Basic defining elements are common to almost all remote manipulators. An input device or control handle allows the operator to command the remote manipulator. The movement of the input device is received by a control station that translates the inputs into a form that can be transmitted over the distance separating the human and remote manipulator. This translation can be mechanical, using cables and linkages, or electrical/electromagnetic, using the movement of the input device to generate an electrical or electromagnetic signal that is easily transmitted to the remote manipulator. Since vision is an important cue that humans use in direct manipulation, visual feedback of a remote manipulator's actions typically must be provided. In some remote manipulation systems, tactile feedback to the human operator is provided; that is, forces proportional to those being exerted by the remote manipulator on the object are fed back to the human through the input device. Such force feedback is important in certain tasks where the possibility of damage to the manipulator or object can occur.

The growth in the number and variety of remote manipulator applications has been aided by enabling technologies such as digital computers, lightweight materials, and video communication links. Space applications include the space shuttle remote manipulator arm, which has been used to retrieve and launch large satellites. The arm is operated by astronauts in the shuttle orbiter cabin, and employs graphic displays of the forces and torques being applied by the manipulator arm to the satellite. Other applications include use in crewless underwater vehicles and surgical procedures. *See* SPACE SHUTTLE; UNDERWATER VEHICLE.

Aiding the disabled is an important use of remote manipulators. One example is devices that allow individuals with little or no control of their upper extremities to feed themselves. Such devices have been referred to as teletheses (alluding to the extrasensory perception of distant objects).

Devices that augment the strength of the human have been proposed for industrial applications. For example, a load-sharing manipulator has been envisioned in which human arm-manipulator coordination effectively allows the human to work with a "partner" that has considerably more strength. *See* CONTROL SYSTEMS; HUMAN-MACHINE SYSTEMS; ROBOTICS. [R.A.He.]

Remote sensing The gathering and recording of information about terrain and ocean surfaces without actual contact with the object or area being investigated. Remote sensing uses the visual, infrared, and microwave portions of the electromagnetic spectrum. Remote sensing is generally conducted by means of remote sensors installed in aircraft and satellites.

Photography. Photography is probably the most useful remote sensing system. Much of the experience gained over the years from photographs of the terrain taken from aircraft is being drawn upon for use in space.

Multispectral photography isolates the reflected energy from a surface in a number of given wavelength bands and records each spectral band separately on film. This technique allows selection of the significant bandwidths in which a given area of terrain displays maximum tonal contrast and, hence, increases the effective spectral resolution of the system over conventional black-and-white or color systems. Because of its spectral selectivity capabilities, the multispectral approach provides a means of collecting a great amount of specific information.

Multispectral imagery. Multispectral scanning systems record the spectral reflectance by photoelectric means (rather than by photochemical means as in multispectral photography) simultaneously in several individual wavelengths within the visual and near-infrared portions of the electromagnetic spectrum.

In satellite applications, optical energy is sensed by an array of detectors simultaneously in four spectral bands from 0.47 to 1.1 micrometers. As the optical sensors for the various frequency bands sweep across the underlying terrain in a plane perpendicular to the flight direction of the satellite, they record energy from individual areas on the ground. The smallest individual area distinguished by the scanner is called a picture element or pixel, and a separate spectral reflectance is recorded in analog or digital form for each pixel. The spectral reflectance values for each pixel can be transmitted electronically to ground receiving stations in near-real time, or stored on magnetic tape in the satellite until it is over a receiving station. When the signal intensities are received on the ground, they can be reconstructed almost instantaneously into the virtual equivalent of conventional aerial photographs.

Infrared. Thermal infrared radiation is mapped by means of infrared scanners similar to multispectral scanners, but in this case radiated energy is recorded generally in the 8–14-μm portion of the electromagnetic spectrum. The imagery provided by an infrared scanning system gives information that is not available from ordinary photography or from multispectral scanners operating in the visual portion of the electromagnetic spectrum. *See* EMISSIVITY; INFRARED RADIATION.

In the past, thermal infrared images were generally recorded on photographic film. Videotape records are replacing film as the primary recording medium and permit better imagery to be produced and greater versatility in interpretation of data.

Thermal infrared mapping (thermography) from satellite altitudes is proving to be useful for a number of purposes, one of which is the mapping of thermal currents in the ocean. Thermal infrared mapping from aircraft and satellite altitudes has many other uses also, including the mapping of volcanic activity and geothermal sites, location of groundwater discharge into surface and marine waters, and regional pollution monitoring.

Microwave radar. This type of remote sensing utilizes both active and passive sensors. The active sensors such as radar supply their own illumination and record the reflected energy. The passive microwave sensors record the natural radiation. A variety of sensor types are involved. These include imaging radars, radar scatterometers and altimeters, and over-the-hori-zon radars using large ground-based antenna arrays, as well as passive microwave radiometers and imagers. One of the most significant advantages of these instruments is their all-weather capability, both day and night. *See* MICROWAVE; RADAR.

High-frequency (hf) radar. Such radars utilize frequencies in the 3–30-MHz portion of the electromagnetic spectrum (median wavelength of about 20 m) and are thus not within the microwave part of the spectrum. The energy is transmitted by ground-based antennas in either a sky-wave or surface-wave mode. In the sky-wave mode, the energy is refracted by the various ionospheric layers back down to the Earth's surface some 480–1800 mi or 800–3000 km (on a single-hop basis) away from the hf radar antenna site. The incident waves are reflected from such surface features as sea waves. [P.C.B.]

Renewable resources

Agricultural materials used as feedstocks for industrial processes. For many centuries agricultural products were the main sources of raw material for the manufacturing of soap, paint, ink, lubricants, grease, paper, cloth, drugs, and a host of other nonfood products. During the early 1900s, the advances in organic synthesis in western Europe and the United States led to the use of coal as an alternative resource; in the 1940s, oil and natural gas were added as starting materials as a result of great advances in catalysis and polymer sciences. Since then the petrochemical industry has grown rapidly as the result of the abundance and low price of the starting materials as well as the development of new products. However, with the rapidly increasing economies of the nations of the world, these developments did not ever result in reduction in the utilization of agricultural products as industrial materials.

Animal fats, marine and vegetable oils, and their fatty acid derivatives have always played a major role in the manufacturing of many industrial products. Some of these commodities are produced solely for industrial end uses; examples are linseed, tung, castor (not counting minor amounts used for medicinal purposes), and sperm whale oils. Others, such as tallow and soybean oil, are used for both edible and industrial products. *See* DETERGENT; FAT AND OIL; LUBRICANT; SOAP.

Starch, cellulosics, and gums also have been used for many centuries as industrial materials, whereas sugar crops, such as sugarcane and sugarbeet, have mainly satisfied world food requirements. *See* CELLULOSE; GUM; STARCH.

Natural rubber and turpentine are excellent examples of plant-derived hydrocarbons. The development of synthetic rubbers during and after World War II has never threatened the demand for natural rubber; there is generally a world shortage. Turpentine is a product of the wood and paper pulp industry and is used as a solvent and thinner in paints and varnishes. *See* RUBBER.

The threat that industrial nations might be separated from part or all of their traditional sources of raw materials through political and economic upheavals or natural calamities has resulted in a renewed effort to develop additional crops for local agriculture. In the United States, research has provided a number of candidate species that either are now in commercial development or are ready for the time when circumstances warrant such development. Examples are jojoba (liquid wax ester to replace sperm whale oil), guayule (alternate source of natural rubber), kenaf (paper fiber with annual yields much higher than available from trees), and crambe and meadow-foam (long-chain fatty acids, since erucic acid is no longer available from rapeseed oil). There is also active research involving *Cuphea* species (alternate source of lauric and other medium-chain fatty acids, to augment coconut oil), *Vernonia* (source of epoxy oil), and several other promising plants. For example, the Chinese tallow tree has the potential of producing 2.2 tons per acre (5 metric tons per hectare) of seed oil that could be used for manufacturing fuel and other chemicals. [L.H.P.]

Renner-Teller effect

The splitting, into two, of the potential function along the bending coordinate in degenerate electronic states of linear triatomic or polyatomic molecules. Most of the areas and methods of molecular physics and spectroscopy assume the validity of the Born-Oppenheimer approximation. The nuclei generally move much more slowly than the electrons, the frequencies associated with electronic transitions are much higher than vibrational frequencies, and one can consider separately the three types of molecular motion: electronic, vibrational, and rotational. These statements are no longer necessarily valid for electronic states which are degenerate or at least close to degeneracy, and the Born-Oppenheimer approximation breaks down.

Degenerate electronic states usually occur in molecules having a high degree of symmetry. The symmetric equilibrium geometry which causes the electronic degeneracy is, in general, lowered in the course of molecular vibrations, and this may lead to splitting of the potential. The molecular potential is usually expressed in terms of a polynomial expansion in displacements r, and, in nonlinear molecules, the linear terms may lead to coupling of the electronic and vibrational degrees of freedom. The resulting breakdown of the Born-Oppenheimer approximation is in this case known as the Jahn-Teller effect. In linear molecules the symmetry is lowered during bending vibrations. In the bending potential the linear (and other odd) terms are zero by symmetry. The first nonvanishing terms which can couple the degenerate electronic states are quadratic in the bending coordinate. The results of this coupling in linear molecules are referred to as the Renner-Teller effect, or simply the Renner effect. *See* JAHN-TELLER EFFECT; MOLECULAR STRUCTURE AND SPECTRA. [V.E.B.; T.A.M.]

Rennin

Rennin The common name for chymosin, a proteolytic enzyme that is used to coagulate milk in cheese making. Rennin participates in the cheese-ripening process through its proteolytic activity.

The traditional source of rennin is the fourth stomach (abomasum) of calves that have been fed only milk. The stomachs are dried or salted, cut into small pieces, and soaked in 10% salt brine to extract enzyme components from the stomach lining. Rennin also is produced commercially by using genetically engineered microorganisms.

Approximately 6% of the rennin used to coagulate milk is retained in active form in cheese curd. During cheese ripening, rennin modifies the curd protein structure through its proteolytic action on α-casein, leading to textural changes described as a loss of curdiness. Casein peptides resulting from rennin action become precursors for flavor compounds in some cheeses such as Cheddar. *See* CASEIN; CHEESE; ENZYME; MILK. [P.Ki.]

Renormalization A program in quantum field theory consisting of a set of rules for calculating S-matrix amplitudes which are free of ultraviolet (or short-distance) divergences, order by order in perturbative calculations in an expansion with respect to coupling constants. *See* SCATTERING MATRIX.

So far the only field theories known to be renormalizable in four dimensions are those which include spin-0, spin-$^1/_2$, and spin-1 fields such that no term in the lagrangian exceeds operator dimension 4. The operator dimension of any term is calculated by assigning dimension 1 to bosons and derivatives ∂_μ, and dimension $^3/_2$ to fermions. Spin-1 fields are allowed only if they correspond to the massless gauge potentials of a locally gauge-invariant Yang-Mills-type theory associated with any compact Lie group. The gauge invariance can remain exact or can be allowed to break via spontaneous breakdown without spoiling the renormalizability of the theory. In the latter case the spin-1 field develops a mass. The successful quantum chromodynamics theory describing the strong forces and the $SU(2) \times U(1)$ Weinberg-Salam-Glashow gauge model of unified electroweak particle interactions are such renormalizable gauge models containing spin 0, $^1/_2$, and 1 fields. *See* ELECTROWEAK INTERACTION; FUNDAMENTAL INTERACTIONS; GAUGE THEORY; LIE GROUP; QUANTUM CHROMODYNAMICS; QUANTUM ELECTRODYNAMICS; WEAK NUCLEAR INTERACTIONS. [I.Ba.]

Effective field theory is a general and powerful method for analyzing quantum field theories over a wide range of length scales. Together with a closely related idea, the Wilson renormalization group, it places renormalization theory on a more general, physical, and rigorous basis. This method is most naturally developed in the Feynman path integral formulation of quantum field theory, where amplitudes are given by an integral over all histories. Each history is weighted by a phase equal to the classical action divided by Planck's constant. *See* ACTION. [J.Pol.]

Reproduction (animal) The formation of new individuals, which may occur by asexual or sexual methods. In the asexual methods, which occur mainly among the lower animals, the offspring are derived from a single individual. Sexual methods are general throughout the animal kingdom, with offspring ordinarily derived from the paired union of special cells, the gametes, from two individuals. Basic to all processes of reproduction is the origin of the new individual from one or more living cells of the parent or parents.

Asexual reproduction. Asexual processes of reproduction include binary fission, multiple fission, fragmentation, budding, and polyembryony. Among the protozoa and lower metazoa, these are common methods of reproduction. However, the last-mentioned process can occur in mammals, including humans.

Binary fission involves an equal, or nearly equal, longitudinal or transverse splitting of the body of the parent into two parts, each of which grows to parental size and form. This method of reproduction occurs regularly among protozoans.

Multiple fission, schizogony, or sporulation produces several new individuals from a single parent. It is common among the Sporozoa, such as the malarial parasite, which form cystlike structures containing many cells, each of which gives rise to a new individual.

Fragmentation is a form of fission occurring in some metazoans, especially the Platyhelminthes, or flatworms; the Nemertinea, or ribbon worms; and the Annelida, or segmented worms. The parent worm breaks up into a number of parts, each of which regenerates missing structures to form a whole organism.

Budding is a form of asexual reproduction in which the new individual arises from a relatively small mass of cells that initially forms a growth or bud on the parental body. The bud may assume parental form either before separation from the body of the parent as in external budding, or afterward, as in internal budding. External budding is common among sponges, coelenterates, bryozoans, flatworms, and tunicates. Internal budding occurs among fresh-water sponges and bryozoans. In the sponges the internal buds, termed gemmules, consist of groups of primitive cells surrounded by a dense capsule formed by the body wall. If the parent animal dies as a result of desiccation or low temperature, the cells of the gemmules can later be released and form new sponges. In the bryozoans the similarly functioning buds are known as statoblasts.

Polyembryony is a form of asexual reproduction, occurring at an early developmental stage of a sexually produced embryo, in which two or more offspring are derived from a single egg. Examples are found scattered throughout the animal kingdom, including humans; in humans it is represented by identical twins, triplets, or quadruplets.

Sexual reproduction. Sexual reproduction in animals assumes various forms which may be classified under conjugation, autogamy, fertilization (syngamy), and parthenogenesis. Basically, the various processes all involve the occurrence of certain special nuclear changes, termed meiotic divisions, preliminary to the production of the new individual. *See* GAMETOGENESIS; MEIOSIS.

Conjugation occurs principally among the ciliate protozoans, such as *Paramecium*, and involves a temporary union of two individuals during which each is "fertilized" by a micronucleus from the other.

In autogamy the nuclear changes described for conjugation take place, but since there is no mating, there is no transfer of micronuclei. Instead, the prospective migratory micronucleus reunites with the stationary one. The process may be considered related to parthenogenesis.

Fertilization, or syngamy, comprises a series of events in which two cells, the gametes, fuse and their nuclei, which had previously undergone meiotic divisions, fuse. In metazoans, the gametes are of two morphologically distinct types: spermatozoa, or microgametes, and eggs, also called ova or macrogametes. These types are produced by male and female animals, respectively, but in some cases both may be produced by a single, hermaphroditic individual. The nucleus of the spermatozoon has half the number of chromosomes characteristic of the ordinary (somatic) cells of the animal. The nucleus of the ripe egg in some animals, for instance, coelenterates and echinoderms, also has attained this haploid condition, but in most species of animals it is at an early stage of the meiotic divisions when ready for fertilization. In the latter situation, the meiotic divisions of the egg, characterized by formation of small, nonfunctional cells termed polar bodies, are completed after the sperm enters, whereupon the haploid egg nucleus fuses with the haploid sperm nucleus. Fertilization thus produces a zygote with the diploid chromosome number typical of the somatic cells of the species (23 pairs in humans), and this is maintained during the ensuing cell divisions.

Parthenogenesis is the development of the egg without fertilization by a spermatozoon. It is listed as a form of sexual reproduction because it involves development from a gamete. Rotifers, crustaceans, and insects are the principal groups in which it occurs naturally. It has also been induced (artificial parthenogenesis) in species from all the major phyla by various kinds of chemical or physical treatment of the unfertilized egg. Even in mammals, several adult rabbits have reportedly been thus produced. *See* ESTRUS; OOGENESIS; OVUM; SPERM CELL; SPERMATOGENESIS. [A.T.; H.L.H.]

Reproduction (plant)

The formation by a plant of offspring that are either exact copies or reasonable likenesses. When the process is accomplished by a single individual without fusion of cells, it is referred to as asexual; when fusion of cells is involved, whether from an individual or from different donors, the process is sexual.

Asexual reproduction. Using the technique of tissue culture, higher green plants can be regenerated from a single cell and can usually flower and set seed normally when removed and placed in soil. This experiment shows that each cell of the plant body carries all the information required for formation of the entire organism. The culture of isolated cells or bits of tissue thus constitutes a means of vegetative propagation of the plant and can provide unlimited copies identical to the organism from which the cells were derived. *See* TISSUE CULTURE.

All other vegetative reproductive devices of higher plants are elaborations of this basic ability and tendency of plant cells to produce tissue masses that can organize into growing points (meristems) to yield the typical patterns of differentiated plant organs. For example, a stem severed at ground level may produce adventitious roots. Similarly, the lateral buds formed along stems can, if excised, give rise to entire plants. The “eyes” of the potato tuber, a specialized fleshy stem, are simply buds used in vegetative propagation of the crop. In many plants, cuttings made from fleshy roots can similarly form organized buds and reconstitute the plant by vegetative propagation. Thus, each of the vegetative organs of the plant (leaf, stem, and root) can give rise to new plants by asexual reproduction. *See* PLANT PROPAGATION.

Sexual reproduction. While in asexual reproduction, the genetic makeup of the progeny rarely differs greatly from that of the parent, the fusion of cells in sexual reproduction can give rise to new genetic combinations, resulting in new types of plants. The life cycle of higher green plants consists of two distinct generations, based on the chromosomal complement of their cells. The sporophyte generation is independent and dominant in the flowering plants and ferns, but small, nongreen, and dependent in the mosses, and contains the $2n$ number of chromosomes. The diploidy results in each case from the fusion of sperm and egg to form the zygote, which then develops into an embryo and finally into the mature sporophyte. The sporophyte generation ends with the formation of $1n$ spores by reduction division, or meiosis, in a spore mother cell. The spore then develops into the gametophyte generation, which in turn produces the sex cells, or gametes. The gametophyte generation ends when gametes fuse to form the zygote, restoring the $2n$ situation typical of sporophytes. *See* MEIOSIS.

In flowering plants, the gametophyte or $1n$ generation is reduced to just a few cells (generally three for the male and eight for the female). The male gametophyte is formed after meiosis occurs in the microspore mother cells of the anther, yielding a tetrad of $1n$ microspores. Each of these microspores then divides mitotically at least twice. The first division produces the tube nucleus and the generative nucleus. The generative nucleus then divides again to produce two sperms. These nuclei are generally not separated by cell walls, but at this stage the outer wall of the spore becomes thickened and distinctively patterned—a stage typical of the mature male gametophyte, the pollen grain. *See* FLOWER; MITOSIS; POLLEN; POLLINATION.

Each pollen grain has a weak pore in its wall, through which the pollen tube emerges at the time of germination. Pollen germinates preferentially in the viscous secretion on the surface of the stigma, and its progress down the style to the ovary is guided through specific cell-to-cell recognition processes. Throughout its growth, which occurs through the deposition of new cell wall material at the advancing tip, the pollen tube is controlled by the tube nucleus, usually found at or near the tip. When the pollen tube, responding to chemical signals, enters the micropyle of the ovule, its growth ceases and the tip bursts, discharging the two sperms into the embryo sac, the female gametophyte of the ovary.

The female gametophyte generation, like the male, arises through meiotic division of a $2n$ megaspore mother cell. This division forms four $1n$ megaspores, of which three usually disintegrate, the fourth developing into an eight-nucleate embryo sac by means of three successive mitotic divisions. The eight nuclei arrange themselves into two groups of four, one at each pole of the embryo sac. Then one nucleus from each pole moves to the center of the embryo sac. One of the three nuclei at the micropylar end of the embryo sac is the female gamete, the egg, which fuses with one of the sperm nuclei to form the zygote, the first cell of the sporophyte generation, which produces the embryo. The second sperm fuses with the two polar nuclei at the center of the embryo sac to form a $3n$ cell that gives rise to the endosperm of the seed, the tissue in which food is stored. The entire ovule ripens into the seed, with the integuments forming the protective seed coat. The entire ovary ripens into a fruit, whose color, odor, and taste are attractive to animals, leading to dispersal of the seeds. The life cycle is completed when the seed germinates and grows into a mature sporophyte with flowers, in which meiotic divisions will once again produce $1n$ microspores and megaspores.

Nonflowering higher plants such as the ferns and mosses also show a distinct alternation of generations. The familiar fern plant of the field is the sporophyte generation. Meiosis occurs in sporangia located in special places on the leaves, generally the undersides or margins. A spore mother cell produces a tetrad of $1n$ spores, each of which can germinate to produce a free-living, green gametophyte called a prothallus. On the prothallus are produced male and female sex organs called antheridia and archegonia, which give rise to sperms and eggs, respectively. Sperms, motile because of their whiplike flagella, swim to the archegonium, where they fertilize the egg to produce the zygote that gives rise to the sporophyte generation again.

In mosses, by contrast, the dominant green generation is the gametophyte. Antheridia or archegonia are borne at the tips of these gametophytes, where they produce sperms and eggs, respectively. When suitably wetted, sperms leave the antheridium, swim to a nearby archegonium, and fertilize the egg to produce a $2n$ zygote that gives rise to a nongreen, simple, dependent sporophyte. The moss sporophyte consists mainly of a sporangium at the end of a long stalk, at the base of which is a mass of tissue called the foot, which absorbs nutrients from the green, photosynthetic gametophyte. Meiosis occurs in the sporangium when a spore mother cell gives rise to four reduced spores. Each spore can germinate, giving rise to a filamentous structure from which leafy gametophytic branches arise, completing the life cycle.

Various members of the algae that reproduce sexually also display alternation of generations, producing sperms and eggs in antheridia and oogonia. Sporophyte and gametophyte generations may each be free-living and independent, or one may be partially or totally dependent on the other. *See* FRUIT; PLANT PHYSIOLOGY; POPULATION DISPERSAL; SEED. [A.W.G.]

Reproductive behavior Behavior related to the production of offspring; it includes such patterns as the establishment of mating systems, courtship, sexual behavior, parturition, and the care of young. Successful reproductive efforts require the establishment of a situation favorable for reproduction, often require behavior leading to the union of male and female gametes, and often require behavior that facilitates or ensures the survival and development of the young; the mere union of gametes is not generally sufficient for successful reproduction. For each species, there is a complex set of behavioral adaptations that coordinate the timing and patterning of reproductive activity. Typically, this entails integration of both overt behavioral and internal physiological events in both male and female, all of which are intricately enmeshed in manners adapted to the environment in which the animals live. The behavioral patterns related to reproduction tend to be relatively stereotyped within a species, but diverse among different species—especially distantly related species. The end products of cycles of reproductive activity are viable, fertile offspring which, in turn, will reproduce and thus perpetuate the species.

The relationships between individual males and females and the degree of exclusivity in mating are part of the mating system of a species or population. There are three basic mating system types: monogamy, polygamy, and promiscuity. In monogamy the reproductive unit is generally a single male and a single female, the partners copulate only with each other, there may be shared parental care, and there is some kind of prolonged pair bond. In polygamous mating systems, there is again a prolonged association, but more than two individuals are involved in the relationship. In the promiscuous mating system, there is no prolonged bond formed, and there are multiple matings by members of at least one of the sexes.

Territoriality or dominance occurs in many kinds of mating systems. A territory is an area that is defended against conspecific animals (those of the same species). It may be occupied by a single individual, a bonded male-female pair, or a larger group. The resident of a territory generally has privileged access to the resources on that territory. Where the territory is relatively large, as in many diurnal songbirds, it may include sufficient resources to support a bonded pair and their offspring. By contrast, in many colonially nesting marine birds the territories may encompass little more than a nest site, while food and other resources are collected at a distance. In a special form of territoriality, a lek, males of some species, such as sage grouse, defend small territories that are used only for breeding. *See* TERRITORIALITY.

Whereas in a territorial system the outcome of a contest for resources is generally predictable given only the location of the encounter, in a dominance relationship an individual wins regardless of location. In troops of various species of primates, for example, there may be a single dominant male and a hierarchy of males ranking below him. There are many varieties of dominance relationships, with male hierarchies, female hierarchies, mixed-sex hierarchies, and triangular relationships that are departures from linearity. Dominance-related contests may occur seasonally, generally peaking in intensity during the breeding season, and can be of great importance in determining which individuals reproduce.

Mate choice and then courtship are both essential to successful reproduction in animals. The importance of female choice remains controversial. Ultimately, females can benefit by mating with males that are exceptional either in their ability to accrue resources or in the possession of "good genes," or both. Males forming prolonged pair bonds invest much, and it is not surprising that they may exercise mate choice as well. In a variety of species of invertebrates, for example, males prefer large females to small ones.

Courtship entails a sequence of behavioral patterns that eventually may lead to the completed mating. Patterns of courtship are quite diverse among different species but generally entail reciprocal signaling between male and female. Mate choice is an important function of courtship. Many bouts of courtship break off without going to completed matings, often as a result of choice on the part of one or both partners. Another function of courtship relates to synchronization. The gametes must be shed at a time when sperm are viable, eggs are ripe, male and female are in the appropriate state of readiness, and the environment is supportive of reproductive effort. The progressive interactive sequence of the courtship episode allows for coordinated events to occur at times appropriate for successful reproduction.

Prior to birth or hatching of offspring, parents may engage in behavioral patterns that will aid the young when they arrive. This may entail preparation of a burrow or nest, provision of stored food, or acquisition of other resources. In some species the parent's aid ends with such preparations, but in others parental care may be extensive and prolonged. Parental care, especially maternal care, is highly developed in all species of mammals. By definition, the females of all mammalian species possess mammary glands for the nourishment of young. It is probably for this physiological reason that role reversal is less common among mammals than in other taxa.

Parental investment entails any investment by the parent that increases the ability of the young to survive and reproduce at some cost to the parent. Much parental investment, like milk, cannot be shared; that which is given to one offspring cannot be given to another. Other kinds of parental investment, like defense against predators, is shareable. In addition, the parent making any investment is prevented from engaging in other activities, such as searching for his or her own food or seeking additional mates.

Because they contribute larger gametes and often engage in more extensive parental behavior, the females of most species display a higher level of parental investment than males. Members of the sex investing more (typically females) thus become a limiting resource for the sex investing less (typically males). It is generally agreed that this gives rise to the disparity between female and male reproductive strategies—with males more often competing for access to females and females more choosy than males. *See* ANIMAL COMMUNICATION; BEHAVIORAL ECOLOGY; ETHOLOGY; REPRODUCTION (ANIMAL). [D.A.D.]

Reproductive system The structures concerned with the production of sex cells (gametes) and perpetuation of the species. The reproductive function constitutes the only vertebrate physiological function that necessitates the existence of two morphologically different kinds of individuals in each animal species, the males and the females (sexual dimorphism). The purpose of the reproductive function is fertilization, that is, the fusion of a male and a female sex cell produced by two distinct individuals.

Anatomy. Egg cells, or ova, and sperm cells, or spermatozoa, are formed in the primary reproductive organs, which are collectively known as gonads. Those of the male are called testes; those of the female are ovaries. The gonads are paired structures, although in some forms what appears to be an unpaired gonad is the result either of fusion of paired structures or of unilateral degeneration.

The reproductive elements formed in the gonads must be transported to the outside of the body. In most vertebrates, ducts are utilized for this purpose. These ducts, together with the structures that serve to bring the gametes of both sexes together, are known as accessory sex organs. The structures used to transport the reproductive cells in the male are known as deferent ducts and those of the female as oviducts. In a few forms no ducts are present in either sex, and eggs and sperm escape from the body cavity through genital or abdominal pores.

Oviducts, except in teleosts and a few other fishes, are modifications of Möllerian ducts formed during early embryonic development. In all mammals, each differentiates into an anterior, nondistensible Fallopian tube and a posterior, expanded uterus. In all mammals except monotremes the uterus leads to a terminal vagina which serves for the reception of the penis of the male during copulation. The lower part, or neck, of the uterus is usually telescoped into the vagina to a slight degree. This portion is referred to as the cervix.

In most vertebrates the reproductive ducts in both sexes open posteriorly into the cloaca. In some, modifications of the cloacal region occur and the ducts open separately to the outside or, in the male, join the excretory ducts to emerge by a common orifice. *See* COPULATORY ORGAN; OVARY; PENIS; REPRODUCTION (ANIMAL); TESTIS. [C.K.W.]

Physiology. The physiological process by which a living being gives rise to another of its kind is considered one of the outstanding characteristics of plants and animals. It is one of the two great drives of all animals; self-preservation and racial perpetuation.

Estrous and menstrual cycles. The cyclic changes of reproductive activities in mammalian females are known as estrous or menstrual cycles.

Most mammalian females accept males only at estrus (heat). Estrus in mammals can occur several times in one breeding season; the mare, ewe, and rat come to estrus every 21, 16, and 5 days respectively if breeding does not take place. This condition is called poly estrus. The bitch is monestrous; she has only one heat, or estrus, to the breeding season and if not served then, she does not come into heat again for a prolonged interval, 4–6 months according to different breeds. In monestrous and seasonally polyestrous species the period of sexual quiescence between seasons is called anestrus. *See* ESTRUS.

The reproductive cycle of the female in the primate and human is well marked by menstruation, the period of vaginal blood flow. Menstruation does not correspond to estrus but occurs between the periods of ovulation at the time the corpus luteum declines precipitously. *See* MENSTRUATION.

Mating. Mating, also called copulation or coitus, is the synchronized bodily activity of the two sexes which enables them to deposit their gametes in close contact. It is essential for successful fertilization because sperm and ovum have a very limited life span.

The logistics of sperm transport to the site of fertilization in the oviduct present many interesting features in mammals, but it is important to distinguish between passive transport of sperm cells in the female genital tract, and sperm migration, which clearly attributes significance to the intrinsic motility of the cell. Viable spermatozoa are actively motile, and although myometrial contractions play a major role in sperm transport through the uterus, progressive motility does contribute to migration into and within the oviducts. Even though a specific attractant substance for spermatozoa has not yet been demonstrated to be released from mammalian eggs or their investments, some form of chemotaxis may contribute to the final phase of sperm transport and orientation toward the egg surface.

Although in most mammalian species the oocyte is shed from the Graafian follicle in a condition suitable for fertilization, ejaculated spermatozoa must undergo some form of physiological change in the female reproductive tract before they can penetrate the egg membranes. The interval required for this change varies according to species, and the process is referred to as capacitation. The precise changes that constitute capacitation remain unknown, although there is strong evidence that they are—at least in part—membrane-associated phenomena, particularly in the region of the sperm head, that permit release of the lytic acrosomal enzymes with which the spermatozoon gains access to the vitelline surface of the egg.

Fertilization takes place in the oviducts of mammals and the fertilized eggs or embryos do not descend to the uterus for some 3 to 4 days in most species. During this interval, the embryo undergoes a series of mitotic divisions until it comprises a sphere of 8 or 16 cells and is termed a morula. Formation of a blastocyst occurs when the cells of the morula rearrange themselves around a central, fluid-filled cavity, the blastocoele. As the blactocyst develops within the uterine environment, it sheds its protective coat and undergoes further differentiation before developing an intimate association with the endometrium, which represents the commencement of implantation or nidation.

Association of the embryo with the uterine epithelium, either by superficial attachment or specific embedding in or beneath the endometrium, leads in due course to the formation of a placenta and complete dependence of the differentiating embryo upon metabolic support from the mother. Implantation and placentation exhibit a variety of forms, but in all instances the hormonal status of the mother is of great importance in determining whether or not implantation can proceed. *See* PREGNANCY.

Endocrine function. The endocrine glands secrete certain substances (hormones) which are necessary for growth, metabolism, reproduction, response to stress, and various other physiological processes. The endocrine glands most concerned with the process of reproduction are the pituitary and the gonads.

The posterior lobe of the pituitary gland secretes two neurohumoral agents, vasopressin and oxytocin. These are involved in reproduction only indirectly, through their effect on uterine contractility in labor and on the release of milk from the mammary gland when a suckling stimulus is applied. The anterior lobe secretes a variety of trophic hormones, including two gonadotrophic hormones, the follicle-stimulating hormone (FSH) and the luteinizing or interstitial-cell stimulating hormone (LH or ICSH). These hormones act directly on both ovaries and testes. *See* PITUITARY GLAND.

The gonadal (steroidal) hormones control the secretion of gonadotrophins by acting on the hypothalamus. It has been suggested that steroids act by means of a “negative feedback”; that is, high levels of circulating gonadal hormones stop further release of gonadotropins. However, although this is true for experiments involving pharmacological doses of such hormones, it may not be the case with endogenous physiological levels. It is certainly true that less steroid is required to inhibit pituitary function in the female than in the male. Under certain circumstances small doses of gonadal hormones can stimulate release of gonadotropic hormones from the pituitary. Estrogen can simulate the release of LH; hence the occurrence of ovulation in rats, rabbits, sheep, and women. Progesterone can also facilitate ovulation in persistently estrous rats, in chickens, and in estrous sheep and monkeys. *See* ESTROGEN; PROGESTERONE.

The formation of gametes (spermatogenesis and oogenesis) is controlled by anterior pituitary hormones. The differentiation of male and female reproductive tracts is influenced, and mating behavior and estrous cycles are controlled, by male or female hormones. The occurrence of the breeding season is mainly dependent upon the activity of the anterior lobe of the pituitary, which is influenced through the nervous system by external factors, such as light and temperature. The transportation of ova from the ovary to the Fallopian tube and their subsequent transportation, development, and implantation in the uterus are controlled by a balanced ratio between estrogen and progesterone. Furthermore, it is known that estrogens, androgens, and progesterone can all have the effect of inhibiting the production or the secretion, or both, of gonadotrophic hormones, permitting the cyclic changes of reproductive activity among different animals.

Mammary glands are essential for the nursing of young. Their growth, differentiation, and secretion of milk, and in fact the whole process of lactation, are controlled by pituitary hormones as well as by estrogen and progesterone. Other glands and physiological activities also influence lactation, although this is largely via the trophic support of other pituitary hormones.

[M.C.C.; M.J.K.H.; R.H.F.H.]

Reproductive system disorders Those disorders which involve the structures of the human female and male reproductive systems.

Female system. Disorders of the female reproductive system may involve the ovaries, Fallopian tubes, uterus, cervix, vagina, or vulva.

Failure of the ovaries to form normally results in short stature, sterility, and lack of development of female secondary sex characteristics, such as breast growth, fat deposition in buttocks and thighs and mons pubis, and female escutcheon. Destruction of the ovaries after puberty results in loss of fertility, cessation of menses, loss of secondary sex characteristics, and osteoporosis. *See* OSTEOPOROSIS.

Neoplastic enlargement of the ovary can be cystic or solid, benign or malignant. Malignant ovarian tumors are commonly asymptomatic in their early stages, and may be quite widely spread in the pelvic and abdominal cavity before they are discovered. *See* OVARIAN DISORDERS; OVARY.

Endometriosis, which is a condition involving the presence of ectopic endometrial tissue, can affect the ovaries. Endometriosis can be found as large "chocolate" cysts of the ovary, called endometriomas, or small "blue domed" cysts; both are filled with old, dark brown blood. Tiny implants of endometriosis commonly called powder burns also occur on the surface of the ovaries, on other pelvic peritoneum, and over the Fallopian tubes and uterus as well. Endometriomas of the ovary may be painful, or may rupture and cause diffuse pelvic pain, while the smaller endometrial implants may cause severe pain with menstrual periods, generalized pelvic pain, pain with intercourse, and infertility.

Inflammation is the most common disorder of the Fallopian tubes, and if it is repeated or severe, destruction of the tubal lining with closure of the outer ends of the tubes can occur. This inflammation can be caused by several organisms. Sterility commonly results because the tube is permanently closed to passage of egg and sperm. The second most common problem involving the tube is pregnancy. The egg is fertilized in the outer portion of the tube and descends to implant in the uterus, but in some cases the passage is delayed and the conceptus attaches to the wall of the tube. The tube has a small lumen and thin wall, and the growing pregnancy quickly enlarges and grows through the tube, leading usually to rupture and hemorrhage into the peritoneal cavity. *See* PREGNANCY DISORDERS.

Developmental abnormalities can occur during formation of the uterus. The Fallopian tubes might not join at all, or might join partially from the cervical end upward. Septae or walls in the vagina and uterus can also occur. These abnormalities are more common in females who are exposed to diethylstilbesterol (DES) during the mother'spregnancy. The muscle (myometrium) and lining (endometrium) of the uterus are susceptible to various problems, including tumors, infections, and hormonal derangements. Benign tumors of the myometrium (fibroids) are a common disorder, producing irregular enlargement of the uterus and sometimes causing pain, obstruction of the urinary tract, and heavy vaginal bleeding. The uterus can be one site of a significant infection which produces fever and pain and usually involves other organs, such as ovaries and tubes. Hormonal abnormalities resulting in anovul can lead to overgrowth and irregular shedding of the endometrium. Pregnancy usually proceeds uneventfully, but certain accidents of pregnancy, such as threatened, incomplete, or missed abortion, can produce irregular bleeding and some uterine discomfort. *See* PREGNANCY; UTERINE DISORDERS; UTERUS.

Infection of the endocervical glands with gonococcus or chlamydia trachomatis agent can occur. This may be asymptomatic, except for producing a mucopurulent discharge, or it may cause pain when the cervix is manipulated, particularly during intercourse. The infection can ascend from this area into the internal genital organs and adjacent structures. The cervix can be affected by malignant tumors which can be adenocarcinomas, or tumors of the glandular cells, or more commonly squamous tumors. Cervical cancer is associated with several factors, including early age at first coitus, multiple sex partners, especially at an early age, smoking, and infection with certain subtypes of human papilloma virus. There is no single factor that "causes" this cancer, but rather a combination of these factors is critical. Papanicolaou smears are used to detect early changes suggestive of this cancer. Further evaluation is by low-power magnification, called colposcopy, and biopsy. *See* GONORRHEA.

Developmental abnormalities of the vagina may include imperforate hymen, septae, both vertical and horizontal, and complete failure of development. Inflammation of the lining of the vagina can be due to several common organisms. Specific chemical treatment is available for each of these entities. Postmenopausal women can experience atrophy or shrinkage of the vagina and mucosa secondary to estrogen deprivation. This produces itching, bleeding, and pain with intercourse. Estrogen therapy can relieve these symptoms. The vaginal support can be weakened through childbirth, or may simply be naturally poor, allowing the bladder and rectum to bulge inward, and the cervix and uterus to protrude from the introitus. This condition can cause a variety of symptoms, including involuntary loss of urine with a cough or laugh, inability to move the bowels without mechanically pushing the stool out, and a sensation of pelvic heaviness. Intravaginal devices called pessaries may improve support, but surgical correction may be necessary. Vaginal cancer can occur, but it is rare, and cervical cancer can also involve the vagina. Treatment is usually surgical. Vaginal trauma can lead to significant bleeding. Penetrating straddle injuries can occur, and trauma with intercourse or childbirth can produce lacerations. Surgical repair is usually undertaken. Vaginismus, or painful spasm of the muscular sidewalls of the vagina, can occur, making intercourse painful. *See* VAGINAL DISORDERS.

Infection of the female external genitalia can be diffuse or localized, involving bacteria, viruses, or fungal agents. Inflammation can be caused by allergic reactions to soap, powders, semen, lubricant, or even clothing.

Male system. The principal organs of the male reproductive system are the testicles, epididymis, vas deferens and seminal vesicles, prostate gland, urethra, and penis.

During fetal life the testicles form in the abdominal cavity near the kidneys and migrate down into the scrotum. Failure of descent permanently damages the sperm-producing cells, but allows the interstitial cells which produce hormones to survive. Other causes of male infertility are organic problems which block passage of seminal fluid or interfere with sperm production. The testes are sites of malignant tumors which carry a high mortality rate. Undescended testicles are more susceptible to malignant transformation, and for that reason should be removed when discovered, and appropriate hormonal replacement instituted. The membranes covering the testicle can become filled with fluid, a condition known as hydrocele. *See* TESTIS.

The major disorder of the epididymis is infection and inflammation, which can lead to scarring and permanent blockage of the ducts.

The vas deferens and seminal vesicles are rarely afflicted by disease, although the network of veins surrounding the vas deferens can become engorged and tortuous, and is called a variococoele.

Inflammation and development of small calculi are relatively minor ailments of the prostate. Benign overgrowth of this gland is the most common and troublesome complaint. This enlargement results in constriction of the urethra, which obstructs urinary outflow and leads to an increasing residual of urine in the bladder. Cancer of the prostate is another relatively frequent problem in older males. This tumor spreads primarily to bones, where it is markedly painful. *See* PROSTATE GLAND DISORDERS.

Inflammation is the chief disorder of the urethra, causing dysuria and a discharge.

Inflammation (balanitis) or narrowing (phimosis) of the foreskin, which covers the glans penis, can occur and may interfere with urination. Viral infections can produce warty growths (condyloma acuminata) or painful ulcers (herpetic lesions) of the glans or shaft of the penis, and a syphilitic infection can result in the firm, painless ulcer known as a chancre. *See* Herpes; Syphilis.

Disorders of erectile capability range from tumescence unaccompanied by sexual desire (Peyronie's disease, priapism) to impotence, both psychologic and secondary to old age. Carcinoma can arise from the surface epithelium of the penis and spread both locally and via the lymphatic system to the nodes of the groin. This disease is virtually unknown in populations where males are circumcised at birth. *See* Infertility; Oncology; Reproductive system; Reproductive technology. [G.M.Gu.]

Reproductive technology Any procedure undertaken to aid in conception, intrauterine development, and birth when natural processes do not function normally. The most common are in vitro fertilization and gamete intrafallopian transfer.

Infertility, which is the inability to conceive during at least 12 months of unprotected intercourse, is an increasingly common problem. Hormonal therapy and microsurgery are used to overcome many hormonal and mechanical forms of infertility, but many types of infertility do not respond to such treatment. *See* Infertility.

In vitro fertilization bypasses the Fallopian tubes. Immediately prior to ovulation the mature oocyte is removed from the ovary and placed, together with prepared sperm, in a petri dish for 2–3 days. Fertilization takes place during this time and the fertilized oocyte develops into a two- to eight-cell embryo, which is then transferred into the uterus. In vitro fertilization is useful for females with absent or severely damaged Fallopian tubes; couples in which the female has endometriosis; when the male has severely reduced sperm counts; or when the couple has immunologic or unexplained infertility for a period of 2 or more years. The four principal steps of in vitro fertilization are induction and timing of ovulation, oocyte retrieval, fertilization, and embryo transfer.

Gamete intrafallopian transfer, or GIFT, is similar to in vitro fertilization with a few important distinctions. In gamete intrafallopian tube transfer, the spermatozoa and oocytes are placed into the fimbriated end of the Fallopian tube during the laparoscopy. It is unusual for more than two oocytes to be placed into either Fallopian tube. Indications for gamete intrafallopian transfer include unexplained infertility of two or more years' duration, cervical stenosis, immunologic infertility, oligospermia, and endometriosis. At least one Fallopian tube must appear normal; where there has been severe pelvic adhesions or distorted tubal anatomy from any cause, gamete intrafallopian transfer should not be considered. *See* Pregnancy; Reproductive system disorders. [M.M.S.]

Reptilia A class of vertebrates composed of four living orders, the turtles or Chelonia, the tuatara or Sphenodonta, the lizards and snakes or Squamata, and the crocodylians or Crocodylia. Numerous extinct orders are also known. The group first appeared in the Carboniferous and underwent a culminating evolutionary radiation in the Mesozoic, often called the age of reptiles. Although the major portion of the class is now extinct, several Recent groups, particularly the Squamata, are very successful, and there are approximately 5000 living species of reptiles as compared to about 4000 living mammals. A classification is given below; see separate articles on each of the groups listed.

- Class Reptilia
  - Subclass Anapsida
    - Order: Captorhinida
      - Mesosauria
      - Chelonia
  - Subclass Diapsida
    - Infraclass Sauropterygia
      - Order: Nothosauria
        - Plesiosauria
        - Placodontia
    - Infraclass Lepidosauria
      - Order: Araeoscelida
        - Eosuchia
        - Sphenodonta
        - Squamata
    - Infraclass Archosauria
      - Order: Protorosauria
        - Rhynchosauria
        - Thecodontia
        - Crocodylia
        - Pterosauria
        - Saurisachia
        - Ornithischia
  - Subclass Ichthyopterygia
  - Subclass Synapsida
    - Order: Pelycosauria
      - Therapsida

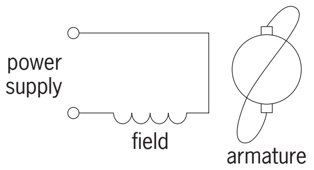
The reptiles are the most primitive of the completely terrestrial vertebrates and are consequently the first to exhibit amniote features. Reptile eggs are covered by a complex series of protective layers, including a leathery or calcareous shell. A rich supply of food material in the form of yolk is deposited inside the ovum to furnish food for the developing embryo. A series of protective extraembryonic membranes, the serosa and amnion, appears later in embryogenesis to protect the embryo from water loss and shock. A third such membrane, the allantois, functions as a storage sac for nitrogenous wastes. The serosa and allantois usually fuse to form a respiratory structure. Gaseous exchanges take place across the shell and seroallantoic membrane between the outside air and the blood vessels of the allantois. These adaptations allowed the reptile egg to be deposited on land, undergo its development there, and hatch into a fully developed form without a gilled larval stage. Most reptilian eggs are buried in the soil or in rotting vegetation out of direct sunlight. *See* Amniota.

Paleoherpetology, the study of fossil reptiles, is especially important for two reasons. First, the class Reptilia lies at the center of vertebrate history; the reptiles evolved from the amphibians (which themselves had originated from the fishes), and both birds and mammals evolved from the reptiles. Thus reptiles are concerned in three of the four major "jumps" (the class-to-class transitions) in vertebrate evolution. The distinction between the living representatives of two successive classes is always very clear, being based on a number of features of their anatomy, physiology, and embryology; the distinction between their fossil members, however, is inevitably less clear, not only because the distinction must be based almost entirely upon characters of the skeleton but also because there must have been animals with a mixture of the characters of both classes during the transitional period. These help elucidate the reasons for the jumps and the precise mechanism by which each occurred. *See* Amphibia; Animal evolution.

Second, the Reptilia were the dominant class of land vertebrates (and were also important in the sea and in the air) during a very long period of the Earth's history. Knowledge of the extinct reptiles, their morphology and their habits, is vital to an understanding of the life of those times, of how the animals and plants and the physical environment reacted upon each other (paleoecology). *See* Paleoecology; Paleontology. [A.J.C.]

Repulsion motor An alternating-current (ac) commutator motor designed for single-phase operation. The chief distinction between the repulsion motor and the single-phase series motors is the way in which the armature receives its power. In the series motor the armature power is supplied by conduction from the line power supply. In the repulsion motor, however, armature power is supplied by induction (transformer action) from the field of the stator winding. For discussion of the ac series motor *see* Universal motor; Alternating-current motor.

The repulsion motor primary or stationary field winding is connected to the power supply. The secondary or armature winding is mounted on the motor shaft and rotates with it. The



Schematic of a repulsion motor.

terminals of the armature winding are short-circuited through a commutator and brushes. There is no electrical contact between the stationary field and rotating armature (see illustration). *See* Windings in electric machinery. [I.L.K.]

Reservoir A place or containment area where water is stored. Where large volumes of water are to be stored, reservoirs usually are created by the construction of a dam across a flowing stream. When water occurs naturally in streams, it is sometimes not available when needed. Reservoirs solve this problem by capturing water and making it available at later times. *See* Dam.

In addition to large reservoirs, many small reservoirs are in service. These include varieties of farm ponds, regulating lakes, and small industrial or recreational facilities. In some regions, small ponds are called tanks. Small reservoirs can have important cumulative effects in rural regions

Reservoirs can be developed for single or multiple purposes, such as to supply water for people and cities, to provide irrigation water, to lift water levels to make navigation possible on streams, and to generate electricity.

Another purpose of reservoirs is to control floods by providing empty spaces for flood waters to fill, thereby diminishing the rate of flow and water depth downstream of the reservoir.

Reservoirs also provide for environmental uses of water by providing water to sustain fisheries and meet other fish and wildlife needs, or to improve water quality by providing dilution water when it is needed in downstream sections of rivers. Reservoirs may also have esthetic and recreational value, providing boating, swimming, fishing, rafting, hiking, viewing, photography, and general enjoyment of nature. *See* Pumped storage; River engineering; Water supply engineering. [N.S.Gr.]

Resin Originally a category of vegetable substances soluble in ethanol but insoluble in water, but generally in modern technology an organic polymer of indeterminate molecular weight. The class of flammable, amorphous secretions of conifers or legumes are considered true resins. Water- swellable secretions of various plants, especially the Burseraceae, are called gum resins. The natural vegetable resins are largely polyterpenes and their acid derivatives, which find application in the manufacture of lacquers, adhesives, varnishes, and inks.

The synthetic resins, originally viewed as substitutes for certain natural resins, have a large place of their own in industry and commerce. Phenol-formaldehyde, phenol-urea, and phenol-melamine resins are important commercially. Any unplasticized organic polymer is considered a resin, thus nearly any one of the common plastics may be viewed as a synthetic resin. Water-soluble resins are marketed chiefly as substitutes for vegetable gums and in their own right for highly specialized applications. Carboxymethy[cellulose, hydroxyalkylated cellulose derivatives, modified starches, polyvinyl alcohol, polyvinylpyrrolindone, and polyacrylamides are widely used as thickening agents for foods, paints, and drilling muds, as fiber sizings, in various kinds of protective coatings, and as encapsulating substances. *See* Polymer. [F.W.]

Resistance heating The generation of heat by electric conductors carrying current. The degree of heating for a given current is proportional to the electrical resistance of the conductor. If the resistance is high, a large amount of heat is generated, and the material is used as a resistor rather than as a conductor.

In addition to having high resistivity, heating elements must be able to withstand high temperatures without deteriorating or sagging. Other desirable characteristics are low temperature coefficient of resistance, low cost, formability, and availability of materials. Most commercial resistance alloys contain chromium or aluminum or both, since a protective coating of chrome oxide or aluminum oxide forms on the surface upon heating and inhibits or retards further oxidation.

Since heat is transmitted by radiation, convection, or conduction or combinations of these, the form of element is designed for the major mode of transmission. The simplest form is the helix, using a round wire resistor, with the pitch of the helix approximately three wire diameters. This form is adapted to radiation and convection and is generally used for room or air heating. It is also used in industrial furnaces, utilizing forced convection up to about 1200°F (650°C). Such helixes are stretched over grooved high-alumina refractory insulators and are otherwise open and unrestricted.

The electrical resistance of molten salts between immersed electrodes can be used to generate heat. Limiting temperatures are dependent on decomposition or evaporization temperatures of the salt, Parts to be heated are immersed in the salt. Heating is rapid and, since there is no exposure to air, oxidation is largely prevented. Disadvantages are the personnel hazards and discomfort of working close to molten salts.

A major application of resistance heating is in electric home appliances, including electric ranges, clothes dryers, water heaters, coffee percolators, portable radiant heaters, and hair dryers. Resistance heating also has application in home or space heating.

If the resistor is located in a thermally insulated chamber, most of the heat generated is conserved and can be applied to a wide variety of heating processes. Such insulated chambers are called ovens or furnaces, depending on the temperature range and use. The term oven is generally applied to units which operate up to approximately 800°F (430°C). Typical uses are for baking or roasting foods, drying paints and organic enamels, baking foundry cores, and low-temperature treatments of metals. The term furnace generally applies to units operating above 1200°F (650°C). Typical uses of furnaces are for heat treatment or melting of metals, for vitrification and glazing of ceramic wares, for annealing of glass, and for roasting and calcining of ores. *See* Electric heating; Furnace. [W.Ro.]

Resistance measurement The quantitative determination of that property of an electrically conductive material, component, or circuit called electrical resistance. The ohm, which is the International System (SI) unit of resistance, is defined through the application of Ohm's law as the electric resistance between two points of a conductor when a constant potential difference of 1 volt applied to these points produces in the conductor a current of 1 ampere. Ohm's law can thus be taken to define resistance R as the ratio of dc voltage V to current I, Eq. (1). For bulk metallic conductors, for example, bars, sheets,

$$R = \frac{V}{I} \tag{1}$$

wires, and foils, this ratio is constant. For most other substances, such as semiconductors, ceramics, and composite materials, it may vary with voltage, and many electronic devices depend on this fact. The resistance of any conductor is given by the integral of expression (2), where l is the length, A the cross-sectional

$$\int_0^l \frac{\rho\, dl}{A} \tag{2}$$

area, and ρ the resistivity. *See* Electrical conductivity of metals; Electrical resistance; Electrical resistivity; Ohm's law; Semiconductor.

Since January 1, 1990, all resistance measurements worldwide have been referred to the quantized Hall resistance standard, which is used to maintain the ohm in all national standards laboratories. Conventional wire-wound working standards are measured in terms of the quantized Hall resistance and then used to disseminate the ohm through the normal calibration chain. These working standards can be measured in terms of the quantized Hall resistance with a one-standard-deviation uncertainty of about 1 part in 10^8. *See* HALL EFFECT.

The value of an unknown resistance is determined by comparison with a standard resistor. The Wheatstone bridge is perhaps the most basic and widely used resistance- or impedance-comparing device. Its principal advantage is that its operation and balance are independent of variations in the supply. The greatest sensitivity is obtained when all resistances are similar in value, and the comparison of standard resistors can then be made with a repeatability of about 3 parts in 10^8, the limit arising from thermal noise in the resistors. In use, the direction of supply is reversed periodically to eliminate effects of thermal or contact emf's.

The bridge is normally arranged for two-terminal measurements, and so is not suitable for the most accurate measurement at values below about 100 Ω, although still very convenient for lower resistances if the loss of accuracy does not matter. However, a Wheatstone bridge has also been developed for the measurement of four-terminal resistors. This involves the use of auxiliary balances, and resistors of the same value can be compared with uncertainties of a few parts in 10^8.

Typically a bridge will have two decade-ratio arms, for example, of 1, 10, 100, 1000, and 10,000 Ω, and a variable switched decade arm of 1–100,000 Ω, although many variations are encountered. For the measurement of resistors of values close to the decade values, a considerable increase in accuracy can be obtained by substitution measurement, in which the bridge is used only as an indicating instrument. The resistors being compared can be brought to the same value by connecting a much higher variable resistance across the larger of them, and the accuracy of this high-resistance shunt can be much less than that of the resistance being compared. *See* WHEATSTONE BRIDGE.

The Kelvin double bridge is a double bridge for four-terminal measurements, and so can be used for very low resistances. The addition to its use for accurate laboratory measurement of resistances below 100 Ω, it is very valuable for finding the resistance of conducting rods or bars, or for the calibration in the field of air-cooled resistors used for measurement of large currents. *See* KELVIN BRIDGE.

Measurements of resistances from 10 megohms to 1 terohm (10^{12} Ω) or even higher with a Wheatstone bridge present additional problems. The resistance to be measured will usually be voltage-dependent, and so the measurement voltage must be specified. The resistors in the ratio arms must be sufficiently high in value that they are not overloaded. If a guard electrode is fitted, it is necessary to eliminate any current flowing to the guard from the measurement circuit. The power dissipated in the 1-MΩ resistor is then 10 mW, and the bridge ratio is 10^6. The guard is connected to a subsidiary divider of the same ratio, so that any current flowing to it does not pass through the detector. Automated measurements can be made by replacing the ratio arms of the Wheatstone bridge by programmable voltage sources. An alternative method that can also be automated is to measure the RC time constant of the unknown resistor R combined with a capacitor of known value C. *See* INSULATION RESISTANCE TESTING.

An obvious and direct way of measuring resistance is by the simultaneous measurement of voltage and current, and this is usual in very many indicating ohmmeters and multirange meters. In most digital instruments, which are usually also digital voltage meters, the resistor is supplied from a constant-current circuit and the voltage across it is measured by the digital voltage meter. This is a convenient arrangement for a four-terminal measurement, so that long leads can be used from the instrument to the resistor without introducing errors. The simplest systems, used in passive pointer instruments, measure directly the current through the meter which is adjusted to give full-scale deflection by an additional resistor in series with the battery. This gives a nonlinear scale of limited accuracy, but sufficient for many practical applications. *See* CURRENT MEASUREMENT; VOLTAGE MEASUREMENT. [C.H.Di.; R.G.Jon.]

Resistance welding A process in which the heat for producing the weld is generated by the resistance to the flow of current through the parts to be joined. The application of external force is required; however, no fluxes, filler metals, or external heat sources are necessary. Most metals and their alloys can be successfully joined by resistance welding processes. Several methods are classified as resistance welding processes: spot, roll-spot, seam, projection, upset, flash, and percussion.

In resistance spot welding, coalescence at the faying surfaces is produced in one spot by the heat obtained from the resistance to electric current through the work parts held together under pressure by electrodes. The size and shape of the individually formed welds are limited primarily by the size and contour of the electrodes. *See* SPOT WELDING.

In roll resistance spot welding, separated resistance spot welds are made with one or more rotating circular electrodes. The rotation of the electrodes may or may not be stopped during the making of a weld.

In resistance seam welding, coalescence at the faying surfaces is produced by the heat obtained from resistance to electric current through the work parts held together under pressure by electrodes. The resulting weld is a series of overlapping resistance spot welds made progressively along a joint by rotating the electrodes.

In projection welding, coalescence is produced by the heat obtained from resistance to electric current through the work parts held together under pressure by electrodes. The resulting welds are localized at predetermined points by projections, embossments, or intersections.

In upset welding, coalescence is produced simultaneously over the entire area of abutting surfaces or progressively along a joint, by the heat obtained from resistance to electric current through the area of contact of those surfaces. Pressure is applied before heating is started and is maintained throughout the heating period.

In flash welding, coalescence is produced simultaneously over the entire area of abutting surfaces by the heat obtained from resistance to electric current between the two surfaces and by the application of pressure after heating is substantially completed. Flash and upsetting are accompanied by expulsion of the metal from the joint. *See* FLASH WELDING.

In percussion welding, coalescence is produced simultaneously over the entire abutting surfaces by the heat obtained from an arc produced by a rapid discharge of electrical energy with pressure percussively applied during or immediately following the electrical discharge.

Most metals and alloys can be resistance-welded to themselves and to each other. The weld properties are determined by the metal and by the resultant alloys which form during the welding process. Stronger metals and alloys require higher electrode forces, and poor electrical conductors require less current. Copper, silver, and gold, which are excellent electrical conductors, are very difficult to weld because they require high current densities to compensate for their low resistance. Medium- and high-carbon steels, which are hardened and embrittled during the normal welding process, must be tempered by multiple impulses. [E.F.N.]

Resistor One of the three basic passive components of an electric circuit that displays a voltage drop across its terminals and produces heat when an electric current passes through it. The electrical resistance, measured in ohms, is equal to the ratio of the voltage drop across the resistor terminals measured in volts divided by the current measured in amperes. *See* OHM'S LAW.

Resistors are described by stating their total resistance in ohms along with their safe power-dissipating ability in watts. The tolerance and temperature coefficient of the resistance value may also be given. *See* ELECTRICAL RESISTANCE; ELECTRICAL RESISTIVITY.

All resistors possess a finite shunt capacitance across their terminals, leading to a reduced impedance at high frequencies. Resistors also possess inductance, the magnitude of which depends greatly on the construction and is largest for wire-wound types. *See* CAPACITANCE; ELECTRICAL IMPEDANCE; INDUCTANCE.

Resistors may be classified according to the general field of engineering in which they are used. Power resistors range in size from about 5 W to many kilowatts and may be cooled by air convection, air blast, or water. The smaller sizes, up to several hundred watts, are used in both the power and electronics fields of engineering.

Direct-current (dc) ammeters employ resistors as meter shunts to bypass the major portion of the current around the low-current elements. These high-accuracy, four-terminal resistors are commonly designed to provide a voltage drop of 50–100 mV when a stated current passes through the shunt. *See* AMMETER.

Voltmeters of both the dc and the ac types employ scale-multiplying resistors designed for accuracy and stability. The arc-over voltage rating of these resistors is of importance in the case of high-voltage voltmeters. *See* VOLTMETER.

Standard resistors are used for calibration purposes in resistance measurements and are made to be as stable as possible, in value, with time, temperature, and other influences. Resistors with values from 1 ohm to 10 megohms are wound by using wire made from special alloys. The best performance is obtained from quaternary alloys, which contain four metals. The proportions are chosen to give a shallow parabolic variation of resistance with temperature, with a peak, and therefore the slowest rate of change, near room temperature. *See* ELECTRICAL UNITS AND STANDARDS.

By far the greatest number of resistors manufactured are intended for use in the electronics field. The major application of these resistors is in transistor analog and digital circuits which operate at voltage levels between 0.1 and 200 V, currents between 1 μA and 100 mA, and frequencies from dc to 100 MHz. Their power-dissipating ability is small, as is their physical size.

Since their exact value is rarely important, resistors are supplied in decade values (0.1, 1, 10, 100 ohms, and so forth) with the interval between these divided into a geometric series, thus having a constant percentage increase. For noncritical applications, values from a series with intervals of 20% (12 per decade) are appropriate. A series with 10% intervals (24 per decade) is often used for resistors having a tolerance of 1%. Where the precise value of a resistor is important, a series with 2.5% intervals (96 per decade) may be used.

Resistors are also classified according to their construction, which may be composition, film-type, wire-wound, or integrated circuit.

The composition resistor is in wide use because of its low cost, high reliability, and small size. Basically it is a mixture of resistive materials, usually carbon, and a suitable binder molded into a cylinder. Copper wire leads are attached to the ends of the cylinder, and the entire resistor is molded into a plastic or ceramic jacket. Composition resistors are commonly used in the range from several ohms to 10–20 MΩ, and are available with tolerances of 20, 10, or 5%.

The film-type resistor is now the preferred type for most electronic applications because its performance has surpassed that of composition resistors and mass-production techniques have reduced the cost to a comparable level. Basically this resistor consists of a thin conducting film of carbon, metal, or metal oxide deposited on a cylindrical ceramic or glass former. The resistance is controlled by cutting a helical groove through the conducting film. This helical groove increases the length and decreases the width of the conducting path, thereby determining its ohmic value. By controlling the conductivity, thickness of the film, and pitch of the helix, resistors over a wide range of values can be manufactured. Film construction is used for very high value resistors, up to and even beyond 1 TΩ (10^{12} ohms).

Wire remains the most stable form of resistance material available; therefore, all high-precision instruments rely upon wire-wound resistors. Wire also will tolerate operation at high temperatures, and so compact high-power resistors use this construction. Power resistors are available in resistance values from a fraction of an ohm to several hundred thousand ohms, at power ratings from one to several thousand watts, and at tolerances from 10 to 0.1%. The usual design of a power resistor is a helical winding of wire on a cylindrical ceramic former. After winding, the entire resistor is coated in vitreous enamel. Alternatively, the wound element may be fitted inside a ceramic or metal package, which will assist in heat dissipation. The helical winding results in the resistor having significant inductance, which may become objectionable at the higher audio frequencies and all radio frequencies. Precision wire-wound resistors are usually wound in several sections on ceramic or plastic bobbins and are available in the range from 0.1 Ω to 10 MΩ.

Integrated circuit resistors must be capable of fabrication on a silicon integrated circuit chip along with transistors and capacitors. There are two major types: thin-film resistors and diffused resistors. Thin-film resistors are formed by vacuum deposition or sputtering of nichrome, tantalum, or Cermet (Cr-SiO). Such resistors are stable, and the resistance may be adjusted to close tolerances by trimming the film by using a laser. Typical resistor values lie in the range from 100 Ω to 10 kΩ with a matching tolerance of ±0.2% and a temperature coefficient of resistance of ±10 to ±200 ppm/°C.

Diffused resistors are based upon the same fabrication geometry and techniques used to produce the active transistors on the silicon chip or die. A diffused base, emitter, or epitaxial layer may be formed as a bar with contacts at its extremities. The resistance of such a semiconductor resistor depends upon the impurity doping and the length and cross section of the resistor region. In the case of the base-diffused resistor, the emitter and collector regions may be formed so as to pinch the base region to a very small cross-sectional area, thereby appreciably increasing the resistance. The relatively large impurity carrier concentration in *n*- and *p*-type regions limits the resistance value. Resistor values between 100 Ω and 10 kΩ are common. *See* INTEGRATED CIRCUITS.

The deposited-film and wire-wound resistors lend themselves to the design of adjustable resistors or rheostats and potentiometers. Adjustable-slider power resistors are constructed in the same manner as any wire-wound resistor on a cylindrical form except that when the vitreous outer coating is applied an uncovered strip is provided. The resistance wire is exposed along this strip, and a suitable slider contact can be used to adjust the overall resistance, or the slider can be used as the tap on a potentiometer. *See* POTENTIOMETER; RHEOSTAT. [R.B.D.K.]

Resolving power (optics) A quantitative measure of the ability of an optical instrument to produce separable images. The images to be resolved may differ in position because they represent (1) different points on the object, as in telescopes and microscopes, or (2) images of the same object in light of two different wavelengths, as in prism and grating spectroscopes. For the former class of instruments, the resolving limit is usually quoted as the smallest angular or linear separation of two object points, and for the latter class, as the smallest difference in wavelength or wave number that will produce separate images. Since these quantities are inversely proportional to the power of the instrument to resolve, the term resolving power has generally fallen into disfavor. It is still commonly applied to spectroscopes, however, for which the term chromatic resolving power is used, signifying the ratio of the wavelength itself to the smallest wavelength interval resolved. The figure quoted as the resolving power or resolving limit of an instrument may be the theoretical value that would be obtained if all optical parts were perfect, or it may be the actual value found experimentally. Aberrations of lenses or defects in the ruling of gratings usually cause the actual resolution to fall below the theoretical value, which therefore represents the maximum that could be obtained with the given dimensions of the instrument in question. This maximum is fixed by the wave nature of light and may be calculated for given conditions by diffraction theory. *See* Diffraction; Optical image. [F.A.J.; G.R.H.]

Resonance (acoustics and mechanics) When a mechanical or acoustical system is acted upon by an external periodic driving force whose frequency equals a natural free oscillation frequency of the system, the amplitude of oscillation becomes large and the system is said to be in a state of resonance.

A knowledge of both the resonance frequency and the sharpness of resonance is essential to any discussion of driven vibrating systems. When a vibrating system is sharply resonant, careful tuning is required to obtain the resonance condition. Mechanical standards of frequency must be sharply resonant so that their peak response can easily be determined. In other circumstances, resonance is undesirable. For example, in the faithful recording and reproduction of musical sounds, it is necessary either to have all vibrational resonances of the system outside the band of frequencies being reproduced or to employ heavily damped systems. *See* Acoustic resonator; Sympathetic vibration; Vibration. [L.E.K.]

Resonance (alternating-current circuits) A condition in a circuit characterized by relatively unimpeded oscillation of energy from a potential to a kinetic form. In an electrical network there is oscillation between the potential energy of charge on capacitance and the kinetic energy of current in inductance. This is analogous to the mechanical resonance seen in a pendulum.

Three kinds of resonant frequency in circuits are officially defined. Phase resonance is the frequency at which the phase angle between sinusoidal current entering a circuit and sinusoidal voltage applied to the terminals of the circuit is zero. Amplitude resonance is the frequency at which a given sinusoidal excitation (voltage or current) produces the maximum oscillation of electric charge in the resonant circuit. Natural resonance is the natural frequency of oscillation of the resonant circuit in the absence of any forcing excitation. These three frequencies are so nearly equal in low-loss circuits that they do not often have to be distinguished.

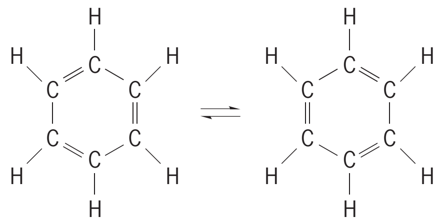
Resonance is of great importance in communications, permitting certain frequencies to be passed and others to be rejected. Thus a pair of telephone wires can carry many messages at the same time, each modulating a different carrier frequency, and each being separated from the others at the receiving end of the line by an appropriate arrangement of resonant filters. A radio or television receiver uses much the same principle to accept a desired signal and to reject all the undesired signals that arrive concurrently at its antenna; tuning a receiver means adjusting a circuit to be resonant at a desired frequency. [H.H.Sk.]

Resonance (molecular structure) A feature of the valence-bond method, which is a mathematical procedure to obtain approximate solutions to the Schrödinger equation for molecules. The valence-bond method is based on the theorem that if two or more solutions to the Schrödinger equation are available, certain linear combinations of them will also be solutions. It has this basis in common with its rival, the molecular orbital method. The valence-bond and molecular orbital approaches are both approximations and, if carried out to their logical and exact extremes, must yield identical results; nevertheless, both are often described as theories. In the valence-bond theory, combinations of solutions represent hypothetical structures of the molecule in question. These structures are said to be resonance (or contributing) structures, and the real molecule is said to be the resonance hybrid (or just simply the hybrid) of these structures. *See* Molecular orbital theory; Schrödinger's wave equation.

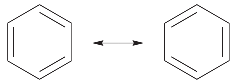
The resonance theory provided a solution for a molecule which had baffled and preoccupied chemists for a century—benzene. The principal use of resonance still lies in the qualitative description of molecules whose properties would otherwise be difficult to understand. *See* Benzene.

Until the beginning of the 20th century, benzene posed a baffling challenge to organic chemists. In spite of its relatively simple formula, C_6H_6, they were unable to conceive of a suitable structure for it. While a great many structures were proposed, the properties of benzene corresponded to none of them.

In the early 1870s F. A. Kekulé proposed a revolutionary idea; benzene must be represented by two structures, (**1**) and (**2**), rather than one, and all compounds containing the benzene skeleton must be subject to a rapid equilibration (oscillation) between the two. Kekulé's description of benzene was not completely satisfactory. While it accounted for the number of substituted benzene isomers, it did not explain why the compound failed to exhibit reactivity indicating the presence of multiple bonds. The problem was resolved with the advent of quantum mechanics in the early part of this century. In a sense, this solution is an expansion of Kekulé's oscillating pair; the so-called activation energy (the energy which must be imparted to a molecule in order to make it overcome the barrier that keeps it from being converted into another molecule) is negative in the case of benzene with respect to the oscillation, and this molecule therefore exists neither as (**1**) nor as (**2**) at any time, but it is an intermediate form (**3**) all the time. This intermediate structure of benzene is described in terms of Kekulé's structures with the symbol ↔ between them; this is intended to signify that benzene has neither structure, but in fact is a hybrid of the two. The properties of benzene are thereby indicated to be those of neither (**1**) nor (**2**), but to be intermediate between the two.



(1) (2)



(3)

The only property of the hybrid which is not intermediate between those of the hypothetical contributing structures is the energy: the energy of a resonance hybrid is by definition always at a minimum. This fact is responsible for the abnormal reluctance of benzene to undergo addition reactions; such reactions would lead to products that no longer have the resonance energy.

Although benzene is the classical example of resonance, the phenomenon is certainly not limited to it. Furthermore, the properties of all compounds are affected by resonance to some degree.

Although the molecular orbital approach has largely supplanted the valence-bond method, the resonance language remains so convenient that it is still used. *See* Chemical bonding; Molecular structure and spectra; Quantum chemistry. [W.J.LeN.]

Resonance (quantum mechanics) An enhanced coupling between quantum states with the same energy. The concept of resonance in quantum mechanics is closely related to resonances in classical physics. *See* RESONANCE (ACOUSTICS AND MECHANICS); RESONANCE (ALTERNATING-CURRENT CIRCUITS).

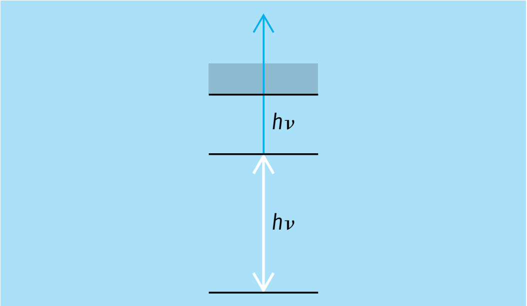
The matching of frequencies is central to the concept of resonance. An example is provided by waves, acoustic or electromagnetic, of a spectrum of frequencies propagating down a tube or waveguide. If a closed side tube is attached, its characteristic natural frequencies will couple and resonate with waves of those same frequencies propagating down the main tube. This simple illustration provides a description of all resonances, including those in quantum mechanics. The propagation of all quantum entities, whether electrons, nucleons, or other elementary particles, is represented through wave functions and thus is subject to resonant effects. *See* ACOUSTIC RESONATOR; CAVITY RESONATOR; HARMONIC (PERIODIC PHENOMENA); WAVEGUIDE.

An important allied element of quantum mechanics lies in its correspondence between frequency and energy. Instead of frequencies, differences between allowed energy levels of a system are considered. In the presence of degeneracy, that is, of different states of the system with the same energy, even the slightest influence results in the system resonating back and forth between the degenerate states. These states may differ in their internal motions or in divisions of the system into subsystems. The above example of wave flow suggests the terminology of channels, each channel being a family of energy levels similar in other respects. These energies are discretely distributed for a closed channel, whereas a continuum of energy levels occurs in open channels whose subsystems can separate to infinity. If all channels are closed, that is, within the realm of bound states, resonance between degenerate states leads to a theme of central importance to quantum chemistry, namely, stabilization by resonance and the resulting formation of resonant bonds. *See* DEGENERACY (QUANTUM MECHANICS); ENERGY LEVEL (QUANTUM MECHANICS); RESONANCE (MOLECULAR STRUCTURE).

Resonances occur in scattering when at least one channel is closed and one open. Typically, a system is divided into two parts: projectile + target, such as electron + atom or nucleon + nucleus. One channel consists of continuum states with their two parts separated to infinity. The other, closed channel consists of bound states. In the atomic example, a bound state of the full system would be a state of the negative ion and, in the nuclear example, a state of the larger nucleus formed by incorporating one extra nucleon in the target nucleus. *See* QUANTUM MECHANICS; SCATTERING EXPERIMENTS (ATOMS AND MOLECULES); SCATTERING EXPERIMENTS (NUCLEI). [A.R.P.R.]

Resonance ionization spectroscopy A form of atomic and molecular spectroscopy in which wavelength-tunable lasers are used to remove electrons from (that is, ionize) a given kind of atom or molecule. Laser-based resonance ionization spectroscopy (RIS) methods have been developed and used with ionization detectors, such as proportional counters, to detect single atoms. Resonance ionization spectroscopy is combined with mass spectrometers to provide analytical systems for a wide range of applications, including physics, chemistry, materials sciences, medicine, and the environmental sciences.

When an atom or molecule is irradiated with a light source of frequency ν, photons at this selected frequency are absorbed only when the energy $h\nu$ (h is Planck's constant) is almost exactly the same as the difference in energy between some excited state and the ground state of the atom or molecule. If a laser source is tuned to a very narrow bandwidth at a frequency that excites a given kind of atom (see illustration), it is highly unlikely that any other kind of atom will be excited. An atom in an excited state can be ionized by photons of the specified frequency ν, provided that $2h\nu$ is greater than the ionization potential of the atom. While the final ionization step can occur with any energy above a threshold, the entire process of ionization is a resonance one. Resonance ionization spectroscopy is a selective process in which only those atoms that are in resonance with the light source are ionized. Modern pulsed lasers have made resonance ionization spectroscopy a practical method for the sensitive (and highly selective) detection of nearly every type of atom in the periodic table. *See* ATOMIC STRUCTURE AND SPECTRA; IONIZATION POTENTIAL; LASER; LASER SPECTROSCOPY; PHOTOIONIZATION; RESONANCE (QUANTUM MECHANICS).



Basic laser scheme for resonance ionization spectroscopy. The atom or molecule is irradiated by a light source with frequency ν and photons of energy $h\nu$, where h is Planck's constant.

Resonance ionization spectroscopy is used to analyze very low levels of trace elements in extremely pure materials, for example, semiconductors in the electronics industry. A sputter-initiated resonance ionization spectroscopy (SIRIS) apparatus uses an argon ion beam to sputter a tiny cloud of atoms from a sample placed in a high-vacuum system and a pulsed laser tuned to detect the specified impurity atom. *See* SPUTTERING.

The sputter-initiated resonance ionization spectroscopy method is also used for chemical and materials research, geophysical research and explorations, medical diagnostics, biological research, and environment analysis. Thermal-atomization resonance ionization spectroscopy (TARIS) may be used for the bulk analysis of materials. By simply using resonance ionization spectroscopy with ionization chambers or proportional counters, gas-phase work can be done to study the diffusion of atoms, measure chemical reaction rates, and investigate the statistical behavior of atoms and molecules. *See* CHEMICAL DYNAMICS; DIFFUSION.

Resonance ionization spectroscopy is used in sophisticated nuclear physics studies involving high-energy accelerators. It is used as an on-line detector to record the hyperfine structure of nuclei with short lifetimes and hence to determine several nuclear properties such as nuclear spin and the shape of nuclei. *See* FINE STRUCTURE (SPECTRAL LINES); NUCLEAR STRUCTURE.

Resonance ionization spectroscopy is used for measurements of krypton-81 in the natural environment to determine the ages of polar ice caps and old ground-water deposits. Oceanic circulation and the mixing of oceans could also be studied by measuring the concentrations of noble-gas isotopes by resonance ionization spectroscopy. *See* DATING METHODS; RADIOISOTOPE (GEOCHEMISTRY). [G.S.H.]

Respiration The various processes associated with the biochemical transformation of the energy available in the organic substrates derived from foodstuffs, to energy usable for synthetic and transport processes, external work, and, eventually, heat. This transformation, generally identified as metabolism, most commonly requires the presence of oxygen and involves the complete oxidation of organic substrates to carbon dioxide and water (aerobic respiration). If the oxidation is incomplete, resulting in organic compounds as end products, oxygen is typically not involved, and the process is then identified as anaerobic respiration. *See* METABOLISM.

The term “external respiration” is more appropriate for describing the exchange of O_2 and CO_2 between the organism and its environment. In most multicellular organisms, and nearly all vertebrates (with the exception of a few salamanders lacking both lungs and gills), external respiration takes place in specialized structures termed respiratory organs, such as gills and lungs. *See* LUNG; RESPIRATORY SYSTEM.

The ultimate physical process causing movement of gases across living tissues is simple passive diffusion. Respiratory gas exchange also depends on two convective fluid movements. The first is the bulk transport of the external medium, air or water, to and across the external respiratory exchange surfaces. The second is the transport of coelomic fluid or blood across the internal surfaces of the respiratory organ. These two convective transports are referred to as ventilation and circulation (or perfusion). They are active processes, powered by ciliary or muscular pumps.

In all vertebrates and many invertebrates, the circulating internal medium (coelomic fluid, hemolymph, or blood) contains a respiratory pigment, for example, hemocyanin or hemoglobin, which binds reversibly with O_2, CO_2, and protons. Respiratory pigments augment respiratory gas exchange, both by increasing the capacity for bulk transport of the gases, and by influencing gas partial pressure (concentration) gradients across tissue exchange surfaces. *See* BLOOD; HEMOGLOBIN; RESPIRATORY PIGMENTS (INVERTEBRATE).

The physiological adjustment of organisms to variations in their need for aerobic energy production involves regulated changes in the exchange and transport of respiratory gases. The adjustments are effected by rapid alterations in the ventilatory and circulatory pumps and by longer-term modifications in the respiratory properties of blood. [K.J.]

Respirator

A device designed to protect the wearer from noxious gases, vapors, and aerosols or to supply oxygen or doses of medication to the wearer. Respirators are used widely in industry to protect workers against harmful atmospheres, and in the military to protect personnel against chemical, biological, or radioactive warfare agents. Respirators are classified according to whether they are atmosphere-supplying or air-purifying.

Atmosphere-supplying respirators are used in atmospheres deficient in oxygen or extremely hazardous to the health of the wearer. Such atmospheres can occur in unventilated cellars, wells, mines, burning buildings, and enclosures containing inert gas. The self-contained breathing apparatus (SCBA) is a completely self-contained unit with the air supply or the oxygen-generating material being carried by the wearer. Air-supplied respirators are equipped with the same variety of facepieces as the SCBA, however these respirators can have the air supplied to the facepiece by means of a hose and a blower—the hose mask—or from a compressed-air source equipped with proper airflow and pressure-regulating equipment—the air-line mask.

In an air-purifying respirator, ambient air is passed through a purifying medium to remove the contaminants. However, these devices do not provide oxygen or protect against oxygen-deficient atmospheres. A widely used air-purifying respirator is the nonpowered, or negative-pressure, respirator (see illustration). Ambient air is inhaled through the purifying medium in the replaceable cartridges and exhaled through an exhaust valve. In the case of the powered air-purifying respirator, an external blower, usually powered by a belt or helmet-mounted battery pack, forces air through the purifying medium and supplies it to the wearer under positive pressure, thus minimizing the problem of face-seal leakage. [B.Y.H.L.; D.A.Ja.]

Negative-pressure air-purifying respirator.

Respiratory pigments (invertebrate)

Colored, metal-containing proteins which combine reversibly with oxygen, and which are found in the body fluids or tissues of invertebrate animals. The role of these pigments is primarily to aid in the transport of molecular oxygen. Thus they are distinguished from respiratory enzymes, which are concerned with the metabolic consumption of oxygen. Four distinctly colored groups of respiratory pigments exist among invertebrates: hemoglobins (purple, become orange-red with oxygen), chlorocruorins (green, become red with oxygen), hemocyanins (colorless, become blue with oxygen), and hemerythrins (colorless, become red with oxygen).

Each of the pigments is composed of two parts, a large protein molecule to which is bound one or more small moieties called prosthetic groups, each of which is or contains a metal. The metal binds the oxygen, and this binding imparts the characteristic color to the pigment. In hemoglobins the prosthetic group is an iron porphyrin compound called heme. Chlorocruorin contains a similar iron porphyrin which differs from heme only in that a vinyl group in the molecule is replaced by formyl. The prosthetic group of hemerythrin consists of two adjacent iron atoms which bind an oxygen molecule between them. The prosthetic group of hemocyanin is analogous and consists of two adjacent copper atoms. Pigments containing vanadium have been found in tunicates, but these substances do not combine reversibly with oxygen and so cannot be considered respiratory pigments.

The protein part of the pigment confers reversibility upon the combination of the metal with oxygen. In the absence of protein, the prosthetic groups lose their capacity to combine with oxygen reversibly. Instead, the metals are irreversibly oxidized: Electrons are transferred from metal to oxygen. The bonds between metal and protein so alter the electronic energy levels of the metal that this transfer, if it occurs, is reversible. For this reason, the combination of hemoglobin with oxygen is described as oxygenation rather than oxidation. The protein is also responsible for certain physiological adaptations of the pigment to the environment. Thus the affinity of the pigment for oxygen is often highest in animals which inhabit environments with the lowest oxygen content. *See* HEMOGLOBIN. [A.F.R.]

Respiratory syncytial virus

A virus belonging to the Paramyxoviridae, genus *Pneumovirus*. This virus, although unrelated to any other known respiratory disease agent and differing from the parainfluenza viruses in a number of important characteristics, has been associated with, a large proportion of respiratory illnesses in very young children, particularly bronchiolitis and pneumonia. It appears to be one of the major causes of these serious illnesses of infants. It is the only respiratory virus that occurs with its greatest frequency in infants in their first 6 months of life. In older infants and children, a milder illness is produced.

The clinical disease in young infants may be the result of an antigen-antibody reaction that occurs when the infecting virus meets antibody transmitted from the mother. For this reason respiratory syncytial vaccines that stimulate production of antibodies in the serum, but not in the nasal secretions, may do more harm than good. *See* ANIMAL VIRUS; VIRUS CLASSIFICATION. [J.I.L.; M.E.Re.]

Respiratory system The system of organs involved in the acquisition of oxygen and the elimination of carbon dioxide by an organism. The lungs and gills are the two most important structures of vertebrates involved in the phase known as external respiration, or gaseous exchanges, between the blood and environment. Internal respiration refers to the gaseous exchanges which occur between the blood and cells. Certain other structures in some species of vertebrates serve as respiratory organs; among these are the integument or skin of fishes and amphibians. The moist, highly vascular skin of anuran amphibians is important in respiration. Certain species of fish have a vascular rectum which is utilized as a respiratory structure, water being taken in and ejected regularly by the animal. Saclike cloacal structures occur in some aquatic species of turtles. These are vascular and are intermittently filled with, and emptied of, water. It is thought that they may function in respiration. During embryonic life the yolk sac and allantois are important respiratory organs in certain vertebrates. *See* ALLANTOIS; YOLK SAC.

Structurally, respiratory organs usually present a vascular surface that is sufficiently extensive to provide an adequate area of absorption for gaseous exchange. This surface is moist and thin enough to allow for the passage of gases. [R.S.McE./T.S.P.]

The shape and volume of the lung, because of its pliability, conforms almost completely to that of its cavity. The lungs are conical; each has an apex and a base, two surfaces, two borders, and a hilum. The apex extends into the superior limit of the thoracic cavity. The base is the diaphragmatic surface. The costal surface may show bulgings into the intercostal spaces. The medial surface has a part lying in the space beside the vertebral column and a part imprinted by the form of structures bulging outward beneath the mediastinal pleura. The cardiac impression is deeper on the left lung because of the position of the heart.

For convenience the lung may be divided into anatomical areas. The bronchial tree branches mainly by dichotomy. The ultimate generations, that is, the respiratory bronchioles, alveolar ducts, and alveoli constitute all of the respiratory portion of the lung. The trachea and extrapulmonary bronchi are kept open by C-shaped bars of hyaline cartilage. When in their branching the bronchi and bronchioles are reduced to a diameter of 1 mm or less, they are then free of cartilage and are called terminal bronchioles. One of the terminal bronchioles enters the apex of a secondary lobule of the lung. These secondary lobules are anatomic units of the lung, whose hexagonal bases rest on the pleura or next to a bronchiole or blood vessel. Finer lines divide the bases of the secondary lobules into smaller areas. These are the bases of primary lobules, each served by a respiratory bronchiole. *See* LUNG; RESPIRATION.

The blood supply to the lung is provided by the pulmonary and the bronchial arteries. The nerves which supply the lung are branches of the vagus and of the thoracic sympathetic ganglia 2, 3, and 4. Efferent vagal fibers are bronchoconstrictor and secretory, whereas the afferents are part of the arc for the breathing reflex. Efferent sympathetic fibers are bronchodilators; hence, the use of adrenalin for relief of bronchial spasm resulting from asthma. *See* ASTHMA; NERVOUS SYSTEM (VERTEBRATE). [L.P.C.]

Respiratory system disorders Dysfunction of the respiratory system, which supplies the body with the oxygen needed for metabolic activities in the cells and removes carbon dioxide, a product of cellular metabolism. The respiratory system includes the nose, mouth, throat, larynx, trachea, bronchi, lungs, and the muscles of respiration such as the intercostal muscles and the diaphragm. *See* RESPIRATION.

The lung has a great reserve capacity, and therefore a significant amount of disease usually must be present to produce clinical signs and symptoms. Shortness of breath (dyspnea) on exertion is the most common symptom of a respiratory disorder. Shortness of breath while at rest is indicative of severe respiratory disease and usually implies a severe abnormality of the lung tissue. If the respiratory system is so diseased that normal oxygenation of the blood cannot occur, blood remains dark, and a bluish color can be seen in the lips or under the fingernails; this condition is referred to as cyanosis. Other signs and symptoms of respiratory disorder can include fever, chest pain, coughing, excess sputum production, and hemoptysis (coughing up blood). Most of these signs and symptoms are nonspecific. *See* HYPOXIA.

Most diseases of the airways increase the resistance against which air is sucked in and pushed out of the lungs. Diseases of the nose usually have little influence since collateral respiration through the mouth compensates easily. Diseases of the throat, larynx, and trachea can significantly inhibit the flow of air into the lungs. Infections in the back of the throat, such as in diphtheria, can cause marked swelling of mucous membranes, resulting in air obstruction. Edema (swelling) of the mucosal lining of the larynx can also cause a reduction in air flow. Likewise, air flow can be inhibited in asthma, in which the smooth muscle in the trachea and bronchi episodically constricts. Chronic bronchitis results in inflammation of and excess mucus production by the bronchi and this also can lead to a reduction in air flow. Bronchiolitis, a condition that usually occurs in children and is often caused by a respiratory virus, results in narrowing and inflammation of small airways and a decrease in air flow.

Pneumonia, cancer, and emphysema are the most common lung diseases and are a major cause of morbidity and mortality in the United States. Of the four major types of lung cancer, approximately 90% can be attributed to the carcinogens present in cigarette smoke. Lung cancer may be detected in asymptomatic persons with a routine chest x-ray, or it may be discovered because of pain, excess coughing, or hemoptysis. *See* CANCER (MEDICINE); EMPHYSEMA; PNEUMONIA.

Among the diseases of pulmonary circulation, congenital malformations of the heart and pulmonary artery account for many cases of respiratory insufficiency in newborn and younger children. In adults, acquired heart diseases can cause backup of blood into the lung and an increased pressure in the pulmonary circulatory system. Also, blood clots, which usually develop first in the deep veins of the legs, can break free and flow to the heart. There they enter the pulmonary arteries and wedge in their small branches, where the clots are referred to as pulmonary thromboemboli, and can cause areas of death in the lung tissue (pulmonary infarcts). Persons who develop thromboemboli usually have chest pain and shortness of breath, and some have hemoptysis. *See* CARDIOVASCULAR SYSTEM; CIRCULATION DISORDERS.

Some neuromuscular diseases, such as poliomyelitis and amyotrophic lateral sclerosis (Lou Gehrig's disease), can cause dysfunction of the muscles of respiration. The resulting inability of these muscles to move air into the lungs can cause severe shortness of breath and predispose the patient to pneumonia. *See* MUSCULAR SYSTEM DISORDERS; POLIOMYELITIS; RESPIRATORY SYSTEM. [S.P.H.]

Response A quantitative expression of the manner in which a microphone, amplifier, loudspeaker, or other component or system performs its intended function. A linear response means that the output signal is exactly proportional to the input signal for the entire range of frequencies over which the device is intended to operate. A logarithmic response means that the output signal is a logarithmic function of the input signal. The frequency response of a device, often presented as a curve on a graph, is the deviation over the frequency range from the response at some selected frequency, such as 1000 Hz. *See* AMPLIFIER; CHARACTERISTIC CURVE; LOUDSPEAKER; MICROPHONE. [J.Mar.]

Rest mass A constant intrinsic to a body which determines its inertial and energy-momentum properties. It is a fundamental concept of special relativity, and in particular it determines the internal energy content of a body. It is the same as the inertial mass of classical mechanics. According to the principle of equivalence, the basic physical principle of general relativity, the inertial mass of a body is also equal to its gravitational mass. *See* Classical mechanics; Gravitation; Relativistic mechanics; Relativity.

The rest mass or inertial mass of a body, m, is a measure of its resistance to being accelerated at a by $\mathbf{a}$ force $\mathbf{F}$; in classical mechanics the relation between inertial mass, acceleration, and force is given by Newton's law, Eq. (1). In special relativity

$$\mathbf{F} = m\mathbf{a} \qquad (1)$$

Newton's law holds exactly only in the body's rest frame, that is, the frame in which the body is instantaneously at rest. *See* Newton's laws of motion.

Associated with the rest mass of a body, there is an internal or rest energy. In the system where the body is at rest, the energy of the body is given by Eq. (2).

$$E = mc^2 \qquad \text{(body at rest)} \qquad (2)$$

The experimental realization of the interconversion of mass and energy is accomplished in the reactions of nuclei and elementary particles. In particular, the energy source of nuclear bombs and nuclear fission reactors is a small decrease in the total mass of the interacting nuclei, which gives rise to a large energy release because of the large numerical value of c^2. *See* Elementary particle; Nuclear fission. [R.J.A.]

Restionales An order of flowering plants, division Magnoliophyta (Angiospermae), in the subclass Commelinidae of the class Liliopsida (monocotyledons). The order consists of 4 families and about 450 species, some 400 of them belonging to the Restionaceae. The vast majority of the species grow in temperate regions of the Southern Hemisphere. The Restionales are wind- or self-pollinated, with reduced flowers and a single, pendulous, orthotropous ovule in each of the 1–3 locules of the ovary. *See* Commelinidae; Cyperales; Liliopsida; Magnoliophyta. [A.Cr.; T.M.Ba.]

Restoration ecology A field in the science of conservation that is concerned with the application of ecological principles to restoring degraded, derelict, or fragmented ecosystems. The primary goal of restoration ecology (also known as ecological restoration) is to return a community or ecosystem to a condition similar in ecological structure, function, or both, to that existing prior to site disturbance or degradation.

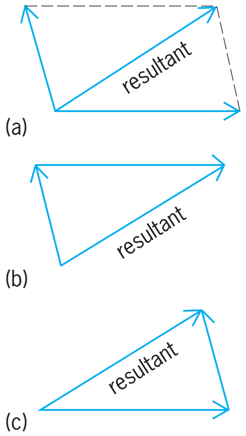
A reference framework is needed to guide any restoration attempt—that is, to form the basis of the design (for example, desired species composition and density) and monitoring plan (for example, setting milestones and success criteria for restoration projects). Such a reference system is derived from ecological data collected from a suite of similar ecosystems in similar geomorphic settings within an appropriate biogeographic region. Typically, many sites representing a range of conditions (for example, pristine to highly degraded) are sampled, and statistical analyses of these data reveal what is possible given the initial conditions at the restoration site. *See* Ecology, applied; Ecosystem. [P.L.Fi.]

Restriction enzyme An enzyme, specifically an endode-oxyribonuclease, that recognizes a short specific sequence within a deoxyribonucleic acid (DNA) molecule and then catalyzes double-strand cleavage of that molecule. Restriction enzymes have been found only in bacteria, where they serve to protect the bacterium from the deleterious effects of foreign DNA. *See* Deoxyribonucleic acid (DNA).

There are three known types of restriction enzymes. Type I enzymes recognize a specific sequence on DNA, but cleave the DNA chain at random locations with respect to this sequence. They have an absolute requirement for the cofactors adenosine triphosphate (ATP) and *S*-adenosylmethionine. Because of the random nature of the cleavage, the products are a heterogeneous array of DNA fragments. Type II enzymes also recognize a specific nucleotide sequence but differ from the type I enzymes in that they do not require cofactors and they cleave specifically within or close to the recognition sequence, thus generating a specific set of fragments. It is this exquisite specificity which has made these enzymes of great importance in DNA research, especially in the production of recombinant DNAs. Type III enzymes have properties intermediate between those of the type I and type II enzymes. They recognize a specific sequence and cleave specifically a short distance away from the recognition sequence. They have an absolute requirement for the ATP cofactor, but they do not hydrolyze it.

A key feature of the fragments produced by restriction enzymes is that when mixed in the presence of the enzyme DNA ligase, the fragments can be rejoined. Should the new fragment carry genetic information that can be interpreted by the bacterial cell containing the recombinant molecule, then the information will be expressed as a protein and the bacterial cell will serve as an ideal source from which to obtain that protein. For instance, if the DNA fragment carries the genetic information encoding the hormone insulin, the bacterial cell carrying that fragment will produce insulin. By using this method, the human gene for insulin has been cloned into bacterial cells and used for the commercial production of human insulin. The potential impact of this technology forms the basis of the genetic engineering industry. *See* Enzyme; Genetic engineering. [R.Ro.]

Resultant of forces A system of at most a single force and a single couple whose external effects on a rigid body are identical with the effects of the several actual forces that act on the body. For analytic purposes, forces are grouped and replaced by their resultant. Forces can be added graphically (see illustration) or analytically. The sum of more than two vector forces can be found by extending the method of illustration *c* to a three-dimensional vector polygon in which one force is drawn from the tip of the previous one until all are laid out.



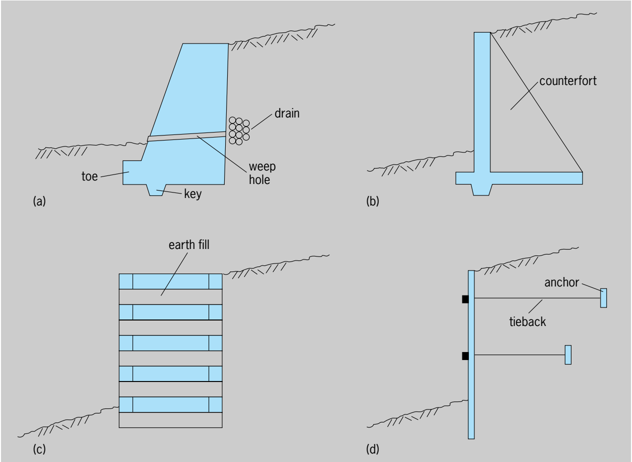
Resultant of two forces acting through a common center. (*a*) Diagonal of parallelogram. (*b, c*) Hypotenuse of triangle.

The resultant force is the force vector required to close the polygon directed from the tail of the first force vector to the tip of the last. A force system has a zero force resultant if its vector polygon closes. *See* Calculus of vectors.

Two force systems are equivalent if their resultant forces, as described above, are equal and if their total vector moments about the same point are also equal. Vector moments are combined in the same manner as forces, that is, by parallelograms, triangles, or polygons. A resultant is the equivalent force system having the fewest possible forces and couples. *See* Couple; Force; Statics. [N.S.F.]

Retaining wall A generic structure that is employed to restrain a vertical-faced or near-vertical-faced mass of earth. The earth behind the wall may be either the natural embankment or the backfill material placed adjacent to the retaining wall. Retaining walls must resist the lateral pressure of the earth, which tends to cause the structure to slide or overturn.

There are several types of retaining walls. A gravity wall is typically made of concrete and relies on its weight for stability (illus. *a*). The mass of the structure must be sufficient to develop enough frictional resistance to sliding, and the base or footing of the structure must be wide enough to develop sufficient moment to resist overturning earth forces. A cantilever retaining wall (illus. *b*) gains a larger effective mass by virtue of the soil placed on the horizontal cantilevered section of the wall. Reinforced counterforts are spaced along the wall to increase its strength. A variation of the gravity retaining wall is the crib wall (illus. *c*) is usually constructed of prefabricated interlocking concrete units. The crib is then filled with soil before the backfill adjacent to the crib is placed. Bulkhead retaining walls (illus. *d*) consist of vertical sheet piling that extends down into the soil and is stabilized by one or more tiebacks and anchors periodically spaced along the structure. The sheet piling may be made of reinforced concrete, steel, or aluminum. *See* CANTILEVER.

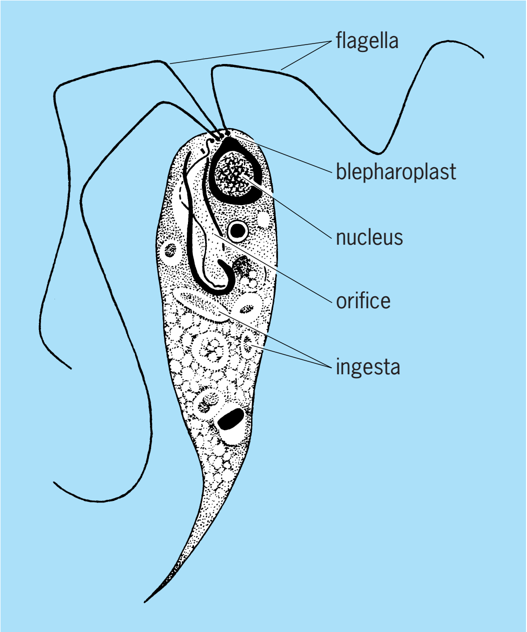


Common types of retaining walls. (*a*) Gravity wall. (*b*) Cantilever wall. (*c*) Crib wall. (*d*) Bulkhead.

Retaining walls are often used in the marine environment, where they separate the retained soil from the water. Gravity walls (known as seawalls) can be constructed where strong wave and current forces are exerted on the wall. Bulkheads are more commonly found in sheltered areas such as harbors and navigation channels. *See* HARBORS AND PORTS. [R.M.S.]

Reticular formation Characteristic clusters of nerve cell bodies (gray matter) and their meshwork or reticulum, of fibers which are found in the brainstem and the diencephalon. The reticular formation is thought to be a complex, highly integrated mechanism which exerts both inhibition and facilitation on almost every type of activity of the central nervous system. *See* NERVOUS SYSTEM (VERTEBRATE). [D.B.W.]

Reticulosa An order of the subclass Hexasterophora in the class Hexactinellida. This is a group of Paleozoic hexactinellids with a branching form. Each branch is provided with dermal, parenchymal, and gastral spicule reticulations. *See* HEXASTEROPHORA. [W.D.H.]



A retortamonad, *Chilomastix aulastomi*.

Retortamonadida An order of parasitic flagellate protozoa belonging to the class Zoomastigophorea. All retortamonads are medium to large in size and have a complicated blepharoplast-centrosome-axo-style apparatus. Retortamonadida have two or four flagella, one turned ventrally into a cytostomal depression. The nucleus, containing a distinct endosome, is located at the anterior tip. The body is twisted. These organisms are actually symbionts, ingesting bacteria in the digestive tracts of their hosts. *Retortamonas* has several species, some of which infest insects and vertebrates. *Chilomastix* also has a number of species, found in vertebrates and invertebrates (see illustration). *See* PROTOZOA; SARCOMASTIGOPHORA; ZOOMASTIGOPHOREA. [J.B.L.]

Retrograde motion (astronomy) In astronomy, either an apparent east-to-west motion of a planet or comet with respect to the background stars or a real east-to-west orbital motion of a comet about the Sun or of a satellite about its primary. The majority of the objects in the solar system revolve from west to east about their primaries. However, near the time of closest approach of Earth and a superior planet, such as Jupiter, because of their relative motion, the superior planet appears to move from east to west with respect to the background stars. The same apparent motion occurs for an inferior planet, such as Venus, near the time of closest approach to Earth.

Actual, rather than apparent, retrograde motion occurs among the satellites and comets; the eighth and ninth satellites of Jupiter and the ninth satellite of Saturn are examples. *See* ORBITAL MOTION. [R.L.Du.]

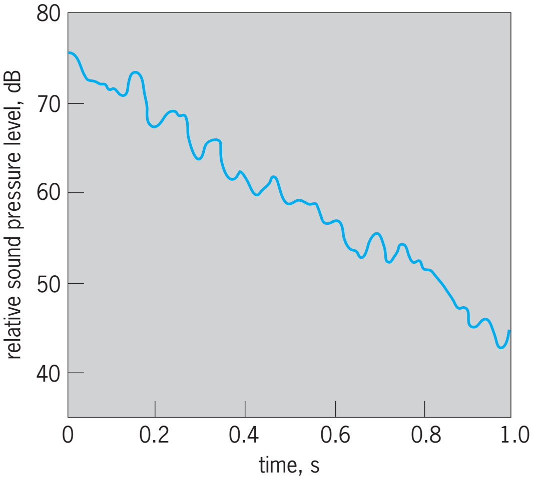
Retrovirus A family of viruses distinguished by three characteristics: (1) genetic information in ribonucleic acid (RNA); (2) virions possess the enzyme reverse transcriptase; and (3) virion morphology consists of two proteinaceous structures, a dense core and an envelope that surrounds the core. Some viruses outside the retrovirus family have some of these characteristics, but none has all three. Numerous retroviruses have been described; they are found in all families of vertebrates. *See* ANIMAL VIRUS; REVERSE TRANSCRIPTASE; RIBONUCLEIC ACID (RNA).

The genome is composed of two identical molecules of single-stranded RNA, which are similar in structure and function to cellular messenger RNA. Deoxyribonucleic acid (DNA) is not present in the virions of retroviruses. The reverse transcriptase in each virus makes a DNA copy of the RNA genome shortly after entry of the virus into the host cell. The discovery of this enzyme changed thinking in biology. Previously, the only known direction for the flow of genetic information was from DNA to RNA, yet retroviruses make DNA copies of their genome by using an RNA template. This reversal of genetic information was considered backward and hence the family name retrovirus, meaning backward virus.

Once the DNA copy of the RNA genome is made, it is inserted directly into one of the chromosomes of the host cell. This results in new genetic information being acquired by the host species. The study of reverse transcriptase has led to other discoveries of how retroviruses add a variety of new genetic information into the host. One such class of genes carried by retroviruses is oncogenes, meaning tumor genes. Retroviral oncogenes appear to be responsible for tumors in animals. *See* ONCOGENES; VIRUS CLASSIFICATION.

Two distinct retroviruses have been discovered in humans. One is human T-cell lymphotropic virus type 1 (HTLV-1), a type C-like virus associated with adult T-cell leukemia. The other is the human acquired immune deficiency syndrome (AIDS) virus, a type E lentivirus. *See* ACQUIRED IMMUNE DEFICIENCY SYNDROME (AIDS); LEUKEMIA. [P.A.Ma.]

Reverberation After sound has been produced in, or enters, an enclosed space, it is reflected repeatedly by the boundaries of the enclosure, even after the source ceases to emit sound. This prolongation of sound after the original source has stopped is called reverberation. A certain amount of reverberation adds a pleasing characteristic to the acoustical qualities of a room. However, excessive reverberation can ruin the acoustical properties of an otherwise well-designed room. A typical record representing the sound-pressure level at a given point in a room plotted against time, after a sound source has been turned off, is given in the decay curve shown in the illustration. The rate of sound decay is not uniform but fluctuates about an average slope. *See* ARCHITECTURAL ACOUSTICS; SOUND. [C.M.H.]



Typical decay curve illustrating reverberation.

Reverse transcriptase Any of the deoxyribonucleic acid (DNA) polymerases present in particles of retroviruses which are able to carry out DNA synthesis using an RNA template. This reaction is called reverse transcription since it is the opposite of the usual transcription reaction, which involves RNA synthesis using a DNA template. *See* RETROVIRUS.

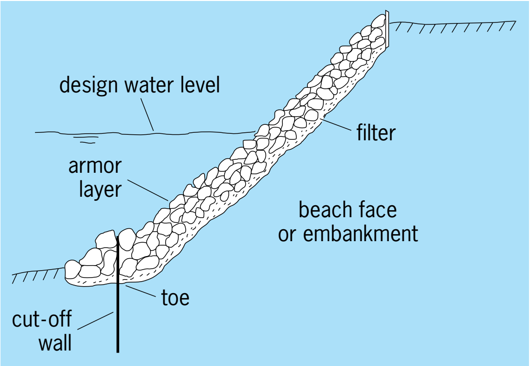
The transfer of genetic information from RNA to DNA in retrovirus replication was proposed in 1964 by H. M. Temin in the DNA provirus hypothesis for the replication of Rous sarcoma virus, an avian retrovirus which causes tumors in chickens and transformation of cells in culture, and reverse transcriptase has since been purified from virions of many retroviruses. The avian, murine, and human retrovirus DNA polymerases have been extensively studied.

Studies indicate that reverse transcriptase is widely distributed in living organisms and that all reverse transcriptases are evolutionarily related. For example, the organization of the nucleotide sequence of integrated retroviral DNA has a remarkable resemblance to the structure of bacterial transposable elements, in particular, transposons.

Reverse transcriptase genes are present in the eukaryotic organisms in retrotransposons and in retroposons or long interspersed (LINE) elements. Both of these types of elements can transpose in cells. *See* DEOXYRIBONUCLEIC ACID (DNA); RIBONUCLEIC ACID (RNA); TRANSPOSONS. [H.M.T.]

Revetment A facing or veneer of stone, concrete, or other materials constructed on a sloping embankment, dike, or beach face to protect it against erosion caused by waves or currents. The revetment may be a rigid cast-in-place concrete structure; but more commonly it is a flexible structure constructed of stone riprap or interlocking concrete blocks. It is sometimes an articulated block structure where the armor blocks are set in a form known as a flexible carpet; that is, the blocks interlock for stability, but the interlocking makes them flexible enough to respond to settlement of the underlying soil. A flexible revetment provides protection from exterior hydraulic forces, and it also can tolerate some settlement or consolidation of the underlying soil.

A typical revetment might employ stone riprap as the armor material (see illustration). A revetment typically has three major components: (1) the armor layer, which resists the wave or current-induced hydraulic forces; (2) a filter layer under the armor layer to allow water seepage out of the underlying soil without the removal of fine soil particles; and (3) a mechanism to stabilize the structure toe. Toe stabilization is particularly important where waves break on the structure, but may not be necessary if the revetment extends to sufficient depths where hydraulic forces will not erode the toe of the slope. The design water level (see illus.) for the structure may be higher than the normal water level during nonstorm conditions. If the revetment is exposed to waves that will break and run up the face of the revetment, the upper extent of the revetment must be sufficiently high to counter the force exerted by the waves.



Cross-sectional profile of a typical stone revetment.

Although stone riprap is the most commonly used material for revetment armor layers, a wide variety of other materials have been used, including cast-in-place concrete and poured asphalt, wire bags filled with stone (gabions), interlocking concrete blocks, soil cement, cement-filled bags, interlocked tires, woven wooden mattresses, and vegetation (only used for surfaces exposed to very low waves or slow-moving currents). *See* RETAINING WALL; RIVER ENGINEERING. [R.M.S.]

Reynolds number In fluid mechanics, the ratio $\rho v d/\mu$, where ρ is fluid density, v is velocity, d is a characteristic length, and μ is fluid viscosity. The Reynolds number is significant in the design of a model of any system in which the effect of viscosity is important in controlling the velocities or the flow pattern. In the evaluation of drag on a body submerged in a fluid and moving with respect to the fluids, the Reynolds number is important.

The Reynolds number also serves as a criterion of type of fluid motion. In a pipe, for example, laminar flow normally exists at Reynolds numbers less than 2000, and turbulent flow at Reynolds numbers above about 3000. *See* Dynamic similarity; Fluid mechanics; Laminar flow; Turbulent flow. [G.Mu.]

Rh incompatibility A condition in which red blood cells of the fetus become coated with an immunoglobulin (IgG) antibody [Rh (rhesus) antibody] of maternal origin which is directed against an antigen (Rh D antigen) of paternal origin that is present on fetal cells. *See* Antibody; Antigen; Blood groups; Immunoglobulin.

A pregnant woman may develop an antibody to a red blood cell antigen that the fetus has but that she does not possess. This occurs because the fetus has inherited the antigen from the father; fetal red cells pass into the maternal circulation and are recognized as foreign by the mother. The mother develops antibodies to the foreign protein; the antibodies pass across the placenta and attack the fetal red blood cells, producing a hemolytic anemia. This phenomenon is known as alloimmunization. Alloimmunization of the mother results in hemolytic disease of the newborn (also known as erythroblastosis fetalis). *See* Anemia; Autoimmunity.

The development of Rh incompatibility is determined by the Rh types of the parents. Some Rh-incompatible pregnancies do not result in sensitization. Factors influencing the occurrence of sensitization include the timing and extent of the transplacental hemorrhage, the degree and strength of antibody development in the mother, and the ABO status of mother and fetus. Most immunizations result from transplacental hemorrhage during placental separation at delivery.

The at-risk mother is monitored for the development and progression of Rh incompatibility with serial serum antibody titers to anti-D. The presence of anti-D and its titer do not necessarily correlate with the status of the fetus. To monitor the status, amniocentesis is performed. This procedure permits measurement of bile pigment concentration and assessment of lung maturity. These tests are done serially to decide when to deliver the fetus or whether to transfuse the fetus until it is mature enough to be delivered safely. *See* Prenatal diagnosis.

Following delivery, the infant may require transfusion immediately or during the postnatal period. This may involve simple replacement or exchange transfusion, in which the infant's blood volume is replaced with compatible blood. The aim of exchange is to remove bilirubin and antibody-coated red blood cells and to correct the anemia while replacing the infant's blood with blood that is antigen negative for the offending antibody. Other medical treatment for jaundice may also be required. *See* Transfusion.

Rh immune globulin (RhIG) is a concentrated solution of IgG anti-D obtained from pooled human plasma. Its action is to interfere with antigen recognition. RhIg should be administered to any Rh-negative mother of an Rh-positive infant within 72 h after delivery. Administration of RhIG at the twenty-eighth week of pregnancy followed by a second dose at birth has been very successful in all but eliminating Rh hemolytic disease. *See* Pregnancy. [N.L.C.L.]

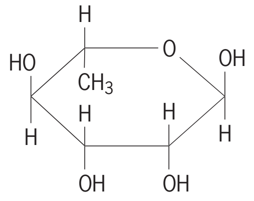
Rhabditida An order of nematodes in which the number of labia varies from a full complement of six to three or two or none. The tubular stoma may be composed of five or more sections called rhabdions. The three-part esophagus always ends in a muscular bulb that is invariably valved. The excretory tube is cuticularly lined, and paired lateral collecting tubes generally run posteriorly from the excretory cell; some taxa have anterior tubules also. Females have one or two ovaries; when only one is present, the vulva shifts posteriorly. The cells of the intestine may be uninucleate, binucleate, or tetranucleate, and the hypodermal cells may also be multinucleate.

There are eight superfamilies in the order: Rhabditoidea, Allionematoidea; Bunonematoidea, Cephaloboidea, Panagrolaimoidea, Robertioidea, Chambersiellolidea, and Elaphonematoidea. The Rhabditoidea are one of the largest nematode superfamilies and contain many important parasites of humans and domestic animals. This superfamily is distinguished by the well-developed cylindrical stoma and three-part esophagus that ends in a valved terminal bulb. In parasitic species, adult stages and some larval stages lack the valved terminal bulb. Though most species of Rhabditoidea are free-living feeders on terrestrial bacteria, others are important in the biological control of insects or as parasites of mammals. *See* Medical parasitology. [A.R.M.]

Rhabdocoela Formerly considered an order of the Turbellaria, the group Rhabdocoela is now usually divided into three orders, Catenulida, Macrostomida, and Neorhabdocoela. The temocephalids are a group of rhabdocoeles closely related to the Dalyelloida. They are sometimes considered a distinct order but are usually classified under the Neorhabdocoela. They differ from other rhabdocoeles chiefly in the possession of tentacles and adhesive organs and in the absence of epidermal cilia in most species.

The rhabdocoeles have a simple, unbranched intestine, with little if any diverticulations. The pharynx is simple or bulbous, the gonads are usually compact, a cuticular apparatus is associated with the copulatory organ, and there are two main longitudinal nerves. This large group includes most small freshwater Turbellaria as well as many marine and some terrestrial species. *See* Turbellaria. [E.R.J.]

L-Rhamnose A methyl pentose, known also as 6-deoxy-L-mannose and L-mannomethylose. The free sugar, with the structure shown, occurs in leaves and flowers of poison ivy (*Rhus toxicodendron*). It is a constituent of many of the plant glycosides such as quercitrin and rutin. The type *II Pneumococcus* specific polysaccharides and a wide variety of gums and mucilages contain L-rhamnose, and there is evidence that this sugar is present in a number of bacterial polysaccharides. *See* Monosaccharide. [W.Z.H.]



Rhenium A chemical element, Re, with atomic number 75 and atomic weight 186.2. Rhenium is a transition element. It is a dense metal (21.04) with the very high melting point of 3440°C (6220°F). *See* Periodic table.

Rhenium is similar to its homolog technetium in that it may be oxidized at elevated temperatures by oxygen to form the volatile heptoxide, Re_2O_7; this in turn may be reduced to a lower oxide, ReO_2. The compounds ReO_3, Re_2O_3, and Re_2O, are well known. Perrhenic acid, $HReO_4$, is a strong monobasic acid and is only a very weak oxidizing agent. Complex perrhenates, such as cobalt hexammine perrhenate, $[Co(NH_3)_6(ReO_4)_3]$, are also known.

The halogen compounds of rhenium are very complicated, and a large series of halides and oxyhalides have been reported. Rhenium forms two well-characterized sulfides, Re_2S_7 and ReS_2, as well as two selenides, Re_2Se_7 and $ReSe_2$. The sulfides have their counterparts in the technetium compounds, Tc_2S_7 and TcS_2. *See* Technetium; Transition elements. [S.F.]

Rheology In the broadest sense of the term, that part of mechanics which deals with the relation between force and deformation in material bodies. The nature of this relation depends on the material of which the body is constituted. It is customary to represent the deformation behavior of metals and other solids by a model called the linear or hookean elastic solid (displaying the property known as elasticity) and that of fluids by the model of the linear viscous or newtonian fluid (displaying the property known as viscosity). These classical models are, however, inadequate to depict certain nonlinear and time-dependent deformation behavior that is sometimes observed. It is these nonclassical behaviors which are the chief interest of rheologists and hence referred to as rheological behavior. *See* ELASTICITY; STRESS AND STRAIN; VISCOSITY.

Rheological behavior is particularly readily observed in materials containing polymer molecules which typically contain thousands of atoms per molecule, although such properties are also exhibited in some experiments on metals, glasses, and gases. Thus rheology is of interest not only to mathematicians and physicists, who consider it to be a part of continuum mechanics, but also to chemists and engineers who have to deal with these materials. It is of special importance in the plastics, rubber, film, and coatings industries. *See* FLUID MECHANICS; PAINT; PLASTICS PROCESSING; POLYMER; RUBBER; SURFACE COATING.

Models and properties. Consider a block of material of height h deformed in the manner indicated in Fig. 1; the bottom surface is fixed and the top moves a distance w parallel to itself. A measure of the deformation is the shear strain γ given by Eq. (1).

$$\gamma = \frac{w}{h} \tag{1}$$

To achieve such a deformation if the block is a linear elastic material, it is necessary to apply uniformly distributed tangential forces on the top and bottom of the block as shown in Fig. 1*b*. The intensity of these forces, that is, the magnitude of the net force per unit area, is called the shear stress S. For a linear elastic material, γ is much less than unity and is related to S by Eq. (2),

$$S = G\gamma \tag{2}$$

where the proportionality constant G is a property of the material known as the shear modulus.

If the material in the block is a newtonian fluid and a similar set of forces is imposed, the result is a simple shearing flow, a deformation as pictured in Fig. 1*b* with the top surface moving with a velocity dw/dt. This type of motion is characterized by a rate of shear $\dot{\gamma} = (dw/dt)/h$, which is proportional to the shear stress S as given by Eq. (3), where η is a property of the material called the viscosity.

$$S = \eta\dot{\gamma} \tag{3}$$

Linear viscoelasticity. If the imposed forces are small enough, time-dependent deformation behavior can often be described by the model of linear viscoelasticity. The material properties in this model are most easily specified in terms of simple experiments.

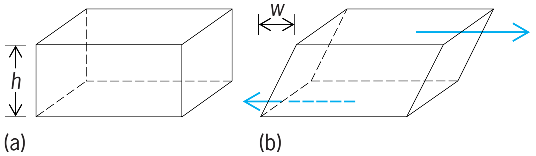


Fig. 1. Simple shear. (*a*) Undeformed block of height *h*. (*b*) Deformed block after top has moved a distance *w* parallel to itself. The arrows indicate the net forces acting on the top and bottom faces. The forces which must be applied to left and right faces to maintain a steady state are not indicated.

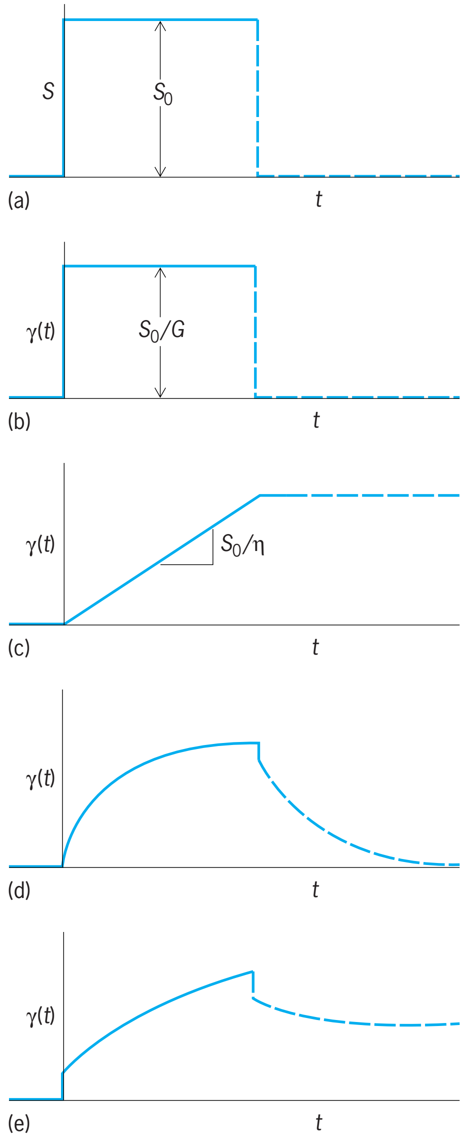

Fig. 2. Creep and recovery; solid lines indicate creep; broken lines indicate recovery. (*a*) Applied stress history. (*b*) Corresponding strain history for linear elastic solid, (*c*) linear viscous fluid, (*d*) viscoelastic solid, and (*e*) viscoelastic fluid.

In a creep experiment a stress is suddenly applied and then held constant; the deformation is then followed as a function of time. This stress history is indicated in the solid line of Fig. 2*a* for the case of an applied constant shear stress S_0. If such an experiment is performed on a linear elastic solid, the resultant deformation is indicated by the full line in Fig. 2*b* and for the linear viscous fluid in Fig. 2*c*. In the case of elasticity, the result is an instantly achieved constant strain; in the case of the fluid, an instantly achieved constant rate of strain. In the case of viscoelastic materials, there are some which eventually attain a constant equilibrium strain (Fig. 2*d*) and hence are called viscoelastic solids. Others eventually achieve constant rate of strain (Fig. 2*e*) and are called viscoelastic fluids. If the material is linear viscoelastic, the deformation $\gamma(S_0, t)$ is a function of the time t since the stress was applied and also a linear function of S_0; that is, Eq. (4) is satisfied, where $J(t)$ is independent of S_0. The

$$\gamma(S_0, t) = S_0 J(t) \tag{4}$$

function $J(t)$ is a property of the material known as the shear creep compliance. *See* CREEP (MATERIALS).

Nonlinear viscoelasticity. If stresses become too high, linear viscoelasticity is no longer an adequate model for materials which exhibit time-dependent behavior. In a creep experiment, for example, the ratio of the strain to stress, $\gamma(t, S_0)/S_0$, is no longer independent of S_0; this ratio generally decreases with increasing S_0. Two examples of nonlinear viscoelasticity are shear thinning and thixotropy.

For polymer melts, solutions, and suspensions, generally speaking, the viscosity decreases as the shear rate increases. This type of behavior, called shear thinning, is of considerable industrial significance. For example, paints are formulated to be shear-thinning. A high viscosity at low flow rates keeps the paint from dripping from the brush or roller and prevents sagging of the paint film newly applied to a vertical wall. The lower viscosity at the high deformation rates while brushing or rolling means that less energy is required, and hence the painter's arm does not become overly tired.

