surfactants can be neutral, positively charged, or negatively charged. *See* Detergent.

Aqueous micelles are spherical aggregates, 4–8 nanometers in diameter, formed dynamically from surfactants in water above a characteristic concentration, the critical micelle concentration. *See* Micelle.

Monomolecular layers are formed by spreading naturally occurring lipids or synthetic surfactants, dissolved in volatile solvents, over water in a trough. The polar head groups of the surfactants are in contact with water, the subphase, while their hydrocarbon tails protrude above it. *See* Monomolecular film.

Other systems used in membrane mimetics are multilayer assemblies (Langmuir-Blodgett films), bilayer lipid membranes, and vesicles prepared by sonication from naturally occurring lipids. *See* SONOCHEMISTRY.

Membrane mimetic chemistry has become a versatile chemical tool. Applications of compartmentalization of reactants in membrane mimetic systems involve altered reaction rates, products, stereochemistries, and isotope distributions. Monolayers and organized multilayers can be employed profitably as molecular electronic devices. Opportunities also exist for using different surfactant aggregates with polymeric membranes for the control and regulation of reverse osmosis and ultrafiltration. *See* SURFACTANT; ULTRAFILTRATION. [J.H.Fe.]

Membrane separations Processes for separating mixtures by using thin barriers (membranes) between two miscible fluids. A suitable driving force across the membrane, for example concentration or pressure differential, leads to the preferential transport of one or more feed components.

Membrane separation processes are classified under different categories depending on the materials to be separated and the driving force applied: (1) In ultrafiltration, liquids and low-molecular-weight dissolved species pass through porous membranes while colloidal particles and macromolecules are rejected. The driving force is a pressure difference. (2) In dialysis, low-molecular-weight solutes and ions pass through while colloidal particles and solutes with molecular weights greater than 1000 are rejected under the conditions of a concentration difference across the membrane. (3) In electrodialysis, ions pass through the membrane in preference to all other species, due to a voltage difference. (4) In reverse osmosis, virtually all dissolved and suspended materials are rejected and the permeate is a liquid, typically water. (5) For gas and liquid separations, unequal rates of transport can be obtained through nonporous membranes by means of a solution and diffusion mechanism. Pervaporation is a special case of this separation where the feed is in the liquid phase while the permeate, typically drawn under subatmospheric conditions, is in the vapor phase. (6) In facilitated transport, separation is achieved by reversible chemical reaction in the membrane. High selectivity and permeation rate may be obtained because of the reaction scheme. Liquid membranes are used for this type of separation. *See* DIALYSIS; ION-SELECTIVE MEMBRANES AND ELECTRODES; OSMOSIS; TRANSPORT PROCESSES; ULTRAFILTRATION. [N.N.L; S.S.K.]

Memory The ability to store and access information that has been acquired through experience. Memory is a critical component of practically all aspects of human thinking, including perception, learning, language, and problem solving. *See* PERCEPTION; PROBLEM SOLVING (PSYCHOLOGY).

Stages. The information-processing approach divides memory into three general stages: sensory memory, short-term memory, and long-term memory. Sensory memory refers to the sensations that briefly continue after something has been perceived. Short-term memory includes all of the information that is currently being processed in a person's mind, and is generally thought to have a very limited capacity. Long-term memory is where all the information that may be used at a later time is kept.

A number of interesting facts are known about sensory memory, including the following: (1) sensory memories appear to be associated with mechanisms in the central nervous system rather than at the sensory receptor level, and (2) the amount of attention that a person pays to a stimulus can affect the duration of the sensory memory. Although all of the functions of sensory memory are not understood, one of its most important purposes is to provide people with additional time to determine what should be transferred to the next stage in the memory system, that is, short-term memory.

Information obtained from either sensory memory or long-term memory is processed in short-term memory in order for a person to achieve current goals. In some situations, short-term memory processing simply involves the temporary maintenance of a piece of information, such as remembering a phone number long enough to dial it. Other times, short-term memory can involve elaborate manipulations of information in order to generate new forms. For example, when someone reads 27 + 15, the person manipulates the symbols in short-term memory in order to come up with the solution. One useful manipulation that can be done in short-term memory is to reorganize items into meaningful chunks. For example, it is a difficult task to keep the letters S K C A U Q K C U D E H T in mind all at once. However, if they are rearranged in short-term memory, in this case reversing them, they can be reduced to a single simple chunk: THE DUCK QUACKS. Short-term memory can accommodate only five to seven chunks at any one time. However, the amount of information contained in each chunk is constrained only by one's practice and ingenuity. In order to increase the amount of information that can be kept in short-term memory at one time, people need to develop specific strategies for organizing that information into meaningful chunks. In addition, many studies have also demonstrated that the transfer of information from short-term to long-term memory is much greater when the information is manipulated rather than simply maintained.

One can keep massive amounts of information in long-term memory. In general, recall from long-term memory simply involves figuring out the heading under which a memory has been filed. Many tricks for effective retrieval of long-term memories involve associating the memory with another more familiar memory that can serve as an identification tag. This trick of using associations to facilitate remembering is called mnemonics. Long-term memory stores related concepts and incidents in close range of one another. This logical association of memories is indicated by subjects' reaction times for identifying various memories. Generally, people are faster at recalling memories if they have recently recalled a related memory. One good way to locate a long-term memory is to remember the general situation under which it was stored. Accordingly, techniques that reinstate the context of a memory tend to facilitate remembering.

Sometimes information may not have been filed in long-term memory in the first place, or if it has, is inaccessible. In these situations, the long-term memory system often fills in the gaps by using various constructive processes. One common component to memory constructions is a person's expectations. Countless studies have also indicated that memories tend to systematically change in the direction of a prior expectation or inference about what is likely to have occurred.

Physiology. A number of physiological mechanisms appear to be involved in the formation of memories, and the mechanisms may differ for short-term and long-term memory. There is both direct and indirect evidence suggesting that short-term memory involves the temporary circulation of electrical impulses around complex loops of interconnected neurons. A number of indirect lines of research indicate that short-term memories are eradicated by any event that either suppresses neural activity (for example, a blow to the head or heavy anesthesia) or causes neurons to fire incoherently (for example, electroconvulsive shock). More direct support for the electric circuit model of short-term memory comes from observing electrical brain activity. By implanting electrodes in the brain of experimental animals, researchers have observed that changes in what an animal is watching are associated with different patterns of circulating electrical activity in the brain. These results suggest that different short-term memories may be represented by different electrical patterns. However, the nature of these patterns is not well understood. *See* ELECTROENCEPHALOGRAPHY.

Long-term memories appear to involve some type of permanent structural or chemical change in the composition of the brain. This conclusion is derived both from general observations of the imperviousness of long-term memories and from physiological studies indicating specific changes in brain composition. Even in acute cases of amnesia where massive deficits in long-term memory are reported, often, with time, all long-term memories return. Similarly, although electroconvulsive therapy is known to eliminate recent short-term memories, it has practically no effect on memories for events occurring more than an hour prior to shocking. Thus the transfer from a fragile short-term memory to a relatively solid long-term memory occurs within an hour. This process is sometimes called consolidation. *See* ELECTROCONVULSIVE THERAPY.

The nature of the “solid” changes associated with long-term memories appears to involve alterations in both the structural (neural connections) and chemical composition of the brain. One study compared the brains of rats that had lived either in enriched environments with lots of toys or in impoverished environments with only an empty cage. The cerebral cortices of the brains of the rats from the enriched environment were thicker, heavier, endowed with more blood vessels, and contained significantly greater amounts of certain brain chemicals (such as the neurotransmitter acetylcholine). Other researchers have observed that brief, high-frequency stimulation of a neuron can produce long-lasting changes in the neuron’s communications across synapses.