Thixotropy is a property of suspensions (for example, bentonite clay in water) which, after remaining at rest for a long time, act as solids; for example, they cannot be poured. However, if it is stirred, such a suspension can be poured quite freely. If the suspension is then allowed to rest, the viscosity increases with time and finally sets again. This whole process is reversible; it can be repeated again and again. *See* GEL; NON-NEWTONIAN FLUID. [H.Mark.]

Rheostat A variable resistor constructed so that its resistance value may be changed without interrupting the circuit to which it is connected. It is used to vary the current in a circuit. The resistive element of a rheostat may be a metal wire or ribbon, carbon disks, or a conducting liquid. *See* RESISTOR.

The metallic rheostat is the most common. The wire or ribbon is constructed in a coil or a grid, and taps are brought out from different sections of the element to a multicontact switch which can short-circuit any section of the resistor or switch it out of the circuit. For more continuous control, as is needed for laboratory rheostats, a sliding-contact finger bears directly on closely wound coils of resistive wire.

Typical applications of rheostats are for starting or controlling the speed of motors, for adjusting generator characteristics, for controlling storage-battery charging, for dimming lights, and for imposing artificial loads on electrical equipment during tests. [F.H.R.]

Rheumatic fever An illness that follows an upper respiratory infection with the group A streptococcus (*Streptococcus pyogenes*) and is characterized by inflammation of the joints (arthritis) and the heart (carditis). Arthritis typically involves multiple joints and may migrate from one joint to another. The carditis may involve the outer lining of the heart, the heart muscle itself, or the inner lining of the heart. A minority of affected individuals also develop a rash (erythema marginatum), nodules under the skin, or Sydenham's chorea (a neurologic disorder characterized by involuntary, uncoordinated movements of the legs, arms, and face). Damage to heart valves may be permanent and progressive, leading to severe disability or death from rheumatic heart disease years after the initial attack. The disease occurs an average of 19 days after the infection and is thought to be the result of an abnormal immunologic reaction to the group A streptococcus. Initial attacks of rheumatic fever generally occur among individuals aged 5 to 15. Those who have had one attack are highly susceptible to recurrences after future streptococcal infections.

Initial attacks of rheumatic fever can be prevented by treatment of strep throat with penicillin for at least 10 days. Patients who have had an episode of rheumatic fever should continue taking antibiotics for many years to prevent group A streptococcal infections that may trigger a recurrence of rheumatic fever. *See* HEART DISORDERS; STREPTOCOCCUS. [A.L.Bi.; J.B.Da.]

Rheumatism Any combination of muscle or joint pain, stiffness, or discomfort arising from nonspecific disorders. It is generally used as a lay expression to indicate a chronic or recurrent condition affecting a certain area and precipitated by cold, dampness, or emotional stress.

Lumbago, wryneck, charleyhorse and shinsplint are commonly used expressions included under the catchall category of rheumatism. [R.Se.]

Rhinoceros Odd-toed ungulates (order Perissodactyla) which are members of the family Rhinoceratidae. The bodies and limbs of these mammals are massive and thick-skinned. Also characteristic of the family are the horns (epidermal derivatives), either one or two, which are composed of a solid mass of hairs attached to a bony prominence on the skull. The feet are tridactyl, with three hooves; the middle one is the most developed. There are five species, found in Asia and Africa.

Sight is poorly developed in these animals; however, hearing is quite good and the sense of smell is excellent. Most species are solitary and aggressive and are extremely dangerous since they are unpredictable in behavior. All species are vegetarians. *See* PERISSODACTYLA. [C.B.C.]

Rhinovirus A genus of the family Picornaviridae. Members of the human rhinovirus group include at least 113 antigenically distinct types. Like the enteroviruses, the rhinoviruses are small (17–30 nanometers), contain ribonucleic acid (RNA), and are not inactivated by ether. Unlike the enteroviruses, they are isolated from the nose and throat rather than from the enteric tract, and are unstable if kept under acid conditions (pH 3–5) for 1–3 h. Rhinoviruses have been recovered chiefly from adults with colds and only rarely from patients with more severe respiratory diseases. *See* COMMON COLD; ENTEROVIRUS.

In a single community, different rhinovirus types predominate during different seasons and during different outbreaks in a single season, but more than one type may be present at the same time.

Although efforts have been made to develop vaccines, none is available. Problems that hinder development of a useful rhinovirus vaccine include the short duration of natural immunity even to the specific infecting type, the large number of different antigenic types of rhinovirus, and the variation of types present in a community from one year to the next. *See* ANIMAL VIRUS; PICORNAVIRIDAE; VIRUS CLASSIFICATION. [J.L.Me.; M.E.Re.]

Rhizocephala An order of crustacean parasites related to the barnacles. Worldwide in distribution, they prey on other crustaceans, principally Decapoda, such as crabs, shrimp, and their allies. Rhizocephala produce modifications affecting the abdomen of the crab, making males resemble females and causing immature females to acquire precociously the adult form. These parasites have become so modified by their mode of life that, as adults, they are no longer recognizable as barnacles, or even as crustaceans.

An adult rhizocephalan is a thin-walled sac enclosing a visceral mass, composed chiefly of ovaries and testes. It shows no trace of segmentation, appendages, or sense organs. Even an alimentary tract is missing. Instead, it possesses a threadlike root system which penetrates the interior of the host in all directions and absorbs nourishment from the body fluids of the crab. [P.G.Re.]

Rhizomastigida An order of the class Zoomastigophorea, also known as the Rhizomastigina. All Rhizomastigida species are microscopic and ameboid, and have one or two flagella. Rhizomastigida are small, colorless, and rarely abundant. They generally occur at the mud–water interface and are holozoic, saprozoic, or parasitic. Life histories are poorly known, except for *Mastigella*. The group is small, but species occur in both fresh and salt water. *See* ZOOMASTIGOPHOREA. [J.B.L.]

Rhizophorales An order of flowering plants, division Magnoliophyta (Angiospermae), in the subclass Rosidae of the class Magnoliopsida (dicotyledons). The order contains a single family, Rhizophoraceae, with about 100 species widely distributed in the tropics. The plants are mostly tanniferous trees and shrubs with the leaves opposite, simple, and entire. The flowers are regular, mostly perfect, and variously perigynous or epigynous. The sepals are four or five and commonly fleshy or leathery; the petals are the same number as the sepals and likewise small and fleshy. The stamens are twice as many as the petals or sometimes more. The fruit is berrylike or rarely a capsule. Most members of the family are inland species, but the most conspicuous group are some 17 species of shoreline shrubs, the mangroves. *See* MAGNOLIOPHYTA; MAGNOLIOPSIDA; PLANT KINGDOM. [T.M.Ba.]

Rhizopodea A class of Sarcodina including both parasitic and free-living species found in fresh and salt water and the soil. No species forms true axopodia; instead, pseudopodia may be filopodia, lobopodia, or reticulopodia; or there may be no pseudopodia in some cases. Rhizopodea include five subclasses: Lobosia, Filosia, Granuloreticulosia, Mycetozoia, and Labyrinthulia. *See* FILOSIA; GRANULORETICULOSIA; LABYRINTHULIA; LOBOSIA; SARCODINA. [R.P.H.]

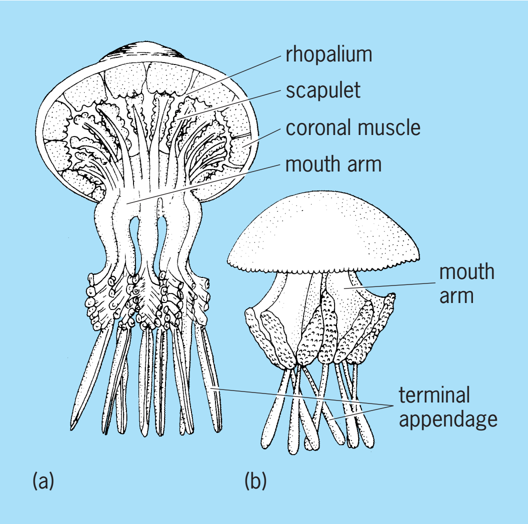
Rhizosphere The soil region subject to the influence of plant roots. It is characterized by a zone of increased microbiological activity and is an example of the relationship of soil microbes to higher plants.

A sharp boundary cannot be drawn between the rhizosphere and the soil unaffected by the plant (edaphosphere). At the root surface the rhizosphere effect is most intense, falling off sharply with increasing distance.

Growth of a plant markedly changes the microbial population of soil within its influence. In the rhizosphere there are more microorganisms than in soil distant from the plant. This increase is most pronounced with bacteria but is evident with other groups. The rhizosphere effect is seen in seedling plants; it increases with the age of the plant and usually reaches a maximum at the stage of greatest vegetative growth. Upon death of the plant the microbial population reverts to the level of the surrounding soil. Leguminous plants support higher rhizosphere populations than nonlegumes. The stimulation of microorganism growth in the rhizosphere results chiefly from the liberation of readily available organic substances by the growing plant. *See* SOIL MICROBIOLOGY. [A.G.L.]

Rhizostomeae An order of the class Scyphozoa with the most highly organized features of this class. The umbrella is generally higher than it is wide. The margin of the umbrella is divided into many lappets but is not provided with tentacles. Many radial canals, which are connected with each other to form a complicated network, issue from the cruciform stomach. The oral part is eight-sided, with many suctorial mouths surrounded by numerous small tentacles (see illustration). Usually there is no central mouth. No species of this group is injurious to the human skin. Some large forms, such as *Rhopilema*, are used as food in China and Japan.

A fair number of fossils of this order were found in the strata of the Jurassic Period. *See* SCYPHOZOA. [T.U.]



Rhizostomeae. (*a*) *Rhizostoma.* (*b*) *Mastigias.* (*After L. Hyman, The Invertebrates, vol. 1, McGraw-Hill, 1940*)

Rho-theta system A navigation system in which one or more signals are emitted from a facility (or colocated facilities) to produce simultaneous indication of bearing and distance. Since a bearing is a radial line of position and a distance is a circular line of position, the rho-theta system always ensures a position fix produced by the intersection of two lines of position which are at right angles to each other. This produces a minimum geometric dilution of position, a figure of merit for all radio navigation systems, and is one of the chief advantages of a rho-theta system. Another major advantage is that it is a single-site system and can thus be installed on a ship or an island. This has also made it attractive politically, enabling small countries to have their own navigation systems. *See* DOPPLER VOR; ELECTRONIC NAVIGATION SYSTEMS; TACAN; VOR (VHF OMNIDIRECTIONAL RANGE). [S.V.D.]

Rhodium A chemical element, Rh, atomic number 45, relative atomic weight 102.905. Rhodium is a transition metal and one of the group of platinum metals (ruthenium, osmium, rhodium, iridium, palladium, and platinum) that share similar chemical and physical properties. *See* METAL; PERIODIC TABLE; PLATINUM.

The terrestrial abundance of rhodium is exceedingly low; it is estimated to be 0.0004 part per million in the Earth's crust. It is found as a single isotope, ^{103}Rh, with a nuclear spin of 12. Since the platinum metals share common reactivities and are mined from a common source, there is an involved chemical process that is used to separate the individual elements, including rhodium. *See* ISOTOPE.

Metallic rhodium is the whitest of the platinum metals and does not tarnish under atmospheric conditions. Its surface is normally covered by a thin, firmly bound layer of rhodium(IV) oxide (RhO_2). Rhodium is insoluble in all acids, including aqua regia. It

Physical properties of rhodium metal

Property	Value
Crystal structure	Face-centered cubic
Lattice constant *a*, at 25°C (77°F), nm	0.38031
Thermal neutron capture cross section, barns (10^{-28} m^2)	149
Density at 25°C (77°F), g/cm^3	12.43
Melting point	1963°C (3565°F)
Boiling point	3700°C (6700°F)
Specific heat at 0°C, cal/g (J/kg)	0.0589 (246)
Thermal conductivity, 0–100°C, cal cm/cm^{2}s °C (J · m/m^2 · s · °C)	0.36 (151)

Electronegativity	2.2

dissolves in molten potassium bisulfate ($KHSO_4$), a useful property for its extraction from platinum ores, since iridium, ruthenium, and osmium are insoluble in this melt. Important physical properties of metallic rhodium are given in the table. *See* Acid and base; Aqua regia; Halogen elements.

Metallic rhodium is available as powder, sponge, wire, and sheets. It is ductile when hot and retains its ductility when cold. However, it work-hardens rapidly. Molten rhodium dissolves oxygen. Upon cooling, the oxygen gas is liberated, and this can lead to ruptures in the external surface of the crust of the metal. As a result, molten rhodium is best handled under an inert atmosphere of argon, which does not dissolve in rhodium.

Complexes of Rh(III), including $RhCl_3(pyridine)_3$, $Rh(CO)Cl_3[P(C_6H_5)_3]_2$, and $RhCl_6^{3-}$, are diamagnetic six-coordinate with octahedral geometry. The most common chemical form of rhodium is $RhCl_3 \cdot 3H_2O$, a red-brown, deliquescent material that is a useful starting material for the preparation of other rhodium compounds. In contrast to the hydrated material, red anhydrous rhodium(III) chloride ($RhCl_3$) is a polymeric, paramagnetic compound that does not dissolve in water. *See* Diamagnetism.

The low natural abundance and high cost of rhodium limit its uses to specialty applications. The major use is in catalysis, which accounts for over 60% of its production. Rhodium is a component of catalytic converters used in the control of exhaust emissions from automobiles. *See* Catalytic converter.

Rhodium is also used in the hydrogenation of olefins to alkanes. For hydrogenation, both heterogeneous catalysis and homogeneous catalysis are used. Heterogeneous conditions are achieved with rhodium metal finely dispersed on an inert support (activated carbon, charcoal, or alumina).

Rhodium complexes have been developed as catalysts for the synthesis of one optical isomer of L-dopa (used in treatment of Parkinson's disease). Greater selectivity makes rhodium catalysts more useful in hydroformylation or oxo reactions than the less expensive cobalt catalysts. A platinum-rhodium alloy is an efficient commercial catalyst for the formation of nitric acid through ammonia oxidation. *See* Catalysis; Heterogeneous catalysis; Homogeneous catalysis; Hydroformylation; Hydrogenation.

Rhodium-platinum alloys are favored for high-temperature applications. The International Temperature Scale over the range 630.5–1063°C (1134.9–1945.4°F) is defined by a thermocouple using a 10% rhodium-platinum alloy. Electroplated rhodium retains its bright surface under atmospheric conditions and finds use as electrical contacts and reflective surfaces. The reflectivity of rhodium surfaces is high (80%) and does not tarnish. About 6% of the rhodium production goes into jewelry manufacturing. *See* Electroplating of metals; Transition elements. [A.L.Ba.]

Rhodochrosite The mineral form of manganese carbonate. Calcium, iron, magnesium, and zinc have all been reported to replace some of the manganese. The equilibrium replacement of manganese by calcium increases with the temperature of crystallization.

Rhodochrosite occurs more often in massive or columnar form than in distinct crystals. The color ranges from pale pink to brownish pink. Hardness is 3.5–4 on Mohs scale, and specific gravity is 3.70.

Well-known occurrences of rhodochrosite are in Europe, Asia, and South America. In the United States large quantities occur at Butte, Montana. As a source of manganese, rhodochrosite is also important at Chamberlain, South Dakota, and in Aroostook County, Maine. *See* Carbonate minerals; Manganese. [R.I.Ha.]

Rhodonite A mineral inosilicate with composition $MnSiO_3$. Hardness is 5.5–6 on Mohs scale, and specific gravity is 3.4–3.7. The luster is vitreous and the color is rose red, pink, or brown. Rhodonite is similar in color to rhodochrosite, manganese carbonate, but it may be distinguished by its greater hardness and insolubility in hydrochloric acid. It has been found at Langban, Sweden; near Sverdlovsk in the Ural Mountains; and at Broken Hill, Australia. Fine crystals of a zinc-bearing variety, fowlerite, are found at Franklin, New Jersey. *See* Silicate minerals. [C.S.Hu.]

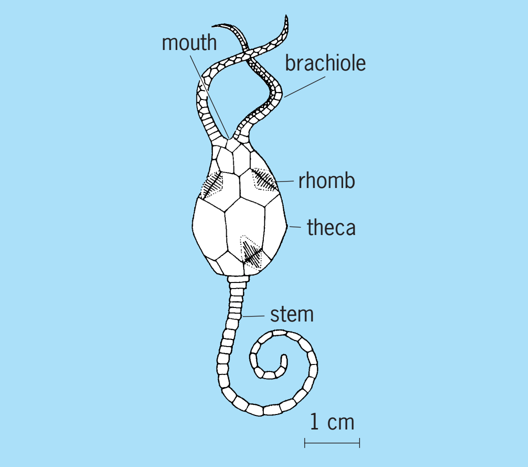
Rhodophyceae A large class of plants, commonly called red algae, coextensive with the division Rhodophycota. Most red algae are found in the ocean, growing on rocks, wood, other plants, or animals in the intertidal zone and to depths limited by the availability of light. A few genera and species occur in fresh water, and these are usually found in rapidly flowing, well-aerated, cold streams. Some, however, grow in quiet warm water, while a few are subaerial. Most red algae are photosynthetic, but some grow on other algae with varying degrees of parasitism. Approximately 675 genera and 4100 species are recognized. *See* Algae.

Rhodophyceae are characterized by a unique combination of biochemical, reproductive, and ultrastructural features. The primary photosynthetic pigment is chlorophyll *a*. Water-soluble tetrapyrrolic compounds called phycobilins serve as accessory photosynthetic pigments. The chief food reserve, floridean starch, is a branched polymer of glucose similar to amylopectin of green plants. It occurs as granules in the cytoplasm. Multinucleate cells are common. Rhodophyceae are distinctive among eukaryotic algae in their lack of flagella, a feature shared among major groups only by the chlorophycean order Zygnematales. Some unicellular forms and many spores and male gametes of multicellular forms are capable of gliding or feeble ameboid motion. Unicellular red algae, which may form mucilaginous colonies, are considered primitive. Most red algae have multicellular thalli of microscopic or macroscopic size, including individual filaments, blades, and complex plants of distinctive form produced by the interplay of filamentous systems. *See* Corallinales; Zygnematales.

Two subclasses of Rhodophyceae are traditionally recognized: the Bangiophycidae and the Florideophycidae. Classification within the Bangiophycidae is based largely on vegetative and asexual reproductive features, while that of the Florideophycidae is based primarily on details of the development of the female reproductive system and carposporophyte, secondarily on vegetative features. Rhodophyceae seem most closely related to Cyanophyceae in their use of chlorophyll *a* and phycobilins as photosynthetic pigments and the absence of flagella. They probably did not evolve directly from Cyanophyceae, however, but from a colorless, nonflagellate, eukaryotic ancestor that acquired pigments from an endosymbiotic blue-green alga.

The most salient feature of red algae is their beauty, which has drawn admiration from generations of seaside visitors. Their greatest significance, however, is their role in the formation of coral reefs, the Corallinales being responsible for cementing together various animal and algal components. Of more apparent economic importance is their use as food, a centuries-old tradition of maritime peoples in many parts of the world. *See* Agar; Carrageenan; Reef. [P.C.Si.; R.L.Moe]

Rhombifera An extinct class of Echinodermata in which the thecal canals crossed the sutures at the edges of the plates, so that one-half of any canal lay in one plate and the other half on an adjoining plate. The canals sometimes occurred in lozenge-shaped clusters, called rhombls (see illustration). The theca was ovoid and sessile in earlier forms and comprised numerous irregular plates. The ambulacral grooves were trimerous and were restricted to the brachioles. In later forms the thecal plates became fewer and larger, and were arranged in five horizontal rows, termed cycles. A stem developed aborally and the ambulacra became pentamerous, traversing part of the theca



Ordovician *Pleurocystis.* (*Simplified after O. Jaekel*)

before ascending the brachioles. Rhombifera probably died out in the Devonian. *See* ECHINODERMATA. [H.B.F.]

Rhubarb A herbaceous perennial, *Rheum rhaponticum*, of Mediterranean origin, belonging to the plant order Polygonales. Rhubarb is grown for its thick petioles which are used mainly as a cooked dessert; it is frequently called the pieplant. The leaves, which are high in oxalic acid content, are not commonly considered edible. Outdoor rhubarb is a common garden vegetable in most areas of the United States except the South. Michigan and Washington are important centers for forced or hothouse rhubarb. *See* POLYGONALES. [H.J.C.]

Rhynchobdellae An order of the class Hirudinea. These leeches possess an eversible proboscis and lack hemoglobin in the blood. They may be divided into two families, the Glossiphoniidae and the Ichthyobdellidae. Glossiphoniidae are flattened, mostly small leeches occurring chiefly in fresh water. Ichthyobdellidae typically have cylindrical bodies with conspicuous, powerful suckers used to attach themselves to passing fish. They frequently have lateral appendages which aid in respiration. *See* HIRUDINEA. [K.H.M.]

Rhynchocoela A phylum of bilaterally symmetrical, unsegmented, ribbonlike worms, frequently referred to as the Nemertinea. They have an eversible proboscis and a complete digestive tract with an anus. There is no coelom or body cavity, and the mesenchyme or parenchyma and the muscle fibers fill the area between the ciliated epidermis and the cellular lining of the digestive tract. Many species are brightly colored, sometimes having stripes or transverse bars.

The nemertineans are the simplest animals with a circulatory system. There are two lateral blood vessels and in some a third, unpaired dorsal vessel. The blood consists of a colorless fluid which may contain blood cells of several types. In species in which the blood is colored, the pigment is present in the cells. There is no heart, but the walls of the principal vessels may be contractile.

The nervous system has a pair of cerebral ganglia forming the brain as well as two longitudinal nerve cords and many smaller nerves. The ganglia and lateral cords may contain unusually large neurochord cells. In the epidermis there are scattered sensory nerve cells, probably tactile. A few to many simple eyes, or ocelli, may be present in front of the cerebral ganglia. There are no special respiratory organs; respiration occurs through the body surface. Nemertineans are usually either male or female, but a few individuals have both sex organs. Fertilization occurs outside the body in many species but may be internal in certain forms.

The nemertineans are mostly marine, bottom-dwelling worms, found in greatest numbers along the coasts of northern temperate regions. They live under stones, among the tangled masses of plants, in sand, mud, or gravel, and sometimes form mucus-lined tubes. A few are pelagic, fresh-water, or terrestrial. Certain species are commensal with other animals, but none can be regarded as parasitic in a strict sense.

That the Rhynchocoela represent the most highly organized acoelomate animals is indicated by the circulatory system, the presence of an anus, and the specialization of the epidermis. All groups of animals more, complex than the nemertineans have some kind of cavity, a pseudocoele or coelom, between the body wall and the gut, instead of solid mesenchyme. *See* COELOM.

The phylum Rhynchocoela, containing about 550 known species, is divided into two classes, Anopla and Enopla. *See* ANOPLA; ENOPLA. [A.G.Hu.: J.B.J.]

Rhynchonellida An extant order of brachiopods that has been an important component of marine benthic communities since the Ordovician. Rhynchonellids possess unequally biconvex valves typically with a fold and sulcus; many species contain strong radial ribs that produce deflections in the commissure, the line of junction between the two valves. Their shells are generally impunctate and also typically lack a hinge line parallel to the hinge axis, resulting in a pointed beak or umbo when viewed in lateral profile. Internally, rhynchonellids possess calcareous processes (crura) that in extant species provide support for the lophophore. Rhynchonellids are sessile, attached, epifaunal suspension feeders. They have a functional pedicle that they use to attach to the substrate. Although rhynchonellids were never diverse compared to other brachiopod orders, they were commonly important members of local communities. They achieved a diversity peak in the Devonian and again in the Jurassic.

Rhynchonellids have shifted their habitat preference in the oceans since their origin in the Middle Ordovician when they originated in shallow low-latitude seas; however, presently they are more common in deep-water habitats from middle and high latitudes and are rare members of benthic communities in low-latitude shallow seas. *See* ARTICULATA (ECHINODERMATA); BRACHIOPODA. [M.E.P.]

Rhynchonelliformea One of three subphyla currently recognized in the phylum Brachiopoda. The name is derived from the stratigraphically oldest subclade with extant representatives, the order Rhynchonellida. Rhynchonelliforms constitute over 90% of the more than 4500 named brachiopod genera, most of which (over 95%) are extinct. Rhynchonelliformea includes all taxa formerly referred to the class Articulata, in addition to several groups either newly discovered as fossils, formerly placed in class Inarticulata, or of uncertain taxonomic affiliation.

All rhynchonelliforms have an organic-rich, bivalved calcite shell and can be distinguished from other brachiopods by the following shared, derived characters: the presence of a fibrous secondary shell layer, a pedicle without a coelomic core, a diductor muscle system, and the presence of articulation between the two valves.

Rhynchonelliformea includes 19 orders organized in five classes. Chileata (Chileida and Dictyonellida), Obollellata (Obolellida and Naukatida), Kutorginata (Kutorginida), Strophomenata (Strophomenida, Productida, Orthotetida, and Billingsellida), Rhynchonellata (Protorthida, Orthida, Pentamerida, Rhynchonellida, Atrypida, Spiriferida, Spiriferinida, Thecideida, Athyridida, and Terebratulida).

Living rhynchonelliforms are distributed globally, but enjoy their greatest abundance and diversity in temperate latitudes. They live from deep intertidal to abyssal depths, reaching greatest abundance and diversity in the shallow to relatively deep (few hundred meters) subtidal. *See* BRANCHIOPODA; ORTHIDA; PENTAMERIDA; SPIRIFERIDA; STROPHOMENIDA; TEREBRATULIDA. [S.Ca.]

Rhynchosauria An order of herbivorous diapsid reptiles in the infraclass Archosauria, limited to the Triassic System but with a worldwide distribution. Rhynchosaurs were pig- or sheep-sized quadrupedal reptiles that were common in the Middle and Upper Triassic Series of India, South America, Europe, and eastern Africa. Except for the earliest South African genus, *Mesosuchus*, they are characterized by multiple rows of teeth on both the upper and lower jaws that were fused into deep sockets. Teeth were not replaced as they were worn but were added posteriorly as the jaw grew. In most genera, the premaxillae are devoid of teeth and overhang the front of the lower jaw like a beak. The external nostril is median rather than paired.

Rhynchosaurs were elements of the early archosauromorph radiation that included the protorosaurs and primitive archosaurs. The structure of the ankle is nearly identical in the early members of these groups, but later rhynchosaurs enlarged the centrals which contributed to a simple hinge joint between the lower leg and the tarsals.

Rhynchosaurs were locally common in the Late Triassic but are unknown in the Jurassic. Their rapid extinction may have resulted from changes in the vegetation on which they fed, or from predation from the expanding community of predaceous archosaurs, including early dinosaurs. *See* ARCHOSAURIA; DIAPSIDA; PROTOROSAURIA; REPTILIA. [R.L.C.]

Rhyniophyta A division of the subkingdom Embryobionta. The bryophytes and vascular plants are included in this subkingdom. The category Rhyniophyta was devised for the relatively simple Silurian-Devonian vascular plants long held to be ancestral to other groups of vascular plants and usually referred to as Psilophytales. These plants have leafless stems and lack roots; their general morphological structure is not complex. The three classes of Rhyniophyta currently recognized are Rhyniopsida, Zosterophyllopsida, and Trimerophytopsida. *See* EMBRYOBIONTA; PSILOPHYTALES; RHYNIOPSIDA; TRIMEROPHYTOPSIDA; ZOSTEROPHYLLOPSIDA. [H.P.B.]

Rhyniopsida The earliest demonstrable vascular land plants, appearing in Silurian (mid- Ludlovian) time. Their small, leafless axes were usually branched dichotomously in three planes; adventitious and perhaps pseudomonopodial branching also occurred. Sporangia were usually terminal on the main axes. Some terminated in lateral branches, and some were subtended by adventitious branches. *See* RHYNIOPHYTA. [H.P.B.]

Rhyolite A very light-colored, aphanitic (not visibly crystalline), volcanic rock that is rich in silica and broadly equivalent to granite in composition. Migration of rhyolitic magma through the Earth's crust, which causes much of the Earth's explosive and hazardous volcanic activity, represents a major process of chemical fractionation by which continental crust grows and evolves. *See* GRANITE.

Rhyolites are formed by the process of molten silica-rich magma flowing toward the Earth's surface. Small differences in this process, notably those related to the release of gas from the magma at shallow depth, produce extremely diverse structural features. The high silica content gives rhyolitic lava a correspondingly high viscosity; this hinders crystallization and often causes young rhyolite to be a mixture of microcrystalline aggregates and glassy material. Because of the glassy nature of most rhyolites, they are best characterized by chemical analysis. They typically have 70–75 wt % silicon dioxide (SiO_2) and more potassium oxide (K_2O) than sodium oxide (Na_2O). *See* LAVA; MAGMA; VOLCANIC GLASS; VOLCANO.

Rhyolite is one of the most common volcanic rocks in continental regions; it is virtually absent in the ocean basins. The rock often occurs in large quantities associated with andesite and basalt. It is common in environments ranging from accretionary prisms at continental margins to magmatic arcs related to subduction zones. Rhyolite is also prevalent in extensional regions and hot spots in continental interiors. *See* ANDESITE; BASALT. [L.W.Y.]

Riboflavin Also known as vitamin B_2, riboflavin is widely distributed in nature, and is found mostly in milk, egg white, liver, and leafy vegetables. It is a water-soluble yellow-orange fluorescent pigment.

Riboflavin deficiency results in poor growth and other pathologic changes in the skin, eyes, liver, and nerves. Riboflavin deficiency in humans is usually associated with a cracking at the comers of the mouth called cheilosis; inflammation of the tongue, which appears red and glistening (glossitis); corneal vascularization accompanied by itching; and a scaly, greasy dermatitis about the corners of the nose, eyes, and ears. *See* VITAMIN. [S.N.G.]

Ribonuclease A group of enzymes, widely distributed in nature, which catalyze hydrolysis of the internucleotide phosphodiester bonds in ribonucleic acid (RNA). The sites of hydrolysis may vary considerably, depending upon the specificity of the particular enzyme. Differences in specificity for the site of cleavage have led to the use of these various ribonucleases as tools in determining the structure and chemistry of RNA. *See* ENZYME; NUCLEIC ACID.

Research on ribonuclease has played a prime role in advancing the understanding of protein structure and function; also, it was the first protein to be totally synthesized from its component amino acids. Since the elucidation of the amino acid sequence of ribonuclease, much information has been compiled with regard to the three-dimensional structure of the enzyme and to specific regions of the molecule which are catalytically important. *See* PROTEIN. [R.L.He.]

Ribonucleic acid (RNA) One of the two major classes of nucleic acid, mainly involved in translating into proteins the genetic information that is carried in deoxyribonucleic acid (DNA). Ribonucleic acids serve two functions in protein synthesis: transfer RNAs (tRNAs) and ribosomal RNAs (rRNAs) function in the synthesis of all proteins, while messenger RNAs (mRNAs) are a diverse set, each member of which acts specifically in the synthesis of one protein. Messenger RNA is the intermediate in the usual biological pathway DNA → RNA → protein. Ribonucleic acid is a very versatile molecule, however. In addition to the roles in protein synthesis, other types of RNA serve other important functions for cells and viruses, such as the involvement of small nuclear RNAs (snRNAs) in mRNA splicing. In some cases, RNA performs functions typically considered DNA-like, such as serving as the genetic material for certain viruses, or roles typically carried out by proteins, such as RNA enzymes or ribozymes. *See* DEOXYRIBONUCLEIC ACID (DNA).

Structure. RNA is a linear polymer of four different nucleotides. Each nucleotide is composed of three parts: a five-carbon sugar known as ribose, a phosphate group, and one of four bases attached to each ribose, either adenine (A), cytosine (C), guanine (G), or uracil (U). The structure of RNA is basically a repeating chain of ribose and phosphate moieties, with one of the four bases attached to each ribose. The structure and function of the RNA vary depending on its sequence and length. *See* NUCLEOTIDE; RIBOSE.

In its basic structure, RNA is quite similar to DNA. It differs by a single change in the sugar group (ribose instead of deoxyribose) and by the substitution of uracil for the base thymine (T). Typically, RNA does not exist as long double-stranded chains as does DNA, but rather as short single chains with higher-order structure due to base pairing and tertiary interactions within the RNA molecule. Within the cell, RNA usually exists in association with specific proteins in a ribonucleoprotein complex.

The nucleotide sequence of RNA is encoded in genes in the DNA, and it is transcribed from the DNA by a complementary templating mechanism that is catalyzed by one of the RNA polymerase enzymes. In this templating scheme, the DNA base T specifies A in the RNA, A specifies U, C specifies G, and G specifies C.

Transfer RNA. These small RNAs (70–90 nucleotides) that act as adapters to translate the nucleotide sequence of mRNA into protein sequence. They do this by carrying the appropriate amino acid to the ribosome during the process of protein synthesis. Each cell contains at least one type of tRNA specific for each of the 20 amino acids, and usually several types. The base sequence in the mRNA directs the appropriate amino acid-carrying tRNAs to the ribosome to ensure that the correct protein sequence is made. *See* Protein.

Ribosomal RNA. Ribosomes are complex ribonucleoprotein particles that are the site of protein synthesis, that is, the process of linking amino acids to form proteins. The RNA components of the ribosome account for more than half of its weight. Like tRNAs, rRNAs are stable molecules and exist in complex folded structures. Each of these rRNAs is essential in determining the exact structure of the ribosome. In addition, the rRNAs, rather than the ribosomal proteins, are likely the basic functional elements of the ribosome. *See* Ribosomes.

Messenger RNA. Whereas most types of RNA are the final products of their genes, mRNA is an intermediate in information transfer. It carries information from DNA to the ribosome in a genetic code that the protein-synthesizing machinery translates into protein. Specifically, mRNA sequence is recognized in a sequential fashion as a series of nucleotide triplets by tRNAs via base pairing to the three-nucleotide anticodons in the tRNAs. There are specific triplet codons that specify the beginning and end of the protein-coding sequence. Thus, the function of mRNA involves the reading of its primary nucleotide sequence, rather than the activity of its overall structure. Messenger RNAs are typically shorter-lived than the more stable structural RNAs, such as tRNA and rRNA. *See* Genetic code.

Small nuclear RNA. Small RNAs, generally less than 300 nucleotides long and rich in uridine (U), are localized in the nucleoplasm (snRNAs) and nucleolus (snoRNAs) of eukaryotic cells. There they take part in RNA processing, such as intron removal during eukaryotic mRNA splicing and posttranscriptional modification that occurs during production of mature rRNA. *See* Intron.

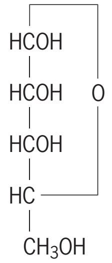
Catalytic RNA. RNA enzymes, or ribozymes, are able to catalyze specific cleavage or joining reactions either in themselves or in other molecules of nucleic acid. *See* Catalysis; Ribozyme.

Viral RNA. While most organisms carry their genetic information in the form of DNA, certain viruses, such as polio and influenza viruses, have RNA as their genetic material. The viral RNAs occur in different forms in different viruses. For example, some are single-stranded and some are double-stranded; some occur as a single RNA chromosome while others are multiple. In any case, the RNA is replicated as the genetic material and either its sequence, or a complementary copy of itself, serves as mRNA to encode viral proteins. The RNA viruses known as retroviruses contain an enzyme that promotes synthesis of complementary DNA in the host cell, thus reversing the typical flow of information in biological systems. *See* Animal virus; Retrovirus; Virus.

Other types of RNA. There are RNAs that serve other important and diverse cellular functions. For example, a ribonucleoprotein enzyme is responsible for replication of chromosome ends. Also, there is an essential RNA component in a ribonucleoprotein complex that ensures that membrane and secreted proteins are synthesized in the appropriate cellular location.

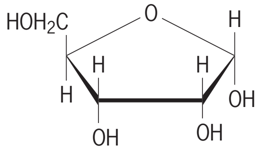
RNA molecules can function both as carriers of genetic information and as enzymes. The discoveries of RNA catalysis and of the central role of rRNA in protein synthesis have led to an enhanced appreciation of RNA as the probable original informational macromolecule, preceding both the more specialized DNA and protein molecules in evolution. *See* Molecular biology; Nucleic acid. [A.L.Be.; M.W.G.]

Ribose A water-soluble pentose, also known as D-ribose (see first structural formula), which, together with 2-deoxy-D-ribose, makes up the carbohydrate constituents of nucleic acids, which are found in all living organisms. The universal occurrence of nucleic acids in all living cells makes this pentose highly interesting to biochemists and biologists. The type of nucleic acid that yields D-ribose is referred to as ribonucleic acid (RNA). D-Ribose is a constituent not only of the nucleic acids, but also of several vitamins and coenzymes. As in the nucleic acids, this sugar occurs in the furanose configuration (see second structural formula) in these natural products. *See* Coenzyme; Deoxyribose; Nucleic acid; Vitamin. [W.Z.H.]



D-Ribose

or



α-D-Ribofuranose

Ribosomes Small particles, present in large numbers in every living cell, whose function is to convert stored genetic information into protein molecules. In this synthesis process, a molecule of messenger ribonucleic acid (mRNA) is fed through the ribosome, and each successive trinucleotide codon on the messenger is recognized by complementary base-pairing to the anticodon of an appropriate transfer RNA (tRNA) molecule, which is in turn covalently bound to a specific amino acid. The successive amino acids become linked together on the ribosome, forming a polypeptide chain whose amino acid sequence has thus been determined by the nucleic acid sequence of the mRNA. The polypeptide is subsequently folded into an active protein molecule. Ribosomes are themselves complex arrays of protein and RNA molecules, and their fundamental importance in molecular biology has prompted a vast amount of research, with a view to finding out how these particles function at the molecular level. *See* Genetic code; Protein; Ribonucleic acid (RNA).

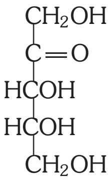
Ribosomes are composed of two subunits, one approximately twice the size of the other. In the bacterium *Escherichia coli*, whose ribosomes have been the most extensively studied, the smaller subunit (30S) contains 21 proteins and a single 16S RNA molecule. The larger (50S) subunit contains 32 proteins, and two RNA molecules (23S and 5S). The overall mass ratio of RNA to protein is about 2:1. Cations, in particular magnesium and polyamines, play an important role in maintaining the integrity of the ribosomal structures. The ribosomes are considerably larger in the cytoplasm of higher organisms (eukaryotes). Nevertheless, all ribosomal RNA molecules have a central core of conserved structure, which presumably reflects the universality of the ribosomal function. *See* Cell (biology); Organic evolution.

The process of protein biosynthesis is essentially very similar in both prokaryotes and eukaryotes; what follows is a brief summary of what happens in *E. coli*. The first step is that an initiator tRNA molecule attached to the amino acid *N*-formyl methionine recognizes its appropriate codon on a mRNA molecule, and binds with the mRNA to the 30S subunit. A 50S subunit then joins the complex, forming a complete 70S ribosome. A number of proteins (initiation factors, which are not ribosomal proteins) are also involved in the process. At this stage, the initiator aminoacyl tRNA occupies one binding site, the P-site (peptidyl site), on the ribosome, while a second tRNA binding site (the A-site, or aminoacyl site) is free to accept the next aminoacyl tRNA molecule. In the subsequent steps, the elongation process aminoacyl tRNA molecules are brought to the A-site as ternary complexes together with guanosine triphosphate (GTP) and a protein factor (elongation factor Tu). Once an aminoacyl tRNA is in the A-site, the initiator amino acid (or at later stages the growing polypeptide chain) is transferred from the P-site tRNA to the A-site aminoacyl tRNA. It is not clear whether this peptidyl transferase activity requires the active participation of a ribosomal component. After peptide transfer has taken place, the peptide is attached to the A-site tRNA, and an "empty" tRNA molecule is at the P-site. The peptidyl tRNA complex must now be translocated to the P-site, in order to free the A-site for the next incoming tRNA molecule. Here again protein factors and GTP are involved, and it is probable that the empty tRNA occupies a third ribosomal site (exit or E-site) before finally leaving the complex. Studies show that elongation factor G hydrolyzes GTP to bring about translocation of the tRNA molecules. The protein chain is completed by the appearance of a "stop" codon in the mRNA. This is recognized by yet another set of protein factors, which causes the completed polypeptide chain to be released from the ribosome. At any one time a number of ribosomes are engaged in the reading of a single mRNA molecule, which leads to the appearance of polyribosomes (polysomes). *See* Molecular biology. [R.Bri.; H.G.W.; S.Jo.]

Ribozyme A ribonucleic acid (RNA) molecule that, like a protein, can catalyze specific biochemical reactions. Examples include self-splicing rRNA and RNase P, both involved in catalyzing RNA processing reactions (that is, the biochemical reactions that convert a newly synthesized RNA molecule to its mature form). Different ribozyme structures catalyze quite distinct RNA processing reactions, just as protein enzyme families that are composed of different structures catalyze different types of biochemical reactions.

Ribozymes share many similarities with protein enzymes, as assessed by two parameters that are used to describe a biological catalyst. The Michaelis-Menten constant K_m relates to the affinity that the catalyst has for its substrate, and ribozymes possess K_m values which are comparable to K_m values of protein enzymes. The catalytic rate constant describes how efficiently a catalyst converts substrate into product. The values of this constant for ribozymes are markedly lower than those values observed for protein enzymes. Nevertheless, ribozymes accelerate the rate of chemical reaction with specific substrates by 10^{11} compared with the rate observed for the corresponding uncatalyzed, spontaneous reaction. Therefore, ribozymes and protein enzymes are capable of lowering to similar extents the activation energy for chemical reaction. *See* Enzyme; Protein; Ribonucleic acid (RNA). [D.W.Ce.]

Ribulose A pentose sugar, also known as D-riboketose and D-erythropetulose; it has never been prepared in crystalline form, and exists only as a syrup. The structural formula of ribulose is shown below.



$$\begin{array}{c} CH_2OH \\ | \\ C{=}O \\ | \\ HCOH \\ | \\ HCOH \\ | \\ CH_2OH \end{array}$$

Ribulose-5-phosphate occurs in animal and plant tissues. It can be converted to ribulose-l, 5-diphosphate by a phosphokinase enzyme acting in the presence of adenosine triphosphate (ATP). The ribulose-5-phosphate is also a significant intermediate in the carbohydrate metabolism through the pentose phosphate pathway. *See* Carbohydrate metabolism; Monosaccharide. [W.Z.H.]

Rice The plant *Oryza sativa* is the major source of food for nearly one-half of the world's population. The most important rice-producing countries are mainland China, India, and Indonesia, but in many smaller countries rice is the leading food crop. In the United States, rice production is largely concentrated in selected areas of Arkansas, California, Louisiana, and Texas. *See* Carbohydrate; Cyperales; Wheat.

Over 95% of the world rice crop is used for human food. Although most rice is boiled, a considerable amount is consumed as breakfast cereals. Rice starch also has many uses. Broken rice is used as a livestock feed and for the production of alcoholic beverages. The bran from polished rice is used for livestock feed; the hulls are used for fuel and cellulose. The straw is used for thatching roofs in the Orient and for making paper, mats, hats, and baskets. Rice straw is also woven into rope and used as cordage for bags. This crop serves a multitude of purposes in countries where agriculture is dependent largely upon rice.

Rice is unlike many other cereal grains in that all cultivated varieties belong to the same species and have 12 pairs of chromosomes, as do most wild types. The extent of variation in morphological and physiological characteristics within this single species is greater than for any other cereal crop. *See* Genetics.

Rice is an annual grass plant varying in height from 2 to 6 ft (0.6 to 1.8 m). Plants tiller, that is, develop new shoots freely, the number depending upon spacing and soil fertility. The inflorescence is an open panicle. Flowers are perfect and normally self-pollinated, with natural crossing seldom exceeding 3–4%. A distinct characteristic of the flower is the six anthers rather than the customary three of other grasses. Spikelets have a single floret, lemma and palea completely enclosing the caryopsis or fruit, which may be yellow, red, brown, or black. Lemmas may be awnless, partly awned, or fully awned. Threshed rice, which retains its lemma and palea, is called rough rice or paddy. *See* Flower; Fruit; Grass crops; Inflorescence; Reproduction (plant).

In the United States, only about 25 varieties are in commercial production. Cultivated rices are classified as upland and lowland. Upland types, which can be grown in high-rainfall areas without irrigation, produce relatively low yields. The lowland types, which are grown submerged in water for the greater part of the season, produce higher yields. In contrast to most plants, rice can thrive when submerged because oxygen is transported from the leaves to the roots. All rice in the United States is produced under lowland or flooded conditions. Rice varieties are also classified as long- or short-grain. Most long-grain rices have high amylose content and are dry or fluffy when cooked, while most short-grain rices have lower amylose content and are sticky when cooked. In the United States a third grain length is recognized: medium-grain. The medium-grain rices have cooking qualities similar to those of short-grain varieties. *See* Agricultural science (plant); Grain crops. [J.N.R.]

The rice kernel has four primary components: the hull or husk, the seedcoat or bran, the embryo or germ, and the endosperm. The main objective of milling rice is to remove the indigestible hull and additional portions of bran to yield whole unbroken endosperm. Rice milling involves relatively uncomplicated abrasive and separatory procedures which provide a variety of products dependent on the degree of bran removal or the extent of endosperm breakage.

Instant rice is made from whole grain rice by pretreating under controlled cooking, cooling, and drying conditions to impart the quick-cooking characteristic. Ready-to-eat breakfast rice cereals are prepared from milled rice as flakes or puffs. Rice bran oil was developed as a result of increased extraction of lipids from rice bran. It is utilized as an edible-grade oil in a variety of applications as well as an industrial feedstock for soap and resin manufacture. *See* Cereal; Fat and oil (food); Food manufacturing; Solvent extraction. [M.A.U.]

Ricinulei An order of extremely rare arachnids, also known as the Podogona, with a body less than 1 in. (2.5 cm) in length. Superficially, they resemble ticks in general appearance and movement, and are found only in tropical Africa and in the Americas, from the Amazon to Texas. The two anterior pairs of appendages are chelate. Less than 25 modern species are known. The occurrence of several fossils from Carboniferous time suggests that the group was formerly more common. *See* ARACHNIDA. [C.C.Ho.]

Rickettsioses Often severe infectious diseases caused by several diverse and specialized bacteria, the rickettsiae and rickettsia-like organisms. The best-known rickettsial diseases infect humans and are usually transmitted by parasitic arthropod vectors.

Rickettsiae and rickettsia-like organisms are some of the smallest microorganisms visible under a light microscope. Although originally confused with viruses, in part because of their small size and requirements for intracellular replication, rickettsiae and rickettsia-like organisms are characterized by basic bacterial (gram-negative) morphologic features. Their key metabolic enzymes are variations of typical bacterial enzymes. The genetic material of rickettsiae and rickettsia-like organisms likewise seems to conform to basic bacterial patterns. The genome of all rickettsia-like organisms consists of double-stranded deoxyribonucleic acid (DNA).

Rickettsiae enter host cells by phagocytosis and reproduce by simple binary fission. The site of growth and reproduction varies among the various genera.

Clinically, the rickettsial diseases of humans are most commonly characterized by fever, headache, and some form of cutaneous eruption, often including diffuse rash, as in epidemic and murine typhus and Rocky Mountain spotted fever, or a primary ulcer or eschar at the site of vector attachment, as in Mediterranean spotted fever and scrub typhus. Signs of disease may vary significantly between individual cases of rickettsial disease. Q fever is clinically exceptional in several respects, including the frequent absence of skin lesions.

All of the human rickettsial diseases, if diagnosed early enough in the infection, can usually be effectively treated with the appropriate antibiotics. Tetracycline and chloramphenicol are among the most effective antibiotics used; they halt the progression of the disease activity, but do so without actually killing the rickettsial organisms. Presumably, the immune system is ultimately responsible for ridding the body of infectious organisms. Penicillin and related compounds are not considered effective. *See* ANTIBIOTIC.

Most rickettsial diseases are maintained in nature as diseases of nonhuman vertebrate animals and their parasites. Human infection may usually be regarded as peripheral to the normal natural infection cycles, and human-to-human transmission is not the rule. However, the organism responsible for epidemic typhus (*Rickettsia prowazekii*) and the agent responsible for trench fever (*Rochalimaea quintana*) have the potential to spread rapidly within louse-ridden human populations. *See* ZOONOSES.

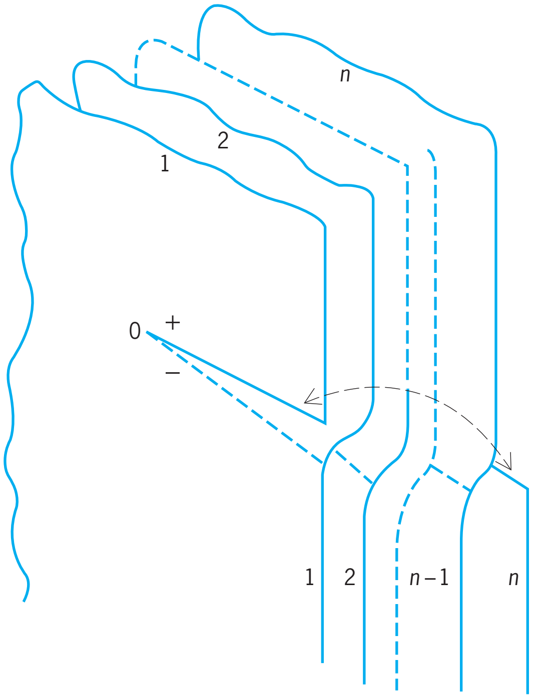
All known spotted fever group organisms are transmitted by ticks. Despite a global distribution in the form of various diseases, nearly all spotted fever group organisms share close genetic, antigenic, and certain pathologic features. Examples of human diseases include Rocky Mountain spotted fever (in North and South America), fièvre boutonneuse or Mediterranean spotted fever (southern Europe), South African tick-bite fever (Africa), Indian tick typhus (Indian subcontinent), and Siberian tick typhus (northeastern Europe and northern Asia). If appropriate antibiotics are not administered, Rocky Mountain spotted fever, for example, is a life-threatening disease. *See* INFECTIOUS DISEASE. [R.L.Re.]

Riemann surface A generalization of the complex plane that was originally conceived to make sense of mathematical expressions such as $\sqrt{z}$ or $\log z$. These expressions cannot be made single-valued and analytic in the punctured plane $\mathbf{C}\backslash\{0\}$ (that is, the complex plane with the point 0 removed). The difficulty is that for some closed paths the value of the expression when reaching the end of the path is not the same as it is at the beginning. For example, the closed path can be chosen to be the unit circle centered at $z = 0$ and followed counterclockwise from $z = 1$. If $\sqrt{z}$ is assigned the value $+1$ at $z = 1$, its value at the end of the circuit is -1. Similarly, if $\log z$ is assigned the value 0 at $z = 1$, at the end of the circuit, allowing the values to change continuously, the value is $2\pi i$. *See* COMPLEX NUMBERS.

The construction of an abstract surface for $\sqrt{z}$ on which $\sqrt{z}$ has a single value at each point and on which the values of $\sqrt{z}$ vary continuously around each closed path, always ending with the starting value, proceeds as follows. From the complex plane $\mathbf{C}$ the nonnegative half of the real axis $\{z = x + iy : y = 0,\ 0 \leq x\}$ is removed. This slit is thought of as having two edges: an upper or + edge and a lower or – edge ($z = 0$ is not counted). Another copy of this slit plane is then placed over, and parallel to, the original, as the first and second floors in a building. Next, the two sheets are connected by attaching the − edge of the bottom sheet to the + edge of the top sheet, and the + edge of the bottom sheet to the − edge of the top sheet. The abstract surface thus constructed is not embedded in euclidean 3-space because the attachments cannot be done in 3-space without creating self-intersections. The expression $\sqrt{z}$ is defined at the point over z on the upper sheet to have positive imaginary part and on the lower to have negative part.

The abstract surface constructed is called the Riemann surface for $\sqrt{z}$. It is two-sheeted over the z plane, except that only one point lies over $z = 0$, which is therefore called a branch point. The Riemann surface for $\sqrt[n]{z}$, which has n branches instead of 2, is shown in the illustration.

In the early 1920s, H. Weyl defined a Riemann surface in the context of the newly developing field of topology. This definition does not depend on having a particular function in hand, and does not require the use of such seemingly artificial devices as slits. A Riemann surface is a two-dimensional connected



Riemann surface for $\sqrt[n]{z}$. (*After A. D. Sveshnikob and A. N. Tikhonov, The Theory of Functions of a Complex Variable, Mir Publishers, 1973*)

topological manifold (surface) with a complex structure. *See* Manifold (mathematics); Topology. [A.M.]

Riemannian geometry The geometry of riemannian manifolds. Riemannian geometry was initiated by B. Riemann in 1854, following the pioneering work of C. F. Gauss on surface theory in 1827. Riemann introduced a coordinate space in which the infinitesimal distance between two neighboring points is specified by a quadratic differential form, given below. Such a space is a natural generalization of euclidean geometry and Gauss's geometry of surfaces in three-dimensional euclidean space, as well as the noneuclidean geometries: hyperbolic geometry (previously discovered by J. Bolyai and N. I. Lobachevsky) and elliptic geometry. A riemannian manifold is a topological space that further generalizes this notion. Riemannian geometry derives great importance from its application in the general theory of relativity, where the universe is considered to be a riemannian manifold. *See* Differential geometry; Euclidean geometry; Noneuclidean geometry; Relativity.

An n-dimensional riemannian space is a space whose points can be characterized by n coordinates u^i ($i = 1, 2, \ldots, n$), and where an infinitesimal distance ds between two points with coordinate differences du^i is given by a quadratic differential form, Eq. (1), to be called the metric. In general, the quantities g_{ij} are functions of the coordinates u^i.

$$ds^2 = \sum_{i,j} g_{ij}\; du^i\; du^j \qquad (1)$$

$$g_{ij} = g_{ji} \qquad 1 \le i, j \le n$$

Riemannian geometry is local in the sense that it is valid in a neighborhood of the u^i coordinates. It studies properties that are invariant under coordinate transformations of the form of Eq. (2), where the functions are smooth with the functional determinant $\det(\partial u'^i/\partial u^j) \neq 0$.

$$u'^i = u'^i(u^1, \ldots, u^n) \qquad 1 \le i \le n \qquad (2)$$

At the foundation of riemannian geometry is the notion of a riemannian manifold. A differentiable manifold is a topological space with a covering by coordinate neighborhoods, such that in the domain where the u^i coordinates and the u'^i coordinates are both valid, they are related by the transformation of Eq. (2) with the conditions mentioned there. The manifold is called riemannian if a riemannian metric is defined in each neighborhood that gives the same value of ds^2 in the intersection of any two neighborhoods. Riemannian geometry is divided between local and global: the former dealing with properties in a neighborhood, the latter with properties of the manifold as a whole. *See* Manifold (mathematics); Topology. [S.S.C.]

Rift valley One of the geomorphological expressions between two tectonic plates that are opening relative to each other or sliding past each other. The term originally was used to describe the central graben structures of such classic continental rift zones as the Rhinegraben and the East African Rift, but the definition now encompasses mid-oceanic ridge systems with central valleys such as the Mid-Atlantic Ridge. *See* Mid-Oceanic Ridge; Plate tectonics.

Continental and oceanic rift valleys are end members in what many consider to be an evolutionary continuum. In the case of continental rift valleys, plate separation is incomplete, and the orientation of the stress field relative to the rift valley can range from nearly orthogonal to subparallel. Strongly oblique relationships are probably the norm. In contrast, oceanic rift valleys mark the place where the trailing edges of two distinctly different plates are separating. The separation is complete, and the spreading is organized and focused, resulting in rift valleys that tend to be oriented orthogonal or suborthogonal to the spreading directions.

The basic cross-sectional form of rift valleys consists of a central graben surrounded by elevated flanks. It is almost universally accepted that the central grabens of continental rift valleys are subsidence features. The crystalline basement floors of some parts of the Tanganyika and Malawi (Nyasa) rift valleys in East Africa lie more than 5 mi (9 km) below elevated flanks. *See* Graben.

In continental rift valleys the true cross-sectional form is typically asymmetric, with the rift floors tilted toward the most elevated flank. Most of the subsidence is controlled by one border fault system, and most of the internal faults parallel the dip of the border faults. *See* Fault and fault structures.

Oceanic rift valleys are also distinctly separated into segments by structures known as transform faults. The cross-sectional form of oceanic rift valleys can be markedly asymmetric. It is unlikely that the cross-sectional form of oceanic rift valleys is related genetically to that of continental rift valleys, except in the broadest possible terms. *See* Transform fault. [B.R.R.]

Rift Valley fever An arthropod-borne (primarily mosquito), acute, febrile, viral disease of humans and numerous species of animals. Rift Valley fever is caused by a ribonucleic acid (RNA) virus in the genus *Phlebovirus* of the family Bunyaviridae. In sheep and cattle, it is also known as infectious enzootic hepatitis. First described in the Rift Valley of Africa, the disease presently occurs in west, east, and south Africa and has extended as far north as Egypt. Historically, outbreaks of Rift Valley fever have occurred at 10–15-year intervals in normally dry areas of Africa subsequent to a period of heavy rainfall.

In humans, clinical signs of Rift Valley fever are influenzalike, and include fever, headache, muscular pain, weakness, nausea, epigastric pain, and photophobia. Most people recover within 4–7 days, but some individuals may have impaired vision or blindness in one or both eyes; a small percentage of infected individuals develop a hemorrhagic syndrome and die.

Rift Valley fever should be suspected when high abortion rates, high mortality, or extensive liver lesions occur in newborn animals. The diagnosis is confirmed by isolating the virus from tissues of the infected animal or human. Control of the disease is best accomplished by widespread vaccination of susceptible animals to prevent amplification of the virus and, thus, infection of vectors. Any individual that works with infected animals or live virus in a laboratory should be vaccinated. *See* Animal virus; Vaccination. [C.A.Me.]

Rigel The bright star in the southwest corner of the constellation Orion (apparent magnitude +0.12), also referred to as β Orionis. It is a blue-white supergiant of spectral type B8, one of the most luminous stars known. Its intrinsic brightness is estimated to be more than 50,000 times that of the Sun. Rigel is a very young star by stellar standards, with such an enormous rate of energy output that its life span is only a few million years. By comparison, the Sun is approximately 5×10^9 years old, and is still only half way through its main-sequence evolution. Rigel is the brightest member of the Orion OB1 Association, a large molecular cloud complex in which active star formation is currently taking place. In addition to its high luminosity, Rigel has a photosphere which is so large that if the star were placed where the Sun is, it would almost fill the orbit of Mercury. *See* Molecular cloud; Orion; Spectral type; Star; Stellar rotation; Supergiant star. [D.W.L.]

Rigid body An idealized extended solid whose size and shape are definitely fixed and remain unaltered when forces are applied. Treatment of the motion of a rigid body in terms of Newton's laws of motion leads to an understanding of certain important aspects of the translational and rotational motion of real bodies without the necessity of considering the complications involved when changes in size and shape occur. Many of the principles used to treat the motion of rigid bodies apply in good approximation to the motion of real elastic solids. *See* Rigid-body dynamics. [D.Wi.]

Rigid-body dynamics The study of the motion of a rigid body under the influence of forces. A rigid body is a system of particles whose distances from one another are fixed. The general motion of a rigid body consists of a combination of translations (parallel motion of all particles in the body) and rotations (circular motion of all particles in the body about an axis). Its equations of motion can be derived from the equations of motion of its constituent particles. *See* RECTILINEAR MOTION; ROTATIONAL MOTION.

The location of a mass point m_i can be specified relative to a fixed-coordinate system by a position vector $\vec{r}_i$ with cartesian components (x_i,y_i,z_i). The vector force $\vec{F}_i$ which acts on the mass points has corresponding components (F_{ix},F_{iy},F_{iz}). Newton's second law for the motion of m_i is stated in Eq. (1). Here

$$\vec{F}_i = m_i\ddot{\vec{r}}_i \tag{1}$$

$\ddot{\vec{r}}_i \equiv d^2\vec{r}_i/dt^2 = \vec{a}$ is the acceleration of m_i. *See* ACCELERATION; FORCE; NEWTON'S LAWS OF MOTION.

Translational motion. If Eq. (1) is summed over all particles in the rigid body, the left-hand side becomes the total force acting

$$\vec{F} = \sum_i \vec{F}_i$$

on the rigid body. If the internal forces satisfy Newton's third law (to each action there is an equal but opposite reaction), the contributions of the internal forces cancel in pairs and $\vec{F}$ is the total external force on the rigid body, $\vec{F}^{\text{ext}}$. The right-hand side can be expressed in terms of the center-of-mass (CM) position vector defined by Eq. (2), where M is the total mass of the body. Then the sum of the equations of motion, Eq. (1), takes the form of Eq. (3). This equation of motion for the center of mass

$$\begin{aligned} \vec{R} &= \frac{1}{M}\sum_i m_i\vec{r}_i \\ M &= \sum_i m_i \end{aligned} \tag{2}$$

$$\vec{F}^{\text{ext}} = M\ddot{\vec{R}} \tag{3}$$

of the rigid body has exactly the form of the equation of motion for a particle of mass M and position $\vec{R}$, under the influence of an external force $\vec{F}^{\text{ext}}$. Consequently, the second law of motion holds, not just for a particle, but for an arbitrary rigid body, if the position of the body is interpreted to mean the position of its center of mass. *See* CENTER OF MASS.

The momentum of a mass point is given by the product of the mass and the velocity, $\vec{p}_i = m_i\dot{\vec{r}}_i$, where $\dot{\vec{r}}_i \equiv d\vec{r}_i/dt$. The total momentum of the center of mass of the rigid body, obtained by summing over the momenta $\vec{P}_i$ of its constituent masses, is given by Eq. (4). In terms of the center-of-mass momentum $\vec{P}$, the equation of motion for the center of mass is expressed by Eq. (5). For an isolated rigid body, the external force is zero and

$$\vec{P} = M\dot{\vec{R}} \tag{4}$$

$$\dot{\vec{P}} = \vec{F}^{\text{ext}} \tag{5}$$

therefore $\vec{P}$ is constant. According to Eq. (4), this implies that the center of mass moves with constant velocity $\vec{V} = \vec{P}/M$. *See* CONSERVATION OF MOMENTUM; MOMENTUM.

In fact, the preceding equations for translational motion hold for any body, rigid or nonrigid.

Rotational motion. The total angular momentum of a rigid body about a point O with coordinate $\vec{r}_O$ is the sum of the angular momenta of its constituent masses, and is given by Eq. (6). Here

$$\vec{L}_O = \sum_i (\vec{r}_i - \vec{r}_O) \times m_i(\dot{\vec{r}}_i - \dot{\vec{r}}_O) \tag{6}$$

$\times$ denotes the cross-product of the coordinate vector $(\vec{r}_i - \vec{r}_O)$ with the momentum vector $m_i(\dot{\vec{r}}_i - \dot{\vec{r}}_O)$. The time derivative of $\vec{L}$ is given in Eq. (7). Hereafter the point O is taken to be either a

$$\dot{\vec{L}}_O = \sum_i (\vec{r}_i - \vec{r}_O) \times m_i(\ddot{\vec{r}}_i - \ddot{\vec{r}}_O) \tag{7}$$

fixed point (in which case $\dot{\vec{r}}_O = \ddot{\vec{r}}_O = 0$) or the center-of-mass point. Using the equation of motion (1), $m_i\ddot{\vec{r}}_i$ can be replaced by $\vec{F}_i$. Thus the rotational equation of motion (8) is obtained.

$$\dot{\vec{L}}_O = \sum_i (\vec{r}_i - \vec{r}_O) \times \vec{F}_i \tag{8}$$

The right-hand side of Eq. (9) is known as the torque, $\vec{N}$. The contribution of the internal forces to the torque vanishes if the "extended third law" holds; namely, action equals reaction and is directed along a line between the particles. In this circumstance the rotational equation of motion is given by Eqs. (9), where $\vec{N}^{\text{ext}}$

$$\dot{\vec{L}}_0 = \vec{N}_0^{\text{ext}} \tag{9a}$$

$$\vec{N}_0^{\text{ext}} = \sum_i (\vec{r}_i - \vec{r}_O) \times \vec{F}_i^{\text{ext}} \tag{9b}$$

is the total torque associated with external forces that act on the rigid body. *See* ANGULAR MOMENTUM; TORQUE.

It is straightforward to show from Eq. (6) that the angular momentum about an arbitrary point O is related to the angular momentum about the center of mass by Eq. (10). The torque about an arbitrary point O can also be easily related to the torque about the center of mass, by Eq. (11).

$$\vec{L}_O = \vec{L}_{\text{CM}} + (\vec{R} - \vec{r}_O) \times \vec{P} \tag{10}$$

$$\vec{N}_O^{\text{ext}} = \vec{N}_{\text{CM}}^{\text{ext}} + (\vec{R} - \vec{r}_O) \times \vec{F}^{\text{ext}} \tag{11}$$

Six coordinates determine the positions of all particles in a rigid body, and the motion of a rigid body is described by six equations of motion. The translational motion of the center of mass is determined by Eq. (5), and the rotational motion about the center of mass, or a fixed point, is determined by Eq. (9). These six equations, which hold for any system of particles, completely describe the motion of a rigid body.

Motion of an isolated system. The equation $\dot{\vec{L}} = \vec{N}^{\text{ext}}$ has the same form as $\dot{\vec{P}} = \vec{F}^{\text{ext}}$. Both $\vec{L}$ and $\vec{p}$ are constants for an isolated system since $\vec{N}^{\text{ext}} = 0$ and $\vec{F}^{\text{ext}} = 0$. Even though the two conditions $\vec{N}^{\text{ext}} = 0$ and $\vec{F}^{\text{ext}} = 0$ appear similar, there are some important differences for systems in which internal motion is possible. If $\vec{F}^{\text{ext}} = 0$, a center of mass which is at rest will remain so, regardless of internal forces or internal motion. If $\vec{N}^{\text{ext}} = 0$, the total angular momentum is constant, and if initially zero, will remain zero. However, $\vec{L} = 0$ does not exclude changes in orientation of the system by the use of merely internal forces. There is no rotational analog to the equation $\vec{r}(t) = (\vec{P}/M)t + \vec{r}(0)$ for linear motion of the center of mass.

Static equilibrium. In the design of permanent structures, the conditions under which a rigid body remains in steady motion under the action of a set of forces are of great importance. The six conditions for complete equilibrium of a rigid body are given in Eqs. (12). However, in many circumstances equilibrium

$$\begin{aligned} \vec{F}^{\text{ext}} &= \textstyle\sum_i \vec{F}_i^{\text{ext}} = 0 \\ \vec{N}_{\text{CM}}^{\text{ext}} &= \textstyle\sum_i (\vec{r}_i - \vec{R}) \times \vec{F}_i^{\text{ext}} = 0 \end{aligned} \tag{12}$$

is desired only for a subset of the six independent directions of motion. To illustrate, the external force in the direction of motion of an accelerating automobile is nonzero, but equilibrium is maintained in all other directions. *See* STATICS. [V.D.B.]

Rinderpest An acute or subacute, contagious viral disease of ruminants and swine, manifested by high fever, lacrimal discharge, profuse diarrhea, erosion of the epithelium of the mouth and of the digestive tract, and high mortality.

Rinderpest (also known as cattle plague) is caused by a ribonucleic acid (RNA) virus classified in the genus *Morbillivirus* within the Paramyxoviridae family. This virus is closely associated with the viruses of human measles, peste des petits ruminants of sheep and goats, canine distemper, and phocine distemper, and with the dolphin morbillivirus. Although there are significant differences in virulence, only one serotype of rinderpest virus is known. The rinderpest virus is easily inactivated by heat and survives outside the host for a short time. Therefore, transmission of rinderpest is by direct contact between animals.

Although all cloven-hoofed animals are considered susceptible to rinderpest, clinical cases are mostly seen in cattle and water buffalo. Rinderpest is characterized by the development of high fever that lasts for several days until just prior to death. The morbidity in susceptible cattle and buffalo is greater than 90%, with death of almost all clinically affected animals. Rinderpest has been controlled in most African nations, but persists in regions of eastern Africa. *See* ANIMAL VIRUS; PARAMYXOVIRUS. [A.To.]

Ring A tie member or chain link. Tension or compression applied through the center of a ring produces bending moment, shear, and normal force on radial sections. Because shear stress is zero at the boundaries of the section where bending stress is maximum, it is usually neglected. [W.J.K./W.G.B.]

Ring theory The mathematical term ring is used to designate a type of algebraic system with two compositions satisfying most but not all the properties of addition and multiplication in the system of integers, $0, \pm 1, \pm 2, \ldots$. In precise terms a ring is a set R with two binary compositions called addition and multiplication whose results on an ordered pair (a,b), a,b in R, are denoted by $a + b$ and ab, respectively.

These compositions must satisfy the following conditions:

C. $a + b$ and ab belong to R (closure).
A1. $a + b = b + a$ (commutative law).
A2. $(a + b) + c = a + (b + c)$ (associative law).
A3. There exists an element 0 (called zero) in R satisfying $a + 0 = a$ for every a in R.
A4. For each a in R there exists an element $-a$ (called the negative of a) in R such that $a + (-a) = 0$.
M1. $(ab)c = a(bc)$.
D. $a(b + c) = ab + ac$; $(b + c)a = ba + ca$ (distributive laws).

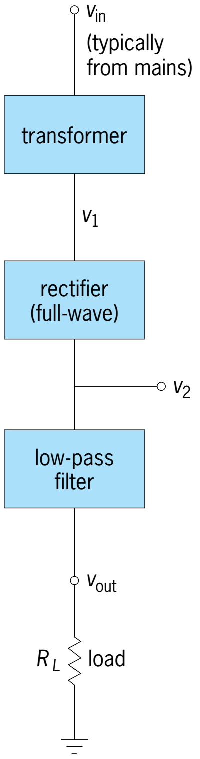
In the ring I of integers (addition and multiplication as usual) there are further conditions, for example, the commutative law of multiplication ($ab = ba$) and the cancellation law that if $a \neq 0$ and $ab = ac$, then $b = c$. *See* SET THEORY.

The importance of the concept of a ring stems from the fact that it embraces many special cases which are fundamental in all branches of mathematics. Thus it includes the ring I of integers, the ring R_0 of rational numbers, the ring $R^{\neq}$ of real numbers, the ring C of complex numbers, various rings of functions, rings of matrices, and so on.

The conditions A1–A4 on the addition composition are exactly equivalent to the statement that any ring is a commutative group relative to its addition composition. This group is called the additive group of the ring. The algebraic system consisting of the set of elements of a ring together with its multiplication composition is called the multiplicative semigroup of the ring. *See* GROUP THEORY.

Various classes of rings are singled out by imposing conditions on the multiplicative semigroup. Thus integral domains are rings in which the product of nonzero elements is nonzero. Division rings are rings whose sets of nonzero elements are groups relative to the multiplication composition, and fields are division rings satisfying the commutative law of multiplication. [N.J.]

Ripple voltage The time-varying part of a voltage that is ideally time-invariant. Most electronic systems require a direct-current voltage for at least part of their operation. An ideal direct-current voltage is available from a battery, but batteries are impractical for many applications. To obtain a direct-current voltage from the alternating-current power mains requires using some type of power supply.



System configuration of a power supply system.

A typical linear power supply system configuration (see illustration) consists of a transformer to change the voltage at the mains to the desired level, a rectifier to convert the alternating-current input voltage v_1 to a pulsating direct-current voltage v_2, followed by a low-pass filter. The output voltage v_{out} of the filter consists of a large direct-current voltage with a superimposed alternating-current voltage. This remaining superimposed alternating-current voltage is called the ripple voltage.

Practical linear power supplies often include a voltage regulator between the low-pass filter and the load. The voltage regulator is usually an electronic circuit that is specifically designed to provide a very stable dc output voltage even if large variations occur in the input. Nonlinear power supplies, which are often termed switching power supplies or switched-mode power supplies, are becoming increasingly popular as a practical alternative for producing a low-ripple dc output. *See* ELECTRIC FILTER; ELECTRONIC POWER SUPPLY; RECTIFIER; VOLTAGE REGULATOR. [S.G.Bu.]

Risk assessment and management The scientific study of risk, the potential realization of undesirable consequences from hazards arising from a possible event, the assessment of the acceptability of the risks, and the management of unacceptable risks. For example, the probability of contracting lung cancer (unwanted consequence) is a risk caused by carcinogens (hazards) contained in second-hand tobacco smoke (event). The risk is estimated using scientific methods, and then the acceptability of that risk is assessed by public health officials. Risk management is the term for the systematic analysis and control of risk, such as prohibiting smoking in public places. Risks are caused by exposure to hazards. Sudden hazards are referred to as acute (for example, a flash flood caused by heavy rains); prolonged hazards are referred to as chronic (for example, carcinogens in second-hand tobacco smoke and polluted air).

The definition of risk contains two components: the probability of an undesirable consequence of an event and the seriousness of that consequence. In the example of a flash flood, risk can be defined as the probability of having a flood of a given magnitude. Sometimes the probability is expressed as a return period, which means, for instance, that a flood of a specified magnitude is expected to occur once every 100 years. The scope of a flood can be expressed as the level or stage of a river, or the dollar amount of property damage.

Most human activities involve risk. The risk of driving, for example, can be subdivided according to property damage, human injuries, fatalities, and harm to the environment. Even the stress and lack of exercise due to driving create health risks. Although risk pervades modern society and is widely acknowledged, it continues to cause unending controversy and debate.

Risk estimates are seldom accurate to even two orders of magnitude, and widely varying perceptions of risk by different interest groups can add confusion and conflict to the risk management process. Environmental risk assessment is laden with uncertainty, particularly with respect to the quantification of chemical emissions; the nature of contaminant transport (such as the region over which a chemical may spread and the velocity of movement) in the water, air, and soil; the type of exposure pathway (such as inhalation, ingestion, and dermal contact); the effects on people based on dose-response studies (which are extrapolated from animals); ecological impacts; and so forth.

Thousands of natural and other hazards are subjected to the statistical analysis of mortality and morbidity data. Society selects a small number of risks to manage, but often some high risks (such as radon in houses) may not be managed, while some low risks (such as movement of dangerous goods) may be selected for management. Management alternatives include banning of the hazard (drugs), regulating the hazard (drivers' tests and licensing), controlling the release and exposure of hazardous materials, treatment after exposure, and penalties for damages. Each management alternative may be analyzed to estimate the impact on risk.

Risk estimates are uncertain, are described in technical language, and are outside the general understanding or experience of most people. Perception plays a crucial role, tending to exaggerate the significance, for example, of risks that are involuntary, catastrophic, or newsworthy. Effective risk management therefore requires effective risk communication.

Risk assessment is the evaluation of the relative importance of an estimated risk with respect to other risks faced by the population, the benefits of the activity source of the risk, and the costs of managing the risk. For risks due to long-term exposure to chemicals, the risk assessment activity generally incorporates the estimation of the response of people to the exposure (that is, risk analysis is a part of risk assessment). The methods used include studies on animals, exposure of tissues, and epidemiology. *See* Environmental engineering; Environmental toxicology; Hazardous waste. [K.W.H.; J.Sh.]

Ritz's combination principle The empirical rule, formulated by W. Ritz in 1905, that sums and differences of the frequencies of spectral lines often equal other observed frequencies. The rule is an immediate consequence of the quantum-mechanical formula $hf = E_i. - E_f$ relating the energy hf of an emitted photon to the initial energy E_i. and final energy E_f, of the radiating system; h is Planck's constant and f is the frequency of the emitted light. *See* Atomic structure and spectra; Energy level (quantum mechanics); Quantum mechanics. [E.G.]

River A natural, fresh-water surface stream that has considerable volume compared with its smaller tributaries. The tributaries are known as brooks, creeks, branches, or forks. Rivers are usually the main stems and larger tributaries of the drainage systems that convey surface runoff from the land. Rivers flow from headwater areas of small tributaries to their mouths, where they may discharge into the ocean, a major lake, or a desert basin.

Rivers flowing to the ocean drain about 68% of the Earth's land surface. Regions draining to the sea are termed exoreic, while those draining to interior closed basins are endoreic. Areic regions are those which lack surface streams because of low rainfall or lithoogic conditions.

Sixteen of the largest rivers account for nearly half of the total world river flow of water. The Amazon River alone carries nearly 20% of all the water annually discharged by the world's rivers. Rivers also carry large loads of sediment. The total sediment load for all the world's rivers averages about 22×10^9 tons (20×10^9 metric tons) brought to the sea each year. Sediment loads for individual rivers vary considerably. The Yellow River of northern China is the most prolific transporter of sediment. Draining an agricultural region of easily eroded loess, this river averages about 2×10^9 tons (1.8×10^9 metric tons) of sediment per year, one-tenth of the world average. *See* Depositional systems and environments; Loess.

River discharge varies over a broad range, depending on many climatic and geologic factors. The low flows of the river influence water supply and navigation. The high flows are a concern as threats to life and property. However, floods are also beneficial. The ancient Egyptian civilization was dependent upon the Nile River floods to provide new soil and moisture for crops. Floods are but one attribute of rivers that affect human society. Means of counteracting the vagaries of river flow have concerned engineers for centuries. In modern times many of the world's rivers are managed to conserve the natural flow for release at times required by human activity, to confine flood flows to the channel and to planned areas of floodwater storage, and to maintain water quality at optimum levels. *See* Floodplain; River engineering. [V.R.B.]

River engineering A branch of civil engineering that involves the control and utilization of rivers for the benefit of humankind. Its scope includes river training, channel design, flood control, water supply, navigation improvement, hydraulic structure design, hazard mitigation, and environmental enhancement. River engineering is also necessary to provide protection against floods and other river disasters. The emphasis is often on river responses, long-term and short-term, to changes in nature, and stabilization and utilization, such as damming, channelization, diversion, bridge construction, and sand or gravel mining. Evaluation of river responses is essential at the conceptual, planning, and design phases of a project and requires the use of fundamental principles of river and sedimentation engineering. *See* Canal; Dam; River; Stream transport and deposition. [H.H.C.]

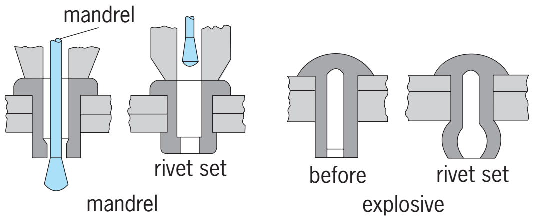
River tides Tides that occur in rivers emptying directly into tidal seas. These fides show three characteristic modifications of ocean tides. (1) The speed at which the tide travels upstream depends on the depth of the channel. (2) The further upstream, the longer the duration of the falling tide and the shorter the duration of the rising tide. (3) The range of the tide decreases with distance upstream. *See* Tide.

In a river the difference between the depths of water at high and low tides may be relatively large, leading to a marked difference between the speeds at which high and low tides move. The difference in depth between various points on the river also partially explains the second modification, or duration of fall and rise. In addition, the river flow, which may fluctuate widely, helps a failing tide but hinders a rising tide, increasing the difference in duration.

The third modification or decrease in tidal range upstream may be accounted for by loss of energy of the water through friction with the sides and bottom of the channel. Although friction always saps energy from the tide, if the channel becomes constricted within a short distance, the water may be forced into a smaller space, thus producing a larger tidal range. [B.K.]

Rivet A short rod with a head formed on one end. A rivet is inserted through aligned holes in two or more parts to be joined; then by pressing the protruding end, a second head is formed to hold the parts together permanently. The first head is called the manufactured head and the second one the point. In forming the point, a hold-on or dolly bar is used to back up the manufactured head and the rivet is driven, preferably by a machine riveter.

Blind rivets are special rivets that can be set without access to the point. They are available in many designs but are of three general types: screw, mandrel, and explosive (see illustration). In the mandrel type the rivet is set as the mandrel is pulled through. In the explosive type an explosive charge in the point is set off by a special hot iron; the explosion expands the point and sets the rivet. [P.H.B.]



Two types of blind rivet.

Robotics A field of engineering concerned with the development and application of robots, and computer systems for their control, sensory feedback, and information processing. The many types of robotic systems include robotic manipulators, robotic hands, mobile robots, walking robots, aids for disabled persons, telerobots, and microelectromechanical systems.

The term "robotics" has been broadly interpreted. It includes research and engineering activities involving the design and development of robotic systems. Planning for the use of industrial robots in manufacturing or evaluation of the economic impact of robotic automation can also be viewed as robotics. This breadth of usage arises from the interdisciplinary nature of robotics, a field involving mechanisms, computers, control systems, actuators, and software. *See* Biomechanics; Computer; Control systems; Cybernetics; Electrical engineering; Industrial engineering; Mechanical engineering; Software engineering.

Robots produce mechanical motion that, in most cases, results in manipulation or locomotion. Mechanical characteristics for robotic mechanisms include degrees of freedom of movement, size and shape of the operating space, stiffness and strength of the structure, lifting capacity, velocity, and acceleration under load. Performance measures include repeatability and accuracy of positioning, speed, and freedom from vibration.

A robot control system directs the motion and sensory processing of a robot or system of cooperating robots. The controller may consist of only a sequencing device for simple robots, although most multiaxis industrial robots today employ servo-controlled positioning of their joints by a microprocessor-based system.

The robot sensory system gathers specific information needed by the control system and, in more advanced systems, maintains an internal model of the environment to enable prediction and decision making. The joint position transducers on industrial robots provide a minimal sensory system for many industrial applications, but other sensors are needed to gather data about the external environment. Sensors may detect position, velocity, acceleration, visual, proximity, acoustic, force-torque, tactile, thermal, and radiation data.

As information moves up from the sensory device, the amount of information increases and the speed of data acquisition decreases. These control architectures form the basis for computer integrated manufacturing (CIM), a hierarchical approach to organizing automated factories. A new paradigm has emerged, based on the interconnection of intelligent system elements that can learn, reason, and modify their configuration to satisfy overall system requirements. One of the most important of these approaches is based on holonic systems. *See* Automation; Computer-integrated manufacturing; Intelligent machine.

A telerobotic system augments humans by allowing them to extend their ability to perform complex tasks in remote locations. It is a technology that couples the human operator's visual, tactile, and other sensory perception functions with a remote manipulator or mobile robot. These systems are useful for performing tasks in environments that are dangerous or not easily accessible for humans. Telerobotic systems are used in nuclear handling, maintenance in space, undersea exploration, and servicing electric transmission lines. Perhaps the most important sensory data needed for telepresence are feedback of visual information, robot position, body motion and forces, as well as tactile information. Master-slave systems have been developed in which, for example, a hand controller provides control inputs to an articulated robotic manipulator. These systems are capable of feeding back forces felt by the robot to actuators on the exoskeletal master controller so that the operator can "feel" the remote environment. *See* Human-machine systems; Remote manipulators.

Graphical simulation is used to design and evaluate a workcell layout before it is built. The robot motion can be programmed on the simulation and downloaded to the robot controller. Companies market software systems that include libraries of commercially available robots and postprocessors for off-line robot programming. *See* Simulation. [W.A.G.]

Roche limit The closest distance which a satellite, revolving around a parent body, can approach the parent without being pulled apart tidally. The simplest formal definition is that the Roche limit is the minimum distance at which a satellite can be in equilibrium under the influence of its own gravitation and that of the central mass about which it is describing a circular orbit. If the satellite is in a circular orbit and has negligible mass, the same density as the primary, and zero tensile strength, the Roche limit is 2.46 times the radius of the primary.

When a star has exhausted the supply of hydrogen in its core, its radius will increase by a factor of 10 to 100. A star in a binary system may then exceed its Roche limit, material will thus escape from that star, and its companion will receive the excess material. *See* Binary star. [P.K.S.]

Rock A relatively common aggregate of mineral grains. Some rocks consist essentially of but one mineral species (monomineralic, such as quartzite, composed of quartz); others consist of two or more minerals (polymineralic, such as granite, composed of quartz, feldspar, and biotite). Rock names are not given for those rare combinations of minerals that constitute ore deposits, such as quartz, pyrite, and gold. In the popular sense rock is considered also to denote a compact substance, one with some coherence; but geologically, friable volcanic ash also is a rock. A genetic classification of rocks is shown below.

Igneous
  Intrusive
    Plutonic (deep)
    Hypabyssal (shallow)
  Extrusive
    Flow
    Pyroclastic (explosive)
  Sedimentary
    Clastic (mechanical or detrital)
    Chemical (crystalline or precipitated)
    Organic (biogenic)

- Metamorphic
  - Cataclastic
  - Contact metamorphic and pyrometasomatic
  - Regional metamorphic (dynamothermal)
- Hybrid
  - Metasomatic
  - Migmatitic

Exceptions to the requirement that rocks consist of minerals are obsidian, a volcanic rock consisting of glass; and coal, a sedimentary rock which is a mixture of organic compounds. *See* COAL; IGNEOUS ROCKS; METAMORPHIC ROCKS; OBSIDIAN; ROCK MECHANICS; SEDIMENTARY ROCKS; VOLCANIC GLASS. [E.W.H.]

Rock, electrical properties of The effect of changes in pressure and temperature on electrical properties of rocks. There has been increasing interest in the electrical properties of rocks at depth within the Earth and the Moon. The reason for this interest has been consideration of the use of electrical properties in studying the interior of the Earth and its satellite, particularly to depths of tens or hundreds of kilometers. At such depths pressures and temperatures are very great, and laboratory studies in which these pressures and temperatures are duplicated have been used to predict what the electrical properties at depth actually are. More direct measurements of the electrical properties deep within the Earth have been made by using surface-based electrical surveys of various sorts. An important side aspect of the study of electrical properties has been the observation that, when pressures near the crushing strength are applied to a rock, marked changes in electrical properties occur, probably caused by the development of incipient fractures. Such changes in resistivity might be used in predicting earthquakes, if they can be measured in the ground. *See* GEOELECTRICITY; GEOPHYSICAL EXPLORATION.

Attempts to measure the electrical properties of rocks to depths of tens or hundreds of kilometers in the Earth indicate that the Earth's crust is zoned electrically. The surface zone, with which scientists are most familiar, consists of a sequence of sedimentary rocks, along with fractured crystalline and metamorphic rocks, all of which are moderately good conductors of electricity because they contain relatively large amounts of water in pore spaces and other voids. This zone, which may range in thickness from a kilometer to several tens of kilometers, has conductivities varying from about $\frac{1}{2}$ ohm-m in recent sediments to 1000 ohm-m or more in weathered crystalline rock.

The basement rocks beneath this surface zone are crystalline, igneous, or metamorphic rocks which are much more dense, having little pore space in which water may collect. Since most rock-forming minerals are good insulators at normal temperatures, conduction of electricity in such rocks is determined almost entirely by the water in them. As a result, this part of the Earth's crust is electrically resistant (the resistivity lies in the range 10,000–1,000,000 ohm-m).

At rather moderate depths beneath the surface of the second zone, resistivity begins to decrease with depth. This decrease is considered to be the result of higher temperatures, which almost certainly are present at great depths. High temperatures lead to partial ionization of the molecular structure of minerals composing a rock, and the ions render even the insulating minerals conductive. [G.V.K.]

Rock age determination Finding the age of rocks based on the presence of naturally occurring long-lived radioactive isotopes of several elements in certain minerals and rocks. Measurements of rock ages have enabled geologists to reconstruct the geologic history of the Earth from the time of its formation 4.6×10^9 years ago to the present. Age determinations of rocks from the Moon have also contributed to knowledge of the history of the Moon, and may someday be used to study the history of Mars and of other bodies within the solar system. *See* EARTH, AGE OF; RADIOACTIVITY.

Parent-daughter pairs used for dating rocks and minerals

Parent	Daughter	Half-life, 10^9 years
Potassium-40	Argon-40	11.8
Potassium-40	Calcium-40	1.47
Rubidium-87	Strontium-87	48.8
Samarium-147	Neodymium-143	107
Rhenium-187	Osmium-187	43
Thorium-232	Lead-208	14.008
Uranium-235	Lead-207	0.7038
Uranium-238	Lead-206	4.468

Many rocks and minerals contain radioactive atoms that decay spontaneously to form stable atoms of other elements. Under certain conditions these radiogenic daughter atoms accumulate within the mineral crystals so that the ratio of the daughter atoms divided by the parent atoms increases with time. This ratio can be measured very accurately with a mass spectrometer, and is then used to calculate the age of the rock by means of an equation based on the law of radioactivity. The radioactive atoms used for dating rocks and minerals have very long half-lives, measured in billions of years. They occur in nature only because they decay very slowly. The pairs of parents and daughters used for dating are listed in the table. *See* DATING METHODS.

The rubidium-strontium method is based on rubidium-87, which decays to stable strontium-87 (^{87}Sr) by emitting a beta particle from its nucleus. The abundance of the radiogenic strontium-87 therefore increases with time at a rate that is proportional to the Rb/Sr ratio of the rock or mineral. The method is particularly well suited to the dating of very old rocks such as the ancient gneisses near Godthaab in Greenland, which are almost 3.8×10^9 years old. This method has also been used to date rocks from the Moon and to determine the age of the Earth by analyses of stony meteorites.

The potassium-argon method is based on the assumption that all of the atoms of radiogenic argon-40 that form within a potassium-bearing mineral accumulate within it. This assumption is satisfied only by a few kinds of minerals and rocks, because argon is an inert gas that does not readily form bonds with other atoms. The K-Ar method of dating has been used to establish a chronology of mountain building events in North America beginning about 2.8×10^9 years ago and continuing to the present. In addition, the method has been used to date reversals of the polarity of the Earth's magnetic field during the past 1.3×10^7 years. *See* OROGENY; PALEOMAGNETISM.

The uranium, thorium-lead method is based on uranium and thorium atoms which are radioactive and decay through a series of radioactive daughters to stable atoms of lead (Pb). Minerals that contain both elements can be dated by three separate methods based on the decay of uranium-238 to lead-206, uranium-235 to lead-207, and thorium-232 to lead-208. The three dates agree with each other only when no atoms of uranium, thorium, lead, and of the intermediate daughters have escaped. Only a few minerals satisfy this condition. The most commonly used mineral is zircon ($ZrSiO_4$), in which atoms of uranium and thorium occur by replacing zirconium. *See* LEAD ISOTOPES (GEOCHEMISTRY); RADIOACTIVE MINERALS.

The common-lead method is based on the common ore mineral galena (PbS) which consists of primordial lead that dates from the time of formation of the Earth and varying amounts of radiogenic lead that formed by decay of uranium and thorium in the Earth. The theoretical models required for the interpretation of common lead have provided insight into the early history of the solar system and into the relationship between meteorites and the Earth.

The fission-track method is based on uranium-238 which can decay both by emitting an alpha particle from its nucleus and by spontaneous fission. The number of spontaneous fission tracks per square centimeter is proportional to the concentration of uranium and to the age of the sample. When the uranium content is known, the age of the sample can be calculated. This method is suitable for dating a variety of minerals and both natural and manufactured glass. Its range extends from less than 100 years to hundreds of millions of years. *See* FISSION TRACK DATING.

The samarium-neodymium method of dating separated minerals or whole-rock specimens is similar to the Rb-Sr method. The Sm-Nd method is even more reliable than the Rb-Sr method of dating rocks and minerals, because samarium and neodymium are less mobile than rubidium and strontium. The isotopic evolution of neodymium in the Earth is described by comparison with stony meteorites. *See* METEORITE.

The rhenium-osmium method is based on the beta decay of naturally occurring rhenium-187 to stable osmium-187. It has been used to date iron meteorites and sulfide ore deposits containing molybdenite. [G.Fau.]

Rock burst A sudden and violent rock failure around a mining excavation on a sufficiently large scale to be considered a hazard endangering the existence of mine openings, equipment, and personnel. It has been estimated that the energy released in some big bursts was equivalent to that released in exploding 200 tons (180 metric tons) of TNT. Such bursts resemble small earthquakes and may be detected several hundred miles away.

Rock bursts are related to the fracture of rock in place and require two conditions for their occurrence: a stress in the rock mass sufficiently high to exceed its strength, and physical characteristics of the rock which enable it to store energy up to the threshold value for sudden rupture. Rocks which yield gradually in plastic strain when under load usually do not generate rock bursts. *See* ROCK MECHANICS. [S.H.B.]

Rock cleavage A secondary, planar structure of deformed rocks. A cleavage is penetrative and systematic, as opposed to fractures and shear zones which may occur alone or in widely spaced sets. It is generally better developed in fine grained rocks than in coarse ones. Application of the term derives from the ability to split rocks along the structure.

Simple cleavages are generally parallel to the axial surfaces of folds. This is true for folds formed by uniform flow of the rock mass where primary layering behaves as a passive marker. When rock layers are buckled, the primary layering behaving as mechanical discontinuities, cleavage that develops early may be fanned by subsequent growth of the fold. Cleavage is also associated with faults. *See* FAULT AND FAULT STRUCTURES; FOLD AND FOLD SYSTEMS.

Continuous (microscopically penetrative) cleavages, as in slates, are the earliest tectonic fabric elements that can be recognized in rocks. Cleavage also develops in rocks of lower deformational and metamorphic grade than slates. In these rocks, the cleavage occurs as discrete surfaces or seams, often coated with a film of clay or carbonaceous material; the cleavage surfaces are separated by zones of undeformed sedimentary rock. The surfaces may be smooth, anastomosing, or stylolitic. *See* METAMORPHISM; ROCK MECHANICS; SLATE. [D.B.Bi.]

Rock magnetism The permanent and induced magnetism of rocks and minerals on scales ranging from the atomic to the global, including applications to magnetic field anomalies and paleomagnetism. Natural compasses, concentrations of magnetite (Fe_3O_4) called lodestones, are one of humankind's oldest devices. W. Gilbert in 1600 discovered that the Earth itself is a giant magnet, and speculated that its magnetism might be due to subterranean lodestone deposits. Observations by B. Brunhes in 1906 that some rocks are magnetized reversely to the present Earth's magnetic field, and by M. Matuyama in 1929 that reversely and normally magnetized rocks correspond to different geological time periods, made it clear that geomagnetism is dynamic, with frequent reversals of north and south poles. Nevertheless, permanent magnetism of rocks remains important because it alone provides a memory of the intensity, direction, and polarity of the Earth's magnetic field in the geological past. From this magnetic record comes much of the evidence for continental drift, sea-floor spreading, and plate tectonics. *See* CONTINENTAL DRIFT; GEOMAGNETISM; MAGNET; MAGNETISM; PALEOMAGNETISM; PLATE TECTONICS.

The magnetism of rocks arises from the ferromagnetism or ferrimagnetism of a few percent or less of minerals such as magnetite. The magnetic moments of neighboring atoms in such minerals are coupled parallel or antiparallel, creating a spontaneous magnetization M_S. All magnetic memory, including that of computers, permanent magnets, and rocks, is due to the spontaneous and permanent nature of this magnetism. Spontaneous magnetization requires no magnetic field to create it, and cannot be demagnetized.

The magnetism can be randomized on the scale of magnetic mineral grains because different regions of a crystal tend to have their M_S vectors in different directions. These regions are called magnetic domains. Grains so small that they contain only one domain (single-domain grains) are the most powerful and stable paleomagnetic recorders. Larger, multidomain grains can also preserve a paleomagnetic memory, through imbalance in the numbers, sizes, or directions of domains, but this memory is more easily altered by time and changing geological conditions. *See* FERRIMAGNETISM; FERROMAGNETISM; MAGNETISM; MAGNETITE; MAGNETIZATION; MAGNETOMETER. [D.J.Du.]

Rock mechanics Application of the principles of mechanics and geology to quantify the response of rock when it is acted upon by environmental forces, particularly when human-induced factors alter the original ambient conditions. Rock mechanics is an interdisciplinary engineering science that requires interaction between physics, mathematics, and geology, and civil, petroleum, and mining engineering. The present state of knowledge permits only limited correlations between theoretical predictions and empirical results. Therefore, the most useful principles are based upon data obtained from laboratory and in-place measurements and from prototype behavior (behavior of the completed engineering works). Increasing emphasis is upon in-place measurements because rock properties are regarded as site-specific; that is, the properties of the rock system at one site probably will be significantly different from those at another site, even if geologic environments are similar. *See* ENGINEERING GEOLOGY.

Because of the interdisciplinary aspects, there is no standardization of rock mechanics terminology. However, the following terms and definitions are useful.

Environmental factors are the natural factors and human influences that require consideration in engineering problems in rock mechanics. The major natural factors are geology, ambient stresses, and hydrology. The human influences derive from the application of chemical, electrical, mechanical, or thermal energy during construction (or destruction) processes.

The ambient stress field is the distribution and numerical value of the stresses in the environment prior to its disturbance by humans.

The term rock system includes the complete environment that can influence the behavior of that portion of the Earth's crust that will become part of an engineering structure. Generally, all natural environmental factors are included.

A rock element is the coherent, intact piece of rock that is the basic constituent of the rock system and which has physical, mechanical, and petrographic properties that can be described or measured by laboratory tests on each such element. The concepts of rock system and rock element enable the concomitant engineering design to be optimized according to the principles of system engineering. *See* SYSTEMS ENGINEERING.

"Rock failure" occurs when a rock system or element no longer can perform its intended engineering function. Failure may be evidenced by fractures, distortion of shape, or reduction in strength. "Failure mechanism" includes the causes for the manner of rock failure. *See* Rock burst; Soil mechanics; Tunnel; Underground mining. [W.R.J.]

Rock varnish A dark coating on rock surfaces exposed to the atmosphere. Rock varnish is probably the slowest-accumulating sedimentary deposit, growing at only a few micrometers to tens of micrometers per thousand years. Its thickness ranges from less than 5 μm to over 600 μm, and is typically 100 μm or so. Although found in all terrestrial environments, varnish is mostly developed and well preserved in arid to semiarid deserts; thus, another common name is desert varnish. Rock varnish is composed of about 30% manganese and iron oxides, up to 70% clay minerals, and over a dozen trace and rare-earth elements. The building blocks of rock varnish are mostly blown in as airborne dust. Although the mechanism responsible for the formation of rock varnish remains unclear, two hypotheses have been proposed to explain the great enrichment in manganese within varnish (typically over 50 times compared with the adjacent environment such as soils, underlying rock, or dust). The abiotic hypothesis assumes that small changes in pH can concentrate manganese by geochemical processes. The biotic hypothesis suggests that bacteria, and perhaps other microorganisms, concentrate manganese; this is supported by culturing experiments and direct observations of bacterial enhancement of manganese. *See* Sedimentary rocks.

Since rock varnish records environmental, especially climatic, events that are regionally or even globally synchronous, varnish microstratigraphy can be used as a tool for age dating. Without radiometric calibration, varnish microstratigraphy itself may be used to estimate relative ages of varnished geomorphic or archeological features in deserts. Once calibrated, varnish microstratigraphy can provide numerical age estimates for geomorphic and archeological features. Specifically, for petroglyphs and geoglyphs, the layering patterns of rock varnish hold the greatest potential for assigning ages. *See* Archeological chronology; Dating methods; Rock age determination. [T.L.]

Rocket Either a propulsion system or a complete vehicle driven by such a propulsive engine. A rocket engine provides the means whereby chemical matter is burned to release the energy stored in it and the energy is expended, by ejection at high velocity of the products of combustion (the working fluid). The ejection imparts motion to the vehicle in a direction opposite to that of the ejected matter. A rocket vehicle is propelled by rocket reaction and includes all components necessary for such propulsion, and a payload such as an explosive charge, scientific instruments, or a crew. A rocket vehicle also includes guidance and control equipment mounted in a structural airframe or spaceframe. *See* Rocket propulsion; Rocket staging; Satellite (spacecraft); Space flight; Space probe. [G.P.S.]

Rocket astronomy The discipline that makes use of sounding rockets that fly near-vertical paths carrying scientific instruments to altitudes ranging from 25 to more than 900 mi (40 to 1500 km). Altitudes up to 30 mi (48 km) can be reached by balloons, so sounding rockets are typically used for higher altitudes in order to measure emissions from the Sun or other celestial sources that do not penetrate the Earth's atmosphere. Sounding rockets do not achieve orbital velocity; after completion of the launch phase, the payload follows a ballistic trajectory that permits 5–15 min of data taking before reentry. *See* Rocket.

In comparison with experiments launched on satellites, rockets offer the advantages of simplicity, relatively frequent access to launch opportunities, a shorter time scale from conception to reality, lower cost, and recoverability of the payload and the possibility of postflight instrument calibration, refurbishment, and reflight. Major disadvantages are short observing time, localized coverage, and size and weight restrictions on payloads. *See* Satellite astronomy.

Scientific rocket programs focus on the disciplines of aeronomy, magnetospheric physics, meteorology, and material sciences, as well as astronomy and astrophysics. The ability to carry out vertical profile measurements of relevant atmospheric parameters at heights of 25–125 mi (40–200 km) is essential in many of these scientific disciplines. To the extent that the Sun influences or controls conditions in the upper atmosphere and magnetosphere of the Earth, there is a strong connection between solar astronomy and the more local research areas. *See* Aeronomy; Ionosphere; Magnetosphere.

The emission from the solar corona is dominated by ultraviolet and x-ray photons. During the late 1950s and early 1960s, techniques were developed for focusing x-rays and thereby providing direct imaging of the corona. These early studies revealed the highly structured nature of the atmosphere, with approximately semicircular loops of hot plasma outlining the shape of the underlying magnetic field, which confines the hot gas. Among the notable advances in coronal studies from rockets has been the development of a new technique for x-ray imaging: the use of multilayer coatings for enhanced x-ray reflectivity. *See* Sun; X-ray astronomy; X-ray telescope.

Observations of nonsolar sources from sounding rockets are hindered by the low intensity of the emission and the problem of pointing the payload at the source during the flight. [L.Gol.]

Rocket propulsion The process of imparting a force to a flying vehicle, such as a missile or a spacecraft, by the momentum of ejected matter. This matter, called propellant, is stored in the vehicle and ejected at high velocity. In chemical rockets the propellents are chemical compounds that undergo a chemical combustion reaction, releasing the energy for thermodynamically accelerating and ejecting the gaseous reaction products at high velocities. Chemical rocket propulsion is thus differentiated from other types of rocket propulsion, which use nuclear, solar, or electrical energy as their power source and which may use mechanisms other than the adiabatic expansion of a gas for achieving a high ejection velocity. Propulsion systems using liquid propellants (such as kerosine and liquid oxygen) have traditionally been called rocket engines, and those that use propellants in solid form have been called rocket motors. *See* Electrothermal propulsion; Interplanetary propulsion; Ion propulsion; Plasma propulsion; Propulsion; Spacecraft propulsion.

Performance. The performance of a missile or space vehicle propelled by a rocket propulsion system is usually expressed in terms of such parameters as range, maximum velocity increase of flight, payload, maximum altitude, or time to reach a given target. Propulsion performance parameters (such as rocket exhaust velocity, specific impulse, thrust, or propulsion system weight) are used in computing these vehicle performance

Typical performance values of rocket propulsion systems*

Propulsion system parameter	Typical range of values
Specific impulse at sea level	180–390 s
Specific impulse at altitude	215–470 s
Exhaust velocity at sea level	5800–15,000 ft/s (1800–4500 m/s)
Combustion temperature	4000–7200°F (2200–4000°C)
Chamber pressures	100–3000 lb/in.^{2} (0.7–20 MPa)
Ratio of thrust to propulsion system weight	20–150
Thrust	0.01–6.6 × 10^6 lb (0.05–2.9 × 10^7 n)†
Flight speeds	0–50,000 ft/s (0–15,000 m/s)

*Exact values depend on application, propulsion system design, and propellant selection.

†Maximum value applies to a cluster; for a single rocket motor it is 3.3 × 10^6 lb (14,700 kN).

criteria. The table gives typical performance values. *See* SPECIFIC IMPULSE; THRUST.

Applications. Rocket propulsion is used for different military missiles or space-flight missions. Each requires different thrust levels, operating durations, and other capabilities. In addition, rocket propulsion systems are used for rocket sleds, jet-assisted takeoff, principal power plants for experimental aircraft, or weather sounding rockets. For some space-flight applications, systems other than chemical rockets are used or are being investigated for possible future use. *See* GUIDED MISSILE; MISSILE; ROCKET-SLED TESTING; SATELLITE (SPACECRAFT); SPACE FLIGHT; SPACE PROBE.

Liquid-propellant rocket engines. These use liquid propellants stored in the vehicle for their chemical combustion energy. The principal hardware subsystems are one or more thrust chambers, a propellant feed system, which includes the propellant tanks in the vehicle, and a control system.

Bipropellants have a separate oxidizer liquid (such as liquefield oxygen or nitrogen tetroxide) and a separate fuel liquid (such as liquefied hydrogen or hydrazine). Monopropellants consist of a single liquid that contains both oxidizer and fuel ingredients. A catalyst is required to decompose the monopropellant into gaseous combustion products. Bipropellant combinations allow higher performance (higher specific impulse) than monopropellants. *See* PROPELLANT.

The three principal components of a thrust chamber are the combustion chamber, where rapid, high-temperature combustion takes place; the converging-diverging nozzle, where the hot reaction-product gases are accelerated to supersonic velocities; and an injector, which meters the flow of propellants in the desired mixture of fuel and oxidizer, introduces the propellants into the combustion chamber, and causes them to be atomized or broken up into small droplets. Some thrust chambers (such as the space shuttle's main engines and orbital maneuvering engines) are gimbaled or swiveled to allow a change in the direction of the thrust vector for vehicle flight motion control.

Solid-propellant rocket motors. In rocket motors the propellant is a solid material that feels like a soft plastic or soap. The solid propellant cake or body is known as the grain. It can have a complex internal geometry and is fully contained inside the solid motor case, to which a supersonic nozzle is attached.

The propellant contains all the chemicals necessary to maintain combustion. Once ignited, a grain will burn on all exposed surfaces until all the usable propellant is consumed; small unburned residual propellant slivers often remain in the chamber. As the grain surface recedes, a chemical reaction converts the solid propellant into hot gas. The hot gas then flows through internal passages within the grain to the nozzle, where it is accelerated to supersonic velocities. A pyrotechnic igniter provides the energy for starting the combustion.

The nozzle must be protected from excessive heat transfer, from high-velocity hot gases, from erosion by small solid or liquid particles in the gas (such as aluminum oxide), and from chemical reactions with aggressive rocket exhaust products. The highest heat transfer and the most severe erosion occur at the nozzle throat and immediately upstream from there. Special composite materials, called ablative materials, are used for heat protection, such as various types of graphite or reinforced plastics with fibers made of carbon or silica. The development of a new composite material, namely, woven carbon fibers in a carbon matrix, has allowed higher wall temperatures and higher strength at elevated temperatures; it is now used in nozzle throats, nozzle inlets, and exit cones. It is made by carbonizing (heating in a nonoxidizing atmosphere) organic materials, such as rayon or phenolics. Multiple layers of different heat-resistant and heat-insulating materials are often particularly effective. A three-dimensional pattern of fibers created by a process similar to weaving gives the nozzle extra strength. *See* NOZZLE.

Nozzles can have sophisticated thrust-vector control mechanisms. In one such system the nozzle forces are absorbed by a doughnut-shaped, confined, liquid-filled bag, in which the liquid moves as the nozzle is canted. The space shuttle solid rocket boosters have gimbaled nozzles for thrust-vector control, with actuators driven by auxiliary power units and hydraulic pumps.

Hybrid rocket propulsion. A hybrid uses a liquid propellant together with a solid propellant in the same rocket engine. The arrangement of the solid fuel is similar to that of the grain of a solid-propellant rocket; however, no burning takes place directly on the surface of the grain because it contains little or no oxidizer. Instead, the fuel on the grain surface is heated, decomposed, and vaporized, and the vapors burn with the oxidizer some distance away from the surface. The combustion is therefore inefficient.

Testing. Because flights of rocket-propelled vehicles are usually fairly expensive and because it is sometimes difficult to obtain sufficient and accurate data from fast-moving flight vehicles, it is accepted practice to test rocket propulsion systems and components extensively on the ground under simulated flight conditions. Components such as an igniter or a turbine are tested separately. Complete engines are tested in static engine test stands; the complete vehicle stage is also tested statically. In the latter two tests the engine and vehicle are adequately secured by suitable structures. Only in flight tests are they allowed to leave the ground. [G.P.S.]

Rocket-sled testing

A method of subjecting structures and devices to high accelerations or decelerations and aerodynamic flow phenomena under controlled conditions. The test object is mounted on a sled chassis running on precision steel rails and accelerated by rockets and decelerated by water scoops. This captive track testing of full-scale aircraft and missile components makes possible the recovery of expensive test sections, facilitates the instrumentation of the test and the reception and recording of the data, and provides a degree of repeatability not normally achieved under conditions of free flight. The components tested may be the rocket engines themselves, sections of flight vehicles, or equipment intended to operate under conditions of high acceleration or other specific environments such as structural vibration, acoustic vibration, and related aerodynamic conditions.

The test vehicle takes many diversified forms, ranging from the highly faired, aerodynamically clean type used to explore the transonic and supersonic speed ranges to the relatively simple all-purpose utility type used for testing in the subsonic and low transonic ranges. All sleds are carried on shoes or slippers that grip the railhead in order to prevent derailing. They may be powered by either liquid- or solid-propellant rocket engines.

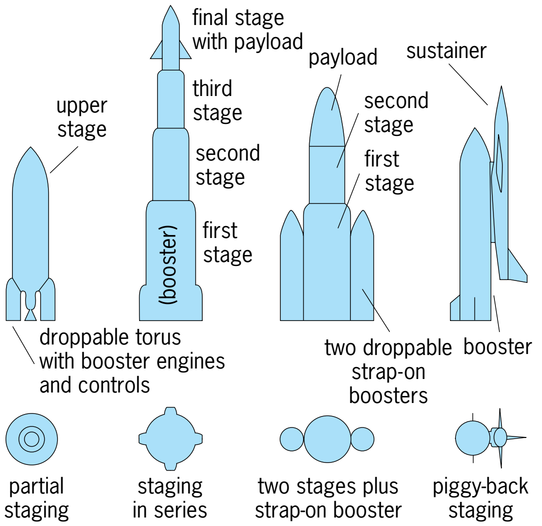
Tests conducted on the track provide initial design data, developmental evaluation, and performance measurements of completed components and equipments. [E.Co.]

Rocket staging

The use of successive rocket sections, each having its own engine or engines. One way to minimize the weight of large missiles, or space vehicles, is to use multiple stages. The first or initial stage is usually the heaviest and biggest and often called the booster; the next few stages are successively smaller and are generally called sustainers. Each stage is a complete vehicle in itself and carries its own propellant (either solid or liquid; both fuel and oxidizer), its own propulsion system, and has its own tankage and control system.

Once the propellant of a given stage is expended, the dead weight of that stage including empty tanks, rocket engine, and controls is no longer useful in contributing additional kinetic energy to the succeeding stages. By dropping off this useless weight, the mass that remains to be accelerated is made smaller; therefore it is possible to accelerate the payload to higher velocity than would be attainable if multiple staging were not used.

It is quite possible to employ different types of power plants, different types of propellants, and entirely different configurations in successive stages of any one multistage vehicle (see



Typical schemes for staging missiles.

illustration). Because staging adds complications, it is impractical to have more than four to seven stages in any one vehicle. *See* ROCKET PROPULSION. [G.P.S.]

Rodentia The mammalian order consisting of the rodents, often known as the gnawing mammals. This is the most diverse group of mammals in the world, consisting of over 2000 species, more than 40% of the known species of mammals on Earth today. Rodents range in size from mice, weighing only a few grams, to the Central American capybara, which is up to 130 cm (4 ft) in length and weighs up to 79 kg (170 lb). Rodents have been found in virtually every habitat and on every continent except Antarctica. Rodents have adapted to nearly every mode of life, including semiaquatic swimming (beavers and muskrats), gliding ("flying" squirrels), burrowing (gophers and African mole rats), arboreal (dormice and tree squirrels), and hopping (kangaroo rats and jerboas). Nearly all rodents are herbivorous, with a few exceptions that are partially insectivorous to totally omnivorous, such as the domestic rat. The great adaptability and rapid evolution and diversity of rodents are mainly due to their short gestation periods (only 3 weeks in some mice) and rapid turnover of generations.

The most diagnostic feature of the Rodentia is the presence of two pair of ever-growing incisors (one pair above and one below) at the front of the jaws. These teeth have enamel only on the front surface, which allows them to wear into a chisellike shape, giving rodents the ability to gnaw. Associated with these unique teeth are a number of other anatomical features that enhance this ability. Behind the incisors is a gap in the jaws where no teeth grow, called a diastema. The diastema of the upper jaw is longer than that of the lower jaw, which allows rodents to engage their gnawing incisors while their chewing teeth (molars and premolars) are not being used. The reverse is also true; rodents can use their chewing teeth (also called cheek teeth) while their incisors are disengaged.

The entire skull structure of rodents is designed to accommodate this task of separating the use of the different types of teeth. Rodent skulls have long snouts; the articulation of the lower jaw with the skull is oriented front to back rather than sideways as in other mammals; the jaw muscles (masseter complex) are extended well forward into the snout; and the number of cheek teeth is less than in most other mammals—all features unique to rodents.

The classification of rodents has always been difficult because of the great diversity of both Recent and fossil species. Traditionally, there are two ways that rodents have been divided: into three major groups based on the structure of the attachment of the jaw muscle on the skull (Sciuromorpha, Hystricomorpha, Myomorpha); or into two groups based on the structure of the lower jaw (Sciurognathi, Hystricognathi). The difficulty in using these groups (usually considered suborders or infraorders) is that the distinctive adaptations of one group of rodents are also present in others, derived in completely separate ways. [W.W.K.]

Rodenticide A toxic chemical that is used to kill pest rodents and sometimes other pest mammals, including moles, rabbits, and hares. Most rodenticides are used to control rats and house mice.

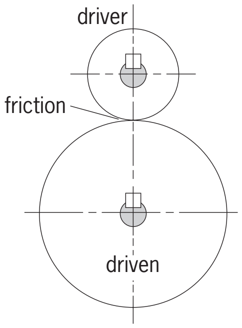
Rodenticides are generally combined with some rodent-preferred food item such as grain (corn, wheat, oats) or a combination of grains in low yet effective amounts. Bait formulations may be in pellet forms or incorporated in paraffin blocks of varying sizes. As a safeguard against accidental ingestion by nontarget species, baits are placed either where they are inaccessible to children, domestic animals, or wildlife, or within tamper-resistant bait boxes designed to exclude all but rodent-size animals.

As a group, anticoagulant rodenticides dominate the market and are sold under a wide variety of trade names. In order of their development, they are warfarin, pindone (Pival), diphacinone, and chlorophacinone. When small amounts of these anticoagulants are consumed over several days, death results from internal bleeding. The newer, second-generation anticoagulant rodenticides, such as brodifacoum, bromadiolone, and difethialone, were developed to counteract the growing genetic resistance in rats and house mice to the earlier anticoagulants, especially warfarin. The second-generation compounds are more potent and capable of being lethal following a single night's feeding, although death is generally delayed by several days. Rodenticides that do not belong to the anticoagulant group include zinc phosphide, bromethalin, and cholecalciferol (vitamin D_3). The feeding and lethal characteristics differ among them. Acutely toxic strychnine baits are also available but are restricted to underground application, primarily for pocket gophers and moles. Several lethal fumigants or materials that produce poisonous gases are used to kill rodents in burrows and within other confined areas such as unoccupied railway cars or buildings. Lethal fumigants include aluminum phosphide, carbon dioxide, chloropicrin, and smoke or gas cartridges, which are ignited to produce carbon monoxide and other asphyxiating gases.

Because of their high toxicity, rodenticides are inherently hazardous to people, domestic animals, and wildlife. They are highly regulated, as are certain other types of pesticides. Some rodenticides can be purchased and used only by trained certified or licensed pest control operators, while others with a greater safety margin can be used by the general public. All rodenticides must be used in accordance with the label directions and may be prohibited where they may jeopardize certain endangered species. *See* PESTICIDE; RODENTIA. [R.E.Ma.]

Roll mill A series of rolls operating at different speeds and used to grind paint or to mill flour. In paint grinding, a paste is fed between two low-speed rolls running toward each other at different speeds. Because the next roll in the mill is turning faster, it develops shear in the paste and draws the paste through the mill. The film is scraped from the last high-speed roll. For grinding flour, rolls are operated in pairs, rolls in each pair running toward each other at different speeds. Grooved rolls crush the grain; smooth rolls mill the flour to the desired fineness. *See* GRINDING MILL. [R.M.H.]

Rolling contact Contact between bodies such that the relative velocity of the two contacting surfaces at the point of contact is zero. Common applications of rolling contact are the friction gearing of phonograph turntables, speed changers, and wheels on roadways. Rolling contact mechanisms are, generally speaking, a special variety of cam mechanisms. The concepts of rolling contact are used in the study of antifriction bearings and



Rolling friction disks.

in the study of the behavior of toothed gearing. *See* ANTIFRICTION BEARING; CAM MECHANISM; GEAR.

Pure rolling contact can exist between two cylinders rotating about their centers, with either external or internal contact. Two friction disks (see illustration) have external rolling contact if no slipping occurs between them. The rotational speeds of the disks are then inversely proportional to their radii. [J.R.Z.]

Romanechite A barium-containing manganese oxide mineral with an ideal composition of $(Ba,H_2O)_2(Mn^{4+},Mn^{3+})_5O_{10}$. Romanechite is a basic member of a group of manganese oxide minerals that are similar in physical appearance and have closely related structures. It is an ore of manganese and occurs in a variety of widespread localities. Its name is derived from its occurrence in Romaneche, Soane-et-Loire, France. *See* MANGANESE; MANGANESE OXIDE MINERALS.

Romanechite is black to steel gray in color, opaque, and fine-grained. It occurs mainly as hard crusts that are botryoidal or reniform, but also as unusual samples that are soft and powdery. Many botryoidal samples have a fine-scale banding or layering parallel to their surfaces. Crystals are rare. The reported specific gravity of romanechite ranges from approximately 4.4 to 4.8, and the Mohs hardness ranges from 5 to 6 (less for powdery varieties). Romanechite is commonly intimately intergrown with other manganese oxide minerals, and is difficult to identify without the use of analytical techniques such as x-ray diffraction or electron microscopy. *See* HARDNESS SCALES. [S.T.]

Roof construction An assemblage to provide cover for homes, buildings, and commercial, industrial, and recreational areas. Roofs are constructed in different forms and shapes with various materials. A properly designed and constructed roof protects the structure beneath it from exterior weather conditions, provides structural support for superimposed loads, provides diaphragm strength to maintain the shape of the structure below, suppresses fire spread, and meets desired esthetic criteria.

Modern roof construction usually consists of an outer roofing assembly that is attached atop a deck or sheathing surface, which in turn is supported by a primary framework such as a series of beams, trusses, or arches. The shape of the roof and type of roof construction are usually determined by, and consistent with, the materials and deck of the primary structure underneath. *See* ARCH; BEAM; TRUSS.

Roof shapes include flat; hipped, where two sloping deck surfaces intersect in a line, the ridge or hip; pyramidal, which involves three of more sloping planes; domed, or other three-dimensional-surface, such as spherical, parabolic, or hyperbolic, shells; and tentlike, which are suspended fabric or membrane surfaces.

A roof assembly is a series of layers of different materials placed on and attached to the roof deck. Each type of roof assembly—related to protection against water entry from rain, snow, or ice; and insulation for temperature change, fire propagation, wind uplift, and moisture migration—has its own design requirements and methods of construction and attachment.

A roof is built upward from the structure below. The framework, or primary structural components, rest on the walls and columns of the structure, and these support the roof deck or the sheathing, which in turn carries the roofing assembly. The walls and columns may have girders framing into them. Beams rest on or are connected to girders. The roof deck or sheathing, the components that provide the basic support for the roofing assembly, span between and are anchored to the primary structural framing.

Long-span roofs are use space trusses, usually, of steel; but reinforced-concrete domes or other shell shapes, including folded plates, may be employed. In cable-supported roofs, the primary framework is composed of cables in tension that are slung between separate posts or from the top of the surrounding building perimeter. Tentlike or membrane roofs are a special application of a cable-supported roof. Air-supported roofs utilize a waterproof coated fabric that is inflated to its rigid shape by developing and maintaining a positive air pressure inside the structure, which keeps the roof surface under tension. Tennis-court "bubbles" utilize this design. *See* BUILDINGS; REINFORCED CONCRETE; STRUCTURAL STEEL. [M.A.]

Root (botany) The absorbing and anchoring organ of vascular plants. Roots are simple axial organs that produce lateral roots, and sometimes buds, but bear neither leaves nor flowers. Elongation occurs in the root tip. The older portion of the root, behind the root tip, may thicken through cambial activity. Some roots, grass for example, scarcely thicken, but tree roots can become 4 in. (10 cm) or more in diameter near the stem. Roots may be very long. The longest maple (*Acer*) roots are usually as long as the tree is tall, but the majority of roots are only a few inches long. The longest roots may live for many years, while small roots may live for only a few weeks or months.

Root tips and the root hairs on their surface take up water and minerals from the soil. They also synthesize amino acids and growth regulators (gibberellins and cytokinins). These materials move up through the woody, basal portion of the root to the stem. The thickened, basal portion of the root anchors the plant in the soil. Thickened roots, such as carrots, can store food that is later used in stem growth. *See* CYTOKININ; GIBBERELLIN.

Roots usually grow in soil where: it is not too dense to stop root tip elongation; there is enough water and oxygen for root growth; and temperatures are high enough (above 39°F or 4°C) to permit root growth, but not so high that the roots are killed (above 104°F or 40°C). In temperate zones most roots are in the uppermost 4 in. (10 cm) of the soil; root numbers decrease so rapidly with increasing depth that few roots are found more than 6 ft (2 m) below the surface. Roots grow deeper in areas where the soil is hot and dry; roots from desert shrubs have been found in mines more than 230 ft (70 m) below the surface. In swamps with high water tables the lack of oxygen restricts roots to the uppermost soil layers. Roots may also grow in the air. Poison ivy vines form many small aerial roots that anchor them to bark or other surfaces.

The primary root originates in the seed as part of the embryo, normally being the first organ to grow. It grows downward into the soil and produces lateral second-order roots that emerge at right angles behind the root tip. Sometimes it persists and thickens to form a taproot. The second-order laterals produce third-order laterals and so on until there are millions of roots in a mature tree root system. In contrast to the primary root, most lateral roots grow horizontally or even upward. In many plants a few horizontal lateral roots thicken more than the primary, so no taproot is present in the mature root system.

Adventitious roots originate from stems or leaves rather than the embryo or other roots. They may form at the base of cut stems, as seen in the horticultural practice of rooting cuttings. [B.F.W.]

Root (mathematics) If a function $f(x)$ has the value 0 for $x = a$, a is a root of the equation $f(x) = 0$. The fundamental theorem of algebra states that any algebraic equation of the form $a_0x^n + a_1x^{n-1} + \cdots a_{n-1}x + a_n = 0$, where the a_k's are real numbers, has at least one root. From this it follows readily that such an equation has roots, real or complex, in number equal to the index (here n) of the highest power of x.

Furthermore, if $a + ib$ (where $i = \sqrt{-1}$) is a complex root of the given equation, so is $a - ib$, the conjugate of $a + ib$. Equations of degrees up to four may be solved algebraically. This statement means that the roots may be expressed as functions of the coefficients, the functions involving the elementary arithmetical processes of addition, multiplication, raising a number to a power, or extracting the root of a certain order of a given number. It was proved by H. Abel and by E. Galois that it is not possible to solve algebraically the *general* algebraic equation of degree higher than four. However, it is possible to determine the real roots of an algebraic equation to any desired degree of approximation. *See* CALCULUS; EQUATIONS, THEORY OF; NUMERICAL ANALYSIS. [A.N.L./S.Bo.]