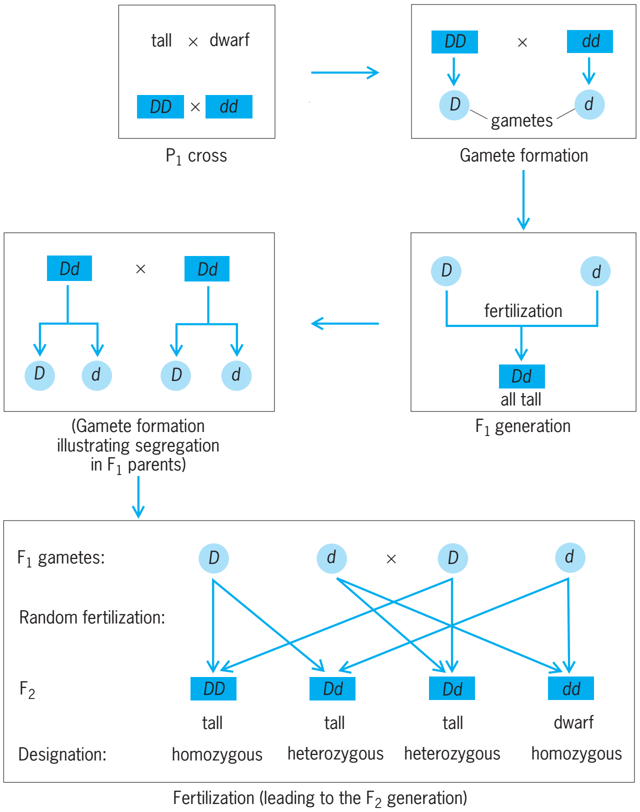
Researchers believe that different brain structures may be involved in the formation and storage of long-term memories. The hippocampus, thalamus, and amygdala are believed to be critical in the formation of long-term memories. Individuals who have had damage to these structures are able to recall memories prior to the damage, indicating that long-term memory storage is intact; however, they are unable to form new long-term memories, indicating that the long-term memory formation process has been disrupted. It is not known where long-term memories are stored, but they may be localized in the same areas of the brain that participated in the actual learning. *See* BRAIN. [J.Sc.; E.F.Lo.]

Mendelevium A chemical element, Md, atomic number 101, the twelfth member of the actinide series of elements. Mendelevium does not occur in nature; it was discovered and is prepared by artificial nuclear transmutation of a lighter element. Known isotopes of mendelevium have mass numbers from 248 to 258 and half-lives from a few seconds to about 55 days. They are all produced by charged-particle bombardments of more abundant isotopes. The amounts of mendelevium which are produced and used for studies of chemical and nuclear properties are usually less than about a million atoms; this is of the order of a million times less than a weighable amount. Studies of the chemical properties of mendelevium have been limited to a tracer scale. The behavior of mendelevium in ion-exchange chromatography shows that it exists in aqueous solution primarily in the $3+$ oxidation state characteristic of the actinide elements. However, it also has a dipositive ($2+$) and a monopositive ($1+$) oxidation state. *See* ACTINIDE ELEMENTS; PERIODIC TABLE; TRANSURANIUM ELEMENTS. [G.T.S.]

Mendelism Fundamental principles governing the transmission of genetic traits, discovered by an Augustinian monk Gregor Mendel in 1856. Mendel performed his first set of hybridization experiments with pea plants. Although the pea plant is normally self-fertilizing, it can be easily crossbred, and grows to maturity in a single season. True breeding strains, each with distinct characteristics, were available from local seed merchants. For his experiments, Mendel chose seven sets of contrasting characters or traits. For stem height, the true breeding strains tall (7 ft or 2.1 m) and dwarf (18 in. or 45 cm) were used. He also selected six other sets of traits, involving the shape and color of seeds, pod shape and color, and the location of flowers on the plant stem.