Root-mean-square The square root of the arithmetic mean of the squares of a set of numbers is called their root-mean-square. If the numbers are $x_1, x_2, x_3, \ldots, x_n$, the root-mean-square is equal to

$$\sqrt{\frac{x_1{}^2 + x_2{}^2 + x_3{}^2 \cdots + x_n{}^2}{n}}$$

It is valuable as an average of the magnitudes of quantities, and it is not affected by the signs of the quantities.

Among applications of root-mean-square the most important is the standard deviation from the arithmetic mean. If the arithmetic mean $\overline{x}$ is equal to

$$\frac{x_1 + x_2 + x_3 \cdots + x_n}{n}$$

then the standard deviation s is equal to

$$\sqrt{\frac{(x_1 - \overline{x})^2 + (x_2 - \overline{x})^2 + (x_3 - \overline{x})^2 + \cdots (x_n - \overline{x})^2}{n}}$$

Thus standard deviation from the mean is the root-mean-square of the deviations from the mean. *See* STATISTICS. [H.R.C.]

Rope A long flexible structure consisting of many strands of wire, plastic, or vegetable fiber such as manila. Rope is classified as a flexible connector and is used generally for hoisting, conveying, or transporting loads; transmitting motion; and occasionally transmitting power. For flexibility and to reduce stresses as the rope bends over the sheave (pulley), a rope is made of many small strands. *See* PULLEY. [P.H.B.]

Rosales An order of flowering plants in the eurosid I group of the rosid eudicots. Recently on the basis of DNA sequence studies the number of families was greatly reduced and changed. The order as now recognized contains only 11 families, many of which are small. Many families in this order are wind-pollinated (the former Urticales) and exhibit the typical syndrome of small petalless flowers with dangling anthers, whereas the other families are insect-pollinated with large, showy flowers in which the carpels are sometimes free. *See* FLOWER; MAGNOLIOPHYTA; MAGNOLIOPSIDA; POLLINATION.

The largest family is Rosaceae with nearly 3000 species. The great number of economically important trees, shrubs, and herbs in this family include apples (*Malus*), pears (*Pyrus*), almonds, cherries, plums, and prunes (*Prunus*), strawberries (*Fragaria*), blackberries, raspberries, and their relatives (*Rubus*), as well as many minor fruits. Many are grown as ornamental plants, including roses (*Rosa*), avens (*Geum*), cinquefoil (*Potentilla*), firethorn (*Pyracantha*), redbush (*Photinia*), and spirea (*Spiraea*). *See* ALMOND; APPLE; BLACKBERRY; CHERRY; PEAR; PLUM; RASPBERRY; STRAWBERRY.

The second-largest family, Rhamnaceae (900 species), includes mostly woody species (shrubs and trees) that differ from Rosaceae in having fused carpels and only five stamens (rather than many) that are placed in the same position as the petals. A number of species in Rhamnaceae are of minor economic importance as timbers, some are of medicinal use or as dyes, and one is a minor fruit crop, the jujube (*Zizyphus*). A few are ornamentals, such as *Ceanothus* and *Colletia*.

Of the families formerly placed in Urticales, the largest are Moraceae (950 species) and Urticaceae (700 species). Many of these are large forest trees, but some are forest herbs and weeds. In Moraceae, many species are sources of timber and fruit, including figs (*Ficus*), mulberries (*Morus*), and breadfruits (*Artocarpus*). In Urticaceae, fiber-producing species are common, including hemp (*Cannabis*), ramie or China grass (*Boehmeria*), and bast-fiber (*Urtica*). Ulmaceae and Celtidaceae are small families of north temperate forest trees, many of which provide useful timbers, including elm (*Ulmus*), hackberries (*Celtis*), and *Zelkova*. *See* ELM; FIBER CROPS; FIG; HACKBERRY; HEMP; MULBERRY; RAMIE. [M.W.C.]

Rose curve A type of plane curve that consists of loops (leaves, petals) emanating from a common point and that has a roselike appearance. Taking the common point O as the pole of a polar coordinate system (see illustration), these curves have equations of the form $\rho = a \cdot \sin n\theta$, where $a > 0$ and n is a positive integer (also $\rho = a \cdot \cos n\theta$, with a different choice of the initial line of the coordinate system). The curve is a circle of diameter a for $n = 1$. It has n or $2n$ leaves, according as n is an odd or even integer, respectively. The lemniscate is sometimes called a two-leaved rose, though its equation $\rho^2 = a^2 \cos 2\theta$ is not of the form given above. *See* LEMNISCATE OF BERNOULLI. [L.M.Bl.]

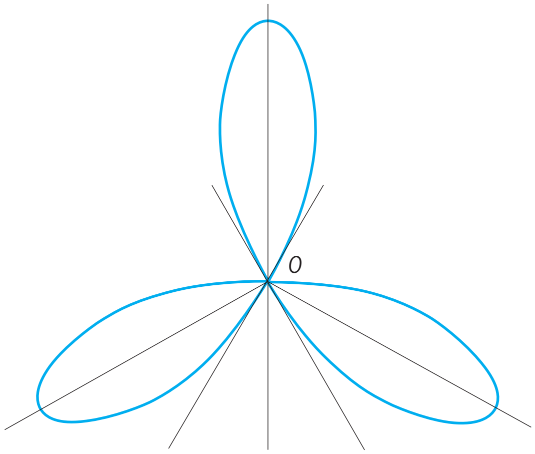


Diagram of rose curve.

Rosemary *Rosmarinus officinalis*, a member of the mint family, grown for its highly aromatic leaves and as an ornamental. Rosemary is an evergreen and perennial which can live as long as 20 years under favorable conditions. Although many varieties exist, *R. officinalis* is the only species. Most varieties are suitable for culinary use, although some (such as Pine Scented) contain high levels of terpenes and have a turpentine-like scent. *See* LAMIALES.

Rosemary is native to the Mediterranean area, and much of the world production is harvested from wild plants growing there. Though it is widely cultivated mainly in France, Spain, and

California, it will grow in most temperate areas not subject to hard frosts.

Rosemary oil has been found to contain chemicals such as rosmanol which inhibit oxidation and bacterial growth. Rosemary is used in poultry seasoning and for flavoring soups and vegetables. *See* SPICE AND FLAVORING. [S.Kir.]

Rosidae A former widely recognized subclass of Magnoliophyta (angiosperms or flowering plants). Deoxyribonucleic acid (DNA) and morphological studies have demonstrated that this group includes many more families than previously thought. Approximately 136 families (roughly 30% of the total angiosperms) in 11 orders are included in the rosids. With the asterids (often recognized as Asteridae), the rosids represent the two most advanced lines of dicots.

The primary distinguishing features of rosids are their diplostemenous flowers (anthers in two whorls, each whorl typically numbering the same as the perianth parts, although in some groups the number of stamens has increased) with unfused parts, except for the carpels (asterids have haplostemenous flowers with fused parts, typically with the stamens fused at least to the bases of the petals). Rosids have ovules with two integuments (that is, they are bitegmic, as opposed to the unitegmic asterids) and a several-layered nucellus (that is, they are crassinucellate, as opposed to the tenuinucellate asterids, which have a single-layered nucellus). There is nuclear endosperm formation (cellular in asterids), a reticulate pollen layer, mucilaginous leaf epidermis, and generally simple perforation vessel end-walls in the wood. The largest rosid orders are Malpighiales (16,100 species), Fabales (17,500), and Myrtales (10,600). *See* APIALES; CELASTRALES; CORNALES; EUPHORBIALES; FABALES; GERANIALES; HALORAGALES; LINALES; MAGNOLIOPSIDA; MYRTALES; PODOSTEMALES; POLYGALALES; PROTEALES; RAFFLESIALES; RHIZOPHORALES; ROSALES; SANTALALES; SAPINDALES. [M.W.C.]

Rosin A brittle resin ranging in color from dark brown to pale lemon yellow and derived from the oleoresin of pine trees. Rosin is insoluble in water, but soluble in most organic solvents. It softens at about 180–190°F (80–90°C). Rosin consists of about 90% resin acids and about 10% neutral materials such as anhydrides, sterols, and diterpene aldehydes and alcohols.

Rosin is obtained by wounding living trees and collecting the exudate (gum rosin), by extraction of pine stumps (wood rosin), and as a by-product from the kraft pulping process (sulfate or tall oil rosin).

The largest single use of rosin is in sizing paper to control water absorption, an application in which fortified rosin is important. Rosin soaps are used as emulsifying and tackifying agents in synthetic rubber manufacture. Other rosin uses include adhesives, printing inks, and chewing gum. [I.S.G.]

Rotary engine Internal combustion engine that duplicates in some fashion the intermittent cycle of the piston engine, consisting of the intake-compression-power-exhaust cycle, wherein the form of the power output is directly rotational.

Four general categories of rotary engines can be considered: (1) cat-and-mouse (or scissor) engines, which are analogs of the reciprocating piston engine, except that the pistons travel in a circular path; (2) eccentric-rotor engines, wherein motion is imparted to a shaft by a principal rotating part, or rotor, that is eccentric to the shaft; (3) multiple-rotor engines, which are based on simple rotary motion of two or more rotors; and (4) revolving-block engines, which combine reciprocating piston and rotary motion. *See* AUTOMOBILE; COMBUSTION CHAMBER; DIESEL CYCLE; DIESEL ENGINE; GAS TURBINE; INTERNAL COMBUSTION ENGINE; OTTO CYCLE. [W.Ch.]

Rotational motion The motion of a rigid body which takes place in such a way that all of its particles move in circles about an axis with a common angular velocity; also, the rotation of a particle about a fixed point in space. Rotational motion is illustrated by (1) the fixed speed of rotation of the Earth about its axis; (2) the varying speed of rotation of the flywheel of a sewing machine; (3) the rotation of a satellite about a planet; (4) the motion of an ion in a cyclotron; and (5) the motion of a pendulum. Circular motion is a rotational motion in which each particle of the rotating body moves in a circular path about an axis. Such motion is exhibited by the first and second examples. For information concerning the other examples *see* HARMONIC MOTION; PARTICLE ACCELERATOR; PENDULUM.

The speed of rotation, or angular velocity, remains constant in uniform circular motion. In this case, the angular displacement θ experienced by the particle or rotating body in a time t is $\theta = \omega t$, where ω is the constant angular velocity.

A special case of circular motion occurs when the rotating body moves with constant angular acceleration. If a body is moving in a circle with an angular acceleration of α radians/s^2, and if at a certain instant it has an angular velocity ω_0, then at a time t seconds later, the angular velocity may be expressed as $\omega = \omega_0 + \alpha t$, and the angular displacement as $\theta = \omega_0 t + {}^1\!/_2 \alpha t^2$. *See* ACCELERATION; VELOCITY.

A rotating body possesses kinetic energy of rotation which may be expressed as $T_{\text{rot}} = {}^1\!/_2 I\omega^2$, where ω is the magnitude of the angular velocity of the rotating body and I is the moment of inertia, which is a measure of the opposition of the body to angular acceleration. The moment of inertia of a body depends on the mass of a body and the distribution of the mass relative to the axis of rotation. For example, the moment of inertia of a solid cylinder of mass M and radius R about its axis of symmetry is ${}^1\!/_2 MR^2$.

The action of a torque L is to produce an angular acceleration α according to the equation below, where $I\omega$, the product of

$$L = I\alpha = I\frac{d\omega}{dt} = \frac{d}{dt}(I\omega)$$

moment of inertia and angular velocity, is called the angular momentum of the rotating body. This equation points out that the angular momentum $I\omega$ of a rotating body, and hence its angular velocity ω, remains constant unless the rotating body is acted upon by a torque. Both L and $I\omega$ may be represented by vectors.

It is readily shown that the work done by the torque L acting through an angle θ on a rotating body originally at rest is exactly equal to the kinetic energy of rotation. *See* ANGULAR MOMENTUM; MOMENT OF INERTIA; RIGID-BODY DYNAMICS; TORQUE; WORK. [C.E.H./R.J.S.]

Rotifera A phylum of pseudocoelomate, microscopic, mainly free-living aquatic animals, characterized by an anterior ciliary apparatus, the corona, whose cilia when in motion have the appearance of a pair of rapidly rotating wheels. This structure is implicit in the phyletic name (literally "wheel bearers") and the older popular name wheel animalcules.

The Rotifera show considerable diversity in form and structure, but all are bilaterally symmetrical, pseudocoelomate animals possessing complete digestive, excretory, nervous, and reproductive systems, but lacking separate respiratory and circulatory systems. They possess two features unique to their phylum: the corona, which is a retractile trochal disk, and the mastax, which is a gizzardlike structure derived from the modified pharynx.

Rotifers are dioecious and sexually dimorphic; females are commoner than males, some of which are degenerate organisms lacking a mouth and digestive organs. Males, when produced in the life cycle, are short-lived and survive for only hours or at the most a few days.

The three major subdivisions of the Rotifera, now given class status, are the Seisonacea, Bdelloidea, and Monogononta. *See* BDELLOIDEA; MONOGONONTA; SEISONACEA. [J.B.J.]

Rous sarcoma The first filterable agent (virus) known to cause a solid tumor in chickens. It was discovered in 1911 by P. F. Rous, who won the Nobel prize in 1967 for his discovery. It is a ribonucleic acid virus and belongs to the avian leukosis group. Certain strains of the virus cause tumors in hamsters, rabbits, monkeys, and other species. The Rous virus is known as a "defective" virus in that it is incapable of producing tumors by itself but requires another closely related virus of the avian leukosis group to act as a "helper" for the production of the foci. *See* ANIMAL VIRUS; TUMOR VIRUSES; VIRUS, DEFECTIVE. [A.E.Mo.]

Rubber Originally, a natural or tree rubber, which is a hydrocarbon polymer of isoprene units. With the development of synthetic rubbers having some rubbery characteristics but differing in chemical structure as well as properties, a more general designation was needed to cover both natural and synthetic rubbers. The term elastomer, a contraction of the words elastic and polymer, was introduced, and defined as a substance that can be stretched at room temperature to at least twice its original length and, after having been stretched and the stress removed, returns with force to approximately its original length in a short time.

Three requirements must be met for rubbery properties to be present in both natural and synthetic rubbers: long thread like molecules, flexibility in the molecular chain to allow flexing and coiling, and some mechanical or chemical bonds between molecules.

Natural rubber and most synthetic rubbers are also commercially available in the form of latex, a colloidal suspension of polymers in an aqueous medium. Natural rubber comes from trees in this form; many synthetic rubbers are polymerized in this form; some other solid polymers can be dispersed in water. *See* POLYMER.

Latexes are the basis for a technology and production methods completely different from the conventional methods used with solid rubbers.

In the crude state, natural and synthetic rubbers possess certain physical properties which must be modified to obtain useful end products. The raw or unmodified forms are weak and adhesive. They lose their elasticity with use, change markedly in physical properties with temperature, and are degraded by air and sunlight. Consequently, it is necessary to transform the crude rubbers by compounding and vulcanization procedures into products which can better fulfill a specific function.

Although natural rubber may be obtained from hundreds of different plant species, the most important source is the rubber tree (*Hevea brasiliensis*). Natural rubber is *cis*-1,4-polyisoprene, containing approximately 5000 isoprene units in the average polymer chain. *See* RUBBER TREE.

Styrene-butadiene rubber (SBR) is the most important synthetic rubber and the most widely used rubber in the entire world. Formerly designated GR-S, SBRs are obtained by the emulsion polymerization of butadiene and styrene in varying ratios. However, in the most commonly used type, the ratio of butadiene to styrene is approximately 78:22. Unlike natural rubber, SBR does not crystallize on stretching and thus has low tensile strength unless reinforced. The major use for SBR is in tires and tire products. Other uses include belting, hose, wire and cable coatings, flooring, shoe products, sponge, insulation, and molded goods.

Butyl rubber is essentially a polyisobutylene except for the presence of diolefin, usually isoprene, to provide the unsaturation necessary for vulcanization. Butyl rubbers have excellent resistance to oxygen, ozone, and weathering. In addition, these rubbers exhibit good electrical properties and high impermeability to gases. The high impermeability to gases results in use of butyl as an inner liner in tubeless tires. Other widespread uses are for wire and cable products, injection-molded and extruded products, hose, gaskets, and sealants, and where good damping characteristics are needed.

Ethylene-propylene polymers are produced by the copolymerization of ethylene and propylene. These copolymers exhibit outstanding resistance to heat, oxygen, ozone, and other aging and degrading agents. Abrasion resistance in tire treads is excellent. The mechanical properties of their vulcanizates are generally approximately equivalent to those of SBR.

One of the first synthetic rubbers used commercially in the rubber industry is neoprene, a polymer of chloroprene, 2-chlorobutadiene-1,3. The neoprenes have exceptional resistance to weather, sun, ozone, and abrasion. They are good in resilience, gas impermeability, and resistance to heat, oil, and flame. They are fairly good in low temperature and electrical properties. This versatility makes them useful in many applications requiring oil, weather, abrasion, or electrical resistance or combinations of these properties, such as wire and cable, hose, belts, molded and extruded goods, soles and heels, and adhesives.

Nitrile-type rubbers are copolymers of acrylonitrile and a diene, usually butadiene. The nitrile rubbers can be blended with natural rubber, polysulfide rubbers, and various resins to provide characteristics such as increased tensile strength, better solvent resistance, and improved weathering resistance.

Fluoroelastomers are basically copolymers of vinylidene fluoride and hexafluoropropylene. Because of their fluorine content, they are the most chemically resistant of the elastomers and also have good properties under extremes of temperature conditions. They are useful in the aircraft, automotive, and industrial areas.

Polyurethane elastomers are of interest because of their versatility and variety of properties and uses. They can be used as liquids or solids in a number of manufacturing methods. The largest use has been for making foam for upholstery and bedding. *See* POLYURETHANE RESINS.

Polysulfide rubbers have a large amount of surlfur in the main polymer chain and are therefore very chemically resistant, particularly to oils and solvents. They are used in such applications as putties, caulks, and hose for paint spray, gasoline, and fuel. Polyacrylate rubbers are useful because of their resistance to oils at high temperatures, including sulfur-bearing extreme-pressure lubricants. *See* POLYSULFIDE RESINS.

Proper choice of catalyst and order of procedure in polymerization have led to development of thermoplastic elastomers. The leading commercial types are styrene block copolymers having a structure which consists of polystyrene segments or blocks connected by rubbery polymers such as polybutadiene, polyisoprene, or ethylene-butylene polymer. Thermoplastic elastomers are very useful in providing a fast and economical method of producing a variety of products. One of the disadvantages for many applications is the low softening point of the thermoplastic elastomers. [E.G.P.]

Rubber tree *Hevea brasiliensis*, a member of the spurge family (Euphorbiaceae) and a native of the Amazon valley. It is the natural source of commercial rubber.

It has been introduced into all the tropical countries supporting the rainforest type of vegetation, and is grown extensively in established plantations, especially in Malaysia. The latex from the trees is collected and coagulated. The coagulated latex is treated in different ways to produce the kind of rubber desired. Rubber is made from the latex of a number of other plants, but *Hevea* is the rubber plant of major importance. *See* EUPHORBIALES; RUBBER. [P.D.St./E.L.C.]

Rubella A benign, infectious virus disease of humans characterized by coldlike symptoms and transient, generalized rash. This disease, also known as German measles, is primarily a disease of childhood. However, maternal infection during early pregnancy may result in infection of the fetus, giving rise to serious abnormalities and malformations. The congenital infection persists in the infant, who harbors and sheds virus for many months after birth.

In rubella infection acquired by ordinary person-to-person contact, the virus is believed to enter the body through respiratory pathways. Antibodies against the virus develop as the rash fades, increase rapidly over a 2–3-week period, and then fall during the following months to levels that are maintained for life. One attack confers life-long immunity, since only one antigenic type of the virus exists. Immune mothers transfer antibodies to their offspring, who are then protected for approximately 4–6 months after birth. *See* IMMUNITY.

Live attenuated rubella vaccines have been available since 1969. The vaccine induces high antibody titers and an enduring and solid immunity. It may also induce secretory immunoglobulin (IgA) antibody in the respiratory tract and thus interfere with establishment of infection by wild virus. This vaccine is available as a single antigen or combined with measles and mumps vaccines (MMR vaccine). The vaccine induces immunity in at least 95% of recipients, and that immunity endures for at least 10 years. *See* BIOLOGICALS; VACCINATION. [J.L.Me.]

Rubellite The red to red-violet variety of the gem mineral tourmaline. Perhaps the most sought-for of the many colors in which tourmaline occurs, it was named for its resemblance to ruby. The color is thought to be caused by the presence of lithium. It has a hardness of 7–7.5 on Mohs scale, a specific gravity near 3.04, and refractive indices of 1.624 and 1.644. Fine gem-quality material is found in Brazil, Madagascar, Maine, southern California, the Ural Mountains, and elsewhere. *See* GEM; TOURMALINE. [R.T.L.]

Rubiales An order of flowering plants, division Magnoliophyta (Angiospermae), in the subclass Asteridae of the class Magnoliopsida (dicotyledons). The order consists of the large family Rubiaceae, with about 6500 species and the family Theligoniaceae with only 3 species. The Rubiales are marked by their inferior ovary; regular or nearly regular corolla with the petals grown together by their margins; stamens (equal in number to the petals) which are attached to the corolla tube alternate with the lobes; and opposite leaves with interpetiolar stipules or whorled leaves without stipules. The most familiar species of temperate regions are herbs with whorled leaves, such as madder (*Rubia tinctorium*, the traditional source of red dye), but opposite-leaved tropical shrubs such as *Coffea* (the source of coffee) are more typical of the group. *See* COFFEE; IPECAC; MAGNOLIOPHYTA; MAGNOLIOPSIDA. [A.Cr.; T.M.Ba.]

Rubidium A chemical element, Rb, atomic number 37, and atomic weight 85.47. Rubidium is an alkali metal. It is a light, low-melting, reactive metal. *See* PERIODIC TABLE.

Most uses of rubidium metal and rubidium compounds are the same as those of cesium and its compounds. The metal is used in the manufacture of electron tubes, and the salts in glass and ceramic production.

Rubidium is a fairly abundant element in the Earth's crust, being present to the extent of 310 parts per million (ppm). This places it just below carbon and chlorine and just above fluorine and strontium in abundance. Sea water contains 0.2 ppm of rubidium, which (although low) is twice the concentration of lithium. Rubidium is like lithium and cesium in that it is tied up in complex minerals; it is not available in nature as simple halide salts as are sodium and potassium.

Rubidium has a density of 1.53 g/cm^3 (95.5 lb/ft^3, a melting point of 39°C (102°F), and a boiling point of 688°C (1270°F).

Rubidium is so reactive with oxygen that it will ignite spontaneously in pure oxygen. The metal tarnishes very rapidly in air to form an oxide coating, and it may ignite. The oxides formed are a mixture of Rb_2O, Rb_2O_2, and RbO_2. The molten metal is spontaneously flammable in air.

Rubidium reacts violently with water or ice at temperatures down to −100°C (−148°F). It reacts with hydrogen to form a hydride which is one of the least stable of the alkali hydrides. Rubidium does not react with nitrogen. With bromine or chlorine, rubidium reacts vigorously with flame formation. Organorubidium compounds can be prepared by techniques similar to those used for sodium and potassium. *See* ALKALI METALS; CESIUM. [M.Si.]

Ruby The red variety of the mineral corundum, in its finest quality the most valuable of gemstones. Only medium to dark tones of red to slightly violet-red or very slightly orange-red are called ruby; light reds, purples, and other colors are properly called sapphires. In its pure form the mineral corundum, with composition Al_2O_3, is colorless. The rich red of fine-quality ruby is the result of the presence of a minute amount of chromic oxide. The chromium presence permits rubies to be used for lasers producing red light. *See* CORUNDUM; LASER; SAPPHIRE.

The finest ruby is the transparent type with a medium tone and a high intensity of slightly violet-red, which has been likened to the color of pigeon's blood. Star rubies do not command comparable prices, but they, too, are in great demand. The ruby was among the first of the gemstones to be duplicated synthetically and the first to be used extensively in jewelry. *See* GEM. [R.T.L.]

Rugosa An order of extinct corals which flourished during the Paleozoic Era. The Rugosa, or Tetracorallia, first appeared in the Ordovician and became extinct in the Permian. Nothing is known of the soft parts. Both simple and compound skeletons are common, the simple ones having typically a curved, horn-shaped appearance, and the compound ones forming groups of cylindrical stems or polygonal columns. The simple form is called a corallite, the compound one a corallum. *See* COELENTERATA. [E.C.Stu.]

Runge vector The Runge vector describes certain unchanging features of a nonrelativistic two-body interaction for which the potential energy is inversely proportional to the distance r between the bodies or, alternatively, in which each body exerts a force on the other that is directed along the line between them and proportional to r^{-2}. Two basic interactions in nature are of this type: the gravitational interaction between two masses (called the classical Kepler problem), and the Coulomb interaction between like or unlike charges (as in the hydrogen atom). Both at the classical level and the quantum-mechanical level, the existence of a Runge vector is a reflection of the symmetry inherent in the interaction. *See* COULOMB'S LAW; QUANTUM MECHANICS; SYMMETRY LAWS (PHYSICS). [D.M.Fr.]

Running fit The intentional difference in dimensions of mating mechanical parts that permits them to move relative to each other. A free running fit has liberal allowance; it is used on high-speed rotating journals or shafts. A medium fit has less allowance; it is used on low-speed rotating shafts and for sliding parts. Running fits are affected markedly by their surface finish and the effectiveness of lubrication. *See* ALLOWANCE. [P.H.B.]

Rust (microbiology) Plant diseases caused by fungi of the order Uredinales and characterized by the powdery and usually reddish spores produced. There are more than 4000 species of rust fungi. All are obligate parasites (require a living host) in nature, and each species attacks only plants of particular genera or species. Morphologically identical species that attack different host genera are further classified as special forms (*formae speciales*); for example, *Puccinia graminis* f. sp. *tritici* attacks wheat and *P. graminis* f. sp. *hordei* attacks barley. Each species or special form can have many physiological races that differ in their ability to attack different cultivars (varieties) of a host species. Rusts are among the most destructive plant diseases. Economically important examples include wheat stem rust, white pine blister rust, and coffee rust. *See* UREDINALES.

Rust fungi have complex life cycles, producing up to five different fruiting structures with distinct spore types that appear in a definite sequence. Macrocyclic (long-cycled) rust fungi produce all five spore types, whereas microcyclic (short-cycled) rust fungi produce only teliospores and basidiospores. Some macrocyclic rust fungi complete their life cycle on a single host and are called autoecious, whereas others require two different or alternate hosts and are called heteroecious. *See* Fungi; Plant pathology. [E.A.M.]

Rutabaga The plant *Brassica napobrassica*, a cool-season, hardy biennial crucifer of European origin, belonging to the order Capparales and probably resulting from the natural crossing of cabbage and turnip. The fleshy roots are cooked and usually eaten mashed as a vegetable. Rutabagas have been widely grown as a livestock feed in northern Europe and eastern Canada. Commercial production is limited to Canada and the northern part of the United States. *See* Capparales; Turnip. [H.J.C.]

Ruthenium A chemical element, Ru, atomic number 44. The element is a brittle gray-white metal of low natural abundance, usually found alloyed with other platinum metals in nature. Ruthenium occurs as seven stable isotopes, and more than ten radioactive (unstable) isotopes are known. Four allotropes of the metal are known. Ruthenium is a hard white metal, workable only at elevated temperatures. It can be melted with an electric arc or an electron beam. *See* Isotope; Metal; Periodic table; Radioisotope; Transition elements.

The metal is not oxidized by air at room temperature, but it does oxidize to give a surface layer of ruthenium dioxide (RuO_2) at about 900°C (1650°F); at about 1000°C (1830°F) the volatile compounds ruthenium tetraoxide (RuO_4) and ruthenium monoxide (RuO) form, which can result in loss of the metal. Metallic ruthenium is insoluble in common acids and aqua regia up to 100°C (212°F). The principal properties of ruthenium ore given in the table. *See* Aqua regia.

Ruthenium is relatively rare, having a natural abundance in the Earth's crust of about 0.0004 part per million. It is always found in the presence of other platinum metals. The major commercial sources of the element are the native alloys osmiridium and iridiosmium and the sulfide ore laurite. The element is also separated from other platinum metals by an intricate process, involving treatment with aqua regia (in which ruthenium, osmium, rhodium, and iridium are insoluble), to yield the pure metal.

Ruthenium is used commercially to harden alloys of palladium and platinum. The alloys are used in electrical contacts, jewelry, and fountain-pen tips. Application of ruthenium to industrial catalysis (hydrogenation of alkenes and ketones) and to automobile emission control (catalytic reduction of nitric oxide) and detection have been active areas of research. In medicine, ruthenium complexes have attracted some attention as potential antitumor reagents and imaging reagents. Ruthenium tetraoxide is finding increasing use as an oxidant for organic compounds. *See* Catalysis; Catalytic converter; Hydrogenation; Osmium; Palladium; Platinum; Technetium. [C.Cr.]

Principal properties of ruthenium

Property	Value
Atomic number	44
Atomic weight	101.07
Crystal structure	Hexagonal close-packed
Lattice constant *a* at 25°C (77°F),	0.27056
nm *c/a* at 25°C (77°F)	1.5820
Density at 25°C (77°F), g/cm^3	12.37
Thermal neutron capture cross section, barns (10^{-28} m^2)	2.50
Melting point	2310°C (4190°F)
Boiling point	4080°C (7380°F)
Specific heat at 0°C, cal/g (J/kg)	0.0551 (231)
Thermal conductivity, 0–100°C, cal cm/cm^2 °C	0.25
Linear coefficient of thermal expansion, 20–100°C, μin./(in.)(°C) or μm/(m)(°C)	9.1
Electrical resistivity at 0°C, microhm-cm	6.80
Temperature coefficient of electrical resistance, 0–100°C/°C	0.0042
Tensile strength (annealed), $kN \cdot m^{-2}$	4.96×10^5
Young's modulus at 20°C (68°F), lb/in.^{2} (Pa)	
Static	60×10^6 (4.1×10^{11})
Dynamic	69×10^6 (4.75×10^{11})
Vickers hardness number (diamond pyramid hardness)	200–350

Rutherfordium A chemical element, symbol Rf, atomic number 104. Rutherfordium is the first element beyond the actinide series. In 1964 G. N. Flerov and coworkers at the Dubna Laboratories in Russia claimed the first identification of rutherfordium. A. Ghiorso and coworkers made a definitive identification at the Lawrence Radiation Laboratory, Berkeley, University of California, in 1969. *See* Periodic table.

The Dubna group claimed the preparation of rutherfordium, mass number 260, by irradiating plutonium-242 with neon-22 ions in the heavy-ion cyclotron. The postulated nuclear reaction was $^{242}\text{Pu} + {}^{22}\text{Ne} \rightarrow {}^{260}\text{Rf} + 4$ neutrons. By 1969 the Berkeley group had succeeded in discovering two alpha-emitting isotopes of rutherfordium with mass numbers 257 and 259 by bombarding ^{249}Cf with ^{12}C and ^{13}C projectiles from the Berkeley heavy-ion linear accelerator (HILAC).

A number of years after the discovery at Berkeley, a team at Oak Ridge National Laboratory confirmed discovery of the isotope ^{257}Rf by detecting the characteristic nobelium x-rays following alpha decay. *See* Actinide elements; Nobelium; Transuranium elements. [A.Gh.]

Rutile The most frequent of the three polymorphs of titania, TiO_2; the two other polymorphs are brookite and anatase.

The mineral occurs as striated tetragonal prisms and needles, commonly repeatedly twinned. The color is deep blood red, reddish brown, to black, rarely violet or yellow. Specific gravity is 4.2, and hardness 6.5 on Mohs scale. Melting point is 1825°C (3317°F).

Rutile occurs as an accessory in many rock types, ranging from plutonic to metamorphic rocks, and even as detrital material in sediments and placers because of its resistance to weathering. Large crystals have been found in some granite pegmatites; in Brazil it often occurs as inclusions in clear quartz crystals (rutilated quartz). Rutile is commonly associated with apatite in high-temperature veins. In sufficient quantities, it is marketed as an ore of titanium. *See* Titanium. [P.B.M.]

Rydberg atom An atom which possesses one valence electron orbiting about an atomic nucleus within an electron shell well outside all the other electrons in the atom. Such an atom approximates the hydrogen atom in that a single electron is interacting with a positively charged core. Early observations of atomic electrons in such Rydberg quantum states involved studies of the Rydberg series in optical spectra. Electrons jumping between Rydberg states with adjacent principal quantum numbers, n and $n - 1$, with n near 80 produce microwave radiation. Microwave spectral lines due to such electronic transitions in Rydberg atoms have been observed both in laboratory experiments and in the emissions originating from certain low-density partially ionized portions of the universe called HII regions. *See* Electron configuration; Interstellar matter; Microwave.

The advent of the laser has made possible the production of sizable numbers of Rydberg atoms within a bulb containing gas at low pressures, 10^{-2} torr (1.3 pascals) or less. The rapid energy-resonance absorption of several laser light photons by an atom in its normal or ground state results in a Rydberg atom in a state with a selected principal quantum number. Aggregates of Rydberg atoms have been used as sensitive detectors of infrared radiation, including thermal radiation. They have also been observed to collectively participate in spontaneous photon emission, called superradiance. Such aggregates form the active medium for infrared lasers that operate through the usual laser mechanism of collective stimulated photon emission. All these developments are based upon the great sensitivity of Rydberg atoms to external electromagnetic radiation fields. Atoms with n near 40 can absorb almost instantaneously over a hundred microwave photons and become ionized at easily achievable microwave power levels. Isotope separation techniques have been developed that combine the selectivity of laser excitation of Rydberg states with the ready ionizability of Rydberg atoms. Such applications have been pursued for atoms ranging from deuterium through uranium. *See* INFRARED RADIATION; ISOTOPE SEPARATION; LASER. [J.E.B.]

Rydberg constant The most accurately measured of the fundamental constants; it is a universal scaling factor for any spectroscopic transition and an important cornerstone in the determination of other constants.

This constant was introduced empirically. J. Balmer's formula described the visible spectral lines of atomic hydrogen, while J. Rydberg's formula applied to the spectra of many elements. Their results may be summarized by Eq. (1), where λ is the wavelength

$$\frac{1}{\lambda} = R\left(\frac{1}{n_1^2} - \frac{1}{n_2^2}\right) \qquad (1)$$

of the spectral line and R is a constant. In Balmer's account of the visible hydrogen spectrum, n_1 was equal to 2, while n_2 took on the integer values 3, 4, 5, and so forth. In Rydberg's more general work, n_1 and n_2 differed slightly from integer values. A remarkable result of Rydberg's work was that the constant R was the same for all spectral series he studied, regardless of the element. This constant R has come to be known as the Rydberg constant.

Applied to hydrogen, Niels Bohr's atomic model leads to Balmer's formula with a predicted value for the Rydberg constant given by Eq. (2), where m_e is the electron mass, e is the

$$R_\infty = \frac{m_e e^4}{8h^3 \epsilon_0^2 c} \qquad (2)$$

electron charge, h is Planck's constant, ϵ_0 is the permittivity of vacuum, and c is the speed of light. The equation expresses the Rydberg constant in SI units. To express it in cgs units, the right-hand side must be multiplied by $(4\pi\epsilon_0)^2$. The subscript ∞ means that this is the Rydberg constant corresponding to an infinitely massive nucleus.

E. Schrödinger's wave mechanics predicts the same energy levels as the simple Bohr model, but the relativistic quantum theory of P. A. M. Dirac introduces small corrections or fine-structure splittings. The modern theory of quantum electrodynamics predicts further corrections. Additional small hyperfine-structure corrections account for the interaction of the electron and nuclear magnetic moments. *See* FINE STRUCTURE (SPECTRAL LINES); HYPERFINE STRUCTURE; NONRELATIVISTIC QUANTUM.

The Rydberg constant is determined by measuring the wavelength or frequency of a spectral line of a hydrogenlike atom or ion. The highest resolution and accuracy has been achieved by the method of Doppler-free two-photon spectroscopy, which permits the observation of very sharp resonance transitions between long-living states. The 2002 adjustment of the fundamental constants, taking into account different measurements, adopted the value $R_\infty = 10{,}973{,}731.568{,}525 \pm 0.000{,}073\ \text{m}^{-1}$ for the Rydberg constant. The measurements provide an important cornerstone for fundamental tests of basic laws of physics. *See* ATOMIC STRUCTURE AND SPECTRA; FUNDAMENTAL CONSTANTS; LASER; LASER SPECTROSCOPY. [T.W.Ha.; M.We.]

Rye A winter-hardy and drought-resistant cereal plant, *Secale cereale*, in the grass family (Graminae). It resembles wheat, with which it intercrosses to a limited extent. Rye is propagated almost completely by cross-pollination. The inflorescence is a spike or ear (see illustration). Spikelets are arranged flatwise against a zigzag rachis; they usually have two flowers, enclosed by a lemma and palea with two adjacent glumes. The young florets contain three stamens and a pistil. The fertilized pistil develops into a naked grain, or kernel, that is easily threshed. There are several recognized species of *Secale*, most of which have shattering spikes and small kernels. There are both perennial and winter-annual species of rye, with winter forms being favored over spring types for production. The only commercially cultivated species is the nonshattering *S. cereale*. *See* CYPERALES; GRASS CROPS; WHEAT.

Rye spikes or ears.

Rye is more important in Europe and Asia than in the Western Hemisphere. Russia is the leading world producer, followed by Poland and Germany. Canada and Argentina produce significant amounts, and Switzerland and northwest Europe have high yields. Rye production in the United States is mostly in South Dakota, North Dakota, Minnesota, and Georgia.

Rye grain is used for animal feed, human food, and production of spirits. Ground rye is mixed with other feeds for livestock. It is often fall-sown to provide soil cover and pasturage for livestock. Egg yolks of chickens and butter from cows fed on rye have a rich yellow color. *See* DISTILLED SPIRITS.

Compared to other small grains, rye has a fewer number of cultivars (agricultural varieties). Short-strawed types are gaining favor. Plant and kernel characteristics of rye are variable, partly because of cross-pollination. Height may range from 4 to 6 ft (120 to 180 cm) under moderately fertile conditions. Kernel color may be amber, gray, green, blue, brown, or black.

Tetraploid forms, whose chromosome number has been doubled, are available. Tetraploid wheat and rye have been hybridized and chromosomes doubled to form Triticales, which is increasing in usage. *See* BREEDING (PLANT); GRAIN CROPS. [H.L.S.]

Rye grain is milled into flour in a manner similar to that used for wheat flour. Variations are made based on the compositional and structural differences between these grains. Rye bread production requires blending of rye flours with wheat flours to provide sufficient dough strength. Specialty varieties of rye breads are classified according to ethnic origins or as sweet or sour doughs. Sour rye breads may be developed from natural lactic fermentations or through the incorporation of cultured milk. Swedish rye crisp breads are generally prepared from whole ground meal. *See* FOOD ENGINEERING. [M.A.U.]

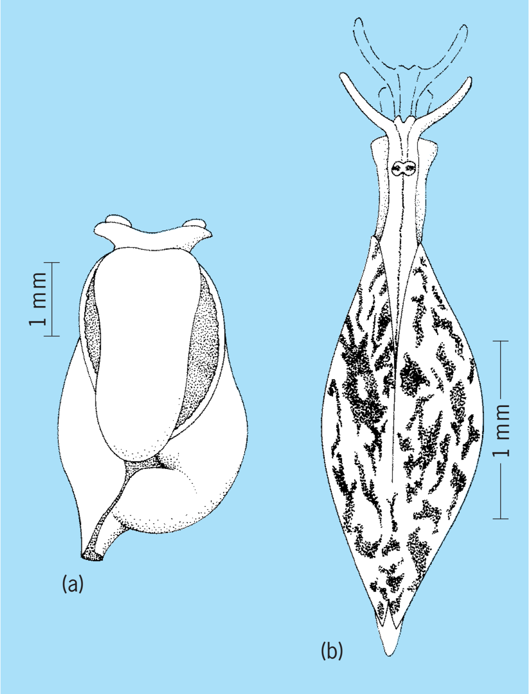
S

Sable A carnivore, *Martes zibellina*, of the family Mustelidae, found in northern Asia from the Urals to Japan; it is a valuable fur-bearing animal and quite similar to the American marten. The sable obtains food by preying upon other arboreal animals, principally birds and small mammals. It is well adapted to these activities, with its slender, supple body and short limbs with five short toes on each foot that terminate in sharp curved claws. The long bushy tail serves as a balancing organ. Mating occurs in summer, and three or four young are born the following spring. *See* Carnivora; Marten. [C.B.C.]

Saccharin The sodium salt of *o*-sulfobenzimide, manufactured by processes that start with toluene or phthalic anhydride. The free imide, called insoluble saccharin because it is insoluble in water, has limited use as a flavoring agent in pharmaceuticals. The sodium and calcium salts are very soluble in water and are widely used as sweetening agents.

Sodium saccharin is 300–500 times sweeter than cane sugar (sucrose). The saccharin salts are used to improve the taste of pharmaceuticals and toothpaste and other toiletries, and as nonnutritive sweeteners in special dietary foods and beverages. Using noncaloric saccharin in place of sugar permits the formulation of low-calorie products for people on calorie-restricted diets and of low-sugar products for diabetics. *See* Aspartame. [K.M.B.]

Sacoglossa An order of the gastropod subclass Opisthobranchia containing a thousand living species of herbivorous sea slugs; sometimes called Ascoglossa. They occur in all the oceans, at shallow depths, reaching their greatest size and diversity in tropical seas.



Representative sacoglossans: (*a*) *Volvatella*; (*b*) *Berthelinia*.

Members of this abundant order have two common features: the herbivorous habit (except for *Olea* and a species of *Stiliger* which eat the eggs of other mollusks) and the possession of a uniseriate radula in which the oldest, often broken, teeth are usually retained within the body, not discarded.

Sacoglossans possess varied shells; there may be a single shell, capacious and coiled (*Volvatella*, illus. *a*; *Cylindrobulla*), a flattened open dorsal shell (*Lobiger*), or two lateral shells (the bivalved gastropods, *Berthelinia*, illus. *b*). In the highest sacoglossans (*Elysia*, *Limapontia*) the true shell is completely lost after larval metamorphosis. The association between sacoglossan species and the algae of the sea bottom may be extraordinarily precise, as evidenced in the shallow waters of Florida. *See* Opisthobranchia. [T.E.T.]

Safety glass A unitary structure formed of two or more sheets of glass between each of which is interposed a sheet of plastic, usually polyvinyl butyral. In usual manufacture, two clean and dry sheets of plate glass and a sheet of plastic are preliminarily assembled as a sandwich under slight pressure to produce a void-free bond. The laminate is then pressed under heat long enough to unite. For use in surface vehicles the finished laminated glass is approximately $^{1}/_{4}$ in. (6 mm) thick; for aircraft it is thicker. *See* Glass. [F.H.R.]

Safety valve A relief valve set to open at a pressure safely below the bursting pressure of a container, such as a boiler or compressed air receiver. Typically, a disk is held against a seat by a spring; excessive pressure forces the disk open (see illustration). Construction is such that when the valve opens slightly, the opening force builds up to open it fully and to hold the valve open until the pressure drops a predetermined amount.

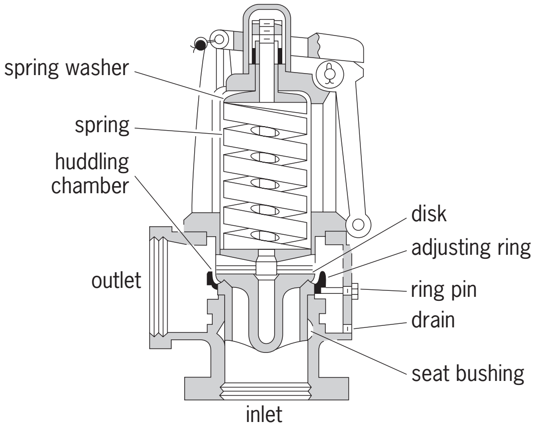


Diagram of a typical safety valve.

This differential or blow-down pressure and the initial relieving pressure are adjustable. *See* VALVE. [T.Ba.]

Safflower An oilseed crop (*Carthamus tinctorius*) that is a member of the thistle (Compositae) family and produces its seed in heads. Flowers vary in color from white through shades of yellow and orange to red. The seed is shaped like a small sunflower seed, and is covered with a hull that may be white with a smooth surface or off-white to dark gray with a ridged surface. Depending on hull thickness, the oil content varies from 25 to 45%. Safflower is grown commercially in Mexico, Australia, and California. *See* ASTERALES.

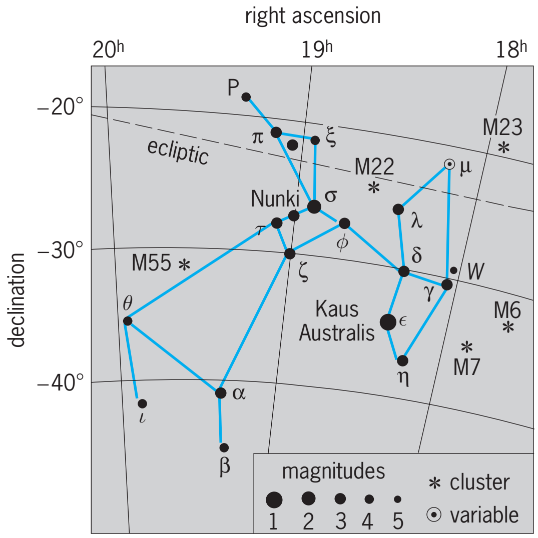
There are two types of safflower oil, both with 6–8% palmitic acid and 1–2% stearic acid. One type, the standard or polyunsaturated type, has 76–79% linoleic acid and 11–17% oleic acid. This high-linoleic type has been used in soft margarines, in salad oils, and in the manufacture of paints and varnishes. It has had limited use for frying foods, because heat causes it to polymerize and form a tough film on the cooking vessel. The second type of oil, called the high–oleic-acid or monounsaturated type, has 76–79% oleic acid and 11–17% linoleic acid. Its fatty-acid composition is similar to that of olive oil, but the flavor is bland. Hign-oleic safflower oil is a premium frying oil. The meal left after the extraction of the oil may contain 20–45% protein, depending on the amount of hull removed from the seed before processing. The meal is used as a poultry and livestock feed. *See* FAT AND OIL (FOOD). [P.F.K.]

Saffron The plant *Crocus sativus*, a member of the iris family (Iridaceae). A native of Greece and Asia Minor, it is now cultivated in various parts of Europe, India, and China. This crocus is the source of a potent yellow dye used for coloring foods and medicine. The dye is extracted from the styles and stigmas of the flowers, which appear in autumn. It takes 4000 flowers to produce 1 oz (28 g) of the dye. *See* LILIALES. [P.D.St./E.L.C.]

Sage A shrubby perennial plant in the genus *Salvia* of the mint family (Limiaceae). There are several species, including garden, or true, sage (*S. officinalis*), the sage most commonly used in foods. Many varieties of garden sage are known, but the Dalmatian type possesses the finest aroma. Garden sage is native to southern and eastern Europe, and is still cultivated extensively there and in the United States and Russia. It is a plant of low stature (2 ft or 60 cm), with hairy, oblong grayish-green leaves about $1\frac{1}{2}$–2 in. (4–5 cm) long. Sage does best in warm, dry regions, with full sun.

To preserve the essential oil content and leaf color, sage is dried, as are most other herbs. Once dried, sage is separated from the stems and made available to consumers as whole, rubbed (crushed), or ground leaves. The dried leaves are among the most popular spices in western foods. Sage is highly aromatic and fragrant, with a pungent, slightly bitter and astringent taste. Both the dried leaves and essential oil of sage are used in flavoring and for antioxidant properties in cheeses, pickles, processed foods, vermouth, and bitters. *See* LAMIALES; SPICE AND FLAVORING. [S.Kr.]

Sagittarius The Archer, in astronomy, a zodiacal and summer constellation, the major portion of which lies directly in the Milky Way. Sagittarius is the ninth sign and the southernmost constellation of the zodiac (see illustration). In mythology, it is represented by a centaur, Chiron, drawing his bow to release an arrow. Its most prominent feature is a star group commonly called the Little Milk Dipper. The Milky Way in Sagittarius is very bright, containing rich star fields and clusters, because its direction lies in the center of the Milky Way stellar system. *See* CONSTELLATION. [C.S.Y.]



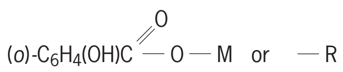
Line pattern of the constellation Sagittarius. The grid lines in the chart represent the coordinates of the sky. The apparent brightness, or magnitude, of the stars is shown by the sizes of the dots, which are graded by appropriate numbers as indicated.

Saint Elmo's fire A type of corona discharge observed on ships under conditions approaching those of an electrical storm. The charge in the atmosphere induces a charge on the masts and other elevated structures. The result of this is a corona discharge which causes a spectacular glow around these points. *See* CORONA DISCHARGE. [G.H.M.]

Salenioida An order of Echinacea in which the apical system includes one or several large angular plates covering the periproct, with the other characters similar to those of the hemicidaroid urchins. There are two families: the Acrosaleniidae, an extinct group confined to the Jurassic and Cretaceous; and the Saleniidae, which ranged from the Jurassic onward, with two surviving deep-sea genera. *See* ECHINACEA. [H.B.F.]

Salicales An order of flowering plants, division Magnoliophyta (Angiospermae), in the subclass Dilleniidae of the class Magnoliopsida (dicotyledons). The order consists of the single family Salicaceae, with about 350 species. There are only two genera, *Salix* (willow) and *Populus* (poplar and cottonwood), the former by far the larger. The Salicales are dioecious, woody plants, with alternate, simple, stipulate leaves and much reduced flowers that are aggregated into catkins. The mature seeds are plumose-hairy and are distributed by the wind. *See* DILLENIIDAE; MAGNOLIOPSIDA; POPLAR; WILLOW. [A.Cr.]

Salicylate A salt or ester of salicylic acid having the general formula shown below and formed by replacing the carboxylic



$$(o)\text{-}\mathrm{C_6H_4(OH)C}(=\mathrm{O})\text{—O—M} \quad \text{or} \quad \text{—R}$$

hydrogen of the acid by a metal (M) to give a salt or by an organic radical (R) to give an ester. Alkali-metal salts are water-soluble; the others, insoluble. Sodium salicylate is used in medicines as an antirheumatic and antiseptic, in the manufacture of dyes, and as a preservative (illegal in foods). Salicylic acid is used in the preparation of aspirin. The methyl ester is the chief component of oil of wintergreen. This ester is used in pharmaceuticals as a component of rubbing liniment. It is also used as a flavoring agent and an odorant. *See* ASPIRIN. [E.H.H.]

Saline evaporites Deposits of bedded sedimentary rocks composed of salts precipitated during solar evaporation of surface or near-surface brines derived from seawater or continental waters. Dominant minerals in ancient evaporite beds are anhydrite (along with varying amounts of gypsum) and halite, which make up more than 85% of the total sedimentary evaporite salts. Many other salts make up the remaining 15%; their varying proportions in particular beds can be diagnostic of the original source of the mother brine. *See* ANHYDRITE; EVAPORATION; GYPSUM; HALITE; SALT (CHEMISTRY); SEAWATER; SEDIMENTARY ROCKS.

Today, brines deposit their salts within continental playas or coastal salt lakes and lay down beds a few meters thick and tens of kilometers across. In contrast, ancient, now-buried evaporite beds are often much thicker and wider; they can be up to hundreds of meters thick and hundreds of kilometers wide. Most ancient evaporites were formed by the evaporation of saline waters within hyperarid areas of huge seaways typically located within arid continental interiors. The inflow brines in such seaways were combinations of varying proportions of marine and continental ground waters and surface waters. There are few modern depositional counterparts to these ancient evaporites, and none to those beds laid down when whole oceanic basins dried up, for example, the Mediterranean some 5.5 million years ago. *See* BASIN; DEPOSITIONAL SYSTEMS AND ENVIRONMENTS; MEDITERRANEAN SEA; PLAYA.

Evaporite salts precipitate by the solar concentration of seawater, continental water, or hybrids of the two. The chemical makeup, salinity (35‰), and the proportions of the major ions in modern seawater are near-constant in all the world's oceans, with sodium (Na) and chloride (Cl) as the dominant ions and calcium (Ca) and sulfate (SO_4) ions present in smaller quantities [$Na(Ca)SO_4Cl$ brine]. Halite and gypsum anhydrites have been the major products of seawater evaporation for at least the past 2 billion years, but the proportions of the more saline minerals, such as sylvite/magnesium sulfate ($MgSO_4$) salts, appear to have been more variable. *See* CALCIUM; CHLORINE; ION; MAGNESIUM; SODIUM; SULFUR. [J.Wa.]

Salmonelloses Diseases caused by *Salmonella*. These include enteritis and septicemia with or without enteritis. *Salmonella typhi*, *S. paratyphi A*, *B*, and *C*, and occasionally *S. cholerae suis* cause particular types of septicemia called typhoid and paratyphoid fever, respectively; while all other types may cause enteritis or septicemia, or both together.

Typhoid fever has an incubation period of 5–14 days. It is typified by a slow onset with initial bronchitis, diarrhea or constipation, a characteristic fever pattern (increase for 1 week, plateau for 2 weeks, and decrease for 2–3 weeks), a slow pulse rate, development of rose spots, swelling of the spleen, and often an altered consciousness; complications include perforation of the bowel and osteomyelitis. Typhoid fever leaves the individual with a high degree of immunity. Vaccination with an oral vaccine gives an individual considerable protection for about 3 years. The only effective antibiotic is chloramphenicol. *See* ANTIBIOTIC; IMMUNITY; VACCINATION.

Paratyphoid fever has a shorter course and is generally less severe than typhoid fever. Vaccination is an ineffective protective measure.

Enteric fevers, that is, septicemias due to types of *Salmonella* other than those previously mentioned, are more frequent in the United States than typhoid and paratyphoid fever but much less frequent than *Salmonella* enteritis. In children and in previously healthy adults, enteric fevers are most often combined with enteritis and have a favorable outlook. The organisms involved are the same as those causing *Salmonella* enteritis. Chloramphenicol or ampicillin are used in treatment. However, resistant strains have been observed. *See* DRUG RESISTANCE.

Inflammation of the small bowel due to *Salmonella* is one of the most important bacterial zoonoses. The most frequent agents are *S. typhimurium*, *S. enteritidis*, *S. newport*, *S. heidelberg*, *S. infantis*, and *S. derby*. The incubation period varies from 6 h to several days. Diarrhea and fever are the main symptoms; the intestinal epithelium is invaded, and early bacteremia is probable. Predisposed are persons with certain preexisting diseases (the same as for enteric fevers), very old and very young individuals, and postoperative patients. Antimicrobial treatment serves only to prolong the carrier state and has no effect on the disease. [A.W.C.V.G.]

Salmoniformes An order of soft-rayed fishes comprising salmon and their allies. They make up the stem group from which most higher teleostean fishes have evolved.

Salmoniformes are generalized fishes characterized by soft or articulated fin rays; adipose dorsal fin usually present; cycloid (smooth) scales; pelvic fin in an abdominal position (well back on the trunk), usually with more than six rays, and with pelvic girdle free from pectoral girdle; pectoral fin placed low on the side and more or less horizontal; upper jaw usually bordered by premaxillae and maxillae; premaxillae not protractile; no weberian apparatus connecting the swim bladder with the inner ear, but a duct joining the bladder with the gut; and branchiostegal rays variable in number and arrangement.

Salmoniform fishes have an imperfect fossil record; they were present in the Cretaceous and likely earlier. The order consists of 8 suborders, 37 families, some 212 genera, and about 950 species. Most are marine fishes, and they are common in all seas. A few are adapted to pelagic or shore waters, most live in the bathypelagic zone, some tolerate arctic seas, and many inhabit warm or cold fresh water, or are anadromous; that is, they enter fresh water to reproduce.

The suborder Salmonoidei includes many of the most important and best known of all fishes, especially in the family Salmonidae, or salmon, trouts, whitefishes, and graylings. The Argentinoidei (argentines, deep-sea smelts, and related fishes), Alepocephaloidei (slickheads), and Bathylaconoidei are found chiefly in deep marine waters. The Galaxioidei are mostly small, fresh-water fishes of south temperate lands, especially Australia and New Zealand. Esocoidei are a small group, the pikes and mudminnows of northern fresh waters. The Stomiatoidei, lightfishes and allies, inhabit the middle depths of the oceans. They are of small size and often grotesque form, and are equipped with photophores. The Myctophoidei is the largest of the suborders. All species are marine; some, including lizardfishes, inhabit shore waters, but the majority are oceanic. Those that live at moderate to considerable depths, such as the lantern fishes, commonly have photophores on the head and body. *See* PHOTOPHOR GLAND; TELEOSTEI. [R.M.B.]

Salt (chemistry) A compound formed when one or more of the hydrogen atoms of an acid are replaced by one or more cations of the base. The common example is sodium chloride in which the hydrogen ions of hydrochloric acid are replaced by the sodium ions (cations) of sodium hydroxide. There is a great variety of salts because of the large number of acids and bases which has become known.

Salts are classified in several ways. One method—normal, acid, and basic salts—depends upon whether all the hydrogen ions of the acid or all the hydroxide ions of the base have been replaced:

Class	*Examples*
Normal salts	$NaCl$, NH_4Cl, Na_2SO_4, Na_2CO_3, Na_3PO_4, $Ca_3(PO_4)_2$
Acid salts	$NaHCO_3$, NaH_2PO_4, Na_2HPO_4, $NaHSO_4$
Basic salts	$Pb(OH)Cl$, $Sn(OH)Cl$

The other method—simple salts, double salts (including alums), and complex salts—depends upon the character of completeness of the ionization:

Class	*Examples*
Simple salts	$NaCl$, $NaHCO_3$, $Pb(OH)Cl$
Double salts	$KCl{\cdot}MgCl_2$
Alums	$KAl(SO_4)_2$, $NaFe(SO_4)_2$, $NH_4Cr(SO_4)_2$
Complex salts	$K_3Fe(CN)_6$, $Cu(NH_3)_4Cl_2$, $K_2Cr_2O_7$

See Acid and base; Chemical bonding. [A.B.G.]

Salt (food) The chemical compound sodium chloride. It is used extensively in the food industry as a preservative and flavoring, as well as in the chemical industry to make chlorine and sodium. *See* Chlorine; Food preservation; Salt (chemistry); Sodium.

Salt was originally made by evaporating sea water (solar salt). This method is still in common usage; however, impurities in solar salt make it unsatisfactory for most commercial uses, and these impurities also lead to clumping. Salt, freshly produced from sea-water evaporation ponds, may contain large numbers of halophilic (salt-loving) microorganisms. In the United States refined salt is obtained from underground mines located in Michigan and Louisiana. Salt is usually handled during the refining processes as brine.

Salt is liable to clumping during periods of high humidity, so preventives are added. Materials used include magnesium carbonate and certain silicates. Iodides are added in those areas where iodine deficiencies exist. [R.E.M.]

Salt dome An upwelling of crystalline rock salt and its aureole of deformed sediments. A salt pillow is an immature salt dome comprising a broad salt swell draped by concordant strata. A salt stock is a more mature, pluglike diapir of salt that has pierced, or appears to have pierced, overlying strata. Most salt stocks are 0.6–6 mi (1–10 km) wide and high. Salt domes are closely related to other salt upwellings, some of which are much larger. Salt canopies, which form by coalescence of salt domes and tongues, can be more than 200 mi (300 km) wide. *See* Diapir.

Exploration for oil and gas has revealed salt domes in more than 100 sedimentary basins that contain rock salt layers several hundred meters or more thick. The salt was precipitated from evaporating lakes in rift valleys, intermontaine basins, and especially along divergent continental margins. Salt domes are known in every ocean and continent. *See* Basin.

Salt domes consist largely of halite ($NaCl$, common table salt). Other evaporites, such as anhydrite ($CaSO_4$) and gypsum ($CaSO_4{\cdot}2H_2O$), form thinner layers within the rock salt. *See* Halite; Saline evaporites.

Salt domes supply industrial commodities, including fuel, minerals, chemical feedstock, and storage caverns. Giant oil or gas fields are associated with salt domes in many basins around the world, especially in the Middle East, North Sea, and South Atlantic regions. Salt domes are also used to store crude oil, natural gas (methane), liquefied petroleum gas, and radioactive or toxic wastes. *See* Oil and gas storage. [M.P.A.J.]

Salt-effect distillation A process of extractive distillation in which a salt that is soluble in the liquid phase of the system being separated is used in place of the normal liquid additive introduced to the extractive distillation column in order to effect the separation.

Extractive distillation is a process used to separate azeotrope-containing systems or systems in which relative volatility is excessively low. An additive, or separating agent, that is capable of raising relative volatility and eliminating azeotropes in the system being distilled is supplied to the column, where it mixes with the feed components and exerts its effect. The agent is subsequently recovered from one or both product streams by a separate process and recycled for reuse. *See* Azeotropic mixture.

In salt-effect distillation, the process is essentially the same as for a liquid agent, although the subsequent process used to recover the agent for recycling is different; that is, evaporation is used rather than distillation. The salt is added to the system by being dissolved in the reentering reflux stream at the top of the column. Being nonvolatile, it will reside in the liquid phase, flowing down the column and out in the bottom product stream.

The major commercial use of salt-effect distillation is in the concentration of aqueous nitric acid, using the salt magnesium nitrate as the separating agent. Other commercial applications include acetone-methanol separation using calcium chloride and isopropanol-water separation using the same salt. *See* Azeotropic distillation; Distillation. [W.F.F.]

Salt gland A specialized gland located around the eyes and nasal passages in marine turtles, snakes, and lizards, and in birds such as the petrels, gulls, and albatrosses, which spend much time at sea. In the marine turtle it is an accessory lacrimal gland which opens into the conjunctival sac. In seagoing birds and in marine lizards it opens into the nasal passageway. Salt glands copiously secrete a watery fluid containing a high percentage of salt, higher than the salt content of urine in these species. As a consequence, these animals are able to drink salt-laden sea water without experiencing the dehydration necessary to eliminate the excess salt via the kidney route. *See* Gland. [O.E.N.]

Salt marsh A maritime habitat characterized by grasses, sedges, and other plants that have adapted to continual, periodic flooding. Salt marshes are found primarily throughout the temperate and subarctic regions.

The tide is the dominating characteristic of a salt marsh. The salinity of the tide defines the plants and animals that can survive in the marsh area. The vertical range of the tide determines flooding depths and thus the height of the vegetation, and the tidal cycle controls how often and how long vegetation is submerged. Two areas are delineated by the tide: the low marsh and the high marsh. The low marsh generally floods and drains twice daily with the rise and fall of the tide; the high marsh, which is at a slightly higher elevation, floods less frequently. *See* Mangrove.

Salt marshes usually are developed on a sinking coastline, originating as mud flats in the shallow water of sheltered bays, lagoons, and estuaries, or behind sandbars. They are formed where salinity is high, ranging from 20 to 30 parts per thousand of sodium chloride. Proceeding up the estuary, there is a transitional zone where salinity ranges from 20 to less than 5 ppt. In the upper estuary, where river input dominates, the water has only a trace of salt. This varying salinity produces changes in the marsh—in the kinds of species and also in their number. Typically, the fewest species are found in the salt marsh and the greatest number in the fresh-water tidal marsh. *See* Estuarine oceanography.

The salt marsh is one of the most productive ecosystems in nature. In addition to the solar energy that drives the photosynthetic process of higher rooted plants and the algae growing on the surface muds, tidal energy repeatedly spreads nutrient-enriched waters over the marsh surface. Some of this enormous supply of live plant material may be consumed by marsh animals, but the most significant values are realized when the vegetation dies and is decomposed by microorganisms to form detritus. Dissolved organic materials are released, providing an essential energy source for bacteria that mediate wetland biogeochemical cycles (carbon, nitrogen, and sulfur cycles). *See* BIOGEOCHEMISTRY; BIOLOGICAL PRODUCTIVITY.

The salt marsh serves as a sediment sink, a nursery habitat for fishes and crustaceans, a feeding and nesting site for waterfowl and shorebirds, a habitat for numerous unique plants and animals, a nutrient source, a reservoir for storm water, an erosion control mechanism, and a site for esthetic pleasures. Appreciation for the importance of salt marshes has led to federal and state legislation aimed at their protection. [F.C.D.]

Salviniales A small order of heterosporous, leptosporangiate ferns (division Polypodiophyta) which float on the surface of the water. The delicate, branching stem is provided with small, simple to bifid or more or less dissected leaves. The sporangia are enclosed in specialized appendages of the leaves, called sporocarps. The order contains only a single family, with two widely distributed genera, *Salvinia* and *Azolla*, with only about 20 species in all. *See* POLYPODIOPHYTA. [A.Cr.]

Samarium A chemical element, Sm, atomic number 62, belonging to the rare-earth group. Its atomic weight is 150.35, and there are 7 naturally occurring isotopes; ^{147}Sm, ^{148}Sm, and ^{149}Sm are radioactive and emit α particles. *See* PERIODIC TABLE.

Samarium oxide is pale yellow, is readily soluble in most acids, and gives topaz-yellow salts in solutions. Samarium has found rather limited use in the ceramic industry, and it is used as a catalyst for certain organic reactions. One of its isotopes has a very high cross section for the capture of neutrons, and therefore there has been some interest in samarium in the atomic industry for use as control rods and nuclear poisons. *See* LANTHANUM; RARE-EARTH ELEMENTS. [F.H.Sp.]

Sampled-data control system A type of digital control system in which one or more of the input or output signals is a continuous, or analog, signal that has been sampled. There are two aspects of a sampled signal: sampling in time and quantization in amplitude. Sampling refers to the process of converting an analog signal from a continuously valued range of amplitude values to one of a finite set of possible numerical values. This sampling typically occurs at a regular sampling rate, but for some applications the sampling may be aperiodic or random.

While the device to be controlled is usually referred to as the plant, sampled-data control systems are also used to control processes. The term plant refers to machines or mechanical devices which can usually be mathematically modeled by an analysis of their kinematics, such as a robotic arm or an engine. A process refers to a system of operations such as a batch reactor for the production of a particular chemical, or the operation of a nation's economy. The output of the plant which is to be controlled is called the controlled variable. A regulator is one type of sampled-data control system, and its purpose is to maintain the controlled variable at a preset value (for example, the robotic arm at a particular position, or an airplane turboprop engine at a constant speed) or the process at a constant value (for example, the concentration of an acid, or the inflation rate of an economy). This input is called the reference or setpoint. The second type of sampled-data control system is a servomechanism, whose purpose is to make the controlled variable follow an input variable. Examples of servomechanisms are a robotic arm used to paint automobiles which may be required to move through a predefined path in three-dimensional space while holding the sprayer at varying angles, an automobile engine which is expected to follow the input commands of the driver, a chemical process that may require the pH of a batch process to change at a specified rate, and an economy's growth rate which is to be changed by altering the money supply. *See* ANALOG-TO-DIGITAL CONVERTER; PROCESS CONTROL; REGULATOR; SERVOMECHANISM.

The analog-to-digital converter changes the sampled signal into a binary number so that it can be used in calculations by the digital compensator. Since a digital controller computes the control signal used to drive the plant, a digital-to-analog converter must be used to change this binary number to an analog voltage. The digital compensator in the typical sampled-data control system takes the digitized values of the analog feedback signals and combines them with the setpoint or desired trajectory signals to compute a digital control signal, to actuate the plant through the digital-to-analog converter. A compensator is used to modify the feedback signals in such a way that the dynamic performance of the plant is improved relative to some performance index. *See* CONTROL SYSTEMS; DIGITAL COMPUTER; DIGITAL CONTROL; DIGITAL-TO-ANALOG CONVERTER. [K.J.Hi.]

Sand Unconsolidated granular material consisting of mineral, rock, or biological fragments between 63 micrometers and 2 mm in diameter. Finer material is referred to as silt and clay; coarser material is known as gravel. Sand is usually produced primarily by the chemical or mechanical breakdown of older source rocks, but may also be formed by the direct chemical precipitation of mineral grains or by biological processes. Accumulations of sand result from hydrodynamic sorting of sediment during transport and deposition. *See* CLAY MINERALS; DEPOSITIONAL SYSTEMS AND ENVIRONMENTS; GRAVEL; MINERAL; ROCK; SEDIMENTARY ROCKS.

Most sand originates from the chemical and mechanical breakdown, or weathering, of bedrock. Since chemical weathering is most efficient in soils, most sand grains originate within soils. Rocks may also be broken into sand-size fragments by mechanical processes, including diurnal temperature changes, freeze-thaw cycles, wedging by salt crystals or plant roots, and ice gouging beneath glaciers. *See* WEATHERING PROCESSES.

Because sand is largely a residual product left behind by incomplete chemical and mechanical weathering, it is usually enriched in minerals that are resistant to these processes. Quartz not only is extremely resistant to chemical and mechanical weathering but is also one of the most abundant minerals in the Earth's crust. Many sands dominantly consist of quartz. Other common constituents include feldspar, and fragments of igneous or metamorphic rock. Direct chemical precipitation or hydrodynamic processes can result in sand that consists almost entirely of calcite, glauconite, or dense dark-colored minerals such as magnetite and ilmenite. *See* FELDSPAR; QUARTZ.

Although sand and gravel has one of the lowest average per ton values of all mineral commodities, the vast demand makes it among the most economically important of all mineral resources. Sand and gravel is used primarily for construction purposes, mostly as concrete aggregate. Pure quartz sand is used in the production of glass, and some sand is enriched in rare commodities such as ilmenite (a source of titanium) and in gold. *See* CONCRETE. [M.J.J.]

Sand dollar An echinoderm belonging to the order Clypeasteroida in the class Echinoidea. Sand dollars have a flat, disk-shaped body, with the mouth in a mid-ventral position and with the anus also on the ventral surface. There are several species.

Sand dollars live in sand, on the surface or partly buried, from the low-tide mark to depths of 4800 ft (1460 m). Burrowing and locomotion are assisted by the short spines which cover the body. Sand dollars ingest sand grains covered with diatoms or other algae. *See* CLYPEASTEROIDA. [C.B.C.]

Sandalwood The name applied to any species of the genus *Santalum* of the sandalwood family (Santalaceae). However, the true sandalwood is the hard, close-grained, aromatic heartwood of a parasitic tree, *S. album*, of the Indo-Malayan region. This fragrant wood is used in ornamental carving, cabinet work, and as a source of certain perfumes. The odor of the wood is an insect repellent, and on this account the wood is much used in making boxes and chests. The fragrant wood of a number of species in other families bears the same name, but none of these is the real sandalwood. *See* SANTALALES. [P.D.St./E.L.C.]

Sandstone A clastic sedimentary rock comprising an aggregate of sand-sized (0.06–2.0-mm) fragments of minerals, rocks, or fossils held together by a mineral cement. Sandstone forms when sand is buried under successive layers of sediment. During burial the sand is compacted, and a binding agent such as quartz, calcite, or iron oxide is precipitated from ground water which moves through passageways between grains. Sandstones grade upward in grain size into conglomerates and breccias; they grade downward in size into siltstones and shales. When the proportion of fossil fragments or carbonate grains is greater than 50%, sandstones grade into clastic limestones. *See* BRECCIA; CONGLOMERATE; LIMESTONE; SAND; SHALE.

The basic components of a sandstone are framework grains (sand particles), which supply the rock's strength; matrix or mud-sized particles, which fill some of the space between grains; and crystalline cement. The composition of the framework grains reveals much about the history of the derivation of the sand grains, including the parent rock type and weathering history of the parent rock. Textural attributes of sandstone are the same as those for sand, and they have the same genetic significance. *See* SAND. [L.J.S.]

Sandstones are classified according to the relative proportion of quartz to other grain types, and according to the ratio of feldspar grains to finely crystalline lithic fragments. Quartz-rich sandstones are commonly called quartz-arenite. Sandstones poor in quartz are commonly called arkose, when feldspar grains are more abundant than lithic fragments, and litharenite (or graywacke) when the reverse is true. Subarkose and sublitharenite (or subgraywacke) refer to analogous sandstones of intermediate quartz content. Sandstones composed dominantly of calcareous grains are called calcarenite, and represent a special variety of limestone. Other sandstones composed exclusively of volcanic debris are called volcanic sandstone, and are gradational, through the interplay of eruptive and erosional processes, to tuff, the fragmental volcanic rocks produced by the disintegration of magma during explosive volcanic eruptions. *See* ARENACEOUS ROCKS; ARKOSE; FELDSPAR; GRAYWACKE; QUARTZ; TUFF. [W.R.D.]

Because sandstone can possess up to 35% connected pore space, it is the most important reservoir rock in the Earth's crust. In the future sandstone may serve as a reservoir into which hazardous fluids, such as nuclear wastes, are injected for storage. *See* HAZARDOUS WASTE.

Sandstone which is easily split (flagstone) and has an attractive color is used as a building stone. Sandstone is also an important source of sand for the glass industry and the construction industry, where it is used as a filler in cement and plaster. Crushed sandstone is used as road fill and railroad ballast. Silica-cemented sandstone is used as firebrick in industrial furnaces. Some of the most extensive deposits of uranium are found in sandstones deposited in ancient stream channels. *See* GLASS; SEDIMENTARY ROCKS; STONE AND STONE PRODUCTS; URANIUM. [L.J.S.]

Santalales An order of flowering plants, division Magnoliophyta (Angiospermae), in the subclass Rosidae of the class Magnoliopsida (dicotyledons). The order consists of 10 families and about 2000 species. The largest families are the Loranthaceae (about 900 species), Santalaceae (about 400 species), Viscaceae (about 350 species), and Olacaceae (about 250 species). A few of the more primitive members of the Santalales are autotrophic, but otherwise the order is characterized by progressive adaptation to parasitism, accompanied by progressive simplification of the ovules. Some members of the Santalales, such as sandalwood (*Santalum album*, a small tree of southern Asia), are rooted in the ground and produce small branch roots which invade and parasitize the roots of other plants. Others, such as mistletoe (*Viscum* and other genera of the Viscaceae), grow on trees, well above the ground. *See* FLOWER; MAGNOLIOPHYTA; MAGNOLIOPSIDA; MISTLETOE; SANDALWOOD. [A.Cr.; T.M.Ba.]

Sapindales An order of flowering plants, division Magnoliophyta (Angiospermae), in the subclass Rosidae of the class Magnoliopsida (dicotyledons). The order consists of 15 families and about 5400 species. The largest families are the Rutaceae (about 1500 species), Sapindaceae (about 1500 species), Meliaceae (about 550 species), Anacardiaceae (about 600 species), and Burseraceae (about 600 species). Most of the Sapindales are woody plants, with compound or lobed leaves and polypetalous, hypogynous to perigynous flowers with one or two sets of stamens and only one or two ovules in each locule of the ovary. A large proportion of the species have glandular cavities in the leaves, or resin ducts in the bark and wood, or other sorts of secretory structures.

Poison ivy (*Toxicodendron radicans*), a characteristic member of the family Anacardiaceae in the order Sapindales, division Magnoliophyta. (*John Gerard*, *National Audubon Society*)

Some of the Anacardiaceae, including poison ivy (*Toxicodendron radicans*; see illustration) and the lacquer tree (*T. vernicifluum*) of the Orient, are notoriously allergenic to humans. Some other well-known members of the order are orange, lemon, lime, and grapefruit (all species of *Citrus* in the Rutaceae); the various kinds of maple (*Acer*, in the Aceraceae); and the horse chestnut (*Aesculus* hippocastanum, in the Hippocastanaceae). *See* BUCKEYE; CASHEW; CITRON; GRAPEFRUIT; KUMQUAT; LEMON; LIGNUMVITAE; LIME (BOTANY); MAGNOLIOPHYTA; MAGNOLIOPSIDA; MAHOGANY; MANDARIN; MAPLE; ORANGE; PISTACHIO; POISON IVY; QUEBRACHO; TANGERINE; VARNISH TREE. [A.Cr.; T.M.Ba.]

Sapphire The name given to all gem varieties of the mineral corundum, except those that have medium to dark tones of red that characterize ruby. Although the name sapphire is most commonly associated with the blue variety, there are many other colors of gem corundum to which sapphire is applied correctly; these include yellow, brown, green, pink, orange, purple, colorless, and black. Sapphire has a hardness of 9, a specific gravity near 4.00, and refractive indices of 1.76–1.77. Asterism, the star effect, is the result of reflections from tiny, lustrous, needlelike inclusions of the mineral rutile, plus a domed form of cutting. *See* CORUNDUM; GEM; RUBY; RUTILE. [R.T.L.]

Sapropel A term originally defined as an aquatic sediment rich in organic matter that formed under reducing conditions (lack of dissolved oxygen in the water column) in a stagnant water body. Such inferences about water-column dissolved-oxygen contents are not always easy to make for ancient environments. Therefore, the term sapropel or sapropelic mud has been used loosely to describe any discrete black or dark-colored sedimentary layers (>1 cm or 0.4 in. thick) that contain greater than 2 wt % organic carbon. Sapropels may be finely laminated (varved) or homogeneous, and may less commonly exhibit structures indicating reworking or deposition of the sediment by currents. Sapropels largely contain amorphous organic matter derived from planktonic organisms (such as planktonic or benthic algae in lakes or plankton in marine settings). Such organic matter possesses a large hydrogen-to-carbon ratio; therefore, sapropelic sequences are potential petroleum-forming deposits. The enhanced preservation of amorphous organic matter in sapropels may indicate conditions of exceptionally great surface-water productivity, extremely low bottom-water dissolved-oxygen contents, or both. Some sapropels may, however, contain substantial amounts of organic matter derived from land plants. *See* ANOXIC ZONES; MARINE SEDIMENTS; ORGANIC GEOCHEMISTRY; PETROLEUM; VARVE. [M.A.Ar.]

Sarcodina A superclass of Protozoa (in the subphylum Sarcomastigophora) in which movement involves protoplasmic flow, often with recognizable pseudopodia. Gametes may be flagellated, as in certain Foraminiferida. Most species are floating or creeping; a few are sessile. The pellicle is relatively thin, and the body is apt to be plastic unless restrained by skeletal structures. Sarcodina live in fresh, brackish, or salt waters; soil or sand; and as endoparasites in animals and plants. A group may be limited to a specific habitat, but many have a rather wide range. Sarcodina include two major classes: Rhizopodea and Actinopodea. *See* ACTINOPODEA; RHIZOPODEA; SARCOMASTIGOPHORA. [R.P.H.]

Sarcomastigophora A subphylum of Protozoa, including those forms that possess flagella or pseudopodia or both. Organisms have a single type of nucleus, except the developmental stages of some Foraminiferida. Sexuality, if present, is syngamy, the fusion of two gametes. Spores typically are not formed. Flagella may be permanent or transient or confined to a certain stage in the life history; this is true also of pseudopodia. Both flagella and pseudopodia may be present at the same time.

Three superclasses are included: (1) Mastigophora, commonly flagellates, contains 19 orders. (2) Opalinata includes 1 order; these organisms were once considered as ciliates, but further research has indicated flagellate kinships. (3) Sarcodina comprises organisms which normally possess pseudopodia and are flagellated only in the developmental stages; 13 orders possess irregularly distributed lobose or filose and branching pseudopodia, while 7 orders have radially distributed axopodia, often with axial filaments. *See* MASTIGOPHORA; SARCODINA.

Most of the plant flagellates will live in either fresh water or in both fresh and salt water. The zooflagellates are small and are not sufficiently abundant to enter markedly into the food chain. But the parasites and symbionts are of considerable interest economically and theoretically, for example, the trypanosomes and the peculiar xylophagous (wood-eating) symbionts of termites. In the termites these parasites actually digest the wood eaten by the host. Conspicuous in the ecology of marine waters are the dinoflagellates, radiolarians, and acantharians, especially in tropical waters of otherwise low productivity. *See* PROTOZOA. [J.B.L.]

Sarcopterygii A name often employed to unite the lobefin, or crossopterygian, fishes and the lungfishes as a subclass of the Osteichthyes. The older names Amphibioidei and Choanichthyes are equivalent to Sarcopterygii. The structural differences between lobefin fishes and lungfishes are great, and their common ancestry, if any, lies in the Lower Devonian, long antedating the origin of the earliest tetrapods which have since diverged into four classes. It seems best to rank the Crossopterygii (lobefins) and Dipnoi (lungfishes) each equivalent in rank to the subclass Actinopterygii (rayfin fishes), in which the vast majority of fishes are classified. *See* ACTINOPTERYGII; CROSSOPTERYGII; DIPNOI; OSTEICHTHYES. [R.M.B.]

Sarcoptiformes One of the five suborders of the order Acarina. These are minute (0.012–0.06 in. or 0.3–1.5 mm long) globular mites without stigmata, but there may be a tracheal system. The legs may be simple, or enlarged in the male, and may terminate in suckers, claws, or in a modification of both; their coxae form subdermal apodemes on the venter. The chelicerae are normally pincerlike. In normal development these creatures pass through four stages (larva and first, second, and third nymphal stages) before becoming adult. Under certain conditions a dispersal form, the hypopus, may develop between the first and second nymphal stages.

This group can be separated rather easily into the pale, weakly sclerotized Acaridiae and the dark, heavily sclerotized Oribatei. The former group includes such economically significant forms as the free-living grain and cheese mites, parasitic itch mites, and feather mites, while the latter group includes the oribatid mites, all of which are free-living, though some act as intermediate hosts of tapeworms. *See* ACARI. [H.H.J.N.]

Sarcosporida An order of Protozoa of the class Haplosporea which comprises parasites in skeletal and cardiac muscle of vertebrates. The organisms have a very wide distribution both geographically and in host species, infecting reptiles, birds, and mammals (including marsupials). Humans are occasionally infected by the parasite referred to as *Sarcocystis lindemanni.* It is doubtful whether Sarcosporida found in different hosts are themselves always different, though this has often been assumed. Host specificity is known not to be strict; however, it is unlikely that there is only one species—*S. miescheriana*—as proposed by some investigators.

The criteria of species are very hard to define for *Sarcocystis*. Species descriptions have usually been based on an assumed host specificity, size of spores, and cyst characteristics. But host specificity has seldom been proved, spore size is variable (degree of variation often in part dependent on the host species), and cyst morphology is frequently inconstant. Nevertheless, cyst morphology is probably more stable than anything else about the parasite.

In general, the cyst wall is said to have one or two layers, the outer one being either smooth or provided with spines or villi. The genesis of the wall is in some dispute; some think it is formed by the host as a reaction to the parasite, but the majority opinion is that the parasite itself forms the cyst. The cyst is divided internally into compartments, and the outer wall is smooth or rough, depending on the species, with numerous, minute villuslike projections on the outer surface. The spores are crescent-shaped and have a minute projection, termed a conoid, at the more pointed or anterior end, from which fibrils pass anteriorly. These fibrils are called toxonemes at the point of origin, and sarconemes (in *Sarcocystis*) farther back. The nucleus and several mitochondria are in the posterior half.

The life cycle of *Sarcocystis* is quite typical of the Sporozoa, since sexual stages are lacking and schizogony (multiple fission), though sometimes claimed, apparently does not occur. Instead, reproduction is by binary fission, with the eventual development of cysts (Miescher's tubules) in the muscles. These cysts are relatively large structures, easily visible with the unaided eye, and contain myriads of the minute crescentic spores. Infection of a new host is believed to be by the ingestion of these spores with food and water contaminated by feces from an infected animal.

Most natural infections appear to be mild and to do the host little harm. *See* HAPLOSPOREA; PROTOZOA; SPOROZOA. [R.D.M.]

Sassafras A medium-sized tree, *Sassafras albidum*, of the eastern United States, extending north as far as southern Maine. Sometimes it is only a shrub in the north, but from Pennsylvania southward heights of 90 ft (27 m) or more with diameters of 4–7 ft (1.2–2.1 m) have been reported for this plant. Sassafras is said to live from 700 to 1000 years. It can be recognized by the bright-green color and aromatic odor of the twigs and leaves. The leaves are simple or mitten-shaped (hence a common name "mitten-tree"), or they may have lobes on both sides of the leaf blade. *See* MAGNOLIALES. [A.H.G./K.P.D.]

Satellite (astronomy) A relatively small body orbiting a larger one that in turn orbits a star. In the solar system, all of the planets except Mercury and Venus have satellites. Well over 100 planetary satellites are known to exist, of which a total of 101 were definitely established by July 2004, distributed as follows: Earth 1, Mars 2, Jupiter 38, Saturn 30, Uranus 21, Neptune 8, and Pluto 1. Additional satellites have been observed in all four giant systems; more observations are needed to define their orbits. The close flyby of the *Galileo* spacecraft (en route to Jupiter) of the asteroid 243 Ida in 1993 revealed the presence of a 0.9-mi (1.5-km) diameter satellite, now known as Dactyl. This unexpected discovery was soon followed by the detection of several other asteroid satellites by Earth-based observers. Several Kuiper Belt objects (distant comet nuclei) have also been observed to be binaries. *See* ASTEROID; KUIPER BELT.

It is customary to distinguish between regular satellites that have nearly circular orbits lying essentially in the plane of a planet's equator and irregular satellites whose orbits are highly inclined, very elliptical, or both. The former almost certainly originated with the parent planet, while the latter must be captured objects. The Earth's Moon is a special case. The most widely favored hypothesis for its origin invokes an impact with Earth by a Mars-sized planetesimal, and ejection of material that first formed a ring around the Earth and then coalesced to form the Moon. Pluto's Charon may have formed through a similiar collision. *See* MOON; PLUTO. [T.C.O.]

Satellite (spacecraft) A spacecraft that is in orbit about a planet (usually the Earth). Spacecraft are devices intended for observation, research, or communication in space. Even those spacecraft which are on the way to probe the outer reaches of the solar system usually complete at least a partial revolution around Earth before being accelerated into an interplanetary trajectory. Devices such as sounding rockets follow ballistic (approximately parabolic) paths after fuel exhaustion, but they are not satellites because they do not achieve velocities great enough to avoid falling back to Earth before completing even one revolution. *See* ROCKET ASTRONOMY; SPACE PROBE.

The space shuttle, the International Space Station (ISS), and many automated (crewless, robotic) satellites travel in low Earth orbits (LEO) about 100 mi (160 km) above Earth's surface. They have typical orbital periods of about 90 min. These satellites have lifetimes of days, weeks, months, or years, depending on their altitudes, their mass-to-drag ratios, and atmospheric drag variations caused by solar activity. The International Space Station would have an orbital lifetime of only a few years without the periodic orbital boosts provided by the space shuttle or other rocket-powered space vehicles such as the Russian *Progress*. Most LEO satellites spend up to nearly half of their time in Earth's shadow. The space shuttle provides its electric power from fuel cells, but almost every other LEO spacecraft depends on solar cells for its power and batteries to operate through the sixteen 35-min "nights" which occur during each 24-h terrestrial day. *See* SPACE SHUTTLE; SPACE STATION.

Earth is not a perfect sphere. Its rotation causes its equatorial diameter to be 26 mi (42 km) greater than its corresponding polar dimension. For LEO satellites at altitudes below 3700 mi (6000 km), a retrograde inclination slightly greater than 90° may be selected which will cause the orbital plane to rotate eastward at exactly one revolution per year. This equatorial bulge phenomenon has the desirable result of permitting the plane of such Sun-synchronous orbits, as viewed from the Sun, to remain in the same apparent orientation throughout the year. In more practical terms, if such a Sun-synchronous satellite crosses the Equator in Brazil at 10:00 a.m. on January 1, it will also do so on June 30 or on any other day of the year. Since the orbital plane remains fixed relative to the Earth-Sun axis, the equatorial crossing time also occurs at the same local time at any longitude. This is ideal for weather, Earth resources monitoring, and reconnaissance purposes, because shadows will fall with the same relative length in the same direction and daily weather buildups will be imaged at essentially the same stage from each orbit to the next. *See* METEOROLOGICAL SATELLITES; MILITARY SATELLITES; REMOTE SENSING.

Earth has a period of rotation relative to the fixed stars of 23 h 56 min 4 s, which is one sidereal day. A satellite orbit of this period is said to be a geosynchronous orbit (GEO). If this orbit is also circular and equatorial, the spacecraft is said to be geostationary, because it remains in a fixed position relative to any observer on the approximately one-third of Earth from which the satellite is visible. Its principal advantage for communications is that, once pointed at the GEO spacecraft, an antenna on Earth never needs to be repointed. *See* COMMUNICATIONS SATELLITE.

In addition to communications, the GEO arc is used for weather observation spacecraft. Three such spacecraft evenly spaced along the Equator can monitor continuously severe weather around the entire globe, with the exception of regions within about 10° of the North and South poles, where hurricanes and tornadoes are absent.

Many *Explorer*-class spacecraft [special-purpose smaller satellites, typically 150– 500 lb (70–230 kg) mass] have been devoted to studying phenomena whose investigation requires direct sampling of the local environment, such as magnetic fields and associated ionized plasma particles in Earth's magnetosphere and radiation (Van Allen) belts. Their orbits have been quite varied. Most have traveled in highly eccentric Earth orbits, characterized by perigees (lowest altitudes) of 100–200 mi (160–320 km) and apogees (highest altitudes) out to lunar distances. *See* SCIENTIFIC SATELLITES.

During the 1990s, radio navigation satellite systems assumed global importance. The two leading systems are the U.S. Global Positioning Satellite (GPS) constellation and the Russian GLONASS system. *See* SATELLITE NAVIGATION SYSTEMS.

The size and shape of a spacecraft is almost always dictated primarily by its mission requirements. The principal constraints are usually imposed by the dimensions and shape of the satellite payload provisions of the launch vehicle. An important requirement of virtually all powered automated spacecraft is sufficient solar cell mounting area both to power the payload in sunlight and to charge its batteries to continue payload operations during solar eclipse periods. Another requirement is to provide spacecraft attitude stabilization and control so that sensors and antennas can be pointed in the required directions. *See* SPACE FLIGHT; SPACECRAFT STRUCTURE. [J.F.Cl.]

Satellite astronomy The study of astronomical objects by using detectors mounted on Earth-orbiting satellites or deep-space probes so that observations unobstructed by the Earth's atmosphere can be made. The Earth's atmosphere allows only a narrow slice of the visible and near-infrared spectrum through, in addition to much of the radio band. Even at visible and near-infrared wavelengths, atmospheric turbulence distorts the light and smears the images of ground-based telescopes, limiting their resolution to about 1 arc-second.

This article discusses orbiting telescopes that observe electromagnetic radiation that is blocked by the Earth's atmosphere in the microwave, infrared, ultraviolet, x-ray, and gamma-ray regions of the electromagnetic spectrum. For a discussion of the Hubble Space Telescope, which was launched in 1990 to make visible, ultraviolet, and near-infrared observations at a higher resolution than previously possible, *see* SPACE TELESCOPE, HUBBLE.

Cosmic background radiation. The shortest radio wavelengths are blocked so that studies of the high-frequency end of the spectrum of the cosmic microwave background radiation, which is the thermal blackbody radiation at approximately 3-K temperature and is the signature of the big bang, must be made from high-altitude balloons, rockets, or satellites. The *Cosmic Background Explorer* (*COBE*) satellite carried out such studies from 1989 to 1991 and provided discoveries of historic importance, as did the Wilkinson Microwave Anisotropy Probe (WMAP), launched in 2001. *See* COSMIC BACKGROUND RADIATION.

Infrared astronomy. At infrared wavelengths longer than about 2 micrometers (that is, some four times that of visible light), the atmosphere is largely opaque, and again astronomy must be done from balloons, rockets, and satellites. In 1983 the United States launched the *Infrared Astronomical Satellite* (*IRAS*) into low Earth orbit, where it carried out the first all-sky survey in four different infrared-wavelength bands over the next 2 years.

The European Space Agency's *Infrared Space Observatory* (*ISO*; 1995–1998) was designed to do detailed studies of selected regions of the sky with better angular resolution, wider wavelength coverage, enhanced imaging and spectroscopic capabilities, and higher sensitivity than *IRAS*. In 2003, the National Aeronautics and Space Administration (NASA) launched the Spitzer Telescope, the last of its four great observatories, with infrared arrays that were substantially larger and more sensitive than those on *ISO*. *See* INFRARED ASTRONOMY.

Ultraviolet astronomy. Since the Earth's atmosphere is opaque to ultraviolet (UV) light with wavelengths shorter than about 310 nanometers, ultraviolet astronomy had to await the space age. Astrophysical problems were explored with the several ultraviolet detector systems flown on the *OSO* (*Orbiting Solar Observatory*) and *OAO* (*Orbiting Astronomical Observatory*) satellite series in the 1960s and early 1970s, as well as with the subsequent *IUE* (*International Ultraviolet Explorer*) satellite. A much more powerful tool became available in 1990 with the launch of the Hubble Space Telescope. In June 1990 the *ROSAT* satellite was launched by NASA for the Germans, and carried out the first far-ultraviolet sky survey with the Wide Field Camera supplied by United Kingdom investigators. The first dedicated ultraviolet astronomy satellite, the *Extreme Ultraviolet Explorer* (*EUVE*), was launched in 1992 and operated until January 2001.

The Wide Field Camera ultraviolet telescope on *ROSAT* and the ultraviolet telescopes on *EUVE* detected some 400 far-ultraviolet objects in several bands in the wavelength range 6–80 nm. *EUVE* also enabled ultraviolet spectra on a great variety of objects to be measured, from coronae of relatively nearby stars (such as alpha Centauri) to measurements of an unexpectedly bright ultraviolet halo around the active galaxy M87 in the Virgo cluster of galaxies.

The major leap forward in ultraviolet observations, both imaging and spectra, of galactic objects came with the Hubble Space Telescope. Even with its initially blurred vision, this instrument made countless discoveries by obtaining much higher spatial resolution in the ultraviolet than ever before. Its images of SN1987A were able to resolve the expanding ring of ejecta from the bright supernova and the presupernova shell of gas expelled by the giant. With the enhanced ultraviolet sensitivity of the repaired Hubble Space Telescope, significant studies of the nature of quasars and distant galaxies became possible. *See* GALAXY, EXTERNAL; SUPERNOVA.

The *Far Ultraviolet Spectroscopic Explorer* (*FUSE*), launched in 1999, studies a wide range of astronomical problems in the 90.5-118.7-nanometer wavelength region through the use of high-resolution spectroscopy. The *FUSE* bandpass complements the spectral coverage provided by the Hubble Space Telescope, which extends down to about 117 nm.

X-ray astronomy. X-ray astronomy can be done only from above the Earth's atmosphere. The first *Small Astronomy Satellite* (*SAS 1;* 1970), designated *Uhuru*, carried two proportional-counter x-ray detectors. The *OSO* satellites also carried cosmic x-ray detectors (proportional counters similar to *Uhuru*) and contributed much to the detailed understanding of individual sources. The *Astronomical Netherlands Satellite* (*ANS*; 1974) was the first x-ray observatory. Both it and the *SAS 3* satellite (1975) contained a variety of x-ray detectors. A major increase in sensitivity for x-ray astronomy was achieved with the *High Energy Astronomical Observatory* (*HEAO*) satellite (1977).

The *HEAO 2* satellite, or *Einstein Observatory* (1978), provided the first x-ray images of celestial objects and detected thousands of new sources. The European satellite *EXOSAT* (1982) provided follow up x-ray imaging and spectroscopy to *Einstein*. It was particularly sensitive to very low energy x-ray sources, although its total collecting area was much less than that of the *Einstein Observatory*.

ROSAT (1990–1999) was a relatively large x-ray telescope with approximately twice the sensitivity of the *Einstein Observatory*. *ROSAT* carried out the first all-sky imaging x-ray survey, discovering more than 60,000 sources, and thus was as revealing as the Palomar survey for optical astronomy. The all-sky survey was followed by pointed observations.

In 1993 the Japanese x-ray program launched *ASCA*, the first x-ray imaging telescope with energy response extending up to 8 keV. This was a major breakthrough since it allowed imaging and spectroscopy of objects in the x-ray light of their iron emission lines.

NASA's *Rossi X-ray Timing Explorer* (*RXTE*), launched in 1995, carries three telescopic instruments that cover a wide energy range, 2–200 keV, provide accurate timing and measurement of x-ray sources, and can detect emissions as brief as 10–100 microseconds.

The Italian-Dutch x-ray satellite *BeppoSAX* (1996) is characterized by a very wide spectral coverage (0.1–300 keV) with balanced performances from its low- and high-energy instrumentation. It discovered the x-ray afterglow of gamma-ray bursts, enabling them to be more precisely located and allowing follow-up radio and optical observations that confirmed that the bursts are of cosmological origin.

The *Chandra X-ray Observatory* (*CXO*; 1999), the third of NASA's great observatories, has the highest spatial and energy resolution of any x-ray observatory in orbit. At the focus of this 50-foot-long (15-m) telescope are two detectors, the Advanced CCD Imaging Spectrometer (ACIS) and the High-Resolution Camera (HRC). The ACIS uses 10 charge-coupled devices (CCDs) to measure the energy, location, and arrival time of each photon, while the HRC uses a microchannel plate. *See* CHARGE-COUPLED DEVICES.

The European Space Agency's *X-ray Multimirror Observatory*, renamed *XMM-Newton* (2000), carries three advanced telescopes, each containing 58 concentric mirrors, nested so as to offer the largest possible collecting area. Its highly eccentric orbit enables long, uninterrupted observations. *See* X-RAY ASTRONOMY.

Gamma-ray astronomy. Gamma rays, more energetic than x-rays, still do not penetrate the Earth's atmosphere. *SAS 2*, launched in 1972, first established the existence of gamma-ray point sources (such as the Crab and Vela pulsars) at energies of about 100 MeV. A more sensitive follow-up mission, *COS-B*, was launched by the European Space Agency in 1975.

The *Compton Gamma-Ray Observatory* (*CGRO*; 1991–2000), the second of NASA's great observatories, carried four high-sensitivity gamma-ray detectors: EGRET (Energetic Gamma-Ray Experiment Telescope, a much larger and more sensitive spark chamber than on *COS-B*), for the energy range 30 MeV–10 GeV; COMPTEL (Compton Telescope), a Compton-scattering telescope sensitive in the poorly explored 1–30-MeV band; OSSE (Oriented Scintillation Spectrometer Experiment), a scintillator detector sensitive in the 100-keV–10-MeV band, and thus able to detect hard x-ray sources; and BATSE (Burst and Transient Source Experiment), a detector system specifically designed to study gamma-ray bursts and determine their arrival directions. Each of these instruments obtained numerous significant discoveries. *See* GAMMA-RAY ASTRONOMY. [J.E.Gr.]

Satellite meteorology The branch of meteorological science that uses meteorological sensing elements on satellites to define the past and present state of the atmosphere. Meteorological satellites can measure a wide spectrum of electromagnetic radiation in real time, providing the meteorologist with a supplemental source of data.

Modern satellites are sent aloft with multichannel high-resolution radiometers covering an extensive range of infrared and microwave wavelengths. Radiometers sense cloudy and clear-air atmospheric radiation at various vertical levels, atmospheric moisture content, ground and sea surface temperatures, and ocean winds, and provide visual imagery as well. *See* METEOROLOGICAL SATELLITES.

There are two satellite platforms used for satellite meteorology: geostationary and polar. Geostationary (geo) satellites orbit the Earth at a distance that allows them to make one orbit every 24 hours. By establishing the orbit over the Equator, the satellite appears to remain stationary in the sky. This is important for continuous scanning of a region on the Earth for mesoscale (approximately 10–1000 km horizontal) forecasting.

Polar satellites orbit the Earth in any range of orbital distances with a high inclination angle that causes part of the orbit to fly over polar regions. The orbital distance of 100–200 mi (160–320 km) is selected for meteorological applications, enabling the satellite to fly over a part of the Earth at about the same time every day. With orbital distances of a few hundred miles, the easiest way to visualize the Earth-satellite relationship is to think of a satellite orbiting the Earth pole-to-pole while the Earth rotates independently beneath the orbiting satellite. The advantage of polar platforms is that they eventually fly over most of the Earth. This is important for climate studies since one set of instruments with known properties will view the entire world.

The enormous aerial coverage by satellite sensors bridges many of the observational gaps over the Earth's surface. Satellite data instantaneously give meteorologists up-to-the minute views of current weather phenomena.

Images derived from the visual channels are presented as black and white photographs. The brightness is solely due to the reflected solar light illuminating the Earth. Visible images are useful for determining general cloud patterns and detailed cloud structure. In addition to clouds, visible imagery shows snowcover, which is useful for diagnosing snow amount by observing how fast the snow melts following a storm. Cloud patterns defined by visual imagery can give the meteorologist detailed information about the strength and location of weather systems, which is important for determining storm motion and provides a first guess or forecast as to when a storm will move into a region. *See* CLOUD.

More quantitative information is available from infrared sensors, which measure radiation at longer wavelengths (from infrared to microwave). By analyzing the infrared data, the ground surface, cloud top, and even intermediate clear air temperatures can be determined 24 hours a day. By relating the cloud top temperature in the infrared radiation to an atmospheric temperature profile from balloon data, cloud top height can be estimated. This is a very useful indicator of convective storm intensity since more vigorous convection will generally extend higher in the atmosphere and appear colder. *See* BLACKBODY; MICROWAVE; PLANCK'S RADIATION LAW.

The advent of geosynchronous satellites allowed the position of cloud elements to be traced over time. These cloud movements can be converted to winds, which can provide an additional source of data in an otherwise unobserved region. These techniques are most valuable for determination of mid- and high-level winds, particularly over tropical ocean areas. Other applications have shown that low-level winds can be determined in more spatially limited environments, such as those near thunderstorms, but those winds become more uncertain when the cloud elements grow vertically into air with a different speed and direction (a sheared environment). *See* WIND.

By using a wide variety of sensors, satellite data provide measurements of phenomena from the largest-scale global heat and energy budgets down to details of individual thunderstorms. Having both polar orbiting and geosynchronous satellites allows coverage over most Earth locations at time intervals from 3 minutes to 3 hours.

The greatest gain with the introduction of weather satellites was in early detection, positioning, and monitoring of the strength of tropical storms (hurricanes, typhoons). Lack of conventional meteorological data over the tropics (particularly the oceanic areas) makes satellite data indispensable for this task. The hurricane is one of the most spectacular satellite images. The exact position, estimates of winds, and qualitative determination of strength are possible with continuous monitoring of satellite imagery in the visible channels. In addition, infrared sensors provide information on cloud top height, important for locating rain bands. Microwave sensors can penetrate the storm to provide an indication of the interior core's relative warmth, closely related to the strength of the hurricane, and sea surface temperature to assess its development potential. *See* HURRICANE; TROPICAL METEOROLOGY.

Most significant weather events experienced by society—heavy rain or snow, severe thunderstorms, or high winds—are organized by systems that have horizontal dimensions of about 60 mi (100 km). These weather systems, known as mesoscale convective systems, often fall between stations of conventional observing networks. Hence, meteorologists might miss them were it not for satellite sensing. *See* HAIL; MESOMETEOROLOGY; METEOROLOGY; PRECIPITATION (METEOROLOGY); STORM; THUNDERSTORM; TORNADO; WEATHER FORECASTING AND PREDICTION. [D.L.B.; J.A.McG.]

Satellite navigation systems Electronic navigation systems employing artificial satellites as radio signal sources and position references. Satellites have the advantage that their signals have line-of-sight propagation to almost an entire hemisphere of the Earth. These systems have become the preeminent radio navigation systems and are gradually replacing ground-based systems such as Loran and Omega. Two main types of satellite navigation systems have been developed, Doppler systems and differential-time-of-arrival systems. *See* ELECTRONIC NAVIGATION SYSTEMS; LORAN; SATELLITE (SPACECRAFT).

The first operational systems were Doppler systems. The Doppler technique uses the Doppler shift of signals received from a low-orbit satellite. The frequency of the signal received from a moving source is shifted by an amount proportional to its velocity toward or away from the receiver. As the satellite passes the receiver, the Doppler shift will decrease from a positive to a negative value. The distance from the satellite track determines the magnitude of the shift. The crossover from a positive to negative shift will occur at the point of closest approach. The Earth's rotation during the satellite pass changes the shape of the curve in a way that indicates which side of the satellite track the receiver is on. These satellites orbit at relatively low altitude, about 900 km (550 mi), in order to produce a large Doppler shift. *See* DOPPLER EFFECT.

Doppler systems have inherent limitations. They provide only two-dimensional position fixes. Altitude must be determined by some other means. They provide limited accuracy and no velocity information. Because of their low altitude and limited coverage area, they provide at most a few position fixes a day. As a result, these systems have been phased out.

In differential-time-of-arrival systems, the receiver measures the difference of the time of arrival of signals transmitted simultaneously from several satellites. Two such systems have been put into operation. The Global Positioning System (GPS) was developed by the United States. The former Soviet Union developed a similar system called Glonass, which is now operated by Russia and operates with some minor differences, similarly to GPS.

The Global Positioning System provides worldwide coverage with four satellites in each of six planes for a total of 24 satellites. The orbits are nearly circular and have an inclination of 55°. The ascending nodes of the six planes are equally spaced around the Equator. An altitude of 20,200 km (12,500 mi) gives the orbits a subsynchronous period such that they repeat their ground track every second orbit. The satellites are three-axis-stabilized by a combination of reaction wheels and magnetic torque applied against the Earth's magnetic field. The satellite is rotated so that the Earth panel with the antennas always faces the Earth and the solar panels are at right angles to the Sun.

Each satellite broadcasts a ranging signal which is measured by all satellites in view. The satellites then broadcast a data message which contains the satellite ephemeris and all the measurements which it received. In this way, each member of a pair of ranging satellites has access to the pseudorange measurements in both directions (from the first satellite to the second, and vice versa). Each intersatellite range measurement is a combination of the geometric distance between the satellites and the difference of their clock biases. The two pseudoranges can be combined to yield an independent derived clock measurement and a derived true range measurement. The actual implementation of this requires additional terms to compensate for the satellite's motion and to account for the general-relativistic offset between the two satellites.

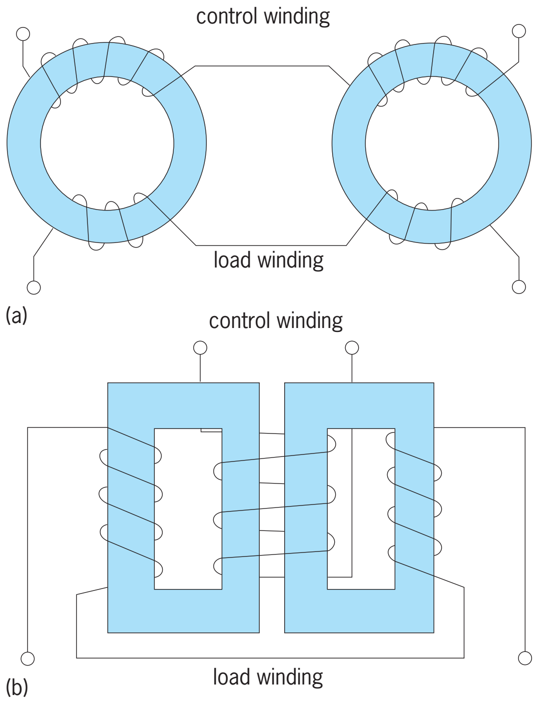
In a satellite navigation receiver, the antenna converts the radio signal from the satellite to electric current which can be filtered, amplified, and processed by the receiver. The phase center of the antenna is the position which the receiver locates. A preamplifier filters and amplifies the radio-frequency signal. A mixer shifts the L-band frequency to a lower intermediate frequency (IF) by, in effect, subtracting the frequency of a local oscillator from the incoming signal while preserving the signal modulation. Most newer receiver designs convert the intermediate-frequency signal to digital samples at this point. *See* ANALOG-TO-DIGITAL CONVERTER; MIXER.

In addition to providing navigation service to aircraft, vehicles, and watercraft, many other uses have become practical because of the accuracy, global coverage, and low cost of satellite navigation receivers. Small, inexpensive, handheld receivers are available for use in hiker, boating, and other recreational activities. In other applications, the receiver is combined with a communication system or a geographic database. Surveying has been revolutionized by a very accurate type of differential system. A surveying system can take advantage of the fact that it is not moving for the duration of its measurements. This yields very precise position estimates relative to a local reference point. The tectonic motion of the Earth's crust around fault lines has been measured with an accuracy of 1 cm (0.4 in.) or less. *See* SURVEYING.

In automobile systems, the navigation receiver is combined with a display and a digitized map which is stored on a CD-ROM. Vehicle tracking systems use satellite navigation to determine a vehicle's position, which is then periodically reported to a central location by using a cellular telephone or some other communications system. Variations of this concept have been employed to track livestock, weather balloons, wildlife migration, and many other things. The ability to easily record the exact location at any point makes satellite navigation receivers ideal for mapping environmental data such as soil conditions, forest growth patterns, and pollution. Such data are used to monitor environmental damage. In aircraft navigation systems, satellite navigation is often combined with an inertial navigation system. The inertial system improves short-term accuracy, particularly during a maneuver. The satellite navigation maintains accuracy over the long term. *See* INERTIAL GUIDANCE SYSTEM. [L.J.D.]

Saturable reactor An iron-core inductor in which the effective inductance is changed by varying the permeability of the core. Saturable-core reactors are used to control large alternating currents where rheostats are impractical. Theater light dimmers often employ saturable reactors.

In the illustration of two types of saturable-core reactors, illus. *a* shows two separate cores, while in illus. *b* a three-legged core is formed by placing two two-legged cores together. The load winding, connected in series with the load, carries the alternating current and acts as an inductive element. The control winding carries a direct current of adjustable magnitude, which can saturate the magnetic core.



Typical construction of saturable-core reactors. (*a*) Two separate cores. (*b*) Three-legged cores.

Reducing the magnitude of the control current reduces the intensity of saturation. This increases the reactance of the load winding. As the reactance increases, the voltage drop in the load winding increases and causes a reduction in the magnitude of the voltage applied to the load. *See* INDUCTANCE; MAGNETIC PERMEABILITY; MAGNETIZATION. [W.S.P.]

Saturation The condition in which, after a sufficient increase in a causal force, further increase in the force produces no additional increase in the resultant effect. Many natural phenomena display saturation. For example, after a magnetizing force becomes sufficiently strong, further increase in the force produces no additional magnetization in a magnetic circuit; all the magnetic domains have been aligned, and the magnetic material is saturated. *See* MAGNETIC MATERIALS.

After a sponge has absorbed all the liquid it can hold, it is saturated. In thermionic vacuum tubes thermal saturation is reached when further increase in cathode temperature produces no (or negligible) increase in cathode current; anode saturation is reached when further increase in plate voltage produces substantially no increase in anode current. *See* DISTORTION (ELECTRONIC CIRCUITS); SATURATION CURRENT; VACUUM TUBE.

In colorimetry the purer a color is, the higher its saturation. Radiation from a color of low saturation contains frequencies throughout much of the visible spectrum. *See* COLORIMETRY. [F.H.R.]

Saturation current A term having a variety of specific applications but generally meaning the maximum current which can be obtained under certain conditions.

In a simple two-element vacuum tube, it refers to either the space-charge-limited current on one hand or the temperature-limited current on the other. In the first case, further increase in filament temperature produces no significant increase in anode current, whereas in the latter a further increase in voltage produces only a relatively small increase in current. *See* VACUUM TUBE.

In a gaseous-discharge device, the saturation current is the maximum current which can be obtained for a given mode of discharge. Attempts to increase the current result in a different type of discharge. *See* ELECTRICAL CONDUCTION IN GASES.

A third case is that of a semiconductor. Here again the saturation current is that maximum current which just precedes a change in conduction mode. *See* SEMICONDUCTOR. [G.H.M.]

Saturn The second-largest planet in the solar system and the sixth in order of distance to the Sun. The outermost planet known prior to 1781, Saturn is surrounded by a beautiful system of rings. Saturn is also the only planet that has a satellite (Titan) with a dense atmosphere. This distant planetary system has been visited by four NASA spacecraft, including *Cassini*, which went into orbit around the planet in July 2004.

Saturn makes one revolution about the Sun in 29.42 years. The equatorial diameter of Saturn is about 75,000 mi (120,540 km), and the polar diameter about 67,600 mi (108,700 km). The volume is 769 (Earth = 1) with a few percent uncertainty. The mass is about 95.2 (Earth = 1) or 1/3500 (Sun = 1). The mean density is 0.70 g/cm^3, the lowest mean density of all the planets. The rotation axis of both the planet and the rings is inclined 27° to the perpendicular to the orbital plane. The visible cloud layers of Saturn are much more homogeneous than those of Jupiter. There is no feature comparable to the Great Red Spot, and the contrast of the features that are visible is very low (Fig. 1).

The optical spectrum of Saturn is characterized by strong absorption bands of methane (CH_4) and by much weaker bands of ammonia (NH_3). Absorption lines of molecular hydrogen (H_2) have also been detected.

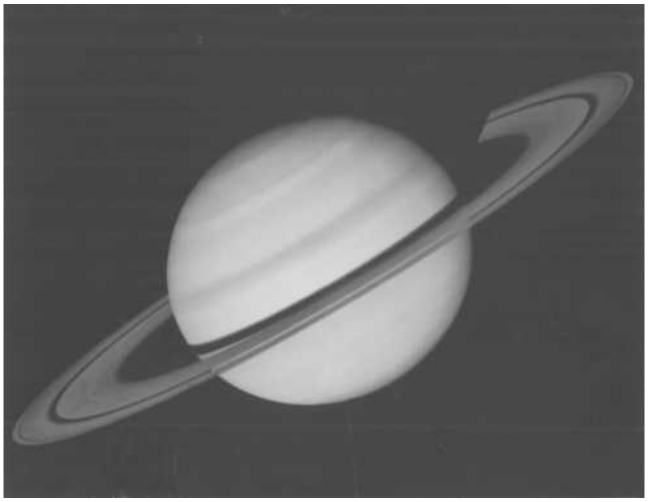


Fig. 1. Saturn, viewed from *Voyager 1*. The soft, velvety appearance of the low-contrast banded structure is due to scattering by a haze layer above the planet's cloud deck. (*NASA*)

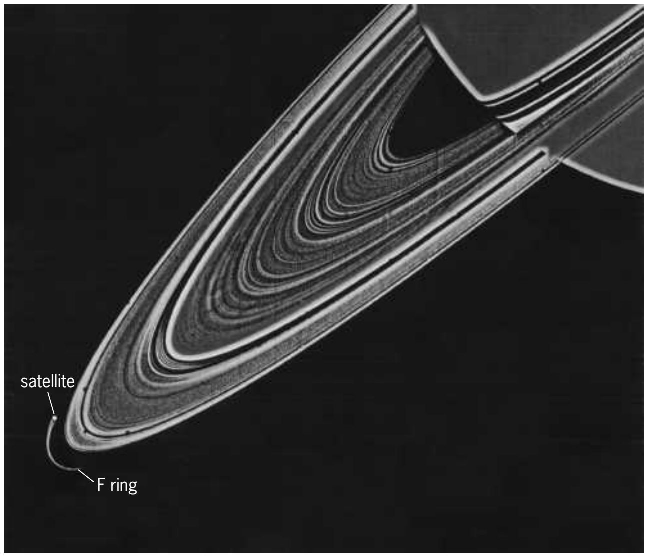

Fig. 2. Saturn's rings, viewed from *Voyager 1*. Approximately 95 individual concentric features are visible. One of the satellites discovered by *Voyager 1* is visible just inside the narrow F ring. (*NASA*)

The temperature the planet should assume in response to solar heating is calculated to be about 76 K (−323°F), somewhat lower than the measured value of 92 K (−294°F). This suggests that Saturn has an internal heat source of roughly the same magnitude as that on Jupiter. As in the case of Jupiter, a thermal inversion exists in the upper atmosphere. The inversion region is well above the main cloud layer, which is thought to consist primarily of frozen ammonia crystals, with an admixture of some other substances to provide the yellowish color sometimes observed in the equatorial zone.

Theoretical models for the internal structure of Saturn are similar to those for Jupiter, that is, a dense core surrounded by hydrogen compressed to a metallic state which gradually merges into an extremely deep atmosphere. The fact that the two planets radiate comparable amounts of energy despite their difference in size means that smaller Saturn must have some additional energy source besides gravitational contraction. The existence of a magnetic field and belts of trapped electrons has been deduced from observations of nonthermal radiation and mapped out in detail by the Pioneer and Voyager spacecraft.

Jupiter and Saturn are relatively similar bodies. Both seem to have compositions virtually identical with that of the Sun and the other stars—rich in hydrogen and helium. In that sense, they may represent the primitive material from which the entire solar system was formed, whereas the other planets have undergone fractionation processes resulting in the loss of most of the light gases. This conclusion has been strengthened by measurements of the heavy isotope of hydrogen known as deuterium. They demonstrate that the hydrogen that makes up most of the mass of both Jupiter and Saturn was captured directly from the solar nebula when these planets formed 4.5 billion years ago. However, both Jupiter and Saturn show an enhancement of the carbon/hydrogen ratio (as determined from methane and hydrogen) compared with the Sun. This suggests that both of these planets formed in a two-stage process that led initially to formation of a large core with an outgassed, secondary atmosphere, followed by the attraction of an envelope of gases from the surrounding nebula. *See* PLANETARY PHYSICS.

The most remarkable feature associated with Saturn is the complex ring system that surrounds the planet (Fig. 2). The system is divided into four main regions, designated A through D. The narrow F ring is located just beyond the edge of ring A, and there are G and E rings still farther out. Each of the four main regions is subdivided into many individual "ringlets," so that Saturn is actually surrounded by thousands of rings. The ring system is made up of myriad separate particles that move independently in flat, mostly circular orbits in Saturn's equatorial plane. Periodic perturbations by the major satellites are responsible, in part, for the main divisions of Saturn's rings.

As of July 2004, Saturn had 30 confirmed satellites. The largest and brightest, Titan, is visible with small telescopes; the other satellites are much fainter. Titan's mean apparent diameter corresponds to a linear diameter of approximately 3440 mi (5550 km). But this diameter refers to the satellite's atmosphere, which is filled with a dense aerosol produced photochemically by incident sunlight. The solid surface of Titan has a diameter of 3200 mi (5150 km), making this satellite larger than Mercury but smaller than Jupiter's giant Ganymede. This object contains a large fraction of icy material and is thus quite different from the Moon or the inner planets in composition. Furthermore, it is large and cold enough to retain a thick, nitrogen (N_2)-dominated atmosphere that contains a few percent of methane (CH_4) and exerts a surface pressure of 1.5 bars (1.5×10^5 Pa), or 1.5 times the sea-level pressure on Earth. The main constituent of this atmosphere is molecular nitrogen. The surface of Titan is so cold [94 ± 2K or (-290 ± 4°F] that takes of liquid ethane may be present. *See* PLANET; SATELLITE (ASTRONOMY). [T.C.O.]

Saurischia One of two orders of extinct reptiles popularly known as dinosaurs, the other being the Ornithischia. The two orders are distinguished by a number of anatomical differences, but foremost is the triradiate shape of the saurischian pelvis, in contrast to the tetraradiate pelvis of ornithischians. Both dinosaurian orders originated from thecodont reptiles by Middle Triassic times and are classified together with the order Thecodontia in the infraclass Archosauria. Saurischian bones have been found on all continents except Antarctica, and in rock strata ranging from Middle Triassic to latest Cretaceous in age.

Most recent classifications recognize two suborders, the Sauropodomorpha and the Theropoda. The latter includes all carnivorous dinosaurs, and the former consists of the *Brontosaurus*-like animals (sauropods), together with their ancestral stock, the prosauropods. The Prosauropoda includes the oldest known saurischians, ranging from Middle Triassic time to the close of the Triassic Period. Like their ancestral thecodont stock, many show pronounced anatomical tendencies toward bipedal posture. Most, like *Plateosaurus*, appear to have been herbivores, but fragmentary evidence indicates that some may have been carnivorous. In general, prosauropods were of moderate size, up to 15–20 ft (4.5–6 m) long, and less than a ton in weight.

The saurischians, like the ornithischians, became extinct at the end of the Cretaceous, due to unknown causes. Most saurischians died out, leaving no descendants, but studies indicate that birds, via *Archaeopteryx*, probably are direct descendants of a small theropod dinosaur. *See* ARCHAEORNITHES; ARCHOSAURIA; DINOSAUR; ORNITHISCHIA. [J.H.O.]

Sauropterygia An infraclass of Mesozoic reptiles that are, without exception, adapted to the marine environment. The infraclass includes the nothosaurs, plesiosaurs, and placodonts. These reptiles, along with the ichthyosaurs, played a significant role as predators within the marine animal community of the Mesozoic Era.

The placodonts are a distinctive but highly varied assemblage of aquatic reptiles. They had short bodies, paddlelike limbs, and flat cheek teeth designed for crushing hard-shelled prey. The genus *Helodus* was covered by a dorsal bony armor and a roofing of dermal scutes, but most other genera lacked armor. Placodonts have come only from rocks of the Middle and Upper Triassic of Europe, North Africa, and the Middle East. *See* PLACODONTIA.

The Nothosauria are the relatively generalized stem group from which the plesiosaurs evolved. With the exception of a single New World species and a record from Japan, nothosaurs are known primarily from Europe and the Near East (Israel) in rocks of Triassic age. The nothosaurs are notably diverse in the mode and degree of secondary aquatic modification. The directions of aquatic specialization involve shortening, or more often lengthening, of the neck; enlargement of the orbits or the temporal fenestrae; and reduction, or more commonly increase, in the number of phalanges in manus (hand), pes (foot), or both. A feature of considerable evolutionary significance in the light of plesiosaurian differentiation is the great individual variability in the number of presacral vertebrae (32–42) in *Pachypleurosaurus edwardsi*.

The Plesiosauria are the successful, compact, and highly specialized offshoot of the nothosaurs that attained worldwide distribution. The early steps of aquatic adaptation, initiated by the nothosaurs, have led to extensive anatomical modifications: The region comprising chest and abdomen became short, stout, and inflexible; the ventral bones of shoulder girdle and pelvis increased in area enormously; and the limbs, transformed into large flippers, became the principal organs of propulsion. Two major trends of plesiosaur evolution may be discerned since the Early Jurassic: In the one group there was a tendency toward a shortening of the neck from 27 to 13 vertebrae and an increase in skull size: in the other group the opposite trend led to forms of bizarre body proportions, for example, *Elasmosaurus*, with a neck containing 76 vertebrae. The plesiosaurs were carnivorous.

The precise affinities of placodonts, nothosaurs, and plesiosaurs remain uncertain. No earlier group of reptiles from which they might have come is known, and they left no descendants. *See* NOTHOSAURIA; PLACODONTIA; PLESIOSAURIA; REPTILIA. [R.Z.; E.C.O.]

Savanna The term savanna was originally used to describe a tropical grassland with more or less scattered dense tree areas. This vegetation type is very abundant in tropical and subtropical areas, primarily because of climatic factors. The modern definition of savanna includes a variety of physiognomically or environmentally similar vegetation types in tropical and extratropical regions. The physiognomically savannalike extratropical vegetation types (forest tundra, forest steppe, and everglades) differ greatly in environment and species composition.

In the widest sense savanna includes a range of vegetation zones from tropical savannas with vegetation types such as the savanna woodlands to tropical grassland and thornbush. In the extratropical regions it includes the "temperate" and "cold savanna" vegetation types known under such names as taiga, forest tundra, or glades. *See* GRASSLAND ECOSYSTEM; TAIGA; TUNDRA. [H.Li.]

Savory A herb of the mint family in the genus *Satureja*. There are more than 100 species, but only *S. hortensis* (summer savory) and *S. montana* (winter savory) are grown for flavoring purposes. *See* LAMIALES.

Summer savory, an annual herb, is characterized by long thin wiry stems with long internodes between small leaves. Winter savory is a perennial in most climates and, unlike summer savory, will tolerate some freezing weather. It can become woody after one or two growing seasons.

Savory is indigenous to areas surrounding the Mediterranean Sea. *Satureja montana* occurs wild from North Africa to as far north as Russia but is little cultivated. *Satureja hortensis*, which is widely cultivated, is native to Europe. Both types of savory are harvested or cut two or three times a year, after which the leaves are dehydrated and separated from the stems to be used as a spice in various foods, including poultry seasoning and beans. *See* SPICE AND FLAVORING. [S.Kir.]

Saxifragales An order of flowering plants near the base of the eudicots. The order's exact relationships to other orders are still under study, but the Saxifragales appear to be related to the rosid eudicots. They include 13 small to moderately sized families and perhaps around 2300 species. There are two categories: woody species that are sometimes wind-pollinated, and insect-pollinated herbs. The members are difficult to characterize morphologically but fall into several sets of families that have been considered closely related by most authors. *See* MAGNOLIOPHYTA; MAGNOLIOPSIDA; POLLINATION; ROSIDAE.

None of the families are of particular economic importance except as ornamentals, although *Cercidiphyllum* (Cercidiphyllaceae), *Liquidambar* (sweet gums), *Altingia* (both Altingiaceae), and a few others produce timbers. The largest family is Crassulaceae (1500 species), which are plants of arid zones, including the stonecrops (*Sedum*) and kalanchoes (*Kalanchoe*). A number of species are commonly cultivated ornamentals, including peony (*Paeonia*, Paeoniaceae), saxifrages (*Saxifraga*, Saxifagaceae), and witch hazel (*Hamamelis*, Hamamelidaceae); a few, the currants and gooseberries (*Ribes*, Grossulariaceae), are cultivated as fruits. *See* HAMAMELIDALES. [M.W.C.]

Scalar A term synonymous in mathematics with "real" in real number or real function. The magnitude of a vector two units in length is the real number of scalar 2. The dot or scalar product of two vectors is the product of three real numbers associated with them (the magnitude of the first vector times the magnitude of the second, times the cosine of the angle between them) and is therefore a scalar. If in the functional relationships $S = S(s, y, z)$, $\mathbf{F} = \mathbf{F}(x, y, z)$, S is a real number and $\mathbf{F}$ is a vector, then $S(s, y, z)$ is a scalar function but $\mathbf{F}(x, y, z)$ is a vector function. *See* CALCULUS OF VECTORS. [H.V.C.]

Scale (music) As a piece of music progresses, it typically outlines a set of pitches by repeatedly sounding a subset of all the possible notes. When these notes are rearranged into ascending or descending order, they are called a musical scale.

There is often a range of pitches that will be heard as the same. Perhaps the trumpet plays middle C a bit flat, while the guitar plays a bit sharp, in accordance with the artistic requirements of the musical context. The mind hears both pitches as the same note, C, and the limits of acceptability are far cruder than the ear's powers of resolution. This suggests a kind of categorical perception, where a continuum of possible stimuli (in this case, pitch) is perceived as consisting of a small number of disjoint classes. Thus scales partition pitch space into disjoint chunks. *See* MUSICAL INSTRUMENTS; PITCH; SENSATION.

In the modern Western tradition, scales are standardized subsets of the 12-tone equal temperament (abbreviated 12-tet, and also called the chromatic scale) in which each octave is divided into 12 (approximately) equal sounding divisions. These are further classified into major and minor depending on the exact ordering of the intervals, and are classified into modes depending on the starting point. Historically, however, scales based on 12-tet are fairly recent. In addition, other cultures use musical scales that are quite different. *See* TUNING. [W.A.Se.]

Scale (zoology) The fundamental unit of the primary scaled integument of vertebrates, of which the epidermal or dermal component may be the more conspicuous or elaborated. Although there is great diversity in detailed structure among vertebrate groups, scaled integuments may be interpreted as the most effective way of producing a physically strong external body surface, with maximum flexibility necessitated by the fundamental pattern of vertebrate locomotion relying on lateral sinusoidal movements of the body.

In the majority of extant fish the epidermis is extremely thin. The term "scale" when used in an ichthyological context usually refers to the relatively large, prominent, dermal ossification, on the outer surface of which lie so-called dental tissues. The latter—enamel or enamellike mineralizations and dentine—are therefore present at the dermoepidermal boundary. The scaled integument of fish shows a definite pattern which is governed by the orientation of the underlying myomeres and by changes in body depth and length. The general evolutionary tendency toward thinning, or size reduction, of integumentary sclerifications seen in various fish lineages is probably associated with weight reduction and increased locomotor efficiency.

Scaled integuments are absent from modern amphibians, although nonoverlapping dermal ossifications are seen in some apodans. It seems probable that the absence of scales in other modern species is associated with the secondary utilization of the integument as a respiratory surface. In most reptilian lineages, there is a ubiquity of scaled integuments, with or without dermal ossifications, but always with elaboration of epidermal tissues. The distribution of keratinaceous protein types varies in different groups of reptiles, and in this respect modern crocodilian scales exactly resemble the leg scales of birds. Scaled integuments prompted the subclass name for lepidosaurs—the tuatara, lizards, and snakes, the last two constituting the order Squamata. Lepidosaurian scales may or may not possess dermal ossifications. Among extant reptiles the extraordinary development of the dermal skeleton in turtles forms the characteristic carapace. [P.F.M.]

Scandium A chemical element, Sc, atomic number 21, atomic weight 44.956. The only naturally occurring isotope is ^{45}Sc. The electronic configuration of the ground-state, gaseous atom consists of the argon rare-gas core plus three more electrons in the 3*d*14*s*2 levels. It has an unfilled inner shell (only one 3*d* electron) and is the first transition metal. It is one of the elements of the rare-earth group. *See* PERIODIC TABLE; RARE-EARTH ELEMENTS; TRANSITION ELEMENTS.

The principal raw materials for the commercial production of scandium are uranium and tungsten tailings and slags from tin smelters or blast furnaces used in cast iron production. Wolframite (WO_3) concentrates contain 500–800 ppm scandium. *See* WOLFRAMITE.

Scandium is the least understood of the 3*d* metals. The major reason has been the unavailability of high-purity scandium metal, especially with respect to iron impurities. Many of the

Room-temperature properties of scandium metal (unless otherwise specified)

Property	Value
Atomic number	21
Atomic weight	44.9559 (^{12}C = 12)
Lattice constant (hcp, α–Sc), a_0	0.33088 nm
c_0	0.52680 nm
Density	2.989 g/cm^3
Metallic radius	0.16406 nm
Atomic volume	15.041 cm^3/mol
Transformation point	1337°C (2439°F)
Melting point	1541°C (2806°F)
Boiling point	2836°C (5137°F)
Heat capacity	25.51 J/mol K
Standard entropy, $S^\circ_{298.15}$	34.78 J/mol K
Heat of transformation	4.01 kJ/mol
Heat of fusion	14.10 kJ/mol
Heat of sublimation (at 298 K)	377.8 kJ/mol
Debye temperature (at 0 K)	345.3 K
Electronic specific heat constant	10.334 mJ/mol K^2
Magnetic susceptibility, χ_A^{298} (a)	297.6×10^{-6} emu/mol
χ_A^{298} (c)	288.6×10^{-6} emu/mol
Electrical resistivity, ρ_a^{300}	70.90 μohm-cm
ρ_c^{300}	26.88 μohm-cm
Thermal expansion, $\alpha_{a,i}$	7.55×10^{-6}
$\alpha_{c,i}$	15.68×10^{-6}
Isothermal compressibility	17.8×10^{-12} m^2/N
Bulk modulus	5.67×10^{10} N/m^2
Young's modulus	7.52×10^{10} N/m^2
Shear modulus	2.94×10^{10} N/m^2
Poisson's ratio	0.279

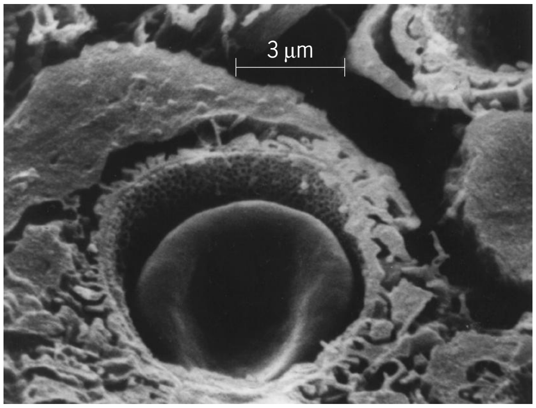
physical properties reported in the literature vary considerably, but the availability of electrotransport-purified scandium has allowed measurement of the intrinsic properties of scandium (see table).

Scandium increases the strength of aluminum. It also strengthens magnesium alloys when added to magnesium together with silver, cadmium, or yttrium. Scandium inhibits the oxidation of the light rare earths and, if added along with molybdenum, inhibits the corrosion of zirconium alloys in high-pressure steam. The addition of ScC to TiC has been reported to form the second-hardest material known. Sc_2O_3 can be used in many other oxides to improve electrical conductivity, resistance to thermal shock, stability, and density. Scandium is used in the preparation of the laser material $Gd_3ScGa_4O_{12}$, gadolinium scandium gallium garnet (GSGG). This garnet when doped with both Cr^{3+} and Nd^{3+} ions is said to be $3^1/_2$ times as efficient as the widely used Nd^{3+}-doped yttrium aluminum garnet (YAG:Nd^{3+}) laser. Ferrites and garnets containing scandium are used in switches in computers; in magnetically controlled switches that modulate light passing through the garnet; and in microwave equipment. Scandium is used in high-intensity lights. Scandium iodide is added because of its broad emission spectrum. Bulbs with mercury, NaI, and ScI_3 produce a highly efficient light output of a color close to sunlight. This is especially important when televising presentations indoors or at night. When used with night displays, the bulbs give a natural daylight appearance. Scandium metal has been used as a neutron filter. It allows 2-keV neutrons to pass through, but stops other neutrons that have higher or lower energies. *See* YTTRIUM. [J.Cap.; K.A.G.]

Scanning electron microscope

An electron microscope that builds up its image as a time sequence of points in a manner similar to that employed in television.

The imaging method of the scanning electron microscope (SEM) allows separation of the two functions of a microscope, localization and information transfer. The SEM utilizes a very fine probing beam of electrons which sweeps over the specimen to emit a variety of radiations. The signal, which is proportional to the amount of radiation leaving an individual point of the specimen at any instant, can be used to modulate the brightness of the beam of the display cathode-ray tube as it rests on the corresponding point of the image. In practice, the points follow one another with great rapidity so that the image of each point becomes an image of a line, and the line in turn can move down the screen so rapidly that the human eye sees a complete image as in television. The image can also be recorded in its entirety by allowing the point-by-point information to build up in sequence on a photographic film (see illustration).



Red blood cell in a capillary of the kidney. Ethanol cryofracture technique was followed by critical-point drying. (*From W. J. Humphreys, B. O. Spurdock, and J. S. Johnson, Critical point drying of ethanol-infiltrated, cryofractured biological specimens for scanning electron microscopy, Proceedings of the Scanning Electron Microscopy Symposium, pp. 275–282, 1974*)

As with all microscopy research, it is very often the preparative methodology that determines the success or failure of the research. A specific requirement of scanning electron microscope preparation is that the material be dried. This preparative step must be done very carefully to minimize surface tension effects. The two methods most often used—critical-point drying and freeze drying—have yielded excellent results even for very fragile biological tissue. Alternatively, the drying step can be avoided completely by observing the specimen while it is still frozen. Interior structure can be revealed by using techniques in which the specimen is broken at a low temperature. *See* ELECTRON MICROSCOPE; MICROTECHNIQUE. [T.L.H.]

Scanning tunneling microscope

An instrument for producing surface images with atomic-scale lateral resolution, in which a fine probe tip is scanned over the surface at a distance of 0.5–1 nanometer, and the resulting tunneling current, or the position of the tip required to maintain a constant tunneling current, is monitored.

Scanning tunneling microscopes have pointed electrodes that are scanned over the surface of a conducting specimen, with help from a piezoelectric crystal whose dimensions can be altered electronically. They normally generate images by holding the current between the tip of the electrode and the specimen at some constant (set-point) value by using a piezoelectric crystal to adjust the distance between the tip and the specimen surface, while the tip is piezoelectrically scanned in a raster pattern over the region of specimen surface being imaged. By holding the force, rather than the electric current, between tip and specimen at a set-point value, atomic force microscopes similarly allow the exploration of nonconducting specimens. In either case, when the height of the tip is plotted as a function of its lateral position over the specimen, an image that looks very much like the surface topography results.

It is becoming increasingly possible to record other signals (such as lateral force, capacitance, scan-related tip displacement, temperature, light intensity, or magnetic resonance) as the tip scans. For example, modern atomic force microscopes can map lateral force and conductivity along with height, while image pairs from scanning tunneling microscopes scanning to and fro can provide information about friction as well as topography.

Scanning tunneling microscopes make it possible not just to view atoms but to push them and even to rearrange them in unlikely combinations (sometimes whether or not these rearrangements are desirable). A few considerations of scale are important in understanding this process. Atoms comprise a positive nucleus and a surrounding cloud of negative electrons. These charges rearrange when another atom approaches, with unlike charges shifting to give rise to the van der Waals force of attraction between neutral atoms. This force makes gravity (and most accelerations) ignorable when contact between solid objects in the micrometer size range and smaller is involved, since surface-to-volume ratios are inversely proportional to object size.

The electric field in the scanning tunneling microscope allows plucking as well, in which adsorbed or substrate atoms are removed and transferred to the electrode tip with a suitable voltage pulse. Because the electric field from the tip falls off less rapidly with separation than do van der Waals forces, the most weakly attached nearby atom rather than the nearest may end up being removed. One solution to this problem is a hybrid approach. By invoking the tip electric field for bond breaking only when the tip is sufficiently close to the target atom that the van der Waals forces contribute as well, atoms on silicon could be singly removed and redeposited at will.

A third kind of selective bond breaking was also demonstrated. It involved the selective breaking of silicon-hydrogen bonds using electron energies (that is, pulse voltages) below those necessary to break bonds directly. Since the desorption probability was observed to vary exponentially with the tip-specimen current, it is believed that vibrational heating from inelastic electron tunneling mediated the chemical transition in this work. This work involves bond alteration at the level of signal atoms, the ultimate frontier for lithographic miniaturization. [P.B.F.]

Scaphopoda A class in the phylum Mollusca, comprising two orders, Gadilida and Dentaliida. The class is wholly marine; it is common and probably most diverse in the deep sea, and poorly represented in brackish, littoral, or estuarine habitats. Scaphopods are characterized by a tapering tubular shell with two apertures: the large ventral aperture that the foot extends out of and a small dorsal aperture. The tapering shells found in the Dentaliida give the class its common names tusk or tooth shells. Adult scaphopods range in length from about 3 to 150 mm. The shell consists of aragonite arranged in three or four layers.

Systematically the class is related to bivalves, and probably arose from a member of the extinct molluscan class, the Rostroconchia. The two orders can be separated on the basis of shell structure. Typically gadilids have the widest part of the shell more toward the middle of the animal, while in the dentaliids the widest part of the shell is the ventral aperture. Gadilid shells are typically highly polished, while dentaliid shells lack this luster. In addition, there are significant internal morphological differences between the two orders.

Scaphopods are bilaterally symmetrical and surrounded by the mantle, which forms a tube. The body is suspended in the tube from the dorsal-anterior part of the shell. The largest part of the mantle cavity is adjacent to the ventral aperture and contains the foot, head, and feeding tentacles, called captacula. Each captaculum consist of a long extendable stalk and a terminal bulb. The captacular bulb is covered with cilia, and the stalk may have a ciliated band or tufts of cilia along it.

Scaphopods eat foraminiferans, and other small shelled organisms such as bivalves or shelled eggs. Dentaliids can also ingest sediment. Prey are captured by the use of the captacula, which have a chemical adhesive system to attach to prey. The foot is used to burrow and construct a feeding cavity.

Scaphopods live in unconsolidated sediments, and most members of any population are typically completely buried at any one time. However, scaphopods back up to the surface and extend the dorsal shell apex to release eggs or sperm, and presumably to flush the mantle cavity with fresh water. *See* Mollusca. [R.Shi.]

Scapolite An aluminosilicate mineral. It is commonly found as light-colored, translucent tetragonal prisms. Scapolite is normally white, but many other colors are known, including some used as semiprecious gems resembling amethyst and citrine. The mineral has a Mohs hardness of 5–6. The formula of scapolite is $(Na,Ca)_4(Al,Si)_6SI_6O_{24}(Cl,CO_3,SO_4)$. In nature significant amounts of K and SO_4 substitute for Na and CO_3.

Scapolite is a common mineral in metamorphic rocks, particularly in those which contain calcite. It is found in marbles, gneisses, skarns, and schists. Scapolite probably forms about 0.1% of the Earth's upper crust. It is commonly found as inclusions in igneous rocks derived from deep within the Earth's crust, and probably makes up several percent of the lower crust. *See* Silicate minerals. [D.E.E.]

Scarlet fever An acute contagious disease that results from infection with *Streptococcus pyogenes* (group A streptococci). It most often accompanies pharyngeal (throat) infections with this organism but is occasionally associated with wound infection or septicemia. Scarlet fever is characterized by the appearance, about 2 days after development of pharyngitis, of a red rash that blanches under pressure and has a sandpaper texture. Usually the rash appears first on the trunk and neck and spreads to the extremities. The rash fades after a week, with desquamation, or peeling, generally occurring during convalescence. The disease is usually self-limiting, although severe forms are occasionally seen with high fever and systemic toxicity. Appropriate antibiotic therapy is recommended to prevent the onset in susceptible individuals of rheumatic fever and rheumatic heart disease. *See* Medical bacteriology; Rheumatic fever; Streptococcus. [E.D.Gr.]

Scattering experiments (atoms and molecules) Experiments in which a beam of incident electrons, atoms, or molecules is deflected by collisions with an atom or molecule. Such experiments provide tests of the theory of scattering as well as information about atomic and molecular forces. Scattering experiments can be designed to simulate conditions in planetary atmospheres, electrical discharges, gas lasers, fusion reactors, stars, and planetary nebulae. *See* Electrical conduction in gases; Gas discharge; Laser; Nuclear fusion; Planetary nebula; Planet; Star.

In general, in any type of collision, scattering occurs, which causes the direction of relative motion of the two systems to be rotated to a new direction after the collision. More than two systems may also result from such an impact. A complete description of a collision event requires measurement of the directions, speeds, and internal states of all the products. *See* Collision (physics).

There are two basic types of scattering experiments. The simpler involves passing a collimated beam of particles (electrons, atoms, molecules, or ions) through a dilute target gas (in a cell or a jet) and measuring the fraction of incident particles that are deflected into a certain angle relative to the incident beam direction. In the second method, a collimated beam of particles intersects a second beam. The scattering events are usually registered by measuring the deflection or internal-state change of the beam particles. *See* Molecular beams.

Scattering in a particular type of collision is specified in terms of a differential cross section. The probability that, in a particular type of collision, the direction of motion of the electron is turned through a specified scattering angle into a specified solid angle is proportional to the corresponding differential scattering cross section. Collision cross sections can be measured with appropriately designed experimental apparatus. Depending on the type of collision process, that apparatus may measure the scattering angle, energy, charge, or mass of the scattered systems.

For the simplest case, the scattering of a beam of structureless particles of specified mass and speed by a structureless scattering center, the differential cross section may be calculated exactly by using the quantum theory. In the special case where the Coulomb force fully describes the interaction, both the quantum and classical theory give the same exact value for the differential cross section at all values of the scattering angle. *See* Nonrelativistic quantum theory.

For scattering of systems with internal structure (for example, molecules, and their ions), no exact theoretical calculation of the cross section is possible. Methods of approximation specific to different types of collisions have been developed. The power of modern high-speed computers has greatly increased their scope and effectiveness, with scattering experiments serving as benchmarks. *See* Atomic structure and spectra; Supercomputer. [R.A.Ph.]

Scattering experiments (nuclei) Experiments in which beams of particles such as electrons, nucleons, alpha particles and other atomic nuclei, and mesons are deflected by elastic collisions with atomic nuclei. Much is learned from such experiments about the nature of the scattered particle, the scattering center, and the forces acting between them. Scattering experiments, made possible by the construction of high-energy particle accelerators and the development of specialized techniques for detecting the scattered particles, are one of the main sources of information regarding the structure of matter. *See* NUCLEAR STRUCTURE; PARTICLE ACCELERATOR; PARTICLE DETECTOR; SCATTERING MATRIX. [K.A.Er.]

Scattering layer A layer of organisms in the sea which causes sound to scatter and returns echoes. Recordings by sonic devices of echoes from sound scatterers indicate that the scattering organisms are arranged in approximately horizontal layers in the water, usually well above the bottom. The layers are found in both shallow and deep water. [J.B.H.]

Scattering matrix An infinite-dimensional matrix or operator that expresses the state of a scattering system consisting of waves or particles or both in the far future in terms of its state in the remote past; also called the S matrix. In the case of electromagnetic (or acoustic) waves, it connects the intensity, phase, and polarization of the outgoing waves in the far field at various angles to the direction and polarization of the beam pointed toward an obstacle. It is used most prominently in the quantum-mechanical description of particle scattering, in which context it was invented in 1937 by J. A. Wheeler to describe nuclear reactions. Because an analog of the Schrödinger equation for the description of particle dynamics is lacking in the relativistic domain, W. Heisenberg proposed in 1943 that the S matrix rather than the hamiltonian or the lagrangian be regarded as the fundamental dynamical entity of quantum mechanics. This program played an important role in high-energy physics during the 1960s but is now largely abandoned. The physics of fundamental particles is now described primarily in terms of quantum gauge fields, and these are used to determine the S matrix and its elements for the collision and reaction processes observed in the laboratory. *See* ELEMENTARY PARTICLE; GAUGE THEORY; NONRELATIVISTIC QUANTUM THEORY; NUCLEAR REACTION; QUANTUM MECHANICS; RELATIVISTIC QUANTUM THEORY; SCATTERING EXPERIMENTS (ATOMS AND MOLECULES); SCATTERING EXPERIMENTS (NUCLEI).

The mathematical properties of the S matrix in nonrelativistic quantum mechanics have been thoroughly studied and are, for the most part, well understood. If the potential energy in the Schrödinger equation, or the scattering obstacle, is spherically symmetric, the eigenfunctions of the S matrix are spherical harmonics and its eigenvalues are of the form $\exp(2i\delta_l)$, where the real number δ_l is the phase shift of angular momentum l. In the nonspherically symmetric case, analogous quantities are called the eigenphase shifts, and the eigenfunctions depend on both the energy and the dynamics. In the relativistic regime, without an underlying Schrödinger equation for the particles, the mathematical properties are not as well known. Causality arguments (no signal should propagate faster than light) lead to dispersion relations, which constitute experimentally verifiable consequences of very general assumptions on the properties of nature that are independent of the detailed dynamics. *See* ANGULAR MOMENTUM; CAUSALITY; DISPERSION RELATIONS; EIGENFUNCTION; SPHERICAL HARMONICS. [R.G.Ne.]

Scattering of electromagnetic radiation The process in which energy is removed from a beam of electromagnetic radiation and reemitted with a change in direction, phase, or wavelength. All electromagnetic radiation is subject to scattering by the medium (gas, liquid, or solid) through which it passes.

It has been known since the work of J. Maxwell in the nineteenth century that accelerating electric charges radiate energy and, conversely, that electromagnetic radiation consists of fields which accelerate charged particles. Light in the visible, infrared, or ultraviolet region interacts primarily with the electrons in gases, liquids, and solids—not the nuclei. The scattering process in these wavelength regions consists of acceleration of the electrons by the incident beam, followed by reradiation from the accelerating charges. *See* ELECTROMAGNETIC RADIATION.

Scattering processes may be divided according to the time between the absorption of energy from the incident beam and the subsequent reradiation. True "scattering" refers only to those processes which are essentially instantaneous. Mechanisms in which there is a measurable delay between absorption and reemission are usually termed luminescence. *See* LUMINESCENCE.

Instantaneous scattering processes may be further categorized according to the wavelength shifts involved. Some scattering is "elastic"; there is no wavelength change, only a phase shift. In 1928 C. V. Raman discovered the process in which light was inelastically scattered and its energy was shifted by an amount equal to the vibrational energy of a molecule or crystal.

In liquids or gases two distinct processes generate inelastic scattering with small wavelength shifts. The first is Brillouin scattering from pressure waves. When a sound wave propagates through a medium, it produces alternate regions of high compression (high density) and low compression (or rarefaction). Brillouin scattering of light to higher (or lower) frequencies occurs because the medium is moving toward (or away from) the light source. This is an optical Doppler effect. *See* DOPPLER EFFECT.

The second kind of inelastic scattering studied in fluids is due to entropy and temperature fluctuations, and is known as Rayleigh scattering. These entropy fluctuations produce a broadening in the scattered radiation centered about the exciting wavelength, rather than sharp, well-defined wavelength shifts. Under the assumption that the scattering in fluids is from particles much smaller than the wavelength of the exciting light, Lord Rayleigh derived in 1871 an equation for such scattering. The dependence of scattering intensity upon the inverse fourth power of the wavelength given in Rayleigh's equation is responsible for the fact that daytime sky looks blue and sunsets red: blue light is scattered out of the sunlight by the air molecules more strongly than red; at sunset, more red light passes directly to the eyes without being scattered. *See* ENTROPY.

Rayleigh's derivation of his scattering equation relies on the assumption of small, independent particles. Under some circumstances of interest, both of these assumptions fail. Colloidal suspensions provide systems in which the scattering particles are comparable to or larger than the exciting wavelengths. Such scattering is called the Tyndall effect and results in a nearly wavelength-independent (that is, white) scattering spectrum. The Tyndall effect is the reason clouds are white (the water-droplets become larger than the wavelengths of visible light). *See* TYNDALL EFFECT.

The breakdown of Rayleigh's second assumption—that of independent particles—occurs in all liquids. There is strong correlation between the motion of neighboring particles. This leads to fixed phase relations and destructive interference for most of the scattered light. The remaining scattering arises from fluctuations in particle density discussed above. [J.F.S.]

Scent gland A specialized skin gland of the tubuloalveolar or acinous variety found in many mammals. These glands produce substances having peculiar odors. In some instances they are large, in others small. Examples of large glands are the civet gland in the civet cat, the musk gland in the musk deer, and the castoreum gland in the beaver. The civet gland is an anal gland, whereas the musk and castoreum are preputial. Examples of small scent glands are the preputial or Tyson's glands in the human male which secrete the smegma, and the vulval glands in the female. The secretions in all of the above glands are sebaceous. *See* GLAND. [O.E.N.]

Scheduling A decision-making function that plays an important role in most manufacturing and service industries. Scheduling is applied in procurement and production, in transportation and distribution, and in information processing and communication. A scheduling function typically uses mathematical optimization techniques or heuristic methods to allocate limited resources to the processing of tasks.

Project scheduling is concerned with a set of activities that are subject to precedence constraints, specifying which jobs have to be completed before a given job is allowed to start its processing. All activities belong to a single (and typically large) project that has to be completed in a minimum time; for example, a large real estate development or the construction of an aircraft carrier.

Production or job shop scheduling is important in manufacturing settings, for example, semiconductor manufacturing. Customer orders have to be executed. Each order entails a number of operations that have to be processed on the resources or the machines available. Each order has a committed shipping date that plays the role of a due date. Production scheduling often also includes lot sizing and batching.

Timetabling occurs often in class room scheduling, scheduling of meetings, and reservation systems. In many organizations, especially in the service industries, meetings must be scheduled in such a way that all necessary participants are present; often other constraints have to be satisfied as well (in the form of space and equipment needed). Such problems occur in schools with classroom and examination scheduling as well as in the renting of hotel rooms and automobiles.

Work-force scheduling (crew scheduling, and so on) is increasingly important, especially in the service industries. For example, large call centers in many types of enterprises (airlines, financial institutions, and others) require the development of complicated personnel scheduling techniques.

In order to determine satisfactory or optimal schedules, it is helpful to formulate the scheduling problem as a mathematical model. Such a model typically describes a number of important characteristics. One characteristic specifies the number of machines or resources as well as their interrelationships with regard to the configuration, for example, machines set up in series, machines set up in parallel. A second characteristic of a mathematical model concerns the processing requirements and constraints. These include setup costs and setup times, and precedence constraints between various activities. A third characteristic has to do with the objective that has to be optimized, which may be a single objective or a composite of different objectives. For example, the objective may be a combination of maximizing throughput (which is often equivalent to minimizing setup times) and maximizing the number of orders that are shipped on time.

The scheduling function is often incorporated in a system that is embedded in the information infrastructure of the organization. This infrastructure may be an enterprise-wide information system that is connected to the main databases of the company. Many other decision support systems may be plugged into such an enterprise-wide information system—for example, forecasting, order promising and due date setting, and material requirements planning (MRP).

The database that the scheduling system relies on usually has some special characteristics. It has static data as well as dynamic data. The static data—for example, processing requirements, product characteristics, and routing specifications—are fixed and do not depend on the schedules developed. The dynamic data are schedule-dependent; they include the start times and completion times of all the operations on all the different machines, and the length of the setup times (since these may also be schedule-dependent).

The economic impact of scheduling is significant. In certain industries the viability of a company may depend on the effectiveness of its scheduling systems, for example, airlines and semiconductor manufacturing. Good scheduling often allows an organization to conduct its operations with a minimum of resources. *See* MATERIAL RESOURCE PLANNING; PRODUCTION PLANNING. [M.Pi.; S.Se.]

Scheelite A mineral consisting of calcium tungstate, $CaWO_4$. Scheelite occurs in colorless to white, tetragonal crystals; it may also be massive and granular. Its fracture is uneven, and its luster is vitreous to adamantine. Scheelite has a hardness of 4.5–5 on Mohs scale and a specific gravity of 6.1. Its streak is white. The mineral is transparent and fluoresces bright bluish-white under ultraviolet light.

Scheelite is an important tungsten mineral and occurs in small amounts in vein deposits. The most important scheelite deposit in the United States is near Mill City, Nevada. *See* TUNGSTEN. [E.C.T.C.]

Schematic drawing Concise, graphical symbolism whereby the engineer communicates to others the functional relationship of the parts in a component and, in turn, of the components in a system. The symbols do not attempt to describe in complete detail the characteristics or physical form of the elements, but they do suggest the functional form which the ensemble of elements will take in satisfying the functional requirements of the component. They are different from a block diagram in that schematics describe more specifically the physical process by which the functional specifications of a block diagram are satisfied.

An electrical schematic is a functional schematic which defines the interrelationship of the electrical elements in a circuit, equipment, or system. The symbols describing the electrical elements are stylized, simplified, and standardized to the point of universal acceptance (Fig. 1).

In a mechanical schematic, the graphical descriptions of elements of a mechanical system are more complex and more intimately interrelated than the symbolism of an electrical system and so the graphical characterizations are not nearly as well standardized or simplified (Fig. 2). However, a mechanical

schematic illustrates such features as components, acceleration, velocity, position force sensing, and viscous damping devices. *See* DRAFTING; ENGINEERING DRAWING. [R.W.M.]

Schist Medium- to coarse-grained, mica-bearing metamorphic rock with well-developed foliation (layered structure) termed schistosity. Schist is derived primarily from fine-grained, mica-bearing rocks such as shales and slates. The schistosity is formed by rotation, recrystallization, and new growth of mica; it is deformational in origin. The planar to wavy foliation is defined by the strong preferred orientation of platy minerals, primarily muscovite, biotite, and chlorite. The relatively large grain size of these minerals (up to centimeters) produces the characteristic strong reflection when light shines on the rock. *See* BIOTITE; CHLORITE; MUSCOVITE.

Schists are named by the assemblage of minerals that is most characteristic in the field; for example, a garnet-biotite schist contains porphyroblasts of garnet and a schistosity dominated by biotite. Schists can provide important information on the relationship between metamorphism and deformation. *See* METAMORPHIC ROCKS; METAMORPHISM; PETROFABRIC ANALYSIS. [B.A.V.D.P.]

Schistosomiasis A disease in which humans are parasitized by any of three species of blood flukes: *Schistosoma mansoni*, *S. haematobium*, and *S. japonicum*. Adult *S. mansoni* prefer the veins of the hemorrhoidal plexus, *S. haematobium* those of the vesical plexus, and *S. japonicum* those of the small intestine. The disease is also known as bilharziasis. *See* DIGENEA.

An embryonated egg passed in feces or urine hatches in fresh water, liberating a miracidium larva which penetrates into specific gastropod snails. The larval cycle in the snail lasts for about 1 month. The cercaria emerges from the mollusk, swims in the water, and penetrates the skin of the final host upon coming in contact with it.

Schistosomiasis is an agricultural hazard for all ages in irrigated lands or swamps. Elsewhere fluvial waters are the main source of infection, in which case incidence is marked in human beings who are less than 15 years old and is higher among boys than among girls. [J.F.M.]

Schistostegales An order of the true mosses (subclass Bryidae), consisting of a single species, *Schistostega pennata*, the cave moss, which is especially characterized by its leaf arrangement and the form of its protonema. The plants grow in dimly lit, cavelike places, such as the undersides of upturned tree roots. The cave moss is widely distributed in north temperate regions. An unrelated moss found in Australia and New Zealand, *Mittenia plumula*, has an identical protonema and habitat.

The leafy plants are erect, unbranched, and dimorphous: sterile shoots have leaves wide-spreading in two rows and confluent because of broad basal decurrencies. Fertile plants have leaves in five rows and erect-spreading in a terminal tuft. All leaves are ecostate, entire, and unbordered. The inflorescences are terminal, the setae elongate, and the capsules subglobose, with a flat operculum but no peristome. *See* BRYIDAE; BRYOPHYTA; BRYOPSIDA. [H.Cr.]

Schizomida An order of Arachnida with two families, Protoschizomidae (*Agastoschizomus, Protoschizomus*) and Schizomida (*Schizomus, Trithyreus, Megaschizomus*), including about 130 described species, mainly in the genus *Schizomus*. Schizomids occur in most tropical and warm temperate regions, but each species has a restricted distribution.

Many undescribed species probably occur in tropical leaf litter and caves. Schizomids are most closely related to Uropygi, with which they share several evolutionary novelties. *See* UROPYGI.

Schizomids are 0.12–0.44 in. (3–11 mm) in size, are white to tan, and lack eyes, although some retain vestigial "eye-spots." The carapace is distinctively tripartite and the abdomen has a short, terminal flagellum.

Because schizomids are vulnerable to desiccation, they inhabit only moist places such as leaf litter, soil, caves, or beneath stones and logs. They are strict carnivores and fast runners. *See* ARACHNIDA. [J.A.Co.]

Schizophrenia A brain disorder that is characterized by bizarre mental experiences such as hallucinations and severe decrements in social, cognitive, and occupational functioning. Patients with schizophrenia demonstrate a series of biological differences when compared to other groups of psychiatric patients. However, no biological marker has yet been found to conclusively indicate the presence of schizophrenia. A diagnosis is made on the basis of a cluster of symptoms reported by the patient, and of signs identified by the clinician.

People with schizophrenia may report perceptual experiences in the absence of a perceptual stimulus. Most common are auditory hallucinations, often reported in the form of words spoken to the person with schizophrenia. The language is often derogatory, and it can be tremendously frightening. *See* HALLUCINATION.

People with schizophrenia often maintain beliefs that are not held by the overwhelming majority of the general population. To be considered delusions, the beliefs must be unshakable. In many cases, these beliefs may be bizarre and stem from odd experiences. In some instances, the delusions have an element of suspicion to them, such as the belief that others are planning to cause the person harm. The delusions may or may not be related to hallucinatory experiences.

Many schizophrenics suffer from social isolation, lack of motivation, lack of energy, slow or delayed speech, and diminished emotional expression, often referred to as blunted affect. They may manifest an odd outward appearance due to the severity of their disorganization. This presentation may include speech that does not follow logically or sensibly, at times to the point of being incoherent. Facial expression may be odd or inappropriate, such as laughing for no reason. In some cases, people with schizophrenia may move in a strange and awkward manner. The extreme aspect of this behavior, referred to as catatonia, has become very rare since pharmacological treatments have become available.

Perhaps the most devastating feature of schizophrenia is the cognitive impairment found in most people with the disorder. On average, such people perform in the lowest 2–10% of the general population on tests of attention, memory, abstraction, motor skills, and language abilities.

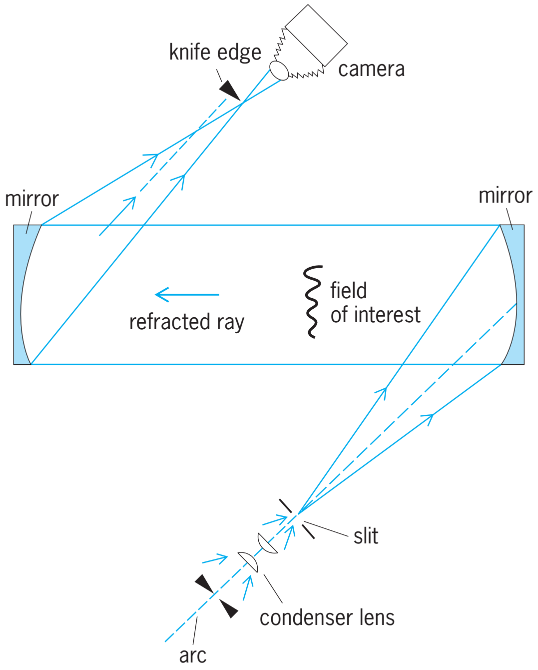
The onset of schizophrenia generally occurs in people in the late teens to early twenties. However, schizophrenia is possible throughout the life span. While the onset of symptoms is abrupt in some people, others experience a more insidious process, including extreme social withdrawal, reduced motivation, mood changes, and cognitive and functional decline. The course of schizophrenia is normally characterized by episodes of relative remission in which only subtle symptoms remain, and episodes of exacerbation of symptoms, which are often caused by failure to continue treatment.

It is likely that there are various forms of schizophrenia, perhaps with different causes. Although schizophrenia appears to be inherited in some cases, the influence of genes is far from complete. Many arguments have been put forth regarding environmental factors that could cause schizophrenia. Very few of these theories are consistently supported.

Magnetic resonance imaging (MRI) has revealed that people with schizophrenia often have changes in the structure of their brain such as enlargement of the cerebral ventricles (the fluid-filled spaces in the brain close to the midline). Various brain regions have been found to be smaller in patients with schizophrenia, including the frontal cortex, temporal lobes, and hippocampi. In addition, studies of patients with schizophrenia have found patterns of abnormal activation of the brain while performing tests of memory and problem solving. *See* BRAIN; MEDICAL IMAGING.

Either a pharmacological or behavioral approach may be used in treating schizophrenia. A variety of antipsychotic medications have been used, and research continues into how to minimize the side effects which are often associated with such drugs. There are several targets for behavioral treatments in schizophrenia. Structured training programs have attempted to teach patients how to function more effectively in social, occupational, and independent living domains. Family interventions have been designed to provide a supportive environment for patients, and have been demonstrated to reduce risk of relapse. Another behavioral treatment area is teaching patients how to cope with hallucinations and delusions. Most patients with schizophrenia do not spontaneously recognize their symptoms as unusual and their experiences as unreal. Cognitive-behavioral treatments have been employed to help patients realize the nature of their symptoms and to develop plans for coping with them. *See* PSYCHOPHARMACOLOGY; PSYCHOTHERAPY. [R.S.E.K.; P.D.H.]

Schlieren photography Any technique for the photographic recording of schlieren, which are regions or stria in a medium that is surrounded by a medium of different refractive index. Refractive index gradients in transparent media cause light rays to bend (refract) in the direction of increasing refractive index. This is a result of the reduced light velocity in a higher-refractive-index material. This phenomenon is exploited in viewing the schlieren, with schlieren photographs as the result. Electronic video recorders, scanning diode array cameras, and holography are widely used as supplements. *See* HOLOGRAPHY; OPTICAL DETECTORS; PHOTOGRAPHY; REFRACTION OF WAVES.



Knife-edge method of viewing schlieren, employing the "z" configuration.

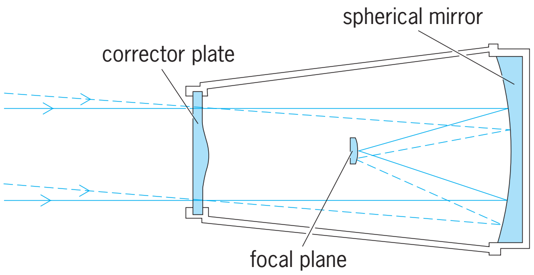
There are many techniques for optically enhancing the appearance of the schlieren in an image of the field of interest. In the oldest of these, called the knife-edge method (see illustration), a point or slit source of light is collimated by a mirror and passed through a field of interest, after which a second mirror focuses the light, reimaging the point or slit where it is intercepted by an adjustable knife edge (commonly a razor blade). The illustration shows the "z" configuration which minimizes the coma aberration in the focus. Mirrors are most often used because of the absence of chromatic aberration. *See* ABERRATION (OPTICS).

Rays of light that are bent by the schlieren in the direction of the knife edge are intercepted and removed from the final image of the region of interest, causing those regions to appear dark. Consequently, the system is most sensitive to the density gradients that are perpendicular to the knife edge. The knife edge is commonly mounted on a rotatable mount so that it can be adjusted during a measurement to optimally observe different gradients in the same field of interest. The intensity in the processed image is proportional to the refractive index gradient. A gradient in the same direction as the knife edge appears dark. Gradients in the opposite direction appear bright. This method, employed with arc light sources, is still one of the simplest ways to view refractive index changes in transparent solids, liquids, and gases. A well-designed schlieren system can easily detect the presence of a refractive index gradient that causes 1 arc-second deviation of a light ray.

Except for locating and identifying schlieren-causing events such as turbulent eddies, shock waves, and density gradients, schlieren systems are usually considered to be qualitative instruments. Quantitative techniques for determining density are possible but are much more difficult to employ. The most common of these is color schlieren. The knife edge is replaced with a multicolored filter. Rays of light refracted through different angles appear in different colors in the final image.

The availability of lasers and new optical components has expanded the method considerably. When a coherent light source such as a laser is used, the knife edge can be replaced by a variety of phase-, amplitude-, or polarization-modulating filters to produce useful transformations in the image intensity. *See* INTERFEROMETRY; LASER; POLARIZED LIGHT. [J.D.Tr.]

Schmidt camera A wide-field telescope that uses a thin aspheric front lens and a larger concave spherical mirror to focus the image (see illustration); it is also known as a Schmidt telescope. The Estonian optician Bernhard Schmidt devised the scheme in 1930. The field of best focus is located midway between the lens and the mirror and is curved toward the mirror, with a radius of curvature equal to the focal length. Usually film or photographic plates are bent to match this curved focus. A field-flattening lens may be used, allowing recording with charge-coupled devices (CCDs). *See* CHARGE-COUPLED DEVICES; GEOMETRICAL OPTICS; LENS (OPTICS); MIRROR OPTICS.



Cross section of Schmidt camera with aspherical corrector plate. (*After J. M. Pasachoff, Astronomy: From the Earth to the Universe, 5th ed., Saunders College Publishing, 1998*)

Schmidt telescopes are very fast, some having focal ratios in the vicinity of *f*/1. Their distinguishing feature is the very wide angle over which good images are obtained. Thus, under a dark sky they are sensitive to extended objects of low surface brightness. Schmidt telescopes have no coma; because the only lens element is so thin, they suffer only slightly from chromatic aberration and astigmatism. The front element, smaller than the main mirror, is sometimes known as a corrector plate. Often the outer surface of the corrector plate is plane, with the inner surface bearing the figure; however, a slight curvature is sometimes introduced to prevent misleading ghost images. This corrector plate almost eliminates the spherical aberration, giving extremely sharp images. For the most critical work, over a wide range of wavelengths, it must be made achromatic. *See* ABERRATION (OPTICS); OPTICAL SURFACES.

The largest Schmidt telescopes are 39–53 in. (1.0–1.3 m) in diameter. Most Schmidt telescopes are still used with film or photographic plates, to cover a wide field. Increasingly, Schmidt telescopes, especially several 24 in. (0.6 m) in diameter, are equipped with charge-coupled devices.

The success of the Schmidt design has led to many other types of catadioptric systems, with a combination of lenses and mirrors. Schmidt optics are often used in microscopes, astronomical spectrographs, and projection televisions. [J.M.P.]

Schottky anomaly A contribution to the heat capacity of a solid arising from the thermal population of discrete energy levels as the temperature is raised. The effect is particularly prominent at low temperatures, where other contributions to the heat capacity are generally small. *See* SPECIFIC HEAT.

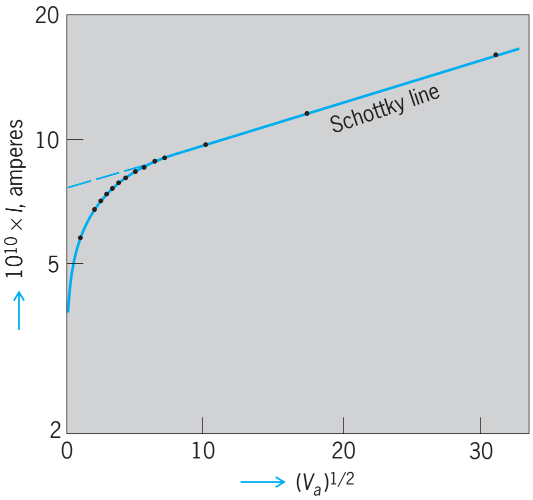
Discrete energy levels may arise from a variety of causes, including the removal of orbital or spin degeneracy by magnetic fields, crystalline electric fields, and spin orbit coupling, or from the magnetic hyperfine interaction. Such effects commonly occur in paramagnetic ions. *See* LOW-TEMPERATURE THERMOMETRY.

Corresponding to the Schottky heat capacity, there is a contribution to the entropy. This can act as a barrier to the attainment of low temperatures if the substance is to be cooled either by adiabatic demagnetization or by contact with another cooled substance. Conversely, a substance with a Schottky anomaly can be used as a heat sink in experiments at low temperatures (generally below 1 K or −457.9°F) to reduce temperature changes resulting from the influx or generation of heat. *See* ADIABATIC DEMAGNETIZATION; LOW-TEMPERATURE PHYSICS. [W.P.W.]

Schottky barrier diode A metal-semiconductor diode (two terminal electrical device) that exhibits a very nonlinear relation between voltage across it and current through it; formally known as a metallic disk rectifier. Original metallic disk rectifiers used selenium of copper oxide as the semiconductor coated on a metal disk. Today, the semiconductor is usually single-crystal silicon with two separate thin metal layers deposited on it to form electrical contacts. One of the two layers is made of a metal which forms a Schottky barrier to the silicon. The other forms a very low resistance, so-called ohmic, contact. The Schottky barrier is an electron or hole barrier caused by an electric dipole charge distribution associated with the contact potential difference which forms between a metal and a semiconductor under equilibrium conditions. The barrier is very abrupt at the surface of the metal because the charge is primarily on the surface. However, in the semiconductor, the charge is distributed over a small distance, and the potential gradually varies across this distance. *See* CONTACT POTENTIAL DIFFERENCE.

A basic useful feature of the Schottky diode is the fact that it can rectify an alternating current. Substantial current can pass through the diode in one direction but not in the other. If the semiconductor is *n*-type, electrons can easily pass from the semiconductor to the metal for one polarity of applied voltage, but are blocked from moving into the semiconductor from the metal by a potential barrier when the applied voltage is reversed. If the semiconductor is *p*-type, holes experience the same type of potential barrier but, since holes are positively charged, the polarities are reversed from the case of the *n*-type semiconductor. In both cases the applied voltage of one polarity (called forward bias) can reduce the potential barrier for charge carriers leaving the semiconductor, but for the other polarity (called reverse bias) it has no such effect. *See* DIODE; SEMICONDUCTOR; SEMICONDUCTOR RECTIFIER. [J.E.N.]

Schottky effect The enhancement of the thermionic emission of a conductor resulting from an electric field at the conductor surface. Since the thermionic emission current is given by the Richardson formula, an increase in the current at a given temperature implies a reduction in the work function of the emitter.



Logarithm of thermionic emission current *I* of tungsten as function of square root of anode voltage V_a. (*After W. B. Nottingham, Phys. Rev., 58:927–928, 1940*)

The reduction in work function can be calculated by considering the effect of a constant externally applied field on the potential energy of an electron near the conductor surface, and is found to be proportional to the square root of the field. *See* THERMIONIC EMISSION; WORK FUNCTION (ELECTRONICS).

A plot of the logarithm of the current versus the square root of the anode voltage should yield a straight line. An example is given in the illustration for tungsten; the deviation from the straight line for low anode voltages is due to space-charge effects. *See* SPACE CHARGE. [A.J.D.]

Schrödinger's wave equation A linear, homogeneous partial differential equation that determines the evolution with time of a quantum-mechanical wave function.

Quantum mechanics was developed in the 1920s along two different lines, by W. Heisenberg and by E. Schrödinger. Schrödinger's approach can be traced to the notion of wave-particle duality that flowed from A. Einstein's association of particlelike energy bundles (photons, as they were later called) with electromagnetic radiation, which, classically, is a wavelike phenomenon. For radiation of definite frequency *f*, each bundle carries energy *hf*. The proportionality factor, $h = 6.626 \times 10^{-34}$ joule-second, is a fundamental constant of nature, introduced by M. Planck in his empirical fit to the spectrum of blackbody radiation. This notion of wave-particle duality was extended in 1923 by L. de Broglie, who postulated the existence of wavelike phenomena associated with material particles such as electrons. *See* PHOTON; WAVE MECHANICS.

There are certain purely mathematical similarities between classical particle dynamics and the so-called geometric optics approximation to propagation of electromagnetic signals in material media. For the case of a single (nonrelativistic) particle moving in a potential $V(\mathbf{r})$, this analogy leads to the association with the system of a wave function, $\Psi(\mathbf{r})$, which obeys Eq. (1).

$$-\frac{\hbar^2}{2m}\nabla^2\Psi + V\Psi = E\Psi \tag{1}$$

Here *m* is the mass of the particle, *E* its energy, $\hbar = h/(2\pi)$, and ∇^2 is the laplacian operator. *See* CALCULUS OF VECTORS; GEOMETRICAL OPTICS; LAPLACIAN.

It is possible to ask what more general equation a time-, as well as space-dependent wave function, $\Psi(\mathbf{r}, t)$, might obey. What suggests itself is Eq. (2), which is now called the Schrödinger equation.

$$i\hbar\frac{\partial\Psi}{\partial t} = -\frac{\hbar^2}{2m}\nabla^2\Psi + V\Psi \tag{2}$$

The wave function can be generalized to a system of more than one particle, say *N* of them. A separate wave function is not assigned to each particle. Instead, there is a single wave function, $\Psi(\mathbf{r_1}, \mathbf{r_2}, \ldots, \mathbf{r_N}, t)$, which depends at once on all the position coordinates as well as time. This space of position variables is the so-called configuration space. The generalized Schrödinger equation is Eq. (3), where the potential *V* may now depend on

$$\mathrm{i}h\frac{\partial\Psi}{\partial t} = -\sum_{i=1}^{N}\frac{\hbar^2}{2m_i}\nabla_i^2\Psi + V\Psi \tag{3}$$

all the position variables. Three striking features of this equation are to be noted:

1. The complex number *i* (the square root of minus one) appears in the equation. Thus Ψ is in general complex. *See* COMPLEX NUMBERS AND COMPLEX VARIABLES.

2. The time derivative is of first order. Thus, if the wave function is known as a function of the position variables at any one instant, it is fully determined for all later times.

3. The Schrödinger equation is linear and homogeneous in Ψ, which means that if Ψ is a solution so is $c\Psi$, where *c* is an arbitrary complex constant. More generally, if Ψ_1 and Ψ_2 are solutions, so too is the linear combination $c_1\Psi_1 + c_2\Psi_2$, where c_1 and c_2 are arbitrary complex constants. This is the superposition principle of quantum mechanics. *See* SUPERPOSITION PRINCIPLE.

The Schrödinger equation suggests an interpretation in terms of probabilities. Provided that the wave function is square integrable over configuration space, it follows from Eq. (3) that the norm, $\langle\Psi|\Psi\rangle$, is independent of time, where the norm is defined by Eq. (4).

$$\langle\Psi \mid \Psi\rangle = \int d^3x_1 d^3x_2 \ldots d^3x_N \Psi^*\Psi \tag{4}$$

It is possible to normalize Ψ (multiply it by a suitable constant) to arrange that this norm is equal to unity. With that done, the Schrödinger equation itself suggests that expression (5) is the

$$\Psi^*\Psi d^3x_1 d^3x_2 \ldots d^3x_N \tag{5}$$

joint probability distribution at time *t* for finding particle 1 in the volume element d^3x_1, particle 2 in d^3x_2, and so forth. [S.Tr.]

Schuler pendulum Any apparatus which swings, because of gravity, with a natural period of 84.4 min, that is, with the same period as a hypothetical simple pendulum whose length is the Earth's radius. In 1923 Max Schuler showed that such an apparatus has the unique property that the pendulum arm will remain vertical despite any motions of its pivot. It is therefore useful as a base for navigational instruments. Schuler also showed how gyroscopes can be used to increase the period of a physical pendulum to the desired 84.4 min.

Gyrocompasses employ the Schuler principle to avoid errors due to ship accelerations. The principle has become the foundation of the science of inertial navigation. *See* GYROCOMPASS; INERTIAL GUIDANCE SYSTEM. [R.H.C.]

Sciatica Pain in the lower extremities, hips, and back caused by irritation of the sciatic nerves. The location of the specific pain and the causes producing it are quite varied.

Sciatica may result from mechanical pressure on the nerves or their roots in the cord. Trauma, herniated intervertebral disks, pregnancy, inflammation, or tumors may cause compression. Toxic or metabolic disorders, such as lead poisoning, diabetes mellitus, alcoholism, and vitamin-B deficiency may induce sciatic pain by producing changes in the nerves. Inflammations, both local and systemic, may also cause temporary or permanent nerve injury. Certain viral diseases, syphilis, and local infections act in this manner. *See* SYPHILIS; VIRUS; VITAMIN.

In addition, lesions in the anal region and the prostate may induce sciatica through reflex stimulation. Joint diseases, pelvic strain, and injury most often precipitate an attack. The pain of sciatica may begin suddenly and violently or gradually, as a nagging discomfort. The pain is usually along the leg, with later extension to the thigh and back. Numbness of the outside of the foot may occur. *See* PAIN. [E.G.St./N.K.M.]

Science In common usage the word science is applied to a variety of disciplines or intellectual activities which have certain features in common. Usually a science is characterized by the possibility of making precise statements which are susceptible of some sort of check or proof. This often implies that the situations with which the special science is concerned can be made to recur in order to submit themselves to check, although this is by no means always the case. There are observational sciences such as astronomy or geology in which repetition of a situation at will is intrinsically impossible, and the possible precision is limited to precision of description.

A common method of classifying sciences is to refer to them as either exact sciences or descriptive sciences. Examples of the former are physics and, to a lesser degree, chemistry; and of the latter, taxonomical botany or zoology. The exact sciences are in general characterized by the possibility of exact measurement.

One of the most important tasks of a descriptive science is to develop a method of description or classification that will permit precision of reference to the subject matter. *See* PHYSICAL SCIENCE. [P.W.Br./G.Ho.]

Scientific methods Strategies or uniform rules of procedure used in some scientific research with a measure of success. Scientific methods differ in generality, precision, and the extent to which they are scientifically justified. Thus, whereas the experimental method can in principle be used in all the sciences dealing with ascertainable facts, the various methods for measuring the electron charge are specific. The search for increasing quantitative precision involves the improvement or invention of special methods of measurement, also called techniques. All scientific methods are required to be compatible with confirmed scientific theories capable of explaining how the methods work. The most general of all the methods employed in science is called the scientific method.

The scientific method may be summarized as the following sequence of steps: identification of a knowledge problem; precise formulation or reformulation of the problem; examination of the background knowledge in a search for items that might help solve the problem; choice or invention of a tentative hypothesis that looks promising; conceptual test of the hypothesis, that is, checking whether it is compatible with the bulk of the existing knowledge on the matter; drawing some testable consequences of the hypothesis; design of an empirical (observational or experimental) test of the hypothesis or a consequence of it; actual empirical test of the hypothesis, involving a search for both favorable and unfavorable evidence (examples and counterexamples); critical examination and statistical processing of the data (for example, calculation of average error and elimination of outlying data); evaluation of the hypothesis in the light of its compatibility with both the background knowledge and the fresh empirical evidence; if the test results are inconclusive, design and performance of new tests, possibly using different special methods; if the test results are conclusive, acceptance, modification, or rejection of the hypothesis; if the hypothesis is acceptable, checking whether its acceptance forces some change (enrichment or correction) in the background knowledge; identifying and tackling new problems raised by the confirmed hypothesis; and repetition of the test and reexamination of its possible impact on existing knowledge.

The scientific method is not a recipe for making original discoveries or inventions; it does not prescribe the pathway that scientists must follow to attain success. The goal of the scientific method is to ascertain whether a hypothesis is true to some degree. Indeed, the nucleus of the scientific method is the confrontation of an idea (hypothesis) with the facts it refers to, regardless of the source of the idea in question. In sum, the scientific method is a means for checking hypotheses for truth rather than for finding facts or inventing ideas. *See* SCIENCE. [M.Bun.]

Scientific satellites Satellites used to gain scientific knowledge. They may be satellites of Earth or of other planets. Satellites used to apply space knowledge and techniques to practical purposes are called applications satellites. Many spacecraft are used for multiple purposes, combining space exploration, science, and applications in various ways. Scientific satellites are often called research satellites, and applications satellites are commonly designated by the application field, for example, navigation satellites. *See* SATELLITE (SPACECRAFT).

The space environment was one of the first areas investigated in scientific satellites. In this environment are cosmic rays, dust, magnetic fields, and various radiations from the Sun and galaxies. The Van Allen radiation belts were discovered by the first United States satellites. Soon thereafter satellites and space probes confirmed the existence of the solar wind. The continued investigation of these phenomena by satellites and space probes has led to the knowledge that a planet with a strong magnetic field, like Earth, is surrounded by a complex region, called a magnetosphere.

Numerous investigations are made of the effect of the space environment on materials and processes, including effects of radiation damage, meteoric erosion processes, and extremely high vacuum for very long periods. The influence of prolonged weightlessness on welding, alloying metals, growing crystals, and biological processes constitutes a promising field for future practical applications.

Scientific satellites, sounding rockets, and space probes are having a profound effect on earth science. The Earth and its atmosphere can now be studied in comparison with the other planets and their atmospheres, providing greater insight into the formation and evolution of the solar system. Satellites also make possible precision measurements of the size and shape of Earth and its gravitational field, and even measurements of the slow drifting of continents relative to each other.

Satellites are also having a great influence on astronomy by making it possible to observe celestial objects in all the wavelengths that reach the vicinity of Earth, whereas the ionosphere and atmosphere prevent most of these radiations from reaching telescopes on the ground. Moreover, even in the visible wavelengths, the small-scale turbulence and continuously varying refraction in the lower atmosphere distorts the image of a stellar object viewed at the ground, so that there is a limit to the improvement that can be achieved by increasing the size of a ground-based telescope. *See* SATELLITE ASTRONOMY.

The applications satellites emphasize the continuing day-to-day practical utilization of the satellite. They are operational in nature, although some of them, either directly or as a by-product of their operational output, contribute significantly to research, for example, with meteorological or Earth survey satellites. An applied research program generally precedes establishment of an applications satellite system. Thus, Tiros and Nimbus laid the groundwork for operational meteorological satellites. Likewise, Syncom satellites preceded the Intelsat communications system. *See* APPLICATIONS SATELLITES; COMMUNICATIONS SATELLITE; METEOROLOGICAL SATELLITES; MILITARY SATELLITES; SATELLITE NAVIGATION SYSTEMS; SPACE FLIGHT. [H.E.N.]

Scintillation counter A particle or radiation detector which operates through emission of light flashes that are detected by a photosensitive device, usually a photomultiplier or a silicon PIN diode. The scintillation counter not only can detect the presence of a particle, gamma ray, or x-ray, but can measure the energy, or the energy loss, of the particle or radiation in the scintillating medium. The sensitive medium may be solid, liquid, or gaseous, but is usually one of the first two. The scintillation counter is one of the most versatile particle detectors, and is widely used in industry, scientific research, medical diagnosis, and radiation monitoring, as well as in exploration for petroleum and radioactive minerals that emit gamma rays. Many low-level radioactivity measurements are made with scintillation counters. *See* LOW-LEVEL COUNTING; PARTICLE DETECTOR; PHOTOMULTIPLIER.

Scintillation counters are made of transparent crystalline materials, liquids, plastics, or glasses. In order to be an efficient detector, the bulk scintillating medium must be transparent to its own luminescent radiation, and since some detectors are quite extensive, covering meters in length, the transparency must be of a high order. One face of the scintillator is placed in optical contact with the photosensitive surface of the photomultiplier or PIN diode (see illustration). In order to direct as much as possible of the light flash to the photosensitive surface, reflecting material is placed between the scintillator and the inside surface of the container.

In many cases it is necessary to collect the light from a large area and transmit it to the small surface of a photomultiplier. In this case, a "light pipe" leads the light signal from the scintillator surface to the photomultiplier with only small loss. The best light guides and light fibers are made of glass, plastic, or quartz. It is also possible to use lenses and mirrors in conjunction with scintillators and photomultipliers. *See* OPTICAL FIBERS.

A charged particle, moving through the scintillator, loses energy and leaves a trail of ions and excited atoms and molecules. Rapid interatomic or intermolecular transfer of electronic excitation energy follows, leading eventually to a burst of luminescence characteristic of the scintillator material. When a particle stops in the scintillator, the integral of the resulting light output, called the scintillation response, provides a measure of the particle energy, and can be calibrated by reference to particle sources of known energy. Photomultipliers or PIN diodes may be operated so as to generate an output pulse of amplitude proportional to the scintillation response.

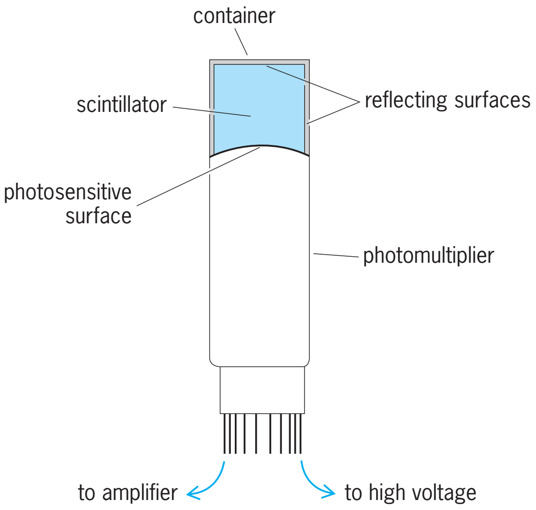


Diagram of a scintillation counter.

When a particle passes completely through a scintillator, the energy loss of the particle is measured. When a gamma ray converts to charged particles in a scintillator, its energy may also be determined. When the scintillator is made of dense material and of very large dimensions, the entire energy of a very energetic particle or gamma ray may be contained within the scintillator, and again the original energy may be measured. Such is the case for energetic electrons, positrons, or gamma rays which produce electromagnetic showers in the scintillator. Energy spectra can be determined in these various cases by using electronic equipment to convert amplitudes of the output pulses from the photomultiplier or PIN diode to digital form, for further processing by computers or pulse-height analyzers. [F.D.B.; R.Ho.]

Scleractinia An order of the subclass Zoantharia which comprises the true or stony corals (see illustration). These are solitary or colonial anthozoans which attach to a firm substrate. They are profuse in tropical and subtropical waters and contribute to the formation of coral reefs or islands. Some species are free and unattached.

Most of the polyp is impregnated with a hard calcareous skeleton secreted from ectodermal calcioblasts. The solitary corals form cylindrical, discoidal, or cuneiform skeletons, whereas colonial skeletons are multifarious. The polyps increase rapidly by intra- or extratentacular budding, and the skeletons of polyps which settle in groups may fuse to form a colony. The pyriform, ciliated planula swims with its aboral extremity, which is composed of an ectodermal sensory layer, directed anteriorly. Planulation occurs periodically in conformity with lunar phases in many tropical species. *See* ZOANTHARIA. [K.At.]

Solitary coral polyps, *Oulangia* sp.

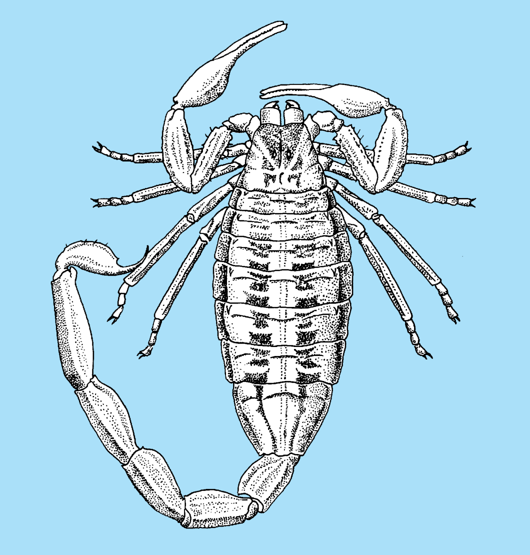
Scleractinian corals possess robust skeletons, so they have a rich fossil record. Because they are restricted mainly to tropical belts, they help indicate the position of the continents throughout the Mesozoic and Cenozoic periods. They are also important for understanding the evolution of corals and the origin and maintenance of reef diversity through time. Pleistocene corals shows persistent reef coral communities throughout the last several hundred thousand years. Environmental degradation has led to the dramatic alteration of living coral communities during the past several decades. [J.M.Pan.]

Sclerenchyma Single cells or aggregates of cells whose principal function is thought to be mechanical support of plants or plant parts. Sclerenchyma cells have thick secondary walls and may or may not remain alive when mature. They vary greatly in form and are of widespread occurrence in vascular plants. Two general types, sclereids and fibers, are widely recognized, but since these intergrade, the distinction is sometimes arbitrary. [N.H.B.]

Sclerospongiae A class of sponges that lay down a compound skeleton including an external, basal mass of calcium carbonate, either aragonite or calcite, as well as internal siliceous spicules and protein fibers. The living tissue forms a thin layer over the basal calcareous skeleton and extends into surface depressions of the skeleton; the organization of the tissue is similar to that of encrusting demosponges. Sclerosponges are common inhabitants of cryptic habitats on coral reefs in both the Caribbean and Indo-Pacific biogeographic regions. *See* DEMOSPONGIAE. [W.D.H.]

Scorpiones An order of the Arachnida which have chelate pedipalps and chelicera, a terminal caudal sting, and abdominal pectines (see illustration). The body is divided into a cephalothorax, which is covered by the unsegmented carapace, and a segmented abdomen. This latter division is differentiated into an anterior preabdomen and a postabdomen which, plus the terminal sting, constitutes the "tail" or cauda. The cephalothorax bears the chelicera, the pedipalps, and four pairs of walking legs. The preabdomen contains seven segments, while the postabdomen has five. The carapace bears three groups of small, simple eyes, a median pair and two groups of anterolateral eyes. True cave scorpions lack eyes.

Approximately 1000 species are known. Scorpions are widely distributed throughout the tropical zone and the warmer areas of the temperate zone. About 56 species are found in the United States, 22 of which are in Arizona. California and Florida also

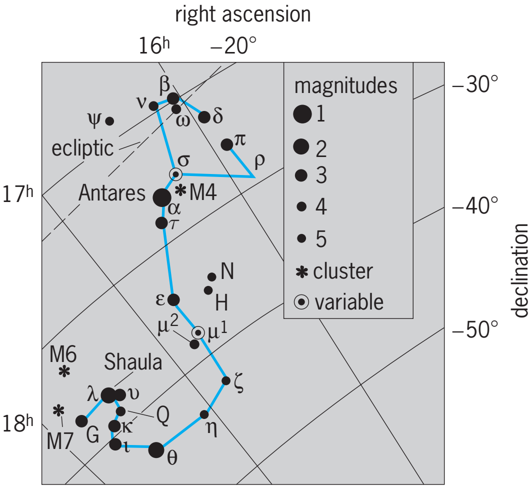


Centruroides vittatus.

have a rich scorpion fauna. Scorpions are found over three-fourths of the United States; they are absent from the New England states, Iowa, and areas immediately surrounding the Great Lakes.

The only species in the United States that are known to be lethal are *Centruroides sculpturatus* and *C. gertschi*, found in southern and central Arizona and the adjacent areas of California, New Mexico, and Mexico. The venom of these scorpions has proved fatal to healthy children up to 16 years of age and to adults suffering from hypertension and general debility. *See* ARACHNIDA. [H.L.St.]

Scorpius The Scorpion, in astronomy, one of the most beautiful and vivid constellations in the sky. Scorpius is the eighth sign of the zodiac (see illustration). The bright red star Antares is situated at the heart. Antares is one of the largest stars known, having a diameter over 450 times that of the Sun. As in Sagittarius, the Milky Way in Scorpius is bright and rich in star clouds and clusters. *See* CONSTELLATION. [C.S.Y.]



Line pattern of the constellation scorpius. The grid lines represent the coordinates of the sky. The apparent brightness, or magnitudes, of the stars is shown by the sizes of the dots, which are graded by appropriate numbers as indicated.

Scrapie A transmissible, usually fatal disease of adult sheep characterized by degeneration of the central nervous system. The disease is known in Great Britain, France, Belgium, Iceland, the United States, Canada, and northern India. Scrapie has certain similarities with kuru, a human disease in New Guinea, and mink encephalopathy.

Scrapie affects both sexes and is insidious in its onset, starting with hyperexcitability and progressive itch. Later, loss of wool occurs when the animal rubs against fixed objects or bites and nibbles its skin. Some animals do not rub but are either nervous and tremble when approached or appear sleepy. Incoordination of gait is constant and usually more evident in the hindquarters. In the final stages the sheep, being unable to stand, lie down, become emaciated, and die. *See* PRION DISEASE. [I.Zl.]

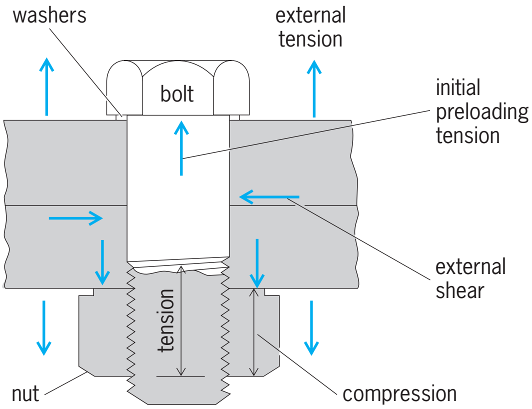
Screening A mechanical method of separating a mixture of solid particles into fractions by size. The mixture to be separated, called the feed, is passed over a screen surface containing openings of definite size. Particles smaller than the openings fall through the screen and are collected as undersize. Particles larger than the openings slide off the screen and are caught as oversize. A single screen separates the feed into only two fractions. Two or more screens may be operated in series to give additional fractions. Screening occasionally is done wet, but most commonly it is done dry.

Industrial screens may be constructed of metal bars, perforated or slotted metal plates, woven wire cloth, or bolting cloth. The openings are usually square but may be circular or rectangular. *See* MECHANICAL CLASSIFICATION; MECHANICAL SEPARATION TECHNIQUES; SEDIMENTATION (INDUSTRY). [W.L.McC.]

Screw A cylindrical body with a helical groove cut into its surface. For practical purposes a screw may be considered to be a wedge wound in the form of a helix so that the input motion is a rotation while the output remains translation. The screw is to the wedge much the same as the wheel and axle is to the lever in that it permits the exertion of force through a greatly increased distance.

The screw is by far the most useful form of inclined plane or wedge and finds application in the bolts and nuts used to fasten parts together; in lead and feed screws used to advance cutting tools or parts in machine tools; in screw jacks used to lift such objects as automobiles, houses, and heavy machinery; in screw-type conveyors used to move bulk materials; and in propellers for airplanes and ships. *See* PROPELLER (AIRCRAFT); PROPELLER (MARINE CRAFT); SCREW FASTENER; SCREW JACK; SCREW THREADS; SIMPLE MACHINE. [R.M.Ph.]

Screw fastener A threaded machine part used to join parts of a machine or structure. Screw fasteners are used when a connection that can be disassembled and reconnected and



Forces on a bolt fastener under preloading.

that must resist tension and shear is required. A nut and bolt is a common screw fastener. Bolt material is chosen to have an extended stress-strain characteristic free from a pronounced yield point. Nut material is chosen for slight plastic flow.

The nut is tightened on the bolt to produce a preload tension in the bolt (see illustration). This preload has several advantageous effects. It places the bolt under sufficient tension so that during vibration the relative stress change is slight with consequent improved fatigue resistance and locking of the nut. Preloading also increases the friction between bearing surfaces of the joined members so that shear loads are carried by the friction forces rather than by the bolt. *See* Bolt; Joint (structures); Nut (engineering); Screw. [F.H.R.]

Screw jack A mechanism for lifting and supporting loads, usually of large size. A screw jack mechanism consists of a thrust collar and a nut which rides on a bolt; the threads between the nut and bolt normally have a square shape. A standard form of screw jack has a heavy metal base with a central threaded hole into which fits a bolt capable of rotation under a collar thrusting against the load. *See* Screw; Simple machine. [J.J.R.]

Screw threads Continuous helical ribs on a cylindrical shank. Screw threads are used principally for fastening, adjusting, and transmitting power. To perform these specific functions, various thread forms have been developed. A thread on the outside of a cylinder or cone is an external (male) thread; a thread on the inside of a member is an internal (female) thread (Fig. 1). *See* Screw.

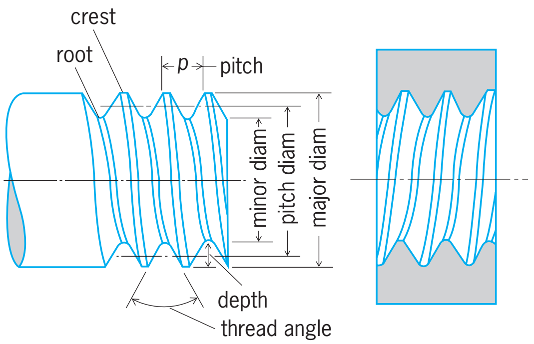


Fig. 1. Screw thread nomenclature.

Types of thread. A thread may be either right-hand or left-hand. A right-hand thread on an external member advances into an internal thread when turned clockwise; a left-hand thread advances when turned counterclockwise. If a single helical groove is cut or formed on a cylinder, it is called a single-thread screw. Should the helix angle be increased sufficiently for a second thread to be cut between the grooves of the first thread, a double thread will be formed on the screw. Double, triple, and even quadruple threads are used whenever a rapid advance is desired, as on valves.

Pitch and major diameter designate a thread. Lead is the distance advanced parallel to the axis when the screw is turned one revolution. For a single thread, lead is equal to the pitch; for a double thread, lead is twice the pitch. For a straight thread, the pitch diameter is the diameter of an imaginary coaxial cylinder that would cut the thread forms at a height where the width of the thread and groove would be equal.

Thread forms have been developed to satisfy particular requirements. Where strength is required for the transmission of power and motion, a thread having faces that are more nearly perpendicular to the axis is preferred. These threads, with their strong thread sections, transmit power nearly parallel to the axis of the screw.

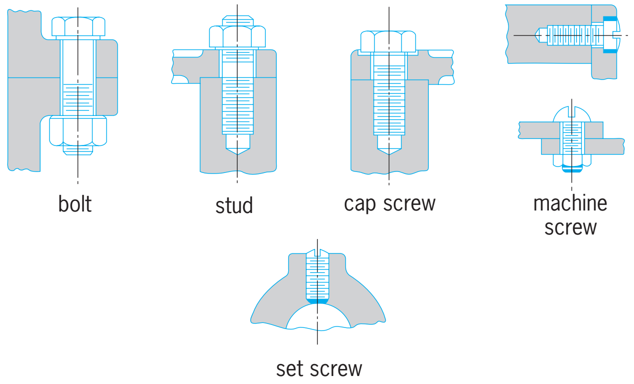

Fig. 2. Common types of fasteners. ***(After T. E. French and C. J. Vierck, Engineering Drawing and Graphic Technology, 12th ed., McGraw-Hill, 1978).***

Thread fastener. Most threaded fasteners are a threaded cylindrical rod with some form of head on one end. Of the many forms available, five types meet most requirements for threaded fasteners and are used for the bulk of production work: bolt, stud, cap screw, machine screw, and set screw (Fig. 2). Bolts and screws can be obtained with varied heads and points.

A bolt is generally used for drawing two parts together. A stud is a rod threaded on both ends. Studs are used for parts that must be removed frequently and for applications where bolts would be impractical.

Cap screws (plated or unplated) are widely used in machine tools and for assembling parts in automotive and aeronautical equipment. They are available in four standard heads: hexagon, flat, round, and fillister. Flathead and roundhead screws have slotted heads (Fig. 3). Machine screws are similar to cap screws and fulfill the same purpose, being employed principally on small work. Set screws made of hardened steel are used to hold parts in a position relative to one another. Wood screws, lag screws, and hanger bolts are used in wood. [W.J.L.]

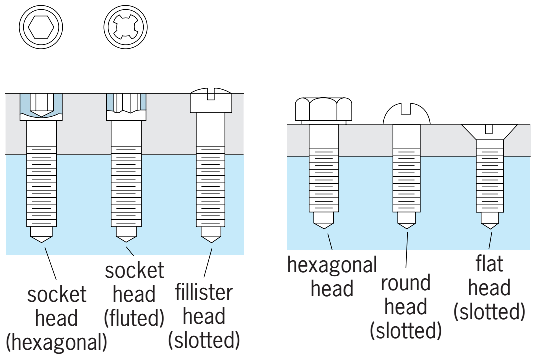

Fig. 3. Cap screws. (*After W. J. Luzadder, Fundamentals of Engineering Drawing, 8th ed., Prentice-Hall, 1981*).

Scrophulariales An order of flowering plants, division Magnoliophyta (Angiospermae), in the subclass Asteridae of the class Magnoliopsida (dicotyledons). The order consists of 12 families and more than 11,000 species. The largest families are the Scrophulariaceae (about 4000 species), Acanthaceae (about 2500 species), Gesneriaceae (about 2500 species), Bignoniaceae (about 800 species), and Oleaceae (about

600 species). The Scrophulariales are Asteridae, with a usually superior ovary and generally either with an irregular corolla or with fewer stamens than corolla lobes, or commonly both. They uniformly lack stipules.

The Scrophulariaceae are characterized by their usually herbaceous habit; irregular flowers with usually only two or four functional stamens; axile placentation; and dry, dehiscent fruits with more or less numerous seeds that have endosperm. The Acanthaceae are distinguished by their chiefly herbaceous habit, mostly simple and opposite leaves, lack of endosperm, and especially the enlarged and specialized funiculus, which is commonly developed into a jaculator that expels the seeds at maturity.

Some well-known members of the Scrophulariales are the African violet (*Saintpaulia ionantha*, in the Gesneriaceae), catalpa (Bignoniaceae), and lilac (*Syringa vulgaris*, in the Oleaceae). *See* ASTERIDAE; FLOWER; MAGNOLIOPHYTA; MAGNOLIOPSIDA; OLIVE; PLANT KINGDOM. [A.Cr.; T.M.Ba.]

Scyphozoa A class of the phylum Coelenterata, containing five living orders—Stauromedusae, Cubomedusae, Coronatae, Semaeostomeae, and Rhizostomeae—and a fossil order, Stromatoporoidea. They are all marine and usually take two forms, the polyp, or scyphopolyp, and the medusa, or scyphomedusa. However, some are polyplike and sessile throughout their lives, while others are always pelagic and lack the sessile polyp stage. Among the Coelenterata, the Scyphozoa are characterized by having well-developed medusae of large size and fairly well-organized polyps of small size.

The scyphomedusae are generally found near the coast. Exceptions are certain pelagic forms and the Coronatae, which are abyssal. Most of the Stauromedusae have a circumpolar distribution, while the Cubomedusae and Rhizostomeae are found mostly in warm and tropical seas. Scyphomedusae are carnivorous, except the Rhizostomeae which are plankton eaters. Some Semaeostomeae and Cubomedusae are injurious to humans because of their nematocysts. On the other hand, some Rhizostomeae are used as food in the Orient. *See* COELENTERATA. [T.U.]

Sea anemone Any polyp of the nearly 1000 anthozoan coelenterates belonging to the order Actiniaria. They occur intertidally and subtidally in marine and estuarine habitats, attached to solid substrates or burrowing into soft sediments. No freshwater or truly planktonic species are known. Anemones may be very small, a fraction of an inch long, to large individuals more than 3 ft (90 cm) in length or diameter. *See* ACTINIARIA.

Sea anemones enter into a number of interesting symbiotic partnerships. Some are host to single-celled marine algae, which grow within the cells of the anemone. The algae provide organic materials which aid in the nutrition of the anemone. Other anemones live on gastropod shells inhabited by hermit crabs. *See* ANTHOZOA; COELENTERATA. [C.H.]

Sea breeze A diurnal, thermally driven circulation in which a surface convergence zone often exists between airstreams having over-water versus over-land histories. The sea breeze is one of the most frequently occurring small-scale (mesoscale) weather systems. It results from the unequal sensible heat flux of the lower atmosphere over adjacent solar-heated land and water masses. Because of the large thermal inertia of a water body, during daytime the air temperature changes little over the water while over land the air mass warms. Occurring during periods of fair skies and generally weak large-scale winds, the sea breeze is recognizable by a wind shift to onshore, generally several hours after sunrise. On many tropical coastlines the sea breeze is an almost daily occurrence. It also occurs with regularity during the warm season along mid-latitude coastlines and even occasionally on Arctic shores. Especially during periods of very light winds, similar though sometimes weaker wind systems occur over the shores of large lakes and even wide rivers and estuaries (lake breezes, river breezes). At night, colder air from the land often will move offshore as a land breeze. Typically the land breeze circulation is much weaker and shallower than its daytime counterpart. *See* ATMOSPHERIC GENERAL CIRCULATION; MESOMETEOROLOGY; METEOROLOGY.

The occurrence and strength of the sea breeze is controlled by a variety of factors, including land-sea surface temperature differences; latitude and day of the year; the synoptic wind and its orientation with respect to the shoreline; the thermal stability of the lower atmosphere; surface solar radiation as affected by haze, smoke, and stratiform and convective cloudiness; and the geometry of the shoreline and the complexity of the surrounding terrain. *See* WIND. [W.A.Ly.]

Sea-floor imaging The process whereby mapping technologies are used to produce highly detailed images of the sea floor. High-resolution images of the sea floor are used to locate and manage marine resources such as fisheries and oil and gas reserves, identify offshore faults and the potential for coastal damage due to earthquakes, and map out and monitor marine pollution, in addition to providing information on what processes are affecting the sea floor, where these processes occur, and how they interact. *See* MARINE GEOLOGY.

Side-scan sonar provides a high-resolution view of the sea floor. In general, a side-scan sonar consists of two sonar units attached to the sides of a sled tethered to the back of a ship. Each sonar emits a burst of sound that insonifies a long, narrow corridor of the sea floor extending away from the sled. Sound reflections from the corridor that echo back to the sled are then recorded by the sonar in their arrival sequence, with echoes from points farther away arriving successively later. The sonars repeat this sequence of “talking” and listening every few seconds as the sled is pulled through the water so that consecutive recordings build up a continuous swath of sea-floor reflections, which provide information about the texture of the sea floor. *See* ECHO SOUNDER; HYDROPHONE; SONAR; SONOBUOY; UNDERWATER SOUND.

The best technology for mapping sea-floor depths or bathymetry is multibeam sonar. These systems employ a series of sound sources and listening devices that are mounted on the hull of a survey ship. As with side-scan sonar, every few seconds the sound sources emit a burst that insonifies a long, slim strip of the sea floor aligned perpendicular to the ship’s direction. The listening devices then begin recording sounds from within a fan of narrow sea-floor corridors that are aligned parallel to the ship and that cross the insonified strip. By running the survey the same way that one mows a lawn, adjacent swaths are collected parallel to one another to produce a complete sea-floor map of an area.

The most accurate and detailed view of the sea floor is provided by direct visual imaging through bottom cameras, submersibles, remotely operated vehicles, or if the waters are not too deep, scuba diving. Because light is scattered and absorbed in waters greater than about 33 ft (10 m) deep, the sea-floor area that bottom cameras can image is no more than a few meters. This limitation has been partly overcome by deep-sea submersibles and remotely operated vehicles, which provide researchers with the opportunity to explore the sea floor close-up for hours to weeks at a time. But even the sea-floor coverage that can be achieved with these devices is greatly restricted relative to side-scan sonar, multibeam sonar, and satellite altimetry.

The technology that provides the broadest perspective but the lowest resolution is satellite altimetry. A laser altimeter is mounted on a satellite and, in combination with land-based radars that track the satellite’s altitude, is used to measure variations in sea-surface elevation to within 2 in. (5 cm). Removing elevation changes due to waves and currents, sea-surface height can vary up to 660 ft (200 m). These variations are caused by minute differences in the Earth’s gravity field, which in turn result from heterogeneities in the Earth's mass. These heterogeneities are often associated with sea-floor topography. By using a mathematical function that equates sea-surface height to bottom elevations, global areas of the sea floor can be mapped within a matter of weeks. However, this approach has limitations. Sea-floor features less than 6–9 mi (10–15 km) in length are generally not massive enough to deflect the ocean surface, and thus go undetected. Furthermore, sea-floor density also affects the gravity field; and where different-density rocks are found, such as along the margins of continents, the correlation between Earth's gravity field and sea-floor topography breaks down. *See* ALTIMETER. [L.F.Pr.]

Sea ice Ice formed by the freezing of seawater. Ice in the sea includes sea ice, river ice, and land ice. Land ice is principally icebergs. River ice is carried into the sea during spring breakup and is important only near river mouths. The greatest part, probably 99% of ice in the sea, is sea ice. *See* ICEBERG.

The freezing point temperature and the temperature of maximum density of seawater vary with salinity. When freezing occurs, small flat plates of pure ice freeze out of solution to form a network which entraps brine in layers of cells. As the temperature decreases more water freezes out of the brine cells, further concentrating the remaining brine so that the freezing point of the brine equals the temperature of the surrounding pure ice structure. The brine is a complex solution of many ions.

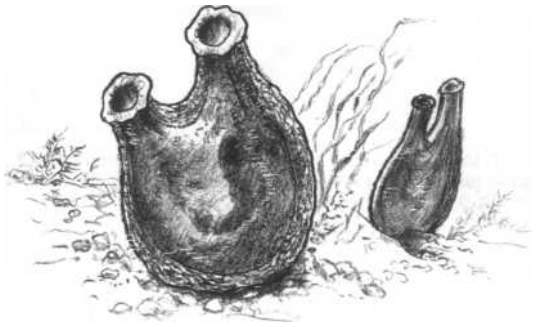
The brine cells migrate and change size with changes in temperature and pressure. The general downward migration of brine cells through the ice sheet leads to freshening of the top layers to near zero salinity by late summer. During winter the top surface temperature closely follows the air temperature, whereas the temperature of the underside remains at freezing point, corresponding to the salinity of water in contact.

The sea ice in any locality is commonly a mixture of recently formed ice and old ice which has survived one or more summers. Except in sheltered bays, sea ice is continually in motion because of wind and current. [W.Ly.]

Sea of Okhotsk A semienclosed basin adjacent to the North Pacific Ocean, bounded on the north, east, and west by continental Russia, the Kamchatka Peninsula, and northern Japan. On its southeast side the Sea of Okhotsk is connected to the North Pacific via a number of straits and passages through the Kuril Islands. The sea covers a surface area of approximately 590,000 mi^2 (1.5 million km^2), or about 1% of the total area of the Pacific, and has a maximum depth of over 9000 ft (3000 m). Its mean depth is about 2500 ft (830 m). Owing to the cold, wintertime Arctic winds that blow to the southeast, from Russia toward the North Pacific Ocean, the Sea of Okhotsk is partially covered with ice during the winter months, from November through April. *See* BASIN; PACIFIC OCEAN.

The amount of water exchanged between the Sea of Okhotsk and the North Pacific Ocean is not well known, but it is thought that the waters of the Sea of Okhotsk that do enter the North Pacific may play an important role in the Pacific's large-scale circulation. The reason is the extreme winter conditions over the Sea of Okhotsk: its waters are generally colder and have a lower salinity than the waters at the same density in the North Pacific. *See* OCEAN CIRCULATION; SEAWATER. [S.C.Ri.]

Sea squirt A sessile tunicate of the class Ascidiacea (phylum Chordata), so named because water is squirted from two openings when the animal is touched. Sea squirts may be solitary, colonial, or compound, but always have a permanent enclosing structure, the test or tunic, composed of polysaccharide material structurally similar to cellulose. In colonies, individuals are loosely attached together; in compound ascidians the individual zooids are embedded in a common test.

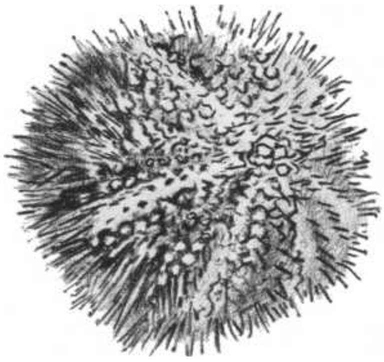


Sea squirts; these saclike tunicates serve as scavengers and as food for higher forms.

The individual is roughly cylindrical in shape and attached at the base (see illustration). The mantle encloses a space or atrial cavity. Suspended within the atrial cavity is a pharynx or branchial sac perforated by numerous oval slits (stigmata), each one bearing a ring of marginal cilia. Constant beating of the cilia draws in water through the inhalant or oral aperture into the branchial sac. Water passes through the stigmata into the atrial cavity and is discharged at the exhalant or atrial aperture. In the branchial sac, food particles from the water are filtered on a mucous sheet which is then rolled up and passed to the esophagus. Sea squirts are dioecious, and fertilization may be internal or external.

Sea squirts occur in all seas and at all depths in the ocean. Most require a hard substratum on which to settle, but a few live in sand or mud. They are particularly common in shallow-water environments such as rocky shores, piers, and boat hulls, and in mangrove lagoons. *See* ASCIDIACEA; TUNICATA. [I.Go.]

Sea urchin A marine echinoderm of the class Echinoidea. These invertebrates are found commonly in shallow waters. The soft internal organs are enclosed in and protected by a test or shell (see illustration) consisting of a number of plates which fit closely together and are located under the skin. The oral surface is in contact with the substratum. Five teeth, located in the mouth, form part of Aristotle's lantern, a complex chewing structure. Like many other species of echinoderms, sea urchins use tube feet for locomotion and pincerlike structures called pedicellariae to keep the shell clean. Sea urchins feed on most available animal and vegetable materials.



The sea urchin shell, which protects the soft internal organs, is covered with spines arranged in five broad areas that are separated by narrow unprotected areas.

Many species burrow into the sand, while others move into rock crevices to protect themselves from severe tidal action. *See* ECHINOIDEA. [C.B.C.]

Seaborgium

A chemical element, symbol Sg, atomic number 106. Seaborgium has chemical properties similar to tungsten. It was synthesized and identified in 1974. This discovery of seaborgium took place nearly simultaneously in two nuclear laboratories, the Lawrence Berkeley Laboratory at the University of California and the Joint Institute for Nuclear Research at Dubna in Russia.

The Berkeley group, under the leadership of A. Ghiorso, used as its source of heavy ions the Super-Heavy Ion Linear Accelerator (SuperHILAC). The production and positive identification of the isotope of seaborgium with the mass number 263 decays with a half-life of $0.9 + 0.2$ s by the emission of alpha particles of principal energy $9.06 + 0.04$ MeV. This isotope is produced in the reaction in which four neutrons are emitted: $^{249}\mathrm{Cf}(^{18}\mathrm{O},4n)$.

The Dubna group, under the leadership of G. N. Flerov and Y. T. Oganessian, produced its heavy ions with a heavy-ion cyclotron. They found a product that decays by the spontaneous fission mechanism with the very short half-life of 7 ms. They assigned it to the isotope $^{259}\mathrm{Sg}$, suggesting reactions in which two or three neutrons are emitted: $^{207}\mathrm{Pb}(^{54}\mathrm{Cr},2n)$ and $^{208}\mathrm{Pb}(\mathrm{Cr}^{54},3n)$. *See* Nobelium; Nuclear chemistry; Periodic table; Transuranium elements. [G.T.S.]

Seamount and guyot

A seamount is a mountain that rises from the ocean floor; a submerged flat-topped seamount is termed a guyot. By arbitrary definition, seamounts must be at least 3000 ft (about 900 m) high, but in fact there is a continuum of smaller undersea mounts, down to heights of only about 300 ft (100 m). Some seamounts are high enough temporarily to form oceanic islands, which ultimately subside beneath sea level. There are on the order of 10,000 seamounts in the world ocean, arranged in chains (for example, the Hawaiian chain in the North Pacific) or as isolated features. In some chains, seamounts are packed closely to form ridges. Very large oceanic volcanic constructions, hundreds of kilometers across, are called oceanic plateaus. *See* Marine geology; Oceanic islands; Volcano.

Almost all seamounts are the result of submarine volcanism, and most are built within less than about 1 million years. Seamounts are made by extrusion of lavas piped upward in stages from sources within the Earth's mantle to vents on the seafloor. Seamounts provide data on movements of tectonic plates on which they ride, and on the rheology of the underlying lithosphere. The trend of a seamount chain traces the direction of motion of the lithospheric plate over a more or less fixed heat source in the underlying asthenosphere part of the Earth's mantle. *See* Lithosphere; Plate tectonics. [E.L.Wi.]

Seaplane

An airplane capable of navigating on, taking off from, and alighting upon the surface of water. Seaplanes are grouped into two main types: flying boats and float planes. In the flying boat, the hull, which provides buoyancy and planing area, is an integral part of the airframe, a specially designed fuselage which supports the wings and tail surfaces and houses the crew, equipment, and cargo. Although multihull flying boats have been built, modern use is confined to single-hull boats with lateral stability on the water provided by small floats or pontoons attached to the wings. The float plane is a standard landplane made capable of water operation by the addition of floats which are attached to the airframe by struts. In practice the twin float is used exclusively, lateral stability on the water being provided by the separation of the two identical floats (see illustration). A seaplane with retracting wheels which permit either land or water operation is known as an amphibian. *See* Airplane. [R.A.Ho.]

A single-engine float plane.

Seasons

The four divisions of the year based upon variations of sunlight intensity (solar energy per unit area at the Earth's surface) at local solar noon (noontime) and daylight period. The variations in noontime intensity and daylight period are the result of the Earth's rotational axis being tilted 23.5° from the perpendicular to the plane of the Earth's orbit around the Sun. The direction of the Earth's axis with respect to the stars remains fixed as the Earth orbits the Sun. If the Earth's axis were not tilted from the perpendicular, there would be no variation in noontime sunlight intensity or daylight period and no seasons. The Earth-Sun distance does not influence the seasons because it varies only slightly, and it is overwhelmed by the effects of variations in sunlight intensity and daylight period due to the alignment of the Earth's axis.

Sunlight intensity at a location depends upon the angle from the horizon to the Sun at local solar noon; this angle in turn depends upon the location's latitude and the position of the Earth in its orbit. At increased angles, a given amount of sunlight is spread over smaller surface areas, resulting in a greater concentration of solar energy, which produces increased surface heating. Intensity is a more important factor than the number of daylight hours in determining the heating effect at the Earth's surface. *See* Earth rotation and orbital motion. [H.P.C.]

Seawater

An aqueous solution of salts of a rather constant composition of elements whose presence determines the climate and makes life possible on the Earth and which constitutes the oceans, the mediterranean seas, and their embayments. The physical, chemical, biological, and geological events therein are the studies that are grouped as oceanography. Water is most often found in nature as seawater (about 98%). The rest is ice, water vapor, and fresh water. The basic properties of seawater, their distribution, the interchange of properties between sea and atmosphere or land, the transmission of energy within the sea, and the geochemical laws governing the composition of seawater and sediments are the fundamentals of oceanography. *See* Hydrosphere; Oceanography.

The major chemical constituents of seawater are cations (positive ions) and anions (negative ions) [see table]. In addition, seawater contains the suspended solids, organic substances, and dissolved gases found in all natural waters. A standard salinity of 35 practical salinity units (psu; formerly parts per thousand, or ‰) has been assumed. While salinity does vary appreciably in oceanic waters, the fractionalcomposition of salts is remarkably

Major constituents of seawater (salinity 35 psu)*

Positive ions	Amount, g/kg	Negative ions	Amount, g/kg
Sodium (Na^+)	10.752	Chloride (Cl^-)	19.345
Magnesium (Mg^{2+})	1.295	Bromide (Br^-)	0.066
Potassium (K^+)	0.390	Fluoride (F^-)	0.0013
Calcium (Ca^{2+})	0.416	Sulfate (SO_4^-)	2.701
Strontium (Sr^{2+})	0.013	Bicarbonate (HCO_3^-)	0.145
		Boron hydroxide ($B(OH)_3^-$)	0.027

*Water, 965 psu; dissolved materials, 35 psu.

constant throughout the world's oceans. In addition to the dissolved salts, natural seawater contains particulates in the form of plankton and their detritus, sediments, and dissolved organic matter, all of which lend additional coloration beyond the blue coming from Rayleigh scattering by the water molecules. Almost every known natural substance is found in the ocean, mostly in minute concentrations. *See* SCATTERING OF ELECTROMAGNETIC RADIATION. [J.L.Re.]

Seawater fertility A measure of the potential ability of seawater to support life. Fertility is distinguished from productivity, which is the actual production of living material by various trophic levels of the food web. Fertility is a broader and more general description of the biological activity of a region of the sea, while primary production, secondary production, and so on, is a quantitative description of the biological growth at a specified time and place by a certain trophic level. Primary production that uses recently recycled nutrients such as ammonium, urea, or amino acids is called regenerated production to distinguish it from the new production that is dependent on nitrate being transported by mixing or circulation into the upper layer where primary production occurs. New production is organic matter, in the form of fish or sinking organic matter, that can be exported from the ecosystem without damaging the productive capacity of the system. *See* BIOLOGICAL PRODUCTIVITY.

The potential of the sea to support growth of living organisms is determined by the fertilizer elements that marine plants need for growth. Fertilizers, or inorganic nutrients as they are called in oceanography, are required only by the first trophic level in the food web, the primary producers; but the supply of inorganic nutrients is a fertility-regulating process whose effect reaches throughout the food web. When there is an abundant supply to the surface layer of the ocean that is taken up by marine plants and converted into organic matter through photosynthesis, the entire food web is enriched, including zooplankton, fish, birds, whales, benthic invertebrates, protozoa, and bacteria. *See* DEEP-SEA FAUNA; FOOD WEB; MARINE FISHERIES.

The elements needed by marine plants for growth are divided into two categories depending on the quantities required: The major nutrient elements that appear to determine variations in ocean fertility are nitrogen, phosphorus, and silicon. The micronutrients are elements required in extremely small, or trace, quantities including essential metals such as iron, manganese, zinc, cobalt, magnesium, and copper, as well as vitamins and specific organic growth factors such as chelators. Knowledge of the fertility consequences of variations in the distribution of micronutrients is incomplete, but consensus among oceanographers is that the overall pattern of ocean fertility is set by the major fertilizer elements—nitrogen, phosphorus, and silicon—and not by micronutrients.

Two types of marine plants carry out primary production in the ocean: microscopic planktonic algae collectively called phytoplankton, and benthic algae and sea grasses attached to hard and soft substrates in shallow coastal waters.

The benthic and planktonic primary producers are a diverse assemblage of plants adapted to exploit a wide variety of marine niches; however, they have in common two basic requirements for the photosynthetic production of new organic matter: light energy and the essential elements of carbon, hydrogen, nitrogen, oxygen, phosphorus, sulfur, and silicon for the synthesis of new organic molecules. These two requirements are the first-order determinants of photosynthetic growth for all marine plants and, hence, for primary productivity everywhere in the ocean.

The regions of the world's oceans differ dramatically in overall fertility. In the richest areas, the water is brown with diatom blooms, fish schools are abundant, birds darken the horizon, and the sediments are fine-grained black mud with a high organic content. In areas of low fertility, the water is blue and clear, fish are rare, and the bottom sediments are well-oxidized carbonate or clay. These extremes exist because the overall pattern of fertility is determined by the processes that transport nutrients to the sunlit upper layer of the ocean where there is energy for photosynthesis. *See* SEAWATER. [R.T.B.]

Sebaceous gland A gland which produces and liberates sebum, a mixture composed of fat, cellular debris, and keratin. When the gland arises in association with a hair follicle, it forms a thickened outpushing from the side of the developing follicle near the epidermis. Central cells in these sebaceous glands form oil droplets within the cytoplasm. These cells disintegrate to liberate the sebaceous substance and are therefore of the holocrine type. The Meibomian or tarsal glands, within the tarsus or supporting plate at the edge of the eyelids, are sebaceous and complex tubuloacinous structures. The numerous separate glands open along the entire edge of the upper and lower lids. Retained secretions of the tarsal glands produce a chalozion or Meibomian cyst. *See* GLAND. [O.E.N.]

Second messengers Molecules used to transmit signals within cells. These molecules trigger a cascade of events by activating other cellular components. The ability of cells to respond to specific extracellular molecules, or agonists, is crucial to growth, development, and homeostasis of multicellular organisms. Signal transduction refers to the movement of a signal initiated outside the cell into the cell interior. Many agonists induce the stimulation of cell growth, differentiation, or expression of specific genes. Signal transduction pathways must, therefore, include mechanisms for the initiation of signals at the cell surface membrane (plasma membrane), as well as a mechanism by which these signals traverse the interior of the cell (cytoplasm), and induce the desired target response. The pathways involve cascades of sequential molecular activation steps that are organized into three major components: (1) a receptor that recognizes and binds agonists, (2) second messengers, or signal transducing molecules, that couple receptors to intracellular pathways, and (3) effectors or molecules responsible for the ultimate response. A central feature of all signaling cascades is that they discriminate among a variety of signals and provide a mechanism for signal amplification. *See* SIGNAL TRANSDUCTION. [D.M.Ra.]

Second sound A type of wave propagated in the superfluid phase of liquid helium (helium II) and in certain other substances under special conditions. The name is misleading since second sound is not in any sense a sound wave, but a temperature or entropy wave. In ordinary or first sound, pressure and density variations propagate with very small accompanying variations in temperature; in second sound, temperature variations propagate with no appreciable variation in density or pressure. *See* LIQUID HELIUM; SUPERFLUIDITY.

The two-fluid model of helium II provides further insight into the nature of second sound. In this model the liquid can be described as consisting of superfluid and normal components of densities ρ_s and ρ_n, respectively, such that the total density $\rho = \rho_s + \rho_n$. The superfluid component is frictionless and devoid of entropy; the normal component has a normal viscosity and contains the entropy and thermal energy of the system. In a temperature or second-sound wave, the normal and superfluid flows are oppositely directed so that $\rho_s \mathbf{V}_s + \rho_n \mathbf{V}_n = 0$, where $\mathbf{V}_s$ and $\mathbf{V}_n$ are the superfluid and normal flow velocities. Thus a variation in relative densities of the two components, and hence a temperature fluctuation, propagates with no change in total density or pressure. In a first-sound wave, the two components move in phase, that is, $\mathbf{V}_n \cong \mathbf{V}_s$.

Theoretical predictions that second sound should exist in certain solid dielectric crystals under suitable conditions have been confirmed experimentally for solid helium single crystals at temperatures between 0.4 and 1.0 K (−459.0 and −457.9°F). *See* DIELECTRIC MATERIALS.

Another quite different class of materials can exhibit second sound. In smectic A liquid crystals, when the wave vector is oblique with respect to the layers of these ordered structures, a modulation of the interlayer spacing can propagate at nearly constant density. *See* LIQUID CRYSTALS. [H.A.F.]

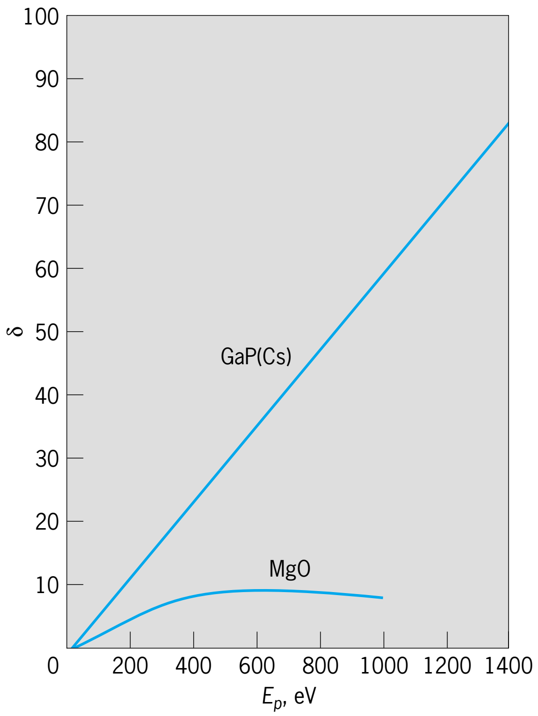
Secondary emission The emission of electrons from the surface of a solid into vacuum caused by bombardment with charged particles, in particular with electrons. The mechanism of secondary emission under ion bombardment is quite different from that under electron bombardment; it is only in the latter case that the term secondary emission is generally used.

The bombarding electrons and the emitted electrons are referred to, respectively, as primaries and secondaries. Secondary emission has important practical applications because the secondary yield, that is, the number of secondaries emitted per incident primary, may exceed unity. Thus, secondary emitters are used in electron multipliers, especially in photomultipliers, and in other electronic devices such as television pickup tubes, storage tubes for electronic computers, and so on.

The emission of secondary electrons can be described as the result of three processes: (1) excitation of electrons in the solid into high-energy states by the impact of high-energy primary electrons, (2) transport of these secondary electrons to the solid-vacuum interface, and (3) escape of the electrons over the surface barrier into the vacuum. The efficiency of each of these three processes, and hence the magnitude of the secondary emission yield δ, varies greatly for different materials.

Most of the materials used in practical devices are semiconductors or insulators whose band-gap energies are much larger than their electron affinities. Examples are magnesium oxide (MgO), beryllium oxide (BeO), cesium antimonide (Cs_3Sb), and potassium chloride (KCl). Maximum δ values in the 8–15 range are typically obtained at primary energies of several hundred volts.

In certain semiconductors the bands are bent downward to such an extent that the vacuum level lies below the bottom of the conduction band in the bulk. A material with this characteristic is said to have negative effective electron affinity. The most important material in this category is cesium-activated gallium phosphide, GaP(Cs). The illustration shows the curve of yield δ versus primary energy E_p for GaP(Cs) by comparison with MgO. Values of δ exceeding 100 are readily obtained, with maximum yields at energies in the 5–10-kV region. *See* BAND THEORY OF SOLIDS; SEMICONDUCTOR. [A.H.So.]



Secondary emission yield versus primary energy for GaP(Cs). The curve for MgO is shown for comparison.

Secondary ion mass spectrometry (SIMS) An instrumental technique that measures the elemental and molecular composition of solid materials. SIMS provides methods of visualizing the two- and three-dimensional composition of solids at lateral resolutions approaching several hundred nanometers and depth resolutions of 1–10 nm. This technique employs an energetic ion beam to remove or sputter the atomic and molecular constituents from a surface in a very controlled manner. The sputtered products include atoms, molecules, and molecular fragments that are characteristic of the surface composition within each volume element sputtered by the ion beam. A small fraction of the sputtered atoms and molecules are ionized as either positive or negative ions, and a measurement by SIMS determines the mass and intensity of these secondary ions by using various mass analysis or mass spectrometry techniques. In this technique, the sputtering ions are referred to as the primary ions or the primary ion beam, while the ions produced in sputtering the solid are the secondary ions. Most elements in the periodic table produce secondary ions, and SIMS can quantitatively detect elemental concentrations in the part-per-million to part-per-billion range.

Secondary ions are formed by kinetic and chemical ionization processes in which sputtering is achieved by energy transfer from the primary ions to the solid surface. Typically, SIMS primary ions impact the surface with kinetic energies of 5–20 keV, and this energy is ultimately transferred to the sample atoms and molecules. The energy transfer initiates a collision cascade within the solid that ejects atoms and molecules at the solid surface-vacuum interface.

SIMS analyses are divided into two broad categories known as dynamic and static. In the dynamic type, the most common SIMS method, a relatively intense primary ion beam sputters the sample surface at high sputter rates, providing a very useful way to determine the in-depth concentration of different elements in a solid. The most common secondary ions detected in a dynamic secondary ion mass spectrometry analysis are elemental ions or clusters of elemental ions.

Static or molecular SIMS utilizes a very low intensity primary ion beam, and static analyses are typically completed before a single monolayer has been removed from the surface. Most static analyses are stopped before 1% of the top surface layer has been chemically damaged or eroded; under these conditions, molecular and molecular fragment ions characteristic of the chemical structure of the surface are often detected. Thus, static SIMS is best suited for near-surface analysis of molecular composition or chemical structure information, while dynamic SIMS provides the best technique for bulk and in-depth elemental analysis. *See* SPUTTERING.

Instrument designs for SIMS require a primary ion gun or column to generate and transport the primary ion beam to the sample surface, a sample chamber with sample mounting facilities, a mass spectrometer which performs mass-to-charge separation of the different secondary ions, and an ion-detection system. The complete instrument is typically housed in an ultrahigh vacuum chamber. *See* ION SOURCES; MASS SPECTROSCOPE.

Dynamic SIMS has been successfully utilized in diverse applications. The analytical issues are the detection and localization of specific elements on the surface or in the bulk of the materials. The most important and common application area of dynamic SIMS is the bulk and in-depth analysis of semiconductor materials. Another important contribution of SIMS to materials science is the identification and localization of trace elements in metal grain boundaries, providing detailed insight into the chemistry of welds and alloys. Dynamic SIMS also has the unique ability to detect specific catalyst poisons on the surface and in the bulk of used or spent catalysts. In geological sciences, SIMS has been used to detect isotopic anomalies in the composition of various geological and meteoritic samples to help determine the age of the universe. Dynamic SIMS has found extensive applications to the characterization of both hard and soft biological tissue. *See* SEMICONDUCTOR.

Applications of static secondry ion mass spectrometry to analyses of the near-surface region of solids has become increasingly important as ever more sophisticated materials are developed. The near-surface region is generally defined as the top five monolayers (2–3 nm) of a solid. Examples of technology areas in which the chemistry of the near-surface region plays a critical role include high-performance glass coatings, liquid-crystal displays, manufacturing, semiconductor processing, biopolymer and biocompatible materials development, and polymer adhesives and coatings. *See* MASS SPECTROMETRY; MATERIALS SCIENCE AND ENGINEERING; SEMICONDUCTOR DIODE. [R.W.O.]

Secretion The export of proteins by cells. With few exceptions, in eukaryotic cells proteins are exported via the secretory pathway, which includes the endoplasmic reticulum and the Golgi apparatus. Secreted proteins are important in many physiological processes, from the transport of lipids and nutrients in the blood, to the digestion of food in the intestine, to the regulation of metabolic processes by hormones. *See* CELL (BIOLOGY); CELL ORGANIZATION; ENDOCRINE MECHANISMS.

Proteins destined for export are synthesized on ribosomes attached to the outside of the rough endoplasmic reticulum, a portion of the endoplasmic reticulum that is specialized for the synthesis of secretory proteins and most of the cell's membrane proteins. After they are folded, the proteins enter small vesicles in which they are transported to the Golgi apparatus. When the proteins reach the last cisterna of the Golgi, a highly tubulated region known as the *trans*-Golgi network, they are sorted and packaged again into transport vesicles, some of which are in the form of elongated tubules. From here, there are two pathways that proteins can take to the cell surface, depending on the cell type. Proteins can be transported directly to the plasma membrane (constitutive secretion) or to secretory granules (regulated secretion). *See* ENDOPLASMIC RETICULUM; GOLGI APPARATUS.

In all cells, there exists a constitutive secretion pathway whereby vesicles and tubules emerging from the *trans*-Golgi network fuse rapidly with the plasma membrane. The emerging vesicles and tubules attach to microtubules, cytoskeletal elements emanating from the Golgi region, that accelerate their transport to the plasma membrane. *See* ABSORPTION (BIOLOGY); CELL MEMBRANES.

In cells that secrete large amounts of hormones or digestive enzymes, most secretory and membrane proteins emerging from the *trans*-Golgi network are not immediately secreted, but are stored in membrane-bounded secretory granules. Secretory granules release their contents into the extracellular space in a process known as exocytosis, when their membranes fuse with the plasma membrane. Exocytosis occurs only after the cell receives a signal, usually initiated by the binding of a hormone or neurotransmitter to a receptor on the cell surface. The receptor triggers a signal transduction cascade that results in increased concentrations of second messengers such as cyclic adenosine 3′, 5′-monophosphate and phosphatidylinositol triphosphate. In most secretory cells, the second messengers or the hormone receptors themselves trigger the opening of calcium channels through which calcium ions stream into the cytoplasm. Calcium initiates the docking of the secretory granules with the plasma membrane and the activation of the fusion apparatus. *See* ENZYME; HORMONE; SIGNAL TRANSDUCTION.

In exceptional cases, proteins can be exported directly from the cytoplasm without using the secretory pathway. One such protein is fibroblast growth factor, a hormone involved in the growth and development of tissues such as bone and endothelium. Several interleukins, proteins that regulate the immune response, are also released via an unconventional route that may involve transport across the plasma membrane through channel proteins. These channels have adenosine 5′-triphosphatase (ATPase) enzyme activity and use the energy derived from the hydrolysis of ATP to catalyze transport. *See* CELLULAR IMMUNOLOGY. [M.Ri.]

Secretory structures (plant) Cells or organizations of cells which produce a variety of secretions. The secreted substance may remain deposited within the secretory cell itself or may be excreted, that is, released from the cell. Substances may be excreted to the surface of the plant or into intercellular cavities or canals. Some of the many substances contained in the secretions are not further utilized by the plant (resins, rubber, tannins, and various crystals), while others take part in the functions of the plant (enzymes and hormones). Secretory structures range from single cells scattered among other kinds of cells to complex structures involving many cells; the latter are often called glands.

Epidermal hairs of many plants are secretory or glandular. Such hairs commonly have a head composed of one or more secretory cells borne on a stalk. The hair of a stinging needle is bulbous below and extends into a long, fine process above. If one touches the hair, its tip breaks off, the sharp edge penetrates the skin, and the poisonous secretion is released.

Glands secreting a sugary liquid—the nectar—in flowers pollinated by insects are called nectaries. Nectaries may occur on the floral stalk or on any floral organ: sepal, petal, stamen, or ovary.

The hydathode structures discharge water—a phenomenon called guttation—through openings in margins or tips of leaves. The water flows through the xylem to its endings in the leaf and then through the intercellular spaces of the hydathode tissue toward the openings in the epidermis. Strictly speaking, such hydathodes are not glands because they are passive with regard to the flow of water.

Some carnivorous plants have glands that produce secretions capable of digesting insects and small animals. These glands occur on leaf parts modified as insect-trapping structures. In the sundews (*Drosera*) the traps bear stalked glands, called tentacles. When an insect lights on the leaf, the tentacles bend down and cover the victim with a mucilaginous secretion, the enzymes of which digest the insect. *See* INSECTIVOROUS PLANTS; VENUS' FLYTRAP.

Resin ducts are canals lined with secretory cells that release resins into the canal. Resin ducts are common in gymnosperms and occur in various tissues of roots, stems, leaves, and reproductive structures.

Gum ducts are similar to resin ducts and may contain resins, oils, and gums. Usually, the term gum duct is used with reference to the dicotyledons, although gum ducts also may occur in the gymnosperms.

Oil ducts are intercellular canals whose secretory cells produce oils or similar substances. Such ducts may be seen, for example, in various parts of the plant of the carrot family (Umbelliferae).

Laticifers are cells or systems of cells containing latex, a milky or clear, colored or colorless liquid. Latex occurs under pressure and exudes from the plant when the latter is cut. [K.E.]

Sedative A medication capable of producing a mild state of inhibition of the central nervous system (CNS) associated with reduced awareness of external stimuli. Numerous pharmacologic agents can induce different degrees of sedation, depending on the following variables: dosage; route of administration; absorption, metabolism, and excretion rates of the compound; specific receptor sites in the central nervous system that are affected by the agent; environmental setting; and state of the patient. *See* CENTRAL NERVOUS SYSTEM.

Ethanol was probably the first sedative compound and was widely used for its analgesic and hypnotic properties, as well as for its ability to decrease inhibitory anxiety with resultant relaxation and occasional euphoria. Subsequent sedative compounds include the barbiturates (for example, phenobarbital and secobarbital) and the benzodiazepines (for example, diazepam and alprazolam). Although these sedative compounds possess properties of tolerance and habituation, they vary in their addictive potential according to specific receptor sites and the particular type of patient. *See* ADDICTIVE DISORDERS; BARBITURATES.

Other classes of chemical agents that are used as sedatives include the antihistamines as well as some antidepressant drugs which possess sedative side effects in addition to their primary pharmacologic properties. Since these classes of compounds are not addicting, they can be safely used as hypnotics. *See* ANXIETY STATES; TRANQUILIZER. [D.M.Ga.]

Sedentaria A group of 28 or more families of polychaete annelids in which the anterior, or cephalic, region is more or less completely concealed by overhanging peristomial structures, or the body is divided into an anterior thoracic and a posterior abdominal region; the pharynx or proboscis is usually soft and epithelial, lacking hard jaws or paragnaths. *See* POLYCHAETA. [O.H.]

Sedimentary rocks Rocks that accumulate at the surface of the Earth, under ambient temperatures. Together with extruded hot lavas, sedimentary rocks form a thin cover of stratified material (the stratisphere) over the deep-seated igneous and metamorphic rocks that constitute the bulk of the Earth's crust. Sediments cover about three-quarters of the land and of the ocean floor. The thickness of the stratisphere is generally measured in kilometers, and locally reaches about 15 km (50,000 ft). *See* EARTH CRUST; IGNEOUS ROCKS; METAMORPHIC ROCKS; ROCK.

Most sediments accumulate as sand and dust or mud. Being deposited from fluids (air, water) under the influence of gravity, they tend to assume level surfaces (though locally steep slopes may be developed, as in dunes and reefs). Changes in supply of sediment and in depositing agencies change the nature of the deposits from day to day and from millennium to millennium, and commonly interrupt the process altogether. As a result, the accumulated mantle of sediment has a layered structure, divided into beds or strata. Sediments become compacted as waters are squeezed out of them during burial and tectonism, and become cemented as remaining pore space becomes filled by newly growing minerals, mainly calcite or quartz. Bacterial degradation of organic matter, invasion by other fluids, and changes in temperature continue to alter the chemical environment, and lead to alteration of unstable mineral phases. Such processes are included in the term diagenesis. Soft sediment thus becomes converted to rock, but the geologist includes both in the concept of sedimentary rocks. *See* CALCITE; DIAGENESIS; QUARTZ.

When sediments are carried to greater depths or are otherwise subjected to high heat or pressure, growth of new minerals and plastic deformation destroy sedimentary structures and metamorphose the rock. Alternatively, the sediment melts in transition to igneous rock. Thus, sedimentary rocks are recycled through geologic time. Most of the crust under the continents, consisting of igneous and metamorphic rocks, has probably passed through the sedimentary state at some point. Despite such losses, sedimentary rocks have locally survived from very early (Archean) times, nearly 4 billion years ago. *See* ARCHEAN.

Sediments are almost entirely derived from transfer of materials within the Earth's crust. First in importance is gradation, the wearing away of the highlands and the deposition of the products in the low spots: subsiding basins and the oceans. Second is crustal volcanism, which produces large ash falls from explosive volcanoes, and recycles ions to the surface in hot springs. Small amounts are contributed from the mantle underlying the crust: mainly pumice produced when mantle-derived oceanic basalts interact with water. A small fraction of sediment consists of organic matter created by organisms from carbon dioxide and water. Water frozen in the atmosphere transiently covers parts of the stratisphere with ice, while traces of extraterrestrial matter continue to be added from meteorites. *See* COSMIC SPHERULES; METEORITE; WEATHERING PROCESSES.

Though sediments contain such a large range of diverse constituents occurring in a wide variety of mixtures, such mixtures are generally dominated by one or two constituents, and thus may be grouped into a number of classes, each of which can be divided into families.

Detrital sediments are alternately transported and deposited, reeroded, and redeposited on their way to a more permanent resting place, so that their constituents may carry the imprints of a complex history, while the structure of the deposit testifies to the last depositional episode. *See* DEPOSITIONAL SYSTEMS AND ENVIRONMENTS.

Pyroclastic sediments originate from volcanic vents. Submarine eruptions form pumice, or frothy glass, much of which floats widely. The important contributions are great eruptions of glass droplets are ejected into atmosphere and stratosphere to fall as a rain of pumice, sand, and silt, in some cases mixed with crystals. Pyroclastic rocks, largely composed of glass, are readily altered to clay minerals (montmorillonite) in weathering. They produce excellent soils. Beds of montmorillonite (bentonites) are mined for preparation of artificial muds such as those used in well drilling. *See* MONTMORILLONITE; PUMICE; VOLCANO; VOLCANOLOGY.

Chemical sediments represent the precipitation of materials carried in solution, either by simple chemical precipitation or by the activity of organisms.

Carbonate rocks form about 20% of all sediments. In natural waters, calcium and magnesium are mainly held in solution by virtue of carbon dioxide. In many fresh waters and in the surficial ocean, withdrawal of carbon dioxide—by warming of the water or by the consumption of carbon dioxide in green-plant photosynthesis—leads to supersaturation and to the deposition of calcium carbonate. This normally yields a lime mud of microscopic crystals. Even more important is the secretion of calcium carbonate skeletons, ultimately deposited on ocean floors, by some algae and by a large variety of animals, ranging from microscopic foraminifera to corals and molluscan shells. Carbonate rocks are a major ingredient of portland cement. They are crushed in large quantities for use in road building, agriculture, and smelting, and in the chemical industry. They also furnish building and ornamental stone. Carbonate rocks contain a large share of the world's petroleum resources. *See* ARAGONITE; CALCITE; CEMENT; DOLOMITE; LIMESTONE; OOLITE; STYLOLITES.