The most simple crosses performed by Mendel involved only one pair of traits; each such experiment is known as a monohybrid cross. The plants used as parents in these crosses are known as the P$_1$ (first parental) generation. When tall and dwarf plants were crossed, the resulting offspring (called the F$_1$ or first filial generation) were all tall. When members of the F$_1$ generation were self-crossed, 787 of the resulting 1064 F$_2$ (second filial generation) plants were tall and 277 were dwarf. The tall trait is expressed in both the F$_1$ and F$_2$ generations, while the dwarf trait disappears in the F$_1$ and reappears in the F$_2$ generation. The trait expressed in the F$_1$ generation Mendel called the dominant trait, while the recessive trait is unexpressed in the F$_1$ but reappears in the F$_2$. In the F$_2$, about three-fourths of the offspring are tall and one-fourth are dwarf (a 3:1 ratio). Mendel made similar crosses with plants exhibiting each of the other pairs of traits, and in each case all of the F$_1$ offspring showed only one of the parental traits and, in the F$_2$, three-fourths of the plants showed the dominant trait and one-fourth exhibited the recessive trait. In subsequent experiments, Mendel found that the F$_2$ recessive plants bred true, while among the dominant plants one-third bred true and two-thirds behaved like the F$_1$ plants. *See* DOMINANCE.

Law of segregation. To explain the results of his monohybrid crosses, Mendel derived several postulates. First, he proposed that each of the traits is controlled by a factor (now called a gene). Since the F$_1$ tall plants produce both tall and dwarf offspring, they must contain a factor for each, and thus he proposed that each plant contains a pair of factors for each trait. Second, the trait which is expressed in the F$_1$ generation is controlled by a dominant factor, while the unexpressed trait is controlled by a recessive factor. To prevent the number of factors from being doubled in each generation, Mendel postulated that factors must separate or segregate from each other during gamete formation. Therefore, the F$_1$ plants can produce two types of gametes, one type containing a factor for tall plants, the other a factor for dwarf plants. At fertilization, the random combination of these gametes can explain the types and ratios of offspring in the F$_2$ generation (see illustration). *See* FERTILIZATION; GENE.



Schematic representation of a monohybrid cross. Pure-bred tall and dwarf strains are crossed, and yield typical 3:1 ratio in the F$_2$ generation. *D* and *d* represent the tall and dwarf factors (genes), respectively. (*After W. S. Klug and M. R. Cummings, Concepts of Genetics, Charles E. Merrill, 1983*)

Independent assortment. Mendel extended his experiments to examine the inheritance of two characters simultaneously. Such a cross, involving two pairs of contrasting traits, is known as a dihybrid cross. For example, Mendel crossed plants with tall stems and round seeds with plants having dwarf stems and wrinkled seeds. The F_1 offspring were all tall and had round seeds. When the F_1 individuals were self-crossed, four types of offspring were produced in the following proportions: 9/16 were tall, round; 3/16 were tall, wrinkled; 3/16 were dwarf, round; and 1/16 were dwarf, wrinkled. On the basis of similar results in other dihybrid crosses, Mendel proposed that during gamete formation, segregating pairs of factors assort independently of one another. As a result of segregation, each gamete receives one member of every pair of factors [this assumes that the factors (genes) are located on different chromosomes]. As a result of independent assortment, all possible combinations of gametes will be found in equal frequency. In other words, during gamete formation, round and wrinkled factors segregate into gametes independently of whether they also contain tall or dwarf factors. *See* Gametogenesis; Meiosis.

It might be useful to consider the dihybrid cross as two simultaneous and independent monohybrid crosses. In this case, the predicted F_2 results are 3/4 tall, 1/4 dwarf, and 3/4 round, 1/4 wrinkled. Since the two sets of traits are inherited independently, the number and frequency of phenotypes can be predicted by combining the two events:

$$3/4\,\text{tall}\begin{cases}3/4\,\text{round} & (3/4)(3/4) = 9/16\,\text{tall, round}\\ 1/4\,\text{wrinkled} & (3/4)(1/4) = 3/16\,\text{tall, wrinkled}\end{cases}$$

$$1/4\,\text{dwarf}\begin{cases}3/4\,\text{round} & (1/4)(3/4) = 3/16\,\text{dwarf, round}\\ 1/4\,\text{wrinkled} & (1/4)(1/4) = 1/16\,\text{dwarf, wrinkled}\end{cases}$$