Evaporites are formed in bays, estuaries, and lakes of arid regions. On progressive evaporation, seawater first forms deposits of calcium sulfate as gypsum or anhydrite, followed by halite (NaCl) and ultimately potash and magnesium salts. Evaporation of lake water may yield different precipitates such as trona, borax, and silicates. Much of what is sold as table salt is mined from evaporite deposits, as is potash fertilizer. Plaster of paris is produced from gypsum or anhydrite, and the chemical industry relies on evaporite deposits of various types. *See* FERTILIZER; GYPSUM; HALITE; PLASTER OF PARIS; SALINE EVAPORITES; SALT (FOOD).

Nondetrital siliceous rocks such as silicon dioxide (silica) is second only to carbonate in the dissolved load of most streams. Organisms take up nearly all silica supplied, covering much of the deep-sea floor with radiolarian and diatomaceous ooze. Over geological time spans, diagenetic alteration converts these into dull white opal-ct or quartz porcellanites, or into the solid, waxy-looking mosaics of fine quartz grains known as chert or flint. Diatom ooze is mined for abrasives and filters, as well as for insulation. *See* CHERT; SILICA MINERALS.

Carbonaceous sediments are the result of organic activity, and are of two sorts: the peat-coal series and the kerogens. Peat is used for local fuel in boggy parts of the world. Lignite and bituminous coals continue to be important fuels. *See* COAL; LIGNITE; PEAT. [A.G.F.]

Sedimentation (industry) The separation of a dilute suspension of solid particles into a supernatant liquid and a concentrated slurry. If the purpose of the process is to concentrate the solids, it is termed thickening; and if the goal is the removal of the solid particles to produce clear liquid, it is called clarification. Thickening is the common operation for separating fine solids from slurries. Examples are magnesia, alumina red mud, copper middlings and concentrates, china clay (kaolin), coal tailings, phosphate slimes, and pulp-mill and other industrial wastes. Clarification is prominent in the treatment of municipal water supplies.

The driving force for separation is the difference in density between the solid and the liquid. Ordinarily, sedimentation is effected by the force of gravity, and the liquid is water or an aqueous solution. For a given density difference, the solid settling process proceeds more rapidly for larger-sized particles. For fine particles or small density differences, gravity settling may be too slow to be practical; then centrifugal force rather than gravity can be used. Further, when centrifugal force is inadequate, the more positive method of filtration may be employed. All those methods of separating solids and liquids belong to the generic group of mechanical separations. *See* CENTRIFUGATION; CLARIFICATION; FILTRATION; THICKENING.

Particles too minute to settle at practical rates may form flocs by the addition of agents such as sodium silicate, alum, lime, and alumina. Because the agglomerated particles act like a single large particle, they settle at a feasible rate and leave a clear liquid behind. [V.W.U.]

Sedimentology The study of natural sediments, both lithified (sedimentary rocks) and unlithified, and of the processes by which they are formed. Sedimentology includes all those processes that give rise to sediment or modify it after deposition: weathering, which breaks up or dissolves preexisting rocks so that sediment may form from them; mechanical transportation; deposition; and diagenesis, which modifies sediment after deposition and burial within a sedimentary basin and converts it into sedimentary rock. Sediments deposited by mechanical processes (gravels, sands, muds) are known as clastic sediments, and those deposited predominantly by chemical or biological processes (limestones, dolomites, rock salt, chert) are known as chemical sediments. *See* SEDIMENTARY ROCKS; WEATHERING PROCESSES.

The raw materials of sedimentation are the products of weathering of previously formed igneous, metamorphic, or sedimentary rocks. In the present geological era, 66% of the continents and almost all of the ocean basins are covered by sedimentary rocks. Therefore, most of the sediment now forming has been derived by recycling previously formed sediment. Identification of the oldest rocks in the Earth's crust, formed more than 3×10^9 years ago, has shown that this process has been going on at least since then. Old sedimentary rocks tend to be eroded away or converted into metamorphic rocks, so that very ancient sedimentary rocks are seen at only a few places on Earth. *See* EARTH CRUST; IGNEOUS ROCKS; METAMORPHIC ROCKS.

Major controls. The major controls on the sedimentary cycle are tectonics, climate, worldwide (eustatic) changes in sea level, the evolution of environments with geological time, and the effect of rare events.

Tectonics are the large-scale motions (both horizontal and vertical) of the Earth's crust. Tectonics are driven by forces within the interior of the Earth but have a large effect on sedimentation. These crustal movements largely determine which areas of the Earth's crust undergo uplift and erosion, thus acting as sources of sediment, and which areas undergo prolonged subsidence, thus acting as sedimentary basins. Rates of uplift may be very high (over 10 m or 33 ft per 1000 years) locally, but probably such rates prevail only for short periods of time. Over millions of years, uplift even in mountainous regions is about 1 m (3.3 ft) per 1000 years, and it is closely balanced by rates of erosion. Rates of erosion, estimated from measured rates of sediment transport in rivers and from various other techniques, range from a few meters per 1000 years in mountainous areas to a few millimeters per 1000 years averaged over entire continents. *See* BASIN; PLATE TECTONICS.

Climate plays a secondary but important role in controlling the rate of weathering and sediment production. The more humid the climate, the higher these rates are. A combination of hot, humid climate and low relief permits extensive chemical weathering, so that a larger percentage of source rocks goes into solution, and the clastic sediment produced consists mainly of those minerals that are chemically inert (such as quartz) or that are produced by weathering itself (clays). Cold climates and high relief favor physical over chemical processes. *See* CLIMATOLOGY.

Tectonics and climate together control the relative level of the sea. In cold periods, water is stored as ice at the poles, which can produce a worldwide (eustatic) lowering of sea level by more than 100 m (330 ft). Changes in sea level, whether local or worldwide, strongly influence sedimentation in shallow seas and along coastlines; sea-level changes also affect sedimentation in rivers by changing the base level below which a stream cannot erode its bed.

One of the major conclusions from the study of ancient sediments has been that the general nature and rates of sedimentation have been essentially unchanged during the last billion years of geological history. However, this conclusion, uniformitarianism, must be qualified to take into account progressive changes in the Earth's environment through geological time, and the operation of rare but locally or even globally important catastrophic events. The most important progressive changes have been in tectonics and atmospheric chemistry early in Precambrian times, and in the nature of life on the Earth, particularly since the beginning of the Cambrian. *See* CAMBRIAN.

Throughout geological time, events that are rare by human standards but common on a geological time scale, such as earthquakes, volcanic eruptions, and storms, produced widespread sediment deposits. There is increasing evidence for a few truly rare but significant events, such as the rapid drying up of large seas (parts of the Mediterranean) and collisions between the Earth and large meteoric or cometary bodies (bolides).

Sediment is moved either by gravity acting on the sediment particles or by the motions of fluids (air, water, flowing ice), which are themselves produced by gravity. Deposition takes place when the rate of sediment movement decreases in the direction of sediment movement; deposition may be so abrupt that an entire moving mass of sediment and fluid comes to a halt (mass deposition, for example, by a debris flow), or so slow that the moving fluid (which may contain only a few parts per thousand of sediment) leaves only a few grains of sediment behind. The settling velocity depends on the density and viscosity of the fluid, as well as on the size, shape, and density of the grains. *See* STREAM TRANSPORT AND DEPOSITION.

Chemical sedimentation. Chemical weathering dissolves rock materials and delivers ions in solution to lakes and the ocean. The concentrations of ions in river and ocean water are quite different, showing that some ions must be removed by sedimentation. Comparison of the modern rate of delivery of ions to the ocean, with their concentration in the oceans, shows that some are removed very rapidly (residence times of only a few thousand years) whereas others, such as chlorine and sodium, are removed very slowly (residence times of hundreds of millions of years).

Biological effects. Many so-called chemical sediments are actually produced by biochemical action. Much is then reworked by waves and currents, so that the chemical sediment shows clastic textures and consists of grains rounded and sorted by transport. Depositional and diagenetic processes, however, are often strongly affected by organic action, no matter what the origin of the sediment. Plants in both terrestrial and marine environments tend to trap sediment, enhancing deposition and slowing erosion.

Sedimentary environments and facies. Sedimentary rocks preserve the main direct evidence about the nature of the surface environments of the ancient Earth and the way they have changed through geological time. Thus, besides trying to understand the basic principles of sedimentation, sedimentologists have studied modern and ancient sediments as records of ancient environments. For this purpose, fossils and primary sedimentary structures are the best guide. These structures are those formed at the time of deposition, as opposed to those formed after deposition by diagenesis, or by deformation. In describing sequences of sedimentary rocks in the field (stratigraphic sections), sedimentologists recognize compositional, structural, and organic aspects of rocks that can be used to distinguish one unit of rocks from another. Such units are known as sedimentary facies, and they can generally be interpreted as having formed in different environments of deposition. Though there are a large number of different sedimentary environments, they can be classified in a number of general classes, and their characteristic facies are known from studies of modern environments. *See* Facies (geology); Stratigraphy; Trace fossils. [G.V.M.]

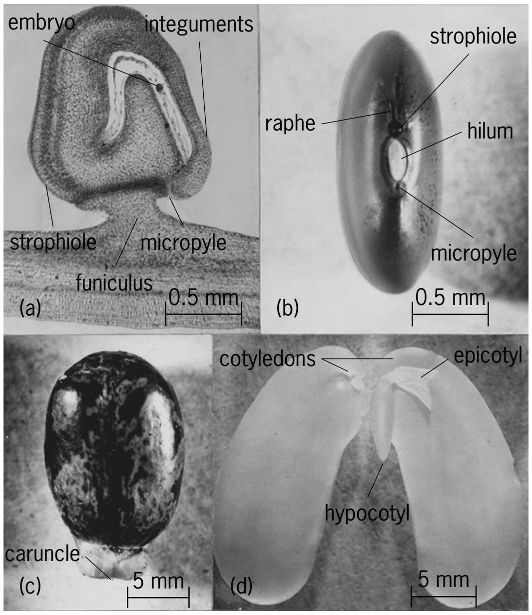
Seebeck effect The generation of a temperature-dependent electromotive force (emf) at the junction of two dissimilar metals. This phenomenon provides the physical basis for the thermocouple. In 1821, T. J. Seebeck discovered that near a closed circuit composed of two linear conductors of two different metals a magnetic needle would be deflected if, and only if, the two junctions were at different temperatures, and that if the temperatures of the two junctions were reversed the direction of deflection would also be reversed. He investigated 35 different metals and arranged them in a series such that at a hot junction, current flows from a metal earlier in the series to a later one. *See* Electromotive force (emf).

A thermocouple consists of a pair of wires of dissimilar metals, joined at the ends. One junction is kept at an accurately known cold temperature, usually that of melting ice, and the other is used for the measurement of an unknown temperature, by measuring the emf generated as a result of the Seebeck effect. *See* Thermocouple; Thermoelectricity. [A.E.Ba.]

Seed A fertilized ovule containing an embryo which forms a new plant upon germination. Seed-bearing characterizes the higher plants—the gymnosperms (conifers and allies) and the angiosperms (flowering plants). Gymnosperm (naked) seeds arise on the surface of a structure, as on a seed scale of a pine cone. Angiosperm (covered) seeds develop within a fruit, as the peas in a pod. *See* Flower; Fruit.

Structure. One or two tissue envelopes, or integuments, form the seed coat which encloses the seed except for a tiny pore, the micropyle (see illustration). The micropyle is near the funiculus (seed stalk) in angiosperm seeds. The hilum is the scar left when the seed is detached from the funiculus. Some seeds have a raphe, a ridge near the hilum opposite the micropyle, and a bulbous strophiole. Others such as nutmeg possess arils, outgrowths of the funiculus, or a fleshy caruncle developed from the seed coat near the hilum, as in the castor bean. The embryo consists of an axis and attached cotyledons (seed leaves). The part of the axis above the cotyledons is the epicotyl (plumule); that below, the hypocotyl, the lower end of which bears a more or less developed primordium of the root (radicle). The epicotyl, essentially a terminal bud, possesses an apical meristem (growing point) and, sometimes, leaf primordia. The seedling stem develops from the epicotyl. An apical meristem of the radicle produces the primary root of the seedling, and transition between root and stem occurs in the hypocotyl. *See* Apical meristem; Root (botany); Stem.

Two to many cotyledons occur in different gymnosperms. The angiosperms are divided into two major groups according to number of cotyledons: the monocotyledons and the dicotyledons. Mature gymnosperm seeds contain an endosperm (albumen or nutritive tissue) which surrounds the embryo. In some mature dicotyledon seeds the endosperm persists, the cotyledons are flat and leaflike, and the epicotyl is simply an apical meristem. In other seeds, such as the bean, the growing embryo absorbs the endosperm, and food reserve for germination is stored in fleshy cotyledons. The endosperm persists in common monocotyledons, for example, corn and wheat; and the cotyledon, known as the scutellum, functions as an absorbing organ during germination. Grain embryos also possess a coleoptile and a coleorhiza sheathing the epicotyl and the radicle, respectively. The apical meristems of lateral seed roots also may be differentiated in the embryonic axis near the scutellum of some grains.



Seed structures. (*a*) Median longitudinal section of pea ovule shortly after fertilization, showing attachment to pod tissues. (*b*) Mature kidney bean. (*c*) Mature castor bean. (*d*) Opened embryo of mature kidney bean.

Many so-called seeds consist of hardened parts of the fruit enclosing the true seed which has a thin, papery seed coat. Among these are the achenes, as in the sunflower, dandelion, and strawberry, and the pits of stone fruits such as the cherry, peach, and raspberry. Many common nuts also have this structure. Mechanisms for seed dispersal include parts of both fruit and seed. *See* Population dispersal.

Economic importance. Propagation of plants by seed and technological use of seed and seed products are among the most important activities of modern society. Specializations of seed structure and composition provide rich sources for industrial exploitation apart from direct use as food. Common products include starches and glutens from grains, hemicelluloses from guar and locust beans, and proteins and oils from soybeans and cotton seed. Drugs, enzymes, vitamins, spices, and condiments are obtained from embryos, endosperms, and entire seeds, often including the fruit coat. Most of the oils of palm, olive, and pine seeds are in the endosperm. Safflower seed oil is obtained mainly from the embryo, whereas both the seed coat and embryo of cotton seed are rich in oils. *See* Food; Plant anatomy; Reproduction (plant). [R.M.R.]

Physiology. Physical and biochemical processes of seed growth and germination are controlled by genetic and environmental factors. Conditions of light, temperature, moisture, and oxygen affect the timing and ability of a seed to mature and germinate. Seed development (embryogenesis) is concerned with the synthesis and storage of carbohydrate, protein, and oil to supply nutrients to the germinating seedling prior to soil emergence. Seed development occurs in several stages: rapid cell division, seed fill, and desiccation. The timing of each stage is species-specific and environmentally influenced.

Dormancy. Seed dormancy is the inability of a living seed to germinate under favorable conditions of temperature, moisture, and oxygen. Dormancy does not occur in all seeds, but typically occurs in plant species from temperate and colder habitats. This process allows for a delay in seed germination until environmental conditions are adequate for seedling survival. At least three types of seed dormancy are recognized: primary, secondary (induced), and enforced. Primary dormancy occurs during seed maturation, and the seed does not germinate readily upon being shed. Secondary and enforced dormancy occur after the seed is shed and may be caused by adverse environmental factors such as high or low temperature, absence of oxygen or light, low soil moisture, and presence of chemical inhibitors. Seeds with secondary dormancy will not germinate spontaneously when environmental conditions improve, and need additional environmental stimuli. Seeds with enforced dormancy germinate readily upon removal of the environmental limitation. Regulation of dormancy may be partly controlled by hormones. *See* ABSCISIC ACID; DORMANCY.

Dormancy is terminated in a large number of species when an imbibed seed is illuminated with white light. Biochemical control of this process is related to the functioning of a single pigment, phytochrome, frequently located in the seed coat or embryonic axis. Phytochrome imparts to the seed the ability to interpret light quality, such as that under an existing vegetative canopy, and to distinguish light from dark with respect to its position in the soil. Phytochrome also is affected by temperature and is involved in the seasonal control of the ending of dormancy. Hormones that promote germination of dormant seeds include gibberellins, cytokinins, ethylene, and auxins. *See* AUXIN; CYTOKININS; ETHYLENE; GIBBERELLIN.

Germination. Germination is the process whereby a viable seed takes up water and the radicle (primary root) or hypocotyl emerges from the seed under species-specific conditions of moisture, oxygen, and temperature. Dormant seeds must undergo additional environmental stimuli to germinate. The germinating seed undergoes cell expansion, as well as increases in respiration, protein synthesis, and other metabolic activities prior to emergence of the growing seedling. [C.A.L.]

Seiche A short-period oscillation in an enclosed or semienclosed body of water, analogous to the free oscillation of water in a dish. The initial displacement of water from a level surface can arise from a variety of causes, and the restoring force is gravity, which always tends to maintain a level surface. Once formed, the oscillations are characteristic only of the geometry of the basin itself and may persist for many cycles before decaying under the influence of friction. The term “seiche” appears to have been first used to describe the rhythmic oscillation of the water surface in Lake Geneva, which occasionally exposed large areas of the lake bed that are normally submerged. *See* WAVE MOTION IN LIQUIDS.

Seiches can be generated when the water is subject to changes in wind or atmospheric pressure gradients or, in the case of semienclosed basins, by the oscillation of adjacent connected water bodies having a periodicity close to that of the seiche or of one of its harmonics. Other, less frequent causes of seiches include heavy precipitation over a portion of the lake, flood discharge from rivers, seismic disturbances, submarine mudslides or slumps, and tides. The most dramatic seiches have been observed after earthquakes. [A.Wu.; D.M.F.]

Seismic exploration for oil and gas Prospecting for oil and gas using exploration seismology, a geophysical method of determining geologic structure by means of prospector-induced elastic waves. By studying body waves such as compressional and shear waves propagating through the Earth’s interior, the constituent and elastic properties of its solid and liquid core, its solid mantle, and its thin crust are defined. The major differences between earthquake seismology and petroleum exploration seismology are scales and knowledge of the location of seismic disturbances. Earthquake seismology studies naturally generated seismic waves, which have periods in minutes and resolution in kilometers. In exploration seismology, artificial sources are used that have periods of tenths of a second and tens of meters of resolution. Production seismology requires higher-frequency seismic waves and better resolution, often resolution in the order of a few meters. *See* EARTH; EARTH INTERIOR.

Computer technology allows resolution of some of the theoretical complexities of elastic wave propagation so that deeper insight into the wave field phenomena can be obtained. The availability of a large number of channels in the recording instrument facilitates three-dimensional and three-component acquisitions. Powerful supercomputers allow manipulation of larger and larger data sets, and they have facilitated display and interpretation of them as a single data unit through the use of advanced computer visualization techniques. *See* COMPUTER; SUPERCOMPUTER.

The availability of powerful workstations led to the wide use of interactive processing and interpretation. When such is coupled with technically advanced algorithms, the amount of information that the interpreter can obtain from the data increases significantly. Better quality control is provided, fine-tuning analysis is achieved more easily, and the data can be enhanced to meet specific objectives. If there are discrepancies between the model and the real data, a hypothesis can be proposed based on information derived from the data. This process can be iterated until the Earth model derived is consistent with all available surface and subsurface geophysical, petrophysical, geological, and engineering data sets. *See* ALGORITHM; MODEL THEORY; SIMULATION.

The seismic method as applied to exploration of oil and gas involves field acquisition, data processing, and geologic interpretation. Seismic field acquisition requires placement of acoustic receivers (geophones) on the surface in the case of land exploration, or strings of hydrophones in the water in the case of marine exploration. Seismic data processing is usually done in large computing centers with digital mainframe computers or a large number of processors in parallel configurations. The end result of seismic data processing is the production of a subsurface profile similar to a geologic cross section. It is commonly plotted in a time scale, but it is also possible to plot it in depth. These time or depth profiles are used for geologic interpretation. Geologic interpretation of seismic data has two key components, structural and stratigraphic. Structural interpretation of seismic data involves mapping of the geologic relief of different subsurface strata by using seismic data as well as information from boreholes and outcrops. Stratigraphic interpretation looks at attributes within a common stratum and interprets changes to infer varying reservoir conditions such as lithology, porosity, and fluid content.

Historically, surface seismic acquisition is done by placing sources and receivers along a straight line so that it can be assumed that all the reflection points fall in a two-dimensional plane formed between the line of traverse and the vertical. This is known as two-dimensional seismic. Three-dimensional seismic is a method of acquiring surface seismic data by placing sources and receivers in an areal pattern. One example of a simple three-dimensional layout is to place the receivers along a line and shoot into these receivers along a path perpendicular to this line. *See* COMPUTER GRAPHICS.

A three-dimensional seismic survey provides a more accurate and detailed image of the subsurface. It offers significantly higher signal quality than the two-dimensional data commonly acquired. It also improves both spatial and temporal resolutions. The three-dimensional seismic technique is being applied to exploration and production of oil and gas, accounting for more than half of the seismic activity in the Gulf of Mexico and North Sea.

Production seismology is the application of seismic techniques to problems related to the production and exploitation of petroleum reservoirs. Since production geophysics is the only effective method available that can image the reservoirs under in-place conditions, it has become an active field of applied research aimed at improving descriptions and understanding of reservoirs and their fluid flow behaviors. *See* GEOPHYSICAL EXPLORATION; PETROLEUM ENHANCED RECOVERY; PETROLEUM GEOLOGY; PETROLEUM RESERVOIR ENGINEERING; SEISMOLOGY. [T.P.N.]

Seismic risk The probability that social or economic consequences of earthquakes will equal or exceed specified values at a site, at several sites, or in an area, during a specified exposure time.

Although the term seismic risk is occasionally used in a general sense to mean the potential for both the occurrence of natural phenomena and the economic and life loss associated with earthquakes, it is useful to differentiate between the concepts of seismic hazard and seismic risk. Seismic hazard may be defined as any physical phenomena that result either from surface faulting during shallow earthquakes or from the ground shaking resulting from an earthquake and that may produce adverse effects on human activities.

The exposure time is the time period of interest for seismic hazard or risk calculations. In practical applications, the exposure time may be considered to be the design lifetime of a building or the length of time over which the numbers of casualties will be estimated. [S.T.A.]

Seismic stratigraphy Determination of the nature of sedimentary rocks and their fluid content from analysis of seismic data. Seismic stratigraphy is divided into seismic-sequence (facies) analysis and reflection-character analysis.

In seismic-sequence analysis the first step is to separate seismic-sequence units, also called seismic-facies units. This is usually done by mapping unconformities where they are shown by angularity. Angularity below an unconformity may be produced by erosion at an angle across the former bedding surfaces or by toplap (offlap), and angularity above an unconformity may be produced by onlap or downlap, the latter distinction being based on geometry. The unconformities are then followed along reflections from the points where they cannot be so identified, advantage being taken of the fact that the unconformity reflection is often relatively strong. The procedure often followed is to mark angularities in reflections by small arrows before drawing in the boundaries. *See* UNCONFORMITY.

Seismic-facies units are three-dimensional, and many of the conclusions from them are based on their three-dimensional shape. The appearance on seismic lines in the dip and strike directions is often very different. For example, a fan-shaped unit might show a progradational pattern in the dip direction and discontinuous, overlapping arcuate reflections in the strike direction. *See* FACIES (GEOLOGY).

Reflection-character analysis may be based on information from boreholes which suggests that a particular interval may change nearby in a manner which increases its likelihood to contain hydrocarbon accumulations. Lateral changes in the wave shape of individual reflection events may suggest where the stratigraphic changes or hydrocarbon accumulations may be located. *See* DRILLING AND BORING, GEOTECHNICAL; SEISMIC EXPLORATION FOR OIL AND GAS.

Where sufficient information is available to develop a reliable model, expected changes are postulated and their effects are calculated and compared to observed seismic data. The procedure is called synthetic seismogram manufacture; it usually involves calculating seismic data based on sonic and density logs from boreholes, sometimes based on a model derived in some other way. The sonic and density data are then changed in the manner expected for a postulated stratigraphic change, and if the synthetic seismogram matches the actual seismic data sufficiently well, it implies that the changes in earth layering are similar to those in the model. *See* GEOPHYSICAL EXPLORATION; SEISMOGRAPHIC INSTRUMENTATION; SEISMOLOGY; STRATIGRAPHY. [R.E.Sh.]

Seismographic instrumentation Various devices or systems of devices for measuring movement in the Earth. Ground motion is generally the result of passing seismic waves, gravitational tides, atmospheric processes, and tectonic processes. Seismographic instrumentation typically consists of a sensing element (seismometer), a signal-conditioning element or elements (galvanometer, mechanical or electronic amplifier, filters, analog-to-digital conversion circuitry, telemetry, and so on), and a recording element (analog visible or direct, frequency modulation, or digital magnetic tape or disk). Seismographs are used for earthquake studies, investigations of the Earth's gravity field, nuclear explosion monitoring, petroleum exploration, and industrial vibration measurement.

Seismographic instruments may be required to measure ground motions accurately over a range approaching 12 orders of magnitude, from as small as 10^{-11} m to as large as several meters (a very large earthquake). The instruments may be required to measure frequencies as low as $\sim 10^{-5}$ Hz (the semidiurnal gravitational tides) to as high as $\sim 10^{4}$ Hz (as observed from acoustic emissions from rock failures in mines). Seismic waves from earthquakes are observed in the bandwidth of $\sim 3 \times 10^{-4}$ Hz (the gravest free oscillations of the Earth) to ~ 200 Hz (a local earthquake). In exploration seismology the frequency range of interest is typically 10–1000 Hz.

The seismometer is the basic sensing element in seismographic instruments, and there are two fundamentally different types: inertial and strain. The inertial seismometer generates an output signal that is proportional to the relative motion between its frame (usually attached to the ground or a point of interest) and an internal inertial reference mass. The strain seismometer (or linear extensometer) generates an output that is proportional to the distance between two points.

A seismoscope is a device that indicates only the occurrence of relatively strong ground shaking and not its time of occurrence or duration. A typical seismoscope inscribes a hodograph of horizontal strong ground motion on a smoked watch glass.

A dilatometer continuously and precisely measures volumetric strain. The quantity measured is the change ΔV in the reference volume V, and the ratio $\Delta V/V$ gives the volumetric strain. Dilatometers are typically installed in a borehole in competent rock (preferably granite) at a depth of 100–300 m (330–1000 ft).

A tiltmeter monitors the relative change in the elevation between two points, usually with respect to a liquid-level surface. The horizontal distance between the reference points may be as little as a few millimeters or as large as several hundred meters.

The gravity meter is just a vertical-component accelerometer, that is, a pendulum sensing ground motion and equipped with a displacement transducer, analogous to the inertial tiltmeter. Gravimeters are widely used in geophysical exploration, in the study of earth tides, and in the recording of very low frequency (0.0003–0.01 Hz) seismic waves from earthquakes. *See* ACCELEROMETER.

The complete seismograph produces a record of the properly conditioned signal from the seismometer, along with appropriate timing information. The recording system may be as simple as a mechanical stylus scratching a line on a smoke-covered drum in a portable microearthquake seismograph, or as complex as a multichannel computer-controlled system handling 25,000 24-bit digital words per second in a modern seismic reflection survey for petroleum exploration. The range between these extremes includes many special-purpose seismographs, all designed to record ground motion in a particular application. *See* EARTH TIDES; EARTHQUAKE; GEOPHYSICAL EXPLORATION; SEISMIC EXPLORATION FOR OIL AND GAS; SEISMOLOGY. [T.V.McE.; R.A.U.]

Seismology The study of the shaking of the Earth's interior caused by natural or artificial sources. Throughout the period in which plate tectonics was advanced and its basic tenets tested and confirmed in the early 1960s, and into the latest phase of inquiry into basic processes, seismology (and particularly seismic imaging) has provided critical observational evidence upon which discoveries have been made and theory has been advanced regarding the structure of the Earth's crust, mantle, and core. *See* Plate tectonics.

Theoretical seismology. A seismic source is an energy conversion process that over a short time (generally less than a minute and usually less than 1–10 s) transforms stored potential energy into elastic kinetic energy. This energy then propagates in the form of seismic waves through the Earth until it is converted into heat by internal (molecular) friction. Large sources, that is, sources that release large amounts of potential energy, can be detected worldwide. Earthquakes above Richter magnitude 5 and explosions above 50 kilotons or so are large enough to be observed globally before the seismic waves dissipate below modern levels of detection. Small charges of dynamite or small earthquakes are detectable at a distance of a few tens to a few hundreds of kilometers, depending on the type of rock between the explosion and the detector. *See* Earthquake.

Seismic vibrations are recorded by instruments known as seismometers that sense the change in the position of the ground (or water pressure) as seismic waves pass underneath. The record of ground motion as a function of time is a seismogram, which may be in either analog or digital form. Advances in computer technology have made analog recording virtually obsolete: most seismograms are recorded digitally, which makes quantitative analysis much more feasible.

The response of the Earth to a seismic disturbance can be approximated by the equation of motion for a disturbance in a perfectly elastic body. This equation holds regardless of the type of source, and is closely related to the acoustic-wave equation governing the propagation of sound in a fluid. The equation of motion for an isotropic perfectly elastic solid separates into two equations describing the propagation of purely dilatational (volume changing, curl-free) and purely rotational (no volume changing, divergence-free) disturbances. These propagate with wave speeds α and β, respectively. These velocities are also known as the compressional or primary (P) and shear or secondary (S) velocities, and the corresponding waves are called P and S waves. The compressional velocity is always faster than the shear velocity. In the Earth, α can range from a few hundred meters per second in unconsolidated sediments to more than 13.7 km/s (8.2 mi/s) just above the core–mantle boundary. Wave speed β ranges from zero in fluids (ocean, fluid outer core) to about 7.3 km/s (4.4 mi/s) at the core-mantle boundary. *See* Hooke's law; Special functions.

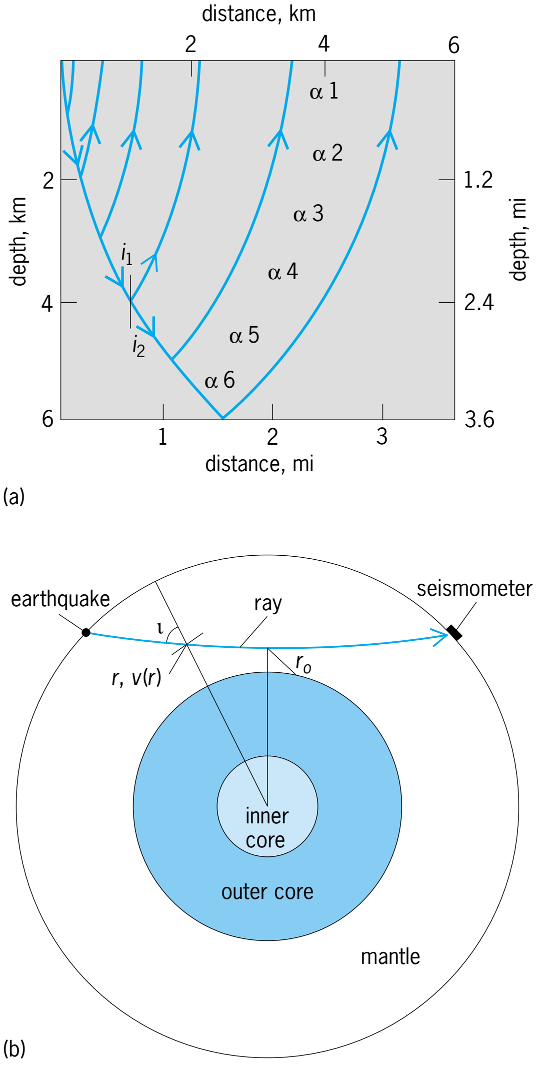
A P wave has no curl and thus only causes the material to undergo a volume change with no other distortion. An S wave has no divergence, thus causing no volume change, but right angles embedded in the material are distorted. Explosions are relatively efficient generators of compressional disturbances, but earthquakes generate both compressional and shear waves. Compressional waves, by virtue of the mechanical stability condition, always arrive before shear waves.

Compressional and shear waves can exist in an elastic body irrespective of its boundaries. For this reason, seismic waves traveling with speed α or β are known as body waves. A third type of wave motion is produced if the elastic material is bounded by a free surface. The free-surface boundary conditions help trap energy near the surface, resulting in a boundary or surface wave. This in turn can be of two types. A Rayleigh wave combines both compressional and shear motion and requires only the presence of a boundary to exist. A Love wave is a pure-shear disturbance that can propagate only in the presence of a change in the elastic properties with depth from the free surface. Both are slower than body waves.

Solutions of the elastic-wave equation in which a wave function of a particular shape propagates with a particular speed are known as traveling waves. An important property of traveling waves is their causality; that is, the wave function has no amplitude before the first predicted arrival of energy. The complete seismic wavefield can be constructed by summing up every possible traveling wave.

Traveling-wave or full-wave theory provides the basis for a very useful theoretical abstraction of elastic-wave propagation in terms of the more common notions of wavefronts and their outwardly directed normals, called rays. Ray theory makes the prediction of certain kinematic quantities such as ray path, travel time, and distance by a simple geometric exercise. Ray theory can be developed in the context of an Earth comprising flat-lying layers of uniform velocities; this is a very useful approximation for most problems in crustal seismology and can be extended to spherical geometry for global studies.

Kinematic equations have been developed to describe what happens to rays as they impinge on the boundaries between layers. The illustration shows a single ray propagating in the



Seismic ray paths. (*a*) A single ray passing through a multilayered Earth comprising a stack of uniform velocity layers will be reflected from each layer and also be refracted as it passes from one layer into the layer below in a manner that obeys Snell's law. Each ray therefore is considered to give rise to a new system of rays. (*b*) Ray diagram for a cross section of the spherical Earth. At the point labeled $v(r)$, r = radial distance and v = velocity. r_0 = radial distance to the turning point. α is the angle of incidence.

stack of horizontal layers that define the model Earth. At each interface, part of the ray's energy is reflected, but a portion also passes through into the layer below. The transmitted portion of the ray is refracted; that is, it changes the angle at which it is propagating. The relationship between the incident angle and the refracted angle is exactly the same as that describing the refraction of light between two media of differing refractive index. *See* REFRACTION OF WAVES.

These simple geometric equations can be extended to the computation of amplitudes provided that there are no sharp discontinuities in the velocity as a function of depth. More exact representations of the amplitudes and wave shapes that solve the full-wave equation to varying extents can be constructed with the aid of powerful computers; these methods are collectively known as seismogram synthesis, and the seismograms thus computed are known as synthetics. Synthetics can be computed for elastic or dissipative media that vary in one, two, or three dimensions.

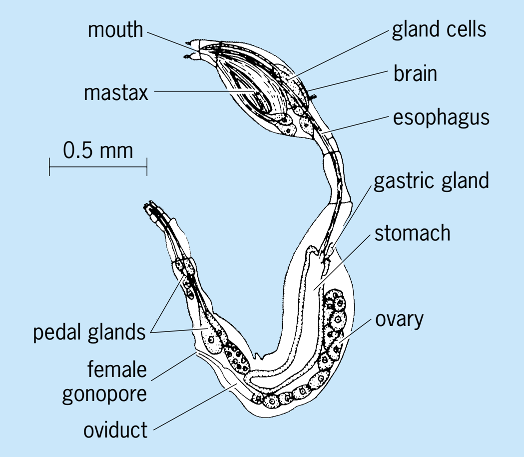
In a typical experiment for crustal imaging, a source of seismic energy is discharged on the surface, and instruments record the disturbance at numerous locations. Many different types of sources have been devised, from simple explosives to mechanical vibrators and devices known as airguns that discharge a "shot" of compressed air. The details of the source-receiver geometry vary with the type of experiment and its objective, but the work always involves collecting a large number of recordings at increasing distance from the source. This seismogram is complex, exhibiting a number of distinct arrivals with a variety of shapes and having amplitudes that change with distance. Although this seismogram clearly does not resemble the structure of the Earth in any sensible way and is therefore not what would normally be thought of as an image, it can be analyzed to recover estimates of those physical properties of the Earth that govern seismic-wave propagation.

Two- and three-dimensional imaging. A volume of the crust can be directly imaged by seismic tomography. In crustal tomography, active sources are used (explosives on land, airguns at sea) so that the source location and shape are already known. Experiments can be constructed in which sources and receivers are distributed in such a way that many rays pass through a particular volume and the tomographic inversion can produce relatively high-resolution images of velocity pertubations in the crust. Crustal tomography uses transmitted rays like those that pass from a surface source through the crust to receivers that are also on the same surface. *See* GEOPHYSICAL EXPLORATION; GROUP VELOCITY; PHASE VELOCITY; SEISMIC EXPLORATION FOR OIL AND GAS; WAVE EQUATION.

Seismic source imaging. Another imaging problem in global seismology is constructing models of the seismic source. So-called first-motion representations of seismic sources (earthquakes) are the result of measurements made on the very first P waves or S waves arriving at an instrument; therefore they represent the very beginning of the rupture on the fault plane. This is not a problem if the rupture is approximately a point source, but this is true in practice only if the earthquake is quite small or exceptionally simple. An alternative is to examine only longer-period seismic phases, including surface waves, to obtain an estimate of the average point source that smooths over the space and time complexities of a large rupture. This so-called centroid-moment-tensor representation is routinely computed for events with magnitudes greater than about 5.5. Because an estimate for a centroid moment tensor is derived from much more of the seismogram than the first arrivals, it gives a better estimate of the energy content of the earthquake. This estimate, known as the seismic moment, represents the total stress reduction resulting from the earthquake; it is the basis for a new magnitude number M_W. This value is equivalent to the Richter body wave (m_b) or surface-wave magnitude (M_S) at low magnitudes, but it is much more accurate for magnitudes above about 7.5.

Some large events comprise smaller subevents distributed in space and time and contributing to the total rupture and seismic moment. The position and individual rupture characteristics of these subevents can be mapped with remarkable precision, given data of exceptional bandwidth and good geographical distribution. An outstanding problem is whether the location of these subevents is related to stress heterogeneities within the fault zone. These stress heterogeneities are known as barriers or asperities, depending on whether they stop or initiate rupture. *See* SEISMOGRAPHIC INSTRUMENTATION. [J.Mu.; A.L.L.]

Seisonacea A class of the phylum Rotifera which comprises a group of little-known marine animals. They form a single family with about seven species and are found only in Europe. The Seisonacea are epizoic or possibly ectoparasitic on crustacea. They have a very elongated jointed body with a small head; a long, slender neck region; a thicker, fusiform trunk; and an elongated foot, terminating in a perforated disk (see illustration). The Seisonacea are larger than other rotifers, attaining sizes up to 0. 12 in. (3 mm) in length. *See* ROTIFERA. [E.H.A.]



***Seison*, a rotifer. (*After Plate, 1887*)**

Seizure disorders Conditions in which there are recurrent seizures. Such conditions are also known as epilepsy; the isolated occurrence of a seizure, however, is not designated as epilepsy. A seizure (ictus) is an event in which there is a sudden alteration in function of nerve cells, most commonly involving excessive electrical activity of the cells. This sudden change in nerve cell function is usually relatively brief, lasting seconds to minutes. Soon after a seizure, the brain may function quite normally. The manifestation of a seizure varies depending on which area of the brain is involved. Focal motor epilepsy, temporal lobe seizures, grand mal, and generalized nonconvulsive seizures are the four common seizure types. *See* BRAIN; NERVOUS SYSTEM (VERTEBRATE).

Focal motor epilepsy, also known as a simple partial seizure with motor symptoms, is manifested by uncontrolled rhythmic jerking of the face, arm, or leg, caused by excessive abnormal discharges of nerve cells within the area of the brain, which under usual circumstances controls movement in that part of the body.

Temporal lobe seizures are known as simple partial seizures and may be manifested by a myriad of symptoms depending upon which part of the lobe is involved. Psychomotor, or complex partial, seizures are the most common type. Clinically, they are characterized by an alteration in the state of consciousness and performance of repetitive, patterned, non-goal-directed activity. These types of seizures are characterized electrically by abnormal discharges occurring within the temporal lobe for the duration of the seizure.

Grand mal seizures, also referred to as generalized tonic-clonic convulsive seizures, major motor seizures, or convulsions, occur if the abnormal discharges involve the entire brain all at once. In this condition there are forceful, generalized, symmetrical musculature contractions accompanied by loss of consciousness, and, at times, by urinary incontinence and tongue biting.

Generalized nonconvulsive seizures may be atonic seizures, which are characterized by a sudden loss of muscle tone, or they may be absences (petit mal), which consist of brief periods of loss of consciousness and immediate recovery. This type of seizure is more frequently seen in children than in adults.

Epilepsy is not a disease in itself. It is a symptom of an underlying disease process. That disease process may be metabolic, such as uremia, decreased brain oxygen, or low calcium levels; or structural brain damage, such as from head trauma at birth, brain injuries, brain tumors, strokes, or congenital malformations, or previous encephalitis or meningitis. In many instances, however, a cause is not found. The disorder is then referred to as idiopathic or primary epilepsy.

Seizures should be distinguished from other conditions which have some clinical similarities. These include fainting from hypoglycemia, cardiovascular disorders, or hysteria. The tools necessary to make this differential diagnosis are the history of the illness, the general physical exam, and a neurologic exam, all of which may be entirely normal or which may demonstrate signs of underlying disease processes. An electroencephalogram may demonstrate abnormal electrical discharges during a time the patient is seizure-free. These discharges may indicate that portion of the brain from which the seizures arise. Computerized tomography scans or magnetic resonance imaging may show any gross structural abnormality. Examination of the blood may demonstrate abnormal circulating chemicals. *See* COMPUTERIZED TOMOGRAPHY; ELECTROENCEPHALOGRAPHY; MEDICAL IMAGING.

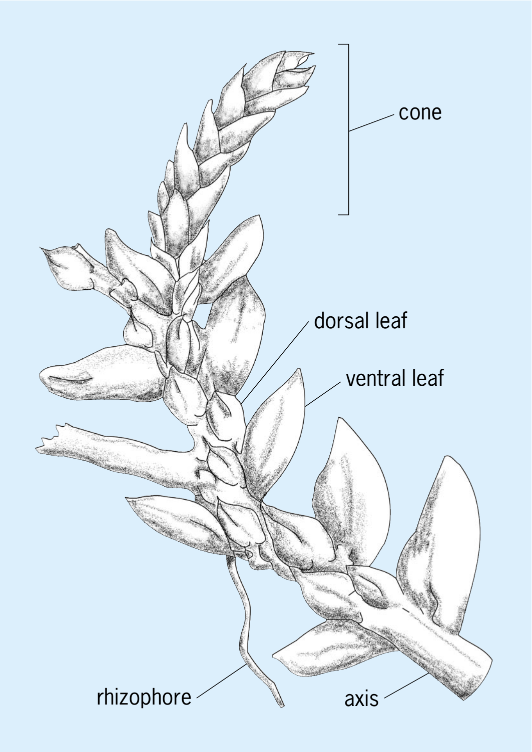
The ideal treatment of epilepsy is removal of the cause. In many instances, however, the cause cannot be established or may not be amenable to direct treatment. When the cause cannot be removed, the symptoms (seizures) are treated. The initial method of obtaining seizure control is antiepileptic drugs. About 80% of the people with epilepsy obtain good control or elimination of seizures with medication. These medications are chemicals of varying structures and may be effective by a number of different brain mechanisms. Brain surgery is a therapeutic potential for some of the 20% of the people with epilepsy who do not achieve control on medication. Surgery may be considered if the abnormally discharging nerve cells which cause the epilepsy are in a dispensable area of brain, that is, one of the frontal or temporal lobes. [L.M.O.]

Selachii An order that includes all fossil and Recent sharks, with the possible exception of Devonian cladoselachians. The selachian endoskeleton is entirely cartilaginous, but it is frequently calcified superficially. The body is covered in minute scales, which in Recent sharks are simple and nongrowing, but which in earlier sharks often fused together and became enlarged during life and may have been more regularly arranged over the body.

Sharks periodically shed their teeth, sometimes replacing several thousand in a lifetime, and their teeth are common in the fossil record. It is therefore rather surprising that the earliest records of sharks are from the Late Devonian, when they were already highly diversified.

There are 5 groups of fossil and living sharks: cladoselachians, symmoriids, ctenacanthids, hybodontids, and neoselachians. *See* CHONDRICHTHYES; SHARK. [J.G.Ma.]

Selaginellales An order of the class Lycopsida (club mosses), regarded as more advanced than the extinct Protolepidodendrales because they produce spores of two sizes, but less advanced than the Lepidodendrales and Isoetales because they lack wood and finite growth. All are perennial herbs, varying in growth habit from prostrate to climbing. *See* ISOETALES; LEPIDODENDRALES; PROTOLEPIDODENDRALES.



Characteristic features of a typical heterophyllous selaginellalean of the *Stachygynandrum* type. (*After T. R. Webster, Developmental problems in Selaginella in an evolutionary context, Ann. Mo. Bot. Gard., 79:633–647, 1992*)

Although the approximately 700 extant species are traditionally assigned to a single genus, *Selaginella*, it is possible that this genus should include only the few species that possess undivided steles and microphyllous leaves of a single morphology. The bulk of the selaginellalean species are included in the genus *Stachygynandrum*. Both genera are geographically widespread and occupy a wide range of habitats.

Both selaginellalean genera show several remarkable biological features (see illustration). *Stachygynandrum* has leaves that are positioned both ventrally and dorsally. This character is regarded as an adaptation to efficient light capture. Moreover, in many species the lower surface of the dorsal leaf and upper surface of the ventral leaf consist of more or less cubic cells that contain only one large chloroplast, whose orientation within the cell can be altered to maintain optimal levels of incident light for photosynthesis.

The origin of the rhizophores (specialized aerial rooting structures) is unclear.

Selaginellaleans have a free-sporing heterosporous life history. Sporangia are borne on sporophylls that are aggregated into cones. Many species possess active mechanisms for ejecting either microspores or entire microsporangia. The megaspores and microspores germinate to produce independent, unisexual gametophytes. Both genders remain largely within the spore wall. The megagametophytes produce several archegonia that yield eggs, which chemically attract the swimming biflagellate spermatozoids released by the microspores. *See* LYCOPHYTA; LYCOPODIALES; LYCOPSIDA. [R.M.Ba.; W.A.DiM.]

Selection rules (physics) General rules concerning the transitions which may occur between the states of a quantum-mechanical physical system. They derive in almost all cases from the symmetry properties of the states and of the interaction which gives rise to the transitions. The system may have a classical (nonquantum) counterpart, and in this case the selection rules may often be related to the classical conserved quantities. A first use of selection rules is in determining the symmetry classes of the states; but in a great variety of ways they may yield other information about the system and the conservation laws. *See* Quantum mechanics; Symmetry laws (physics).

For an isolated system the total angular momentum is a conserved quantity; this fact derives from a fundamental fact of nature, namely, that space is isotropic. Each state is then classifiable by angular momentum J and its z component M ($= -J, -J + 1, \ldots, +J$). Angular momenta combine in a vectorial fashion. Thus, if the system makes a particle-emitting transition $J_1, M_1 \rightarrow J_2, M_2$, the emitted particles must carry away angular momentum (j, μ), where $\mathbf{j} = \mathbf{j}_1 - \mathbf{j}_2$. This implies that $\mu = M_1 - M_2$ and that j takes on values $J_1 - J_2, J_1 - J_2 + 1, \ldots, (J_1 + J_2)$. Thus in transitions ($J = 4 \leftrightarrow J = 2$) the possible j values comprise only 2, 3, 4, 5, 6, and, if it is also specified that $M_1 - M_2 = \pm 4$, only 4, 5, 6. Observe that J_2 is additive. *See* Angular momentum; Quantum numbers.

Another fundamental symmetry, the parity, which determines the behavior of a system (or of its description) under inversion of the coordinate axes, is conserved by the strong and electromagnetic interactions, and gives a classification of systems as even ($\pi = +1$) or odd ($\pi = -1$). Under combination the parity combines multiplicatively. Thus, if the transition above is $4^{\pm} \rightarrow 2^{\pm}$, it follows that $j^{\pi} = 2^{-}, \ldots, 6^{-}$, while $4^{\pm} \rightarrow 2^{\pm}$ would give $j^{\pi} = 2^{+}, \ldots, 6^{+}$. The angular momentum $\mathbf{j}$ may be a combination of intrinsic spin $\mathbf{s}$ and orbital angular momentum $\mathbf{l}$. Scalar, pseudoscalar, vector, and pseudovector particles are respectively characterized by $s^{\pi s} = 0^{+}, 0^{-}, 1^{-}, 1^{+}$, where π_s is the "intrinsic" parity, while l always carries $\pi_l = (-1)^l$. *See* Parity (quantum mechanics); Spin (quantum mechanics).

The isospin symmetry of the elementary particles is almost conserved, being broken by electromagnetic and weak interactions. It is described by the group SU(2), of unimodular unitary transformations in two dimensions. Since the SU(2) algebra is identical with that of the angular momentum SO(3), isospin behaves like angular momentum with its three generators $\mathbf{T}$ replacing $\mathbf{J}$.

The isospin group is a subgroup of SU(3) which defines a more complex fundamental symmetry of the elementary particles. Two of its eight generators commute, giving two additive quantum numbers, T_z and strangeness S' (or, equivalently, charge and hypercharge). The strangeness is conserved ($\Delta S' = 0$) for strong and electromagnetic, but not for weak, interactions. The selection rules and combination laws for SU(3) and its many extensions, and the quark-structure underlying them, correlate an enormous amount of information and make many predictions about the elementary particles. *See* Baryon; Elementary particle; Meson; Quarks; Unitary symmetry.

A great variety of other groups have been introduced to define relevant symmetries for atoms, molecules, nuclei, and elementary particles. They all have their own selection rules, representing one aspect of the symmetries of nature. [J.B.Fr.]

Selectivity The ability of a radio receiver to separate a desired signal frequency from other signal frequencies, some of which may differ only slightly from the desired value. Selectivity is achieved by using tuned circuits that are sharply peaked and by increasing the number of tuned circuits. With a sharply peaked circuit, the output voltage falls off rapidly for frequencies increasingly lower or higher than that to which the circuit is tuned. *See* Q (electricity); Radio receiver; Resonance (alternating-current circuits). [J.Mar.]

Selenium A chemical element, Se, atomic number 34, atomic weight 78.96. The properties of this element are similar to those of tellurium. *See* Periodic table; Tellurium.

Selenium burns in air with a blue flame to give selenium dioxide, SeO_2. The element also reacts directly with a variety of metals and nonmetals, including hydrogen and the halogens. Nonoxidizing acids fail to react with selenium, but nitric acid, concentrated sulfuric acid, and strong alkali hydroxides dissolve the element. The only important compound of selenium with hydrogen is hydrogen selenide, H_2Se, a colorless flammable gas possessing a distinctly unpleasant odor, and a toxicity greater and a thermal stability less than that of hydrogen sulfide. Selenium oxyhalide, $SeOCl_2$, is a colorless liquid widely used as a nonaqueous solvent. The oxybromide, $SeOBr_2$, is an orange solid having chemical properties similar to those of $SeOCl_2$. The oxyflouride, $SeOF_2$, a colorless liquid with a pungent smell, reacts with water, glass, and silicon, and also forms additional compounds. Compounds in which C-Se bonds appear are numerous and vary from the simple selenols, RSeH, to molecules exhibiting biological activity such as selenoamino acids and selenopeptides. *See* Organoselenium compound.

The abundance of this widely distributed element in the Earth's crust is estimated to be about 7×10^{-5} % by weight, occurring as the selenides of heavy elements and to a limited extent as the free element in association with elementary sulfur. Examples of the variety of selenide minerals are berzelianite (Cu_2Se), eucairite (AgCuSe), and jermoite [$As(S,Se)_2$]. Selenium minerals do not occur in sufficient quantity to be useful as commercial sources of the element.

Major uses of selenium include the photocopying process of xerography, which depends on the light sensitivity of thin films of amorphous selenium, the decolorization of glasses tinted by the presence of iron compounds, and use as a pigment in plastics, paints, enamels, glass, ceramics, and inks. Selenium is also employed in photographic exposure meters and as a metallurgical additive to improve the machinability of certain steels. Minor uses include application as a nutritional additive for numerous animal species, use in photographic toning, metal-finishing operations, metal plating, high-temperature lubricants, and as catalytic agents, particularly in the isomerization of certain petroleum products. [J.W.Ge.]

The biological importance of selenium is well established, as all classes of organisms metabolize selenium. In humans and other mammals, serious diseases arise from either excessive or insufficient dietary selenium. The toxic effects of selenium have long been known, particularly for grazing animals. In soils with high selenium content, some plants accumulate large amounts of selenium. Animals that ingest these selenium-accumulating plants develop severe toxic reactions. *See* Soil chemistry.

Although toxic at high levels, selenium is an essential micronutrient for mammalian species. The accepted minimum daily requirement of selenium for adult humans is 70 micrograms. Many types of food provide selenium, particularly seafood, meats, grains, and the onion family. Mammals and birds require selenium for production of the enzyme glutathione peroxidase, which protects against oxidation-induced cancers. Other seleno-proteins of unknown function are found in mammalian blood, various tissues, and spermatozoa. *See* Amino acids. [M.J.Ax.; T.C.St.]

Seligeriales An order of the true mosses (Bryidae), consisting of one family and five or six genera. The plants grow on rocks, and may be exceedingly small and gregarious to moderate in size and tufted. The stems are erect and simple or forked. The linear to lance-subulate leaves have a single costa which often fills the subula. The operculate capsules are terminal, and the peristome is usually present. The calyptra is generally cucullate. *See* Bryidae; Bryophyta; Bryopsida. [H.Cr.]

Semaeostomeae An order of the class Scyphozoa including most of the common medusae. The umbrella of these medusae is more flat than high and is usually domelike. The margin of the umbrella is divided into many lappets. Sensory organs are situated between the lappets. The tentacles are generally well developed and very long except in a few forms.

The life history of this group shows the typical alternation of generations, with forms passing through several larval stages. The Semaeostomeae are distributed mostly in temperate zones and are generally coastal forms with a few exceptions. Some of them are known to have violent poison on their tentacles. Several fossils of this group were found in the strata of the Jurassic period. *See* Scyphozoa. [T.U.]

Semiconductor A solid crystalline material whose electrical conductivity is intermediate between that of a metal and an insulator. Semiconductors exhibit conduction properties that may be temperature-dependent, permitting their use as thermistors (temperature-dependent resistors), or voltage-dependent, as in varistors. By making suitable contacts to a semiconductor or by making the material suitably inhomogeneous, electrical rectification and amplification can be obtained. Semiconductor devices, rectifiers, and transistors have replaced vacuum tubes almost completely in low-power electronics, making it possible to save volume and power consumption by orders of magnitude. In the form of integrated circuits, they are vital for complicated systems. The optical properties of a semiconductor are important for the understanding and the application of the material. Photodiodes, photoconductive detectors of radiation, injection lasers, light-emitting diodes, solar-energy conversion cells, and so forth are examples of the wide variety of optoelectronic devices. *See* Integrated circuits; Laser; Light-emitting diode; Photodiode; Photoelectric devices; Semiconductor diode; Semiconductor rectifier; Thermistor; Transistor; Varistor.

Conduction in semiconductors. The electrical conductivity of semiconductors ranges from about 10^3 to 10^{-9} ohm^{-1} cm^{-1}, as compared with a maximum conductivity of 10^7 for good conductors and a minimum conductivity of 10^{-17} ohm^{-1} cm^{-1} for good insulators. *See* Electric insulator; Electrical conductivity of metals.

The electric current is usually due only to the motion of electrons, although under some conditions, such as very high temperatures, the motion of ions may be important. The basic distinction between conduction in metals and in semiconductors is made by considering the energy bands occupied by the conduction electrons. *See* Band theory of solids; Ionic crystals.

At absolute zero temperature, the electrons occupy the lowest possible energy levels, with the restriction that at most two electrons with opposite spin may be in the same energy level. In semiconductors and insulators, there are just enough electrons to fill completely a number of energy bands, leaving the rest of the energy bands empty. The highest filled energy band is called the valence band. The next higher band, which is empty at absolute zero temperature, is called the conduction band. The conduction band is separated from the valence band by an energy gap, which is an important characteristic of the semiconductor. In metals, the highest energy band that is occupied by the electrons is only partially filled. This condition exists either because the number of electrons is not just right to fill an integral number of energy bands or because the highest occupied energy band overlaps the next higher band without an intervening energy gap. The electrons in a partially filled band may acquire a small amount of energy from an applied electric field by going to the higher levels in the same band. The electrons are accelerated in a direction opposite to the field and thereby constitute an electric current. In semiconductors and insulators, the electrons are found only in completely filled bands, at low temperatures. In order to increase the energy of the electrons, it is necessary to raise electrons from the valence band to the conduction band across the energy gap. The electric fields normally encountered are not large enough to accomplish this with appreciable probability. At sufficiently high temperatures, depending on the magnitude of the energy gap, a significant number of valence electrons gain enough energy thermally to be raised to the conduction band. These electrons in an unfilled band can easily participate in conduction. Furthermore, there is now a corresponding number of vacancies in the electron population of the valence band. These vacancies, or holes as they are called, have the effect of carriers of positive charge, by means of which the valence band makes a contribution to the conduction of the crystal. *See* Hole states in solids.

The type of charge carrier, electron or hole, that is in largest concentration in a material is sometimes called the majority carrier and the type in smallest concentration the minority carrier. The majority carriers are primarily responsible for the conduction properties of the material. Although the minority carriers play a minor role in electrical conductivity, they can be important in rectification and transistor actions in a semiconductor.

Intrinsic semiconductors. A semiconductor in which the concentration of charge carriers is characteristic of the material itself rather than of the content of impurities and structural defects of the crystal is called an intrinsic semiconductor. Electrons in the conduction band and holes in the valence band are created by thermal excitation of electrons from the valence to the conduction band. Thus an intrinsic semiconductor has equal concentrations of electrons and holes. The carrier concentration, and hence the conductivity, is very sensitive to temperature and depends strongly on the energy gap. The energy gap ranges from a fraction of 1 eV to several electronvolts. A material must have a large energy gap to be an insulator.

Extrinsic semiconductors. Typical semiconductor crystals such as germanium and silicon are formed by an ordered bonding of the individual atoms to form the crystal structure. The bonding is attributed to the valence electrons which pair up with valence electrons of adjacent atoms to form so-called shared pair or covalent bonds. These materials are all of the quadrivalent type; that is, each atom contains four valence electrons, all of which are used in forming the crystal bonds. *See* Crystal structure.

Atoms having a valence of +3 or +5 can be added to a pure or intrinsic semiconductor material with the result that the +3 atoms will give rise to an unsatisfied bond with one of the valence electrons of the semiconductor atoms, and +5 atoms will result in an extra or free electron that is not required in the bond structure. Electrically, the +3 impurities add holes and the +5 impurities add electrons. They are called acceptor and donor impurities, respectively. Typical valence +3 impurities used are boron, aluminum, indium, and gallium. Valence +5 impurities used are arsenic, antimony, and phosphorus.

Semiconductor material “doped” or “poisoned” by valence +3 acceptor impurities is termed *p*-type, whereas material doped by valence +5 donor material is termed *n*-type. The names are derived from the fact that the holes introduced are considered to carry positive charges and the electrons negative charges. The number of electrons in the energy bands of the crystal is increased by the presence of donor impurities and decreased by the presence of acceptor impurities. *See* Acceptor atom; Donor atom.

At sufficiently high temperatures, the intrinsic carrier concentration becomes so large that the effect of a fixed amount of impurity atoms in the crystal is comparatively small and the semiconductor becomes intrinsic. When the carrier concentration is predominantly determined by the impurity content, the conduction of the material is said to be extrinsic. Physical defects in the crystal structure may have similar effects as donor or acceptor impurities. They can also give rise to extrinsic conductivity.

Materials. The group of chemical elements which are semiconductors includes germanium, silicon, gray (crystalline) tin, selenium, tellurium, and boron. Germanium, silicon, and gray tin belong to group 14 of the periodic table and have crystal structures similar to that of diamond. Germanium and silicon are two of the best-known semiconductors. They are used extensively in devices such as rectifiers and transistors.

A large number of compounds are known to be semiconductors. A group of semiconducting compounds of the simple type AB consists of elements from columns symmetrically placed with respect to column 14 of the periodic table. Indium antimonide (InSb), cadmium telluride (CdTe), and silver iodide (AgI) are examples of III–V, II–IV, and I–VI compounds, respectively. The various III–V compounds are being studied extensively, and many practical applications have been found for these materials. Some of these compounds have the highest carrier mobilities known for semiconductors. The compounds have zincblende crystal structure which is geometrically similar to the diamond structure possessed by the elemental semiconductors, germanium and silicon, of column 14, except that the four nearest neighbors of each atom are atoms of the other kind. The II–VI compounds, zinc sulfide (ZnS) and cadmium sulfide (CdS), are used in photoconductive devices. Zinc sulfide is also used as a luminescent material. *See* LUMINESCENCE; PHOTOCONDUCTIVITY.

The properties of semiconductors are extremely sensitive to the presence of impurities. It is therefore desirable to start with the purest available materials and to introduce a controlled amount of the desired impurity. The zone-refining method is often used for further purification of obtainable materials. The floating zone technique can be used, if feasible, to prevent any contamination of molten material by contact with the crucible. *See* ZONE REFINING.

For basic studies as well as for many practical applications, it is desirable to use single crystals. Various methods are used for growing crystals of different materials. For many semiconductors, including germanium, silicon, and the III–V compounds, the Czochralski method is commonly used. The method of condensation from the vapor phase is used to grow crystals of a number of semiconductors, for instance, selenium and zinc sulfide. *See* CRYSTAL GROWTH.

The introduction of impurities, or doping, can be accomplished by simply adding the desired quantity to the melt from which the crystal is grown. When the amount to be added is very small, a preliminary ingot is often made with a larger content of the doping agent; a small slice of the ingot is then used to dope the next melt accurately. Impurities which have large diffusion constants in the material can be introduced directly by holding the solid material at an elevated temperature while this material is in contact with the doping agent in the solid or the vapor phase.

A doping technique, ion implantation, has been developed and used extensively. The impurity is introduced into a layer of semiconductor by causing a controlled dose of highly accelerated impurity ions to impinge on the semiconductor. *See* ION IMPLANTATION.

An important subject of scientific and technological interest is amorphous semiconductors. In an amorphous substance the atomic arrangement has some short-range but no long-range order. The representative amorphous semiconductors are selenium, germanium, and silicon in their amorphous states, and arsenic and germanium chalcogenides, including such ternary systems as Ge-As-Te. Some amorphous semiconductors can be prepared by a suitable quenching procedure from the melt. Amorphous films can be obtained by vapor deposition.

Rectification in semiconductors. In semiconductors, narrow layers can be produced which have abnormally high resistances. The resistance of such a layer is nonohmic; it may depend on the direction of current, thus giving rise to rectification. Rectification can also be obtained by putting a thin layer of semiconductor or insulator material between two conductors of different material.

A narrow region in a semiconductor which has an abnormally high resistance is called a barrier layer. A barrier may exist at the contact of the semiconductor with another material, at a crystal boundary in the semiconductor, or at a free surface of the semiconductor. In the bulk of a semiconductor, even in a single crystal, barriers may be found as the result of a nonuniform distribution of impurities. The thickness of a barrier layer is small, usually 10^{-3} to 10^{-5} cm.

A barrier is usually associated with the existence of a space charge. In an intrinsic semiconductor, a region is electrically neutral if the concentration n of conduction electrons is equal to the concentration p of holes. Any deviation in the balance gives a space charge equal to $e(p - n)$, where e is the charge on an electron. In an extrinsic semiconductor, ionized donor atoms give a positive space charge and ionized acceptor atoms give a negative space charge.

Surface electronics. The surface of a semiconductor plays an important role technologically, for example, in field-effect transistors and charge-coupled devices. Also, it presents an interesting case of two-dimensional systems where the electric field in the surface layer is strong enough to produce a potential wall which is narrower than the wavelengths of charge carriers. In such a case, the electronic energy levels are grouped into subbands, each of which corresponds to a quantized motion normal to the surface, with a continuum for motion parallel to the surface. Consequently, various properties cannot be trivially deduced from those of the bulk semiconductor. *See* CHARGE-COUPLED DEVICES; SURFACE PHYSICS. [H.Y.F.]

Semiconductor diode

Semiconductor diode A two-terminal electronic device that utilizes the properties of the semiconductor from which it is constructed. In a semiconductor diode without a *pn* junction, the bulk properties of the semiconductor itself are used to make a device whose characteristics may be sensitive to light, temperature, or electric field. In a diode with a *pn* junction, the properties of the *pn* junction are used. The most important property of a *pn* junction is that, under ordinary conditions, it will allow electric current to flow in only one direction. Under the proper circumstances, however, a *pn* junction may also be used as a voltage-variable capacitance, a switch, a light source, a voltage regulator, or a means to convert light into electrical power. *See* SEMICONDUCTOR.

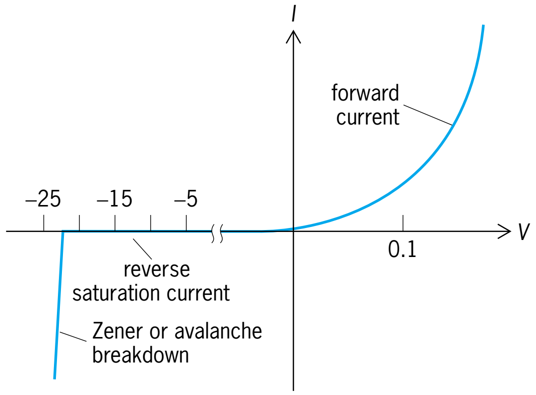
The conductivity of a semiconductor is proportional to the number of electrical carriers (electrons and holes) it contains. In a temperature-compensating diode, or thermistor, the number of carriers changes with temperature. *See* THERMISTOR.

In a photoconductor the semiconductor is packaged so that it may be exposed to light. Light photons whose energies are greater than the band gap can excite electrons from the valence band to the conduction band, increasing the number of electrical carriers in the semiconductor. *See* PHOTOCONDUCTIVITY.

In some semiconductors the conduction band has more than one minimum. This results in a region of negative differential conductivity, and a device operated in this region is unstable. The current pulsates at microwave frequencies, and the device, a Gunn diode, may be used as a microwave power source. *See* MICROWAVE SOLID-STATE DEVICES.

A rectifying junction is formed whenever two materials of different conductivity types are brought into contact. Most commonly, the two materials are an *n*-type and a *p*-type semiconductor, and the device is called a junction diode. However, rectifying action also occurs at a boundary between a metal and a semiconductor of either type. If the metal contacts a large area of semiconductor, the device is known as a Schottky barrier diode; if the contact is a metal point, a point-contact diode is formed. *See* SCHOTTKY EFFECT.

The contact potential between the two materials in a diode creates a potential barrier which tends to keep electrons on the *n* side of the junction and holes on the *p* side. When the *p* side is made positive with respect to the *n* side by an applied field, the barrier height is lowered and the diode is forward biased. Majority electrons from the *n* side may flow easily to the *p* side, and majority holes from the *p* side may flow easily to the *n* side. When the *p* side is made negative, the barrier height is increased and the diode is reverse-biased. Then, only a small leakage current flows: Minority electrons from the *p* side flow into



Current-voltage characteristic of a *pn* junction.

the *n* side, and minority holes from the *n* side flow into the *p* side. The current-voltage characteristic of a typical diode is shown in the illustration. Rectifying diodes can be made in a variety of sizes, and much practical use can be made of the fact that such a diode allows current to flow in essentially one direction only. *See* JUNCTION DIODE; SEMICONDUCTOR RECTIFIER; TUNNEL DIODE. [S.N.]

Semiconductor heterostructures Structures consisting of two different semiconductor materials in junction contact, with unique electrical or electrooptical characteristics. A heterojunction is a junction in a single crystal between two dissimilar semiconductors. The most important differences between the two semiconductors are generally in the energy gap and the refractive index. In semiconductor heterostructures, differences in energy gap permit spatial confinement of injected electrons and holes, while the differences in refractive index can be used to form optical waveguides. Semiconductor heterostructures have been used for diode lasers, light-emitting diodes, optical detector diodes, and solar cells. In fact, heterostructures must be used to obtain continuous operation of diode lasers at room temperature. Heterostructures also exhibit other interesting properties such as the quantization of confined carrier motion in ultrathin heterostructures and enhanced carrier mobility in modulation-doped heterostructures. Structures of current interest utilize III–V and IV–VI compounds having similar crystal structures and closely matched lattice constants. *See* BAND THEORY OF SOLIDS; LASER; LIGHT-EMITTING DIODE; OPTICAL DETECTORS; REFRACTION OF WAVES; SOLAR CELL.

The most intensively studied and thoroughly documented materials for heterostructures are GaAs and $Al_xGa_{1-x}As$. Several other III–V and IV–VI systems also are used for semiconductor heterostructures. A close lattice match is necessary in heterostructures in order to obtain high-quality crystal layers by epitaxial growth and thereby to prevent excessive carrier recombination at the heterojunction interface.

When the narrow energy gap layer in heterostructures becomes a few tens of nanometers or less in thickness, new effects that are associated with the quantization of confined carriers are observed. These ultrathin heterostructures are referred to as superlattices or quantum well structures, and they consist of alternating layers of GaAs and $Al_xGa_{1-x}As$. These structures are generally prepared by molecular-beam epitaxy. Each layer is 5 to 40 nanometers thick.

In the GaAs layers, the motion of the carriers is restricted in the direction perpendicular to the heterojunction interfaces, while they are free to move in the other two directions. The carriers can therefore be considered as a two-dimensional gas. The Schrödinger wave equation shows that the carriers moving in the confining direction can have only discrete bound states. *See* QUANTUM MECHANICS.

Another property of semiconductor heterostructures is illustrated by a modulation doping technique that spatially separates conduction electrons in the GaAs layer and their parent donor impurity atoms in the $Al_xGa_{1-x}As$ layer. Since the carrier mobility in semiconductors is decreased by the presence of ionized and neutral impurities, the carrier mobility in the modulation-doped GaAs is larger than for a GaAs layer doped with impurities to give the same free electron concentration. Higher carrier mobilities should permit preparation of devices that operate at higher frequencies than are possible with doped layers. *See* SEMICONDUCTOR. [H.C.C.]

Semiconductor memories Devices for storing digital information that are fabricated by using integrated circuit technology. Semiconductor memories are widely used to store programs and data in almost every digital system, and have replaced core memory as the main active computer memory.

Many different types of semiconductor memories are used in digital systems to perform various functions—bulk data storage, program storage, temporary storage, and cache (or intermediate) storage. Almost all of the memories are a form of random-access memory (RAM), in which any storage location can be accessed in the same amount of time.

Even though most semiconductor memories can be randomly accessed, they are not all referred to as RAMs. RAMs are memory chips that cannot retain data without power but permit data to be both read from or written into the memory chip's storage locations.

Within the category of read/write RAMs, many subdivisions have been created to satisfy the performance and system architecture requirements of the various applications. Basically there are two types of read/write RAMs—dynamic and static (DRAMs and SRAMs). The terms "dynamic" or "static" refer to the structure of the actual storage circuit (the cell structure) used to hold each data bit within the memory chip. A dynamic memory uses a storage cell based on a transistor and capacitor combination, in which the digital information is represented by a charge stored on each of the capacitors in the memory array. The memory gets the name "dynamic" from the fact that the capacitors are imperfect and will lose their charge unless the charge is repeatedly replenished (refreshed) on a regular basis (every few milliseconds) by externally supplied signals. Static memories, in contrast, do not use a charge-storage technique; instead, they use either four transistors and two resistors to form a passive-load flip-flop, or six transistors to form a flip-flop with dynamic loads for each cell in the array. Once data are loaded into the flip-flop storage elements, the flip-flops will indefinitely remain in that state until the information is intentionally changed or the power to the memory circuit is shut off.

In addition to static and dynamic RAMs, there is an attempt to combine both technologies, thus merging the high storage density of dynamic memory cells with the simplicity of use of static RAMs. Referred to as pseudostatic or pseudodynamic RAMs, these memories include circuits on the chip to automatically provide the refresh signals needed by the dynamic cells in the memory array. Since the signals do not have to be supplied by the external system, the memory appears to function like a static RAM.

There are many other forms of semiconductor memories in use—mask-programmable read-only memories (ROMs), fuse-programmable read-only memories (PROMs), ultraviolet-erasable programmable read-only memories (UV EPROMs), electrically alterable read-only memories (EAROMs), electrically erasable programmable read-only memories (EEPROMs), flash EPROMs, nonvolatile static RAMs (NV RAMs), and ferroelectric memories. Most of these memory types are randomly accessible, but their main distinguishing feature is that once information has been loaded into the storage cells, the information stays there even if the power is shut off.

The ROM is programmed by the memory manufacturer during the actual device fabrication. Here, though, there are two types of ROMs: one is called late-mask or contact-mask programmable, and the other is often referred to as a ground-up design.

As an alternative to the mask-programmable memories, all the other nonvolatile memory types permit the users to program the memories themselves. The fuse PROM is a one-time programmable memory—once the information is programmed in, it cannot be altered.

The birth of the microprocessor in the early 1970s brought with it nonvolatile memory types that offered reusability. Information stored in the memory can be erased—in the case of the UV EPROM, by an ultraviolet light, and in the case of the EAROM, EEPROM, flash EPROM (often referred to as just a flash memory device), nonvolatile (NV) RAM, or ferroelectric memory, by an electrical signal. Then the circuit can be reprogrammed with new information that can be retained indefinitely. All of these memory types are starting to approach the ideal memory element for the computer, an element that combines the flexibility of the RAM with the permanence of the ROM when power is removed. *See* COMPUTER STORAGE TECHNOLOGY; INTEGRATED CIRCUITS; LOGIC CIRCUITS; MICROPROCESSOR. [D.Bur.]

Semiconductor rectifier A semiconductor diode that is used in rectification and power control. The semiconductor diode conducts current preferentially in one direction and inhibits the flow of current in the opposite direction by utilizing the properties of a junction formed from two differently doped semiconductor materials. Doped silicon is by far the most widely used semiconductor. Semiconductor diodes are intrinsic to integrated circuits and discrete device technology and are used to perform a wide variety of isolation, switching, signal processing, level shifting, biasing, control, and alternating-current (ac) to direct-current (dc) conversion (rectification) functions. *See* CONTROLLED RECTIFIER; RECTIFIER; SEMICONDUCTOR; SEMICONDUCTOR DIODE.

Either as a key element of an integrated circuit or as a discrete packaged part, the silicon rectifier diode is used in a plethora of applications from small power supplies for consumer electronics to very large power-rectification industrial installations. Many semiconductor diodes are used in non-power-conversion applications in signal processing and communications. These include avalanche or Zener diodes; diodes used for amplitude-modulation radio detection, mixing, and frequency translation; IMPATT, PIN, and step-recovery diodes, used at microwave frequencies; diodes fabricated from gallium arsenide and related compounds, used in optoelectronics; and light-emitting diodes (LEDs) and solid-state lasers. *See* AMPLITUDE-MODULATION DETECTOR; LASER; LIGHT-EMITTING DIODE; MICROWAVE SOLID-STATE DEVICES; MIXER; ZENER DIODE.

Silicon rectifier diodes. The electrical heart of the semiconductor diode is the junction between *p*-type and *n*-type doped silicon regions. Discrete silicon diodes are commercially available with forward-current specifications from under 1 A to several thousands of amperes. Diodes may be connected in parallel for greater current capability as long as the design provides for the current being uniformly distributed between the parallel diodes. This is usually done with a ballast resistor in series with each diode. *See* BALLAST RESISTOR.

Ideally, the current through a reverse-biased diode, called the saturation current (I_S) or reverse current (I_R), approaches zero. Practically speaking, this current is several orders smaller than the forward current (I_F). The maximum value of the reverse blocking voltage is limited primarily by the structure and doping of the semiconductor layers. This maximum voltage is referred to as the avalanche breakdown voltage, or the peak reverse voltage (PRV) or peak inverse voltage (PIV). It is a very important parameter for power supply and power conversion designs. Exceeding the peak inverse voltage is usually destructive unless the circuit design provides for limiting the avalanche current and resultant heating. In summary, at positive voltages and currents (quadrant I of the voltage-current characteristic), the silicon rectifier diode shows the on-state conducting characteristic, with high current and low forward voltage drop; at negative voltages and currents (quadrant III), it shows the reverse-blocking or reverse-bias, off-state characteristic, with high blocking voltage and low (ideally zero) reverse blocking current. *See* ELECTRICAL BREAKDOWN.

Integrated-circuit diode-junction avalanche breakdown voltages are of the order of several tens of volts. Single silicon rectifier diodes designed for power conversion applications are available with ratings from a few hundred to a few thousand volts. Several diodes can be connected in series for greater voltage capability. Prepackaged series diode strings can be rated to tens of thousands of volts at several amperes. This series connection must ensure equal voltage division across each diode to guard against catastrophic failure of the entire series. Typically this is done by including a high-value equal-value resistor in parallel with each diode to obtain equal voltages, and a parallel capacitor to provide a low-impedance path for high-voltage transients that are often present in industrial environments. *See* JUNCTION DIODE.

Schottky diodes. Unlike a silicon diode formed from a *pn* junction, the Schottky diode makes use of the rectification effect of a metal-to-silicon interface and the resultant barrier potential. The Schottky diode, sometimes called the Schottky-barrier diode, overcomes the major limitation of the *pn* junction diode; being a majority carrier device, it has a lower forward voltage drop (0.2–0.3 V, compared to 0.7–1.0 V) and faster switching speed than its minority-carrier *pn* junction counterpart. However, other factors confine its use to low-voltage power applications, chiefly the relatively small breakdown voltage, typically 45 V. Secondary shortcomings include a high reverse current and restricted temperature of operation, with commercial devices providing a maximum of 175°C (347°F) compared with 200°C (392°F) for *pn* junction diodes.

Integrated circuits used in computer and instrument systems commonly require voltages less than 15 V and as low as 3.3 V. Thus the advantage of low forward-voltage drop and faster switching favors the Schottky diode. This is particularly true for high-frequency switching voltage regulator power supply applications where voltages at 20–50 kHz must be rectified. The higher reverse current can be tolerated. However, cooling or heat sinking is more critical because of the higher reverse-current temperature coefficient and lower maximum operating temperature. *See* SCHOTTKY BARRIER DIODE.

Rectifier circuits. The greatest usage of rectifier diodes is the conversion of ac to dc. The single diode of a half-wave rectifier for a single-phase ac voltage conducts only on the positive half-cycle. Because of this, the output voltage across the load resistance is unidirectional and has a nonzero average value. This output waveform is called a pulsating dc. Therefore the input ac voltage has been rectified to a dc voltage. For most applications, a filter, usually consisting of large electrolytic capacitors, must be employed at the output to smooth the ripple present on the pulsating dc voltage to come close to a constant dc voltage value. *See* CAPACITOR; ELECTRIC FILTER; ELECTRONIC POWER SUPPLY; RIPPLE VOLTAGE.

In lower-power applications from a few watts to a few hundred watts, such as used in computers, television receivers, and laboratory instruments, a switching voltage regulator is commonly used to generate a 10-kHz–50-kHz ac signal from the high-ripple ac power supply voltage. The advantage is the ease and lower cost in filtering the ripple resulting from rectifying high-frequency ac as opposed to filtering low-frequency ac. *See* VOLTAGE REGULATOR.

Thyristors. Whereas the basic semiconductor rectifier has two terminals, an anode and cathode, a silicon controlled rectifier (SCR) has three terminals: an anode, cathode, and control electrode called the gate. The silicon controlled rectifier is a four-layer device modeled as two interconnected *pnp* and *npn* transistors.

Normally, there is no current flow from the anode to cathode. Both transistors are off; that is, they are blocking any current flow. By applying a relatively small trigger pulse control signal to the gate electrode, the *npn* transistor is switched on. When the *npn* transistor is switched on, the *pnp* transistor is also switched on. Consequently the silicon controlled rectifier is turned on and a current flows through the silicon controlled rectifier and external circuit. The resultant internal voltages keep both the *npn* and *pnp* transistors on even when the gate voltage is removed. The device is said to exhibit regenerative, positive-feedback, or latching-type switching action. There is a voltage drop of about 1 V across the on-state silicon controlled rectifier. The power dissipation rating required in specifying a silicon controlled rectifier is given by this 1-V drop multiplied by the peak current flowing through the device. *See* TRANSISTOR.

Current continues to flow even when the gate signal is reduced to zero. To reset the silicon controlled rectifier, the external current must be reduced below a certain value. Thus, the thyristor can be switched into the on state (conducting condition) by applying a signal to the gate, but must be restored to the off state by circuit action. If the anode current momentarily drops below some holding current or if the anode voltage is reversed, the silicon controlled rectifier reverts to its blocking state and the gate terminal regains control. Typical silicon controlled rectifiers turn on in 1–5 microseconds and require 10–100 μs of momentary reverse voltage on the anode to regain their forward-blocking ability.

Other semiconductor diode topologies are also used for power control. A generic term for these power-control devices is the thyristor.

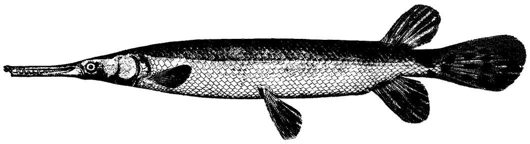
Thyristor applications fall into two general categories. The devices can be used from an ac supply, much like silicon rectifier diodes. However, unlike the rectifier diode, which conducts load current as soon as the anode voltage exceeds about 0.7 V, the thyristor will not conduct load current until it is triggered into conduction. Therefore, the power delivered to the load can be controlled. This mode of operation is called ac phase control. It is extensively used in applications requiring conversion from ac to variable-voltage dc output, such as adjustable-speed dc motor drives, and in lighting and heating control. *See* DIRECT-CURRENT MOTOR.

The other category of applications is operation in dc circuits. This allows power conversion from a battery or rectified ac line to a load requiring either an alternating supply (dc-to-ac conversion) or a variable-voltage dc supply (dc-to-dc conversion). Since the rate of switching the thyristors in dc circuits can be varied by the control circuit, a thyristor inverter circuit can supply an ac load with a variable frequency. The fundamental approach in both cases is to convert a dc voltage to a chopped voltage of controllable duty cycle. Changing the duty cycle either at a variable rate (frequency power modulation) or by varying the pulse width at a fixed frequency (pulse-width power modulation) effectively controls the power delivered to the load. *See* CHOPPING; PULSE MODULATION.

Important applications for dc-to-dc conversion, dc-to-ac power conversion at variable frequency, and dc-to-ac power conversion at fixed frequency are, respectively, control of battery-powered industrial vehicles such as forklift trucks and mining locomotives, adjustable-speed operation of ac synchronous and induction motors in industrial processing, and power transmission conversion. *See* ALTERNATING-CURRENT MOTOR; CONVERTER; INDUSTRIAL TRUCKS. [S.G.Bu.]

Semionotiformes An order of actinopterygian fishes which appeared first in the upper Permian, reached maximum development in the Triassic and Jurassic, and persists in the Recent fauna as the gars.

In the Semionotiformes the body is encased in a heavy armor of interlocking ganoid scales, which are thick, are more or less rhomboidal, and have an enameilike surface. Modern forms have an elongate body and bony jaws provided with enlarged conical teeth (see illustration).



Spotted gar (*Lepisosteus oculatus*). (*After G. B. Goode, Fishery Industries of the United States, 1884*)

The single Recent family, Lepisosteidae, contains one genus, *Lepisosteus*, with seven species restricted to lowland fresh and brackish waters of North and Central America. *See* ACTINOPTERYGII. [R.M.B.]

Sendai virus A member of the viruses in the type species Parainfluenza 1, genus *Paramyxovirus*, family Paramyxoviridae; it is also called hemagglutinating virus of Japan (HVJ). Sendai virus was originally recovered in Sendai, Japan, from mice inoculated with autopsy specimens from newborns who died of fatal pneumonitis in an epidemic in 1952. Subsequent attempts to isolate this virus from humans were, however, mostly unsuccessful, although mice are commonly infected with Sendai virus along with rats, guinea pigs, hamsters, and pigs. It is believed that the natural host of Sendai virus is the mouse and that the virus is usually nonpathogenic for humans. *See* ANIMAL VIRUS; PARAINFLUENZA VIRUS. [N.I.]

Sensation A term commonly used to refer to the subjective experience resulting from stimulation of a sense organ, for instance, a sensation of warm, sour, or green. As a general scientific category, the study of sensation is the study of the operation of the senses. Sense receptors are the means by which information presented as one form of energy, for example, light, is converted to information in the form used by the nervous system, that is, impulses traveling along nerve fibers. *See* SENSE ORGAN.

Each sense has mechanisms and characteristics peculiar to itself, but all display the phenomena of absolute threshold, differential threshold, and adaptation. Not until sufficient stimulation impinges on a receptor can the presence of a stimulus be detected. The quantity of stimulation required is known as the absolute threshold. Not until a sufficient change occurs in some aspect of a stimulus can the change be detected. The magnitude of the change required is called the differential threshold. Under steady stimulation there is a decrease in sensitivity of the corresponding sense, as indicated by a shift in the absolute threshold and in the magnitude of sensation. After the stimulation ceases, sensitivity increases. An obvious example of visual adaptation occurs when one goes from bright to dim surroundings or vice versa.

With fairly good accuracy humans can localize visual objects, sounds, and cutaneous contacts and can discriminate the spatial orientation of the body and its members. With rather poor accuracy humans can localize many of the stimuli originating within the body.

With the exception of hearing, in which sense localization depends on differences in the acoustic stimuli reaching the two ears, there appears to be a common principle involved in giving spatially separated receptors their different local signs. Stimulation at different points on the receptive surface results in peaks of electrical activity at different loci in the brain. In no sense is there anything like a private wire from each sensory cell to a corresponding point in the brain. In fact, there are so many opportunities for a signal to go astray on its way from the receptor to the brain that it is surprising that spatial discrimination is as good as it is. Nevertheless, there is clear evidence that, by a combination of anatomical and functional arrangements, spatial differences at the receptor level are translated into topologically similar spatial differences in brain activity. *See* HEARING (HUMAN).

The nerve fibers between receptor and brain do not serve merely as transmitters of sensory information. Their interconnections enable them to influence one another's sensitivity and to perform logical operations like those carried out inside computers. As a result the information arriving in the sensory areas of the brain is not merely a more or less faithful replica of that presented to the receptors but in addition has had certain aspects of the information selected for special signaling. *See* CHEMICAL SENSES; PAIN; SOMESTHESIS; TASTE; VISION. [J.F.H.]

Sense amplifier An electronic amplifier circuit used to sense and refresh the value of a bit stored in a memory cell of a dynamic random access memory (DRAM) integrated circuit.

In DRAM, bits are represented in memory by the presence or absence of an electric charge stored on tiny capacitors. Cell capacitance is directly proportional to cell area, and since the chip area devoted to each bit-cell must decrease with an increase in the memory capacity of a given size of chip, the resulting cell capacitance is tiny, typically on the order of femtofarads (1 femtofarad $= 10^{-15}$ farad). Since the voltage used to charge these capacitors is usually limited to 5 V or less, the charge stored in each memory cell also is quite small, on the order of femtocoulombs. *See* CAPACITANCE; CAPACITOR.

In order to read out the value of a given bit of a word in this type of memory, the bit-cell voltage, or equivalently the magnitude of its charge, needs to be sensed, and the results of this sense operation must be delivered to the rest of the circuit. Both the sense amplifier used to read the bit-cell voltage and the interconnect wiring (the bit line) between the bit cell and the amplifier have inherent parasitic capacitances which, in total, are much larger than the bit-cell capacitance. If the sense amplifier is simply switched across the bit cell, the charge on the bit-cell capacitor will redistribute across the parasitic capacitor and the bit-cell capacitor in accordance with Kirchhoff's law, which requires that the two capacitors have the same voltage, where the total charge must come from the original charge stored on the memory-cell capacitor. Thus the voltage seen by the amplifier is equal to the original bit-cell voltage multiplied by the ratio of the bit-cell capacitance to the sum of the two capacitances, and the charge remaining on the memory cell capacitor after sensing would be reduced from the original charge in the same proportion. If the parasitic capacitance is much larger than the cell capacitance, it follows that the voltage available at the sense amplifier input will be small and the voltage and charge remaining on the memory cell will be considerably reduced. More sophisticated approaches need to be taken to sense this tiny voltage and to refresh the memory cell during sense, so that the memory cell capacitor is left fully charged (or fully discharged) when sensing is complete. *See* KIRCHHOFF'S LAWS OF ELECTRIC CIRCUITS.

The sense amplifier action is based on metal-oxide-semiconductor field-effect transistors (MOSFETs). These can be thought of as simple switches that are opened and closed in a predetermined sequence to carry out the read/refresh memory cycle. To assist the sense, a memory reference cell, containing a capacitor of approximately one-half the capacitance of the bit-cell capacitor, is added to the circuit. *See* SEMICONDUCTOR MEMORIES; TRANSISTOR. [P.V.L.]

Sense organ A structure which is a receptor for external or internal stimulation. A sense organ is often referred to as a receptor organ. External stimuli affect the sensory structures which make up the general cutaneous surface of the body, the exteroceptive area, and the tissues of the body wall or the proprioceptive area. These somatic area receptors are known under the general term of exteroceptors. Internal stimuli which originate in various visceral organs such as the intestinal tract or heart affect the visceral sense organs or interoceptors. A receptor structure is not necessarily an organ; in many unicellular animals it is a specialized structure within the organism. Receptors are named on the basis of the stimulus which affects them, permitting the organism to be sensitive to changes in its environment.

Photoreceptors are structures which are sensitive to light and in some instances are also capable of perceiving form, that is, of forming images. Light-sensitive structures include the stigma of phytomonads, photoreceptor cells of some annelids, pigment cup ocelli and retinal cells in certain asteroids, the eye-spot in many turbellarians, and the ocelli of arthropods. The compound eye of arthropods, mollusks, and chordates is capable of image formation and is also photosensitive. *See* PHOTORECEPTION.

Phonoreceptors are structures which are capable of detecting vibratory motion or sound waves in the environment. The most common phonoreceptor is the ear, which in the vertebrates has other functions in addition to sound perception. *See* EAR; PHONORECEPTION.

Statoreceptors are structures concerned primarily with equilibration, such as the statocysts found throughout the various phyla of invertebrates and the inner ear or membranous labyrinth filled with fluid.

The sense of smell is dependent upon the presence of olfactory neurons, called olfactoreceptors, in the olfactory epithelium of the nasal passages among the vertebrates. *See* OLFACTION.

The sense of taste is mediated by the taste buds, or gustatoreceptors. In most vertebrates these taste buds occur in the oral cavity, on the tongue, pharynx, and lining of the mouth; however, among certain species of fish, the body surface is supplied with taste buds as are the barbels of the catfish. *See* TASTE.

The surface skin of vertebrates contains numerous varied receptors associated with sensations of touch, pain, heat, and cold. *See* CHEMICAL SENSES; CUTANEOUS SENSATION; SENSATION. [C.B.C.]

Sensitivity (engineering) A property of a system, or part of a system, that indicates how the system reacts to stimuli. The stimuli can be external (that is, an input signal) or a change in an element in the system. Thus, sensitivity can be interpreted as a measure of the variation in some behavior characteristic of the system that is caused by some change in the original value of one or more of the elements of the system.

Sensitivity is commonly used as a figure of merit for characterizing system performance. As a figure of merit, the sensitivity is a numerical indicator of system performance that is useful for predicting system performance in the presence of elemental variations or comparing the relative performance of two or more systems that ideally have the same performance. In the latter case, the performance of the systems relative to some parameter of interest is rank-ordered by the numerical value of the corresponding sensitivity functions. If T is the performance characteristic and X is the element or a specified input level, then mathematically sensitivity is expressed as a normalized derivative of T with respect to X.

A limiting factor in using the sensitivity of a system to characterize performance at low signal levels is the noise. Noise is a statistical description of a random process inherent in all elements in a physical system. The noise is related to the minimum signal that can be processed in a system as a function of physical variables such as pressure, visual brightness, audible tones, and temperature. *See* ELECTRICAL NOISE.

There exist many situations where the sensitivity measure indicates the ability of a system to meet certain design specifications. For example, in an electronic system the sensitivity of the output current with respect to the variation of the power-supply voltage can be very critical. In that case, a system with a minimum sensitivity of the output current with respect to the power-supply voltage must be designed. Another example is a high-fidelity audio amplifier whose sensitivity can be interpreted as the capacity of the amplifier to detect the minimum amplifiable signal. [E.S.Si.]

Sensory system regeneration The replacement of receptor cells within a given sensory endorgan (retina, cochlea, taste buds, olfactory epithelium). In order to detect environmental cues efficiently, receptor cells must be exposed to the environment. This exposure makes them susceptible to the damaging effects of the very stimuli they are designed to detect. Such sensory deficits are of great significance to the survival of the organism, and numerous mechanisms have evolved to protect sensory systems from permanent extensive damage. In many systems, one of these protective mechanisms is the ability to regenerate. In the context of sensory systems, regeneration normally involves addition of newly differentiated cells to the system rather than the recuperation of damaged cells.

Generally, regeneration requires that undifferentiated cells known as progenitor cells go through at least one cell division prior to developing as a specific cell type (cell differentiation). However, the presence of progenitor cells within a given epithelium and their propensity to reenter the cell cycle varies greatly from system to system. For example, taste buds and the olfactory epithelium contain relatively large numbers of progenitor cells that undergo constant cell division. Both taste receptor cells and olfactory neurons undergo constant renewal (replacement) in all adult vertebrates. These systems are capable of substantial regeneration. *See* Cell cycle; Cell differentiation; Cell lineage; Olfaction; Taste.

In contrast, the regeneration of photoreceptors in the retina and sensory hair cells in the inner ear is dependent upon the species and age of a given animal. Numerous studies in teleost fish and amphibians have demonstrated that both the eye and the inner ear are capable of regeneration long after embryonic development. The retinas of reptiles, birds, and mammals, however, lose their regenerative capability during embryonic development. Consequently, photoreceptor loss in the retinas of adult mammals such as humans is irreversible. *See* Embryonic differentiation; Embryonic induction; Eye (vertebrate).

For many years, the inner ears of higher vertebrates were also thought to be totally incapable of regeneration beyond embryonic development. However, landmark studies in the 1980s provided new data that indicated otherwise. Using a radioactive marker that labels dividing cells, these studies demonstrated that sound- or drug-induced damage to the cochleae of adult birds caused dormant progenitor cells to become active and produce new sensory hair cells. It was subsequently shown that a portion of the bird ear responsible for the sense of balance (the vestibular system) is also capable of regeneration in response to damage and maintains a small but constant number of dividing progenitor cells under normal conditions. Finally, it has been demonstrated that the regeneration of sensory cells in the bird inner ear results in a high level of functional recovery in both the auditory and vestibular systems of these animals. *See* Ear (vertebrate).

Cells in the nonauditory parts of the mammalian inner ear are also capable of very limited hair cell regeneration. It is increasingly clear, however, that the adult mammalian cochlea is not. The adult mammalian cochlea has no innate ability to regenerate and in fact loses its ability to produce new hair cells a day or two prior to the birth of the animal. Consequently, research has turned to the normal embryonic development of the mammalian cochlea to search for molecular factors that might be used to stimulate hair cell addition in the mature animal. Several groups of molecules have been identified that play a significant role. These include the Notch signaling pathway, a genetic program that is present in both vertebrates and invertebrates and which functions as a switching mechanism by which progenitor cells may be directed to develop as one type of cell versus another, or to continue to divide. *See* Hearing (human); Hearing impairment. [P.L.]

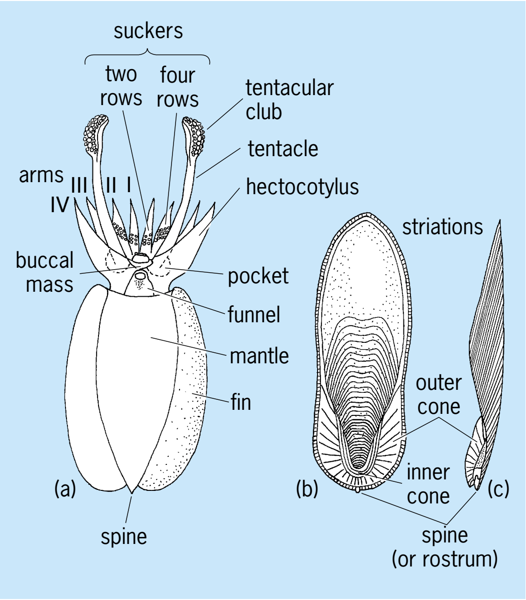


Diagram of some features of (*a*) a cuttlefish and of (*b*) a cuttlebone shown in ventral view and (*c*) in cross section.

Sepioidea An order of the class Cephalopoda (subclass Coleoidea) including the cuttlefishes (*Sepia*), the bobtail squids (*Sepiola*), and the ram's-hom squid (*Spirula*). The group is characterized by an internal shell that is calcareous and broad with closely packed laminate chambers (the cuttlebones of cuttlefishes). The mouth is surrounded by ten appendages (eight arms and two longer tentacles) that bear suckers with chitinous rings. The tentacles are contractile and retractile into pockets at their bases (see illustration).

Cuttlefishes are common benthic or epibenthic (living on or just above the bottom, respectively) animals that occur in the warm and temperate waters of the nearshore and continental shelf zones of the Old World, but they are excluded from the Western Hemisphere (North and South America). They prey on shrimps, crabs, small fishes, and other cuttlefishes. The sexes are separate, and during mating, which follows a colorful ritualistic courting behavior, sperm is transferred to the female in cylindrical packets (spermatophores) by a modified arm (the hectocotylus) of the male.

The cuttlebones are used to control the buoyancy of the cuttlefishes as fluid is pumped into and out of the laminar chambers. Dried cuttlebones are a source of calcium for cage birds and are used for fine jewelry molds, dentifrices, and cosmetics. The cuttlefishes eject an attention-getting blob of brownish-black ink when threatened by predators, then change color, become transparent, and jet-swim away, leaving the predator to attack the false body (pseudomorph) of ink. Artists have used the ink, called sepia, for centuries. Cuttlefishes are important in world fisheries; about 200,000 metric tons are caught each year for human food. *See* Cephalopoda; Coleoidea. [C.F.E.R.]

Sepiolite A complex hydrated magnesium silicate mineral named for its resemblance to cuttlefish bone, alternately named meerschaum (sea foam). The ideal composition, $Mg_8(H_2O)_4(OH)_4Si_{12}O_{30}$, is modified by some additional water of hydration, but is otherwise quite representative. Interlaced disoriented fibers aggregate into a massive stone so porous that it floats on water. These stones are easily carved, take a high polish with wax, and harden when warmed. *See* Clay minerals; Silicate minerals. [W.F.B.]

Septibranchia A subclass of bivalve mollusks (class Bivalvia) that are unique in their possession of a muscular septum instead of a filamentous gill. The Septibranchia equate in great part to the superfamily Poromyacea, which includes the septibranch families Cuspidariidae and Poromyidae, and the Verticordiidae. The Verticordiidae have gills that are greatly reduced in size. Although there are a few cuspidariid species in shallow seas, the great majority of septibranchs are found at lower slope and abyssal depths which are deficient in food for filter-feeding bivalves. They live close to the surface in soft sediments. Most species are less than 20 mm maximum length. *See* BIVALVIA; MOLLUSCA.

The term septibranch remains extremely useful because it describes mollusks having a septum and other morphological specializations that relate to the septibranch's unique carnivorous habits. The septum is a muscular, horizontal partition dividing the mantle cavity. It is derived from the enormous gill found in the mollusks of the subclass Lamellibranchia: The filaments are reduced in size and modified. Other modifications include a muscular stomach for crushing the prey and high proteolytic activity of the gastric juice. [J.A.A.]

Septic tank A single-story, watertight, on-site treatment system for domestic sewage, consisting of one or more compartments, in which the sanitary flow is detained to permit concurrent sedimentation and sludge digestion. The septic tank is constructed of materials not subject to decay, corrosion, or decomposition, such as precast concrete, reinforced concrete, concrete block, or reinforced resin and fiberglass. The tank must be structurally capable of supporting imposed soil and liquid loads. Septic tanks are used primarily for individual residences, isolated institutions, and commercial complexes such as schools, prisons, malls, fairgrounds, summer theaters, parks, or recreational facilities. Septic tanks have limited use in urban areas where sewers and municipal treatment plants exist. *See* CONCRETE; REINFORCED CONCRETE; STRUCTURAL MATERIALS.

Septic tanks do not treat sewage; they merely remove some solids and condition the sanitary flow so that it can be safely disposed of to a subsurface facility such as a tile field, leaching pools, or buried sand filter. The organic solids retained in the tank undergo a process of liquefaction and anaerobic decomposition by bacterial organisms. The clarified septic tank effluent is highly odorous, contains finely divided solids, and may contain enteric pathogenic organisms. The small amounts of gases produced by the anaerobic bacterial action are usually vented and dispersed to the atmosphere without noticeable odor or ill effects. *See* RURAL SANITATION; SEWAGE; SEWAGE TREATMENT. [G.Pa.]

Sequence stratigraphy The study of stratigraphic sequences, defined as stratigraphic units bounded by unconformities. With improvements in the acquisition and processing of reflection-seismic data by petroleum exploration companies in the 1970s came the recognition that unconformity-bounded sequences could be recognized in most sedimentary basins. This was the beginning of an important development, seismic stratigraphy, which also included the use of seismic reflection character to make interpretations about large-scale depositional facies and architecture. *See* SEISMIC STRATIGRAPHY; UNCONFORMITY.

Underpinning sequence-stratigraphic methods are the following interrelated principles: (1) The volume of sediment accumulating in any part of a sedimentary basin is dependent on the space made available for sediment by changes in sea level or basin-floor elevation. This space is referred to as accommodation. (2) Changes in accommodation tend to be cyclic, and they are accompanied by corresponding changes in sedimentary environment and depositional facies. Thus, a rise in base level typically leads to an increase in accommodation, deepening of the water in the basin, with corresponding changes in facies, and a transgression, with a consequent landward shift in depositional environments and in depositional facies. A fall in base level may lead to exposure and erosion (negative accommodation), with the development of a widespread unconformity. (3) These predictable changes provide the basis for a model of the shape and internal arrangement or architecture of a sequence, including the organization and distribution of sedimentary facies and the internal bedding surfaces that link these facies together. *See* BASIN; DEPOSITIONAL SYSTEMS AND ENVIRONMENTS; FACIES (GEOLOGY).

Clastic-dominated sequences are bounded by unconformities. These surfaces (sequence boundaries) are typically well developed within coastal and shelf sediments, where they form as a result of subaerial exposure and erosion during falling sea level. In deeper-water settings, including the continental slope and base of slope, there may be no corresponding sedimentary break; and sequences may be mapped into such settings only if the unconformity can be correlated to the equivalent conformable surface (the correlative conformity). In some instances, the surface of marine transgression, which develops during the initial rise in sea level from a lowstand, forms a distinctive surface that is close in age to the subaerial unconformity and may be used as the sequence boundary. *See* MARINE GEOLOGY; MARINE SEDIMENTS.

The cycle of rise and fall of sea level may be divided into four segments: lowstand, transgressive, highstand, and falling stage. The deposits that form at each stage are distinctive, and are assigned to systems tracts named for each of these stages.

Carbonate-dominated sequences are derived from carbonate sedimentation which is most active in warm, clear, shallow, shelf seas. During the sea-level cycle, these conditions tend to be met during the highstand phase. Sediment production may be so active, including that of reef development at the platform margin, that it outpaces accommodation generation, leading to deposition on the continental slope. Oversteepened sediment slopes there may be remobilized, triggering sediment gravity flows and transportation into the deep ocean. This process is called highstand shedding.

There are several processes of sequence generation that range from a few tens of thousands of years to hundreds of millions of years for the completion of a cycle of rise and fall of sea level. More than one such process may be in progress at any one time within a basin, with the production of a range of sequence styles nested within or overlayering each other.

High-frequency sequence generation is driven by orbital forcing of climate (the so-called Milankovitch effects), of which glacial eustasy is the best-known outcome. The effects of glacioeustasy have dominated continental-margin sedimentation since the freeze-up of Antarctica in the Oligocene. Regional tectonism—such as the process of thermal subsidence following rifting, and flexural loading in convergent plate settings—develops changes in basement elevation that drive changes in relative sea level. These cycles have durations of a few millions to a few tens of millions of years, and they are confined to individual basins or the flanks of major orogens or plate boundaries. *See* PALEOGEOGRAPHY.

Sequence concepts enable petroleum exploration and development geologists to construct predictive sequence models for stratigraphic units of interest from the limited information typically available from basins undergoing petroleum exploration. These models can guide regional exploration, and can also assist in the construction of production models that reflect the expected partitioning of reservoir-quality facies within individual stratigraphic units. *See* CLIMATE HISTORY; GEOLOGIC TIME SCALE; GEOPHYSICAL EXPLORATION; GLACIOLOGY; PALEOCLIMATOLOGY; STRATIGRAPHY. [A.D.M.]

Sequoia The giant sequoia or big tree (*Sequoia gigantea*) occupies a limited area in California and is said to be the oldest and most massive of all living things. The leaves are evergreen, scalelike, and overlapping on the branches. In height sequoia is a close second to the redwood (300–330 ft or 90–100 m) but the trunk is more massive. Sequoia trees may be 27–30 ft (8–9 m) in diameter 10 ft (3 m) from the ground. The stump of one tree showed 3400 annual rings. The red-brown bark is 1–2 ft (0.3–0.6 m) thick and spongy. Vertical grooves in the trunk give it a fluted appearance. The heartwood is dull purplish-brown and lighter and more brittle than that of the redwood. The wood and bark contain much tannin, which is probably the cause of the great resistance to insect and fungus attack. The most magnificent trees are within the General Grant and Sequoia National Parks. *See* PINALES; REDWOOD. [A.H.G./K.P.D.]

Series The indicated sum of a succession of numbers or terms. Series are used to obtain approximate values of infinite repeating decimals, to solve transcendental equations, to obtain values of logarithms or trigonometric functions, to evaluate integrals, and to solve boundary value problems.

For a finite series, with only a limited number of terms, the sum is found by addition. For an infinite series, with an unlimited number of terms, a sum or value can be assigned only by some limiting process. When the simplest such process yields a value, the infinite series is convergent. Many tests for convergence enable one to learn whether a sum can be found without actually finding it.

If each term of an infinite series involves a variable x and the series converges for each value of x in a certain range, the sum will be a function of x. Often the sum is a given function of x, $f(x)$, for which a series having terms of some given form is desired. Thus the Taylor's series expansion

$$f(x) = \sum_{n=0}^{\infty} f^{(n)}(a)\frac{(x-a)^n}{n!}$$

can be found for a large class of functions, the analytic functions, and represent such functions for sufficiently small values of $|x - a|$. For a much less restricted type of function on the interval $-\pi < x < \pi$, a Fourier series expansion of the form

$${}^1/_2 A_0 + \sum_{n=1}^{\infty}(A_n \cos nx + B_n \sin nx)$$

can be found.

Finite series. Here the problem of interest is to determine the sum of the first n terms,

$$S_n = u_0 + u_1 + u_2 + \cdots + u_{n-1}$$

when u_n is a given function of n. Examples are the arithmetic series, with $u_n = a + nd$ and $S_n = (n/2)[2a+(n-1)d]$, and the geometric series, with $u_n = ar^n$ and $S_n = a(1 - r^n)/(1 - r)$. *See* PROGRESSION (MATHEMATICS).

Convergence and divergence. An infinite series is the indicated sum of an unlimited number of terms

$$u_0 + u_1 + u_2 + \cdots u_n \cdots$$

or more briefly

$$\sum_{n=0}^{\infty} u_k$$

or simply Σu_n, read "sigma of u_n." The sum S_n of the first n terms is known as the nth partial sum. Thus S_n is the finite sum

$$\sum_{k=0}^{n-1} u_k$$

If, as n increases indefinitely or becomes infinite, the partial sum S_n approaches a limit S, then the infinite series Σu_n is convergent. S denotes the sum or value of the series. For example, if $|r| < 1$,

$$S = \sum ar^n = \frac{a}{1-r} \text{ since } S_n = a\frac{1-r^n}{1-r}$$

If, as n becomes infinite, the partial sum S_n does not approach a finite limit, then the infinite series Σu_n is divergent. For example, $\Sigma 1$ diverges, since here $S_n = n$ becomes infinite with n. Also $\Sigma(-1)^n$ diverges, since here $S_n = {}^1/_2[1 - (-1)^{n+1}]$ which is alternately one and zero.

Positive series are series each of whose terms is a positive number or zero. For such series, the partial sum S_n increases as n increases. If for some fixed number A no sum S_n ever exceeds A, the sums are bounded and admit A as an upper bound. In this case, S_n must approach a limit, and the series is convergent. If every fixed number is exceeded by some S_n, the sums are unbounded. In this case, S_n must become positively infinite and the series is divergent. The tests for convergence of positive series are tests for boundedness, and this is shown by a comparison of S_n with the partial sums of another series or with an integral.

For any series Σu_n, which may have both positive and negative terms, the series of absolute values, $\Sigma|u_n|$, is a positive series whose convergence may be proved by one of the tests for positive series. If $\Sigma|u_n|$ converges, then Σu_n necessarily converges and is said to converge absolutely. The sum of an absolutely convergent series is independent of the order of the terms.

A series which converges but which does not converge absolutely is said to be conditionally convergent. For such a series, a change in the order of the terms may change the sum or cause divergence.

Power series. There are series with $u_n = a_n x^n$. For such a series, it may happen that

$$\lim_{n\to\infty}\left|\frac{a_{n+1}}{a_n}\right| = A$$

If $A = 0$, the series converges for all values of x. If $A \neq 0$, the series converges for all x of the interval $-1/A < x < 1/A$. It will diverge for all x with $|x|$ $1/A$. For any power series, the interval of convergence is related in this way to a number A, which, however, in the general case has to be given by the superior limit of

$$\sqrt{|a_n|}$$

Similar remarks apply to the series with $u_n = a_n(x - c)^n$. Here the interval of convergence is $|x - c| < 1/A$.

One of the most important power series is the binomial series:

$$1 + mx + \frac{m(m-1)}{1.2}x^2 + \cdots + \frac{m(m-1)(m-2)\cdots(m-n+1)}{n!}x^n + \cdots$$

When m is a positive integer, this is a finite sum of $m + 1$ terms which equals $(1 + x)^m$ by the binomial theorem. When m is not a positive integer, the interval of convergence is $-1 < x < 1$, and for x in this interval, the sum of the series is $(1 + x)^m$. *See* BINOMIAL THEOREM.

Let the power series $\Sigma a_n(x - c)^n$ have the sum function $f(x)$. Then $a_0 = f(c)$, $a_n = f^{(n)}(c)/n!$, and the series is the Taylor series of $f(x)$ at $x = c$. Thus, every power series whose interval of convergence has positive length can be put in the form

$$f(x) = f(c) + f'(c)\frac{x-c}{1!} + \cdots + f^{(n)}(c)\frac{(x-c)^n}{n!} + \cdots$$

where $f(x)$ is the sum function.

The Maclaurin series is the special case of Taylor series with $c = 0$:

$$f(x) = f(0) + f'(0)\frac{x}{1!} + \cdots + f^{(n)}(0)\frac{x^n}{n!} + \cdots$$

Uniform convergence. Let each term of a series be a function of z, $u_n = g_n(z)$. Let S_n be the sum of the first n terms, and S the sum to which the series converges for a particular value of z. Then $R_n = S - S_n$ is the remainder after n terms, and for the particular value of z, $\lim R_n$ must equal zero. If, for a given range of z, it is possible to make $R_n(z)$ arbitrarily small for sufficiently large n without specifying which z in the range is under consideration, the series converges uniformly. *See* FOURIER SERIES. [P.F./S.Bo.]

Series sometimes appear in disguised form in arithmetic. Thus the approximation of a rational number by an infinite repeating decimal is really a geometric series.

Series circuit An electric circuit in which the principal circuit elements have their terminals joined in sequence so that a common current flows through all the elements. The circuit may consist of any number of passive and active elements, such as resistors, inductors, capacitors, electron tubes, and transistors. *See* CIRCUIT (ELECTRICITY). [R.L.R.]

Serology The division of biological science concerned with antigen-antibody reactions in serum. It properly encompasses any of these reactions, but is often used in a limited sense to denote laboratory diagnostic tests, especially for syphilis. The techniques of blood grouping have come from the study of antigen-antibody reactions in serum, as have techniques for identification of genetic polymorphism and quantitation of numerous serum proteins. With these advances came the means for developing transfusion therapy with cells and plasma. In addition, these techniques led to identification of antibodies involved in incompatibility reactions, such as in erythroblastosis fetalis, and the development of effective measures to prevent their occurrence. Further, extension of these techniques to identification of antigens on white cells led to effective methods of histocompatibility typing, facilitating organ transplantation. *See* Transplantation biology. [D.R.]

Serotonin A compound, also known as 5-hydroxytryptamine (5-HT), derived from tryptophan, an indole-containing amino acid. It is widely distributed in the animal and vegetable kingdoms. In mammals it is found in gastrointestinal enterochromaffin cells, in blood platelets, and in brain and nerve tissue. Serotonin is a local vasoconstrictor, plays a role in brain and nerve function and in regulation of gastric secretion and intestinal peristalsis, and has pharmacologic properties. It is inactivated by monoamine oxidases (MAO-A and -B), enzymes that also inactivate other neurotransmitters such as norepinephrine and dopamine.

Serotonin is concentrated in certain areas of the brain; the hypothalamus and midbrain contain large amounts, while the cortex and cerebellum contain low concentrations. Like most neurotransmitters, it is stored in granules inside nerve endings, and is thus not exposed to inactivation by monoamine oxidases until it is released into the synaptic space between nerves. When a serotonin-containing nerve fires, serotonin is released and can bind to any one of a series of at least 14 distinct downstream serotonin receptors (5-HT receptors). Release of serotonin or other stored neurotransmitters can also be induced by alkaloids such as reserpine, which have been used as tranquilizing agents in the treatment of nervous and mental disorders. Although pharmacologic doses of serotonin produce a type of sedation and other depressant conditions of the nervous system, several types of clinically useful antidepressants, such as monoamine oxidase (MAO) inhibitors, tricyclic antidepressants, and selective serotonin reuptake inhibitors (SSRIs), act by increasing the amount of active serotonin in nerve synapses in particular brain regions. Conversely, various conditions that lower serotonin levels are associated with depression, suggesting that normal to slightly elevated serotonin levels tend to elevate mood and prevent depression. *See* Affective disorders; Brain; Nervous system (vertebrate); Neurosecretion; Psychopharmacology. [M.K.S.; B.A.St.]

Serpentine The name traditionally applied to three hydrated magnesium silicate minerals, antigorite, chrysotile, and lizardite. All have similar chemical compositions but with three different but closely related layered crystal structures. Serpentine also has been used as a group name for minerals with the same layered structures but with a variety of compositions. The general formula is $M_3T_2O_5(OH)_4$, where M may be magnesium (Mg), ferrous iron (Fe^{2+}), ferric iron (Fe^{3+}), aluminum (Al), nickel (Ni), manganese (Mn), cobalt (Co), chromium (Cr), zinc (Zn), or lithium (Li); and T may be silicon (Si), Al, Fe^{3+}, or boron (B).

Lizardite has a planar structure, with the misfit accommodated by slight adjustments of the atomic positions within the layers. Chrysotile has a cylindrical structure in which the layers are either concentrically or spirally rolled to produce fiber commonly ranging from 15 to 30 nanometers in diameter, and micrometers to centimeters in length. These fibers have great strength and flexibility and are the most abundant and commonly used form of asbestos. Antigorite has a modulated wave structure, with wavelengths generally varying between 3 and 5 nm. *See* Asbestos. [F.J.W.]

Serpentinite A common rock composed of serpentine minerals; usually formed through the hydration of ultramafic rocks, dunites, and peridotites in a process known as serpentinization. The result is the formation of hydrated magnesium-rich minerals, such as antigorite, chrysotile, or lizardite, commonly with magnetite or, less frequently, brucite. *See* Asbestos; Dunite; Peridotite.

Serpentinites can be distinguished by, and are named for, the dominant serpentine mineral in the rock, that is, antigorite-serpentinite, chrysotile-serpentinite, and lizardite-serpentinite. Lizardite-serpentinites are the most abundant. They have been formed in retrograde terrains and are characterized by the pseudomorphic replacement of the original olivine, pyroxenes, amphiboles, and talc by lizardite with or without magnetite or brucite. Antigorite-serpentinites can form directly from minerals such as olivine, pyroxene, and so forth in retrograde terrains similar to lizardite, but at a high temperature. Chrysotile-serpentinites usually occur only in chrysotile asbestos deposits. The occurrence of serpentinites is widespread, particularly in greenstone belts, mountain chains, and mid-ocean ridges, where they have formed through the serpentinization of ultramafic rocks. *See* Mid-Oceanic Ridge; Serpentine. [F.J.W.]

Serum The liquid portion that remains when blood is allowed to clot spontaneously and is then centrifuged to remove the blood cells and clotting elements. It has approximately the same volume (55%) as plasma and differs from it only by the absence of fibrinogen. *See* Fibrinogen.

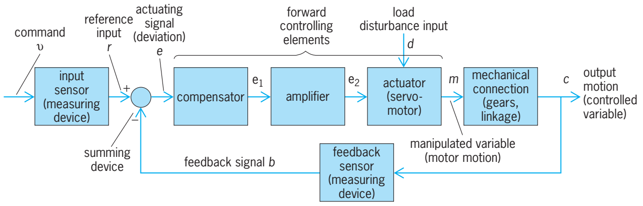
Blood serum contains 6–8% solids, including macromolecules such as albumin, antibodies and other globulins, and enzymes; peptide and lipid-based hormones; and cytokines; as well as certain nutritive organic materials in small amounts, such as amino acids, glucose, and fats. Somewhat less than 1% of the serum consists of inorganic substances. Small amounts of respiratory gases are dissolved in the serum, as is the gas nitric oxide, which serves as a chemical messenger and vasodilator. Small amounts of waste material are also present. These substances, along with other small molecules which are not bound to blood proteins, are filtered out as blood flows through the kidney. *See* Blood; Clinical pathology; Kidney.

Certain types of sera, both human and animals, are used in clinical medicine. Immune serum and hyperimmune serum either are developed by naturally occurring disease or are deliberately prepared by repeated injection of antigens to increase antibody titer for either diagnostic tests or the treatment of active disease. These sera are referred to as antisera, since they have a specific antagonistic action against specific antigens. *See* Antibody; Antigen; Biologicals; Immunity.

By custom, the clear portion of any liquid material of animal origin separated from its solid or cellular elements is also referred to as sera. These fluids are more properly referred to as effusions. *See* Serology. [R.Str.; B.A.St.]

Servomechanism A system for the automatic control of motion by means of feedback. The term servomechanism, or servo for short, is sometimes used interchangeably with feedback control system (servosystem). In a narrower sense, servomechanism refers to the feedback control of a single variable (feedback loop or servo loop). In the strictest sense, the term servomechanism is restricted to a feedback loop in which the controlled quantity or output is mechanical position or one of its derivatives (velocity and acceleration). *See* Control systems.

The purpose of a servomechanism is to provide one or more of the following objectives: (1) accurate control of motion without the need for human attendants (automatic control); (2) maintenance of accuracy with mechanical load variations, changes in the environment, power supply fluctuations, and aging and deterioration of components (regulation and self-calibration);



Servo loop elements and their interconnections. Cause-and-effect action takes place in the directions of arrows. (*After American National Standards Institute*, *Terminology for Automatic Control*, *ANSI C85.1*)

(3) control of a high-power load from a low-power command signal (power amplification); (4) control of an output from a remotely located input, without the use of mechanical linkages (remote control, shaft repeater).

The illustration shows the basic elements of a servomechanism and their interconnections; in this type of block diagram the connection between elements is such that only a unidirectional cause-and-effect action takes place in the direction shown by the arrows. The arrows form a closed path or loop; hence this is a single-loop servomechanism or, simply, a servo loop. More complex servomechanisms may have two or more loops (multiloop servo), and a complete control system may contain many servomechanisms. *See* Block diagram.

Servomechanisms were first used in speed governing of engines, automatic steering of ships, automatic control of guns, and electromechanical analog computers. Today, servomechanisms are employed in almost every industrial field. Among the applications are cutting tools for discrete parts manufacturing, rollers in sheet and web processes, elevators, automobile and aircraft engines, robots, remote manipulators and teleoperators, telescopes, antennas, space vehicles, mechanical knee and arm prostheses, and tape, disk, and film drives. *See* Computer storage technology; Flight controls; Governor; Magnetic recording; Remote manipulators; Robotics. [G.W.]

Set theory A mathematical term referring to the study of collections or sets. Consider a collection of objects (such as points, dishes, equations, chemicals, numbers, or curves). This set may be denoted by some symbol, such as X. It is useful to know properties that the set X has, irrespective of what the elements of X are. The cardinality of X is such a property.

Two sets A and B are said to have the same cardinal written $C(A) = C(B)$, provided there is a one-to-one correspondence between the elements of A and the elements of B. For finite sets this notion coincides with the phrase "A has the same number of elements as B." However, for infinite sets the above definition yields some interesting consequences. For example, let A denote the set of integers and B the set of odd integers. The function $f(n) = 2n{-}1$ shows that $C(A) = C(B)$. Hence, an infinite set may have the same cardinal as a part or subset of itself.

A is called a subset of B if each element of A is an element of B, and it is expressed as $A \subset B$. The collection of odd integers is a subset of itself.

One approved method of forming a set is to consider a property P possessed by certain elements of a given set X. The set of elements of X having property P may be considered as a set Y. The expression $p \epsilon X$ is used to denote the fact that p is an element of X. Then $Y = \{p \mid p \epsilon X$ and p has property $P\}$. Another approved method is to consider the set Z of all subsets of a given set X. Paradoxically, it is not permissible to regard the collection of all sets as a set.

In set theory, one is interested not only in the properties of sets but also in operations involving sets: addition, subtraction, multiplication, and mapping. The sum of A and B ($A + B$ or $A \cup B$) is the set of all elements in either A or B; that is, $A + B = \{p \mid p \epsilon A$ or $p \epsilon B\}$. The intersection of A and B ($A \cdot B$, $A \cap B$, or AB) is the set of all elements in both A and B; that is, $A \cdot B = \{p \mid p \epsilon A$ and $p \epsilon B\}$. If there is no element which is in both A and B, one says that A does not intersect B and writes $A \cdot B = 0$. The expression $A - B$ is used to denote the collection of elements of A that do not belong to B; that is $A - B = \{p \mid p \epsilon A$ and $p \notin B\}$. [R.H.Bi]

Sewage Water-carried wastes, in either solution or suspension, that flow away from a community. Also known as wastewater flows, sewage is the used water supply of the community. It is more than 99.9% pure water and is characterized by its volume or rate of flow, its physical condition, its chemical constituents, and the bacteriological organisms that it contains. Depending on their origin, wastewaters can be classed as sanitary, commercial, industrial, or surface runoff.

The spent water from residences and institutions, carrying body wastes, ablution water, food preparation wastes, laundry wastes, and other waste products of normal living, are classed as domestic or sanitary sewage. Liquid-carried wastes from stores and service establishments serving the immediate community, termed commercial wastes, are included in the sanitary or domestic sewage category if their characteristics are similar to household flows. Wastes that result from an industrial process or the production or manufacture of goods are classed as industrial wastes. Their flows and strengths are usually more varied, intense, and concentrated than those of sanitary sewage. Surface runoff, also known as storm flow or overland flow, is that portion of precipitation that runs rapidly over the ground surface to a defined channel. Precipitation absorbs gases and particulates from the atmosphere, dissolves and leaches materials from vegetation and soil, suspends matter from the land, washes spills and debris from urban streets and highways, and carries all these pollutants as wastes in its flow to a collection point. Discharges are classified as point-source when they emanate from a pipe outfall, or non-point-source when they are diffused and come from agriculture or unchanneled urban land drainage runoff. *See* Hydrology; Precipitation (meteorology).

Wastewaters from all of these sources may carry pathogenic organisms that can transmit disease to humans and other animals; contain organic matter that can cause odor and nuisance problems; hold nutrients that may cause eutrophication of receiving water bodies; and may contain hazardous or toxic materials. Proper collection and safe, nuisance-free disposal of the liquid wastes of a community are legally recognized as a necessity in an urbanized, industrialized society. *See* Analytical chemistry; Public health; Sewage solids; Sewage treatment; Toxicology. [G.Pa.]

Sewage collection systems Configurations of inlets, catch basins, manholes, pipes, drains, mains, holding basins, pump stations, outfalls, controls, and special devices to move wastewaters from points of collection to discharge. The system of pipes and appurtenances is also known as the sewerage system. Wastewaters may be sanitary sewage, industrial wastes, storm runoff, or combined flows.

A sewer is a constructed ditch or channel designed to carry away liquid-conveyed wastes discharged by houses and towns. Modern sewer systems typically are gravity-flow pipelines installed below the ground surface in streets and following the ground slope. The depth of cover over pipelines is controlled by factors such as the location of rock and ground water, the ability to receive flows from all buildings by gravity, depth to frost line, economics of maintaining gravity flow as compared with pumping, and location and elevation of other existing utilities and infrastructures.

Sewerage systems are designed to carry the liquid wastes smoothly, without deposition, with a minimum of wasted hydraulic energy, and at minimum costs for excavation and construction; they should provide maximum capacity for future populations and flows. Engineered construction, controlled by availability of time, material, personnel, and finances, affects the choice and use of individual components within sewerage systems. *See* INDUSTRIAL HEALTH AND SAFETY; SEWAGE; SEWAGE DISPOSAL. [G.Pa.]

Sewage disposal The ultimate return of used water to the environment. Disposal points distribute the used water either to aquatic bodies such as oceans, rivers, lakes, ponds, or lagoons or to land by absorption systems, groundwater recharge, and irrigation. Wastewaters must be mixed, diluted, and absorbed so that receiving environments retain their beneficial use, be it for drinking, bathing, recreation, aquaculture, silviculture, irrigation, groundwater recharge, or industry.

Wastewater is treated to remove contaminants or pollutants that affect water quality and use. Discharge to the environment must be accomplished without transmitting diseases, endangering aquatic organisms, impairing the soil, or causing unsightly or malodorous conditions. The type and degree of treatment are dependent upon the absorption capability or dilution capacity at the point of ultimate disposal. *See* SEWAGE; SEWAGE TREATMENT; SOIL ECOLOGY; SOIL MICROBIOLOGY; STREAM POLLUTION.

Discharges into any aquatic system cannot contravene the standards set for the most beneficial use of that water body. Water quality standards are used to measure an aquatic ecosystem after the discharge has entered and mixed with it. Water quality standards relate to the esthetics and use of the receiving environment for public water supply, recreation, maintenance of aquatic life and wildlife, or agriculture. The parameters of water quality, which define the physical, chemical, and biological limits, include floating and settleable solids, turbidity, color, temperature, pH, dissolved oxygen, biochemical oxygen demand (BOD), numbers of coliform organisms, toxic materials, heavy metals, and nutrients.

Effluent standards define what is allowed within the wastewaters discharged into the aquatic environment. Effluent standards specify the allowed biochemical oxygen demand, suspended solids, temperature, pH, heavy metals, certain organic chemicals, pesticides, and nutrients in the discharge. Point-source wastewater effluent discharge standards, established for ease of sampling, simplicity of repetitive testing, and clarity for enforcement, are more likely to be used by regulatory agencies. *See* ENVIRONMENTAL ENGINEERING; EUTROPHICATION; FRESH-WATER ECOSYSTEM; LIMNOLOGY; WATER CONSERVATION; WATER POLLUTION. [G.Pa.]

Sewage solids The accumulated, semiliquid material consisting of suspended, colloidal, and dissolved organic and inorganic matter separated from wastewater during treatment. Sludges are developed as contained pollutants, and contaminants are separated by mechanical, hydraulic, biological, or chemical processes. The various classes of solids that are removed and collected must be disposed of in a safe, nuisance-free manner without hazard to health or the environment. Collection, handling, transporting, and disposal of removed solids are difficult and costly, since they are offensive and putrescible, with 92–99.5% water content. Sewage solids must be treated by thickening, chemical conditioning, mechanical dewatering, thermal action, biological stabilization, or digestion to convert putrescible organic matter to relatively inert end products, remove water, and reduce weight and volume.

Sewage solids are classified as screenings, scum, grit, septage, or sewage sludges. Screenings are large solids, carried by incoming wastewater, that are captured mechanically on screens or racks with openings of various sizes. These protective units remove floating debris, including wood, clothing, cans, rags, paper, rubber and plastic goods, and stringy material that could damage equipment or create problems in plant maintenance and operation.

Scum is defined as the floating fraction of sewage solids, with specific gravity under 1.0, that, under quiescent conditions, rises to the surface of the wastewater. Primary tank skimmings contain oils, fats, soaps, rubber and plastic hygienic products, cigarette filter tips, paper, and similar materials.

Heavy suspended solids consisting of sand, cinders, coffee grounds, seeds, small metal objects, and other generally inorganic particles carried in wastewater inflow are collectively known as grit. The amount of grit varies with type of sewer, season, weather, intensity of runoff, condition of streets and sewers, and use of household garbage disposal units.

Septage consists of partially digested material pumped from on-site sanitary waste-water disposal systems. It contains a mixture of grit, scum, and suspended solids, adding to treatment plant sludge. *See* LEACHING; SEPTIC TANK.

Sludge derives its name from the unit process from which it settles out. Primary sludge, or raw sludge, develops as solids in incoming wastewater settle hydraulically. Raw sludge, containing up to 5% solids by weight, is gray, greasy, viscous, unsightly, contains visible fecal solids and scraps of household wastes, and has a disagreeable odor. Sludge thickening is a process that is used to remove water, increase the concentration of solids, reduce weight and volume, and prepare sludges for further treatment and handling. *See* PRECIPITATION (CHEMISTRY); WATER TREATMENT.

Solids are generally disposed of in landfills, buried, composted, or recycled as soil amendments. *See* AIR POLLUTION; HAZARDOUS WASTE; SEWAGE; SEWAGE DISPOSAL; SEWAGE TREATMENT. [G.Pa.]

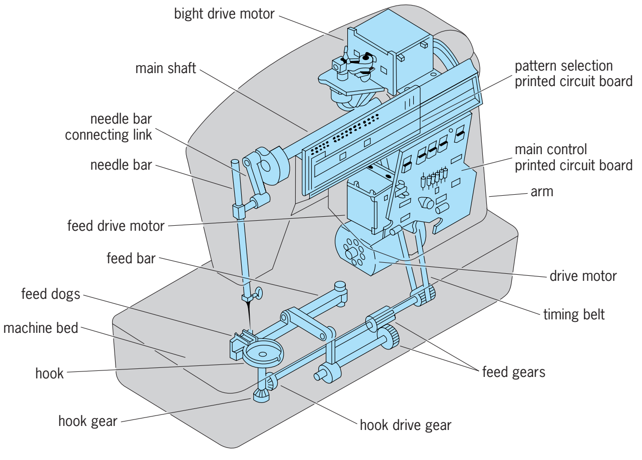
Sewage treatment Unit processes used to separate, modify, remove, and destroy objectionable, hazardous, and pathogenic substances carried by wastewater in solution or suspension in order to render the water fit and safe for intended uses. Treatment removes unwanted constituents without affecting or altering the water molecules themselves, so that wastewater containing contaminants can be converted to safe drinking water. Stringent water quality and effluent standards have been developed that require reduction of suspended solids (turbidity), biochemical oxygen demand (related to degradable organics), and coliform organisms (indicators of fecal pollution); control of pH as well as the concentration of certain organic chemicals and heavy metals; and use of bioassays to guarantee safety of treated discharges to the environment.

In all cases, the impurities, contaminants, and solids removed from all wastewater treatment processes must ultimately be collected, handled, and disposed of safely, without damage to humans or the environment. *See* SEWAGE SOLIDS.

Treatment processes are chosen on the basis of composition, characteristics, and concentration of materials present in solution or suspension. The processes are classified as pretreatment, preliminary, primary, secondary, or tertiary treatment, depending on type, sequence, and method of removal of the harmful and unacceptable constituents. Pretreatment processes equalize flows and loadings, and precondition wastewaters to neutralize or remove toxics and industrial wastes that could adversely affect sewers or inhibit operations of publicly owned treatment works. Preliminary treatment processes protect plant mechanical equipment; remove extraneous matter such as grit, trash, and debris; reduce odors; and render incoming sewage more amenable to subsequent treatment and handling. Primary treatment employs mechanical and physical unit processes to separate and remove floatables and suspended solids and to prepare wastewater for biological treatment. Secondary treatment utilizes aerobic microorganisms in biological reactors to feed on dissolved and colloidal organic matter. As these microorganisms reduce biochemical oxygen demand and turbidity (suspended solids), they grow, multiply, and form an organic floc, which must be captured and removed in final settling tanks. Tertiary treatment, or advanced treatment, removes specific residual substances, trace organic materials, nutrients, and other constituents that are not removed by biological processes. Most advanced wastewater treatment systems include denitrification and ammonia stripping, carbon adsorption of trace organics, and chemical precipitation. Evaporation, distillation, electrodialysis, ultrafiltration, reverse osmosis, freeze drying, freeze-thaw, floatation, and land application, with particular emphasis on the increased use of natural and constructed wetlands, are being studied and utilized as methods for advanced wastewater treatment to improve the quality of the treated discharge to reduce unwanted effects on the receiving environment. *See* Absorption; Distillation; Evaporation; Sewage; Sewage disposal; Ultrafiltration; Wetlands.

On-site sewage treatment for individual homes or small institutions uses septic tanks, which provide separation of solids in a closed, buried unit. Effluent is discharged to subsurface absorption systems. *See* Septic tank; Stream pollution; Unit processes; Water treatment. [G.Pa.]

Sewing machine A mechanism that stitches cloth, leather, book pages, and other material by means of a double-pointed needle or any eye-pointed needle. In ordinary two-threaded machines, a lock stitch is formed (see illustration). A presser foot held against the material with a yielding spring adjusts itself automatically to variations in thickness of material and allows the operator to turn the material as it feeds through the machine. A cluster of cams, any one of which can be selected to guide the needle arm, makes possible a variety of stitch patterns. *See* Cam mechanism. [F.H.R.]



Components of a modern sewing machine. (*Singer Co.*)

Sex determination The genetic mechanisms by which sex is determined in all living organisms. The nature of the genetic basis of sex determination varies a great deal among the various forms of life.

There are two aspects of sexuality: the primary form involves the gametes, and the secondary aspect is gender. In its broadest usage the term "sex" refers to the processes that enable species to exchange materials between homologous chromosomes, that is, to effect recombination. Generally, recombination is essential to their mechanism for reproduction. For most organisms this involves, either exclusively or as one stage in the life cycle, the formation of special cells, known as gametes, by meiosis. *See* Gametogenesis.

Most sexually reproducing species produce two different kinds of gametes. The relatively large and sessile form, an ovum or egg, usually accumulates nutriments in its cytoplasm for the early development of the offspring. The relatively mobile form, a sperm (or pollen grain in many plants), contributes little beyond a haploid chromosome set. Thus the primary form of sex differentiation determines which kind of gamete will be produced. The formation of gametes usually involves the concomitant differentiation of specialized organs, the gonads, to produce each kind of gamete. The ova-producing gonad is usually known as an archegonium or ovary (in flowering plants it is part of a larger organ, the pistil or carpel); the gonad producing the more mobile gametes is usually known as a testis in animals and an antheridium or stamen in plants. *See* Ovary; Ovum; Sperm cell; Testis.

In most animals and many plants, individuals become specialized to produce only one kind of gamete. These individuals usually differ not only in which kind of gonad they possess but also in a number of other morphological and physiological differences, or secondary sex characteristics. The latter may define a phenotypic sex when present, even if the typical gonad for that sex is absent or nonfunctional. The form that usually produces ova is known as female; the one that usually produces sperm or pollen is known as male. Since some sexual processes do not involve gametes, the more universal application of the term "gender" refers to any donor of genetic material as male and the recipient as female.

In plants, sexual reproduction is not always accompanied by the kinds of differentiation described above. The majority of plant species are monoecious, with both kinds of gonads on the same plant. Plants that bear male and female gonads on separate plants are dioecious. They occur in about 60 of the 400 or so families of flowering plants, 20 of which are thought to contain exclusively dioecious species. *See* Reproduction (plant).

Although the sexes are distinct in most animals, many species are hermaphroditic; that is, the same individual is capable of producing both eggs and sperm. This condition is particularly common among sessile or sluggish, slowly moving forms. Some hermaphroditic and monoecious species are homothallic; that is, the eggs and sperm of the same individual can combine successfully; but most are heterothallic, the gametes being capable only of cross-fertilization, often evolving special mechanisms to ensure its occurrence.

Sex differentiations are often accompanied by consistent chromosomal dimorphisms, leading to the presumption that the chromosomal differences are related to, and possibly responsible for, the sex differences. Indeed, the chromosomes that are not alike in the two sexes were given the name sex chromosomes. Some workers use the term "heterosomes" to distinguish them from the autosomes, which are the chromosomes that are morphologically identical in the two sexes.

In most species, one of the sex chromosomes, the X chromosome, normally occurs as a pair in one gender but only singly in the other. The gender with two X chromosomes is known as the homogametic sex, because each of its gametes normally receives an X chromosome after meiosis. The gender with only one X chromosome generally also has a morphologically different sex chromosome, the Y chromosome. The X and Y chromosomes usually pair to some extent at meiosis, with the result that the XY is the heterogametic sex, with half its gametes containing an X and half containing a Y. Geneticists noted that the fundamental dimorphism of X and Y chromosomes lies in their genic contents: X chromosomes of the species share homologous loci, just as do pairs of autosomes, whereas the Y chromosome usually has few, if any, loci that are also represented on the X. Thus X and Y chromosomes are sometimes very similar in shape or size but are almost always very different in genetic materials.

The major factor in sex differentiation in humans is a locus on the short arm of the Y chromosome designated *SRY* or *SrY* (for sex-determining region of the Y). This comparatively small gene contains no introns and encodes for a protein with only 204 amino acids. The protein appears to be a deoxyribonucleic acid (DNA)-binding type that causes somatic cells of the developing gonad to become Sertoli cells that secrete a hormone, Müllerian inhibiting substance (MIS), that eliminates the Müllerian duct system (the part that would produce major female reproductive organs). The gonad is now a testis, and certain cells in it become the Leydig cells that produce testosterone, which causes the primordial Wolffian duct system of the embryo to develop the major male reproductive organs. If no MIS is produced, further development of the Müllerian duct structures occurs, and in the absence of testosterone the Wolffian ducts disappear, producing the normal female structures. Embryos lacking *SRY* or having mutated forms of it normally become females even if they are XY. This system of sex determination is called Y-dominant. It appears to be characteristic of almost all mammals, even marsupials, plus a few other forms. While *SRY* is the primary gene, many other genes, both autosomal and X-chromosomal, are involved in the course of developing the two sexes in mammals. *See* HUMAN GENETICS; MUTATION. [M.Le.]

Sex-influenced inheritance Inherited characteristics that are conditioned by the sex of the individual. These traits are determined by genes that act differently in the two sexes. The usual result is that a given trait appears preponderantly in one sex. The reasons for such inheritance are neither the chromosomal location of the responsible genes, which may therefore be autosomal as well as X-linked, nor the normal sex-determining mechanism of the species. *See* SEX DETERMINATION.

A special class of sex-influenced genes can be called sex-limited. These are manifested in only one sex because the other lacks the requisite organs. Some examples are milk production in cows and egg production in chickens.

Some traits are sex-influenced because of genes that interact with a substance that is not produced equally in males and females. An example is early pattern baldness. Since male-to-male transmission occurs, the responsible gene must be autosomal. There is a preponderance of this trait in males because the action of the gene depends on the level of male hormones (androgens) present. *See* GENE ACTION.

Some sex differences in expression of inherited traits may result from genetic imprinting. Genetic imprinting refers to different expression of chromosomes, parts of chromosomes, or single genes, depending on which of the two sexes they are inherited from. To achieve imprinting, some genetic materials can be modified during gamete production or early embryonic development in one of the two sexes, so the traits determined by the imprinted genes are expressed differently than would be expected under typical mendelian inheritance. A growing body of evidence points to methylation of cytosine residues in the context of cytosine-guanine (CpG) dinucleotides as the mechanism of imprinting. Such methylation, especially if it occurs in the promoter regions of genes, can nullify the ability of the genes to be transcribed. Certain genes that can be imprinted will be methylated in the production of sperm, others in the production of ova, and they can be reactivated by demethylation when they pass through gametogenesis in the opposite sex. It is still not known why certain alleles are subject to imprinting while others are not, and why they are more likely to be imprinted in one sex than the other.

Imprinting can involve amplification of genes rather than inactivation; that is, as the gene passes through gametogenesis in one of the sexes, sections of it become duplicated and the gene thereby is enlarged. This is seen in neuroblastoma, where one commonly finds an increased number of DNA segments containing the *N-myc* protooncogene: such amplification is correlated with poor prognosis of the disease. In an overwhelming proportion of cases, it is the paternal *N-myc* gene that is amplified, suggesting that imprinting is responsible. A similar phenomenon occurs in Huntington's chorea, an autosomal dominant condition that usually does not become manifested until middle age or beyond. Earlier manifestation, often even in childhood, is associated with amplification of certain segments of DNA in the gene; but the amplifications, if they occur, are only in *HC* genes inherited from fathers. *See* DEOXYRIBONUCLEIC ACID (DNA); GENETICS; HUMAN GENETICS; ONCOGENES; OOGENESIS; SEX DETERMINATION; SEX-LINKED INHERITANCE; SPERMATOGENESIS. [M.Le.]

Sex-linked inheritance The inheritance of a trait (phenotype) that is determined by a gene located on one of the sex chromosomes. Genetic studies of many species have been facilitated by focusing on such traits because of their characteristic patterns of familial transmission and the ability to localize their genes to a specific chromosome. As the ability to map a gene to any of an organisms chromosomes has improved markedly, reliance on the specific pattern of inheritance has waned.

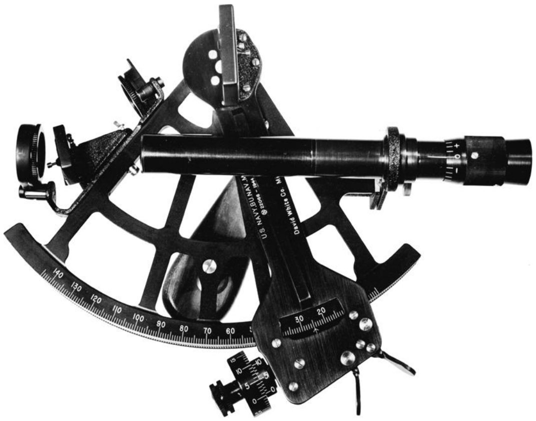
The expectations of sex-linked inheritance in any species depend on how the chromosomes determine sex. For example, in humans, males are heterogametic, having one X chromosome and one Y chromosome, whereas females are homogametic, having two X chromosomes. In human males, the entire X chromosome is active (not all genes are active in every cell), whereas one of a female's X chromosomes is largely inactive. Random inactivation of one X chromosome occurs during the early stages of female embryogenesis, and every cell that descends from a particular embryonic cell has the same X chromosome inactivated. The result is dosage compensation for X-linked genes between the sexes. A specific gene on the long arm of the X chromosome, called XIST at band q13, is a strong candidate for the gene that controls X inactivation. This pattern of sex determination occurs in most vertebrates, but in birds and many insects and fish the male is the homogametic sex. *See* SEX DETERMINATION.

In general terms, traits determined by genes on sex chromosomes are not different from traits determined by autosomal genes. Sex-linked traits are distinguishable by their mode of transmission through successive generations of a family. In humans it is preferable to speak in terms of X-linked or Y-linked inheritance.

Red-green color blindness was the first human trait proven to be due to a gene on a specific chromosome. The characteristics of this pattern of inheritance are readily evident. Males are more noticeably or severely affected than females; in the case of red-green color blindness, women who have one copy of the mutant gene (that is, are heterozygous or carriers) are not at all affected. Among offspring of carrier mothers, on average one-half of their sons are affected, whereas one-half of their daughters are carriers. Affected fathers cannot pass their mutant X chromosome to their sons, but do pass it to all of their daughters, who thereby are carriers. A number of other well-known human conditions behave in this manner, including the two forms of hemophilia, Duchenne muscular dystrophy, and glucose-6-phosphate dehydrogenase deficiency that predisposes to hemolytic anemia. *See* ANEMIA; COLOR VISION; HEMOPHILIA; MUSCULAR DYSTROPHY.

Refined cytogenetic and molecular techniques have supplemented family studies as a method for characterizing sex-linked inheritance and for mapping genes to sex chromosomes in many species. Over 400 human traits and diseases seem to be encoded by genes on the X chromosome, and over 200 genes have been mapped. Among mammals, genes on the X chromosome are highly conserved. Thus, identifying a sex-linked trait in mice is strong evidence that a similar trait, and underlying gene, exists on the human X chromosome. *See* GENETICS; HUMAN GENETICS; SEX-INFLUENCED INHERITANCE. [R.E.Py.]

Sextant A navigation instrument used for measuring angles, primarily altitudes of celestial bodies. Originally, the sextant had an arc of 60°, or 1/6 of a circle, from which the instrument derived its name. Because of the double-reflecting principle used, such an instrument could measure angles as large as 120°. In modem practice, the name sextant is commonly applied to all instruments of this type regardless of the length of the arc, which is seldom exactly 60°. The optical principles of the sextant are similar to those of the prismatic astrolabe. *See* PRISMATIC ASTROLABE.



A marine sextant.

Modern sextants may be grouped into two classes, marine and air. The marine sextant (see illustration) is designed for use by mariners. It utilizes the visible sea horizon as the horizontal reference. An instrument designed for use in aircraft is called an air sextant. Such sextants have built-in artificial horizons. Most modern air sextants are periscopic to permit observation of celestial bodies without need of an astrodome in the aircraft. *See* CELESTIAL NAVIGATION. [A.B.M.]

Sexual dimorphism Any difference, morphological or behavioral, between males and females of the same species. In many animals, the sex of an individual can be determined at a glance. For example, roosters have bright plumage, a comb, and an elaborate tail, all of which are lacking in hens. Sexual dimorphism arises as a result of the different reproductive functions of the two sexes and is a consequence of both natural selection and sexual selection. Primary differences such as the structure of the reproductive organs are driven by natural selection and are key to the individual's function as a mother or father. Other differences such as the peacock's (*Pavo cristatus*) enormous tail are driven by sexual selection and increase the individual's success in acquiring mates. *See* ORGANIC EVOLUTION.

A less obvious sexual dimorphism is the difference in size of male and female gametes. In nearly all cases, the sperm (or pollen) are substantially smaller and more numerous than the ova. Eggs are large because they contain nutrients essential for development of the embryo. However, the sole purpose of sperm is to fertilize the egg. Sperm do not contain any nutrients and can therefore be small. For the same investment of nutrients, a male can produce more sperm than a female can produce eggs. Human males, for example, produce about 300 million motile sperm per ejaculate, whereas females normally produce only one egg (30,000 times larger than a single sperm) per month. *See* FERTILIZATION; GAMETOGENESIS; REPRODUCTION (ANIMAL); REPRODUCTIVE SYSTEM.

In nearly all animal groups (apart from mammals and birds), females are larger than males because larger females tend to produce more eggs and contribute more young to the next generation. In contrast, size does not appear to limit males' ability to produce sperm. However, among mammals and birds males are generally the larger sex. Differences in body size and shape can be caused by factors other than reproductive success. Sexual dimorphism can arise as a consequence of competition between the sexes over resources, or because the sexes use different resources. For example, in many species of snake, males and females use different habitats and eat different food, which has led to differences in their head shape and feeding structures.

Plants also differ in showiness. Many plants bear both male and female flowers (simultaneous hermaphrodites), but male flowers are sometimes larger and more conspicuous. For example, the female catkins of willow are dull gray compared with the bright yellow male catkins, because male flowers compete with each other to attract pollinators. In plant species with separate sexes (dioecious), males tend to produce more flowers than females. For example, males of the American holly (*Ilex opaca*) produce seven times as many flowers as females in order to increase their chances of pollen transfer to females. *See* FLOWER; POLLINATION.

Animals and plants show marked sexual dimorphism in other traits. Calling, singing, pheromones, and scent marking can all be explained by competition between males and by female mate choice. *See* ANIMAL COMMUNICATION.

Associated with morphological sexual dimorphism are several behavioral differences between males and females. Many of these are related to locating a mate, competition between males, and female choosiness. Animals also show sexual dimorphism relating to their roles as parents. Many parents continue to provide for their young after birth, with the female performing the bulk of the care in most species. Female mammals suckle their young, whereas males cannot because they lack mammary glands. However, some mammals (such as gibbons and prairie voles) and many birds share parental duties, with both males and females feeding and protecting the young. *See* MATERNAL BEHAVIOR. [A.M.Du.; N.W.]

Sexually transmitted diseases Infections that are acquired and transmitted by sexual contact. Although virtually any infection may be transmitted during intimate contact, the term sexually transmitted disease is restricted to conditions that are largely dependent on sexual contact for their transmission and propagation in a population. The term venereal disease is literally synonymous with sexually transmitted disease but traditionally is associated with only five long-recognized diseases (syphilis, gonorrhea, chancroid, lymphogranuloma venereum, and donovanosis). Sexually transmitted diseases occasionally are acquired nonsexually (for example, by newborn infants from their mothers, or by clinical or laboratory personnel handling pathogenic organisms or infected secretions), but in adults they are virtually never acquired by contact with contaminated intermediaries such as towels, toilet seats, or bathing facilities. However, some sexually transmitted infections (such as human immunodeficiency virus infection, viral hepatitis, and cytomegalovirus infection) are transmitted primarily by sexual contact in some settings and by nonsexual means in others. *See* GONORRHEA; SYPHILIS.

The sexually transmitted diseases may be classified in the traditional fashion, according to the causative pathogenic organisms, as follows:

- Bacteria
  - *Chlamydia trachomatis*
  - *Neisseria gonorrhoeae*
  - *Treponema pallidum*
  - *Mycoplasma genitalium*
  - *Mycoplasma hominis*
  - *Ureaplasma urealyticum*
  - *Haemophilis ducreyi*
  - *Calymmatobacterium granulomatis*
  - *Salmonella* species
  - *Shigella* species
  - *Campylobacter* species
- Viruses
  - Human immunodeficiency viruses (types 1 and 2)
  - Herpes simplex viruses (types 1 and 2)
  - Hepatitis viruses B, C, D
  - Cytomegalovirus
  - Human papillomaviruses
  - Molluscum contagiosum virus
  - Kaposi sarcoma virus

Protozoa
  Trichomonas vaginalis
  Entamoeba histolytica
  Giardia lamblia
  Cryptosporidium and related species
Ectoparasites
  Phthirus pubis (pubic louse)
  Sarcoptes scabiei (scabies mite)

Sexually transmitted diseases may also be classified according to clinical syndromes and complications that are caused by one or more pathogens as follows:

1. Acquired immunodeficiency syndrome (AIDS) and related conditions
2. Pelvic inflammatory disease
3. Female infertility
4. Ectopic pregnancy
5. Fetal and neonatal infections
6. Complications of pregnancy
7. Neoplasia
8. Human papillomavirus and genital warts
9. Genital ulcer-inguinal lymphadenopathy syndromes
10. Lower genital tract infection in women
11. Viral hepatitis and cirrhosis
12. Urethritis in men
13. Late syphilis
14. Epididymitis
15. Gastrointestinal infections
16. Acute arthritis
17. Mononucleosis syndromes
18. Molluscum contagiosum
19. Ectoparasite infestation

See ACQUIRED IMMUNE DEFICIENCY SYNDROME (AIDS); CANCER (MEDICINE); DRUG RESISTANCE; GASTROINTESTINAL TRACT DISORDERS; HEPATITIS; PUBLIC HEALTH; URINARY TRACT DISORDERS.

Most of these syndromes may be caused by more than one organism, often in conjunction with nonsexually transmitted pathogens. They are listed in the approximate order of their public health impact. [H.H.Ha.]

Sferics

Electromagnetic radiations produced primarily by lightning strokes from thunderstorms. It is estimated that globally there occur about 2000 thunderstorms at any one time, and that these give rise to about 100 lightning strokes every second. The radiations are short impulses that usually last a few milliseconds, with a frequency content ranging from the low audio well into the gigahertz range. Sferics (short for atmospherics) are easily detected with an ordinary amplitude-modulation (AM) radio tuned to a region between radio stations, especially if there are thunderstorms within a few hundred miles. These sounds or noises have been identified and characterized with specific names, for example, hiss, pop, click, whistler, and dawn chorus. They fall into what is generally known as radio noise. *See* ATMOSPHERIC ELECTRICITY; DUST STORM; ELECTROMAGNETIC RADIATION; LIGHTNING; THUNDERSTORM.

The various types of sferics include terrestrial, magnetospheric, and Earth-ionospheric. Terrestrial sferics includes anthropogenic noise from sources such as automobile ignition, motor brushes, coronas from high-voltage transmission lines, and various high-current switching devices. Dust storms and dust devils have also been observed to produce sferics. *See* ELECTRICAL NOISE.

Lightning-generated sferics are sometimes coupled into the magnetosphere, where they are trapped and guided by the Earth's magnetic field. In this mode, the impulse travels in an ionized region. As a result, the frequencies present in the original impulse are separated by dispersion (the higher frequencies travel faster than the lower) and produce the phenomena known as whistlers. *See* MAGNETOSPHERE.

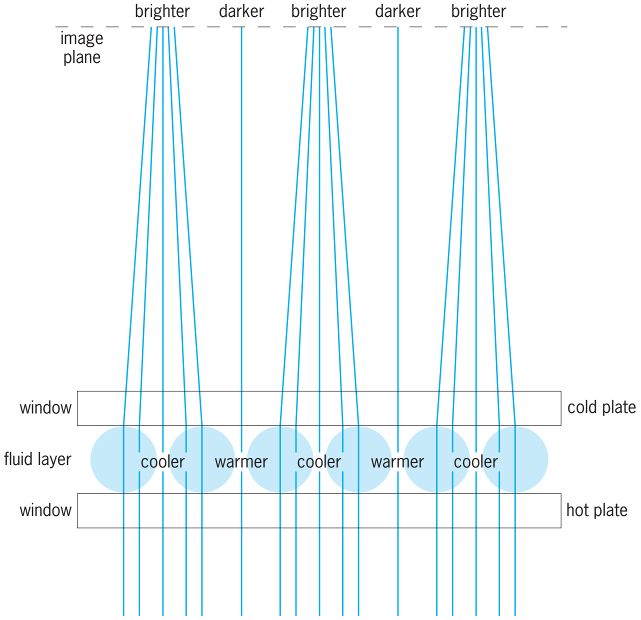
By far the dominant and most readily observed sferics are the lightning-produced impulses that travel in the spherical cavity formed by the ionosphere and the Earth's surface. Lightning currents produce strong radiation in the very low-frequency band, 3–30 kHz, and in the extremely low-frequency band, 6 Hz–3 kHz. *See* IONOSPHERE; RADIO-WAVE PROPAGATION. [M.Bro.]

Shadow

A region of darkness caused by the presence of an opaque object interposed between such a region and a source of light. A shadow can be totally dark only in that part called the umbra, in which all parts of the source are screened off. With a point source, the entire shadow consists of an umbra, since there can be no region in which only part of the source is eclipsed. If the source has an appreciable extent, however, there exists a transition surrounding the umbra, called the penumbra, which is illuminated by only part of the source. Depending on what fraction of the source is exposed, the illumination in the penumbra varies from zero at the edge of the full shadow to the maximum where the entire source is exposed. The edge of the umbra is not perfectly sharp, even with an ideal point source, because of the wave character of light. *See* DIFFRACTION; ECLIPSE. [F.A.J./W.W.W.]

Shadowgraph

An optical method of rendering fluid flow patterns visible by using index-of-refraction differences in the flow. The method relies on the fact that rays of light bend toward regions of higher refractive index while passing through a transparent material. The fluid is usually illuminated by a parallel beam of light. The illustration depicts the method as it might be applied to a fluid sample undergoing thermal convection between two parallel plates, with the lower plate being kept warmer than the upper one. As illustrated, the rays bend toward the cooler down-flowing regions, where the refractive index is higher, and away from the warmer up-flowing ones. After they have passed through the fluid layer, the rays tend to focus above the cooler regions and defocus above the warmer regions. If an image of the light beam is recorded not too far from the sample, brighter areas of the image will lie above regions of down flow, where the rays have been concentrated, and darker areas will lie above regions of up flow. Because the light passes completely



Schematic of the shadowgraph method applied to reveal convection patterns in a fluid layer. A cross section of the apparatus perpendicular to the convection rolls is shown.

through the sample, the bending effect for each ray is averaged over the sample thickness. *See* Convection (heat); Refraction of waves.

In convection experiments the refractive index varies because of thermal expansion of the fluid, but the method is not restricted regarding the mechanism responsible for disturbing the refractive index. Thus the same method may be used to visualize denser and less dense regions in a gas flowing in a wind tunnel, including Mach waves and shock waves, where the denser regions have a higher-than-average refractive index. *See* Shock wave; Supersonic flow; Wind tunnel.

Images are usually recorded by means of a charge-coupled-device (CCD) camera, digitized, and stored in a computer. Such a digitized image consists of an array of numbers, each number being proportional to the brightness at a particular point in the image. The image points (pixels) form a closely spaced rectangular grid. A reference image may be taken in the absence of any fluid flow, and the reference image may be divided point by point into images taken with the fluid moving. *See* Charge-coupled devices. [D.S.Ca.]

Shaft balancing The process (often referred to as rotor balancing) of redistributing the mass attached to a rotating body in order to reduce vibrations arising from centrifugal force.

A rotating shaft supported by coaxial bearings (for example, ball bearings together with any attached mass, such as a turbine disk or motor armature) is called a rotor. If the center of mass of a rotor is not located exactly on the bearing axis, a centrifugal force will be transmitted via the bearings to the foundation. The horizontal and vertical components of this force are periodic shaking forces that can travel through the foundation to create serious vibration problems in neighboring components.

Any rigid shaft may be dynamically balanced by adding or subtracting a definite amount of mass at any convenient radius in each of two arbitrary transverse cross sections of the rotor. The so-called balancing planes selected for this purpose are usually located near the ends of the rotor, where suitable shoulders or balancing rings have been machined to permit the convenient addition of mass (lead weights, calibrated bolts, and so on) or the removal of mass (by drilling or grinding). Long rotors, running at high speeds, may undergo appreciable elastic deformations. For such flexible rotors it is necessary to utilize more than two balancing planes. *See* Mechanical vibration. [B.P.]

Shafting The machine element that supports a roller and wheel so that they can perform their basic functions of rotation. Shafting, made from round metal bars of various lengths and machined to dimension the surface, is used in a great variety of shapes and applications. Because shafts carry loads and transmit power, they are subject to the stresses and strains of operating machine parts. Most shafting is rigid and carries bending loads without appreciable deflection. Some shafting is highly flexible; it is used to transmit motion around comers.

Shafts used in special ways are given specific names, although fundamentally all applications involve transmission of torque. The primary shafting connection between a wheel and a housing is an axle. A short shaft is a spindle. A short stub shaft mounted as part of a motor or engine or extending directly therefrom is a head shaft. A secondary shaft that is driven by a main shaft and from which power is supplied to a machine part is called a countershaft. *See* Belt drive; Pulley. [J.J.R.]

Shale A class of fine-grained clastic sedimentary rocks with a mean grain size of less than 0.0625 mm (0.0025 in.), including siltstone, mudstone, and claystone. One-half to two-thirds of all sedimentary rocks are shales. *See* Sedimentary rocks.

Shale is deposited as mud, that is, small particles of silt and clay. The particles are deposited when fluid turbulence caused by currents or waves is no longer adequate to counteract the force of gravity, or if the water evaporates or infiltrates into the ground. Clay particles often form larger aggregates which settle from suspension more rapidly than individual particles. Silt particles and clay aggregates are often deposited as thin layers less than 10 mm (0.4 in.) thick called laminae. *See* Depositional systems and environments.

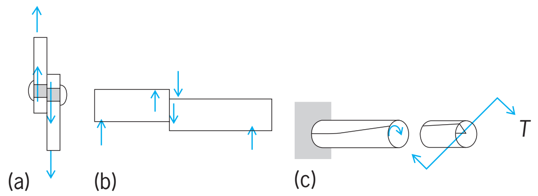
Mineralogically, most shales are made up of clay minerals, silt-sized quartz and feldspar grains, carbonate cements, accessory minerals such as pyrite and apatite, and amorphous material such as volcanic glass, iron and aluminum oxides, silica, and organic matter. The most common clay minerals in shales are smectite, illite, kaolinite, and chlorite. The type of clay particles deposited is dependent on the mineralogy, climate, and tectonics of the source area. *See* Clay minerals; Chlorite; Illite; Kaolinite.

Shales are usually classified or described according to the amount of silt, the presence and type of lamination, mineralogy, chemical composition, and color. Variations in these properties are related to the type of environment in which the shale was deposited and to postdepositional changes caused by diagenesis and compaction. *See* Diagenesis.

The small size of pores in shale relative to those in sandstone causes shale permeability to be much lower than sand permeability. Although fracturing due to compaction stresses or to tectonic movements can create deviations from this general trend, shales often form permeability barriers to fluid movement; this has important bearing on the occurrence of subsurface water and hydrocarbons. Ground-water aquifers are commonly confined by an underlying low-permeability shale bed or aquiclude, which prevents further downward movement of the water. Hydrocarbon reservoirs are often capped by low-permeability shale which forms an effective seal to prevent hydrocarbons from escaping. *See* Aquifer. [J.R.D.]

Shape memory alloys A group of metallic materials that can return to some previously defined shape or size when subjected to the appropriate thermal procedure. That is, shape memory alloys can be plastically deformed at some relatively low temperature and, upon exposure to some higher temperature, will return to their original shape. Materials that exhibit shape memory only upon heating are said to have a one-way shape memory, while those which also undergo a change in shape upon recooling have a two-way memory. Typical materials that exhibit the shape memory effect include a number of copper alloy systems and the alloys of gold-cadmium, nickel-aluminum, and iron-platinum. *See* Alloy; Crystallography; Heat treatment (metallurgy); Metal, mechanical properties of. [M.Sc.]

Shear A straining action wherein applied forces produce a sliding or skewing type of deformation. A shearing force acts parallel to a plane as distinguished from tensile or compressive forces, which act normal to a plane. Examples of force systems producing shearing action are forces transmitted from one plate to another by a rivet that tend to shear the rivet, forces in a beam that tend to displace adjacent segments by transverse shear, and forces acting on the cross section of a bar that tend to twist it by torsional shear (see illustration). Shear forces are usually accompanied by normal forces produced by tension, thrust, or bending. Shearing stress is the intensity of distributed force expressed as force per unit area. *See* Stress and strain. [J.B.S.]



Shearing actions. (*a*) Single shear on rivet. (*b*) Transverse shear in beam. (*c*) Torsion.

Shear center A point on a line parallel to the axis of a beam through which any transverse force must be applied to avoid twisting of the section. A beam section will rotate when the resultant of the internal shearing forces is not collinear with the externally applied force. The shear center may be determined by locating the line of action of the resultant of the internal shear forces. A rolled wide flange beam section has two axes of symmetry, and therefore the shear center coincides with the geometric center or centroid of the section. When such a beam member is loaded transversely in the plane of the axes, it will bend without twisting. *See* Loads, transverse. [J.B.S.]

Sheep Sheep are members of the family Bovidae in the order Artiodactyla, the even-toed, hoofed mammals. Sheep were possibly the first animals to be domesticated about 11,000 years ago in southwestern Asia. *See* Artiodactyla.

Wild sheep range over the mountainous areas of the Northern Hemisphere. They have long, curved, massive horns and mixed coats with a hairy outercoat and a woolly undercoat. Although wild sheep vary in size, they are usually larger than domestic sheep and have shorter tails.

Sheep are called lambs until about 12 months of age, from which time to 24 months they are referred to as yearlings, and thereafter as two-year-olds, and so on. The female sheep is called a ewe and the male, a ram or buck; the castrated male is called a wether. Sheep meat is called lamb or mutton depending on the age at slaughter.

A precise definition is difficult since sheep are so variable. Horns, if present, tend to curl in a spiral. If horns occur in both sexes, they are usually larger for the ram. In some breeds only the rams have horns but many breeds are hornless. The hairy outercoat common to wild sheep was eliminated by breeding in most domestic sheep. Wool may cover the entire sheep, or the face, head, legs, and part of the underside may be bare; or wool may be absent as in some breeds (bred for meat) with a short hairy coat or a coat which constantly sheds. Although domestic sheep are mostly white, shades of brown, gray, and black occur, sometimes with spotting or patterns of color. *See* Wool.

Hundreds of breeds of sheep of all types, sizes, and colors are found over the world. Wool-type breeds, mostly of Merino origin, are important in the Southern Hemisphere, but both fine- and long-wool types are distributed all over the world. Sheep with fat tails or fat rumps are common in the desert areas of Africa and Asia. These usually produce carpet wool. Milk breeds are found mostly in central and southern Europe. Meat breeds from the British Isles are common over the world. [C.E.T.]

Sheet-metal forming The shaping of thin sheets of metal (usually less than $^1/_4$ in. or 6 mm) by applying pressure through male or female dies or both. Parts formed of sheet metal have such diverse geometries that it is difficult to classify them. Sheet forming is accomplished basically by processes such as stretching, bending, deep drawing, embossing, bulging, flanging, roll forming, and spinning. In most of these operations there are no intentional major changes in the thickness of the sheet metal. *See* Metal forming.

Stretch forming is a process in which the sheet metal is clamped between jaws and stretched over a form block. The process is used primarily in the aerospace industry to form large panels with varying curvatures.

Bending is one of the most common processes in sheet forming. The part may be bent not only along a straight line, but also along a curved path (stretching, flanging). In addition to male and female dies used in most bending operations, the female die can be replaced by a rubber pad (Fig. 1). The roll-forming process replaces the vertical motion of the dies by the rotary motion of rolls with various profiles. Each successive roll bends the strip a little further than the preceding roll.

While many sheet-forming processes are carried out in a press with male and female dies usually made of metal, there are some processes which utilize rubber to replace one of the dies. The simplest of these processes is the Guerin process (Fig. 2).

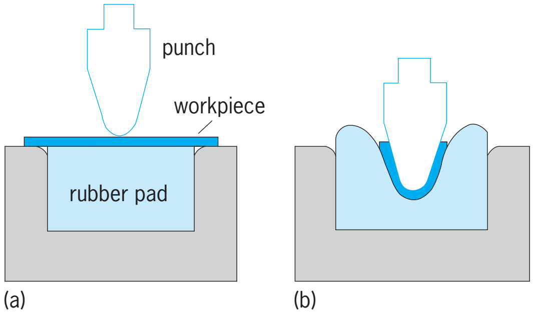


Fig. 1. Bending process with a rubber pad. (*a*) Before forming. (*b*) After forming.

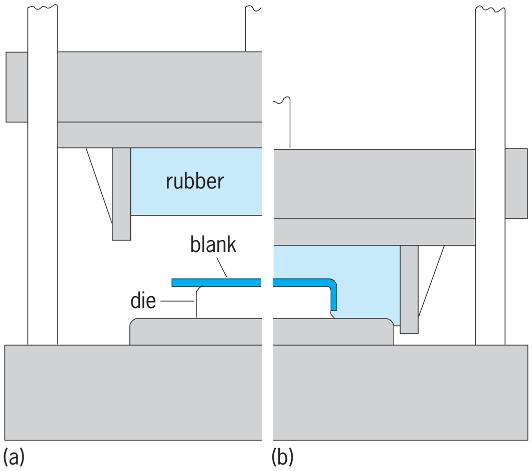

Fig. 2. Guerin process, the simplest rubber forming process. (*a*) Before forming. (*b*) After forming.

A great variety of parts are formed by the deep-drawing process (Fig. 3), the successful operation of which requires a careful control of factors such as blank-holder pressure, lubrication, clearance, material properties, and die geometry.

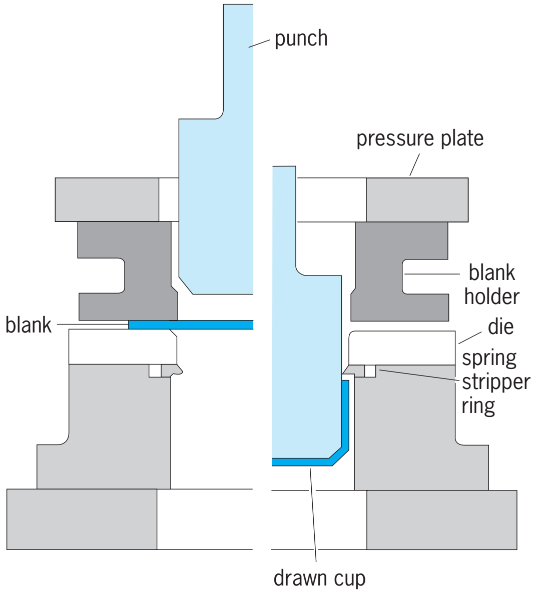

Fig. 3. Deep-drawing process.

Many parts require one or more additional processes. Embossing consists of forming a pattern on the sheet by shallow drawing. Coining consists of putting impressions on the surface by a process that is essentially forging, the best example being the two faces of a coin. Shearing is separation of the material by the cutting action of a pair of sharp tools, similar to a pair of scissors. *See* COINING.

The spinning process forms parts with rotational symmetry over a mandrel with the use of a tool or roller. There are two basic types of spinning: conventional or manual spinning, and shear spinning. The conventional spinning process forms the material over a rotating mandrel with little or no change in the thickness of the original blank. In shear spinning (hydrospinning, floturning) the deformation is carried out with a roller in such a manner that the diameter of the original blank does not change but the thickness of the part decreases by an amount dependent on the mandrel angle. Shear spinning produces parts with various shapes (conical, curvilinear, and also tubular by tube spinning on a cylindrical mandrel) with good surface finish, close tolerances, and improved mechanical properties. *See* METAL COATINGS; SPINNING (METALS). [S.Ka.]

Shellac The lac resin (secreted by the lac insect) when used in flake (or shell) form. Shellac varnish is a solution of shellac in denatured alcohol.

Shellac varnish is used in wood finishing where a fast-drying, light-colored, hard finish is desired. Drying is by simple evaporation of the alcohol. Shellac varnish is not water-resistant and is not suitable for exterior coatings. When used as a finish, it has the distinct advantage that it remains soluble. When touch-up is required, it therefore merges completely with the original finish, and no scratches or worn spots show. *See* SURFACE COATING; VARNISH. [C.R.Ma.; C.W.Si.]

Ship design A process which translates a set of owner's requirements into the drawings, specifications, and other technical data necessary to actually build a ship. Naval architects lead the process, but engineers and designers with many other skills contribute. These other skills include marine engineering, structural design, and production engineering. The ship design process is iterative, and is subdivided into several phases during which the design is developed in increasing degrees of detail. Typically, the owner's requirements specify the mission that the new ship must perform and define such parameters as required speed, fuel endurance, and cargo weight and capacity. Generally, the cost to build and operate a ship is constrained by the prospective owner. The ship design process involves numerous trade-off studies in order to achieve the desired capability and, at the same time, stay within the established cost. *See* NAVAL ARCHITECTURE.

Mission requirements and constraints are unique to each ship being considered. For some ships, such as point-to-point cargo ships, the mission requirements can be simply stated; for example, "Transport 5000 20 ft ISO standard cargo containers at an average sea speed of 18 knots with 10,000 nautical miles between refuelings. On- and off-load the 5000 containers using shore-based cranes in less than XX hours." For other ship types, such as industrial ships performing missions at sea, the mission requirements are more complex. The requirements for a fisheries research vessel, for example, might specify the ability to catch fish using several different techniques, radiated noise limitations, required sonar performance, and several different aspects of maneuvering and seakeeping performance, such as low-speed stationkeeping and the ability to maintain a specified track over the sea floor in the face of cross currents, winds, and seas. *See* MERCHANT SHIP; OCEANOGRAPHIC VESSELS; SHIP POWERING, MANEUVERING, AND SEAKEEPING.

Cost, both to design and build the ship and to operate it, is usually constrained. The two primary elements of operating cost are crew and fuel, so there is nearly always pressure on the designer to reduce crew size and fuel consumption. Physical constraints may also be imposed on the design related to construction, operational, or maintenance requirements. Weight or dimensional constraints may be imposed if the ship is to be built or maintained in a specific dry dock. Pier or harbor limitations may also impose dimensional constraints. Ship length may be limited by the requirement to tie up to a certain pier. Ship air draft (vertical distance from the water surface to the highest point on the ship) may be limited by the need to pass under bridges of a certain height. Ship navigational draft (vertical distance from the water surface to the lowest point on the ship) may be limited by the depth of a dredged channel in a particular harbor.

In addition to unique mission requirements and constraints, every ship must satisfy certain physical principles. The fundamental principles are that (1) the ship hull and superstructure must have adequate storage space, and (2) the ship must float at an acceptable waterline (draft neither too great nor too small) when it is fully loaded. Another principle is that the ship must be statically stable; that is, when it is displaced from its equilibrium condition, it must tend to return to that condition. For example, when the ship is heeled to one side by a disturbing force such as a wind gust, it must tend to return to the vertical rather than continuing to roll and capsizing. The ship's hull must have sufficient strength to withstand the forces that will act upon it over a range of loading and sea conditions. The ship must possess sufficient propulsive power to achieve the desired speed even with a fouled bottom and in adverse sea conditions. In addition, it must generate sufficient electric power to satisfy the requirements of mission systems; ship machinery; heating, ventilation, and air conditioning (HVAC) systems; hotel; and other ship services. *See* BUOYANCY; HYDROSTATICS; MARINE ENGINEERING; MARINE MACHINERY. [P.A.Ga.]

Ship nuclear propulsion Nuclear reactors for shipboard propulsion can be of any type used for the production of useful heat. Nuclear power is particularly suitable for vessels which need to be at sea for long periods without refueling or for powerful submarine propulsion. Only the pressurized water reactor and the liquid metal reactor have actually been applied to operating vessels. The pressurized water reactor has been most widely applied since it uses a readily available coolant and has a relatively simple cycle and control system and a large industrial and technical base. The supposed advantages of a liquid metal reactor (compactness, fast response, and higher propulsion plant efficiency) have not been proven in application, and liquid metal reactors are not now in marine service. *See* NUCLEAR POWER; NUCLEAR REACTOR; REACTOR PHYSICS.

In all the shipboard nuclear power plants that have been built, energy conversion is based on the steam turbine cycle, and that portion of the plant is more or less conventional. There are two types in use: a steam turbine geared to a fixed-pitch propeller (called a geared turbine), and a steam turbine generator whose output drives an electric motor connected to a propeller (called a turboelectric unit). Any energy conversion process that converts heat into mechanical energy could be used to propel a ship. For example, a closed-cycle helium gas turbine has been studied, but none has been built for ship propulsion. *See* MARINE ENGINE; MARINE MACHINERY; PROPELLER (MARINE CRAFT); SHIP POWERING, MANEUVERING, AND SEAKEEPING. [A.R.N.]

Ship powering, maneuvering, and seakeeping The three central areas of ship hydrodynamics. Basic concepts of powering, maneuvering, and seakeeping are critical to an understanding of high-speed craft. *See* NAVAL ARCHITECTURE; NAVAL SURFACE SHIP; SHIP DESIGN; SHIPBUILDING.

Powering. The field of powering is divided into two related issues: resistance, the study of forces opposed to the ship's forward speed, and propulsion, the study of the generation of forces to overcome resistance.

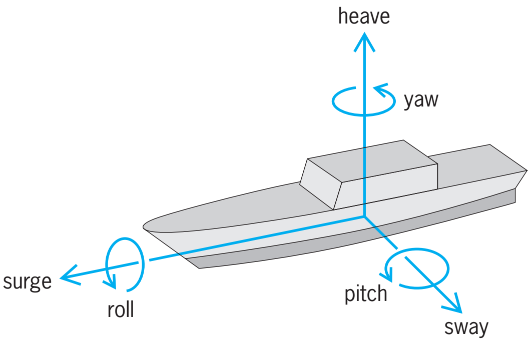
A body moving through a fluid experiences a drag, that is, a force in the direction opposite to its movement. In the specific context of a ship's hull, this force is more often called resistance. Resistance arises from a number of physical phenomena, all of which vary with speed, but in different ways. These phenomena are influenced by the size, shape, and condition of the hull, and other parts of the ship. They include frictional resistance and form drag (often grouped together as viscous resistance), wavemaking resistance, and air resistance. *See* STREAMLINING; VISCOSITY.

Many devices have been used to propel a ship. In approximate historical order they include paddles, oars, sails, draft animals (working on a canal towpath), paddlewheels, marine screw propellers, vertical-axis propellers, airscrews, and waterjets. A key distinction is whether or not propulsive forces are generated in the same body of fluid that accounts for the main sources of the ship's resistance, resulting in hull-propulsor interaction. *See* PROPELLER (MARINE CRAFT).

Any propulsor can be understood as a power conversion device. Delivered power for a rotating propulsor is the product of torque times rotational speed. The useful power output from the system is the product of ship resistance times ship speed, termed effective power. The efficiency of this power conversion is often termed propulsive efficiency. *See* BOAT PROPULSION.

Maneuvering. Maneuvering (more generally, ship controllability) includes consideration of turning, course-keeping, acceleration, deceleration, and backing performance. The field of maneuvering has also come to include more specialized problems of ship handling, for example, the production of sideways motion for docking or undocking, turning in place, and position-keeping using auxiliary thrusters or steerable propulsion units. In the case of submarines, maneuvering also includes depth-change maneuvers, either independently or in combination with turning.

Seakeeping. The modern term "seakeeping" is used to describe all aspects of a ship's performance in waves, affected primarily by its motions in six degrees of freedom (see illustration).



Ship motion degrees of freedom.

Seakeeping issues are diverse, including the motions, accelerations, and structural loads caused by waves. Some are related to the comfort of passengers and crew, some to the operation of ship systems, and others to ship and personnel safety. Typical issues include the incidence of motion sickness, cargo shifting, loss of deck cargo, hull bending moments due to waves, slamming (water impact loads on sections of the hull), added powering in waves, and the frequency and severity of water on deck.

In the past, initial powering, maneuvering, and seakeeping predictions for new designs depended almost entirely on design rules of thumb or, at best, applicable series or regression data from previous model tests, subsequently refined by additional model tests. With the increase in computing power available to the naval architect, computational fluid dynamic methods are now applied to some of these problems in various stages of the ship design process. *See* COMPUTATIONAL FLUID DYNAMICS. [R.M.Sc.]

Ship routing

The selection of the most favorable route for a ship's transit, based upon the environment conditions expected during the voyage, and the effect of these conditions upon the ship's performance. Ship routing is also referred to as weather routing, optimum track ship routing, and meteorological navigation.

Routes can be computed to minimize transit time, avoid waves over a specific height, or, more typically, provide a compromise between travel time and the roughness of the seaway to be encountered. Routing offices compute the initial route based on the long-range weather forecast, but maintain a daily plot of both the ship and the storm positions. If conditions warrant, an amended route is sent to the ship master based on the latest weather changes. *See* OCEAN WAVES; WEATHER FORECASTING AND PREDICTION.

Although the effect of waves is the predominant factor considered, the ship router also utilizes knowledge of ocean currents, wind, and hazards to navigation such as ice fields or fog banks. On United States east coast runs, the currents are more important than the waves. Most major oil companies have their tankers follow the Gulf Stream on the northbound runs and avoid it on the return trip. *See* OCEAN CIRCULATION. [R.W.J.]

Ship salvage

Voluntary response to a maritime peril by other than the ship's own crew. The property in danger can be any type or size of vessel or maritime cargo. Salvage is encouraged by compensating the salvor based on risk to the salvor and the salvor's equipment, conditions under which the salvage service was performed, the value of the vessel and cargo saved and, more recently, minimizing environmental damage.

Salvage services can be performed using either dedicated salvage vessels or vessels hired for the specific operation. Salvage ships are typically large seagoing tugs, usually capable of 5000–10,000 hp (3750–7500 kW), designed and outfitted to work at remote sites in all weather. Salvage ships carry a variety of portable salvage equipment such as firefighting gear, pumps and patching material, electrical generators, compressors, diving equipment, wire and chain, beach gear, pollution control equipment, and the material to make whatever might be needed on-site.

True salvage is time-critical, involving assets that are immediately available. Assistance is provided in situations involving collisions, firefighting, flooding and damage control, damage from hostile action, and breakdowns of propulsion or steering systems. The salvage team may fight fire from off-ship or board the casualty to fight fires. Salvors also may board the ship to control flooding and stabilize the casualty if required. Rescue towing often results from one or more of the above and the need to reach a safe haven or avoid going aground.

Stranding results when a ship drives, or is driven, aground through engine or steering casualty, error, problem with navigation or navigation aid, or bad weather, and cannot extricate itself. Time-criticality may be due to coming bad weather, tidal range, ongoing damage to the ship from the grounding, or other requirement such as clearing a blocked shipping channel. The salvor must assess the condition of the casualty and what is required to refloat it, the potential for further damage to the ship, and the potential for loss of cargo and damage to the environment.

Environmental salvage is the protection of the environment from damage by pollutants that may result from a maritime casualty. International agreements such as the International Convention for the Prevention of Pollution from Ships (MARPOL 73/78) and national laws such as the Oil Pollution Act of 1990 highlight the need for protecting the environment. This is most effectively accomplished by keeping pollutants in a ship during a casualty, minimizing dispersion, and rapidly recovering any spilled pollutants, usually cargo crude oil or petroleum products, or ship's fuel stored in bunkers. Salvage actions such as pumping air into a damaged tank to restore buoyancy may blow oil out through the damaged hull below the waterline. Salvors must be prepared to deal with pollutants when this occurs, and plan salvage operations to minimize oil release.

Wreck removal involves recovery of a stranded or sunken vessel, and is usually not time-critical. Many salvage techniques can be brought to bear. If the main deck of the stranded or sunken vessel is above water, a combination of patching and pumping may be sufficient to refloat the casualty. If the main deck is not submerged too deeply, a watertight wall, known as a cofferdam, may be built around the main deck to above the water surface. Patching and pumping may then refloat the casualty.

A ship's cargo may be of more value than the ship itself, and the salvor may recover the cargo without recovering the ship. The best-known type of cargo salvage is the recovery of jewels or precious metals. But even something as mundane as copper ingots may be considered worth recovering by both the salvor and the owner or underwriter. [R.P.Fi.]

Shipbuilding The construction of large vessels which travel over seas, lakes, or rivers. Many different approaches have been used in the construction of ships. Sometimes a ship must be custom-built to suit the particular requirements of a low-volume trade route with unique cargo characteristics. On the other hand, there are many instances where a significant number of similar ships are constructed, providing an opportunity to employ procedures which take advantage of repetitive processes.

The building of a ship can be divided into seven phases: design, construction planning, work prior to keel laying, ship erection, launching, final outfitting, and sea trials. *See* SHIP DESIGN.

The construction planning process establishes the construction techniques to be used and the schedules which all of the shipbuilding activities must follow. Construction planners generally start with an erection diagram on which the ship is shown broken down into erection zones and units. To facilitate the fabrication of steel, insofar as possible, the erection units are designed to be identical. The size (or weight) of the erection units selected is usually limited by the amount of crane capacity available. Once the construction planners have established the manner in which the ship is to be erected and the sequence of construction, the schedules for construction can be developed. Working backward from the time an erection unit is required in the dock, with allowances made for the many processes involved, a schedule of working plans and for procurement of purchased equipment is prepared.

Before the keel of a ship is laid (or when the first erection unit is placed in position) a great deal of work must have been accomplished for work to proceed efficiently. The working drawings prepared by ship designers completely define a ship, but often not in a manner that can be used by the construction trades people. Structural drawings prescribe the geometry of the steel plates used in construction, but they cannot be used, in the form prepared, to cut steel plates. Instead, the detailed structural drawings must be translated into cutting sketches, or numerical-control cutting tapes, which are used to fabricate steel. Several organizations have developed sophisticated computer programs which readily translate detailed structural drawings into machine-sensible tapes which can be used to drive cutting torches.

If all of the preceding work has been accomplished properly and on schedule, the erection of a ship can proceed rapidly; however, problem areas invariably arise. When erecting a ship one plate at a time, there are no serious fitting problems; but when 900-metric-ton erection units do not fit (or align) properly, there are serious problems which tend to offset some of the advantages for this practice.

A ship is launched as soon as the hull structure is sufficiently complete to withstand the strain. Ships may be launched endwise, sidewise, or by in-place flotation (for example, graving docks). The use of a graving dock requires a greater investment in facilities than either of the other two methods, but in some cases there may be an overall advantage due to the improved access to the ship and the simplified launch procedure. *See* DRYDOCKING.

The final outfitting of a ship is the construction phase during which checks are made to ensure that all of the previous work has been accomplished in a satisfactory manner; and last-minute details, such as deck coverings and the top coat of paint, are completed. It is considered good practice to subject as much of the ship as possible to an intensive series of tests while at the dock, where corrections and final adjustments are more easily made than when at sea. As a part of this test program, the main propulsion machinery is subjected to a dock trial, during which the ship is secured to the dock and the main propulsion machinery is operated up to the highest power level permissible.

When a comprehensive program of dockside tests have been completed, the only capabilities which have not been demonstrated are the operation of the steering gear during rated-power conditions and the operation of the main propulsion machinery at rated power; these capabilities must be demonstrated during trials at sea. [R.L.Ha.]

Shipping fever A severe inflammation of the lungs (pneumonia) commonly seen in North American cattle after experiencing the stress of transport. This disease occurs mainly in 6–9-month-old beef calves transported to feedlots. The characteristic pneumonia is caused primarily by the bacterium *Pasteurella haemolytica* serotype A1; thus a synonym for shipping fever is bovine pneumonic pasteurellosis.

Pasteurella haemolytica replicates rapidly in the upper respiratory tract and is inhaled into the lungs, where pneumonia develops in the deepest region of the lower respiratory tract (the pulmonary alveoli). Viruses can also concurrently damage pulmonary alveoli and enhance the bacterial pneumonia.

Symptoms initially include reduced appetite, high fever, rapid and shallow respiration, depression, and a moist cough. During the later stages of disease, cattle lose weight and have labored breathing. The lesion causing these symptoms is a severe pneumonia accompanied by inflammation of the lining of the chest cavity, and is called a fibrinous pleuropneumonia. Without vigorous treatment, shipping fever can cause death in 5–30% of affected cattle.

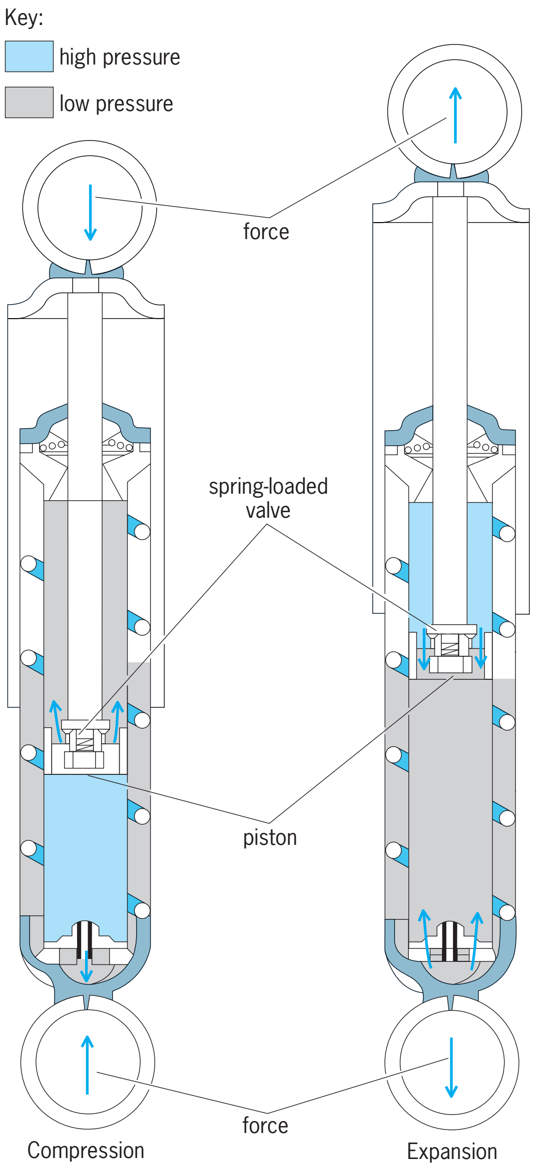
Treatment is aimed at eliminating bacteria by using antibiotics, reducing inflammation by using nonsteroidal anti-inflammatory drugs, and separating affected cattle. Vaccines can stimulate immunity to the viruses and bacteria associated with shipping fever. *See* ANIMAL VIRUS; INFLAMMATION; PNEUMONIA; VACCINATION. [A.W.Co.]

Shipworm A wood-boring mollusk of the family Teredinidae. These borers, also called pileworms, are found around the world in tropical to boreal and marine to nearly freshwater habitats, from the intertidal to depths of about 2000 ft (600 m). It was not until humans became navigators that shipworms became pests. Before the advent of steel ships, they were greatly feared, and even today hundreds of millions of dollars are spent annually on prevention and repair due to their activity. *See* BIVALVIA. [R.D.T.]

Shock absorber Effectively a spring, a dashpot, or a combination of the two, arranged to minimize the acceleration of the mass of a mechanism or portion thereof with respect to its frame or support.

The spring type of shock absorber is generally used to protect delicate mechanisms, such as instruments, from direct impact or instantaneously applied loads. Such springs are often made of rubber or similar elastic material. *See* SHOCK ISOLATION.

An example of the dashpot type of shock absorber is the direct-acting shock absorber in an automotive spring suspension system (see illustration). Here the device is used to dampen and control a spring movement. The energy of the mass in motion is converted to heat by forcing a fluid through a restriction, and the



A dashpot-type shock absorber. (*Plymouth Division, Chrysler Corp.*)

heat is dissipated by radiation and conduction from the shock absorber. *See* VIBRATION DAMPING.

There are also devices available which combine springs and viscous damping (dashpots) in the same unit. They use elastic solids (such as rubber or metal), compressed gas (usually nitrogen), or both for the spring. A flat-viscosity hydraulic fluid is used for the viscous damping. [L.S.L.]

Shock isolation

The application of isolators to alleviate the effects of shock on a mechanical device or system. The term shock generally denotes suddenness, either in the application of a force or in the inception of a motion. *See* SHOCK WAVE.

Shock isolation is accomplished by storing energy in a resilient medium (isolator, cushion, and so on) and releasing it at a slower rate. The effectiveness of an isolator depends upon the duration of the shock impact.

Rubber is the most common material used in commercial shock isolators. Rubber isolators are generally used where the shock forces are created through small displacements. For larger displacement shock forces, such as those experienced by shipping containers in rough handling conditions, thick cushions of felt, rubberized hair, sponge rubber, cork, or foam plastics are used.

The shock load must be divided between the case, the shock cushion, and the equipment. The case, since it must withstand effects of rough handling such as sliding and dropping, is by necessity rigid. The more rigid the case the closer to a 1:1 ratio will be the transfer of the shock from outside to inside. The absorption of the shock is primarily between the cushion and the equipment. *See* DAMPING; SHOCK ABSORBER; SPRING (MACHINES); VIBRATION DAMPING. [K.W.J.]

Shock syndrome

A condition clinically recognized as a state of inadequate blood flow to tissues. The etiologic classification of shock syndrome comprises four categories: cardiogenic (inability of the heart to pump adequately); neurogenic (interference with control of size of blood vessels caused by a change in balance in nerve impulses); vasogenic (sepsis; due to serious infection); and hematogenic (reduction in circulating blood volume).

Cardiogenic shock is manifested by low blood pressure when there is adequate blood volume. This form of shock is indicated by cold skin, low body temperature, and fast pulse.

Neurogenic shock is seen with clinical fainting. Similarly, neurogenic shock is often observed with serious paralysis of nervous influences. Although the blood pressure may be extremely low, the pulse rate is usually slower than normal and is accompanied by dry, warm, and even flushed skin.

Although any agent capable of producing infection, including viruses, parasites, and fungi, may result in vasogenic (septic) shock, the most frequent etiologic organisms are those that originate in the body, such as in the bowel or urinary tract. The initial infectious process appears to be only a stimulus for a series of body responses that may be fatal, even in the absence of infection at the time of death. Clinically, these individuals usually have high fever, low blood pressure, and eventually cold skin.

Hematogenic shock is the most common form of shock, and it is usually caused by hemorrhage. Most of the signs of clinical shock from low blood volume are characteristic of low blood flow. The skin is usually cold, clammy, and pale, accompanied by a very rapid pulse. *See* CARDIOVASCULAR SYSTEM. [G.T.Sh.]

Shock tube

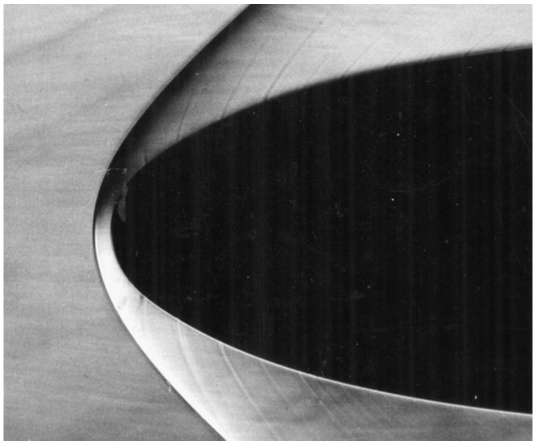
A laboratory device for rapidly raising confined samples of fluids (primarily gases) to preselected high temperatures and densities. This is accomplished by a shock wave, generated when a partition (diaphragm) that separates a low-pressure (driven) section from a high-pressure (driver) section is rapidly removed. Shock tubes can be circular, square, or rectangular in cross section. In the driven section, gaseous samples can be heated to temperatures as high as 27,500°F (15,000 K) under strictly homogeneous conditions. At the shock front the transition from the unshocked to the high-temperature condition is of short but of finite duration. The incident shock wave generates a slower-moving wave that additionally heats the compressed gas. *See* SHOCK WAVE.

With the diaphragm in place the driven section is filled to a modest pressure with an inert gas plus the gas of interest. The driver section is filled to a high pressure with a low-molecular-weight gas: helium or hydrogen. When the diaphragm is rapidly ruptured, expansion of the high-pressure gas acts as a low-mass piston that generates a steepening pressure front, which moves ahead of the boundary between the driver and the test gases.

Shock tubes are used to investigate the gas dynamics of shocks and for preparing test samples for equilibrium or kinetic studies. Many gas dynamic problems can be investigated in shock tubes, such as thermal boundary-layer growth, shock bifurcation, and shock-wave focusing and reflection. Shock tubes are used to prepare gases for study at very low or very high temperatures without thermal contact with extraneous surfaces. Significant applications of shock tubes to chemical kinetics includes the determination of diatom dissociation rates and the study of polyatomic molecules. [S.H.B.]

Shock wave A mechanical wave of large amplitude, propagating at supersonic velocity, across which pressure or stress, density, particle velocity, temperature, and related properties change in a nearly discontinuous manner. Unlike acoustic waves, shock waves are characterized by an amplitude-dependent wave velocity. Shock waves arise from sharp and violent disturbances generated from a lightning stroke, bomb blast, or other form of intense explosion, and from steady supersonic flow over bodies.

The abrupt nature of a shock wave in a gas can best be visualized from a schlieren photograph or shadow graph of supersonic flow over objects. Such photographs show well-defined surfaces in the flow field across which the density changes rapidly, in contrast to waves within the range of linear dynamic behavior of the fluid. Measurements of fluid density, pressure, and temperature across the surfaces show that these quantities always increase along the direction of flow, and that the rates of change are usually so rapid as to be beyond the spatial resolution of most instruments. These surfaces of abrupt change in fluid properties are called shock waves or shock fronts. *See* SCHLIEREN PHOTOGRAPHY; SHADOWGRAPH; WAVE MOTION IN FLUIDS.



Schlieren photograph of supersonic flow over blunt object. Shock wave is approximately parabolic, and detached from object. (*Avco Everett Research Laboratory, Inc.*)

Shock waves in supersonic flow may be classified as normal or oblique according to whether the orientation of the surface of abrupt change is perpendicular or at an angle to the direction of flow. A schlieren photograph of a supersonic flow over a blunt object is shown in the illustration. Although this photograph was obtained from a supersonic flow over a stationary model in a shock tube, the general shape of the shock wave around the object is quite typical of those observed in a supersonic wind tunnel, or of similar objects (or projectiles) flying at supersonic speeds in a stationary atmosphere. The shock wave in this case assumes an approximately parabolic shape and is clearly detached from the blunt object. The central part of the wave, just in front of the object, may be considered an approximate model of the normal shock; the outer part of the wave is an oblique shock wave of gradually changing obliqueness and strength. *See* BALLISTIC RANGE; WIND TUNNEL. [S.C.Li.]

Some common examples of shock waves in condensed materials are encountered in the study of underground or underwater explosions, meteorite impacts, and ballistics problems. The field of shock waves in condensed materials (solids and liquids) has grown into an important interdisciplinary area of research involving condensed matter physics, geophysics, materials science, applied mechanics, and chemical physics. The nonlinear aspect of shock waves is an important area of applied mathematics.

Experimentally, shock waves are produced by rapidly imparting momentum over a large flat surface. This can be accomplished in many different ways: rapid deposition of radiation using electron or photon beams (lasers or x-rays), detonation of a high explosive in contact with the material, or high-speed impact of a plate on the sample surface. The impacting plate itself can be accelerated by using explosives, electrical discharge, underground nuclear explosions, and compressed gases. The use of compressed gas to accelerate projectiles with appropriate flyer plates provides the highest precision and control as well as convenience in laboratory experiments.

Large-amplitude one-dimensional compression and shear waves have been studied in solids. In these experiments, a macroscopic volume element is subjected to both a compression and shear deformation. The combined deformation state is produced by impacting two parallel flyer plates that are inclined at an angle to the direction of the plate motion. Momentum conservation coupled with different wave velocities for compression and shear waves leads to a separation of these waves in the sample interior. These experiments provide direct information about the shear response of shocked solids, and subject samples to more general loading states than the uniaxial strain state. *See* STRESS AND STRAIN.

Shock waves subject matter to unusual conditions and therefore provide a good test of understanding of fundamental processes. The majority of the studies on condensed materials have concentrated on mechanical and thermodynamic properties. These are obtained from measurements of shock velocity, stress, and particle velocity in well-controlled experiments. Advanced techniques using electromagnetic gages, laser interferometry, piezoelectric gages, and piezoresistance gages have given continuous, time-resolved measurements at different sample thicknesses.

The study of residual effects, that is, the postshock examination of samples subjected to a known pulse amplitude and duration, is of considerable importance to materials science and metallurgy. The conversion of graphite to diamonds is noteworthy. Other effects that have been observed are microstructural changes, enhanced chemical activity, changes in material hardness and strength, and changes in electrical and magnetic properties. The generation of shock-induced lattice defects is thought to be important for explaining these changes in material properties. There has been growing interest in using shock methods for material synthesis and powder compaction. *See* DIAMOND; HIGH-PRESSURE CHEMISTRY; HIGH-PRESSURE MINERAL SYNTHESIS; HIGH-PRESSURE PHYSICS. [Y.M.G.]

Short circuit An abnormal condition (including an arc) of relatively low impedance, whether made accidentally or intentionally, between two points of different potential in an electric network or system. *See* CIRCUIT (ELECTRICITY); ELECTRICAL IMPEDANCE.

Common usage of the term implies an undesirable condition arising from failure of electrical insulation, from natural causes (lightning, wind, and so forth), or from human causes (accidents, intrusion, and so forth). From an analytical viewpoint, however, short circuits represent a severe condition that the circuit designer must consider in designing an electric system that must withstand all possible operating conditions. *See* ELECTRIC PROTECTIVE DEVICES; ELECTRICAL INSULATION; LIGHTNING AND SURGE PROTECTION.

In circuit theory the short-circuit condition represents a basic condition that is used analytically to derive important information concerning the network behavior and operating capability. Thus, along with the open-circuit voltage, the short-circuit current provides important basic information about the network at a given point. *See* ALTERNATING-CURRENT CIRCUIT THEORY; DIRECT-CURRENT CIRCUIT THEORY; NETWORK THEORY; THÉVENIN'S THEOREM (ELECTRIC NETWORKS).

The short-circuit condition is also used in network theory to describe a general condition of zero voltage. Thus the term short-circuit admittance (or impedance) is used to describe a network condition in which certain terminals have had their voltage reduced to zero, for the purpose of analysis. This leads to the terms short-circuit driving point admittance, short-circuit transfer admittance, and similar references to the zero voltage condition. *See* Admittance.

Short-circuit protection is a separate discipline dedicated to the study, analysis, application, and design of protective apparatus that are intended to minimize the effect of unintentional short circuits in power supply systems. For these analyses the short circuit is an important limiting (worst) case, and is used to compute the coordination of fuses, circuit reclosers, circuit breakers, and other devices designed to recognize and isolate short circuits. The short circuit is also an important parameter in the specification of these protective devices, which must have adequate capability for interrupting the high short-circuit current. *See* Circuit breaker; Fuse (electricity).

Short circuits are also important on high-frequency transmission lines where shorted stub lines, one-quarter wavelength long and shorted at the remote end, are used to design matching sections of the transmission lines which also act as tuning elements. *See* Transmission lines. [P.M.A.]

Short takeoff and landing (STOL) The term applied to heavier-than-air craft that cannot take off and land vertically, but can operate within areas substantially more confined than those normally required by aircraft of the same size. A pure STOL aircraft is a fixed-wing vehicle that derives lift primarily from free-stream airflow over the wing and its high lift system, sometimes with significant augmentation from the propulsion system. Although all vertical takeoff and landing (VTOL) machines, including helicopters, can lift greater loads by developing forward speed on the ground before liftoff, they are still regarded as VTOL (or V/STOL craft), operating in the STOL mode. *See* Vertical takeoff and landing (VTOL).

It has been customary to define STOL capability in terms of the runway length required to take off or land over a 50-ft (15-m) obstacle, the concept of “short” length being variously defined as from 500 to 2000 ft (150 to 600 m), depending on the high-lift concept employed and on the mission of the aircraft. In addition to being able to operate from short runways, STOL aircraft are usually expected to be able to maneuver in confined airspace so as to minimize the required size of the terminal area. Such aircraft must therefore have unusually good slow-flight stability and control characteristics, especially in turbulence and under instrument flight conditions. *See* Airplane. [R.E.K.]

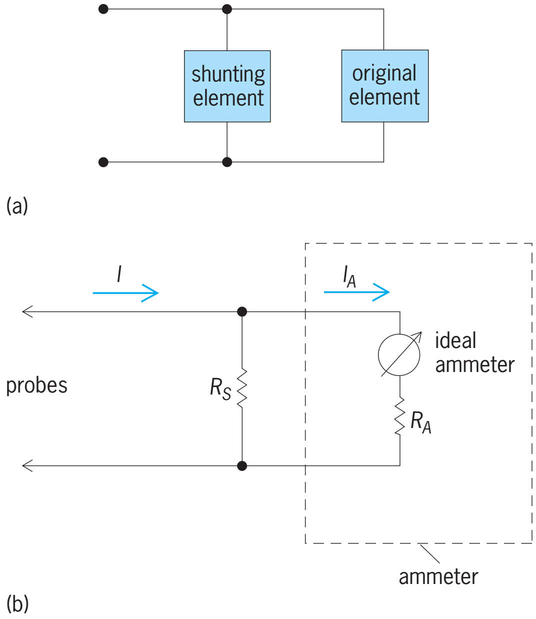
Shrew An insectivorous mammal of the family Soricidae found in Asia, Africa, Europe, and North America. The family includes 265 species grouped into three subfamilies, the red-toothed, white-toothed, and armored shrews. Shrews are small, savage animals with extremely sharp teeth. The tail is moderately long, the eyes are minute, the snout is sharp-pointed, and the ears are small (see illustration).

Shrews are solitary individuals that establish distinct territories. Couples are found together only during mating. The female builds the nest, a hole in the ground lined with leaves and moss, where she deposits her litter of 5-10 young, born after a gestation period of between 2-3 weeks. The female mates at the age of 1 year; however, since the life-span of the shrew is only 15 months, the females always die during the fall after the litter is born. *See* Insectivora. [C.B.C.]

Eurasian common shrew (*Sorex araneus*).

Shrink fit A fit that has considerable negative allowance so that the diameter of a hole is less than the diameter of a shaft that is to pass through the hole, also called a heavy force fit. Shrink fits are used for permanent assembly of steel external members, as on locomotive wheels. The difference between a shrink fit and a force fit is in method of assembly. In shrink fits, the outer member is heated, or the inner part is cooled, or both, as required. The parts are then assembled and returned to the same temperature. *See* Allowance; Force fit. [P.H.B.]

Shunting The act of connecting an electrical element in parallel with (across) another element. The shunting connection is shown in illus. *a*.



Shunting. (*a*) Shunting connection. (*b*) Ammeter shunted by resistor R_S.

An example of shunting involves a measuring instrument whose movement coil is designed to carry only a small current for a full-scale deflection of the meter. To protect this coil from an excessive current that would destroy it when measuring currents that exceed its rating, a shunt resistor carries the excess current.

Illustration *b* shows an ammeter (a current-measuring instrument) with internal resistance R_A. It is shunted by a resistor R_S. The current through the movement coil is a fraction of the measured current, and is given by the equation below.

$$I_A = \frac{R_S}{R_A + R_S} I$$

With different choices of R_S, the measuring range for the current I can be changed. *See* Ammeter; Current measurement.

Similar connections and calculations are used in a shunt ohmmeter to measure electrical resistance. Shunt capacitors are often used for voltage correction in power transmission lines. A shunt capacitor may be used for the correction of the power factor of a load. In direct current shunt motors, the excitation (field) winding is connected in parallel with the armature. *See* Direct-current motor; Ohmmeter; Power factor; Resistance measurement.

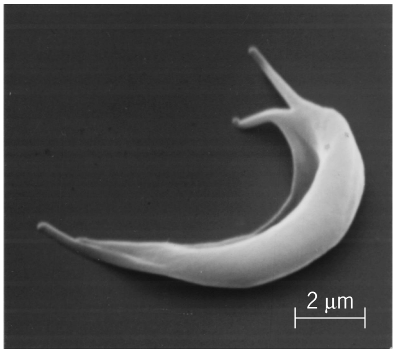
In electronic applications, a shunt regulator is used to divert an excessive current around a particular circuit. In broadband electronic amplifiers, several techniques may be used to extend the bandwidth. For high-frequency extension, a shunt compensation is used where, typically, a capacitor is shunted across an appropriate part of the circuit. Shunt capacitors (or more complicated circuits) are often used to stabilize and prevent undesired oscillations in amplifier and feedback circuits. *See* ALTERNATING-CURRENT CIRCUIT THEORY; AMPLIFIER; DIRECT-CURRENT CIRCUIT THEORY; FEEDBACK CIRCUIT. [S.Kar.]

Sickle cell disease An inherited disorder of red blood cells characterized by lifelong anemia and recurrent painful episodes. The sickle cell mutation is caused by a single nucleotide effecting a change in the β-globin gene, resulting in the substitution of valine for glutamic acid as the sixth amino acid of β-globin. The short circulatory survival of red blood cells that contain sickle cell hemoglobin S results in anemia, and their abnormal rigidity contributes to painful obstruction of small blood vessels. *See* ANEMIA; GENETIC CODE; HEMOGLOBIN.

The sickle cell gene is found most commonly among individuals of African ancestry, but also has a significant incidence in Mediterranean, Middle Eastern, and Asian Indian populations. Inheritance of one sickle gene and one normal β-globin allele results in a simple heterozygous condition known as sickle cell trait. This benign carrier condition is associated with a normal life expectancy, and it does not cause either anemia or recurrent pain. The large amounts of hemoglobin A within sickle-cell-trait red blood cells protect against the deleterious effects of hemoglobin S. The inheritance of homozygous sickle cell anemia results in sufficiently high intracellular concentration of sickle cell hemoglobin S to cause clinical disease. *See* HUMAN GENETICS.

The property of sickle cell hemoglobin S responsible for clinical disease is its insolubility when deoxygenated. Oxygenated sickle cell hemoglobin S is as soluble as oxygenated normal hemoglobin, but when it is deoxygenated it aggregates and forms an insoluble polymer. Polymerization of sickle cell hemoglobin within deoxygenated sickle cells reversibly reduces cellular deformability and distorts cells to the sickle shape (see illustration). Sickle cells usually return from the venous circulation to the arterial, where the hemoglobin is reoxygenated and the cells unsickle. Persistent cycles of sickling and unsickling result in the generation of dehydrated, very dense sickle cells; these are irreversibly sickled cells that are incapable of resuming a normal shape when reoxygenated. As a result of the poor deformability of individual sickle red blood cells, sickle cell blood has high viscosity. The impaired rheologic properties of sickle blood are compounded by abnormal adherence of sickle red cells to endothelial cells lining the blood vessels.

The short-lived nature of sickle red blood cells results in lifelong chronic hemolytic anemia with which accelerated red blood cell production cannot keep pace. The increased turnover of red blood cells results in elevated levels of hemoglobin degradation and bilirubin production by the liver and in very frequent formation of gallstones. Vasoocclusive complications of sickle cell disease include the episodic painful crises and both chronic and acute organ dysfunction. Average life expectancy is in the fifth decade. One disease manifestation that is particularly problematic in young children is susceptibility to infections.



Scanning electron micrograph of a deoxygenated sickle red blood cell. (*Electron micrograph by Dr. James White*)

The standard method of diagnosing sickle cell syndromes is hemoglobin electrophoresis. There are a variety of diagnostic tests based on deoxyribonucleic acid (DNA). These DNA-based diagnostic methods are particularly useful for prenatal diagnosis of sickle cell disease. *See* DEOXYRIBONUCLEIC ACID (DNA); ELECTROPHORESIS; PRENATAL DIAGNOSIS.

Despite the profound understanding of sickle cell disease, treatment of painful episodes often consists of only symptomatic therapy, including analgesics for pain, antibiotics for infections, and transfusions for episodes of severe anemia. Genetic counseling and prenatal diagnosis remain important therapeutic approaches. *See* BLOOD; GENETIC ENGINEERING. [S.H.E.]

Sideband The range of the electromagnetic spectrum located either above (the upper sideband) or below (the lower sideband) the frequency of a sinusoidal carrier signal $c(t)$. The sidebands are produced by modulating the carrier signal in amplitude, frequency, or phase in accordance with a modulating signal $m(t)$ to produce the modulated signal $s(t)$. The resulting distribution of power in the sidebands of the modulated signal depends on the modulating signal and the particular form of modulation employed. *See* AMPLITUDE MODULATION; FREQUENCY MODULATION; MODULATION; PHASE MODULATION. [H.J.He.]

Sidereal time One of several kinds of time scales used in astronomy, whose primary application is as part of the coordinate system to locate objects in the sky. It is also the basis for determining the solar time used in everyday living.

The common measurements of time are based on the motions of the Earth that most affect everyday life: Earth's rotation on its axis, and revolution in orbit around the Sun. Objects in the sky reflect these motions and appear to move westward, crossing the meridian each day. A particular object or point is chosen as a marker, and the interval between its successive crossings of the local meridian is defined to be a day, divided into 24 equal parts called hours. The actual length of the day for comparison between systems depends on the reference object chosen. The time of day is reckoned by the angular distance around the sky that the reference object has moved westward since it last crossed the meridian. In fact, the angular distance west of the meridian is called the hour angle. *See* MERIDIAN.

The reference point for marking sidereal time is the vernal equinox, one of the two points where the planes of the Earth's Equator and orbit appear to intersect on the celestial sphere. The sidereal day is the interval of time required for the hour angle of the equinox to increase by 360°. One rotation of the Earth with respect to the Sun is a little longer, because the Earth has moved in its orbit as it rotates and hence must turn approximately 361° to complete a solar day. A sidereal year is the time required for the mean longitude of the Sun to increase 360°, or for the Sun to make one circuit around the sky with respect to a fixed reference point. *See* EARTH ROTATION AND ORBITAL MOTION; TIME. [A.D.F.]

Siderite A mineral ($FeCO_3$) with the same space group and hexagonal crystal system as calcite ($CaCO_3$). Siderite has a gray, tan, brown, dark brown, or red color, has rhombohedral cleavages, and occasionally may show rhombohedral crystal terminations. It may display curved crystal faces like dolomite ($CaMg[CO_3]_2$), but more commonly is found as massive, compact, or earthy masses. It has a high specific gravity of 3.94, a medium hardness of 3.5–4, and a high index of refraction, 1.88. *See* CARBONATE MINERALS; CRYSTAL STRUCTURE; DOLOMITE.

Siderite, a widespread mineral in near-surface sediments and ore deposits, occurs in hydrothermal veins, lead-silver ore deposits, sedimentary concretions formed in limestones and sandstones, and Precambrian banded iron formations that precipitated under acidic conditions. Famous localities for siderite are found in Styria (Austria), Westphalia (Germany), Cornwall (Britain), Wawa (Northern Ontario, Canada), Minas Gerais (Brazil), and Llallagua and Potosi (Bolivia). These and other occurrences have provided locally significant quantities of siderite as iron ore. *See* IRON; MAGNETITE; METAMORPHISM; ORE AND MINERAL DEPOSITS. [E.J.E.]

Siderophores Low-molecular-mass molecules that have a high specificity for chelating or binding iron. Siderophores are produced by many microorganisms, including bacteria, yeast, and fungi, to obtain iron from the environment. More than 500 different siderophores have been identified from microorganisms. Some bacteria produce more than one type of siderophore. *See* BACTERIA; BIOINORGANIC CHEMISTRY; CHELATION; FUNGI; IRON; YEAST.

Iron is required by aerobic bacteria and other living organisms for a variety of biochemical reactions in the cell. Although iron is the fourth most abundant element in the Earth's crust, it is not readily available to bacteria. Iron is found in nature mostly as insoluble precipitates that are part of hydroxide polymers. Bacteria living in the soil or water must have a mechanism to solubilize iron from these precipitates in order to assimilate iron from the environment. Iron is also not freely available in humans and other mammals. Most iron is found intracellularly in heme proteins and ferritin, an iron storage compound. Iron outside cells is tightly bound to proteins. Therefore, bacteria that grow in humans or other animals and cause infections must have a mechanism to remove iron from these proteins and use it for their own energy and growth needs. Siderophores have a very high affinity for iron and are able to solubilize and transport ferric iron (Fe^{3+}) in the environment and also to compete for iron with mammalian proteins such as transferrin and lactoferrin. The majority of bacteria and fungi use siderophores to solubilize and transport iron. Microorganisms can use either siderophores produced by themselves or siderophores produced by other microorganisms. *See* IRON METABOLISM.

The many different types of siderophores can generally be classified into two structural groups, hydroxamates and catecholate compounds. Despite their structural differences, all form an octahedral complex with six binding coordinates for Fe^{3+}.

Siderophores have potential applications in the treatment of some human diseases and infections. Some siderophores are used therapeutically to treat chronic or acute iron overload conditions in order to prevent iron toxicity in humans. Individuals who have defects in blood cell production or who receive multiple transfusions can sometimes have too much free iron in the body. However, in order to prevent infection during treatment for iron overload, it is important to use siderophores that cannot be used by bacterial pathogens.

A second clinical application of siderophores is in antibiotic delivery to bacteria. Some gram-negative bacteria are resistant to antibiotics because they are too big to diffuse through the outer-membrane porins. However, siderophore-antibiotic combination compounds have been synthesized that can be transported into the cell using the siderophore receptor. *See* ANTIBIOTIC; DRUG RESISTANCE. [P.A.So.]

Sigma-delta converter A class of electronic systems containing both analog and digital subsystems whose most common application is to the conversion of analog signals to digital form and vice versa. The device is also known as a delta-sigma converter. The main advantage of the sigma-delta approach to signal conversion is its minimal reliance on the quality of the analog components required. To achieve this end, the system uses pulse density modulation to create a high-rate stream of single-amplitude pulses. For analog-to-digital conversion, the rate at which the pulses are generated depends on the amplitude of the analog voltage being sensed. For digital-to-analog conversion, the pulse density depends on the numeric digital quantity applied at the converter input. *See* PULSE MODULATION.

The simplest implementation of a sigma-delta analog-to-digital converter uses an analog circuit to generate the single-valued pulse stream from an analog source, and a digital system to repeatedly sum the number of these pulses over a fixed number of pulse intervals. The summing operation converts the pulses to a numeric value, achieving analog-to-digital conversion. Conversely, in a digital-to-analog converter, a digital circuit is used to convert numeric values from a digital processor to a pulse stream, and these pulses then are low-pass-filtered by a relatively simple analog system to produce an analog waveform. This low-pass filtering effectively sums the uniform analog pulse amplitudes over a fixed interval. The circuit—analog or digital—used to generate the pulse stream is called a sigma-delta (or delta-sigma) modulator. *See* ELECTRIC FILTER.

In each case, analog information is contained not in the pulse amplitude but in the number of pulses that occur during the conversion interval. This distribution of the analog information makes the conversion process essentially independent of the amplitude of the pulses and greatly simplifies the design and fabrication of the analog portion of the converter. It does, however, require that the sampling process be rapid, since the resolution of the conversion depends on the number of pulses that can exist in the conversion interval. [P.V.L.]

Signal detection theory A theory in psychology which characterizes not only the acuity of an individual's discrimination but also the psychological factors that bias the individual's judgments. Failure to separate these two aspects of discrimination had tempered the success of theories based upon the classical concept of a sensory threshold. The theory provides a modern and more complete account of the process whereby an individual makes fine discriminations.

The theory of signal detection has two parts of quite different origins. The first comes from mathematical statistics and is a translation of the theory of statistical decisions. The major contribution of this part of the theory is that it permits a determination of the individual's discriminative capacity, or sensitivity, that is independent of the judgmental bias or decision criterion the individual may have had when the discrimination was made. The second part of the theory comes from the study of electronic communications. It provides a means of calculating for simple signals, such as tones and lights, the best discrimination that can be attained. The prediction is based upon physical measurements of the signals and their interfering noise.

This opportunity to compare the sensitivity of human observers with the sensitivity of an "ideal observer" for a variety of signals is of considerable usefulness, and of growing interest, in sensory psychology. Signal detection theory has been applied to several topics in experimental psychology in which separation of intrinsic discriminability from decision factors is desirable. Included are attention, imagery, learning, conceptual judgment, personality, reaction time, manual control, and speech.

The analytical apparatus of the theory has been of value in the evaluation of the performance of systems that make decisions based on uncertain information. Such systems may involve only people, or people and machines together, or only machines, Examples come from medical diagnosis, where clinicians may base diagnostic decisions on a physical examination, or on an x-ray image, or where machines make diagnoses, perhaps by counting blood cells of various types. [J.A.Sw.]

Signal generator A piece of electronic test equipment that delivers a sinusoidal output of accurately calibrated frequency. The frequency may be anywhere from audio to microwave, depending upon the intended use of the instrument.

The frequency and the amplitude are adjustable over a wide range. The oscillator must have excellent frequency stability, and its amplitude must remain constant over the tuning range.

The Wien-bridge oscillator is commonly used for frequencies up to about 200 kHz. For a radio-frequency signal generator up to about 200 MHz, a resonant circuit oscillator is used (such as a tuned-plate tuned-grid, Hartley, or Colpitts). Beyond this range VHF and microwave oscillators are used. *See* OSCILLATOR. [J.Mi.]

Signal-to-noise ratio The quantity that measures the relationship between the strength of an information-carrying signal in an electrical communications system and the random fluctuations in amplitude, phase, and frequency superimposed on that signal and collectively referred to as noise. For analog signals, the ratio, denoted S/N, is usually stated in terms of the relative amounts of electrical power contained in the signal and noise. For digital signals the ratio is defined as the amount of energy in the signal per bit of information carried by the signal, relative to the amount of noise power per hertz of signal bandwidth (the noise power spectral density), and is denoted E_b/N_0. Since both signal and noise fluctuate randomly with time, S/N and E_b/N_0 are specified in terms of statistical or time averages of these quantities.

The magnitude of the signal-to-noise ratio in a communications systems is an important factor in how well a receiver can recover the information-carrying signal from its corrupted version and hence how reliably information can be communicated. Generally speaking, for a given value of S/N the performance depends on how the information quantities are encoded into the signal parameters and on the method of recovering them from the received signal. The more complex encoding methods such as phase-shift keying or quadrature amplitude-shift keying usually result in better performance than simpler schemes such as amplitude- or frequency-shift keying. As an example, a digital communication system operating at a bit error rate of 10^{-5} requires as much as 7 dB less for E_b/N_0 when employing binary phase-shift keying as when using binary amplitude-shift keying. *See* ELECTRICAL COMMUNICATIONS; ELECTRICAL NOISE; INFORMATION THEORY; MODULATION. [H.J.He.]

Signal transduction The transmission of molecular signals from a cell's exterior to its interior. Molecular signals are transmitted between cells by the secretion of hormones and other chemical factors, which are then picked up by different cells. Sensory signals are also received from the environment, in the form of light, taste, sound, smell, and touch. The ability of an organism to function normally is dependent on all the cells of its different organs communicating effectively with their surroundings. Once a cell picks up a hormonal or sensory signal, it must transmit this information from the surface to the interior parts of the cell—for example, to the nucleus. This occurs via signal transduction pathways that are very specific, both in their activation and in their downstream actions. Thus, the various organs in the body respond in an appropriate manner and only to relevant signals. *See* CELL (BIOLOGY).

All signals received by cells first interact with specialized proteins in the cells called receptors, which are very specific to the signals they receive. These signals can be in various forms. The most common are chemical signals, which include all the hormones and neurotransmitters secreted within the body as well as the sensory (external) signals of taste and smell. The internal hormonal signals include steroid and peptide hormones, neurotransmitters, and biogenic amines, all of which are released from specialized cells within the various organs. The external signals of smell, which enter the nasal compartment as gaseous chemicals, are dissolved in liquid and then picked up by specialized receptors. Other external stimuli are first received by specialized receptors (for example, light receptors in the eye and touch receptors in the skin), which then convert the environmental signals into chemical ones, which are then passed on to the brain in the form of electrical impulses.

Once a receptor has received a signal, it must transmit this information effectively into the cell. This is accomplished either by a series of biochemical changes within the cell or by modifying the membrane potential by the movement of ions into or out of the cell. Receptors that initiate biochemical changes can do so either directly via intrinsic enzymatic activities within the receptor or by activating intracellular messenger molecules. Receptors may be broadly classified in four groups that differ in their mode of action and in the molecules that activate them.

The largest family of receptors are the G-protein-coupled receptors (GPCRs), which depend on guanosine triphosphate (GTP) for their function. Many neurotransmitters, hormones, and small molecules bind to and activate specific G-protein-coupled receptors.

A second family of membrane-bound receptors are the receptor tyrosine kinases (RTKs). They function by phosphorylating themselves and recruiting downstream signaling components.

Ion channels are proteins open upon activation, thereby allowing the passage of ions across the membrane. Ion channels are responsive to either ligands or to voltage changes across the membrane, depending on the type of channel. The movement of ions changes the membrane potential, which in turn changes cellular function. *See* BIOPOTENTIALS AND IONIC CURRENTS.

Steroid receptors are located within the cell. They bind cell-permeable molecules such as steroids, thyroid hormone, and vitamin D. Once these receptors are activated by ligand, they translocate to the nucleus, where they bind specific DNA sequences to modulate gene expression. *See* STEROID.

The intracellular component of signal propagation, also known as signal transduction, is receptor-specific. A given receptor will activate only very specific sets of downstream signaling components, thereby maintaining the specificity of the incoming signal inside the cell. In addition, signal transduction pathways amplify the incoming signal by a signaling cascade (molecule A activates several molecule B's, which in turn activate several molecule C's) resulting in an appropriate physiological response by the cell.

Several small molecules within the cell act as intracellular messengers. These include cAMP, cyclic guanosine monophosphate (cGMP), nitric oxide (NO), and Ca^{2+} ions. Increased levels of Ca^{2+} in the cell can trigger several changes, including activation of signaling pathways, changes in cell contraction and motility, or secretion of hormones or other factors, depending on the cell type. Increased levels of nitric oxide cause relaxation of smooth muscle cells and vasodilation by increasing cGMP levels within the cell. Increasing cAMP levels can modulate signaling pathways by activating the enzyme protein kinase A (PKA).

One of the most important functions of cell signaling is to control and maintain normal physiological balance within the body. Activation of different signaling pathways leads to diverse physiological responses, such as cell proliferation, death, differentiation, and metabolism. Signaling pathways in cells may also interact with each other and serve as signal integrators. For example, negative and positive feedback loops in pathways can modulate signals within a pathway; positive interactions between two signaling pathways can increase duration of signals; and negative interactions between pathways can block signals. *See* CELL NUCLEUS; CELL ORGANIZATION; ENDOCRINE SYSTEM (VERTEBRATE); NORADRENERGIC SYSTEM. [P.T.R.; R.I.]

Significant figures Digits that show the number of units in a measurement expressed in decimal notation.

Scientific notation is useful in showing which digits are significant. In scientific notation, a number is expressed as the product of a number 1 to 10 and a power of 10, or the product of 1 and a power of 10. Thus, the number 123,000 is 1.23×10^5.

The precision of a measurement is based on the size of the unit of measurement. The smaller the unit, the more precise is the measurement.

Computations cannot improve the precision of the measurement. To add measures, they should all be rounded to the unit of the least precise measurement. The sum 8.6 cm + 0.14 cm + 2.75 cm is found by rounding each to tenths: 8.6 cm + 0.1 cm + 2.8 cm = 11.5 cm. Even by doing this, the absolute error might be as large as 0.05 + 0.005 + 0.005 or 0.06, and affect the result by as much as 0.1.

In multiplying and dividing approximate numbers, the product or quotient is rounded to the number of significant digits in the number with the fewest significant digits. For example, 6.2 m × 8.75 m by computation is 54.25. The product needs to be rounded to 54 m^2 so as to show two significant digits. *See* NUMERICAL ANALYSIS; STATISTICS. [J.N.P.]

Silica minerals Silica (SiO_2) occurs naturally in at least nine different varieties (polymorphs), which include tridymite, cristobalite, coesite, and stishovite, in addition to high (β) and low (α) quartz. These forms are characterized by distinctive crystallography, optical characteristics, physical properties, pressure-temperature stability ranges, and occurrences.

The crystal structures of all silica polymorphs except stishovite contain silicon atoms surrounded by four oxygens, thus producing tetrahedral coordination polyhedra. Each oxygen is bonded to two silicons, creating an electrically neutral framework. Stishovite differs from the other silica minerals in having silicon atoms surrounded by six oxygens (octahedral coordination.) Ideal high tridymite is composed of sheets of SiO_4 tetrahedra oriented perpendicular to the *c* crystallographic axis (Fig. 1) with adjacent tetrahedra in these sheets pointing in opposite directions. High cristobalite, like tridymite, is composed of parallel sheets of SiO_4 tetrahedra with neighboring tetrahedra pointing in opposite directions. However, the hexagonal rings are distorted and adjacent sheets are rotated 60° with respect to one another, resulting in the geometry shown in Fig. 2. Coesite also contains silicon atoms tetrahedrally coordinated by oxygen. These polyhedra share corners to form chains composed of four-membered rings. Silicon in stishovite is octahedrally coordinated by oxygen. These coordination polyhedra share edges and corners to form chains of octahedra parallel to the *c* crystallographic axis.

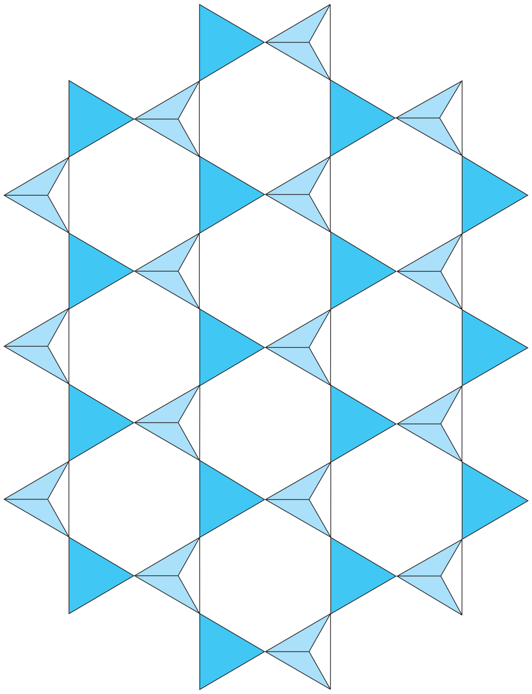


Fig. 1. Portion of an idealized sheet of tetrahedrally coordinated silicon atoms similar to that found in tridymite and cristobalite. Sharing of apical oxygens (which point in alternate directions) between silicons in adjacent sheets generates a continuous framework. (*After J. J. Papike and M. Cameron, Crystal chemistry of silicate minerals of geophysical interest, Rev. Geophys. Space Phys.*, 14:37–80; copyright © 1976 *by American Geophysical Union*)

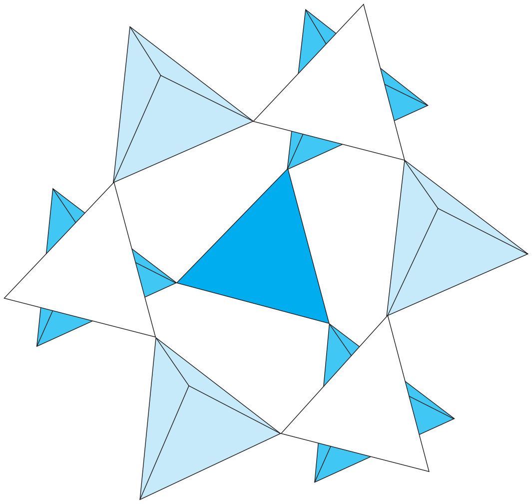

Fig. 2. Portion of cubic high cristobalite illustrating the distortion of tetrahedral sheets, with are oriented parallel to (111), and the 60° rotation of adjacent sheets. (*After J. J. Papike and M. Cameron, Crystal chemistry of silicate minerals of geophysical interest, Rev. Geophys. Space Phys., 14:37–80*; copyright © *1976 by American Geophysical Union*)

Chemically, all silica polymorphs are ideally 100% SiO_2. However, unlike quartz which commonly contains few impurities, the compositions of tridymite and cristobalite generally deviate significantly from pure silica. This usually occurs because of a coupled substitution in which a trivalent ion such as Al^{3+} or Fe^{3+} substitutes for Si^{4+}, with electrical neutrality being maintained by monovalent or divalent cations occupying interstices In the relatively open structures of these two minerals. *See* COESITE; QUARTZ. [J.C.D.]

Silicate minerals All silicates are built of a fundamental structural unit, the so-called SiO_4 tetrahedron. The crystal structure may be based on isolated SiO_4 groups or, since each of the four oxygen ions can bond to either one or two silicon (Si) ions, on SiO_4 groups shared in such a way as to form complex isolated groups or indefinitely extending chains, sheets, or three-dimensional networks. Mixed structures in which more than one type of shared tetrahedra are present also are known. *See* SILICON.

Silicates are classified according to the nature of the sharing mechanism, as revealed by x-ray diffraction study. The sharing mechanism gives rise to a characteristic ratio of Si to O, but it is possible for oxygen ions that are not bonded to Si to be present in the structure, and sometimes some or all of any aluminum present must be counted as equivalent to Si.

The detailed crystallographic and physical properties of the various silicates are broadly related to the type of silicate framework that they possess. Thus, the phyllosilicates as a group typically have a platy crystal habit, with a cleavage parallel to the plane of layering of the structure, and are optically negative with rather high birefringence. The inosilicates, based on an extended one-dimensional rather than two-dimensional linkage of the SiO_4 tetrahedra, generally form crystals of prismatic habit; if cleavage is present, it will be parallel to the direction of elongation. The tectosilicates commonly are equant in habit, without marked preference for cleavage direction, and tend to have a relatively low birefringence.

Silicate minerals make up the bulk of the outer crust of the Earth and form in a wide range of geologic environments. Many silicates are of economic importance. For discussions of certain silicate mineral groups *see* AMPHIBOLE; ANDALUSITE; CHLORITE; CHLORITOID; EPIDOTE; FELDSPAR; FELDSPATHOID; GARNET; HUMITE; MICA; OLIVINE; PYROXENE; SCAPOLITE; SERPENTINE; ZEOLITE. [C.Fr.]

Silicate phase equilibria Silicate phase equilibria studies define the conditions of temperature, composition, and pressure at which silicates can stably coexist. Silicate phase equilibria relations are used by geologists, ceramists, and cement manufacturers to explain the variation of composition of silica-bearing minerals, as well as their number and order of appearance in rocks, slags, glasses, and cements. They are also useful to interpret the chemistry of refractories, boiler scale deposits, and welding fluxes.

Silica itself makes up nearly 60% by weight of the Earth's crust. The next most abundant oxides, in decreasing order, are Al_2O_3, CaO, Na_2O, FeO, MgO, K_2O, and Fe_2O_3; all of these occur principally combined with silica as silicates. Free silica and the hundreds of silicate minerals make up nearly 97% of the Earth's crust. The study of silicate phase equilibria was initiated by geologists seeking to apply the phase rule of J. Willard Gibbs to these abundant natural substances. *See* PHASE EQUILIBRIUM; SILICATE MINERALS.

Dynamic and static methods are used to determine equilibrium in silicate systems. Dynamic methods require large samples of silicates that are difficult to prepare, and require also that equilibrium be reached quickly. Silicates in general are slow to react, and supercooling or superheating of hundreds of degrees before reaction occurs is common. Many silicates react sluggishly at temperatures of 1000°C (1830°F) or higher.

Most silicate phase equilibria are determined by the static method of holding a sample under controlled conditions until equilibrium is attained, then quenching the sample for examination.

Equilibrium is established when the products obtained by heating a sample to a given temperature are identical with the products of cooling a sample to that temperature; no requirement is made regarding the texture, shape, or grain size of the products. Another criterion used in recognizing equilibrium is that no change of the sample can be observed after holding the charge at a given temperature for very long periods of time.

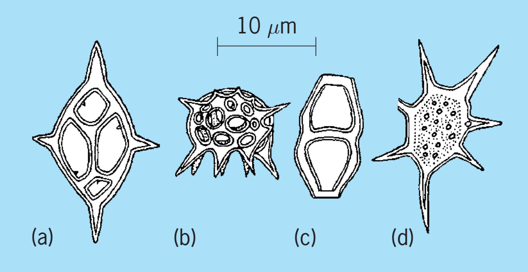
The use of diagrams to present silicate phase equilibria is customary, since such diagrams express quantitatively the amount and composition of each phase present at any bulk composition in the system at any temperature. [D.B.St.]

Siliceous sediment Fine-grained sediment and sedimentary rock dominantly composed of the microscopic remains of the unicellular, silica-secreting plankton diatoms and radiolarians. Minor constituents include extremely small shards of sponge spicules and other microorganisms such as silicoflagellates. Siliceous sedimentary rock sequences are often highly porous and can form excellent petroleum source and reservoir rocks. *See* SEDIMENTARY ROCKS.

Given their biologic composition, siliceous sediments provide some of the best geologic records of the ancient oceans. Diatoms did not evolve until the late Mesozoic; thus the majority of siliceous rocks older than approximately 150 million years are formed by radiolarians. Geologists map the distribution of ancient siliceous sediments now pushed up onto land by plate tectonic processes, and can thus determine which portions of the ancient seas were biologically productive; this knowledge in turn can give great insight into regions of the Earth's crust that may be economically productive (for example oil-containing regions). The vast oil reserves of coastal California are predominantly found in the Monterey Formation, a highly porous diatomaceous siliceous sedimentary sequence distributed along the western seaboard of the United States. *See* CHALK; CHERT; LIMESTONE. [R.W.Mu.]

Siliceous sinter A porous silica deposit formed around hot springs. It is white to light gray and sometimes friable. Geyserite is a variety of siliceous sinter formed around geysers. The siliceous sinters are deposited as the hot subterranean waters cool after issuing at the surface and become supersaturated with silica that was picked up at depth. The sinters are frequently deposited on algae that live in the pools around the hot springs. *See* GEYSER. [R.Si.]

Silicoflagellata A class of unicellular flagellate microorganisms of the plant division Chrysophyta, which are a part of the marine plankton. Their exoskeletons, siliceous and coarsely perforate (see illustration), resemble those of the Radiolaria, with which they have been grouped. They are usually subpyramidal or hemispherical in shape, and delicately filigreed. Two families and 11 genera of silicoflagellates have been described from siliceous sedimentary rocks ranging in age from Upper Cretaceous to Recent, in association with abundant diatoms and siliceous sponge spicules. *See* MICROPALEONTOLOGY; PHYTOPLANKTON. [D.J.J.]



Examples of fossil and modern Silicoflagellata. (*a*) *Dictyocha*, Cretaceous to Recent; (*b*) *Cannopilus*, Miocene; (*c*) *Naviculopsis*, Eocene to Miocene; and (*d*) *Vallacerta*, Upper Cretaceous.

Silicoflagellida An order of the phylum Protozoa, class Phytamastigophorea. These organisms are marine flagellates which have an internal, siliceous, tubular skeleton; numerous small, discoid, yellow chromatophores; and a single flagellum. At times the organisms also put forth, from the ends of their skeletal tubes, long, rather threadlike pseudopodia. The skeleton forms a basket within which the moiety of protoplasm lies, but skeletal elements always have at least a thin covering. There is a single genus, *Dictyocha*, with four species. *See* PHYTAMASTIGOPHOREA. [J.B.L.]

Silicon A chemical element, Si, atomic number 14, and atomic weight 28.086. Silicon is the most abundant electropositive element in the Earth's crust. The element is a metalloid with a decided metallic luster; it is quite brittle. It has a specific gravity of 2.42 at 20°C (68°F), melts at 1420°C (2588°F), and boils at 3280°C (5936°F). The element is usually tetravalent in its compounds, although sometimes divalent, and is decidedly electropositive in its chemical behavior. In addition, pentacoordinate and hexacoordinate compounds of silicon are known. *See* METALLOID; PERIODIC TABLE.

Crude elementary silicon and its intermetallic compounds are used in alloying constituents to strengthen aluminum, magnesium, copper, and other metals. Metallurgical silicon of 98–99% purity is used as the starting material for manufacturing organosilicon compounds and silicone resins, elastomers, and oils. Silicon chips are used in integrated circuits. Photovoltaic cells for direct conversion of solar energy to electricity use wafers sliced from single crystals of electronic-grade silicon. Silicon dioxide is used as the raw material for making elementary silicon and for silicon carbide. Sizable crystals of it are used for piezoelectric crystals. Fused quartz sand becomes silica glass, used in chemical laboratories and plants as well as an electrical insulator. A colloidal dispersion of silica in water is used as a coating agent and as an ingredient in certain polishes.

Naturally occurring silicon contains 92.2% of the isotope of mass number 28, 4.7% of silicon-29, and 3.1% of silicon-30. In addition to these stable, natural isotopes, several artificially radioactive isotopes are known. Elementary silicon has the physical properties of a metalloid, resembling germanium below it in group 14 of the periodic table. In very pure form silicon is an intrinsic semiconductor, although the extent of its semiconduction is greatly increased by the introduction of minute amounts of impurities. Silicon resembles the metals in its chemical behavior. It is about as electropositive as tin, and decidedly more positive than germanium or lead. In keeping with this rather metallic character, silicon forms tetrapositive ions and a variety of covalent compounds; it appears as a negative ion in only a few silicides and as a positive constituent of oxy acid or complex anions.

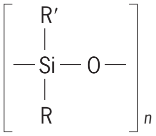
Several series of hydrides are formed, a variety of halides (some of which contain silicon-to-silicon bonds), and also many series of oxygen-containing compounds which may be either ironic or covalent in their properties.

Silicon occurs in many forms of the dioxide and as almost numberless variations of the natural silicates. For a discussion of the structures and compositions of the representative classes, *see* Silicate minerals.

In abundance, silicon exceeds by far every other element except oxygen. It constitutes 27.72% of the solid crust of the Earth, whereas oxygen constitutes 46.6%, and the next element after silicon, aluminum, accounts for 8.13%.

Silicon is reported to form compounds with 64 of the 96 stable elements, and it probably forms silicides with 18 other elements. Besides the metal silicides, used in large quantities in metallurgy, silicon forms useful and important compounds with hydrogen, carbon, the halogen elements, nitrogen, oxygen, and sulfur. In addition, useful organosilicon derivatives have been prepared. [E.P.P.]

Silicone resins Polymers composed of alternating atoms of silicon and oxygen with organic substituents attached to the silicon atoms, as shown in the formula below.



$$\left[-\overset{\displaystyle R'}{\underset{\displaystyle R}{Si}}-O- \right]_n$$

Silicones, also called organopolysiloxanes, may exist as liquids, greases, resins, or rubbers. Silicone polymers have good resistance to water and oxidation, stability at high and low temperatures, and lubricity.

Silicones are obtained by the condensation of hydroxy organosilicon compounds formed by the hydrolysis of organosilicon halides. The first products are usually low in molecular weight ($n = 2$ to 7), and usually consist of a mixture of linear and cyclic species, especially the tetramer. Fluids having a wide range of viscosity are prepared by polymerizing further, using a monofunctional trichlorosilane to limit molecular weights to the value desired. Elastomers are made by polymerization of the purified tetramer using an alkaline catalyst at 100–150°C (212–302°F). Properties can be varied by partial replacement of some of the methyl groups by other substituents and by the use of reinforcing fillers.

The wide range of structural variations makes it possible to tailor compositions for many kinds of applications. Low-molecular-weight silanes containing amino or other functional groups are used as treating or coupling agents for glass fiber and other reinforcements in order to cause unsaturated polyesters and other resins to adhere better.

The liquids, generally dimethyl silicones of relatively low molecular weight, have low surface tension, great wetting power and lubricity for metals, and very small change in viscosity with temperature. They are used as hydraulic fluids, as antifoaming agents, as treating and waterproofing agents for leather, textiles, and masonry, and in cosmetic preparations. The greases are particularly desired for applications requiring effective lubrication at very high and at very low temperatures.

Silicone resins are used for coating applications in which thermal stability in the range 300–500°C (570–930°F) is required. The dielectric properties of the polymers make them suitable for many electrical applications, particularly in electrical insulation that is exposed to high temperatures and as encapsulating materials for electronic devices.

Silicone rubbers are compositions containing high-molecular-weight dimethyl silicone linear polymer, finely divided silicon dioxide as the filler, and a peroxidic curing agent. The silicone rubbers have the remarkable ability of remaining flexible at very low temperatures and stable at high temperatures. *See* Inorganic polymer; Plastics processing; Rubber; Silicon. [J.A.M.]

Silk The lustrous fiber produced by the larvae of silkworms; also the thread or cloth made from such fiber.

The cocoons of the silkworm are delivered to a factory, called a filature, where the silk is unwound from the cocoons and the strands are collected into skeins. The process of unwinding the filament from the cocoon is called reeling. As the filament of a single cocoon is too fine for commercial use, 3–10 strands are usually reeled at a time to produce the desired diameter of raw silk thread. The usable length of the reeled filament is from 1000 to 2000 ft (300 to 600 m). The remaining part of the filament is valuable raw material for the manufacture of spun silk.

The term reeled silk is applied to the raw silk strand that is formed by combining several filaments from separate cocoons. It is reeled into skeins, which are packed in small bundles called books. From the filature, the books of reeled silk go to the throwster where they are transformed into silk yarn, also called silk thread, by a process known as throwing. Silk throwing is analogous to the spinning process that changes cotton, linen, or wool fibers into yarn. The manufacture of those fibers, however, unlike that of silk yarm, does not include carding, combing, and drawing out, the usual processes for producing a continuous yarn. [M.D.P.]

Sillimanite A nesosilicate mineral of composition $Al_2O[SiO_4]$, crystallizing in the orthorhombic system. Sillimanite commonly occurs in slender crystals or parallel groups, and is frequently fibrous, hence the synonym fibrolite. There is one perfect cleavage, luster is vitreous, color is brown, pale green, or white, hardness is 6–7 on Mohs scale, and the specific gravity is 3.23. *See* Hardness scale.

Sillimanite, andalusite, and kyanite are polymorphs of $Al_2O[SiO_4]$. The three $Al_2O[SiO_4]$ polymorphs are important in assessing the metamorphic grade of the rocks in which they crystallized. *See* Andalusite; Kyanite; Silicate minerals. [P.B.M.]

Silurian The third oldest period of the Paleozoic Era, spanning an interval from about 412 to 438 million years before the present. The Silurian system includes all sedimentary rocks deposited and all igneous and metamorphic rocks formed in the Silurian Period. Both the base and top of the Silurian have been designated by international agreement at the first appearances of certain graptolite species in rock sequences at easily examined and well-studied outcrops. *See* Geologic time scale.

The most prominent feature of Silurian paleogeography was the immense Gondwana plate. It included much of present-day South America, Africa, the Middle East, Antarctica, Australia, and the Indian subcontinent. During the Silurian, many plates continued the relative northward motion that had commenced during the mid-Ordovician. Plate positions and plate motions as well as topographic features of the plates controlled depositional environments and lithofacies. These, in turn, significantly influenced organismal development and distributions. Silurian Northern Hemisphere plates, other than a portion of Siberia, are not known north of the Northern Hemisphere tropics. Presumably, nearly all of the Northern Hemisphere north of the tropics was ocean throughout the Silurian. *See* CONTINENTS, EVOLUTION OF; PALEOGEOGRAPHY.

Absence of plates bearing continental or shallow shelf marine environments north of about 45° north latitude indicates that ocean circulation in most of the Silurian Northern Hemisphere was zonal. Ocean surface currents in the tropics would have been influenced strongly by the prevailing westerlies. The large size of the Gondwana plate and the presence of land over much of it would have led to development of seasonal monsoon conditions. Surface circulation south of 30° south would have hit the western side of Laurentia and flowed generally northward. *See* PALEOCEANOGRAPHY.

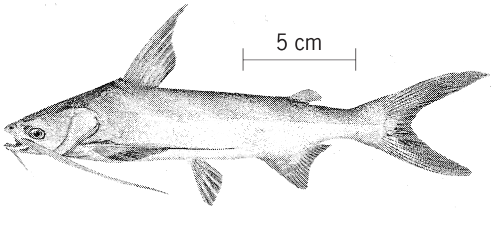
Collision of the Avalonian and Laurentian plates in the latest Ordovician coincides with development of the Southern Hemisphere continental glaciation. Erosion of the land area formed at the Avalon-Laurentian plate collision generated a large volume of coarse to fine-grained siliclastic materials. That part of South America (modern eastern South America) near the South Pole for the early part of the Silurian was the site of as many as four brief glacial episodes. *See* PALEOCLIMATOLOGY.

Both nonvascular and vascular plants continued to develop in land environments following their originations in the early mid-Ordovician. Many of these Silurian plants were mosslike and bryophytelike. Psilophytes assigned to the genus *Cooksonia* were relatively widespread in Late Silurian terrestrial environments. The probable lycopod (club moss) *Baragwanathia* apparently lived in nearshore settings in modern Australia during the latter part of the Silurian. Silurian land life also included probable arthopods and annelid worms. Fecal pellets of wormlike activity have been found as well as remains of centipede-, millepede-, and spiderlike arthropods. *See* PALEOBOTANY; PALEOECOLOGY.

Shallow marine environments in the tropics were scenes of rich growths of algae, mat-forming cyanobacteria, spongelike organisms, sponges, brachiopods, bryozoans, corals, crinoids, and ostracodes. Nearshore marine siliclastic strata bear ostracodes, small clams, and snails and trilobites. Certain nearshore strata bear the remains of horseshoe-crab-like eurypterids. *See* ALGAE; BRACHIOPODA; BRYOZOA; CRINOIDEA; CYANOBACTERIA; OSTRACODA; TRILOBITA.

Fish are prominent in a number of Silurian nearshore and some offshore marine environments. Jawless armored fish include many species of thelodonts that had bodies covered with minute bony scales, heterostracans, and galeaspids that had relatively heavily armored head shields, and anaspids that possessed body armor consisting of scales and small plates. Jawed fish were relatively rare in the Silurian. They were primarily spiny sharks or acanthodians. As well, there are remains of true sharklike fish and fish with interior bony skeletons (osteichthyans) in Late Silurian rocks. *See* ANASPIDA; HETEROSTRACI; OSTEICHTHYES; THELODONTIDA. [W.B.N.B.]

Siluriformes The catfishes, a highly distinctive order (also called Nematognathi) of actinopterygian fishes. In the Siluriformes the Weberian apparatus is more complex than in the related Cypriniformes. The body is usually naked or the scales are enlarged and modified into large, overlapping bony plates. There are one to four pairs of barbels, and both the pectoral and dorsal fins usually have a strong spine (see illustration). This is a large group, including about 26 families and perhaps 2000 species, of which nearly 1200 live in South America. Catfishes are known from Eocene times. *See* ACTINOPTERYGII; CYPRINIFORMES. [R.M.B.]



Gafftopsail catfish (*Bagre marinus*). (*After G. B. Goode, Fishery Industries of the United States, 1884*)

Silver A chemical element, Ag, atomic number 47, atomic mass 107.868. It is a gray-white, lustrous metal. Chemically it is one of the heavy metals and one of the noble metals; commercially it is a precious metal. There are 25 isotopes of silver with atomic masses ranging from 102 to 117. Ordinary silver is made up of the isotopes of masses 107 (52% of natural silver) and 109 (48%). *See* PERIODIC TABLE.

Although silver is the most active chemically of the noble metals, it is not very active in comparison with most other elements. It does not oxidize as iron does when it rusts, but it reacts with sulfur or hydrogen sulfide to form the familiar silver tarnish. Electroplating silver with rhodium prevents this discoloration. Silver itself does not react with dilute nonoxidizing acids (hydrochloric or sulfuric acids) or strong bases (sodium hydroxide). However, oxidizing acids (nitric or concentrated sulfuric acids) dissolve it by reaction to form the unipositive silver ion, Ag^+. The Ag^+ ion is colorless, but a number of silver compounds are colored because of the influence of their other constituents.

Silver is almost always monovalent in its compounds, but an oxide, fluoride, and sulfide of divalent silver are known. Some coordination compounds of silver, also called silver complexes, contain divalent and trivalent silver. Although silver does not oxidize when heated, it can be oxidized chemically or electrolytically to form silver oxide or peroxide, a strong oxidizing agent. Because of this activity, silver finds considerable use as an oxidation catalyst in the production of certain organic materials.

Soluble silver salts, especially $AgNO_3$, have proved lethal in doses as small as 0.07 oz (2 g). Silver compounds may be slowly absorbed by the body tissues, with a resulting bluish or blackish pigmentation of the skin (argyria).

Silver is a rather rare element, ranking 63rd in order of abundance. Sometimes it occurs in nature as the free element (native silver) or alloyed with other metals. For the most part, however, silver is found in ores containing silver compounds. The principal silver ores are argentite, Ag_2S, cerargyrite or horn silver, AgCl, and several minerals in which silver sulfide is combined with sulfides of other metals; stephanite, $5Ag_2S{\cdot}Sb_2S_5$; polybasite, $9(Cu_2S, Ag_2S){\cdot}(Sb_2S_3, As_2S_3)$; proustite, $3Ag_2S{\cdot}As_2S_3$; and pyragyrite, $3Ag_2S{\cdot}Sb_2S_3$. About three-fourths of the silver produced is a by-product of the extraction of other metals, copper and lead in particular. *See* SILVER METALLURGY.

Pure silver is a white, moderately soft metal (2.5–3 on Mohs hardness scale), somewhat harder than gold. When polished, it has a brilliant luster and reflects 95% of the light falling on it. Silver is second to gold in malleability and ductility. Its density is 10.5 times that of water. The quality of silver, its fineness, is expressed as parts of pure silver per 1000 parts of total metal. Commercial silver is usually 999 fine. Silver is available commercially as sterling silver (7.5% copper) and in ingots, plate, moss, sheets, wire, castings, tubes, and powder.

Silver, with the highest thermal and electrical conductivities of all the metals, is used for electrical and electronic contact points and sometimes for special wiring. Silver has well-known uses in jewelry and silverware. Silver compounds are used in many photographic materials. In most of its uses, silver is alloyed with one or more other metals. Alloys in which silver is an ingredient include dental amalgam and metals for engine pistons and bearings. *See* PHOTOGRAPHIC MATERIALS; SILVER ALLOYS. [W.E.C.]

Silver alloys Combinations of silver with one or more other metals. Pure silver is very soft and ductile but can be hardened by alloying. Copper is the favorite hardener and normally is employed in the production of sterling silver, which must contain a minimum of 92.5% silver, and also in the production of coin silver.

Silver-copper eutectic and modifications containing other elements such as zinc, tin, cadmium, phosphorus, or lithium are widely used for brazing purposes, where strong joints having relatively good corrosion resistance are required. Where higher strengths at elevated temperature are required, silver-copper-palladium alloys and other silver-palladium alloys are suitable. The addition of a small amount of silver to copper raises the recrystallizing temperature without adverse effect upon the electrical conductivity.

Silver may be alloyed with gold or palladium in any ratio, producing soft and ductile alloys; certain of these intermediate alloys are useful for electrical contacts, where resistance to sulfide formation must be achieved.

Silver has proved to be a useful component for high-duty bearings in aircraft engines, where it may be overlaid with a thin layer of lead and finally with a minute coating of indium. Specially developed alloys of silver with tin, plus small percentages of copper and zinc in the form of moderately fine powder, can be mixed with mercury to yield a mass which is plastic for a time and then hardens, developing relatively high strength despite the fact that it contains about 50% mercury. This material was developed specifically for dental use and is generally known as amalgam, although the term amalgam actually includes all the alloys of mercury with other metals. *See* AMALGAM; SILVER. [E.M.Wis.]

Silver metallurgy The art and science of extracting silver metal economically from various ores, and the reclamation of silver from the myriad types of industrial processes or scrap produced therefrom. It includes all processes of separating silver from its ores, alloys, and solutions, as well as the smelting, refining, and working of the metal and its alloys and compounds. It deals with the technical application of the chemical and physical properties of silver to its concentration, extraction, purification, alloying, working, and compounding to meet the requirements of technical needs.

Chloridization is an extractive process in which silver is precipitated from aqueous solutions. In chloridization methods the silver contained in ores or metallurgical products is first converted by means of a chloridizing roast into a compound which is soluble in water or in certain aqueous solutions. The silver is then precipitated as an insoluble compound by suitable reagents and the precipitate worked for the metal.

The cyanidation process differs only in minor details, such as strength of the solution and time of treatment, from the cyanide process used in the recovery of gold. No preliminary metallurgical treatment other than fine grinding is required. *See* GOLD METALLURGY.

The Parkes process is based on the greater affinity of silver for zinc than for lead. Slab zinc is added to an argentiferous lead bath, the temperature of which has been raised higher than the melting point of the zinc. When the zinc has been melted and thoroughly mixed into the lead bath, the bath temperature is lowered and a silver-zinc alloy separates and floats on the top of the kettle. This zinc crust, as it is now called, is pressed off to remove the excess lead. The resultant high silver-lead retort bullion is then cupeled to recover the silver and gold.

Cupellation is the oldest and most widely known method of separating and recovering gold and silver from lead. The silver-lead bullion is charged to a reverberatory-type cupellation furnace. After the charge has melted, air is blown across the top of the molten bath, causing oxidation of the lead and other impurities which separate as in impure litharge slag, leaving behind the silver and gold as a doré alloy.

By far the most important method of silver production results from the smelting and subsequent treatment of the silver-rich slimes resulting from the electrolytic refining of copper. Slimes which have been leached with sulfuric acid or air are filtered and charged to a reverberatory-type furnace with appropriate fluxes. The resulting melt slag contains most of the base-metal impurities. Upon completion of this step, the material remaining in the furnace consists of gold, silver, selenium, tellurium, and residual base metals, and is called matte. Treatment of the matte eventually yields dore which is then cast into anodes for subsequent electrolytic refining. *See* SILVER. [R.D.Mu.]

Silviculture The theory and practice of controlling the establishment, composition, and growth of stands of trees for any of the goods (including timber, pulp, energy, fruits, and fodder) and benefits (water, wildlife habitat, microclimate amelioration, and carbon sequestration) that they may be called upon to produce. In practicing silviculture, the forester draws upon knowledge of all natural factors that affect trees growing upon a particular site, and guides the development of the vegetation, which is either essentially natural or only slightly domesticated, to best meet the demands of society in general and ownership in particular. Based on the principles of forest ecology and ecosystem management, silviculture is more the imitation of natural processes of forest growth and development than a substitution for them.

The spatial patterns in which old trees are removed and the species that replace them determine the structure and developmental processes of the new stands. If all the trees are replaced at once with a single species, the result is so-called pure stand or monoculture in which all of the trees form a single canopy of foliage that is lifted ever higher as the stand develops. If several species start together from seeds, from small trees already present, or from sprouts, as a single cohort, the different species usually tend to grow at different rates in height. Some are adapted to develop in the shade of their sun-loving neighbors. The result is a stratified mixture. Such stands grow best on soils or in climates, such as in tropical moist forests, where water is not a limiting factor and the vegetation collectively uses most of the photosynthetically active light. If trees are replaced in patches or strips, the result is an uneven-aged stand which may be of one species or many.

These different spatial and temporal patterns of stand structure are created by different methods of reproduction. The simplest is the clear-cutting method, in which virtually all of the vegetation is removed. Although it is sometimes possible to rely on adjacent uncut stands as sources of seed, it is usually necessary to reestablish the new stand by artificial seeding or planting after clear-cutting. The seed tree method differs only in that a limited number of trees are temporarily left on the area to provide seed.

In the shelterwood method, enough trees are left on the cutting area to reduce the degree of exposure significantly and to provide a substantial source of seed. In this method the growth of a major portion of the preexisting crop continues, and the old trees are not entirely removed until the new stand is well established. The three methods just described lead to the creation of essentially even-aged stands.

The choice of methods of regeneration cutting depends on the ecological status of the species and stands desired. Species that characterize the early stages of succession, the so-called pioneers, will endure, and usually require the kind of exposure to sunlight resulting from heavy cutting or, in nature, severe fire, catastrophic windstorms, floods, and landslides. These pioneer species usually grow rapidly in youth but are short-lived and seldom attain large size. The species that attain greatest age and largest size are ordinarily those which are intermediate in successional position and tolerance of shade. Some of them will become established after the severe exposure of clear-cutting, but they often start best with light initial shade such as that created by shelterwood cutting. Their longevity and large size result from the fact that they are naturally adapted to reproduce after disturbances occurring at relatively long intervals. The shade-tolerant species representing late or climax stages in the succession are adapted to reestablish themselves in their own shade. These species represent natural adaptations to the kinds of fatal disturbance caused by insects, disease, and atmospheric agencies rather than to the more complete disturbance caused by fire. *See* ECOLOGICAL SUCCESSION; FOREST ECOSYSTEM.

Much silvicultural practice is aimed at the creation and maintenance of pure, even-aged stands of single species. This approach is analogous to that of agriculture and simplifies administration, harvesting, and other operations. The analogy is often carried to the extent of clear-cutting and planting of large tracts with intensive site preparation, especially with species representative of the early or intermediate stages of succession. Mixed stands are more difficult to handle from the operational standpoint but are more resistant to injury from insects, fungi, and other damaging agencies which usually tend to attack single species. They are also more attractive than pure stands and make more complete use of the light, water, and nutrients available on the site. They usually do not develop unless these site factors are comparatively favorable; where soil moisture or some other factor is limiting, it may be possible for only a single well-adapted species to grow. If the site is highly favorable, as in tropical rainforest, river floodplains, or moist ravines, it is so difficult to maintain pure stands that mixed stands are inevitable.

The application of silviculture involves a number of accessory practices other than cutting. In localities of high fire risks, it may be desirable to burn the slash (logging debris) after cutting. Not only does this reduce the potential fuel, but it may also help the establishment of seedlings by baring the mineral soil or reducing the physical barrier represented by the slash. Slash disposal is most often necessary where the cutting has been very heavy or where the climate is so cold or dry that decay is slow. Deliberate prescribed burning of the litter beneath existing stands of fire-resistant species is sometimes carried out even in the absence of cutting to reduce the fuel for wild fires, to kill undesirable understory species, to enhance the production of forage for wild and domestic animals, and to improve seedbed conditions. *See* FOREST FIRE.

Integrated schedules of treatment for stands are called silvicultural systems. They cover both intermediate and reproduction treatments but are classified and named in terms of the general method of reproduction cutting contemplated. Such programs are evolved for particular situations and kinds of stands with due regard for all the significant biological and economic considerations involved. These considerations include the desired uses of the land, kinds of products and services sought, prospective costs and returns of the enterprise presented by management of the stand, funds available for long-term investment in stand treatments, harvesting techniques and equipment employed, reduction of losses from damaging agencies, and the natural requirements that must be met in reproducing the stand and fostering its growth. *See* FOREST AND FORESTRY; FOREST MANAGEMENT.

[D.M.S.; M.S.A.]

Simple machine Any of several elementary machines, one or more of which is found in practically every machine. The group of simple machines usually includes only the lever, wheel and axle, pulley (or block and tackle), inclined plane, wedge, and screw. However, the gear drive and hydraulic press may also be considered as simple machines. The principles of operation and typical applications of simple machines depend on several closely related concepts. *See* EFFICIENCY; FRICTION; MECHANICAL ADVANTAGE; POWER; WORK.

Two conditions for static equilibrium are used in analyzing the action of a simple machine. The first condition is that the sum of forces in any direction through their common point of action is zero. The second condition is that the summation of torques about a common axis of rotation is zero. Corresponding to these two conditions are two ways of measuring work. In machines with translation, work is the product of force and distance. In machines with rotation, work is the product of torque and angle of rotation. *See* BLOCK AND TACKLE; GEAR DRIVE; HYDRAULIC PRESS; INCLINED PLANE; LEVER; SCREW; TORQUE; WEDGE; WHEEL AND AXLE.

[R.M.Ph.]

Simulation A broad collection of methods used to study and analyze the behavior and performance of actual or theoretical systems. Simulation studies are performed, not on the real-world system, but on a (usually computer-based) model of the system created for the purpose of studying certain system dynamics and characteristics. The purpose of any model is to enable its users to draw conclusions about the real system by studying and analyzing the model. The major reasons for developing a model, as opposed to analyzing the real system, include economics, unavailability of a “real” system, and the goal of achieving a deeper understanding of the relationships between the elements of the system.

Simulation can be used in task or situational training areas in order to allow humans to anticipate certain situations and be able to react properly; decision-making environments to test and select alternatives based on some criteria; scientific research contexts to analyze and interpret data; and understanding and behavior prediction of natural systems, such as in studies of stellar evolution or atmospheric conditions.

With simulation a decision maker can try out new designs, layouts, software programs, and systems before committing resources to their acquisition or implementation; test why certain phenomena occur in the operations of the system under consideration; compress and expand time; gain insight about which variables are most important to performance and how these variables interact; identify bottlenecks in material, information, and product flow; better understand how the system really operates (as opposed to how everyone thinks it operates); and compare alternatives and reduce the risks of decisions.

The word “system” refers to a set of elements (objects) interconnected so as to aid in driving toward a desired goal. This definition has two connotations: First, a system is made of parts (elements) that have relationships between them (or processes that link them together). These relationships or processes can range from relatively simple to extremely complex. One of the necessary requirements for creating a “valid” model of a system is to capture, in as much detail as possible, the nature of these interrelationships. Second, a system constantly seeks to be improved. Feedback (output) from the system must be used to measure the performance of the system against its desired goal. Both of these elements are important in simulation. *See* SYSTEMS ENGINEERING.

Systems can be classified in three major ways. They may be deterministic or stochastic (depending on the types of elements that exist in the system), discrete-event or continuous (depending on the nature of time and how the system state changes in relation to time), and static or dynamic (depending on whether or not the system changes over time at all). This categorization affects the type of modeling that is done and the types of simulation tools that are used.

Models, like the systems they represent, can be static or dynamic, discrete or continuous, and deterministic or stochastic. Simulation models are composed of mathematical and logical relations that are analyzed by numerical methods rather than analytical methods. Numerical methods employ computational procedures to run the model and generate an artificial history of the system. Observations from the model runs are collected, analyzed, and used to estimate the true system performance measures. *See* MODEL THEORY; STOCHASTIC PROCESS.

There is no single prescribed methodology in which simulation studies are conducted. Most simulation stuides proceed around four major areas: formulating the problem, developing the model, running the model, and analyzing the output. Statistical inference methods allow the comparison of various competing system designs or alternatives. For example, estimation and hypothesis testing make it possible to discuss the outputs of the simulation and compare the system metrics.

Many of the applications of simulation are in the area of manufacturing and material handling systems. Simulation is taught in many engineering and business curricula with the focus of the applications also being on manufacturing systems. The characteristics of these systems, such as physical layout, labor and resource utilization, equipment usage, products, and supplies, are extremely amenable to simulation modeling methods. *See* COMPUTER-INTEGRATED MANUFACTURING; FLEXIBLE MANUFACTURING SYSTEM. [J.Pom.]

Sine wave A wave having a form which, if plotted, would be the same as that of a trigonometric sine or cosine function. The sine wave may be thought of as the projection on a plane of the path of a point moving around a circle at uniform speed. It is characteristic of one-dimensional vibrations and one-dimensional waves having no dissipation. *See* HARMONIC MOTION.

The sine wave is the basic function employed in harmonic analysis. It can be shown that any complex motion in a one-dimensional system can be described as the superposition of sine waves having certain amplitude and phase relationships. The technique for determining these relationships is known as Fourier analysis. *See* FOURIER SERIES; WAVE EQUATION; WAVE MOTION; WAVEFORM. [W.J.G.]

Single crystal In crystalline solids the atoms or molecules are stacked in a regular manner, forming a three-dimensional pattern which may be obtained by a three-dimensional repetition of a certain pattern unit called a unit cell. When the periodicity of the pattern extends throughout a certain piece of material, one speaks of a single crystal. A single crystal is formed by the growth of a crystal nucleus without secondary nucleation or impingement on other crystals. *See* CRYSTAL STRUCTURE; CRYSTALLOGRAPHY.

When grown from a melt, single crystals usually take the form of their container. Crystals grown from solution (gas, liquid, or solid) often have a well-defined form which reflects the symmetry of the unit cell. *See* CRYSTAL GROWTH; CRYSTALLIZATION; ZONE REFINING.

Ideally, single crystals are free from internal boundaries. They give rise to a characteristic x-ray diffraction pattern.

Many types of single crystal exhibit anisotropy, that is, a variation of some of their physical properties according to the direction along which they are measured. For example, the electrical resistivity of a randomly oriented aggregate of graphite crystallites is the same in all directions. This anisotropy exists both for structure-sensitive properties, which are strongly affected by crystal imperfections (such as cleavage and crystal growth rate), and for structure-insensitive properties, which are not affected by imperfections (such as elastic coefficients).

The structure-sensitive properties of crystals (for example, strength and diffusion coefficients) seem governed by internal defects, often on an atomic scale. *See* CRYSTAL DEFECTS. [D.T.]

Single sideband An electronic signal-processing technique in which a spectrum of intelligence is translated from a zero reference frequency to a higher frequency without a change of frequency relationships within the translated spectrum. Single-sideband (SSB) signals have no appreciable carrier.

Amplitude-modulated (AM) signals have identical upper and lower sidebands symmetrically located on each side of the translation frequency, which is often called the carrier. The SSB spectrum differs from the AM spectrum in having little or no carrier and only one sideband. *See* AMPLITUDE MODULATION.

In the SSB signal-processing action, the intelligence spectrum to be translated is applied to the signal input port of a balanced modulator. A higher-frequency sinusoidal signal, often called a carrier, is applied to the other input port of this circuit. Its function is to translate the zero reference spectrum to the carrier frequency and to produce the upper and lower sidebands, which are symmetrically located on each side of the carrier. The carrier frequency power is suppressed to a negligible value by the balanced operation of the modulator and does not appear at the output. Generally, the balanced modulator operates at an intermediate frequency which is lower than the frequency of transmission. Following the balanced modulator is a sideband filter which is designed to remove the unwanted sideband signal power and to allow only the desired intelligence spectrum to pass. *See* AMPLITUDE MODULATOR; MODULATOR.

There are many advantages in the use of SSB techniques for communication systems. The two primary advantages are the reduction of transmission bandwidth and transmission power. The bandwidth required is not greater than the intelligence bandwidth and is one-half that used by amplitude modulation. The output power required to give equal energy in the intelligence bandwidth is one-sixth that of amplitude modulation.

Propagation of radio energy via ionospheric refraction provides the possibility for multiple paths of differing path length which can cause a selective cancellation of frequency components at regular frequency spacings. This produces in amplitude modulation a severe distortion of the intelligence because of the critically dependent carrier-to-sideband amplitude and phase relationships. SSB is much less affected under these conditions. [D.M.H.]

Sintering The welding together and growth of contact area between two or more initially distinct particles at temperatures below the melting point, but above one-half of the melting point in kelvins. Since the sintering rate is greater with smaller than with larger particles, the process is most important with powders, as in powder metallurgy and in firing of ceramic oxides.

Although sintering does occur in loose powders, it is greatly enhanced by compacting the powder, and most commercial sintering is done on compacts. Compacting is generally done at room temperature, and the resulting compact is subsequently sintered at elevated temperature without application of pressure. For special applications, the powders may be compacted at elevated temperatures and therefore simultaneously pressed and sintered. This is called hot pressing or sintering under pressure.

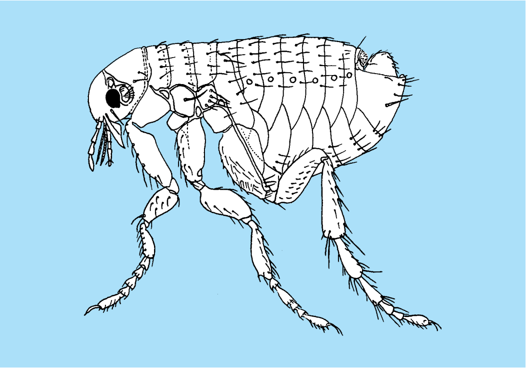
Certain compacts from a mixture of different component powders may be sintered under conditions where a limited amount of liquid, generally less than 25 vol%, is formed at the sintering temperature. This is called liquid-phase sintering, important in certain powder-metallurgy and ceramic applications. *See* CERAMICS; POWDER METALLURGY. [F.V.L.]

Sinus Any space in an organ, tissue, or bone, but usually referring to the paranasal sinuses of the face. In humans, four such sinuses, lined with ciliated, mucus-producing epithelium, communicate with each nasal passage through small apertures. The ethmoid and sphenoid sinuses are located centrally between and behind the eyes. The frontal sinuses lie above the nasal bridge, and the maxillary sinuses are contained in the upper jaw beneath the orbits. The mastoid portion of the temporal bone contains air cells lined with similar epithelium. [T.S.P.]

Siphonaptera An order of insects commonly known as the fleas. These animals are of importance because they are bloodsucking pests of humans and animals and transmit serious diseases from animals to humans.

Fleas in the adult stage are recognized with ease (see illustration). They are small, dark brown in color, laterally flattened, and with three pairs of legs modified for jumping. The body is more or less oval in shape and armed with spines and setae, adapting the flea for living among the hairs of animals. The head is provided with mouthparts modified for sucking blood.

Fleas have a complete metamorphosis; that is, the life history involves four distinct phases: the egg, larva, pupa, and adult.



Human flea, *Pulex irritans*. (*After E. O. Essig, College Entomology, Macmillan, 1942*)

Each adult female flea lays a number of eggs, 400 or more in some species, over a long period of time.

The great majority of species are obscure ectoparasites of mammals, and to a lesser extent birds, and do not affect humans. Host specificity is exhibited in that, ordinarily, a certain taxonomic group of fleas will parasitize a specific taxonomic group of hosts. Nevertheless, some species may leave their favored hosts and attack humans, and these species are the pests and disease carriers. Bubonic plague, which was responsible for millions of deaths in India during the first two decades of this century, is a disease of rats. Murine or endemic typhus fever is another disease transmitted from domestic rats to humans by rat fleas. Flea allergy is the term applied to the severe reactions which sometimes result from flea bites. *See* INSECTA. [I.F.]

Siphonophora An order of the class Hydrozoa of the phylum Coelenterata, characterized by an extremely complex organization of components of several different types, some having the basic structure of a jellyfish, others of a polyp. The components may be connected by a stemlike region or may be more closely united into a compact organism.

Most siphonophores possess a float and are animals of the open seas. Best known is the Portuguese man-of-war, *Physalia*, with a float as much as 16 in. (40 cm) long and tentacles which extend downward for many feet. These animals may be swept shoreward and may make swimming not only unpleasant but dangerous. *See* COELENTERATA; HYDROZOA. [S.Cr.]

Siphonostomatoida An order of Copepoda; all members are parasites of marine and fresh-water fishes or a variety of invertebrate hosts. In fact, it is estimated that 67% of copepod parasites of fishes belong to the Siphonostomatoida. Their obvious success in the parasitic mode of life appears at least in part to be a result of two morphologic adaptations. The first is the modification of the buccal apparatus (mouth and appendages) resulting in a mouth cone that has a small opening near the base through which the mandibles are free to enter. The maxilliae are subchelate or brachiform and serve as the appendage for attachment to the host. The second adaptation is the development of a frontal filament, which is a larval organ of attachment. In those siphono-stomatoids possessing a frontal filament, the brachiform second maxilla may be used to manipulate the frontal organ, and in some species fusion of those two structures forms the attachment structure. *See* COPEPODA; CRUSTACEA; POECILOSTOMATOIDA. [P.A.McL.]

Sipuncula A phylum of sedentary marine vermiform coelomates that are unsegmented, but possibly distantly related to the annelids; they are commonly called peanut worms. Two classes are defined: Sipunculidea and Phascolosomatidea. In all there are 17 genera and approximately 150 species living in a wide variety of oceanic habitats within the sediment or inside any protective shelter such as a discarded mollusk shell, foraminiferan test, or crevice in rock or coral.

Adult sipunculans range in trunk length from 2 to over 500 mm (0.08 to over 20 in.). The shape of the body ranges from almost spherical to a slender cylinder. Sipunculans have a variety of epidermal structures (papillae, hooks, or shields). Many species lack color, but shades of yellow or brown may be present. Internal anatomy is relatively simple. The digestive tract has a straight esophagus and a double-coiled intestine extending toward the posterior end of the body and back terminating in a rectum, sometimes bearing small cecum. A ventral nerve cord with lateral nerves and circumenteric connectives to the pair of cerebral ganglia are present. Two or four pigmented eyespots may be present on the cerebral ganglia, and a chemoreceptor (nuchal organ) is usually present.

Knowledge of the reproductive biology of sipunculans is scanty, and good information on breeding cycles is unavailable for most genera. Most sipunculans are dioecious and lack any sexual dimorphism. These worms play a part in the recycling of detritus and probably consume smaller invertebrates in the process. They are in turn preyed on by fishes and probably other predators (including humans). *See* FEEDING MECHANISMS (INVERTEBRATE). [E.B.Cu.]

Siren (acoustics) A sound source that is based on the regular interruption of a stream of fluid (usually air) by a perforated rotating disk or cylinder. The components of a siren are a source of air, a rotor containing a number of ports which interrupt the airflow at the desired frequency, and ports in a stator through which the air escapes. The air is supplied by a compressor, and a motor drives the rotor. The frequency of the sound wave produced by the siren is the product of the speed of rotation and the number of ports in the rotor. The shape of the rotor and stator ports determines the wave shape at the entrance of the stator port. The stator ports feed into a horn in order to improve radiation. Siren performance parameters are sound power output, acoustic pressure, and efficiency, that is, the ratio of acoustic power output to compressor power. *See* SOUND PRESSURE.

Applications of sirens include acoustic levitation (the use of radiation pressure to levitate small objects), broadband underwater sound projectors, and sonic fatigue (fatigue life and failure of structures subjected to fluctuating pressures generated by acoustic waves). *See* ACOUSTIC LEVITATION.

Electromechanical sirens use an electric motor instead of a compressed air supply to generate the acoustic signal. A second motor spins the rotor. The stator and horn increase the sound power output and efficiency. Electromechanical sirens are widely used as warning devices. *See* SOUND. [B.Li.]]

Sirenia An order of herbivorous aquatic placental mammals, commonly known as sea cows, that includes the living manatees and dugongs and the recently exterminated Steller's sea cow. The order has an extensive fossil record dating from the early Eocene Epoch, some 50 million years ago.

The earliest known sirenians were quadrupedal and capable of locomotion on land. Fossils clearly document the evolutionary transition from these amphibious forms to the modern, fully aquatic species, which have lost the hindlimbs and transformed the forelimbs into paddlelike flippers. The living species have streamlined, fusiform bodies with short necks and horizontal tail fins like those of cetaceans, but no dorsal fins. The skin is thick and nearly hairless. The nostrils are separate, and the ears lack external pinnae.

Sirenians typically feed on aquatic angiosperms, especially seagrasses, but in ecologically marginal situations they also eat algae and even some animal material. They are normally found in tropical or subtropical marine waters, but some have become adapted to fresh water or colder latitudes. Body sizes have ranged from less than 3 m up to 9–10 m (30–33 ft). Sirenians mate and give birth in the water, bearing a single calf (occasionally twins) after about 13–14 months of gestation and then nursing it from one pair of axillary mammae. The closest relatives of sirenians among living mammals are the Proboscidea (elephants). *See* PROBOSCIDEA.

A classification scheme is given below.

Order Sirenia
  Family: Prorastomidae
    Protosirenidae
    Trichechidae
      Subfamily: Miosireninae
        Trichechinae
  Family Dugongidae
      Subfamily: Halitheriinae
        Hydrodamalinae
        Dugonginae [D.P.D.]

Sirius The star α Canis Majoris, also referred to as the Dog Star, the brightest of all the stars in the night sky (apparent magnitude -1.47). Sirius owes its apparent brightness both to its close distance to Earth, only 2.64 parsecs (8.14×10^{13} km or 5.06×10^{13} mi), and to its intrinsic luminosity, which is more than 20 times that of the Sun. It is a main-sequence star of spectral type A1 with an effective temperature of about 9400 K (16,500°F). *See* SPECTRAL TYPE.

Sirius is a very interesting binary system in which the companion is a degenerate star (α CMa B). It is the brightest among the known white dwarfs (apparent magnitude 8.4) and the closest to the Sun. It orbits around the bright star once every 50 years. The luminosity of the white dwarf is 400 times smaller than that of the Sun, which makes it extremely difficult to see because of the overpowering brightness of the nearby primary. Its temperature is estimated to be 24,790 K (44,654°F), much hotter than the primary. The white dwarf's mass is comparable to the Sun, yet is concentrated in a body the size of the Earth. The mean density of the material in α CMa B is about 2×10^6 times that of water, or 2 metric tons/cm^3 (nearly 40 tons/in.^{3}). *See* BINARY STAR; STAR; STELLAR EVOLUTION; WHITE DWARF STAR. [D.W.L.]

Sirocco A southerly or southeasterly wind current from the Sahara or from the deserts of Saudi Arabia which occurs in advance of cyclones moving eastward through the Mediterranean Sea. The sirocco is most pronounced in the spring, when the deserts are hot and the Mediterranean cyclones are vigorous. It is observed along the southern and eastern coasts of the Mediterranean Sea from Morocco to Syria as a hot, dry wind capable of carrying sand and dust great distances from the desert source. The sirocco is cooled and moistened in crossing the Mediterranean and produces an oppressive, muggy atmosphere when it extends to the southern coast of Europe. *See* AIR MASS; WIND. [F.S.]

Sisal A fiber obtained from the leaves of *Agave sisalana*, produced in Brazil, Haiti, and several African countries, including Tanzania, Kenya, Angola, and Mozambique.

Sisal is used mainly for twine and rope, but some of the lower grades are used for upholstery padding and paper. The greatest quantity goes into farm twines, followed by industrial tying twine and rope. Most sisal-fiber ropes made in the United States are small to medium in size, intended for light duty. Sisal is sometimes used for marine cordage in Europe. *See* NATURAL FIBER. [E.G.N.]

Skarn A broad range of rock types made up of calc-silicate minerals such as garnet, regardless of their association with ores, that originate by replacement of precursor rocks. It was a term originally coined by miners in reference to rock consisting of coarse-grained, calc-silicate minerals associated with iron ores in central Sweden. Ore deposits that contain skarn are termed skarn deposits; such deposits are the world's premier sources of tungsten. They are also important sources of copper, iron, molybdenum, zinc, and other metals. Skarns also serve as sources of industrial minerals such as graphite, asbestos, and magnesite. *See* ORE AND MINERAL DEPOSITS; SILICATE MINERALS.

Based on mineralogy, three idealized types of skarn are recognized: calcic skarn characterized by calcium- and iron-rich silicates (andradite, hedenbergite, wollastonite); magnesian skarn characterized by calcium- and magnesium-rich silicates (forsterite, diopside, serpentine); and aluminous skarn characterized by aluminum- and magnesium-rich calc-silicates (grossularite, vesuvianite, epidote). [M.T.E.]

Skeletal system The supporting tissues of animals which often serve to protect the body, or parts of it, and play an important role in the animal's physiology.

Skeletons can be divided into two main types based on the relative position of the skeletal tissues. When these tissues are located external to the soft parts, the animal is said to have an exoskeleton. If they occur deep within the body, they form an endoskeleton. All vertebrate animals possess an endoskeleton, but most also have components that are exoskeletal in origin. Invertebrate skeletons, however, show far more variation in position, morphology, and materials used to construct them.

The vertebrate endoskeleton is usually constructed of bone and cartilage; only certain fishes have skeletons that lack bone. In addition to an endoskeleton, many species possess distinct exoskeletal structures made of bone or horny materials. This dermal skeleton provides support and protection at the body surface.

Various structural components make up the human skeleton, including collagen, three different types of cartilage (hyaline, fibrocartilage, and elastic), and a variety of bone types (woven, lamellar, trabecular, and plexiform). *See* BONE; COLLAGEN; CONNECTIVE TISSUE.

The vertebrate skeleton consists of the axial skeleton (skull, vertebral column, and associated structures) and the appendicular skeleton (limbs or appendages). The basic plan for vertebrates is similar, although large variations occur in relation to functional demands placed on the skeleton.

Axial skeleton. The axial skeleton supports and protects the organs of the head, neck, and torso, and in humans it comprises the skull, ear ossicles, hyoid bone, vertebral column, and rib cage.

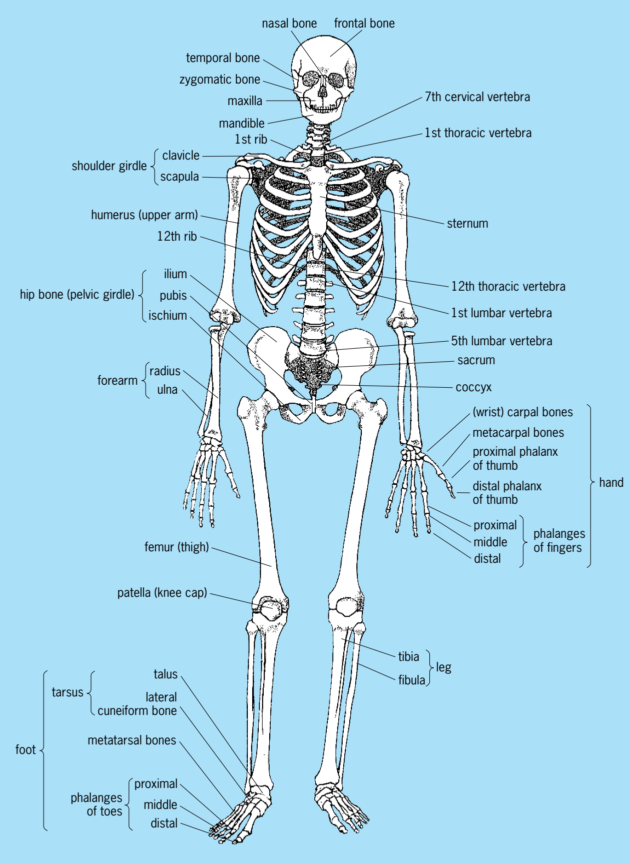
Skull. The adult human skull consists of eight bones which form the cranium, or braincase, and 13 facial bones that support the eyes, nose, and jaws. There are also three small, paired ear ossicles—the malleus, incus, and stapes—within a cavity in the temporal bone. The total of 27 bones represents a large reduction in skull elements during the course of vertebrate evolution. The three components of the skull are the neurocranium, dermatocranium, and visceral cranium. *See* EAR (VERTEBRATE).

The brain and certain sense organs are protected by the neurocranium. All vertebrate neurocrania develop similarly, starting as ethmoid and basal cartilages beneath the brain, and as capsules partially enclosing the tissues that eventually form the olfactory, otic, and optic sense organs. Further development produces cartilaginous walls around the brain. Passages (foramina) through the cartilages are left open for cranial nerves and blood vessels. Endochondral ossification from four major centers follows in all vertebrates, except the cartilaginous fishes. *See* TETRAPODA.

The visceral skeleton, the skeleton of the pharyngeal arches, is demonstrated in a general form by the elasmobranch fishes, where all the elements are cartilaginous and support the jaws and the gills. The mandibular (first) arch consists of two elements on each side of the body: the palatoquadrates dorsally, which form the upper jaw, and Meckel's cartilages, which join ventrally to form the lower jaw. The hyoid (second) arch has paired dorsal hyomandibular cartilages and lateral, gill-bearing ceratohyals. This jaw mechanism attaches to the neurocranium for support. In all jawed vertebrates except mammals, an articulation between the posterior ends of the palatoquadrate and Meckel's cartilages occurs between the upper and lower jaws. The bony fishes have elaborated on the primitive condition, where the upper jaw was fused to the skull and the lower jaw or mandible could move only in the manner of a simple hinge. Teleosts are able to protrude the upper and lower jaws. In the course of mammalian evolution, the dentary of the lower jaw enlarged and a ramus expanded upward in the temporal fossa. This eventually formed an articulation with the squamosal of the skull. With the freeing of the articular bone and the quadrate from their function in jaw articulation, they became ear ossicles in conjunction with the columella, that is, a skeletal rod that formed the first ear ossicle. The remaining visceral skeleton has evolved from jaw and gill structures in the fishes to become an attachment site for tongue muscles and to support the vocal cords in tetrapods. *See* MAMMALIA.

Vertebral column. The vertebral column is an endoskeletal segmented rod of mesodermal origin. It provides protection to the spinal cord, sites for muscle attachment, flexibility, and support, particularly in land-based tetrapods where it has to support the weight of the body (see illustration). Hard, spool-shaped bony vertebrae alternate with tough but pliable intervertebral discs. Each typical vertebral body (centrum) has a bony neural arch extending dorsally. The spinal cord runs through these arches, and spinal nerves emerge through spaces. Bony processes and spines project from the vertebrae for the attachment of muscles and ligaments. Synovial articulations between adjacent vertebrae effectively limit and define the range of vertebral motion.

Vertebral morphology differs along the length of the column. There are two recognized regions in fishes (trunk and caudal) and five in mammals (cervical, thoracic, lumbar, sacral, and caudal), reflecting regional specializations linked to function. Humans have seven cervical, twelve thoracic, five lumbar, five (fused) sacral, and four coccygeal vertebrae. Most amphibians, reptiles, and mammals have seven cervical vertebrae regardless of neck length, whereas the number is variable in birds. Specific modification to the first two cervical vertebrae in most reptiles, birds, and mammals gives the head extra mobility. The presence of large ribs in the thoracic region often limits spinal flexibility. In typical tetrapods, the sacral region is usually modified for support of the pelvic girdle, while the number of caudal vertebrae varies greatly (from 0 to 50) between and within animal groups. *See* SPINE; VERTEBRA.



Human skeleton (anterior view). (*After G. J. Romanes, ed., Cunningham's Textbook of Anatomy, 10th ed., Oxford University Press, 1964*)

Sternum and ribs. Jawed fishes have ribs that help maintain the rigidity and support of the coelomic cavity. These ribs typically follow the connective tissue septa that divide successive muscle groups. In the caudal region, they are often small paired ventral ribs, fused on the midline to form the haemal arches. Ancestral tetrapods had ribs on all vertebrae, and their lengths varied between the vertebral regions. Modern amphibia (frogs and toads) have few thoracic ribs, and these are much reduced and never meet ventrally. Reptiles have varied rib arrangements, ranging from snakes with ribs on each vertebra (important for locomotor requirements) to turtles with only eight ribs which are fused to the inside of the carapace. Flying birds and penguins have a greatly enlarged sternum that links the ribs ventrally. In humans there are twelve pairs of ribs which form a strong but movable cage encompassing the heart and lungs.

Appendicular skeleton. This section of the skeletal system comprises the pectoral and pelvic limb girdles and bones of the free appendages. The girdles provide a supporting base onto which the usually mobile limbs attach.

Pectoral girdle. The pectoral girdle has both endoskeletal and dermal components. The dermal components are derived from postopercular dermal armor of primitive fishes, and are represented by the clavicles and interclavicles in modern vertebrates, except where they are secondarily lost. Endochondral bone forms the scapula. In fishes, the main component of the girdle (the cleithrum) is anchored to the skull by other bony elements. Increased mobility of the girdle is seen in amphibia as it becomes independent of the skull. Further development and skeletal reduction have resulted in a wide range of morphologies, culminating in the paired clavicles and scapulae of mammals.

Birds have fused their paired clavicles and single interclavicle to form the wishbone or furcula. Clavicles have disappeared in certain groups of bounding mammals to allow greater movement of the scapula. Although humans, and most other mammals, have a coracoid process on the scapula, other tetrapods typically have a separate coracoid bracing the scapula against the sternum and forming part of the glenoid fossa.

Pelvic girdle. The pelvic girdle forms by endochondral ossification, that is, the conversion of cartilage into bone. In the fishes, it is a small structure embedded in the body wall musculature just anterior to the cloaca. Each half of the girdle provides an anchor and articulation point for the pelvic fins. In tetrapods, the girdle attaches to the vertebral column to increase its stability and assist in the support of body weight and locomotor forces. Humans, like all other tetrapods, have a bilaterally symmetrical pelvic girdle, each half of which is formed from three fused bones: the ischium, ilium, and pubis. A part of each of these elements forms the acetabulum, the socket-shaped component of the hip joint, that articulates with the femoral head.

All urogenital and digestive products have to pass through the pelvic outlet. This accounts for the pelvic sexual dimorphism seen in most mammals, where the pelvic opening is broader in females, because of the physical demands of pregnancy and parturition. In birds (with the exception of the ostrich and the rhea), both sexes have an open pelvic girdle, a condition also found in female megachiropteran bats (flying foxes), gophers, and mole-rats.

Paired fins and tetrapod limbs. Paired fins in fishes come in different forms, but all are involved in locomotion. In the simplest form they are fairly rigid and extend from the body, functioning as stabilizers, but they are also capable of acting like a wing to produce lift as in sharks. In many fishes, the pectoral fins have narrow bases and are highly maneuverable as steering fins for low-speed locomotion. In addition, some fishes use their pectoral and pelvic fins to walk on the river bed, while others have greatly enlarged pectoral fins that take over as the main propulsive structures.

The basic mammalian pectoral limb consists of the humerus, radius, ulna, carpals, five metacarpals, and fourteen phalanges; and the pelvic limb consists of the femur, tibia, fibula, tarsal, five metatarsals, and fourteen phalanges. A typical bird pelvic limb consists of a femur, tibiotarsus (formed by fusion of the tibia with the proximal row of tarsal bones), fibula, and tarsometatarsus (formed by fusion of metatarsals II–IV), metatarsal I, and four digits (each consisting of two to five phalanges). [M.Ben.]

Skeletal system disorders Disturbances in the structure and function of the skeletal system. The musculoskeletal system provides a rigid structural frame that permits locomotion through muscle action and aids in the functioning of the other organ systems. It also houses blood-forming marrow tissue and stores calcium, phosphorus, magnesium, and a variety of other ionic species. Bone is unique among the tissues of the body in that it responds to injury by re-forming itself identically over time, without scarring.

Trauma. Trauma to the musculoskeletal system can produce a closed or open fracture, a joint dislocation, or a sprain. Fractures are manifested clinically by significant pain, swelling, and false motion, and in long-bone injuries by crepitation. Dislocation occurs more commonly in the shoulder and fingers than in any other joints. Injuries to the ligaments that maintain joint alignment are known as sprains and occur most frequently at the ankle.

Bone healing begins with cellular proliferation and the formation of new blood vessels, which provide provisional stabilization through the formation of a cartilaginous matrix. Calcification of this matrix produces a disorganized bony architecture (callus) that provides mechanical stability at the fracture site until final internal remodeling takes place. The extent and speed of this process depend on both mechanical stress and the age of the individual. *See* BONE.

Neoplasms. Primary neoplasms of bone and connective tissue are relatively uncommon compared with other musculoskeletal conditions. The most frequently occurring malignant neoplasms are multiple myeloma, osteosarcoma, chondrosarcoma, and Ewing's tumor. In young individuals the most common site of a neoplasm is the tibia or femur in the vicinity of the knee, while in older individuals the flat bones, such as the ilium and those of the axial skeleton, are frequently affected.

Benign lesions have many names and are also classified according to the type of tissue primarily affected (bone, cartilage, fibrous tissue). The enchondroma is a lesion of cartilage within the bone; an exostosis is a lesion of cartilage that grows away from bone on a bony pedicle, usually near a joint. Bony lesions include the osteoblastoma and the osteoid osteoma; both of these have the histologic appearance of bone and are benign. Fibrocystic lesions include unicameral bone cysts, fibrous cortical defects, fibrous dysplasia, and giant-cell tumors. Fibrous dysplasia is a developmental lesion that often is characterized by multiply involved bones and is associated with café-au-lait spots on the skin. Unicameral bone cysts occur preferentially on the proximal humerus in adolescent children. They cause thinning of the bone and, occasionally, pathologic fractures. *See* ONCOLOGY; TUMOR.

Metabolic bone disease. Metabolic bone disease is an alteration in the normal bone metabolism. In various metabolic bone diseases, there are disturbances in the balance between osteoblastic and osteoclastic activity that alter the stability of skeletal structures. Vitamin D deficiency results in an inability to mineralize the osteoid, the consequences of which are rickets in children and osteomalacia in adults. Rickets is characterized by shortness of stature and angular deformities of the weight-bearing bones. Osteomalacia is rare but can result when vitamin D is not absorbed through the gastrointestinal tract. It is associated with significant and widespread pain and tenderness of the bones and deformity of the spine and limbs. *See* VITAMIN D.

Osteoporosis, the most common metabolic bone disease, occurs in a variety of diseases. In older persons, it can lead to fracture; thoracic vertebral bodies, the hip, and the wrist are the sites most commonly affected. While postmenopausal and senile osteoporosis results from insufficient bone production (decreased osteoblastic activity) and excessive bone destruction (increased osteoclastic activity), the precise etiology of this disorder is unknown. *See* CALCIUM METABOLISM; OSTEOPOROSIS.

Osteomyelitis. Osteomyelitis is an infection of bone that is the result of either the blood-borne spread of an infectious agent or the secondary contamination of a fracture that has penetrated the skin. The bacterium *Staphylococcus aureus* is the most common causative agent. Acute osteomyelitis is characterized by severe bone tenderness and an unwillingness to use the limb, accompanied by loss of appetite and a fever.

Septic arthritis. Although infection of a joint can result from direct inoculation with an infectious agent, septic arthritis is most often a blood-borne condition. As with osteomyelitis, *S. aureus* is most often responsible. An individual with an infected joint usually experiences muscle spasm, severe tenderness and pain with the slightest movement, elevated temperature, and swelling of the joint.

Osteoarthrosis. Osteoarthrosis is a premature or excessive deterioration of the cartilage surface of a joint. The local deterioration of the cartilage surface is associated with remodeling of the contiguous bone and subsequent secondary inflammation of the membrane lining the joint. When it reaches this stage, it is referred to as osteoarthritis.

Rheumatoid arthritis. Rheumatoid arthritis is one of a family of inflammatory polyarthritides. The condition is thought to be caused by an abnormality in the immune system in which the body produces antibodies against its own tissues. In addition to the joints, other organ systems are often involved. *See* ARTHRITIS; JOINT DISORDERS; SKELETAL SYSTEM. [H.B.Sk.]

Skin The entire outer surface of the body and the principal boundary between the external environment and the body's internal environment of cells and fluids. Skin serves as the primary barrier against the intrusion of foreign elements and organisms into the body, and also as a large and complex sense organ through which animals explore and learn about the external world. In addition, skin functions to maintain the homeostasis of the body's constituents, acting as a barrier to the loss of various ions and nutrients by diffusion. For terrestrial animals, it also serves as an effective barrier to water loss, without which most land animals would rapidly become desiccated and die.

The skin of humans and other mammals can be divided into two distinct regions, the epidermis and the dermis.

The epidermis is the outermost layer of the skin. It varies in thickness from 0.1 mm in most of the protected areas of the skin to approximately 1 mm in those regions exposed to considerable friction, such as the soles of the feet and palms of the hands. The epidermis consists of a great many horizontally oriented layers of cells. The outermost layer, the stratum corneum, consists of many layers of this packed cellular debris, forming an effective barrier to water loss from lower layers of the skin. The lowest levels of stratum germinativum constitute the portion of the skin that contains melanocytes, cells that produce the dark pigment melanin. Different levels of melanin secretion are responsible for the large range of pigmentation observed among humans.

The dermis plays a supportive and nutritive role for the epidermis. The epidermis has no blood supply of its own. However, nutrients and oxygen are apparently provided by diffusion from the blood supply of the underlying dermis. The average thickness of the dermis is 1–3 mm. It is in this layer that the sebaceous and sweat glands are located and in which the hair follicles originate. The products of all these sets of glands are derived from the rich blood supply of the dermis. Hair, sweat glands, and mammary glands (which are modified sweat glands) are skin inclusions unique to mammals. *See* HAIR; INTEGUMENTARY PATTERNS; SWEAT GLAND; THERMOREGULATION. [A.F.Be.]

Skin disorders The skin is subject to localized and generalized disorders, as well as those of primary occurrence in the skin and those secondary to involvement of other tissue. Diseases and disorders may affect any of the structures of the skin. They may be caused by external agents, either infectious or noninfectious, or by the abnormal accumulation of normal or abnormal skin elements, either inborn or acquired.

Infectious diseases. These are classified by the type of infectious agent—bacterial, parasitic, fungal, or viral.

Bacterial infections are distinguished clinically by the skin layer or appendage affected, but treatment is based upon the organism causing the infection. Impetigo and cellulitis are the most common infections of skin. Both infections may be caused by streptococcus, including group B hemolytic streptococcus, and staphylococcus, often species resistant to penicillin. Skin appendages such as hair follicles may be similarly infected. *See* ANTIBIOTIC; DRUG RESISTANCE; STAPHYLOCOCCUS; STREPTOCOCCUS.

Parasitic skin conditions are most often seen in epidemics among individuals who are in close contact, or where hygiene is poor. Head, body, and pubic lice, and scabies are the most common. Pubic lice and scabies are also often transmitted by sexual contact. *See* MEDICAL PARASITOLOGY.

Fungal infections are extremely common. In the United States, most fungal infections in humans are with species incapable of infecting tissue other than keratinized epidermis. These organisms are known as dermatophytes; they cause tinea pedis (athlete's foot), tinea cruris (some forms of jock itch), and tinea capitis (a scalp condition responsible for some forms of hair loss). *See* MEDICAL MYCOLOGY.

Viral diseases often involve the skin; however, viral warts (verruca vulgaris) and molluscum contagiosum are the primary examples of viral diseases that affect only the skin. Both are characterized by single or multiple, somewhat contagious, skin tumors that usually are small but can in rare instances exceed 0.4 in. (1 cm) in diameter. *See* ANIMAL VIRUS; CHICKENPOX AND SHINGLES; HERPES; MEASLES; SMALLPOX.

Inflammatory disease. Most itchy rashes are due to inflammation of the skin; they are usually known as eczema or dermatitis. In the acute stage, eczematous dermatitis is characterized by a vesicular, oozing condition. Seborrheic dermatitis is a common eczematous condition affecting primarily the areas of skin that bear sebaceous glands, that is, scalp, central face, chest, axilla, and groin.

Hereditary disease. Atopic dermatitis is the skin manifestation of atopy, a clinically apparent hypersensitivity. This condition may also be associated with asthma and pollen allergies. Psoriasis is a common disease of unknown etiology. The typical psoriasis consists of well-defined patches and plaques of red skin with a silvery scale that often results in pinpoint bleeding when removed. The most common and persistent sites are the elbows, knees, and scalp, but any area of skin may be involved; there may be significant morbidity and disability.

Other conditions. Acne vulgaris is an extremely common skin disorder, affecting 80–90% of young adults, usually during adolescence. The pilosebaceous organ of the skin is the primary target, particularly the sebaceous gland, its duct, and the infundibulum of the hair follicle. In addition to increased production of sebum, bacteria contribute to the development of acne lesions. These lesions consist of open and closed comedones (blackheads), papules, pustules, and cysts.

Reactions to ingested materials, such as food or medications, often appear in the skin, usually either as a red, itchy, measlelike rash or as urticaria (hives). These reactions indicate allergy to the material, which must then be avoided. *See* ALLERGY.

Neoplasms. Skin neoplasms may be benign or malignant, congenital or acquired, and they may arise from any component of the skin. Almost all skin neoplasms are benign and acquired. The common mole (melanocytic nevus) is a neoplasm of benign melanocytes; usually it is acquired, but it may be present at birth, when it is often known as a birthmark. Other common congenital nevi or birthmarks are of vascular origin, including strawberry and cavernous hemangiomas and port wine stains.

Malignant neoplasms may arise from cellular elements of the epidermis or dermis, or by infiltration of the skin by malignant cells arising from other tissues. By far the most common are basal cell and squamous cell cancers, which arise from basal and squamous keratinocytes of the epidermis, respectively. They usually are characterized by a nonhealing sore, persistent red scaling or crusting patch, or a slowly growing pearly nodule on skin that has been exposed to the sun; they occur mostly on the head, neck, hands, and arms.

Malignant melanoma arises from the pigment-forming melanocyte, and thus it is usually pigmented. It is a metastasizing cancer that is often fatal if not removed surgically in the early stage. It can be recognized as a pigmented lesion, often thought to be a benign nevus initially, that increases in size, changes color, particularly with admixtures of black, blue, red, or white along with the usual tans or browns; and it becomes irregular in size and shape. *See* CANCER (MEDICINE).

Two unusual multicentric primary skin malignancies are mycosis fungoides and Kaposi's sarcoma. Mycosis fungoides is a lymphoma of the skin, that may remain confined to the skin for 10 or more years before eventually spreading to internal organs and causing death. It may be extremely difficult to diagnose, both clinically, when it can appear only as eczematous patches, and histologically, for months or years. Kaposi's sarcoma occurs in two forms, the classic form seen on the legs of elderly Mediterranean men, and a form associated with HIV-1 infection and AIDS that may occur on any part of the body. It is derived from skin blood vessels, is multicentric, and usually appears as red to violet patches, plaques, or nodules. It is usually not fatal, although it may eventually spread to internal organs and may cause significant morbidity. There are numerous other primary skin cancers, but they are rare. *See* ACQUIRED IMMUNE DEFICIENCY SYNDROME (AIDS); SKIN. [A.N.M.]

Skin effect (electricity) The tendency for an alternating current to concentrate near the outer part or "skin" of a conductor. For a steady unidirectional current through a homogeneous conductor, the current distribution is uniform over the cross section; that is, the current density is the same at all points in the cross section. With an alternating current, the current is displaced more and more to the surface as the frequency increases. The conductor's effective cross section is therefore reduced so the resistance and energy dissipation are increased compared with the values for a uniformly distributed current. The effective resistance of a wire rises significantly with frequency; for example, for a copper wire of 1-mm (0.04-in.) diameter, the resistance at a frequency of 1 MHz is almost four times the dc value. *See* ALTERNATING CURRENT; ELECTRICAL RESISTANCE.

A skin depth or penetration depth δ is frequently used in assessing the results of skin effect; it is the depth below the conductor surface at which the current density has decreased to $1/e$ (approximately 37%) of its value at the surface. This concept applies strictly only to plane solids, but can be extended to other shapes provided the radius of curvature of the conductor surface is appreciably greater than δ.

At a frequency of 60 Hz the penetration depth in copper is 8.5 mm (0.33 in.); at 10 GHz it is only 6.6×10^{-7} m. Waveguide and resonant cavity internal surfaces for use at microwave frequencies are therefore frequently plated with a high-conductivity material, such as silver, to reduce the energy losses since nearly all the current is concentrated at the surface. Provided the plating material is thick compared to δ, the conductor is as good as a solid conductor of the coating material. *See* CAVITY RESONATOR; MICROWAVE; WAVEGUIDE. [F.A.Be.]

Skin test A procedure for evaluating the immunity status, involving the introduction of a reagent into or under the skin. Certain toxic antigens applied in minute doses will give a visible, but readily tolerated, lesion if less than a threshold amount of antibody is present in the skin. Examples are the Schick test for diphtheria antitoxin and the Dick test for scarlet fever antitoxin. If sufficient antibody is present, the toxin will be largely or completely neutralized, and the lesion will be minimal or absent. False positive reactions occur in allergies to the reagent toxin, but these can be controlled with inactivated toxins. Other tests involve substances that are not reactive with normal individuals, but give a visible skin reaction in the presence of antibodies acquired as a result of hypersensitivity or allergy to an infecting organism. A positive reaction is thus presumptive for previous contact with a specific infectious agent, for example, the tuberculin and Mantoux tests for tuberculosis, and the Mallein test for glanders. In a few instances, antibody may be injected as a reagent and the neutralization of toxins present in the skin observed, as in the Schultz-Charlton blanching test in scarlet fever. [H.P.T.]

Skink A cosmopolitan reptile belonging to the family Scincidae. They are small- to medium-sized, mostly terrestrial or fossorial lizards with a cylindrical body and short legs; in some instances the legs are vestigial. The body scales have cores of bone. In many species the eyelids are transparent. Skinks exhibit pleurodont dentition; that is, the teeth are attached on the side of the jaw. Most species are ovoviviparous. Three genera, *Neoseps*, *Lygosoma*, and *Eumeces*, occur in the United States. A number of species of *Tiliqua*, largest of the skinks, inhabit Malaysia and Australia. *See* REPTILIA; SQUAMATA. [C.B.C.]

Skunk Any one of a group of carnivores in the family Mustelidae, which also includes otters, weasels, badgers, and martens. Skunks are found only in the New World and range from North America to South America, with six species in the United States. They are characterized by their glossy black and white coat and two musk glands at the base of the tail.

The common striped skunk (*Mephitis mephitis*) has a white stripe on each side running into the tail. These animals are terrestrial and somewhat fossorial (burrowing). They are carnivores primarily but eat vegetation such as seeds, leaves, and nuts during the winter. During the summer they feed on insects, fruit, eggs, and rodents. The spotted skunks (*Spilogale*) range from the eastern United States to Colorado and Wyoming. *See* CARNIVORA; MAMMALIA; MARTEN; OTTER; WEASEL. [C.B.C.]

Skutterudite A mineral with composition $(Co,Ni)AS_3$, an ore of cobalt and nickel. Commonly the mineral is massive with metallic luster and tin-white color. The hardness is $5^1/_2$–6 on Mohs scale and the specific gravity 6.6. Skutterudite is found at Freiberg, Annaberg, and Schneeberg in Germany, and at Cobalt, Ontario. *See* COBALT; NICKEL. [C.S.Hu.]

Slate Any of the deformed fine-grained, mica-rich rocks that are derived primarily from mudstones and shales, containing a well-developed, penetrative foliation that is called slaty cleavage. Slaty cleavage is a secondary fabric element that forms under low-temperature conditions (less than 540°F or 300°C), and imparts to the rock a tendency to split along planes. It is a type of penetrative fabric; that is, the rock can be split into smaller and smaller pieces, down to the size of the individual grains. If there is an obvious spacing between fabric elements (practically, greater than 1 mm), the fabric is called spaced. Slates typically contain clay minerals (for example, smectite), muscovite/illite, chlorite, quartz, and a variety of accessory phases (such as epidote or iron oxides). Under increasing temperature conditions, slate grades into phyllite and schist. *See* ARGILLACEOUS ROCKS; CLAY MINERALS; PHYLLITE; SCHIST; SHALE.

Slaty cleavage is defined by a strong dimensional preferred orientation of clay in a very clay rich, low-grade metamorphic rock, and the resulting rock is a slate. Slaty cleavage tends to be smooth and planar. Coupled with the penetrative nature of slaty cleavage, these characteristics enable slates to split into very thin sheets. This and the durability of the rock are reasons why slates are used in the roofing industry, in the tile industry, and in the construction of pool tables. [B.A.V.D.P.]

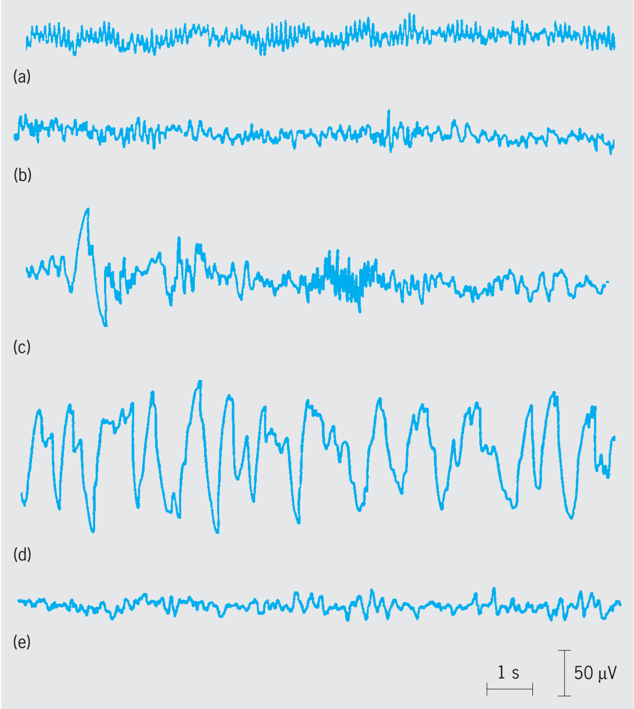
Sleep and dreaming Sleep is generally defined as an easily reversible (with strong or meaningful sensory stimuli), temporary, periodic state of suspended behavioral activity, unresponsiveness, and perceptual disengagement from the environment. Sleep should not be considered a state of general unconsciousness. The sleeper is normally unconscious (but not always) of the nature of events in the surrounding environment. However, the sleeper's attention may be fully engaged in experiencing a dream. And if reportability is accepted as a sufficient condition for conscious mental processes, any dream that can be recalled must be considered conscious. Dreaming, then, can be simply defined as the world-modeling constructive process through which people have experiences during sleep, and a dream is just whatever the dreamer experienced while sleeping.

Nature of sleep. In general, biological organisms do not remain long in states of either rest or activity. For example, if a cat's blood sugar level drops below a certain point, the cat is motivated by hunger to venture from its den in search of a meal. After satisfying the urge to eat, the cat is no longer motivated to expend energy tracking down prey; now its biochemical state motivates a return to its den, to digest in peace, conserve energy, and generally engage in restful, regenerative activities, including sleep. This example tracks a cat through one cycle of its basic rest-activity cycle (BRAC). Such cyclic processes are ubiquitous among living systems.

Sleep and wakefulness are complementary phases of the most salient aspects of the brain's endogenous circadian rhythm, or biological clock. Temporal isolation studies have determined the biological clock in humans to be slightly longer than 24 hours. Several features of sleep are regulated by the circadian system, including sleep onset and offset, depth of sleep, and rapid eye movement (REM) sleep intensity and propensity. In the presence of adequate temporal cues (for example, sunlight, noise, social interactions, and alarm clocks), the internal clock keeps good time, regulating a host of physiological and behavioral processes. *See* BIOLOGICAL CLOCKS; NORADRENERGIC SYSTEM.

Sleep is not a uniform state of passive withdrawal from the world; a version of the BRAC continues during sleep, showing a periodicity of approximately 90 minutes. There are two distinct kinds of sleep: a quiet phase (also known as quiet sleep or QS, slow-wave sleep) and an active phase (also known as active sleep or AS, REM sleep, paradoxical sleep), which are distinguished by many differences in biochemistry, physiology, psychology, and behavior. Recordings of electrical activity changes of the brain (electroencephalogram or EEG), eye movements (electrooculogram or EOG), and chin muscle tone (electromyogram or EMG) are used to define the various stages and substages of sleep. *See* ELECTROENCEPHALOGRAPHY.

Sleep cycle. If sleepy enough, most people can fall asleep under almost any condition. After lying in bed for a few minutes in a quiet, dark room, drowsiness usually sets in. The subjective sensation of drowsiness can be objectively indexed by a corresponding change in brain waves (EEG activity): formerly continuous alpha rhythms (see illustration) gradually break up



Human EEG associated with different stages of sleep and wakefulness. (*a*) Relaxed wakefulness (eyes shut) shows rhythmic 8–12-Hz alpha waves. (*b*) Stage 1 non-REM sleep shows mixed frequencies, especially 3–7-Hz theta waves. (*c*) Stage 2 non-REM sleep shows 12–14-Hz sleep spindles and K-complexes. (*d*) Delta sleep shows large-amplitude ($>75\ \mu$V) 0.5–2-Hz delta waves. (*e*) REM sleep shows low-amplitude, mixed frequencies with sawtooth waves.

into progressively shorter trains of regular alpha waves and are replaced by low-voltage mixed-frequency EEG activity. When less than half of an epoch [usually the staging epoch is the 20–30 seconds it takes to fill one page of polygraph (sleep recording) paper] is occupied by continuous alpha rhythm, sleep onset is considered to have occurred and stage 1 sleep is scored. At this stage, the EOG usually reveals slowly drifting eye movements (SEMs) and muscle tone might or might not decrease. Awakenings at this point frequently yield reports of hypnagogic (leading into sleep) imagery, which can often be extremely vivid and bizarre.

Stage 1 is a very light stage of sleep described by most subjects as "drowsing" or "drifting off to sleep." Normally, it lasts only a few minutes before further EEG changes occur, defining another sleep stage. It is at this point that startlelike muscle jerks known as hypnic myoclonias or hypnic jerks occasionally briefly interrupt sleep. As the subject descends deeper into sleep, the EEG of stage 2 sleep is marked by the appearance of relatively high-amplitude slow waves called K-complexes as well as 12–14-Hz rhythms called sleep spindles. The EOG would generally indicate little eye movement activity, and the EMG would show somewhat decreased muscle tone. Reports of mental activity from this stage of sleep are likely to be less bizarre and more realistic than those from stage 1. However, light sleepers sometimes report lengthy and vivid dreams upon awakening from stage 2 sleep.

After several minutes in stage 2, high-amplitude slow waves (delta waves) gradually begin to appear in the EEG. When at least 20% of an epoch is occupied by these (1–2-Hz) delta waves, stage 3 is defined. Usually this slow-wave activity continues to increase until it completely dominates the appearance of the EEG. When the proportion of delta EEG activity exceeds 50% of an epoch, the criterion for the deepest stage of sleep, stage 4, is met. During stages 3 and 4, often collectively referred to as delta sleep, the EOG shows few genuine eye movements but is obscured by the high-amplitude delta waves. Muscle tone is normally low, although it can be remarkably high, as when sleepwalking or sleep-talking occurs. Recall of mental activity on arousal from delta sleep is generally very poor and fragmentary and is more thoughtlike than dreamlike. It should be noted that cognitive functioning immediately after abrupt wakening from sleep is likely to carry over some of the characteristics of the preceding sleep state. This phenomenon, known as sleep inertia, can be used as an experimental tool for studying cognition during different stages of sleep.

After about 90 minutes, the progression of sleep stages is reversed, back through stage 3 and stage 2 to stage 1 again. But now the EMG shows virtually no activity at all, indicating that muscle tone has reached its lowest possible level, and the EOG discloses the occurrence of rapid eye movements—at first only a few at a time, but later in dramatic profusion. This is REM (or active) sleep. Breathing rate and heart rate become more rapid and irregular, and both males and females show signs of sexual arousal. Brain metabolic rate increases to levels that typically exceed the waking state average. This state of intense brain activation is normally accompanied by experiences that seem vividly real while they last, but often vanish within seconds of waking. When people are abruptly awakened from REM sleep, 80–90% of the time they recall vivid and sometimes extremely detailed dreams.

While all this activity is happening in the brain, the body remains almost completely still (except for small twitches), because it is temporarily paralyzed during REM sleep to prevent dreams from being acted out. The brainstem system that causes the paralysis of REM sleep does not always inactivate immediately upon awakening. The resulting experience, known as sleep paralysis, can be terrifying, but it is quite harmless and normal if it occurs only occasionally. However, frequent sleep paralysis can be a symptom of a disorder of REM sleep called narcolepsy. *See* SLEEP DISORDERS.

After a REM period lasting perhaps 5 to 15 minutes, a young adult will typically go back through the preceding cycle stages, dreaming vividly three or four more times during the remainder of the night, with two major modifications. First, decreasing amounts of slow-wave EEG activity (stages 3 and 4 or delta sleep) occur in each successive cycle. Later in the night, after perhaps the second or third REM period, no delta sleep appears on the EEG at all, only non-REM, stage-2, and REM sleep. Second, as the night proceeds, successive REM periods tend to increase in length, up to a point. The fact that for humans most REM occurs in the last portion of the sleep cycle as dawn approaches suggests that REM serves a function related to preparation for waking activity.

Finally, after four or five periods of dreaming sleep, the sleeper wakes up (for perhaps the tenth time during the night) and gets up for the day. It may be difficult to believe that brief awakenings occur this frequently during an average night; however, they are prompty forgotten. This retrograde amnesia is a normal feature of sleep: information in short-term memory at sleep onset is usually not transferred into more permanent storage.

Evolution and function of sleep. Most organisms are adapted to either the dark or light phase of the day. Therefore, a biological process that limits activity to the phase of the cycle to which the organism is adapted will enhance survival. Most likely sleep developed out of the rest phase of the BRAC, allowing organisms to minimize interactions with the world during the less favorable phase, while engaging in a variety of internal maintenance operations. The fact that different species have many differences in sleep structure, process, and function fits with the idea that sleep serves the specific adaptive needs of each species. Quiet sleep appears to be an older form of sleep with simpler and more universal functions related to energy conservation, growth, and restoration. Active sleep is a mammalian invention with functions that appear to be related to specifically mammalian needs. The portion of total sleep composed of

REM is at its highest level perinatally: newborn humans spend 8 hours per day in REM sleep, with even more time during the last 6 weeks before birth. The time of maximal REM corresponds to the time of maximal growth of the brain. A number of theorists suggest that this points to the main evolutionary function of REM: to provide a source of endogenous stimulation supporting the unfolding of genetic programming and self-organization of the brain. The fact that REM time does not decrease to zero after the full development of the nervous system suggests secondary adaptive advantages afforded by REM during adulthood, which may include facilitation of difficult learning and preparation of the brain for optimal functioning on arousal.

Although the modern understanding of sleep and dreaming has had the benefit of half a century of scientific research, there are still no simple and conclusive answers to the questions of why we sleep.

Dreams. From the biological perspective, the basic task of the brain is to predict and control the organism's actions and regulate those actions to achieve optimal outcomes (in terms of survival and reproduction). To accomplish this task, the brain in some sense internally "models" the world. The waking brain bases the features of its world model primarily on the current information received from the senses and secondarily on expectations derived from past experience. In contrast, the sleeping brain acquires little information from the senses. Therefore in sleep, the primary sources of information available to the brain are the current motivational state of the organism and past experience. According to this theory, dreams result from brains using internal information to create a simulation of the external world, in a manner directly parallel to the process of waking perception, minus most sensory input. *See* Perception. [S.LaB.]

Sleep disorders Sleep is a reversible state during which the individual's voluntary functions are suspended but the involuntary functions, such as circulation and respiration, are uninterrupted; the sleeping subject assumes a characteristic posture with relative immobility and decreased responses to external stimuli.

The sleep state can be divided into nonrapid eye movement (NREM) and rapid eye movement (REM) sleep. NREM sleep is divided into four stages based on electroencephalographic criteria. The first REM in a normal adult occurs 60–90 min after sleep onset, and there are usually four or five NREM-REM cycles, each lasting for 90–110 min. Most dreams occur during REM sleep. The sleep-wake pattern for humans follows a circadian rhythm. An average adult needs approximately 7–8 hours of sleep, but elderly people have frequent awakenings.

Clinical disorders. Sleep disorders are classified as dyssomnias (intrinsic, extrinsic, or circadian rhythm disorders), parasomnias, and disorders associated with medical, psychiatric, and neurological illnesses. Obstructive sleep apnea syndrome, narcolepsy, psychophysiological and idiopathic insomnia, and restless legs syndrome are examples of intrinsic sleep disorders. Extrinsic sleep disorders include inadequate sleep hygiene, insufficient sleep syndrome, and hypnotic-, stimulant-, and alcohol-dependent sleep disorders. Circadian-rhythm disorders include jet lag and shift-work sleep disorders.

Parasomnias are characterized by abnormal movements or behavior intruding into sleep (for example, sleep walking, sleep terrors, sleep talking, nightmares, sleep paralysis, tooth grinding, and bed wetting).

Excessive daytime sleepiness, insomnia (sleeplessness), and abnormal movements and behavior during sleep are the major sleep complaints. An individual with insomnia may have difficulty initiating or maintaining sleep; repeated awakenings or early morning awakenings; or daytime fatigue and impairment of performance. Individuals with hypersomnia complain of excessive daytime sleepiness. Circadian-rhythm sleep disorders may be associated with either insomnia or hypersomnia.

There are two forms of sleep apnea. In central apnea, both the airflow at the mouth and nose and the effort by the diaphragm decrease. In obstructive apnea, the airflow stops but the effort by the diaphragm continues. Obstructive sleep apnea syndrome is common in middle-aged and elderly obese men.

Narcoleptic sleep attacks usually begin in individuals between the ages of 15 and 25. Narcolepsy is characterized by an irresistible desire to sleep, and the attacks may last 15–30 min. Other symptoms may include fearful dreams or feeling of loss of power at sleep onset or offset. Narcolepsy cannot be cured.

The restless legs syndrome occurs during middle age and is characterized by intense disagreeable feelings in the legs at rest and repose with compulsion to move the legs to get relief. Most individuals with this problem also have periodic limb movements in sleep.

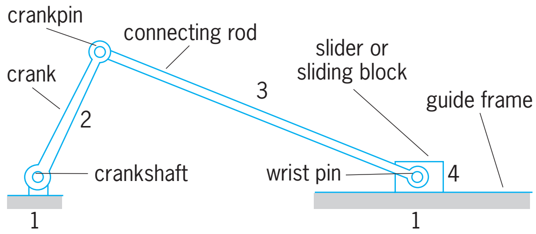
The most common cause of insomnia is psychiatric or psychophysiologic disorder (for example, depression, anxiety, or stress), but other causes include medical disorders or pain. Early morning awakening is characteristic of depression.

Diagnosis and treatment. Overnight polysomnography involves recording of brain waves, muscle activities, eye movements, heart activity, airflow at the nose and mouth, respiratory effort, and oxygen saturation. Polysomnography is needed for individuals with excessive daytime sleepiness, narcolepsy, parasomnias, restless legs-period limb movements, and nocturnal seizures. The multiple sleep latency test is important in documenting pathologic sleepiness and diagnosing narcolepsy; it records brain waves, muscle activities, eye movements, and heart activity.

Treatment of obstructive sleep apnea syndrome consists of avoidance of sedatives or alcohol consumption, weight loss, and use of continuous positive airway pressure which will open the upper airway passage. Narcolepsy is treated by stimulants and short naps. Cataplexy is treated with tricyclics. Chronic insomnia can best be treated by sleep hygiene and behavioral modification. Most parasomnias do not require special treatment; however, psychotherapy may be helpful in some cases. Circadian-rhythm disorders may be treated by bright light and chronotherapy. *See* Biological clocks; Sleep and dreaming. [S.Cho.]

Slider-crank mechanism A four-bar linkage with output crank and ground member of infinite length. A slider crank (see illustration) is most widely used to convert reciprocating to rotary motion (as in an engine) or to convert rotary to reciprocating motion (as in pumps), but it has numerous other applications. Positions at which slider motion reverses are called dead centers. When crank and connecting rod are extended in a straight line and the slider is at its maximum distance from the axis of the crankshaft, the position is top dead center (TDC); when the slider is at its minimum distance from the axis of the crankshaft, the position is bottom dead center (BDC).

The conventional internal combustion engine employs a piston arrangement in which the piston becomes the slider of the slider-crank mechanism. Radial engines for aircraft employ a single master connecting rod to reduce the length of the crankshaft. The master rod, which is connected to the wrist pin in a piston, is part of a conventional slider-crank mechanism. The other pis-



Principal parts of slider-crank mechanism.

tons are joined by their connecting rods to pins on the master connecting rod.

To convert rotary motion into reciprocating motion, the slider crank is part of a wide range of machines, typically pumps and compressors. Another use of the slider crank is in toggle mechanisms, also called knuckle joints. The driving force is applied at the crankpin so that, at TDC, a much larger force is developed at the slider. *See* FOUR-BAR LINKAGE. [D.P.Ad.]

Slip (electricity) A numerical value used in describing the performance of electrical couplings and induction machines. In an electrical coupling, slip is defined simply as the difference between the speeds of the two rotating members. In an induction motor, slip is a measure of the difference between synchronous speed and shaft speed.

When the stator windings of an induction motor are connected to a suitable alternating voltage supply, they set up a rotating magnetic field within the motor. The speed of rotation of this field is called synchronous speed, and is given by Eq. (1) or Eq. (2),

$$\omega_s = \frac{4\pi f}{p} \qquad \text{rad/s} \tag{1}$$

$$n_s = 120\frac{f}{p} \qquad \text{rev/min} \tag{2}$$

where f is the line frequency and p is the number of magnetic poles of the field. The number of poles is determined by the design of the windings. In accord with Faraday's voltage law, a magnetic field can induce voltage in a coil only when the flux linking the coil varies with time. If the rotor were to turn at the same speed as the stator field, the flux linkage with the rotor would be constant. No voltages would be induced in the rotor windings, no rotor current would flow, and no torque would be developed. For motor action it is necessary that the rotor windings move backward relative to the magnetic field so that Faraday's law voltages may be induced in them. That is, there must be slip between the rotor and the field. *See* ELECTROMAGNETIC INDUCTION; INDUCTION MOTOR.

The amount of slip may be expressed as the difference between the field and rotor speeds in revolutions per minute or radians per second. However, the slip of an induction motor is most commonly defined as a decimal fraction of synchronous speed, as in Eq. (3) or Eq. (4). Here n is the motor speed in

$$s = \frac{n_s - n}{n_s} \tag{3}$$

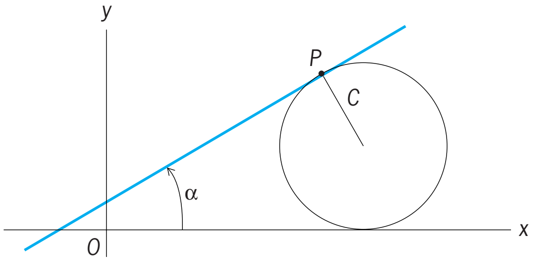
$$s = \frac{\omega_s - \omega}{\omega_s} \tag{4}$$

revolutions per minute, ω is its speed in radians per second, and s is the slip, or more properly the per unit slip. Typical full-load values of slip for an induction motor range from 0.02 to 0.15, depending on rotor design. Slip is sometimes expressed in percent of synchronous speed, rather than per unit. If an induction machine is driven faster than synchronous speed, the slip becomes negative, and the machine acts as a generator, forcing energy back into the electrical supply line. *See* ELECTRIC ROTATING MACHINERY. [G.McP.]

Slip rings Electromechanical components which, in combination with brushes, provide a continuous electrical connection between rotating and stationary conductors. Typical applications of slip rings are in electric rotating machinery, synchros, and gyroscopes. Slip rings are also employed in large assemblies where a number of circuits must be established between a rotating device, such as a radar antenna, and stationary equipment.

Slip rings are usually constructed of steel with the cylindrical outer surface concentric with the axis of rotation. Insulated mountings insulate the rings from the shaft and from each other. Conducting brushes are arranged about the circumference of the slip rings and held in contact with the surface of the rings by spring tension. *See* ELECTRIC ROTATING MACHINERY; MOTOR. [A.R.E.]

Slope The trigonometric tangent of the angle α that a line makes with the x axis. In the illustration the slope of a plane curve C at a point P of C is the slope of the line that is tangent to C at P. If $y = f(x)$ is an equation in rectangular coordinates of curve C, the slope of C at $P(x_0, y_0)$ is the value of the derivative $dy/dx = f'(x)$ at P, denoted by $f'(x_0)$, and hence an equation of the nonvertical tangent to C at P is $y - y_0 = f'(x_0)\,(x - x_0)$. *See* ANALYTIC GEOMETRY; CALCULUS. [L.M.Bl.]



Slope of a curve.

Sloth A mammal, found exclusively in Central and South America, of the family Bradypodidae in the order Edentata. These animals are all slow-moving, arboreal species that cling to branches upside down by means of long, curved claws, and are difficult if not impossible to dislodge. The long hairs of the fur, which are a mixture of white, black, brown, and yellow or green, are unusual in that they are grooved. Algae inhabit the grooves, being green when conditions are damp and turning yellow in times of drought. The sloth has a short stumpy tail, round eyes, a small mouth, and horny lips which assist in eating leaves, a preferred food. The small pinnae of the ears are hidden in the fur. *See* EDENTATA. [C.B.C.]

Slow neutron spectroscopy The use of beams of slow neutrons, from nuclear reactors or nuclear accelerators, in studies of the structure or structural dynamics of solid, liquid, or gaseous matter. Studies of the chemical or magnetic structure of substances are usually referred to under the term neutron diffraction, while studies of atomic and magnetic dynamics go under the terms slow neutron spectroscopy, inelastic neutron scattering, or simply neutron spectroscopy. *See* NEUTRON DIFFRACTION; NUCLEAR REACTOR; PARTICLE ACCELERATOR; SPECTROSCOPY; X-RAY DIFFRACTION.

In a neutron spectroscopy experiment, a beam of neutrons is scattered by a specimen and the scattered neutrons are detected at various angles to the initial beam. From these measurements, the linear momenta of the incoming and outgoing neutrons (and the vector momentum changes experienced by individual neutrons) can be computed. In general, just those neutrons which have been scattered once only by the specimen are useful for analysis; the specimen must be "thin" with respect to neutron scattering power as well as to neutron absorption. In practice, the experiments are usually intensity-limited, since even the most powerful reactors or accelerators are sources of weak luminosity when, as here, individual slow neutrons are to be considered as quanta of radiation. *See* NEUTRON.

Neutron spectroscopy requires slow neutrons, with energies of the order of neutrons in equilibrium with matter at room temperature, or approximately 0.025 eV. The corresponding de Broglie wavelengths are approximately 0.2 nanometer, of the order of interatomic spacings in solids or liquids. The fast neutrons emitted in nuclear or slow fission reactions can be slowed down to thermal velocities in matter which is transparent to neutrons and which contains light elements, such as hydrogen, carbon, and beryllium, by a process of diffusion and elastic (billiard-ball) scattering known as neutron moderation. By selection of those diffusing neutrons which travel in a certain restricted range of directions (collimation), a beam of thermal and near-thermal neutrons can be obtained. *See* Neutron; Quantum mechanics; Thermal neutrons.

The bulk of the observations can be accounted for in terms of scattering of semiclassical neutron waves by massive, moving-point scatterers in the forms of atomic nuclei and their bound electron clouds. The spatial structure of the scatterers, time-averaged over the duration of the experiment, gives rise to the elastic scattering from the specimen that is studied in neutron diffraction; the spatial motions of the scatterers give rise to the Doppler-shifted inelastic scattering involved in slow neutron spectroscopy.

Just as (slow) neutron diffraction is the most powerful available scientific tool for study of the magnetic structure of matter on an atomic scale, so slow neutron spectroscopy is the most powerful tool for study of the atomic magnetic and nuclear dynamics of matter in all its phases. The direct nature of the analysis has in some cases added considerable support to the conceptual structure of solid-state and liquid-state physics and thus to the confidence with which the physics is applied. For example, neutron spectroscopy has confirmed the existence of phonons, magnons, and the quasiparticles (rotons) of liquid helium II. Detailed information has been obtained on the lattice vibrations of most of the crystalline elements and numerous simple compounds, on the atomic dynamics of many simple liquids, on the dynamics of liquid helium in different phases, and on the atomic magnetic dynamics of a great variety of ferromagnetic, ferrimagnetic, antiferromagnetic, and modulated magnetic substances. [B.N.B.]

Slug (zoology) A terrestrial pulmonate mollusk in which the shell is absent or reduced to a small internal or external rudiment. The slug form has evolved independently several times. The incorporation into the muscular foot region of the body organs (which are contained within the shell in other mollusks) results in a streamlined body shape (see illustration), enabling the animal to enter small holes or crevices.

***Limax maximus*. There are two pairs of tentacles on the head, and the opening to the lung is clearly visible.**

Lung respiration occurs as in other pulmonates, but skin respiration is probably at least as important.

A few slugs are carnivorous, such as *Testacella* which eats earthworms, but the majority are herbivores and may become serious horticultural and agricultural pests. *See* Pulmonata. [N.Ru.]

Smallpox An acute infectious viral disease characterized by severe systemic involvement and a single crop of skin lesions that proceeds through macular, papular, vesicular, and pustular stages. Smallpox is caused by variola virus, a brick-shaped, deoxyribonucleic acid-containing member of the Poxviridae family. Strains of variola virus are indistinguishable antigenically, but have differed in the clinical severity of the disease caused. Following a 13-year worldwide campaign coordinated by the World Health Organization (WHO), smallpox was declared eradicated by the World Health Assembly in May 1980. Smallpox is the first human disease to be eradicated.

Humans were the only reservoir and vector of smallpox. The disease was spread by transfer of the virus in respiratory droplets during face-to-face contact. Before vaccination, persons of all ages were susceptible. It was a winter-spring disease; there was a peak incidence in the drier spring months in the Southern Hemisphere and in the winter months in temperate climates. The spread of smallpox was relatively slow. The incubation period was an average of 10–12 days, with a range of 7–17 days. Fifteen to forty percent of susceptible persons in close contact with an infected individual developed the disease.

There were two main clinically distinct forms of smallpox, variola major and variola minor. Variola major, prominent in Asia and west Africa, was the more severe form, with widespread lesions and case fatality rates of 15–25% in unvaccinated persons, exceeding 40% in children under 1 year. From the early 1960s to 1977, variola minor was prevalent in South America and south and east Africa; manifestations were milder, with a case fatality rate of less than 1%.

There is no specific treatment for the diseases caused by poxviruses. Supportive care for smallpox often included the systemic use of penicillins to minimize secondary bacterial infection of the skin. When lesions occurred on the cornea, an antiviral agent (idoxuridine) was advised.

Edward Jenner, a British general medical practitioner who used cowpox to prevent smallpox in 1796, is credited with the discovery of smallpox vaccine (vaccinia virus). However, the global smallpox eradication program did not rely only on vaccination. Although the strategy for eradication first followed a mass vaccination approach, experience showed that intensive efforts to identify areas of epidemiologic importance, to detect outbreaks and cases, and to contain them would have the greatest effect on interrupting transmission. In 1978, WHO established an International Commission to confirm the absence of smallpox worldwide. The recommendations made by the commission included abandoning routine vaccination except for laboratory workers at special risk. *See* Animal virus; Vaccination. [J.Bre.]

Smithsonite A naturally occurring rhombohedral zinc carbonate ($ZnCO_3$), with a crystal structure similar to that of calcite ($CaCO_3$). Smithsonite has a hardness on the Mohs scale of $4^{1}/_{2}$, has a specific gravity of 4.30–4.45, and exhibits perfect rhombohedral cleavage. *See* Calcite; Crystal structure; Hardness scales.

Smithsonite most commonly forms as an alteration product of the mineral sphalerite (ZnS) during supergene enrichment of zinc ores in arid or semiarid environments. It is seldom pure zinc carbonate, commonly containing other divalent metal ions such as manganese (Mn^{2+}), ferrous iron (Fe^{2+}), magnesium (Mg^{2+}), calcium (Ca^{27+}), cadmium (Cd^{2+}), cobalt (Co^{2+}), or lead (Pb^{2+}) substituting for zinc ion. Substitution of other elements for zinc may result in different colors such as blue-green (copper), yellow (cadmium), and pink (cobalt). Smithsonite has been mined as an ore of zinc and has also been used as an ornamental stone. *See* Carbonate minerals; Zinc. [J.C.D.]

Smog The noxious mixture of gases and particles commonly associated with air pollution in urban areas. Harold Antoine des Voeux is credited with coining the term in 1905 to describe the air pollution in British towns. *See* Air pollution.

The constituents of smog affect the human cardio-respiratory system and pose a health threat. Individuals exposed to smog can experience acute symptoms ranging from eye irritation and shortness of breath to serious asthmatic attacks. Under extreme conditions, smog can cause mortality, especially in the case of the infirm and elderly. Smog can also harm vegetation and likely leads to significant losses in the yields from forests and agricultural crops in affected areas.

The only characteristic of smog that is readily apparent to the unaided observer is the low visibility or haziness that it produces, due to tiny particles suspended within the smog. Observation of the more insidious properties of smog—the concentrations of toxic constituents—requires sensitive analytical instrumentation. Technological advances in these types of instruments, along with the advent of high-speed computers to simulate smog formation, have led to an increasing understanding of smog and its causes.

Smog is an episodic phenomenon because specific meteorological conditions are required for it to accumulate near the ground. These conditions include calm or stagnant winds which limit the horizontal transport of the pollutants from their sources, and a temperature inversion which prevents vertical mixing of the pollutants from the boundary layer into the free troposphere. *See* METEOROLOGY; STRATOSPHERE; TROPOSPHERE.

Smog can be classified into three types: London smog, photochemical smog, and smog from biomass burning.

London smog arises from the by-products of coal burning. These by-products include soot particles and sulfur oxides. During cool damp periods (often in the winter), the soot and sulfur oxides can combine with fog droplets to form a dark acidic fog. As nations switch from coal to cleaner-burning fossil fuels such as oil and gas as well as alternate energy sources such as hydroelectric and nuclear, London smogs cease. *See* ACID RAIN; COAL.

Photochemical smog is a more of a haze than a fog and is produced by chemical reactions in the atmosphere that are triggered by sunlight. A. J. Hagen-Smit first unraveled the chemical mechanism that produces photochemical smog. He irradiated mixtures of volatile organic compounds (VOC) and nitrogen oxides (NO_x) in a reaction chamber. After a few hours, Hagen-Smit observed the appearance of cracks in rubber bands stretched across the chamber. Knowing that ozone (O_3) can harden and crack rubber, Hagen-Smit correctly reasoned that photochemical smog was caused by photochemical reactions involving VOC and NO_x, and that one of the major oxidants produced in this smog was O_3. *See* ATMOSPHERIC CHEMISTRY; OZONE; PHOTOCHEMISTRY.

While generally not as dangerous as London smog, photochemical smog contains a number of noxious constituents. Ozone, a strong oxidant that can react with living tissue, is one of these noxious compounds. Another is peroxyacetyl nitrate (PAN), an eye irritant that is produced by reactions between NO_2 and the breakdown products of carbonyls. Particulate matter having diameters of about 10 micrometers or less are of concern because they can penetrate into the human respiratory tract during breathing and have been implicated in a variety of respiratory ailments.

Probably the oldest type of smog known to humankind is produced from the burning of biomass or wood. It combines aspects of both London smog and photochemical smog since the burning of biomass can produce copious quantities of smoke as well as VOC and NO_x. [W.L.Ch.]

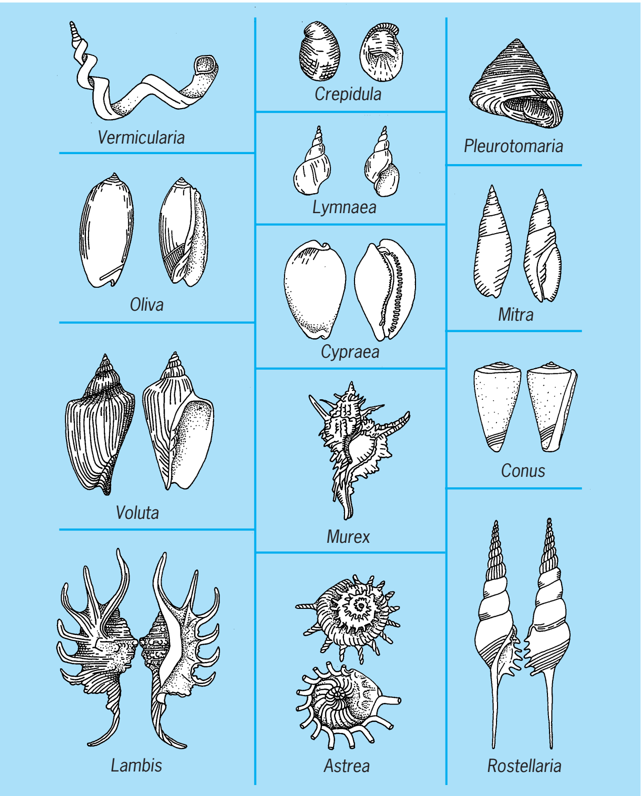
Smoke Fumes and smoke are dispersions of finely divided solids or liquids in a gaseous medium. The particle-size range is 0.01–5.0 micrometers. Typical dispersions are smokes from incomplete combustion of organic matter such as tobacco, wood, and coal; soot or carbon black; oil-vapor mists; chemical fumes such as sulfur trioxide (SO_3) and phosphorus pentoxide (P_2O_5) mists, ammonium chloride (NH_4Cl), and metal oxides; and the products of hydrolysis of metal chlorides by moist air. Oil-vapor and P_2O_5 mists (formed by burning phosphorus in moist air) have been extensively used in military operations to produce screening smokes. *See* AIR POLLUTION. [H.H.St./A.J.T.]

Smut (microbiology) The dark powdery masses of “smut spores” (teliospores) that develop in living plant tissues infected by species of *Ustilago*, *Tilletia*, and similar plant parasitic fungi. Molecular and ultrastructural data show that smut fungi comprise two phylogenetically distinct lines within the Basidiomycota; recent classification places them in two different classes, Ustilaginomycetes and Urediniomycetes. Ustilaginomycetes contains most of the smut fungi, and several groups of morphologically distinct, nonsmut plant parasites, including *Exobasidium*, *Graphiola*, and *Microstroma*. Smut fungi belonging to the genus *Microbotryum*, best known as anther smuts of Caryophyllaceae, are now placed within the Urediniomycetes with rust fungi and allied taxa. Ustilaginomycetes and Urediniomycetes also contain a number of saprotrophic, yeastlike fungi that are related to the plant parasitic smuts. Yeastlike saprotrophs that produce teliospores include *Tilletiaria* in the Ustilaginomycetes, and *Leucosporidium*, *Rhodosporidium*, and *Sporobolomyces* in the Urediniomycetes. Yeastlike saprotrophs in the Ustilaginomycetes that do not form teliospores but reproduce in another manner similar to *Ustilago* and *Tilletia* include *Pseudozyma* and *Tilletiopsis*, respectively. *See* FUNGI.

Teliospores of plant parasitic smut fungi form in a fruiting structure called a sorus. Sori are commonly produced in the inflorescence, leaves, or stems of the host, although the root is the site of sorus formation in smuts belonging to the genus *Entorrhiza*. Teliospores develop within the sorus by conversion of dikaryotic mycelial cells into thick-walled resistant spores within which paired nuclei fuse. Meiosis also occurs in teliospores of some smut fungi, but meiotic division is more characteristic of the tubular basidium that develops at germination.

There are 1200 species and 50 different genera of known smut fungi that infect over 4000 species of angiosperms. Smut fungi occur on both monocotyledonous and dicotyledonous hosts but are most economically important as pathogens of barley, corn, oats, onions, rice, sorghum, sugarcane, and wheat. Control of smut diseases varies with species and includes fungicidal seed treatments and use of resistant crop varieties. *See* BASIDIOMYCOTA; PLANT PATHOLOGY. [J.R.Ba.; L.M.Ca.]

Snail Any of the approximately 74,000 species in the class Gastropoda of the phylum Mollusca or, alternatively, any of the 12 or so species of land pulmonate gastropods used as human food.



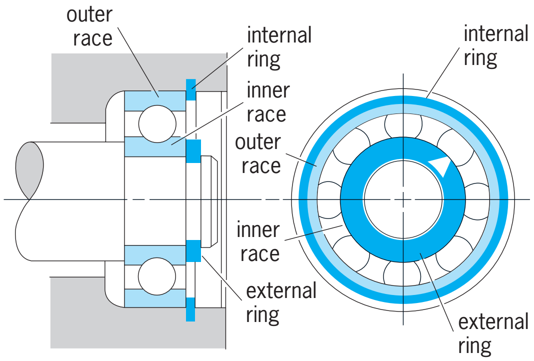
Diversity of snail shells. (*After R. R. Shrock and W. H. Twenhotel, Principles of Invertebrate Paleontology, 2d ed., McGraw-Hill, 1953*)

The shell of snails is in one piece and typically turbinate (see illustration), but may be planospiral or limpet-shaped, or may be secondarily lost (as in land slugs and marine nudibranchs). In development, gastropods have undergone torsion (the visceral mass and the mantle-shell covering it have become twisted through 180° in relation to the head and foot) so that the mantle cavity is placed anteriorly above the head.

In feeding, all snails use a characteristic rasping tongue or radula. This is a chitinous ribbon bearing teeth which is moved over a supporting protrusible "tongue" with a to-and-fro action. The radular apparatus has a twofold function: it serves both for rasping off food material (mechanically like an inverted version of the upper incisor teeth of a beaver) and for transporting the food back into the gut like a conveyor belt.

Both fresh-water and terrestrial snail species serve as vectors (first or sole intermediate hosts) in the transmission of flukes (Trematoda) infecting humans or domestic animals. *See* Clonorchiasis; Digenea; Fascioliasis; Gastropoda; Pulmonata; Schistosomiasis. [W.D.R.-H.]

Snap ring A form of spring used principally as a fastener. Piston rings are a form of snap ring used as seals. The ring is elastically deformed, put in place, and allowed to snap back toward its unstressed position into a groove or recess. The snap ring may be used externally to provide a shoulder that retains a wheel or a bearing race on a shaft, or it may be used internally to provide a construction that confines a bearing race in the bore of a machine frame, as illustrated. [L.S.L.]



Snap rings hold ball-bearing race in place. Internal ring supports axial thrust of axle. External ring aligns Inner race against shoulder of shaft.

Snow Frozen precipitation resulting from the growth of ice crystals from water vapor in the Earth's atmosphere.

As ice particles fall out in the atmosphere, they melt to raindrops when the air temperature is a few degrees above 32°F (0°C), or accumulate on the ground at colder temperatures. At temperatures above −40°F (−40°C), individual crystals begin growth on icelike aerosols (often clay particles 0.1 micrometer in diameter), or grow from cloud droplets (10 μm in diameter) frozen by similar particles. At lower temperatures, snow crystals grow on cloud droplets frozen by random molecular motion. At temperatures near 25°F (−4°C), crystals sometimes grow on ice fragments produced during soft hail (graupel) growth. Snow crystals often grow in the supersaturated environment provided by a cloud of supercooled droplets; this is known as the Bergeron-Findeisen process for formation of precipitation. When crystals are present in high concentrations (100 particles per liter) they grow in supersaturations lowered by mutual competition for available vapor.

Ice crystals growing under most atmospheric conditions (air pressure down to 0.2 atm or 20 kilopascals and temperatures 32 to −58°F or 0 to −50°C) have a hexagonal crystal structure, consistent with the arrangement of water molecules in the ice lattice, which leads to striking hexagonal shapes during vapor growth. The crystal habit (ratio of growth along and perpendicular to the hexagonal axis) changes dramatically with temperature. Both field and laboratory studies of crystals grown under known or controlled conditions show that the crystals are platelike above 27°F (−3°C) and between 18 and −13°F (−8 and −25°C), and columnlike between 27 and 18°F (−3 and −8°C) and below −13°F (−25°C).

Individual crystals fall in the atmosphere at velocity up to $0.5\ \mathrm{m\,s^{-1}}$ ($1.6\ \mathrm{ft\,s^{-1}}$). As crystals grow, they fall at higher velocity, which leads, in combination with the high moisture availability in a supercooled droplet cloud, to sprouting of the corners to form needle or dendrite skeletal crystals.

Under some conditions crystals aggregate to give snowflakes. This happens for the dendritic crystals that grow near 5°F (−15°C), which readily interlock if they collide with each other, and for all crystals near 32°F (0°C). Snowflakes typically contain several hundred individual crystals.

When snow reaches the ground, changes take place in the crystals. At temperatures near 32°F (0°C) the crystals rapidly lose the delicate structure acquired during growth, sharp edges evaporate, and the crystals take on a rounded shape, some 1–2 mm (0.04–0.08 in.) in diameter. These grains sinter together at their contact points to give snow some structural rigidity. The specific gravity varies from ∼0.05 for freshly fallen "powder" snow to ∼0.4 for an old snowpack. *See* Crystal growth; Precipitation (meteorology). [J.Hal.]

Snow gage An instrument for measuring the amount of water equivalent in snow; more commonly known as a snow sampler. Frequently snow samplers are made of a lightweight seamless aluminum tube consisting of easily coupled lengths. Other snow samplers have been developed from material such as fiber glass and plastic for use in shallow snow, deep dense snow, and so forth.

To obtain a measurement the sampler is pushed vertically through the snow to the ground surface. The sampler, together with its snow core, is withdrawn and weighed. The water equivalent of the snow layer is obtained by subtracting the weight of the sampler from the total. In addition to any error introduced by the scale, there is usually a 6–8% error in the weight of samples taken in this manner.

Automatic devices that permit the remote observation of the water equivalent of the snow have been developed. These devices also permit telemetering the data to a central location, eliminating the need for travel to the snowfields. *See* Snow; Snow surveying. [R.T.Be.]

Snow line A term generally used to refer to the elevation of the lower edge of a snow field. In mountainous areas, it is not truly a line but rather an irregular, commonly patchy border zone, the position of which in any one sector has been determined by the amount of snowfall and ablation. These factors may vary considerably from one part to another. On glacier surfaces the snow line is sometimes referred to as the glacier snow line or *névé* line (the outer limit of retained winter snow cover on a glacier).

Year-to-year variation in the position of the orographical snow line is great. The mean position over many decades, however, is important as a factor in the development of nivation hollows and protalus ramparts in deglaciated cirque beds. *See* Glaciology; Snowfield and névé. [M.M.Mi.]

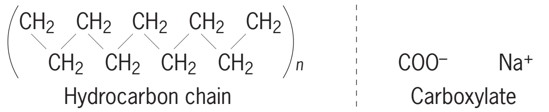
Snow surveying A technique for providing an inventory of the total amount of snow covering a drainage basin or a given region. Most of the usable water in western North America originates as mountain snowfall that accumulates during the winter and spring and appears several months later as streamflow. Snow surveys were established to provide an estimate of the snow water equivalent (that is, the depth of water produced from melting the snow) for use in predicting the volume of spring runoff. They are also extremely useful for flood forecasting, reservoir regulation, determining hydropower requirements, municipal and irrigation water supplies, agricultural productivity, wildlife survival, and building design, and for assessing transportation and recreation conditions.

Conventional snow surveys are made at designated sites, known as snow courses, at regular intervals each year throughout the winter period. A snow sampler is used to measure the snow depth and water equivalent at a series of points along a snow course. Average depth and water equivalent are calculated for each snow course. Satellite remote sensing and data relay are technologies used to obtain information on snow cover in more remote regions. *See* Remote sensing; Snow gage; Surface water. [B.E.Go.]

Snowfield and névé The term snowfield is usually applied to mountain and glacial regions to refer to an area of snow-covered terrain with definable geographic margins. Where the connotation is very general and without regard to geographical limits, the term snow cover is more appropriate; but glaciology requires more precise terms with respect to snowfield areas.

These terms differentiate according to the physical character and age of the snow cover. Technically, a snowfield can embrace only new or old snow (material from the current accumulation year). Anything older is categorized as fim or ice. The term névé is a descriptive phrase used to refer to consolidated granular snow not yet changed to glacier ice. Because of the need for simple terms, however, it has become acceptable to use the term névé when specifically referring to a geographical area of snowfields on mountain slopes or glaciers (that is, an area covered with perennial "snow" and embracing the entire zone of annually retained accumulation). *See* Glaciology. [M.M.Mi.]

Soap A cleansing agent described chemically as an alkali metal salt of a long-carbon-chain monocarboxylic acid, such as sodium myristate ($NaCOOC_{13}H_{27}$), as represented below.



The hydrocarbon portion is hydrophobic and the carboxylate portion is hydrophilic. This duality enables soap to physically remove dirt and oils from surfaces and disperse or emulsify them in water. For detergency purposes, the most useful hydrophobic portion contains 12–18 carbon atoms. When the chain length exceeds 18 carbons, they become insoluble in water.

A soap-making process that was formerly used was based on an alkaline hydrolysis reaction, saponification, according to the reaction below, where R represents the hydrocarbon chain.

$$\underset{\text{Fat}}{C_3H_5(OOCR)_3} + \underset{\substack{\text{Caustic}\\\text{soda}}}{3NaOH} \rightarrow \underset{\text{Soap}}{3NaOOCR} + \underset{\text{Glycerin}}{C_3H_5(OH)_3}$$

Most soap is now made by a continuous process. Fats and oils may be converted directly to soap by the reaction with caustic, and the neat soap separated by a series of centrifuges or by countercurrent washing. The saponification may be carried out with heat, pressure, and recirculation. Other important modern processes hydrolyze the fats directly with water and catalysts at high temperatures. This permits fractionation of the fatty acids, which are neutralized to soap in a continuous process. Advantages for this process are close control of the soap concentration, the preparation of soaps of certain chain lengths for specific purposes, and easy recovery of the by-product glycerin. Tallow and coconut oil are the most common fatty materials used for soapmaking.

Because of the marked imbalance of polarity within the molecules of synthetic detergents and soaps, they have unusual surface and solubility characteristics. The feature of their molecular structure which causes these properties is the location of the hydrophilic function at or near the end of a long hydrocarbon (hydrophobic) chain. One part of the molecule is water-seeking while the other portion is oil-seeking. Thus these molecules concentrate and orient themselves at interfaces, such as an oil-solution interface where the hydrophobic portion enters the oil and the hydrophilic portion stays in the water. Consequently, the interfacial tension is lowered and emulsification can result. At an agitated air-solution interface, the excess detergent concentration leads to sudsing.

Considerable research has also been done on the aqueous solutions of soap. Many of the phase characteristics now known to occur in most surfactant-water systems were first discovered in soap systems. These include micelle formation where, at a critical concentration, soap molecules in solution form clusters (micelles). The hydrocarbon chains associate with each other in the interior, and the polar groups are on the outside. *See* Micelle; Surfactant.

There is one serious disadvantage to the use of soap which has largely caused its replacement by synthetic detergents. The problem is that carboxylate ions of the soap react with the calcium and magnesium ions in natural hard water to form insoluble materials which manifest as a floating curd. Bar soap for personal bathing is the greatest remaining market for soap. Some commercial laundries having soft water continue to use soap powders. Metallic soaps are alkaline-earth or heavy-metal long-chain carboxylates which are insoluble in water but soluble in nonaqueous solvents. They are used as additives to lubricating oils, in greases, as rust inhibitors, and in jellied fuels. *See* Detergent. [R.C.M.]

Soapstone A soft talc-rich rock. Soapstones are rocks composed of serpentine, talc, and carbonates (magnesite, dolomite, or calcite). They represent original periodites which were altered at low temperatures by hydrothermal solutions containing silicon dioxide, carbon dioxide, and other dissolved materials (products of low-grade metasomatism). The whole group of rocks may loosely be referred to as soapstones because of their soft, soapy consistency. [T.F.W.B.]

Social hierarchy A fundamental aspect of social organization that is established by fighting or display behavior and results in a ranking of the animals in a group. Social, or dominance, hierarchies are observed in many different animals, including insects, crustaceans, mammals, and birds. In many species, size, age, or sex determines dominance rank. Dominance hierarchies often determine first or best access to food, social interactions, or mating within animal groups.

When two animals fight, several different behavioral patterns can be observed. Aggressive acts and submissive acts are both parts of a fight. Aggression and submission, together, are known as agonistic behavior. An agonistic relationship in which one animal is dominant and the other is submissive is the simplest type of dominance hierarchy. In nature, most hierarchies involve more than two animals and are composed of paired dominant-subordinate relationships. The simplest dominance hierarchies are linear and are known as pecking orders. In such a hierarchy the top individual (alpha) dominates all others. The second-ranked individual (beta) is submissive to the dominant alpha but dominates the remaining animals. The third animal (gamma) is submissive to alpha and beta but dominates all others. This pattern is repeated down to the lowest animal in the hierarchy, which cannot dominate any other group member.

Other types of hierarchies result from variations in these patterns. If alpha dominates beta, beta dominates gamma, but gamma dominates alpha, a dominance loop is formed. In some species a single individual dominates all members of the social group, but no consistent relationships are formed among the other animals. In newly formed hierarchies, loops or other nonlinear relationships are common, but these are often resolved over time so that a stable linear hierarchy is eventually observed.

Males often fight over access to females and to mating with them. Male dominance hierarchies are seen in many hooved mammals (ungulates). Herds of females use dominance hierarchies to determine access to food. Agonistic interactions among females are often not as overtly aggressive as those among males, but the effects of the dominance hierarchy can easily be observed. In female dairy cattle, the order of entry into the milking barn is determined by dominance hierarchy, with the alpha female entering first. *See* REPRODUCTIVE BEHAVIOR.

Because dominant animals may have advantages in activities such as feeding and mating, they will have more offspring than subordinate animals. If this is the case, then natural selection will favor genes for enhanced fighting ability. Heightened aggressive behavior may be counterselected by the necessity for amicable social interactions in certain circumstances. Many higher primates live in large groups of mixed sex and exhibit complex social hierarchies. In these groups, intra- and intersexual dominance relationships determine many aspects of group life, including feeding, grooming, sleeping sites, and mating. Macaque, baboon, and chimpanzee societies are characterized by cooperative alliances among individuals that are more important than individual fighting ability in maintaining rank. *See* PRIMATES.

Social hierarchies provide a means by which animals can live in groups and exploit resources in an orderly manner. In particular, food can be distributed among group members with little ongoing conflict. Another motivation for group living is mutual defense. Even though subordinates receive less food or have fewer opportunities to mate, they may have greatly increased chances of escaping predation. *See* BEHAVIORAL ECOLOGY; POPULATION ECOLOGY; SOCIAL MAMMALS; TERRITORIALITY. [M.D.Bre.]

Social insects Insects that share resources and reproduce cooperatively. The shared resources are shelter, defense, and food (collection or production). After a period of population growth, the insects reproduce in several ways. As social insect groups grow, they evolve more differentiation between members but reintegrate into a more closely organized system known as eusocial. These are the most advanced societies with individual polymorphism, and they contain insects of various ages, sizes, and shapes. All the eusocial insects are included in the orders Isoptera (termites) and Hymenoptera (wasps, bees, and ants). *See* HYMENOPTERA; INSECTA; ISOPTERA; POLYMORPHISM (GENETICS).

The social insects have evolved in various patterns. In the Hymenoptera, the society is composed of only females; males are produced periodically for their sperm. They usually congregate and attract females, or they visit colonies with virgin females and copulate there. In the Hymenoptera, sex is determined largely by whether the individual has one or two sets of chromosomes. Thus the queen has the power to determine the sex of her offspring: if she lets any of her stored sperm reach the egg, a female is produced; if not, a male results. In the more primitive bees and wasps, social role (caste) is influenced by interaction with like but not necessarily related individuals. The female that can dominate the others assumes the role of queen, even if only temporarily. Domination is achieved by aggression, real or feigned, or merely by a ritual that is followed by some form of salutation by the subordinates. This inhibits the yolk-stimulating glands and prevents the subordinates from contributing to egg production; if it fails to work, the queen tries to destroy any eggs that are laid. Subordinate females take on more and more of the work of the group for as long as the queen is present and well. At first, all the eggs are fertilized and females develop, with the result that virgin females inhabit the nest for the first batches. They are often undernourished, and this, together with their infertility, reduces their urge to leave the nest and start another one. Such workers are said to be produced by maternal manipulation.

Reproductive ants, like termites, engage in a massive nuptial flight, after which the females, replete with sperm, go off to start a new nest. At some stage after the nuptials, the reproductives break off their wings, which have no further use. Workers, however, never have wings because they develop quickly and pass right through the wing-forming stages; their ovaries and genitalia are also reduced. Ant queens can prevent the formation of more queens; as with the honeybee, they do this behaviorally by using pheromones. They also force the workers to feed all larvae the same diet. To this trophogenic caste control is added a blastogenic control; eggs that are laid have a developmental bias toward one caste or another. This is not genetic; bias is affected by the age of the queen and the season: more worker-biased eggs are laid by young queens and by queens in spring. In some ants, workers mature in various sizes. Since they have disproportionately large heads, the biggest workers are used mainly for defense; they also help with jobs that call for strength, like cutting vegetation or cracking nuts.

Social insects make remarkable nests that protect the brood as well as regulate the microclimate. The simplest nests are cavities dug in soil or soft wood, with walls smoothed and plastered with feces that set hard. Chambers at different levels in the soil are frequently connected by vertical shafts so that the inhabitants can choose the chamber with the best microclimate. Termites and ants also make many different types of arboreal nests. These nests are usually made of fecal material, but one species of ant (*Oecophylla*) binds leaves together with silk produced in the salivary glands of their larvae that the workers hold in their jaws and spin across leaves. A whole group of ants (for example, *Pseudomyrmex*) inhabit the pith of plants.

Social bees use wax secreted by their cuticular glands and frequently blended with gums from tree exudates for their nest construction. Cells are made cooperatively by a curtain of young bees that scrape wax from their abdomen, chew it with saliva, and mold it into the correct shape; later it is planed and polished. With honeybees the hexagonal comb reaches perfection as a set of back-to-back cells, each sloping slightly upward to prevent honey from running out. The same cells are used repeatedly for brood and for storage; or they may be made a size larger for rearing males. Only the queen cell is pendant, with a circular cross section and an opening below.

The ubiquity and ecological power of social insects depend as much on their ability to evolve mutualistic relations with other organisms as on the coherence of their social organization. Wood and the cellulose it contains is normally available as a source of energy only to bacteria and fungi. However, it is used as a basic resource by both termites and ants that have evolved a technique of culturing these organisms. Though lower termites have unusual protozoa as intestinal symbionts, higher termites have bacteria in pouches in their hind gut. Many have a fungus that they culture in special chambers in their nests. The termites feed on woody debris, leaves, and grass cuttings; the fungus digests these materials with the aid of termite feces and produces soft protein-rich bodies that the termites share with their juveniles and reproductives, neither of which are able to feed themselves. Protected from the weather, the fungus can remain active throughout the dry seasons—an inestimable advantage in the subtropics.

Many ants collect and store seeds that they mash and feed directly to their larvae. Provided they are collected when dry and stored in well-ventilated chambers, these seeds can remain viable and edible for an entire season. The plants benefit because not all the seeds are eaten; some that start to germinate are thrown out with the rubbish of the colony—in effect a way of planting them. Others are left behind by the ants when they change nests. In this way, grass seeds can extend their range into dry areas that they could not reach alone.

The dispersal of plant pollen by bees is a well-known symbiosis, and it has led to the evolution of many strange shapes, colors, and scents in flowers. Quite specific flower-bee relationships may exist in which one plant may use very few species of bees for the transfer of pollen. *See* POLLINATION; POPULATION ECOLOGY. [M.V.B.]

Social mammals Mammals that exhibit social behavior. This may be defined as any behavior stimulated by or acting upon another animal of the same species. In this broad sense, almost any animal which is capable of behavior is to some degree social. Even those animals which are completely sedentary, such as adult sponges and sea squirts, have a tendency to live in colonies and are social to that extent. Social reactions are occasionally given by species other than the animals' own; an example would be the relations between domestic animals and humans.

The postnatal development of each species is closely related to the social organization typical of the adults. Every highly social animal has a short period early in life when it readily forms attachments to any animal with which it has prolonged contact. The process of socialization begins almost immediately after birth in ungulates like the sheep, and the primary relationship is formed with the mother. In dogs and wolves the process does not begin until about 3 weeks of age, at a time when the mother is beginning to leave the pups. Consequently the strongest relationships are formed with litter mates, thus forming the foundation of a pack. Many rodents stay in the nest long after birth; primary relationships are therefore formed with nest mates. Young primates are typically surrounded by a group of their own kind, but because they are carried for long periods the first strong relationship tends to be with the mother.

Mammals may develop all types of social behavior to a high degree, but not necessarily in every species. Mammals have great capacities for learning and adaptation, which means that social relationships are often highly developed on the basis of learning and habit formation as well as on the basis of heredity and biological differences. The resulting societies tend to be malleable and variable within the same species and to show considerable evidence of cultural inheritance from one generation to the next. Mammalian societies have been completely described in relatively few forms, and new discoveries will probably reveal the existence of a greater variety of social organization.

Basic human social organization and behavior obviously differs from that of all other primates, although it is related to them. At the same time, the range of variability of human societies as seen in the nuclear family does not approach that in mammals as a whole. Human societies are characterized by the presence of all fundamental types of social behavior and social relationships rather than by extreme specialization. *See* ETHOLOGY; HUMAN ECOLOGY; REPRODUCTIVE BEHAVIOR; SOCIOBIOLOGY. [J.P.S.]

Sociobiology A scientific discipline that applies principles of evolutionary biology to the study of animal and human social behavior. It is a synthesis of ethology, ecology, and evolutionary theory in which social behavior is viewed as a product of natural selection and other biological processes. Although most of the research in sociobiology has focused on understanding the behavior of nonhumans, sociobiological explanations have been used to interpret patterns of human behavior as well. *See* ECOLOGY; ETHOLOGY; ORGANIC EVOLUTION.

Sociobiology predicts that individuals will behave in ways that maximize their fitness (their success at projecting copies of their genetic material into succeeding generations) and argues that such behaviors can arise through the same evolutionary processes that operate on other trait systems. The central principle underlying sociobiology is that an individual's behavior is shaped, in part, by its genes, and thus is heritable and subject to natural selection. Natural selection is simply the result of the differential survival and reproduction of individuals who show heritable variation in a trait. The variants of a trait that convey greater fitness will increase in frequency in a population over time. The distinctive sociobiological perspective on behavior views behaviors as strategies that have evolved through natural selection to maximize an individual's fitness. Note that under this view there is absolutely no need to assume that maximizing fitness is in any way a conscious goal underlying an animal's behavior—successful behavior is simply an emergent result of the evolutionary process and not the force driving that process. *See* BEHAVIORAL ECOLOGY.

Altruism. Animals sometimes behave in ways that seem to reduce their own personal fitness while increasing that of other individuals. For example, in many species of social mammals and in numerous species of birds, individuals commonly give alarm vocalizations that alert others to the presence of a predator while seemingly rendering themselves more conspicuous to attack. Evolutionary biologists since Charles Darwin have noted that these seemingly altruistic acts pose a challenge to the notion of an animal's behavior being a strategy to maximize individual fitness. *See* SOCIAL INSECTS; SOCIAL MAMMALS.

One resolution to this paradox comes from taking a "gene's eye view" of evolution, which recognizes that Darwinian fitness (an individual's success in producing offspring) is simply a specific case of the more general concept of inclusive fitness. Because an individual shares genes with its relatives, there are actually two different routes by which it can pass on copies of those genes to the next generation: first, through personal or direct reproduction; and second, by helping relatives to reproduce. Inclusive fitness is a composite measure of an individual's genetic contribution to the next generation that considers both of these routes.

Animals who behave altruistically toward relatives may, in fact, be behaving selfishly in the genetic sense if their behavior sufficiently enhances their inclusive fitness through its effects on the survival and reproduction of relatives. This phenomenon is referred to as kin selection. Because close relatives share more genes, on average, with an individual than do distant relatives, such seemingly altruistic behavior tends to be directed toward closer kin.

Another solution to the altruism paradox—one that can even operate among nonrelatives under certain conditions—is reciprocity. If the recipient of some altruistic behavior is likely to repay a donor in the future, it may be beneficial for the donor to perform the behavior even at some immediate cost to its own fitness. This is especially true if the cost is low and the anticipated benefit is high. Examples include food sharing among unrelated vampire bats and alliance behavior in some primates.

Under some conditions, it is possible for altruism to result from natural selection operating at the level of groups, rather than at the level of individuals or genes (for example, if groups containing altruists were at a sufficient selective advantage compared with groups containing only selfish individuals). However, within such groups, selection acting on individuals would still tend to favor selfishness over altruism. In any event, much of the cogency of sociobiology has resulted from the recognition that selection seems to be most powerful when it acts at lower levels—notably, genes and individuals rather than groups or species.

Other social strategies. Over the past three decades, the sociobiological view of behavior as an evolved strategy for maximizing inclusive fitness has proven to be a powerful explanatory paradigm for investigating many other aspects of animal social behavior. The phenomenon of sociality, for example, has been extensively explored from this perspective. Each species—and individuals within each species—can be investigated as to the relative costs and benefits associated with the decision of whether or not to be social. Similar considerations apply to many other strategic (though typically unconscious) decisions that animals make during their lives, such as whether to reproduce sexually, when in life to begin reproducing (with regard to season and age at maturation), how many partners to mate with and who those partners should be, whether to compete with other individuals over access to partners, and whether to bestow parental care and the level of care to give. *See* Maternal behavior; Reproductive behavior; Sexual dimorphism. [D.P.B.; A.Di.F.]

Soda niter A nitrate mineral having chemical composition $NaNO_3$ (sodium nitrate); also known as nitratite, it is by far the most abundant of the nitrate minerals. It sometimes occurs as simple rhombohedral crystals but is usually massive granular. The mineral has a perfect rhombohedral cleavage, conchoidal fracture, and is rather sectile. Its hardness is 1.5 to 2 on Mohs scale, and its specific gravity is 2.266. It has a vitreous luster and is transparent. It is colorless to white, but when tinted by impurities, it is reddish brown, gray, or lemon yellow. *See* Hardness scales.

Soda niter is a water-soluble salt found principally as a surface efflorescence in arid regions, or in sheltered places in wetter climates. It is usually associated with niter, nitrocalcite, gypsum, epsomite, mirabilite, and halite. The only large-scale commercial deposits of soda niter in the world occur in a belt roughly 450 mi (725 km) long and 10–50 mi (16–80 km) wide along the eastern slope of the coast ranges in the Atacama, Tarapaca, and Antofagasta Deserts of northern Chile. Chilean nitrate had a monopoly of the world's fertilizer market for many years, but now occupies a subordinate position owing to the development of synthetic processes for nitrogen fixation which permit the production of nitrogen from the air. *See* Caliche; Fertilizer; Niter; Nitrate minerals; Nitrogen. [G.Sw.]

Sodalite A mineral of the feldspathoid group with chemical composition $Na_4Al_3Si_3O_{12}Cl$. Sodalite is usually massive or granular with poor cleavage. The Mohs hardness is 5.5–6.0, and the density 2.3. The luster is vitreous, and the color is usually blue but may also be white, gray, or green. Notable occurrences are at Mount Vesuvius; Bancroft, Ontario; and on the Kola Peninsula of Russia. *See* Feldspathoid; Silicate minerals. [L.Gr.]

Sodium A chemical element, Na, atomic number 11, and atomic weight 22.9898. Sodium is between lithium and potassium in the periodic table. The element is a soft, reactive, low-melting metal with a specific gravity of 0.97 at 20°C (68°F). Sodium is commercially the most important alkali metal. The physical properties of metallic sodium are summarized in the table below. *See* Periodic table.

Sodium ranks sixth in abundance among all the elements in the Earth's crust, which contains 2.83% sodium in combined form. Only oxygen, silicon, aluminum, iron, and calcium are more abundant. Sodium is, after chlorine, the second most abundant element in solution in seawater. The important sodium salts found in nature include sodium chloride (rock salt), sodium carbonate (soda and trona), sodium borate (borax), sodium nitrate (Chile saltpeter), and sodium sulfate. Sodium salts are found in seawater, salt lakes, alkaline lakes, and mineral springs. *See* Alkali metals.

Physical properties of sodium metal

	Temperature			
Property	C	F	Metric (scientific) units	British (engineering) units
Density	0	32	0.972 g/cm^3	60.8 lb/ft^3
	100	212	0.928 g/cm^3	58.0 lb/ft^3
	800	1472	0.757 g/cm^3	47.3 lb/ft^3
Melting point	97.5	207.5		
Boiling point	883	1621		
Heat of fusion	97.5	207.5	27.2 cal/g	48.96 Btu/lb
Heat of vaporization	883	1621	1005 cal/g	1809 Btu/lb
Viscosity	250	482	3.81 millipoises	4.3 kinetic units
	400	752	2.69 millipoises	3.1 kinetic units
Vapor pressure	440	824	1 mm	0.019 lb/in.^{2}
	815	1499	400 mm	7.75 lb/in.^{2}
Thermal conductivity	21.2	70.2	0.317 cal/(s)(cm)(°C)	76 Btu/(h)(ft)(°F)
	200	392	0.193 cal/(s)(cm)(°C)	46.7 Btu(h)(ft)(°F)
Heat capacity	20	68	0.30 cal/(g)(°C)	0.30 Btu/(lb)(°F)
	200	392	0.32 cal/(g)(°C)	0.32 Btu/(lb)(°F)
Electrical resistivity	100	212	965 microhm-cm	
Surface tension	100	212	206.4 dynes/cm	
	250	482	199.5 dynes/cm	

Sodium reacts rapidly with water, and even with snow and ice, to give sodium hydroxide and hydrogen. The reaction liberates sufficient heat to melt the sodium and ignite the hydrogen. When exposed to air, freshly cut sodium metal loses its silvery appearance and becomes dull gray because of the formation of a coating of sodium oxide.

Sodium does not react with nitrogen. Sodium and hydrogen react above about 200°C (390°F) to form sodium hydride. Sodium reacts with ammonia, forming sodium amide. Sodium also reacts with ammonia in the presence of coke to form sodium cyanide.

Sodium does not react with paraffin hydrocarbons but does form addition compounds with naphthalene and other polycyclic aromatic compounds and with arylated alkenes. The reaction of sodium with alcohols is similar to, but less rapid than, the reaction of sodium with water. Sodium reacts with organic halides in two general ways. One of these involves condensation of two organic, halogen-bearing compounds by removal of the halogen, allowing the two organic radicals to join directly. The second type of reaction involves replacement of the halogen by sodium, giving an organosodium compound. *See* Organometallic compound.

Sodium chloride, or common salt, NaCl, is not only the form in which sodium is found in nature but (in purified form) is the most important sodium compound in commerce as well. Sodium hydroxide, NaOH, is also commonly known as caustic soda. Sodium carbonate, Na_2CO_3, is best known under the name soda ash.

The largest single use for sodium metal, accounting for about 60% of total production, is in the synthesis of tetraethyllead, an antiknock agent for automotive gasolines. A second major use is in the reduction of animal and vegetable oils to long-chain fatty alcohols; these alcohols are raw materials for detergent manufacture. Sodium is used to reduce titanium and zirconium halides to their respective metals. Sodium chloride is used in curing fish, meat packing, curing hides, making freezing mixtures, and food preparation (including canning and preserving). Sodium hydroxide is used in the manufacture of chemicals, cellulose film, rayon soap pulp, and paper. Sodium carbonate is used in the glass industry and in the manufacture of soap, detergents, various cleansers, paper and textiles, nonferrous metals, and petroleum products. Sodium sulfate (salt cake) is used in the pulp industry and in the manufacture of flat glass. *See* Glass; Halite; Paper. [M.Si.]

The sodium ion (Na^+) is the main positive ion present in extracellular fluids and is essential for maintenance of the osmotic pressure and of the water and electrolyte balances of body fluids. Hydrolysis of adenosine triphosphate (ATP) is mediated by the membrane-bound enzyme Na^+,K^+-ATPase (this enzyme is also called sodium pump). The potential difference associated with the transmembrane sodium and potassium ion gradients is important for nerve transmission and muscle contraction. Sodium ion gradients are also responsible for various sodium ion–dependent transport processes, including sodium-proton exchange in the heart, sugar transport in the intestine, and sodium-lithium exchange and amino acid transport in red blood cells. *See* Potassium. [D.M.DeF.]

Sodium-vapor lamp An arc discharge lamp with sodium vapor as the emitting species. Low-pressure and high-pressure types are used commercially.

The low-pressure sodium lamp has remarkably high luminous efficiency, or efficacy, producing as much as 200 lumens per watt of input power. The radiation is nearly monochromatic yellow in color, and is used where color rendition is unimportant. The very high luminous efficacy is due to very stringent control of heat losses from the arc. The key to the heat conservation is the indium oxide film used to reflect infrared energy back to the arc tube and the evacuated outer jacket that minimizes the conducted thermal losses. Lamps at 18 and 10 W of power have been developed for very low-energy-cost uses. The 10-W lamp produces light at 100 lm/W. *See* ILLUMINATION; LUMINOUS EFFICACY.

When the sodium pressure is increased by a higher liquid-sodium-pool temperature, the yellow sodium D-line resonance radiation reaches a condition where pressure broadening and self-absorption occur, producing a lamp no longer monochromatic yellow but golden-white in color. The high-pressure sodium lamp has a maximum arc tube temperature typically above 2000°F (1100°C) with a sodium amalgam reservoir temperature about 1300°F (700°C). The term high-pressure is used merely to distinguish this light source from the low-pressure sodium lamp. The plasma arc column of the high-pressure sodium lamp has a total pressure of sodium, mercury, and inert gas of typically slightly less than 1 atm (10^5 Pa).

Because of the more compact source size, the light from a high-pressure sodium lamp can be more effectively directed by reflectors and refractors than that from the low-pressure sodium lamp. Therefore the higher efficacy of the low-pressure sodium lamp is offset by its reduced luminous efficiency. Sodium-vapor lamps are replacing high-pressure mercury lamps in many floodlight and roadway applications. More sodium-vapor lamps are manufactured annually than the high-pressure mercury and metal halide lamps combined. *See* LAMP; VAPOR LAMP. [C.I.McV.]

Sofar The acronym for sound fixing and ranging. The concept is based on finding the geographic location of sound that is created by an explosive or other impulsive event, such as a missile impact, by using the time of arrival of the signal at three or more receiving stations. This is known as hyperbolic fixing. This concept was used to locate aircraft that crashed at sea. Although other techniques have replaced this application, the term sofar channel has remained in use, referring to what is also known as the deep sound channel. *See* HYPERBOLIC NAVIGATION SYSTEM; UNDERWATER SOUND. [R.R.G.]

Software A set of instructions that cause a computer to perform one or more tasks. The set of instructions is often called a program or, if the set is particularly large and complex, a system. Computers cannot do any useful work without instructions from software; thus a combination of software and hardware (the computer) is necessary to do any computerized work. A program must tell the computer each of a set of minuscule tasks to perform, in a framework of logic, such that the computer knows exactly what to do and when to do it. *See* COMPUTER PROGRAMMING.

Programs are written in programming languages, especially designed to facilitate the creation of software. In the 1950s, programming languages were numerical languages easily understood by computer hardware; often, programmers said they were writing such programs in machine language.

Machine language was cumbersome, error-prone, and hard to change. In the latter 1950s, assembler (or assembly) language was invented. Assembler language was nearly the same as machine language, except that symbolic (instead of numerical) operations and symbolic addresses were used, making the code considerably easier to change.

The programmable aspects of computer hardware have not changed much since the 1950s. Computers still have numerical operations, and numerical addresses by which data may be accessed. However, programmers now use high-level languages, which look much more like English than a string of numbers or operation codes. *See* NUMBERING SYSTEMS; NUMERICAL REPRESENTATION (COMPUTERS); PROGRAMMING LANGUAGES.

Well-known programming languages include Basic, Java, and C. Basic has been modified into Visual Basic, a language useful for writing the portion of a program that the user "talks to" (i.e., the user interface or graphical user interface or GUI). Java is especially useful for creating software that runs on a network of computers. C and C++ are powerful but complex languages for writing such software as systems software and games. *See* HUMAN-COMPUTER INTERACTION; LOCAL-AREA NETWORKS; WIDE-AREA NETWORKS.

Packaged software such as word processors, spreadsheets, graphics and drawing tools, email systems, and games are widely available and used. Some software packages are enormous; for example, enterprise resource planning (ERP) software can be used by companies to perform almost all of their so-called back-office software work. *See* COMPUTER GRAPHICS; ELECTRONIC MAIL; VIDEO GAMES; WORD PROCESSING.

Systems software is necessary to support the running of an application program. Operating systems are needed to link the machine-dependent needs of a program with the capabilities of the machine on which it runs. Compilers translate programs from high-level languages into machine languages. Database programs keep track of where and how data are stored on the various storage facilities of a typical computer, and simplify the task of entering data into those facilities or retrieving the data. Networking software provides the support necessary for computers to interact with each other, and with data storage facilities, in a situation where multiple computers are necessary to perform a task, or when software is running on a network of computers (such as the Internet or the World Wide Web). *See* DATABASE MANAGEMENT SYSTEM; INTERNET; OPERATING SYSTEM; TELEPROCESSING; WORLD WIDE WEB.

Business applications software processes transactions, produces paychecks, and does the myriad of other tasks that are essential to running any business. Roughly two-thirds of software applications are in the business area.

Scientific and engineering software satisfies the needs of a scientific or engineering user to perform enterprise-specific tasks. Because scientific and engineering tasks tend to be very enterprise-specific, there has been no generalization of this application area analogous to the that of the ERP for backoffice business systems. The scientific-engineering application usually is considered to be in second place only to business software in terms of software products built.

Edutainment software instructs (educates) or plays games with (entertains) the user. Such software often employs elaborate graphics and complex logic. This is one of the most rapidly growing software application areas, and includes software to produce special effects for movies and television programs.

Real-time software operates in a time-compressed, real-world environment. Although most software is in some sense real-time, since the users of modern software are usually interacting with it via a GUI, real-time software typically has much shorter time constraints. For example, software that controls a nuclear reactor must make decisions and react to its environment in minuscule fractions of a second.

With the advent of multiple program portions, software development has become considerably more complicated. Whereas it was formerly considered sensible to develop all of a software system in the same programming language, now the different portions are often developed in entirely different languages. The relatively complex GUI, for example, can most conveniently be developed in one of the so-called visual languages, since those languages contain powerful facilities for creating it. The server software, on the other hand, will likely be built using a database package and the database language SQL (a Structured Query Language, for inquiring into the contents of a database). If the server software is also responsible for interacting with a network such as the Internet, it may also be coded in a network-support language such as Java. An object-oriented approach may be adopted in its development, since the software will need to manipulate objects on the Internet. *See* COMPUTER

PROGRAMMING; OBJECT-ORIENTED PROGRAMMING; SOFTWARE ENGINEERING. [R.L.Gl.]

Software engineering The process of manufacturing software systems. A software system consists of executable computer code and the supporting documents needed to manufacture, use, and maintain the code. For example, a word processing system consists of an executable program (the word processor), user manuals, and the documents, such as requirements and designs, needed to produce the executable program and manuals. *See* SOFTWARE.

Software engineering is ever more important as larger, more complex, and life-critical software systems proliferate. The rapid decline in the costs of computer hardware means that the software in a typical system often costs more than the hardware it runs on. Large software systems may be the most complex things ever built. This places great demands on the software engineering process, which must be disciplined and controlled.

To meet this challenge, software engineers have adapted many techniques from older engineering fields, as well as developing new ones. For example, divide and conquer, a well-known technique for handling complex problems, is used in many ways in software engineering. The software engineering process itself, for example, is usually divided into phases. The definition of these phases, their ordering, and the interactions between the phases specify a software life-cycle model. The best-known life-cycle model is the waterfall model consisting of a requirements definition phase, a design phase, a coding phase, a testing phase, and a maintenance phase. The output of each phase serves as the input to the next. *See* SYSTEMS ENGINEERING.

The purpose of the requirements phase is to define what a system should do and the constraints under which it must operate. This information is recorded in a requirements document. A typical requirements document might include a product overview; a specification of the development, operating, and maintenance environment for the product; a high-level conceptual model of the system; a specification of the user interface; specification of functional requirements; specification of nonfunctional requirements; specification of interfaces to systems outside the system under development; specification of how errors will be handled; and a listing of possible changes and enhancements to the system. Each requirement, usually numbered for reference, must be testable.

In the design phase, a plan is developed for how the system will implement the requirements. The plan is expressed using a design method and notation. Many methods and notations for software design have been developed. Each method focuses on certain aspects of a system and ignores or minimizes others. This is similar to viewing a building with an architectural drawing, a plumbing diagram, an electrical wiring diagram, and so forth.

The coding phase of the software life-cycle is concerned with the development of code that will implement the design. This code is written is a formal language called a programming language. Programming languages have evolved over time from sequences of ones and zeros directly interpretable by a computer, through symbolic machine code, assembly languages, and finally to higher-level languages that are more understandable to humans. *See* PROGRAMMING LANGUAGES.

Most coding today is done in one of the higher-level languages. When code is written in a higher-level language, it is translated into assembly code, and eventually machine code, by a compiler. Many higher-level languages have been developed, and they can be categoriged as functional languages, declarative languages, and imperative languages.

Following the principle of modularity, code on large systems is separated into modules, and the modules are assigned to individual programmers. A programmer typically writes the code using a text editor. Sometimes a syntax-directed editor that “knows” about a given programming language and can provide programming templates and check code for syntax errors is used. Various other tools may be used by a programmer, including a debugger that helps find errors in the code, a profiler that shows which parts of a module spend most time executing, and optimizers that make the code run faster.

Testing is the process of examining a software product to find errors. This is necessary not just for code but for all life-cycle products and all documents in support of the software such as user manuals.

The software testing process is often divided into phases. The first phase is unit testing of software developed by a single programmer. The second phase is integration testing where units are combined and tested as a group. System testing is done on the entire system, usually with test cases developed from the system requirements. Acceptance testing of the system is done by its intended users.

The basic unit of testing is the test case. A test case consists of a test case type, which is the aspect of the system that the test case is supposed to exercise; test conditions, which consist of the input values for the test; the environmental state of the system to be used in the test; and the expected behavior of the system given the inputs and environmental factors.

When software is changed to fix a bug or add an enhancement, a serious error is often introduced. To ensure that this does not happen, all test cases must be rerun after each change. The process of rerunning test cases to ensure that no error has been introduced is called regression testing. *See* SOFTWARE TESTING AND INSPECTION.

Walkthroughs and inspections are used to improve the quality of the software development process. Consequently, the software products created by the process are improved. A quality system is a collection of techniques whose application results in continuous improvement in the quality of the development process. Elements of the quality system include reviews, inspections, and process audits.

Large software systems are not static; rather, they change frequently both during development and after deployment. Maintenance is the phase of the software life-cycle after deployment. The maintenance phase may cost more than all of the others combined and is thus of primary concern to software organizations. The Y2K problem was, for example, a maintenance problem.

Maintenance consists of three activities: adaptation, correction, and enhancement. Enhancement is the process of adding new functionality to a system. This is usually done at the request of system users. This activity requires a full life-cycle of its own. That is, enhancements demand requirements, design, implementation, and test. Studies have shown that about half of maintenance effort is spent on enhancements.

Adaptive maintenance is the process of changing a system to adapt it to a new operating environment, for example, moving a system from the Windows operating system to the Linux operating system. Adaptive maintenance has been found to account for about a quarter of total maintenance effort. Corrective maintenance is the process of fixing errors in a system after release. Corrective maintenance takes about 20% of maintenance effort.

Since software systems change frequently over time, an important activity is software configuration management. This consists of tracking versions of life-cycle objects, controlling changes to them, and monitoring relationships among them. Configuration management activities include version control, which involves keeping track of versions of life-cycle objects; change control, an orderly process of handling change requests to a system; and build control, the tracking of which versions of work products go together to form a given version of a software product. [W.B.Fra.]

Software metric A rule for quantifying some characteristic or attribute of a computer software entity. For example, a simple one is the FileSize metric, which is the total number of characters in the source files of a program. The FileSize metric can be used to determine the measure of a particular program, such as 3K bytes. It provides a concrete measure of the abstract attribute of program size. Other metrics can be used for software entities such as requirements documents, design object models, or database structure models. Metrics for requirements and design documents can be used to guide decisions about development and as a basis for predictions, such as for cost and effort. Metrics for programs can be used to support decisions about testing and maintenance and as a basis for comparing different versions of programs. Ideally, metrics for the development cost of software and for the quality of the resultant program are desirable. *See* COMPUTER PROGRAMMING; SOFTWARE ENGINEERING. [D.A.G.; W.Han.]

Software testing and inspection Procedures for the detection of software faults. When software does not operate as it is intended to do, a software failure is said to occur. Software failures are caused by one or more sections of the software program being incorrect. Each of these incorrect sections is called a software fault. The fault could be as simple as a wrong value. A fault could also be complete omission of a decision in the program. Faults have many causes, including misunderstanding of requirements, overlooking special cases, using the wrong variable, misunderstanding of the algorithm, and even typing mistakes. Software that can cause serious problems if it fails is called safety-critical software. Many applications in aircraft, medicine, nuclear power plants, and transportation involve such software.

Software testing is the execution of the software with the purpose of detecting faults. Software inspection is a manual process of analyzing the source code to detect faults. Many of the same techniques are used in both procedures. Other techniques can also be used to minimize the possibility of faults in the software. These techniques include the use of formal specifications, formal proofs of correctness, and model checking. However, even with the use of these techniques, it is still important to execute software with test cases to detect possible faults.

Software testing involves selecting test cases, determining the correct output of the software, executing the software with each test case, and comparing the actual output with the expected output. More testing is better, but costs time and effort. The value of additional testing must be balanced against the additional cost of effort and the delay in delivering the software. Another consideration is the potential cost of failure of the software. Safety-critical software is usually tested much more thoroughly than any other software.

The number of potential test cases is huge. For example, in the case of a simple program that multiplies two integer numbers, if each integer is internally represented as a 32-bit number (a common size for the internal representation), then there are 2^{32} possible values for each number. Thus, the total number of possible input combinations is 2^{64}, which is more than 10^{19}. If a test case can be done each microsecond (10^{-6} second), then it will take hundreds of thousands of years to try all of the possible test cases. Trying all possible test cases is called exhaustive testing and is usually not a reasonable approach because of the size of the task.

One approach to software testing is to find test cases so that all statements in a program are executed. A more extensive criterion for test selection is "every branch coverage." This means that each branch coming out of every decision is tested. Instead of just requiring the whole decision to be true or false, the "multiple condition coverage" criterion requires all combinations of truth values for each simple comparison in a decision to be covered. Another approach is called dataflow coverage. The basis for coverage is the execution paths between the statement where a variable is assigned a value (a def or definition) and a statement where that value is used. These paths must be free of other definitions of the variable of interest. *See* DATAFLOW SYSTEMS.

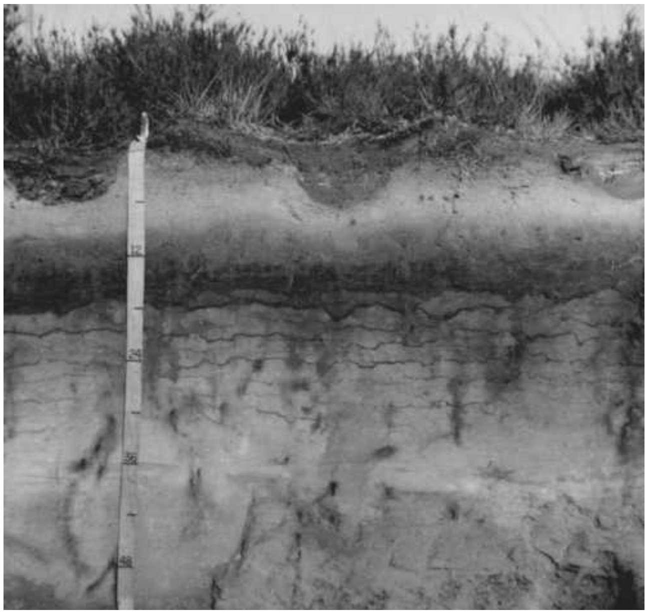
Functional testing compares the actual behavior of the software with the expected behavior. That expected behavior is usually described in a specification. More involved functional test case selection involves analyzing the conditions inherent in the task.

Another approach to test selection concentrates on the boundaries between the subdomains. This approach recognizes that many faults are related to the boundary conditions. Test cases are chosen to check whether the boundary is correct. Test cases on the boundary and test cases just off the boundary are chosen. *See* SOFTWARE; SOFTWARE ENGINEERING. [D.A.G.]

Soil Finely divided rock-derived material containing an admixture of organic matter and capable of supporting vegetation. Soils are independent natural bodies, each with a unique morphology resulting from a particular combination of climate, living plants and animals, parent rock materials, relief, the groundwaters, and age. Soils support plants, occupy large portions of the Earth's surface, and have shape, area, breadth, width, and depth. Soil, as used here, differs in meaning from the term as used by engineers, where the meaning is unconsolidated rock material. *See* PEDOLOGY.

Origin and classification. Soil covers most of the land surface as a continuum. Each soil grades into the rock material below and into other soils at its margins, where changes occur in relief, groundwater, vegetation, kinds of rock, or other factors which influence the development of soils. Soils have horizons, or layers, more or less parallel to the surface and differing from those above and below in one or more properties, such as color, texture, structure, consistency, porosity, and reaction (see illustration). The succession of horizons is called the soil profile.

Soil formation proceeds in stages, but these stages may grade indistinctly from one into another. The first stage is the accumulation of unconsolidated rock fragments, the parent material. Parent material may be accumulated by deposition of rock fragments moved by glaciers, wind, gravity, or water, or it may accumulate more or less in place from physical and chemical weathering of hard rocks. The second stage is the formation of horizons. This stage may follow or go on simultaneously with



Photograph of a soil profile showing horizons. The dark crescent-shaped spots at the soil surface are the result of plowing. The dark horizon is the principal horizon of accumulation of organic matter that has been washed down from the surface. The thin wavy lines were formed in the same manner. 1 in. = 2.5 cm.

Soil orders

Order	Formative element in name	General nature of soils
Alfisols	alf	Gray to brown surface horizons, medium to high base supply, with horizons of clay accumulation; usually moist, but may be dry during summer
Aridisols	id	Pedogenic horizons, low in organic matter, and usually dry
Entisols	ent	Pedogenic horizons lacking
Histosols	ist	Organic (peats and mucks)
Inceptisols	ept	Usually moist, with pedogenic horizons of alteration of parent materials but not of illuviation
Mollisols	oil	Nearly black organic-rich surface horizons and high base supply
Oxisols	ox	Residual accumulations of inactive clays, free oxides, kaolin, and quartz; mostly tropical
Spodosols	od	Accumulations of amorphous materials in subsurface horizons
Ultisols	ult	Usually moist, with horizons of clay accumulation and a low supply of bases
Vertisols	ert	High content of swelling clays and wide deep cracks during some season

the accumulation of parent material. Soil horizons are a result of dominance of one or more processes over others, producing a layer which differs from the layers above and below. *See* WEATHERING PROCESSES.

Systems of soil classification are influenced by concepts prevalent at the time a system is developed. The earliest classifications were based on relative suitability for different crops, such as rice soils, wheat soils, and vineyard soils. Over the years, many systems of classification have been attempted but none has been found markedly superior. Two bases for classification have been tried. One basis has been the presumed genesis of the soil; climate and native vegetation were given major emphasis. The other basis has been the observable or measurable properties of the soil.

The Soil Survey staff of the U.S. Department of Agriculture and the land-grant colleges adopted the current classification scheme in 1965. This system differs from earlier systems in that it may be applied to either cultivated or virgin soils. Previous systems have been based on virgin profiles, and cultivated soils were classified on the presumed characteristics or genesis of the virgin soils. The new system has six categories, based on both physical and chemical properties. These categories are the order, suborder, great group, subgroup, family, and series, in decreasing rank. The orders and the general nature of the included soils are given in the table. The suborder narrows the ranges in soil moisture and temperature regimes, kinds of horizons, and composition, according to which of these is most important. The taxa (classes) in the great group category group soils that have the same kinds of horizons in the same sequence and have similar moisture and temperature regimes. The great groups are divided into subgroups that show the central properties of the great group, intergrade subgroups that show properties of more than one great group, and other subgroups for soils with atypical properties that are not characteristic of any great group. The families are defined largely on the basis of physical and mineralogic properties of importance to plant growth. The soil series is a group of soils having horizons similar in differentiating characteristics and arrangement in the soil profile, except for texture of the surface portion, and developed in a particular type of parent material.

Surveys. Soil surveys include those researches necessary (1) to determine the important characteristics of soils, (2) to classify them into defined series and other units, (3) to establish and map the boundaries between kinds of soil, and (4) to correlate and predict adaptability of soils to various crops, grasses, and trees; behavior and productivity of soils under different management systems; and yields of adapted crops on soils under defined sets of management practices. Although the primary purpose of soil surveys has been to aid in agricultural interpretations, many other purposes have become important, ranging from suburban planning, rural zoning, and highway location, to tax assessment and location of pipelines and radio transmitters. This has happened because the soil properties important to the growth of plants are also important to its engineering uses.

Two kinds of soil maps are made. The common map is a detailed soil map, on which soil boundaries are plotted from direct observations throughout the surveyed area. Reconnaissance soil maps are made by plotting soil boundaries from observations made at intervals. The maps show soil and other differences that are of significance for present or foreseeable uses. [G.D.S.]

Physical properties. Physical properties of soil have critical importance to growth of plants and to the stability of cultural structures such as roads and buildings. Such properties commonly are considered to be: size and size distribution of primary particles and of secondary particles, or aggregates, and the consequent size, distribution, quantity, and continuity of pores; the relative stability of the soil matrix against disruptive forces, both natural and cultural; color and textural properties, which affect absorption and radiation of energy; and the conductivity of the soil for water, gases, and heat. These usually would be considered as fixed properties of the soil matrix, but actually some are not fixed because of influence of water content. The additional property, water content—and its inverse, gas content—ordinarily is transient and is not thought of as a property in the same way as the others. However, water is an important constituent, despite its transient nature, and the degree to which it occupies the pore space generally dominates the dynamic properties of soil. Additionally, the properties listed above suggest a macroscopic homogeneity for soil which it may not necessarily have. In a broad sense, a soil may consist of layers or horizons of roughly homogeneous soil materials of various types that impart dynamic properties which are highly dependent upon the nature of the layering. Thus, a discussion of dynamic soil properties must include a description of the intrinsic properties of small increments as well as properties it imparts to the system.

From a physical point of view it is primarily the dynamic properties of soil which affect plant growth and the strength of soil beneath roads and buildings. While these depend upon the chemical and mineralogical properties of particles, particle coatings, and other factors discussed above, water content usually is the dominant factor. Water content depends upon flow and retention properties, so that the relationship between water content and retentive forces associated with the matrix becomes a key physical property of a soil. *See* EROSION; GROUND-WATER HYDROLOGY; SOIL MECHANICS. [W.H.G.]

Soil chemistry The study of the composition and chemical properties of soil. Soil chemistry involves the detailed investigation of the nature of the solid matter from which soil is constituted and of the chemical processes that occur as a result of the action of hydrological, geological, and biological agents on the solid matter. Because of the broad diversity among soil components and the complexity of soil chemical processes, the application of a wide variety of concepts and methods employed in the chemistry of aqueous solutions, of amorphous and crystalline solids, and of solid surfaces is required.

Elemental composition. The elemental composition of soil varies over a wide range, permitting only a few general statements to be made. Those soils that contain less than 12–20% organic carbon are termed mineral. All other soils are termed organic. Carbon, oxygen, hydrogen, nitrogen, phosphorus, and sulfur are the most important constituents of organic soils and of soil organic matter in general. Carbon, oxygen, and hydrogen are most abundant; the content of nitrogen is often about one-tenth that of carbon, while the content of phosphorus or sulfur is usually less than one-fifth that of nitrogen (Table 1).

Table 1. Average percentages of total carbon, total nitrogen, and organic phosphorus in selected soils

Soil	% C	% N	% P
Sand	2.5	.23	.04
Fine sandy loam	3.3	.23	.06
Medium loam	2.3	.22	.05
Clay loam, well drained	4.6	.36	.10
Clay loam, poorly drained	8.0	.43	.05
Peat	46.1	1.32	.03

Besides oxygen, the most abundant elements found in mineral soils are silicon, aluminum, and iron. The distribution of chemical elements will vary considerably from soil to soil and, in general, will be different in a specific soil from the distribution of elements in the crustal rocks of the Earth. The most important micro or trace elements in soil are boron, copper, manganese, molybdenum, and zinc, since these elements are essential in the nutrition of green plants. Also important are cobalt, selenium, cadmium, and nickel. The average distribution of trace elements in soil is not greatly different from that in crustal rocks (Table 2).

The elemental composition of soil varies with depth below the surface because of pedochemical weathering. The principal processes of this type that result in the removal of chemical elements from a given soil horizon are: (1) soluviation (ordinary dissolution in water), (2) cheluviation (complexation by organic or inorganic ligands), (3) reduction, and (4) suspension. The principal effect of these four processes is the appearance of alluvial horizons in which compounds such as aluminum and iron oxides, aluminosilicates, or calcium carbonate have been precipitated from solution or deposited from suspension. *See* WEATHERING PROCESSES.

Minerals. The minerals in soils are the products of physical, geochemical, and pedochemical weathering. Soil minerals may be either amorphous or crystalline. They may be classified further, approximately, as primary or secondary minerals, depending on whether they are inherited from parent rock or are produced by chemical weathering, respectively.

The bulk of the primary minerals that occur in soil are found in the silicate minerals. Chemical weathering of the silicate minerals is responsible for producing the most important secondary minerals in soil. These are found in the clay fraction and include aluminum and iron hydrous oxides (usually in the form of coatings on other minerals), carbonates, and aluminosilicates. *See* CLAY MINERALS; SILICATE MINERALS.

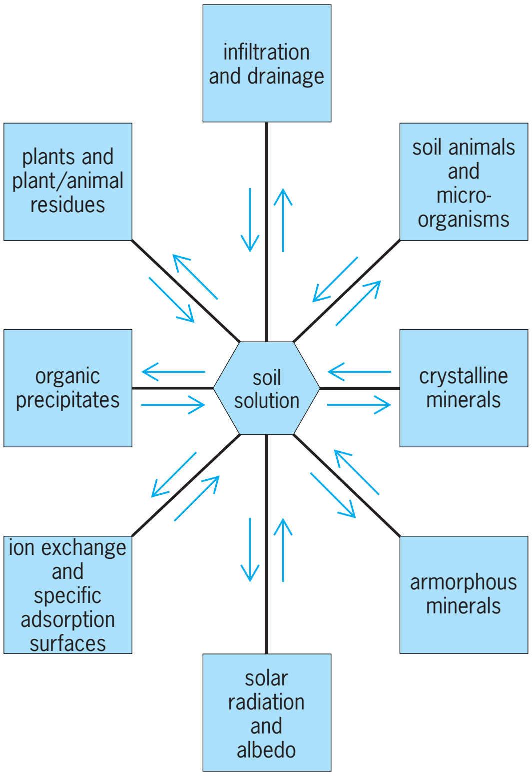
Ion exchange. A portion of the chemical elements in soil is in the form of cations that are not components of inorganic salts but that can be replaced reversibly by the cations of leaching salt solutions or acids. These cations are said to be exchangeable, and their total quantity is termed the cation exchange capacity (CEC) of the soil. The CEC of a soil generally will vary directly with the amounts of clay and organic matter present and with the distribution of clay minerals.

The stoichiometric exchange of the anions in soil for those in a leaching salt solution is a phenomenon of relatively small importance in the general scheme of anion reactions with soils. Under acid conditions ($pH < 5$) the exposed hydroxyl groups at the edges of the structural sheets or on the surfaces of clay-sized particles become protonated and thereby acquire a positive charge. The degree of protonation is a sensitive function of pH, the ionic strength of the leaching solution, and the nature of the clay-sized particle.

Table 2. Average amounts of trace elements commonly found in soils and crustal rocks

Trace element	Soil, ppm*	Crustal rocks, ppm
As	6	1.8
B	10	10
Cd	.06	.2
Co	8	25
Cr	100	100
Cu	20	55
Mo	2	1.5
Ni	40	75
Pb	10	13
Se	.2	.05
V	100	135
Zn	50	70

*ppm = parts per million.



Factors influencing the chemistry of soil solution. (*Modified from J. F. Hodgson, Chemistry of the micronutrients in soil, Adv. Agron., 15:141, 1963*)

Soil solution. The solution in the pore space of soil acquires its chemical properties through time-varying inputs and outputs of matter and energy that are mediated by the several parts of the hydrologic cycle and by processes originating in the biosphere (see illustration). The soil solution thus is a dynamic and open natural water system whose composition reflects the many reactions that can occur simultaneously between an aqueous solution and an assembly of mineral and organic solid phases that varies with both time and space. *See* SOIL. [G.Sp.]

Soil conservation

The practice of arresting and minimizing artificially accelerated soil deterioration. Its importance has grown because cultivation of soils for agricultural production, deforestation and forest cutting, grazing of natural range, and other disturbances of the natural cover and position of the soil have increased greatly in the last 100 years.

Erosion and deterioration. The exact extent of accelerated soil erosion in the world today is not known, particularly as far as the rate of soil movement is concerned. However, it may be said that nearly every semiarid area with cultivation or long-continued grazing, every hill land with moderate to dense settlement in humid temperate and subtropical climates, and all cultivated or grazed hill lands in the Mediterranean climate areas suffer to some degree from such erosion. Recognized problems of erosion are found in such culturally diverse areas as southern China, the Indian plateau, south Australia, the South African native reserves, Russia, Spain, the southeastern and midwestern United States, and Central America.

Within the United States the most critical areas have been the hill lands of the Piedmont and the interior Southeast, the Great Plains, the Palouse area hills of the Pacific Northwest, southern California hills, and slope lands of the Midwest. The high-intensity rainstorms of the Southeast, and the cyclical droughts of the Plains have predisposed the two larger areas to erosion. *See* EROSION.

Soil may deteriorate either by physical movement of soil particles from a given site or by depletion of the water-soluble elements in the soil which contribute to the nourishment of crop plants, grasses, trees, and other economically usable vegetation. The physical movement generally is referred to as erosion. Wind, water, glacial ice, animals, and tools used by humans may be agents of erosion. For purposes of soil conservation, the two most important agents of erosion are wind and water, especially as their effects are intensified by the disturbance of natural cover or soil position.

Depletion of soil nutrients obviously is a part of soil erosion. However, such depletion may take place in the absence of any noticeable amount of erosion. The disappearance of naturally stored nitrogen, potash, phosphate, and some trace elements from the soil also affects the usability of the soil for human purposes. The natural fertility of virgin soils always is depleted over time as cultivation continues, but the rate of depletion is highly dependent on management practices. *See* PLANT MINERAL NUTRITION; SOIL.

Accelerated erosion may be induced by any land use practice which denudes the soil surfaces of vegetative cover. For example, cultivation of any row crop on a slope without soil-conserving practices is an invitation to accelerated erosion. Cultivation of other crops, like the small grains, also may induce accelerated erosion, especially where fields are kept bare between crops to store moisture. Forest cutting, overgrazing, grading for highway use, urban land use, or preparation for other large-scale engineering works also may speed the erosion of soil.

Causes of soil mismanagement. One of the chief causes of erosion-inducing agricultural practices in the United States has been ignorance of their consequences. The cultivation methods of the settlers of western European stock who set the pattern of land use in this country came from a physical environment which was far less susceptible to erosion than North America, because of the mild nature of rainstorms and the prevailing soil textures in Europe. Corn, cotton, and tobacco, moreover, were crops unfamiliar to European agriculture. In eastern North America the combination of European cultivation methods and American interfilled crops resulted in generations of soil mismanagement.

On the Plains and in other susceptible western areas, small grain monoculture, particularly of wheat, encouraged the exposure of the uncovered soil surface so much of the time that water and wind inevitably took their toll. On rangelands, lack of knowledge as to the precipitation cycle and range capacity, and the urge to maximize profits every year contributed to a slower, but equally sure denudation of cover.

Finally, the United States has experienced extensive erosion in mountain areas because of forest mismanagement. Clear-cutting of steep slopes, forest burning for grazing purposes, inadequate fire protection, and shifting cultivation of forest lands have allowed vast quantities of soil to wash out of the slope sites where they could have produced timber and other forest values indefinitely.

Effects on other resources. Accelerated erosion may have consequences which reach far beyond the lands on which the erosion takes place and the community associated with them. During periods of heavy wind erosion, for example, the dust fall may be of economic importance over a wide area beyond that from which the soil cover has been removed. The most pervasive and widespread effects, however, are those associated with water erosion. Removal of upstream cover changes the regimen of streams below the eroding area.

A long chain of other effects also ensues. Because of the extremes of low water in denuded areas during dry seasons, water transportation is made difficult or impossible without regulation, fish and wildlife support is endangered or disappears, the capacity of streams to carry sewage and other wastes safely may be seriously reduced, recreational values are destroyed, and run-of-the-river hydroelectric generation reaches a very low level. *See* WATER CONSERVATION. [E.A.A.; D.J.P.]

Soil degradation

Loss in the quality or productivity of soil as a result of human activities. Degradation is attributed to changes in soil nutrient status, loss of soil organic matter, deterioration of soil structure, and toxicity due to accumulations of naturally occurring or anthropogenic materials. The effects of soil degradation include loss of agricultural productivity, negative impacts on the environment and economic stability, and increased clearing of virgin forest and exploitation of marginally suitable land. *See* SOIL.

Soil degradation may impair the function of soil organisms and thus result in further problems. The soil microbial community is essential to cycling of nutrients and decomposition of wastes; thus hindrance of microbial activities may have serious ecological results. Degradative forces such as erosion that result in loss of organic matter may also result in long-term losses of microbial activity. *See* EROSION; SOIL ECOLOGY.

Soil degradation often affects productivity through depletion of plant nutrients. Excessive leaching of cations involved in buffering soil pH may result in soil acidification, changing the solubility, and thus availability, of certain nutrients to plants. Misuse can also result in concentrations of chemicals that are toxic to plants. *See* SOIL CHEMISTRY; SOIL FERTILITY.

Historically, mining of coal and various metal ores has been among the most devastating forms of land use. Mining often exposes large amounts of reduced (decreased oxidation state) minerals in the form of mine tailings and rubble. The acidic mine tailings are extremely difficult to revegetate, and without intervention they remain exposed, continuing to produce acidic drainage until oxidizable material is depleted. Left untreated, surface (strip) mines may require 50–150 years to recover. *See* AUTOXIDATION; SURFACE MINING.

In some cases, compounds are toxic to soil organisms when present at significant concentrations, and thus produce large shifts in microbial community structure. Eventually, microorganisms present in the soil degrade most organic contaminants, thus alleviating toxic effects.

Unlike organic contaminants, which are degraded to nontoxic forms, toxic metals usually become essentially permanent features of soils. Fortunately, adsorption of metals to soil colloids decreases the availability of the metals for movement in the environment or uptake by plants, animals, and microorganisms. *See* AGRICULTURAL CHEMISTRY. [G.K.S.]

Soil ecology

The study of the interactions among soil organisms, and between biotic and abiotic aspects of the soil environment. Soil is made up of a multitude of physical, chemical, and biological entities, with many interactions occurring among them. Soil is a variable mixture of broken and weathered minerals and decaying organic matter. Together with the proper amounts of air and water, it supplies, in part, sustenance for plants as well as mechanical support. *See* SOIL.

Abiotic and biotic factors lead to certain chemical changes in the top few decimeters (8–10 in.) of soil. The work of the soil ecologist is made easier by the fact that the surface 10–15 cm (4–6 in.) of the A horizon has the majority of plant roots, microorganisms, and fauna. A majority of the biological-chemical activities occur in this surface layer.

The biological aspects of soil range from major organic inputs, decomposition by primary decomposers (bacteria, fungi, and actinomycetes), and interactions between microorganisms and fauna (secondary decomposers) which feed on them. The detritus decomposition pathway occurs on or within the soil after plant materials (litter, roots, sloughed cells, and soluble compounds) become available through death or senescence. Plant products are used by microorganisms (primary decomposers). These are eaten by the fauna which thus affect flows of nutrients, particularly nitrogen, phosphorus, and sulfur. The immobilization of nutrients into plants or microorganisms and their subsequent mineralization are critical pathways. The labile inorganic pool is the principal one that permits subsequent microorganism and plant existence. Scarcity of some nutrient often limits production. Most importantly, it is the rates of flux into and out of these labile inorganic pools which enable ecosystems to successfully function. *See* ECOLOGY; ECOSYSTEM; GUILD; SOIL; SYSTEMS ECOLOGY. [D.C.C.]

Soil fertility The ability of a soil to supply plant nutrients. Sixteen chemical elements are required for the growth of all plants: carbon, oxygen, and hydrogen (these three are obtained from carbon dioxide and water), plus the elements nitrogen, phosphorus, potassium, calcium, magnesium, sulfur, iron, manganese, zinc, copper, boron, molybdenum, and chlorine. Some plant species also require one or more of the elements cobalt, sodium, vanadium, and silicon. *See* PLANT MINERAL NUTRITION.

While carbon and oxygen are supplied to plants from carbon dioxide in the air, the other essential elements are supplied primarily by the soil. Of the latter, all except hydrogen from water are called mineral nutrients. Only part of the 13 essential mineral nutrients in soil are in a chemical form that can be immediately used by plants. The unusable (unavailable) parts, which eventually do become available to plants, are of two kind: they may be in organic combination (such as nitrogen in soil humus) or in solid inorganic soil particles (such as potassium in soil clays). The time for complete decomposition and dissolution of these compounds varies widely, from days to hundreds of years.

Soils exhibit a variable ability to supply the mineral nutrients needed by plants. This characteristic allows soils to be classified according to their level of fertility. This can vary from a deficiency to a sufficiency, or even toxicity (too much), of one or more nutrients. A serious deficiency of only one essential nutrient can still greatly reduce crop yields. Several soil properties are important in determining a soil's inherent fertility. One property is the adsorption and storage of nutrients on the surfaces of soil particles. Such adsorption of a number of nutrients is caused by an attraction of positively charged nutrients to negatively charged soil particles. This adsorption is called cation exchange (adsorbed cations can be exchanged with other cations in solution), and the quantity of nutrient cations a soil can adsorb is called its cation-exchange capacity. *See* ADSORPTION; ION EXCHANGE; SOIL CHEMISTRY.

The negative charge in soils is associated with clay particles, but some of the soil's cation-exchange capacity may arise from organic matter (humus) in the soil. Negative charges of organic matter arise largely from carboxylic and phenolic acid functional groups. Since these functional groups are weak acids, the negative charge from organic matter increases as the soil pH increases. The negative charges of soil organic matter can adsorb the same cations as described for the soil clays. The proportion of cation-exchange capacity arising from mineral clays and from organic matter depends on the proportions of each in the soil and on the kinds of clays. In most mineral soils, the soil clays comprise the greater proportion of cation-exchange capacity. Within the class of mineral soils, those soils with more clay and less sand and silt have the greatest cation-exchange capacity.

The amount and kind of acids on the cation exchange sites can have a substantial influence on a soil's perceived fertility. Two factors cause soils to become acid: when crops are harvested, exchangeable bases are removed as part of the crop; and exchangeable bases move with drainage water below the crop's root zone (leaching). Since much of the nitrogen fertilizer supplied to crops contains ammonium nitrogen (this is true of both manure and chemical fertilizers), the addition of high rates of nitrogen also enhances soil acidification. *See* FERTILIZER; NITROGEN CYCLE; SOIL. [D.E.Ki.]

Soil mechanics The study of the response of masses composed of soil, water, and air to imposed loads. Because both water and air are able to move through the soil pores, the discipline also involves the prediction of these transport processes. Soil mechanics provides the analytical tools required for foundation engineering, retaining wall design, highway and railway subbase design, tunneling, earth dam design, mine excavation design, and so on. Because the discipline relates to rock as well as soils, it is also known as geotechnical engineering. *See* ENGINEERING GEOLOGY.

Soil consists of a multiphase aggregation of solid particles, water, and air. This fundamental composition gives rise to unique engineering properties, and the description of the mechanical behavior of soils requires some of the most sophisticated principles of engineering mechanics. The terms multiphase and aggregation both imply unique properties. As a multiphase material, soil exhibits mechanical properties that show the combined attributes of solids, liquids, and gases. Individual soil particles behave as solids, and show relatively little deformation when subjected to either normal or shearing stresses. Water behaves as a liquid, exhibiting little deformation under normal stresses, but deforming greatly when subjected to shear. Being a viscous liquid, however, water exhibits a shear strain rate that is proportional to the shearing stress. Air in the soil behaves as a gas, showing appreciable deformation under both normal and shear stresses. When the three phases are combined to form a soil mass, characteristics that are an outgrowth of the interaction of the phases are manifest. Moreover, the particulate nature of the solid particles contributes other unique attributes. *See* VISCOSITY.

When dry soil is subjected to a compressive normal stress, the volume decreases nonlinearly; that is, the more the soil is compressed, the less compressible the mass becomes. Thus, the more tightly packed the particulate mass becomes, the more it resists compression. The process, however, is only partially reversible, and when the compressive stress is removed the soil does not expand back to its initial state.

When this dry particulate mass is subjected to shear stress, an especially interesting behavior owing to the particulate nature of the soil solids results. If the soil is initially dense (tightly packed), the mass will expand because the particles must roll up and over each other in order for shear deformation to occur. Conversely, if the mass is initially loose, it will compress when subjected to a shear stress. Clearly, there must also exist a specific initial density (the critical density) at which the material will display zero volume change when subjected to shear stress. The term dilatancy has been applied to the relationship between shear stress and volume change in particulate materials. Soil is capable of resisting shear stress up to a certain maximum value. Beyond this value, however, the material undergoes large, uncontrolled shear deformation. *See* SHEAR.

The other limiting case is saturated soil, that is, a soil whose voids are entirely filled with water. When such a mass is initially loose and is subjected to compressive normal stress, it tends to decrease in volume; however, in order for this volume decrease to occur, water must be squeezed from the soil pores. Because water exhibits a viscous resistance to flow in the microscopic pores of fine-grained soils, this process can require considerable time, during which the pore water is under increased pressure. This excess pore pressure is at a minimum near the drainage face of the soil mass and at a maximum near the center of the soil sample. It is this gradient (or change in pore water pressure with change in position within the soil mass) that causes the outflow of water and the corresponding decrease in volume of the soil mass.

Conversely, if an initially dense soil mass is subjected to shear stress, it tends to expand. The expansion, however, may be time-dependent because of the viscous resistance to water being drawn into the soil pores. During this time the pore water will be under decreased pressure. Thus, in saturated soil masses, changes in pore water pressure and time-dependent volume change can be induced by either changes in normal stress or by changes in shear stress. *See* ROCK MECHANICS; SOIL. [C.A.Mo.]

Soil microbiology The study of biota that inhabit the soil and the processes that they mediate. The soil is a complex environment colonized by an immense diversity of microorganisms. Soil microbiology focuses on the soil viruses, bacteria, actinomycetes, fungi, and protozoa, but it has traditionally also included investigations of the soil animals such as the nematodes, mites, and other microarthropods. These organisms, collectively referred to as the soil biota, function in a belowground ecosystem based on plant roots and litter as food sources. Modern soil microbiology represents an integration of microbiology with the concepts of soil science, chemistry, and ecology to understand the functions of microorganisms in the soil environment.

The surface layers of soil contain the highest numbers and variety of microorganisms, because these layers receive the largest amounts of potential food sources from plants and animals. The soil biota form a belowground system based on the energy and nutrients that they receive from the decomposition of plant and animal tissues. The primary decomposers are the bacteria and fungi.

Microorganisms, especially algae and lichen, are pioneering colonizers of barren rock surfaces. Colonization by these organisms begins the process of soil formation necessary for the growth of higher plants. After plants have been established, decomposition by microorganisms recycles the energy, carbon, and nutrients in dead plant and animal tissues into forms usable by plants. Therefore, microorganisms have a key role in the processing of materials that maintain life on the Earth. The transformations of elements between forms are described conceptually as the elemental cycles.

In the carbon cycle, microorganisms transform plant and animal residues into carbon dioxide and the soil organic matter known as humus. Humus improves the water-holding capacity of soil, supplies plant nutrients, and contributes to soil aggregation. Microorganisms may also directly affect soil aggregation. The extent of soil aggregation determines the workability or tilth of the soil. A soil with good tilth is suitable for plant growth because it is permeable to water, air, and roots. *See* HUMUS.

Soil microorganisms play key roles in the nitrogen cycle. The atmosphere is approximately 80% nitrogen gas (N_2), a form of nitrogen that is available to plants only when it is transformed to ammonia (NH_3) by either soil bacteria (N_2 fixation) or by humans (manufacture of fertilizers). Soil bacteria also mediate denitrification, which returns nitrogen to the atmosphere by transforming NO_3^- to N_2 or nitrous oxide (N_2O) gas. Microorganisms are crucial to the cycling of sulfur, phosphorus, iron, and many micronutrient trace elements.

In addition to the elemental cycles, there are several interactions between plants and microbes which are detrimental or beneficial to plant growth. Some soil microorganisms are pathogenic to plants and cause plant diseases such as root rots and wilts. Many plants form symbiotic relationships with fungi called mycorrhizae (literally fungus-root). Mycorrhizae increase the ability of plants to take up nutrients and water. The region of soil surrounding plant roots, the rhizosphere, may contain beneficial microorganisms which protect the plant root from pathogens or supply stimulating growth factors. The interactions between plant roots and soil microorganisms is an area of active research in soil microbiology. *See* BIOGEOCHEMISTRY; MYCORRHIZAE; NITROGEN CYCLE; NITROGEN FIXATION; NITROGEN OXIDES; RHIZOSPHERE.

The incredible diversity of soil microorganisms is a vast reserve of potentially useful organisms. Many of the medically important antibiotics are produced by filamentous bacteria known as actinomycetes. The soil is the largest reservoir of these medically important microorganisms. *See* ANTIBIOTIC.

The numerous natural substances that are used by microorganisms indicate that soil microorganisms have diverse mechanisms for degrading a variety of compounds. Human activity has polluted the environment with a wide variety of synthetic or processed compounds. Many of these hazardous or toxic substances can be degraded by soil microorganisms. This is the basis for the treatment of contaminated soils by bioremediation, the use of microorganisms or microbial processes to detoxify and degrade environmental contaminants. Soil microbiologists study the microorganisms, the metabolic pathways, and the controlling environmental conditions that can be used to eliminate pollutants from the soil environment. *See* HAZARDOUS WASTE.

Microbiologists traditionally isolate pure strains of microorganisms by using culture methods. Methods that do not rely on culturing microorganisms include microscopic observation and biochemical or genetic analysis of specific cell constituents. The rates or controlling factors for microbial processes are studied by using methods from chemistry, biology, and ecology. Typically, these studies involve measuring the rate of production and consumption of a compound of interest. The results of these studies are commonly analyzed by using mathematical models. Models allow the information from one system to be generalized for different environmental conditions. *See* FLUORESCENCE MICROSCOPE; IMMUNOFLUORESCENCE; MICROBIOLOGY; MOLECULAR BIOLOGY; SOIL; SOIL CHEMISTRY; SOIL ECOLOGY. [J.M.N.]

Soil sterilization A chemical or physical process that results in the death of soil organisms. This control method affects many organisms, even though the elimination of only specific weeds, fungi, bacteria, viruses, nematodes, or pests is desirable. Even if complete sterilization is achieved, it is short lived since organisms will recolonize this biological vacuum quite rapidly. Soil sterilization can be achieved through both physical and chemical means. Physical control measures include steam and solar energy. Chemical control methods include herbicides and fumigants. Dielectric heating and gamma irradiation are used less frequently as soil sterilization methods. Composting can be used to sterilize organic materials mixed with soil, but it is not used for the sterilization of soil alone. Soil sterilization is used in greenhouse operations, the production of high-value or specialty crops, and the control of weeds. [C.A.St.]

Sol-gel process A chemical synthesis technique for preparing gels, glasses, and ceramic powders. The sol-gel process generally involves the use of metal alkoxides, which undergo hydrolysis and condensation polymerization reactions to give gels.

The production of glasses by the sol-gel method permits preparation of glasses at far lower temperatures than is possible by using conventional melting. It also makes possible synthesis of compositions that are difficult to obtain by conventional means because of problems associated with volatilization, high melting temperatures, or crystallization. In addition, the sol-gel approach is a high-purity process that leads to excellent homogeneity. Finally, the sol-gel approach is adaptable to producing films and fibers as well as bulk pieces. *See* GLASS.

The sol-gel process comprises solution, gelation, drying, and densification. The preparation of a silica glass begins with an appropriate alkoxide which is mixed with water and a mutual solvent to form a solution. Hydrolysis leads to the formation of silanol groups (Si—OH). These species are only intermediates. Subsequent condensation reactions produce siloxane bonds (Si—O—Si). The silica gel formed by this process leads to a rigid, interconnected three-dimensional network consisting of submicrometer pores and polymeric chains. During the drying process (at ambient pressure), the solvent liquid is removed and substantial shrinkage occurs. The resulting material is known as a xerogel. When solvent removal occurs under hypercritical (supercritical) conditions, the network does not shrink and a highly porous, low-density material known as an aerogel is produced. Heat treatment of a xerogel at elevated temperature produces viscous sintering (shrinkage of the xerogel due to a small amount of viscous flow) and effectively transforms the porous gel into a dense glass.

Materials used in the sol-gel process include inorganic compositions that possess specific properties such as ferroelectricity, electrochromism, or superconductivity. The most successful applications utilize the composition control, microstructure control, purity, and uniformity of the method combined with the ability to form various shapes at low temperatures. Films and coatings were the first commercial applications of the sol-gel process. The development of sol-gel-based optical materials has also been quite successful, and applications include monoliths (lenses, prisms, lasers), fibers (waveguides), and a wide variety of optical films. Other important applications of sol-gel technology utilize controlled porosity and high surface area for catalyst supports, porous membranes, and thermal insulation. *See* MATERIALS SCIENCE AND ENGINEERING. [B.Du.]

Solanales An order of flowering plants, division Magnoliophyta, in the euasterid I group of the asterid eudicotyledons. The order consists of two large and three small families, of approximately 4275 species. Solanaceae and Convolvulaceae account for all but 25 of the species. Solanales are generally characterized by sympetalous flowers with a superior ovary, and alternate leaves. *See* ASTERIDAE; FLOWER; FRUIT; LEAF; MAGNOLIOPHYTA; MAGNOLIOPSIDA.

Solanaceae, approximately 2600 species, are cosmopolitan herbs, shrubs, lianas, and trees, with branched hairs and often spines and alkaloids. The family is of great economic significance, yielding potatoes, tomatoes, and eggplant (*Solanum*), peppers (*Capsicum*), tobacco (*Nicotiana*) and many ornamentals. Deadly nightshade (*Atropa*), jimson weed (*Datura*), and henbane (*Hyoscyamus*) are well-known poisonous members of the family. *See* BELLADONNA; EGGPLANT; PEPPER; POTATO, IRISH; SOLANALES; TOBACCO.

Convolvulaceae, approximately 1650 species, include herbaceous and woody members that are often climbers. The main economic crop is sweet potato (*Ipomoea*), but the family also includes ornamentals (morning glory, *Ipomoea*; and *Convolvulus*), noxious weeds (*Calystegia* and *Convolvulus*), and parasites (*Cuscuta*). *See* POTATO, SWEET; WEEDS. [M.F.F.]

Solar cell A semiconductor electrical junction device which absorbs and converts the radiant energy of sunlight directly and efficiently into electrical energy. Solar cells may be used individually as light detectors, for example in cameras, or connected in series and parallel to obtain the required values of current and voltage for electric power generation.

Most solar cells are made from single-crystal silicon and have been very expensive for generating electricity, but have found application in space satellites and remote areas where low-cost conventional power sources have been unavailable.

The conversion of sunlight into electrical energy in a solar cell involves three major processes: absorption of the sunlight in the semiconductor material; generation and separation of free positive and negative charges to different regions of the solar cell, creating a voltage in the solar cell; and transfer of these separated charges through electrical terminals to the outside application in the form of electric current.

When light is absorbed in the semiconductor, a negatively charged electron and positively charged hole are created. The heart of the solar cell is the electrical junction which separates these electrons and holes from one another after they are created by the light. An electrical junction may be formed by the contact of: a metal to a semiconductor (this junction is called a Schottky barrier); a liquid to a semiconductor to form a photoelectrochemical cell; or two semiconductor regions (called a *pn* junction).

The fundamental principles of the electrical junction can be illustrated with the silicon *pn* junction. Pure silicon to which a trace amount of a group V element (in the periodic table) such as phosphorus has been added is an *n*-type semiconductor, where electric current is carried by free electrons. Each phosphorus atom contributes one free electron, leaving behind the phosphorus atom bound to the crystal structure with a unit positive charge. Similarly, pure silicon to which a trace amount of a group III element such as boron has been added is a *p*-type semiconductor, where the electric current is carried by free holes. The interface between the *p*- and *n*-type silicon is called the *pn* junction. The fixed charges at the interface due to the bound boron and phosphorus atoms create a permanent dipole charge layer with a high electric field. When photons of light energy from the Sun produce electron-hole pairs near the junction, the built-in electric field forces the holes to the *p* side and the electrons to the *n* side. This displacement of free charges results in a voltage difference between the two regions of the crystal. When a load is connected at the terminals, an electron current flows and useful electrical power is available at the load. *See* SEMICONDUCTOR; SOLAR-ELECTRIC POWER GENERATION; SOLAR ENERGY. [D.G.Sc.]

Solar constant The total solar radiant energy flux incident upon the top of the Earth's atmosphere at a standard distance (1 astronomical unit, 1.496×10^8 km or 9.3×10^7 mi) from the Sun. In 1980 it was discovered that the so-called solar constant actually varies with time, though only by small amounts, around a value of about $1367\ \mathrm{W \cdot m^{-2}}$ ($1.96\ \mathrm{cal \cdot cm^{-2} \cdot min^{-1}}$).

Both expected and unexpected items contribute to the variability of the so-called solar constant. Sunspots can produce deficits of up to a few tenths of 1% of the solar constant, on typical time scales of 1 week. Other surface manifestations of solar magnetic activity, faculae, contribute excesses rather than deficits. Global oscillations of the solar interior, analogous to seismic waves on the Earth, produce variations of a few parts per million on time scales of a few hundred seconds. Finally, and unexpectedly, there is an apparent 11-year sunspot cycle variation amounting to an approximately 0.1% increase of the solar constant during the sunspot maxima. This long-term effect has the opposite dependence from that found for individual sunspots, which block the solar radiant energy and cause decreases rather than increases. *See* HELIOSEISMOLOGY; SUN. [H.S.Hu.]

Solar corona The outer atmosphere of the Sun. The corona is dominated by intense magnetic forces, which penetrate it from denser regions of the Sun. Coronal gas accumulates around these magnetized regions to produce the shapes seen during a solar eclipse, with a coronagraph, or in x-rays. These shapes include long streamers that penetrate interplanetary space, looplike tubes over the strongest fields, and vast regions of very low density called coronal holes. Coronal holes are the source of solar matter streaming into interplanetary space. The general magnetic field of the Sun, about 1 gauss (0.1 millitesla), is revealed near the north and south poles by polar rays that resemble the pattern formed by iron filings near a bar magnet.

From a minimum in the lower atmosphere (approximately 4000 K or 7000°F), the temperature rises to values in the corona of $1\text{–}5 \times 10^6$ K ($2\text{–}9 \times 10^6$ °F) caused by dissipation of mechanical or magnetic energy produced by turbulent flows in the lower atmosphere. The corona is hot enough to emit x-rays, and x-ray telescopes in space can form images of the corona. *See* SUN. [R.C.A.]

Solar energy The energy transmitted from the Sun. The upper atmosphere of Earth receives about 1.5 × 10^{21} watt-hours (thermal) of solar radiation annually. This vast amount of energy is more than 23,000 times that used by the human population of this planet, but it is only about one two-billionth of the Sun's massive outpouring—about 3.9 × 10^{20} MW. *See* Sun.

The power density of solar radiation measured just outside Earth's atmosphere and over the entire solar spectrum is called the solar constant. According to the World Meteorological Organization, the most reliable (1981) value for the solar constant is 1370 ± 6 W/m^2. *See* Solar constant.

Solar radiation is attenuated before reaching Earth's surface by an atmosphere that removes or alters part of the incident energy by reflection, scattering, and absorption. In particular, nearly all ultraviolet radiation and certain wavelengths in the infrared region are removed. However, the solar radiation striking Earth's surface each year is still more than 10,000 times the world's energy use. Radiation scattered by striking gas molecules, water vapor, or dust particles is known as diffuse radiation. Clouds are a particularly important scattering and reflecting agent, capable of reducing direct radiation by as much as 80 to 90%. The radiation arriving at the ground directly from the Sun is called direct or beam radiation. Global radiation is all solar radiation incident on the surface, including direct and diffuse. *See* Solar radiation.

Solar research and technology development aim at finding the most efficient ways of capturing low-density solar energy and developing systems to convert captured energy to useful purposes. Also of significant potential as power sources are the indirect forms of solar energy: wind, biomass, hydropower, and the tropical ocean surfaces. With the exception of hydropower, these energy resources remain largely untapped. *See* Energy sources.

Five major technologies using solar energy are being developed. (1) The heat content of solar radiation is used to provide moderate-temperature heat for space comfort conditioning of buildings, moderate- and high-temperature heat for industrial processes, and high-temperature heat for generating electricity. (2) Photovoltaics convert solar energy directly into electricity. (3) Biomass technologies exploit the chemical energy produced through photosynthesis (a reaction energized by solar radiation) to produce energy-rich fuels and chemicals and to provide direct heat for many uses. (4) Wind energy systems generate mechanical energy, primarily for conversion to electric power. (5) Finally, a number of ocean energy applications are being pursued; the most advanced is ocean thermal energy conversion, which uses temperature differences between warm ocean surface water and cooler deep water to produce electricity. *See* Biomass; Photovoltaic cell; Solar heating and cooling; Wind.

Solar energy can be converted to useful work or heat by using a collector to absorb solar radiation, allowing much of the Sun's radiant energy to be converted to heat. This heat can be used directly in residential, industrial, and agricultural operations; converted to mechanical or electrical power; or applied in chemical reactions for production of fuels and chemicals.

A solar energy system is normally designed to be able to deliver useful heat for 6 to 10 h a day, depending on the season and weather. Storage capacity in the solar thermal system is one way to increase a plant's operating capacity.

There are four primary ways to store solar thermal energy: (1) sensible-heat-storage systems, which store thermal energy in materials with good heat-retention qualities; (2) latent-heat-storage systems, which store solar thermal energy in the latent heat of fusion or vaporization of certain materials undergoing a change of phase; (3) chemical energy storage, which uses reversible reactions (for example, the dissociation-association reaction of sulfuric acid and water); and (4) electrical or mechanical storage, particularly through the use of storage batteries (electrical) or compressed air (mechanical). *See* Energy storage.

Photovoltaic systems convert light energy directly to electrical energy. Using one of the most versatile solar technologies, photovoltaic systems can, because of their modularity, be designed for power needs ranging from milliwatts to megawatts. They can be used to provide power for applications as small as a wristwatch to as large as an entire community. They can be used in centralized systems, such as a generator in a power plant, or in dispersed applications, such as in remote areas not readily accessible to utility grid lines.

Biomass energy is solar energy stored in plant and animal matter. Through photosynthesis in plants, energy from the Sun transforms simple elements from air, water, and soil into complex carbohydrates. These carbohydrates can be used directly as fuel (for example, burning wood) or processed into liquids and gases (for example, ethanol or methane). Biomass is a renewable energy resource because it can be harvested periodically and converted to fuel. *See* Carbohydrate; Photosynthesis.

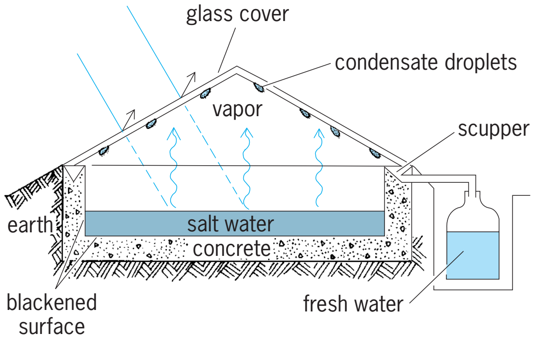
Wind is a source of energy derived primarily from unequal heating of Earth's surface by the Sun. Energy from the wind has been used for centuries to propel ships, to grind grain, and to lift water. Wind turbines extract energy from the wind to perform mechanical work or to generate electricity.

Ocean thermal energy conversion uses the temperature difference between surface water heated by the Sun and deep cold water pumped from depths of 2000 to 3000 ft (600 to 900 m). This temperature difference makes it possible to produce electricity from the heat engine concept. Since the ocean acts as an enormous solar energy storage facility with little fluctuation of temperature over time, ocean thermal energy conversion, unlike most other renewable energy technologies, can provide electricity 24 h a day. [R.L.S.M.]

Solar heating and cooling The use of solar energy to produce heating or cooling for technological purposes. Beneficial uses include distillation of sea water to produce salt or potable water; heating of swimming pools; space heating; heating of water for domestic, commercial, and industrial purposes; cooling by absorption or compression refrigeration; and cooking. *See* Solar energy.

Distillation. Production of potable water from sea water by solar distillation is accomplished in several parts of the world by use of glass-roofed solar stills (see illustration). Production of salt from the sea has been accomplished for hundreds of years by trapping ocean water in shallow ponds at high tide and simply allowing the water to evaporate under the influence of the Sun. *See* Distillation.

Swimming pool heating. Swimming pool heating is a moderate-temperature application which, under suitable weather conditions, can be accomplished with a simple unglazed and uninsulated collector. For applications where a significant temperature difference exists between the fluid within the collector passages and the ambient air, both glazing and insulation are essential.



Roof-type solar still.

Space heating. Space heating can be carried out by active systems which use separate collection, distribution, and storage subsystems, or by passive designs which use components of a building to admit, store, and distribute the heat resulting from absorbing the incoming solar radiation within the building itself.

Passive systems can be classified as direct-gain when they admit solar radiant energy directly into the structure through large south-facing windows, or as indirect-gain when a wall or a roof absorbs the solar radiation, stores the resulting heat, and then transfers it into the building. Passive systems are generally effective where the number of hours of sunshine during the winter months is relatively high, where moderate indoor temperature fluctuations can be tolerated, and where the need for summer cooling and dehumidification is moderate or nonexistent.

Active systems may use either water or air to transport heat from roof-mounted south-facing collectors to storage in rock beds or water tanks. The stored heat may be withdrawn and used directly when air is the transfer fluid. When the heat is collected and stored as hot water, fan-coil units are generally used to transfer the heat to air which is then circulated through the warmed space. Standby energy sources are included in designs for active systems, since some method of providing warmth must be included for use when the Sun's radiant energy is inadequate for long periods of time. The standby heater may be something as simple as a wood-burning stove or fireplace, or as complex as an electrically powered heat pump. *See* COMFORT HEATING; HEAT PUMP.

Service water heating. Solar water heating for domestic, commercial, or industrial purposes is an old and successful application of solar-thermal technology. The most widely used water heater, and one that is suitable for use in relatively warm climates where freezing is a minor problem, is the thermosiphon type. A flat-plate collector is generally used with a storage tank which is mounted above the collector. A source of water is connected near the bottom of the tank, and the hot water outlet is connected to its top. A downcomer pipe leads from the bottom of the tank to the inlet of the collector, and an insulated return line runs from the top of the collector to the upper part of the storage tank which is also insulated.

The system is filled with water, and when the Sun shines on the collector, the water in the tubes is heated. It then becomes less dense than the water in the downcomer, and the heated water rises by thermosiphon action into the storage tank. It is replaced by cool water from the bottom of the tank, and this action continues as long as the Sun shines on the collector with adequate intensity.

For applications where the elevated storage tank is undesirable or where very large quantities of hot water are needed, the tank is placed at ground level. A small pump circulates the water in response to a signal from a controller which senses the temperatures of the collector and the water near the bottom of the tank. Heat exchangers may also be used with water at operating pressure within the tubes of the exchanger and the collector water outside to eliminate the necessity of using high-pressure collectors. *See* HOT-WATER HEATING SYSTEM.

Cooling. Cooling can be provided by both active and passive systems.

The two feasible types of active cooling systems are Rankine cycle and absorption. The Rankine cycle system uses solar collectors to produce a vapor (steam or one of the fluorocarbons generally known as Freon) to drive an engine or turbine. A condenser must be used to condense the spent vapor so it can be pumped back through the vaporizer. The engine or turbine drives a conventional refrigeration compressor which produces cooling in the usual manner. *See* RANKINE CYCLE; REFRIGERATION.

Passive cooling systems make use of three natural processes: convection cooling with night air; radiative cooling by heat rejection to the sky on clear nights; and evaporative cooling from water surfaces exposed to the atmosphere. The effectiveness of each of these processes depends upon local climatic conditions. *See* ENERGY STORAGE; SOLAR CELL. [J.I.Y.]

Solar magnetic field

The magnetic field rooted in the Sun and extending out past the planets into the solar system. The field at the Sun's surface is detected remotely by its effect (the Zeeman effect) on atoms whose radiation is observed from Earth. This technique was first applied in 1908 by G. E. Hale to detect the fields in sunspots. In 1952, H. D. Babcock and his son H. W. Babcock used a scanning technique to make the first magnetic maps of the entire visible disk of the Sun. Their daily "magnetograms" soon revealed a variety of magnetic features, including bipolar regions associated with sunspot groups, and unipolar regions whose fields extend far from the Sun and are responsible for recurrent geomagnetic activity at Earth. The field strengths range from a few gauss (a few hundred microtesla) in quiet areas to 3500 gauss (0.35 tesla) in sunspots. In 1962, the *Mariner 2* spacecraft, en route to Venus, made the first on-site sampling of the extended solar field in space. The average field strength was only 50 microgauss (5 nanotesla), reflecting the rapid (inverse square) fall-off of field strength with distance from the Sun. *See* ZEEMAN EFFECT.

Solar magnetic fields are related to the 11-year variation in the occurrence of sunspots. As the new sunspot cycle begins, concentrations of bipolar flux break through the Sun's surface in each hemisphere, beginning at about 40° latitude and gradually progressing toward the solar equator over the next few years. The bipolar regions are oriented approximately east-west with their leading polarities (in the sense of solar rotation) all positive in the northern hemisphere and negative in the southern hemisphere during a given sunspot cycle (Hale's law). They are tilted slightly so that their trailing polarities are closer to the Sun's poles and the leading polarities are closer to the equator. This small but systematic effect ultimately leads to the formation of unipolar regions at the Sun's poles, positive in one hemisphere and negative in the other.

It is presently believed that convection and differential rotation are responsible for the eruption of bipolar magnetic regions. *See* MAGNETISM; SUN. [N.R.S.]

Solar neutrinos

Neutrinos produced in nuclear reactions inside the Sun. Neutrinos are produced as well in laboratory nuclear reactions. The first direct tests of how the Sun produces its luminosity (observed most conspicuously on Earth as sunlight) have been carried out by observing solar neutrinos. The results of these experiments confirm the theory of how the Sun shines and stars evolve. Moreover, the results show that neutrinos behave differently than predicted by the standard model of particle physics.

Many explanations have been advanced for the discrepancy between the observed and the predicted event rates in the solar neutrino experiments. These explanations can be divided into three general classes: (1) the standard solar model must be significantly modified; (2) something is seriously wrong with the experiments; (3) the standard model of how neutrinos behave must be significantly modified.

Precise measurements of the thousands of frequencies with which the Sun pulsates on its surface (with characteristic periods of the order of 5 minutes) have confirmed to an accuracy of 0.1% the predictions of the standard solar model for these pulsation frequencies. This agreement is convincing evidence that the standard solar model is an accurate description of the Sun. *See* HELIOSEISMOLOGY.

All of the solar neutrino experiments have been examined carefully by many different searchers. A variety of checks have been made to test whether there was a significant error or a large uncertainty in one of the experiments that might explain the difference between prediction and observation. No significant previously unknown errors or uncertainties have been found. Moreover, intense laboratory sources of neutrinos have been placed near the gallium neutrino detectors, and the expected number of events have been observed from these artificial sources. The consensus view among scientists in the field is that the solar neutrino experiments are yielding a valid but surprising result.

The only remaining possibility is that the theory of how the neutrino behaves must be changed. Indeed, in 2000, the results of a decisive experiment showed unequivocally that solar neutrinos change their type on their way from the center of the Sun. All of the results from solar neutrino experiments are consistent with the conclusion that the standard solar model predicts accurately the number of neutrinos of different energies that are emitted by the Sun but that some of the neutrinos change their type on the way from the center of the Sun to the detectors on Earth. *See* NEUTRINO; STANDARD MODEL; SUN. [J.N.B.]

Solar radiation The electromagnetic radiation and particles (electrons, protons, alpha particles, and rarer heavy atomic nuclei) emitted by the Sun. The electromagnetic radiation covers a wavelength range from x-rays to radio waves, that is, from about 0.01 nanometer to 30 km. The annual mean irradiance at Earth, integrated over the whole spectrum, amounts to $1365\ \mathrm{W \cdot m^{-2}}$, and 99% of its energy is carried by radiation with wavelengths between 278 and 4600 nm, with the maximum at 472 nm. *See* ELECTROMAGNETIC RADIATION; SOLAR CONSTANT.

The Sun also emits a continuous stream of particles, the solar wind, which originates in coronal holes and the upper corona. Explosive events on the Sun, the solar flares and coronal mass ejections, emit particles that are much more energetic and numerous than those of the solar wind. Solar flares are produced by the most powerful explosions, releasing energies of up to 10^{25} joules in 100–1000 s and high-speed electrons that emit intense radiation at radio and x-ray wavelengths. They also produce nuclear reactions in the solar atmosphere with the emission of gamma rays and of neutrons that move nearly at the speed of light. Coronal mass ejections expand away from the Sun at speeds of hundreds of kilometers per second, becoming larger than the Sun and removing up to 5×10^{13} kg of coronal material. Both events are believed to be ignited by the reconnection of magnetic fields. If the emitted particles reach the Earth, they give rise to the aurora at high latitudes, and they can damage satellites, endanger humans in space, and on the Earth disturb telecommunications and even disrupt power systems. *See* AURORA; COSMIC RAYS; IONOSPHERE; MAGNETOSPHERE; SOLAR WIND; SUN. [C.Fro.]

Solar system The Sun and the bodies moving in orbit around it. The most massive body in the solar system is the Sun, a typical single star that is itself in orbit about the center of the Milky Way Galaxy. Nearly all of the other bodies in the solar system—the terrestrial planets, outer planets, asteroids, and comets—revolve on orbits about the Sun. Various types of satellites revolve around the planets; in addition, the giant planets all have orbiting rings. The orbits for the planets appear to be fairly stable over long time periods and hence have undergone little change since the formation of the solar system. It is thought that some 4.56×10^9 years ago a rotating cloud of gas and dust collapsed to form a flattened disk (the solar nebula) in which the Sun and other bodies formed. The bulk of the gas in the solar nebula moved inward to form the Sun, while the remaining gas and dust are thought to have formed all the other solar system bodies by accumulation proceeding through collisions of intermediate-sized bodies called planetesimals. Planetary systems are believed to exist around many other stars in the Milky Way Galaxy. Solid evidence for the existence of Jupiter-mass planets around nearby solarlike stars now exists. *See* PLANET.

Composition. The Sun is a gaseous sphere with a radius of about 7×10^5 km (4×10^5 mi), composed primarily of hydrogen and helium and small amounts of the other elements. The terrestrial planets (Mercury, Venus, Earth, and Mars) are the closest to the Sun. They are composed primarily of silicate rock (mantles) and iron (cores). The Earth is the largest terrestrial planet; Mercury is the smallest, with a mass of 0.053 times that of Earth. *See* EARTH; MARS; MERCURY (PLANET); PLANETARY PHYSICS; SUN; VENUS.

The outer planets are subdivided into the gas giant or Jovian planets (Jupiter and Saturn), the ice giant planets (Uranus and Neptune), and Pluto. By far the largest planet is Jupiter, with a mass 318 times that of the Earth, while the other giant planets are more massive by a factor of 15 or more than Earth. Jupiter and Saturn are composed primarily of hydrogen and helium gas, like the Sun, but with rock and ices, such as frozen water, methane, and ammonia, concentrated in their cores. Uranus and Neptune also have rock and ice cores surrounded by envelopes with smaller amounts of hydrogen and helium. Pluto, slightly smaller than the Earth's Moon, is probably composed primarily of rock and ice. *See* JUPITER; NEPTUNE; PLUTO; SATURN; URANUS.

The region between Mars and Jupiter is populated by a large number of rocky bodies called asteroids. The asteroids are smaller than the terrestrial planets. with most known asteroids being about 1 km (0.6 mi) in radius, though a few have radii of hundreds of kilometers. Some asteroids have orbits that take them within the orbits of Earth and the other terrestrial planets. Small fragments of asteroids (or comets) that impact the Earth first appear as meteors in the sky; any meteoric material that survives the passage through the Earth's atmosphere and reaches the surface is called a meteorite. *See* ASTEROID; METEOR; METEORITE.

Comets are icy bodies (so-called dirty snowballs) with diameters on the order of 10 km (6 mi). In contrast to the orbits of most planets, cometary orbits often are highly elliptical and have large inclinations that take them far from the plane where the planets orbit. The region well beyond Pluto's orbit is populated with a very large number (perhaps 10^{12}) of comets, out to a limiting distance of about 10^5 AU. The distribution of comets within this huge volume, the Oort Cloud, is uncertain. Comets have been detected orbiting in the plane of the solar system at distances of 30 to 50 AU; this flattened distribution is called the Edgeworth-Kuiper Belt. *See* COMET; KUIPER BELT.

Origin. The nebular hypothesis, advanced in 1796 by P. S. de Laplace, holds that the Sun and the rest of the bodies in the solar system formed from the same rotating, flattened cloud of gas and dust, now called the solar nebula. The nebular hypothesis explains the gross orbital properties of the solar system: all planets orbit (and most rotate) in the same sense as the Sun rotates, with their nearly circular orbits being confined largely to a single plane almost perpendicular to the Sun's rotation axis.

Observations of present-day regions of star formation in the Milky Way Galaxy confirm the stellar implications of Laplace's nebular hypothesis: very young stars (protostars) are indeed found embedded in dense clouds of gas and dust that often show evidence for flattening and rotation.

The solar nebula was produced by the collapse of a dense interstellar cloud. Radio telescopes have shown that such clouds exist with masses comparable to that of the Sun. Eventually they enter the collapse phase, where supersonic inward motions develop that lead to the formation of a stellar-sized core at the center of the cloud in about 10^5–10^6 years. *See* INTERSTELLAR MATTER; MOLECULAR CLOUD; RADIO ASTRONOMY; STELLAR EVOLUTION.

In a rotating cloud, not all of the in-falling gas and dust falls directly onto the central protostar, because of the conservation of angular momentum. Instead, a disklike solar nebula forms. The disk must evolve in such a way as to transfer mass inward to feed the growing Sun, while transporting outward the excess angular momentum undesired by the Sun but required for the planets. While this sort of evolution may appear to be contrived if not miraculous, it is actually to be expected on very general grounds for any viscous disk that is undergoing a loss of energy, as the solar nebula will, through radiation to space.

The portion of the nebula that is to form the planets must decouple from the gaseous nebula to avoid being swallowed by the Sun. This occurs by the process of coagulation of dust grains through mutual collisions; when solid bodies become large enough (roughly kilometer-sized), they will no longer be tied to the nebula through brownian motion (as is the case with dust grains) or gas drag (as happens with smaller bodies).

About 10^{12} kilometer-sized planetesimals are needed to form just the terrestrial planets; significantly greater numbers of similarly sized bodies would be needed to form the giant planets. These plantesimals are already roughly the size of many asteroids and comets, suggesting that many of these bodies are simply leftovers from intermediate phases of the planet formation process.

The subsequent growth of the planetesimals through gravitational accumulation is in two distinct phases. In the first phase, planetesimals grew by accumulation of other planetesimals at essentially the same distance from the Sun. Once the nearby planetesimals were all swept up, this phase ended.

In the second phase, accumulation requires bodies at significantly different distances from the Sun to collide. This phase may have involved violent collisions between planetary-sized bodies. A glancing collision between a Mars-sized and an Earth-sized body appears to be the best explanation for the formation of the Earth-Moon system; debris from the giant impact would end up in orbit around the Earth and later form the Moon.

Forming gas giant planets by the two-step process requires about 10^7 years for a 10-Earth-mass core to form and then accrete a massive gaseous envelope. The alternative means for forming the gas giant planets is much more rapid, requiring only about 10^3 years for a gravitational instability of the gaseous nebula to produce a massive clump of gas and dust. [A.P.B.]

Solar wind The continuous outward flow of ionized solar gas and a "frozen-in" remnant of the solar magnetic field through the solar system. This flow arises from strong outward pressure in the solar corona, becomes supersonic at a few solar radii (1 solar radius = 6.96×10^5 km or 4.32×10^5 mi) above the visible surface of the Sun (the photosphere), and attains speeds in the range 250–750 km/s (155–465 mi/s) in interplanetary space. The solar wind is believed to remain supersonic out to a distance from the Sun of 50–100 astronomical units (AU), where it is slowed by interaction with the interstellar gas and magnetic field. *See* Interstellar matter; Solar magnetic field.

In 1962, sampling instruments on the *Mariner 2* spacecraft revealed an important pattern in the variations of solar wind speed with time. The observed speed rose systematically from low values to high values in 1 or 2 days and then returned to low values during the next 3 to 5 days. Each of these high-speed streams tended to be seen at approximately 27-day intervals or to recur with the rotation period of the Sun as viewed from the spacecraft. A similar recurrence tendency had been noted in geomagnetic activity, and was widely interpreted as the effect of localized, long-lived streams of particles emitted from the Sun and swept past the Earth once during each solar rotation. The high-speed solar wind streams have been linked to recurrent geomagnetic activity and found to be prominent features of the solar wind much of the time since 1962. *See* Geomagnetism; Magnetosphere.

X-ray and ultraviolet images of the Sun have brought attention to the features known as coronal holes. These are regions of abnormally low corona] density that appear dim in any radiation emitted (x-rays and the ultraviolet) or scattered (the white-light corona observed at eclipse) from the corona. Detailed examination of these images suggests that the holes are regions where the solar magnetic field is open, with field lines reaching from their visible roots in the photosphere out into interplanetary space. In contrast, the structure seen in the bright or dense corona suggests closed magnetic fields, with field lines connecting separated locations in the photosphere. *See* Solar corona.

The largest and longest-lived coronal holes have been observed to occur in the polar regions of the Sun (as defined by its rotation axis); conspicuous polar holes existed for at least 8 years during the last 11-year sunspot cycle. These polar holes are related to the weak, dipolelike, general magnetic field of the Sun and are thus of opposite polarity in the two hemispheres. *See* Sun. [A.J.Hu.]

Soldering A low-temperature metallurgical joining method in which the solder (joining material) has a much lower melting point than the surfaces to be joined (substrates). Because of its lower melting point, solder can be melted and brought into contact with the substrates without melting them. During the soldering process, molten solder wets the substrate surfaces (spreads over them) and solidifies on cooling to form a solid joint.

The most important technological applications of solders are in the assembly of electronic devices, where they are used to make metallic joints between conducting wires, films, or contacts. They are also used for the routine low-temperature joining of copper plumbing fixtures and other devices. In addition, solder is used in the fusible joints of fire safety devices and other high-temperature detectors; the solder joint liquefies if the ambient temperature exceeds the solder's melting point, releasing a sprinkler head or triggering some other protective operation.

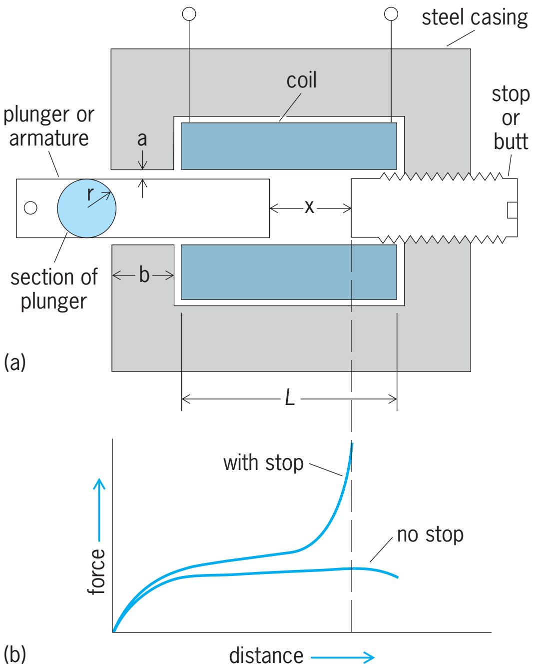
Tin or indium content is included in solder to facilitate bonding to the metals that are most commonly soldered, such as copper (Cu), nickel (Ni), and gold (Au). Tin and indium form stable intermetallic compounds with copper and nickel, and indium also forms intermetallics with gold. The intermetallic reaction at the solder-substrate interface creates a strong, stable bond. *See* Alloy; Intermetallic compounds. [J.W.Mo.]

Solenodon An insectivorous mammal. The two species composing the family Solenodontidae are restricted to the West Indies. The relationship of this family to other insectivores is obscure. Almique (*Atopogale cubana*) is found only in Cuba, while agouta (*Solenodon paradoxus*) is confined to Haiti. Extinct members of the family such as *Apternodus* and *Micropternodus* are known from North America. Both living species are now rare because of the predatory mongoose, which was originally introduced to combat snakes.

Solenodons are about 2 ft (0.6 m) long and have a ratlike body. They resemble tenrecs, except that solenodons have a long tail and no spines. Each of the digits has a powerful claw, with those on the forelimbs being quite large. The eyes are small, the snout is extremely elongate, scent glands are present in both the groin and armpit regions, and the mammary glands are located on the buttocks. They have a total of 40 teeth. Solenodons are nocturnally active, searching for insects, worms, vegetation, and small vertebrates. *See* Dentition; Insectivora; Tenrec. [C.B.C.]

Solenoid (electricity) An electrically energized coil of insulated wire which produces a magnetic field within the coil. If the magnetic field produced by the coil is used to magnetize and thus attract a plunger or armature to a position within the coil, the device may be considered to be a special form of electromagnet and in this sense the words solenoid and electromagnet are synonymous. In a wider scientific sense the solenoid may be used to produce a uniform magnetic field for various investigations. So long as the length of the coil is much greater than its diameter (20 or more times), the magnetic field at the center of the coil is sensibly uniform, and the field intensity is almost exactly that given by the equation for a solenoid of infinite length.

When used as an electromagnet of the plunger type, the solenoid usually has an iron or steel casing. The casing increases the mechanical force on the plunger and also serves to constrain the magnetic field. The addition of a butt or stop at one end of the solenoid greatly increases the force on the plunger when the distance between the plunger and the stop is small. The illustration



Steel-clad solenoid. (*a*) Cross-sectional view. (*b*) Relation of the force acting on the armature to the displacement of the armature.

shows a steel-clad solenoid with plunger and plunger stop. The relation of force versus distance with and without the stop is also shown. *See* ELECTROMAGNET. [J.Mei.]

Solenoid (meteorology)

In meteorological usage, solenoids are hypothetical tubes formed in space by the intersection of a set of surfaces of constant pressure (isobaric surfaces) and a set of surfaces of constant specific volume of air (isosteric surfaces) or density (isopycnic surfaces). The isobaric and isosteric surfaces are such that the values of pressure and specific volume, respectively, change by one unit from one surface to the next. The state of the atmosphere is said to be barotropic when there are no solenoids, that is, when isobaric and isosteric surfaces coincide. The number of solenoids cut by any plane surface element of unit area is a measure of the torque exerted by the pressure gradient force, tending to accelerate the circulation of air around the boundary of the area. *See* BAROCLINIC FIELD; BAROTROPIC FIELD; ISOPYCNIC. [F.S.; H.B.B.]

Solid (geometry)

A three-dimensional geometric figure consisting of points continuously connected, and separated from the rest of space by a surface called the boundary of the solid. Points on the boundary are usually considered part of the solid. A solid is bounded if there exists a sphere having finite radius that could enclose the solid. A solid is convex if all points of any line segment having end points on the boundary also are points of the solid. [H.L.Ba.]

Solid solution

Compositional variation of a crystalline substance due to substitution or omission of various atomic constituents within a crystal structure. Solid solutions can be classified as substitutional, interstitial, or omissional. They may also be categorized by the nature of their thermodynamic properties, such as enthalpy, entropy, and free energy (for example ideal, nonideal, and regular solid solutions).

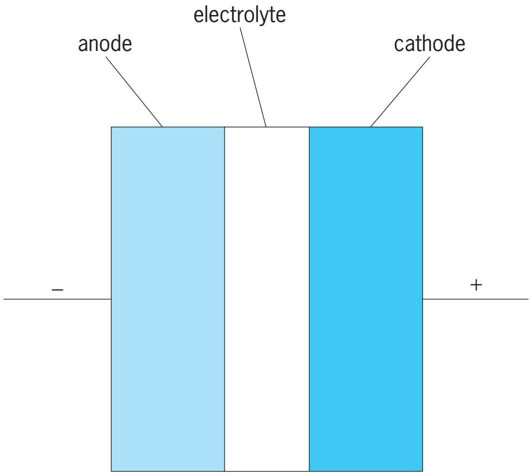
The concept of solid solution can be understood by considering a specific mineral group such as olivine. Although olivine-group minerals may exhibit a range of compositions they all have a similar crystal structure. Thus all of the minerals in the olivine group are isostructural (having a similar crystal structure). Yet within this structural framework, compositions vary considerably. Such chemical variation can be described by defining the nature and extent of the atomic substitutions involved or by describing intermediate compositions in terms of limiting end-member compositions. In addition to substitution within the crystal structure, compositional variation may take place by interstitial substitution or omission solid solution. Interstitial solid solution occurs when ions or atoms occupy a position in a crystal structure that is usually vacant. Omission solid solution occurs when an atom or ion is missing from a specific crystallographic position. *See* OLIVINE.

Solid solution is widespread among minerals. In fact, very few naturally occurring minerals exist as pure end-member substances but exhibit trace to extensive solid solution. The extent of solid solution depends upon the relative sizes of the atoms or ions involved, the charges of the ions, the coexistence and composition of other minerals or liquid (for example, magma), and the temperature and pressure conditions of formation (with temperature having a more pronounced effect). [J.C.D.]

Solid-state battery

A battery in which both electrodes and the electrolyte are solids (see illustration). Solid electrolytes are a class of materials also known as superionic conductors and fast ion conductors, and their study belongs to an area of science known as solid-state ionics. As a group, these materials are very good conductors of ions but are essentially insulating toward electrons, properties that are prerequisites for any electrolyte. The high ionic conductivity minimizes the internal resistance of the battery, thus permitting high power densities, while the high electronic resistance minimizes its self-discharge rate, thus enhancing its shelf life. Examples of such materials include Ag_4RbI_5 for Ag^+ conduction, LiI/Al_2O_3 mixtures for Li^+ conduction, and the clay and β-alumina group of compounds ($NaAl_{11}O_{17}$) for Na^+ and other mono- and divalent ions. At room temperature the ionic conductivity of a single crystal of sodium β-alumina is 0.035 S/cm, comparable to the conductivity of a 0.1 M HCl solution. This conductivity, however, is reduced in a battery by a factor of 2–5, because of the use of powdered or ceramic material rather than single crystals. Of much interest are glassy and polymeric materials that can be readily made in thin-film form, thus enhancing the rate capability of the overall system. *See* ELECTROLYTE; ELECTROLYTIC CONDUCTANCE; IONIC CRYSTALS.

Solid-state batteries generally fall into the low-power-density and high-energy-density category. The former limitation arises because of the difficulty of getting high currents across solid–solid interfaces. However, these batteries do have certain advantages that outweigh this disadvantage: They are easy to miniaturize (for example, they can be constructed in thin-film form), and there



Schematic diagram of solid-state battery.

is no problem with electrolyte leakage. They tend to have very long shelf lives, and usually do not have any abrupt changes in performance with temperature, such as might be associated with electrolyte freezing or boiling. Being low-power devices, they are also inherently safer. The major applications of these batteries are in electronic devices such as cardiac pacemakers, cameras, electrochromic displays, watches, and calculators. *See* BATTERY. [M.S.W.]

Solid-state chemistry The science of the elementary, atomic compositions of solids and the transformations that occur in and between solids and between solids and other phases to produce solids. Solid-state chemistry deals primarily with those microscopic features which are uniquely characteristic of solids and which are the causes for the macroscopic chemical properties and the chemical reactions of solids. As with other branches of the physical sciences, solid-state chemistry also includes related areas that furnish concepts and explanations of those phenomena which are more characteristic of the subject itself.

The overlap of solid-state chemistry and solid-state physics is extensive. However, the perspectives of the two are different. In general, solid-state physics treats properties, such as energy and entropy, which are continuously variable in the solid, whereas solid-state chemistry concerns those properties which are discontinuous because of chemical reactions. Also, solid-state chemistry tends to be based on structure in configuration space, whereas solid-state physics tends to be based on momentum space. *See* INORGANIC CHEMISTRY; SOLID-STATE PHYSICS.

Solid-state chemistry has no single unifying theoretical base and tends to be largely an experimental science supported by several theoretical bases. Consequently, its separation into topics is not well established. Aspects of solid-state chemistry include chemical bonding, crystal defects, crystal structures, crystal field theory, diffusion in solids, ionic crystals, lattice vibrations, and nonstoichiometry. *See* NONSTOICHIOMETRIC COMPOUNDS.

Studies of structures provide a basis for understanding the chemical bonding in solids, their properties, reactions among them, and their variabilities of composition. Numerous binary compounds or phases have layered structures. The layers are displaced relative to each other in such a way that the structures can be classified in the space groups, but when other elements or compounds are incorporated between the layers, the structure is highly distorted. The most widely recognized material to possess the layered structure and the associated solid-state chemistry is graphite. Structural information is represented by the location of atoms on the lattice network. The structures are determined by diffraction of x-rays, neutrons, or electrons. Two other features of the structure of solids are the local structure about a given atom and the extended structure on a more global scale. *See* GRAPHITE.

The structure of a solid is the result of the operation of interatomic or interionic forces and the size and shape of the atoms or ions. Hence, logically, bonding should be described first and structure second. However, the detailed role of the electrons in interionic forces is so complex, and the quantitative aspects of the problem of minimizing the potential energy with respect to all the possible configurations is so difficult, that structures cannot be derived. Rather, it is necessary to derive some information about bonding from structures, cohesive energies, refractive indices, electron binding energies, polarizabilities, and other properties through the use of models. Simple, classically based models can be classified generally as ionic, covalent, and metallic bonding and combinations of the three. *See* CHEMICAL BONDING; STRUCTURAL CHEMISTRY.

The mechanisms of chemical reactions within and between solids are through lattice vibrations, lattice defects, and changes in valence states. These are the structural features through which migration of mass, charge, and energy occur. Consequently, diffusion and conductivity are integral, basic parts of solid-state chemistry. *See* DIFFUSION; ELECTRICAL CONDUCTIVITY OF METALS.

A feature of the electronic structure of solids, which is particularly essential to solid-state chemistry, is the valence state of the ion and the energy required to change the valency in the solid. *See* VALENCE.

Many of the photo-induced processes which occur in solids can be imagined to be solid-state chemical reactions. The classical ones, of course, are those involved in photographic plates and films. *See* PHOTOCHEMISTRY. [R.J.T.]

Solid-state physics The study of the physical properties of solids, such as electrical, dielectric, elastic, and thermal properties, and their understanding in terms of fundamental physical laws. Most problems in solid-state physics would be called solid-state chemistry if studied by scientists with chemical training, and vice versa. Solid-state physics emphasizes the properties common to large classes of compounds rather than the dependence of properties upon compositions, the latter receiving greater emphasis in solid-state chemistry. In addition, solid-state chemistry tends to be more descriptive, while solid-state physics focuses upon quantitative relationships between properties and the underlying electronic structure. *See* SOLID-STATE CHEMISTRY.

Many of the scientists who study the physics of liquids identify with solid-state physics, and the term “condensed-matter physics” has been used by some researchers to replace “solid-state physics” as a division of physics. It includes noncrystalline solids such as glass as well as crystalline solids. *See* AMORPHOUS SOLID; GLASS.

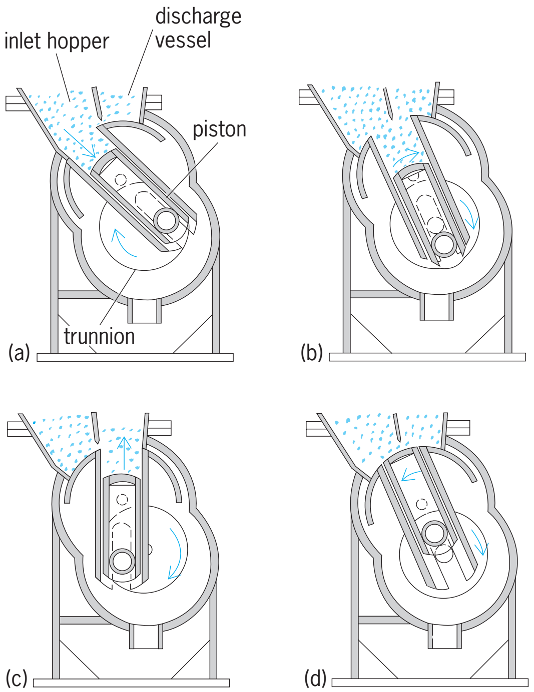
In solid-state physics it is generally assumed that the electronic states can be described as wavelike. The individual electronic states, called Bloch states, have energies which depend upon the wave number (a vector equal to the momentum divided by $\hbar$, which is Planck’s constant divided by 2π), and the wave number is restricted to a domain called the Brillouin zone. This energy given as a function of the wave number is called the band structure. There are several curves, called bands, for each line in the Brillouin zone. *See* BRILLOUIN ZONE.

The total energy of a solid includes a sum of the energies of the occupied electronic states. Since the energy bands depend upon the positions of the atoms, so does the total energy, and the stable crystal structure is that which minimizes this energy. The theory has not proved adequate to really predict the crystal structure of various solids, but it is possible to predict the changes in energy under various distortions of the lattice. There are in fact three times as many independent distortions, called normal modes, as there are atoms in the solid. Each has a wave number, and the frequencies of the normal vibrational modes, as a function of wave number in the Brillouin zone, form vibrational bands in direct analogy with the electronic energy bands. These can be directly calculated from quantum theory or measured by using neutron or x-ray diffraction. *See* CRYSTAL; LATTICE VIBRATIONS; NEUTRON DIFFRACTION; X-RAY DIFFRACTION. [W.A.H.]

Solids pump A device used to move solids upward through a chamber or conduit. It is able to overcome the large dynamic forces at the base of a solids bed and cause the entire bed to move upward.

Solids pumps are used to cause motion of solids in process-type equipment in which treatment of solids under special conditions of temperature, oxidation, and reduction can be combined with upward motion and discharge of the spent solids overhead from the reacting vessel. The solids pump has found its principal application in the operation of oil-shale retorts.

Solids pumps are inherently of the positive displacement type. One practical method uses a reciprocating piston mounted on a trunnion permitting it to swing into an inclined position for filling and then to swing back into vertical position for discharge. The illustration shows a mechanically driven solids pump in four



Operation cycle of mechanically driven solids pump. (*a*) Filling with solids from inlet hopper. (*b*) Piston rotating on a trunnion toward its discharge position. (*c*) The discharge position, with piston pushing charge of solids upward. (*d*) Piston rotating back toward original filling position.

positions through its cycle of operation. *See* Bulk-handling machines. [C.Be.]

Solifugae An order of nonvenomous, spiderlike predatory arachnids found chiefly in arid and semiarid, tropical, and warm-temperate regions. They are also known as sun spiders. The relatively large anterior appendages, or chelicerae, are used for holding and crushing prey. The sun spiders are agile and usually stalk their prey during the night. A fossil form is known from Pennsylvanian time. *See* Arachnida. [C.C.Ho.]

Soliton An isolated wave that propagates without dispersing its energy over larger and larger regions of space. In most of the scientific literature, the requirement that two solitons emerge unchanged from a collision is also added to the definition; otherwise the disturbance is termed a solitary wave.

There are many equations of mathematical physics which have solutions of the soliton type. Correspondingly, the phenomena which they describe, be it the motion of waves in shallow water or in an ionized plasma, exhibit solitons. The first observation of this kind of wave was made in 1834 by John Scott Russell, who followed on horseback a soliton propagating in the windings of a channel. In 1895, D. J. Korteweg and H. de Vries proposed an equation for the motion of waves in shallow waters which possesses soliton solutions, and thus established a mathematical basis for the study of the phenomenon. Interest in the subject, however, lay dormant for many years, and the major body of investigations began only in the 1950s. Researches done by analytical methods and by numerical methods made possible with the advent of computers gradually led to a complete understanding of solitons. *See* Differential equation; Wave motion; Wave motion in liquids.

Eventually, the fact that solitons exhibit particlelike properties, because the energy is at any instant confined to a limited region of space, received attention, and solitons were proposed as models for elementary particles. However, it is difficult to account for all of the properties of known particles in terms of solitons. More recently it has been realized that some of the quantum fields which are used to describe particles and their interactions also have solutions of the soliton type. The solitons would then appear as additional particles, and may have escaped experimental detection because their masses are much larger than those of known particles. In this context the requirement that solitons emerge unchanged from a collision has been found too restrictive, and particle theorists have used the term soliton where traditionally the term solitary wave would be used. *See* Elementary particle; Quantum field theory. [C.R.]

A hydrodynamic soliton is simply described by the equation of Korteweg and de Vries, which includes a dispersive term and a term to represent nonlinear effects. Easily observed in a wave tank, a bell-shaped solution of this equation balances the effects of dispersion and nonlinearity, and it is this balance that is the essential feature of the soliton phenomenon. Tidal waves in the Firth of Forth were found by Scott Russell to be solitons, as are internal ocean waves and tsunamis. At an even greater level of energy, it has been suggested that the Great Red Spot of the planet Jupiter is a hydrodynamic soliton. *See* Jupiter; Ocean waves; Tsunami.

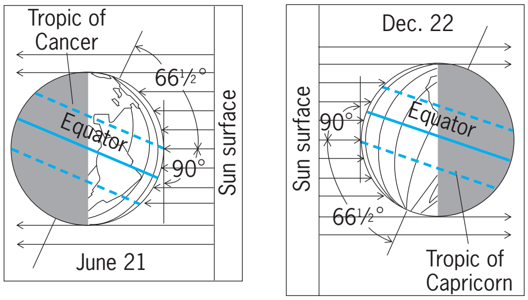
The most significant technical application of the soliton is as a carrier of digital information along an optical fiber. The optical soliton is governed by the nonlinear Schrödinger equation, and again expresses a balance between the effects of optical dispersion and nonlinearity that is due to electric field dependence of the refractive index in the fiber core. If the power is too low, nonlinear effects become negligible, and the information spreads (or disperses) over an ever increasing length of the fiber. At a pulse power level of about 5 milliwatts, however, a robustly stable soliton appears and maintains its size and shape in the presence of disturbing influences. Present designs for data transmission systems based on the optical soliton have a data rate of 4×10^9 bits per second. *See* Optical communications.

A carefully studied soliton system is the transverse electromagnetic (TEM) wave that travels between two strips of superconducting metal separated by an insulating layer thin enough (about 2.5 nanometers) to permit transverse Josephson tunneling. Since each soliton carries one quantum of magnetic flux, it is also called a fluxon if the magnetic flux points in one direction, and an antifluxon if the flux points in the opposite direction. Oscillators based on this system reach into the submillimeter wave region of the electromagnetic spectrum (frequencies greater than 10^{11} Hz). *See* Josephson effect; Waveguide.

The all-or-nothing action potential or nerve impulse that carries a bit of biological information along the axon of a nerve cell shares many properties with the soliton. Both are solutions of nonlinear equations that travel with fixed shape at constant speed, but the soliton conserves energy, while the nerve impulse balances the rate at which electrostatic energy is released from the nerve membrane to the rate at which it is consumed by the dissipative effects of circulating ionic currents. The nerve process is much like the flame of a candle. *See* Biopotentials and ionic currents. [A.Sco.]

Solstice The two days during the year when the Earth is so located in its orbit that the inclination (about $23\frac{1}{2}^{\circ}$, or 23.45°) of the polar axis is toward the Sun. This occurs on June 21, called the summer solstice, when the North Pole is tilted toward the Sun; and on December 22, called the winter solstice, when the South Pole is tilted toward the Sun (see illustration). The adjectives summer and winter, used above, refer to the Northern Hemisphere; seasons are reversed in the Southern Hemisphere.

At the time of the summer solstice every place north of the Arctic Circle will have 24 h of sunlight and the length of day at all places north of the Equator will be more than 12 h, increasing in length with increasing latitude. Identical conditions are found



The Earth at the time of the summer and winter solstices. The dates may vary because of the extra one-fourth day in the year.

in the Southern Hemisphere at the time of the Northern Hemisphere's winter solstice. *See* MATHEMATICAL GEOGRAPHY. [V.H.E.]

Solubility product constant A special type of simplified equilibrium constant (symbol K_{sp}) defined for, and useful for, equilibria between solids (*s*) and their respective ions in solution, for example, reaction (1). For this relatively simple equilibrium, Eqs. (2) and (3) apply.

$$\mathrm{AgCl(s)} \leftrightharpoons \mathrm{Ag^+} + \mathrm{Cl^-} \tag{1}$$

$$[\mathrm{Ag^+}][\mathrm{Cl^-}] \cong K_{sp} \tag{2}$$

$$(\mathrm{Ag^+})(\mathrm{Cl^-})/(\mathrm{AgCl}) = K_{sp} \tag{3}$$

It can be demonstrated experimentally that a small increase in the molar concentration of chloride ion [Cl^-] causes a reduction in the concentration of silver present as Ag^+. Similarly, an increase in [Ag^+] reduces [Cl^-]. The product of the two concentrations is approximately constant as indicated by Eq. (2) and equal to the K_{sp} of Eq. (3). Equation (3) is exact since the variables are activities instead of concentrations. In accordance with the choice of standard state usually made for a solid, the activity of solid AgCl is unity, hence Eq. (4) holds.

$$(\mathrm{Ag^+})(\mathrm{Cl^-}) = K_{sp} = 1.8 \times 10^{-10}\ \mathrm{mole^2\ liter^{-2}} \tag{4}$$

In practice, various complications arise: addition of too much of either ion produces more complicated ions and hence actually increases the apparent concentration of the other ion. Addition of a salt without a common ion (that is, a salt supplying neither Ag^+ nor Cl^-) either may react with Ag^+ or Cl^- or may merely increase the concentration of both ions by a lowering of the mean ionic activity coefficient. *See* IONIC EQUILIBRIUM; PRECIPITATION (CHEMISTRY). [T.F.Y.]

Solubilizing of samples The process by which samples that do not dissolve easily are converted into different chemical compounds that are soluble. The sample may be heated in air to evolve volatile components or to oxidize a component to a volatile higher oxidation state with the formation of an acid-soluble form, as in the roasting of a sulfide to form the oxide and sulfur dioxide. Most frequently, the sample is treated with a solvent which reacts with one or more constituents of the sample. The choice of solvent is determined by the chemical reactions that are required. Reactions used include solvation, neutralization, complex formation, metathesis, displacement, oxidation-reduction, or combinations of these.

Most water-soluble salts dissolve by solvation. Basic oxides such as ferric oxide dissolve in aqueous hydrochloric acid. Metals above hydrogen in the electrochemical series will dissolve in a nonoxidizing acid by reduction of hydrogen ion. Metals such as copper and lead require an oxidizing acid, usually nitric acid. All of the components of brass and bronze are usually dissolved by nitric acid except tin, arsenic, and antimony, which precipitate as hydrated oxides. Alloy steels are usually dissolved by combinations of hydrochloric, nitric, phosphoric, and hydrofluoric acids. Aluminum-base alloys are treated with sodium hydroxide solution and any residues are dissolved in acid.

Many substances do not dissolve at temperatures obtainable in the presence of liquid water. However, fused salt reactions employing temperatures of 400–1100°C (750–2000°F) are necessary for the attack and decomposition of many types of samples. The material used as the solvent is called a flux, and the process of melting the mixture of dry, solid flux with the sample is called a fusion. [C.L.R.]

Solution A homogeneous mixture of two or more components whose properties vary continuously with varying proportions of the components. A liquid solution can be distinguished experimentally from a pure liquid by the fact that during transfers into other single phases at equilibrium (freezing and vaporizing at constant pressure) the temperature and other properties vary continuously, whereas those of a pure liquid remain constant. For an apparent exception *see* AZEOTROPIC MIXTURE. *See also* SOLVENT.

Gases, unless highly compressed, are mutually soluble in all proportions.

A solid solution is, similarly, a single phase whose composition and other properties vary continuously with changing composition of the liquid phase with which it is in equilibrium. *See* SOLID SOLUTION.

The extent to which substances can form solutions depends upon the kind and strength of the attractive forces between the several molecular species involved. It is necessary to consider the attractive forces exerted by molecules of the following types: (1) nonpolar molecules; (2) polar molecules, that is, those containing electric dipoles; (3) ions; and (4) metallic atoms.

Actual solutions may be considered in terms of their departure from a simple idealized model—a mixture of components having the same attractive fields, which mix without change in volume or heat content. This is analogous to an ideal gas mixture, which is formed with no heat of mixing and in which the total pressure is the sum of the partial pressures. In such a solution the escaping tendency of the individual molecules is the same, whether they are surrounded by similar or by different molecules. [J.H.Hi.]

Solution mining The extraction of the valuable components from a mineral deposit using an aqueous leaching solution. In its original sense, solution mining refers to evaporite mining, the dissolution of soluble rock material such as salt by using borehole wells to pump water into the deposit and remove the resulting saturated brine. In its current usage, solution mining also includes ore leaching, the in-place (in-situ) leaching of valuable metal components from an orebody, and the mine-site procedures of heap leaching and dump leaching. Often included is the Frasch process of using superheated water to melt sulfur in its deep deposits and recover the molten sulfur in borehole wells. *See* ORE AND MINERAL DEPOSITS.

Evaporites represent a broad class of water-soluble minerals (salts). Commercially important evaporites include halite (sodium chloride), sylvite and silvinite (potash), bischofite (magnesium chloride), nahcolite (sodium bicarbonate), trona (raw soda ash), and langbeinite and carnallite [both sources of potash and magnesia (magnesium oxide)]. *See* SALINE EVAPORITES.

Solution mining involves injecting a solvent into the pay zone of the deposit through a cased borehole. For evaporites, the solvent is hot water, which forms brine as the soluble minerals dissolve. The brine is brought to the surface via the casing system in the same or another borehole and sent to a processing facility for recovery by the controlled crystallization of the desired product, followed by dewatering and drying. Some minerals may require additional purification steps, such as the flotation of potash crystals. The depleted brine is chemically reconditioned and injected back into the deposit. Thus, solution mining creates minimal surface disturbance and little waste, compared to conventional mining. *See* WELL.

Although solution mining is simple in principle, there are several key issues for successful operation. One is to maintain close control over the solvent parameters, such as pH, oxidation potential, temperature, and pressure. Another issue is isolation of the solution mining zone from the surrounding geologic structures. This requires effective well completion techniques that are compatible with the brine. Once the well is drilled and cased, the casing must be cemented into the formation. This prevents brine from migrating along the annular space outside the casing and contaminating adjacent aquifers. *See* ELECTROCHEMICAL SERIES; OIL AND GAS WELL COMPLETION. [W.J.S.]

Leaching large stockpiles and mine waste dumps (ore heaps) annually accounts for about one-third of both new copper and gold production in the United States, the world's second largest source of both commodities. Ore leaching is an important contributor to the total world production of these commodities, along with silver. Ore leaching's very low unit processing cost, combined with low-cost earthmoving, allows profitable treatment of huge tonnages of low-grade material that could not otherwise be exploited.

Ore containing rock must first be fragmented to allow chemical leaching solutions to percolate through it. The metal-bearing minerals are liberated using an aqueous wetting fluid that penetrates and saturates the microfractures within the ore particles by capillary action. The ore minerals, originally deposited geochemically from hydrothermal solutions, are typically located in these micropores. Once dissolved, the metals are removed from the ore particles by diffusion through the solution-filled micropores and swept out of the ore heap by the flowing leachate. In effect, nature's ore deposition process has been reversed at a quicker pace. Nevertheless, commercial leaching times are measured in weeks, months, and even years. Leachates, or "pregnant liquors," are processed in surface plants to recover the metal and regenerate the leachant for reuse in the ore heap in a closed-loop system. *See* HYDROMETALLURGY; LEACHING. [R.W.Ba.]

Modern sulfur mining dates from the invention of the Frasch process in the late nineteenth century. H. Frasch accomplished in-place sulfur mining by using superheated water. Frasch mining begins by drilling wells into the sulfur deposit. Steel tubing (casing) is run into the drill hole to case off the barren overlying formation, and it is cemented in at the top of the sulfur deposit. Within this casing, three concentric strings of pipe are set within the sulfur deposit. Superheated water at 325°F (163°C) can be pumped down the annulus between the two strings of pipe to leave the casing string through the perforations above the packer, and to circulate in the sulfur deposit. Native sulfur melts at 275°F (135°C) in a cone-shaped area of influence around the well, and because liquid sulfur is denser than water, it settles to the bottom of the well.

The pressure from the heated water forces the molten sulfur into the lower set of perforations and into the inner string of casing. The molten sulfur rises to its hydrostatic head. Compressed air pumped through this inner tubing expands when it leaves the tubing, thus "jetting" the sulfur to the well collar, where it is collected in a tank (sulfur pan). [A.F.E.]

Solvation The association or combination of a solute unit (ionic, molecular, or particulate) with solvent molecules. This association may involve chemical or physical forces, or both, and may vary in degree from a loose, indefinite complex to the formation of a distinct chemical compound. Such a compound contains a definite number of solvent molecules per solute molecule. Solvation occurring in aqueous solutions is referred to as hydration. In certain colloidal suspensions, solvation is, to a large extent, responsible for the stability of the sol. *See* COLLOID; HYDRATION; SOLUTION; SOLVENT. [F.J.J.]

Solvent By convention, the component present in the greatest proportion in a homogeneous mixture of pure substances (solutions). Components of mixtures present in minor proportions are called solutes. Thus, technically, homogeneous mixtures are possible with liquids, solids, or gases dissolved in liquids; solids in solids; and gases in gases. In common practice this terminology is applied mostly to liquid mixtures for which the solvent is a liquid and the solute can be a liquid, solid, or gas. *See* SOLUTION.

Three broad classes of solvents are recognized—aqueous, nonaqueous, and organic. Formalistically, the nonaqueous and organic classifications are both not aqueous, but the term organic solvents is generally applied to a large body of carbon-based compounds that find use industrially and as media for chemical synthesis. Organic solvents are generally classified by the functional groups that are present in the molecule, for example, alcohols, halogenated hydrocarbons, or hydrocarbons; such groups give an indication of the types of physical or chemical interactions that can occur between solute and solvent. Nonaqueous solvents are generally taken to be inorganic substances and a few of the lower-molecular-weight, carbon-containing substances such as acetic acid, methanol, and dimethylsulfoxide. Nonaqueous solvents can be solids (for example, fused LiI), liquids (H_2SO_4), or gases (NH_3) at ambient conditions; the solvent properties of fused sodium iodide (NaI) are manifested in the molten state, whereas hydrogen sulfate (H_2SO_4) and ammonia (NH_3) must be liquefied to act as solvents. [J.J.L.]

Solvent extraction A technique, also called liquid extraction, for separating the components of a liquid solution. This technique depends upon the selective dissolving of one or more constituents of the solution into a suitable immiscible liquid solvent. It is particularly useful industrially for separation of the constituents of a mixture according to chemical type, especially when methods that depend upon different physical properties, such as the separation by distillation of substances of different vapor pressures, either fail entirely or become too expensive.

Industrial plants using solvent extraction require equipment for carrying out the extraction itself (extractor) and for essentially complete recovery of the solvent for reuse, usually by distillation. *See* DISTILLATION.

The petroleum refining industry is the largest user of extraction. In refining virtually all automobile lubricating oil, the undesirable constituents such as aromatic hydrocarbons are extracted from the more desirable paraffinic and naphthenic hydrocarbons. By suitable catalytic treatment of lower boiling distillates, naphthas rich in aromatic hydrocarbons such as benzene, toluene, and the xylenes may be produced. The latter are separated from paraffinic hydrocarbons with suitable solvents to produce high-purity aromatic hydrocarbons and high-octane gasoline. Other industrial applications include so-called sweetening of gasoline by extraction of sulfur-containing compounds; separation of vegetable oils into relatively saturated and unsaturated glyceride esters; recovery of valuable chemicals in by-product coke oven plants; pharmaceutical refining processes; and purifying of uranium.

Solvent extraction is carried out regularly in the laboratory by the chemist as a commonplace purification procedure in organic synthesis, and in analytical separations in which the extraordinary ability of certain solvents preferentially to remove one or more constituents from a solution quantitatively is exploited. Batch extractions of this sort, on a small scale, are usually done in separatory funnels, where the mechanical agitation is supplied by handshaking of the funnel. *See* EXTRACTION. [R.E.Tr.]

Somatic cell genetics The study of mechanisms of inheritance in animals and plants by using cells in culture. In such cells, chromosomes and genes can be reshuffled by parasexual methods, rather than having to depend upon the chromosome segregation and genetic recombination that occur during the meiotic cell divisions preceding gamete formation and sexual reproduction. Genetic analysis is concerned with the role of genes and chromosomes in the development and function of individuals and the evolution of species. Genetic analysis of complex multicellular organisms classically required multiple-generation families, and fairly large numbers of progeny of defined matings had to be scored. As a result, analysis of animals and plants with long generation times, small families, or lack of controlled matings was difficult and slow. Somatic cell genetics circumvents many of these limitations. It has enhanced the scope and speed of genetic analysis in higher plants and animals, especially when combined with the powerful techniques of molecular biology and the ability to generate fertile plants and animals from single cultured cells. With these methods, every gene in any species of interest can be identified and mapped to its position on a particular chromosome, its functions determined, and its evolutionary relationships to genes in other species revealed. Cross-species comparisons have provided essential insights into such poorly understood areas as embryonic differentiation and the development of complex nervous systems. *See* EMBRYONIC DIFFERENTIATION; GENETIC MAPPING; MOLECULAR BIOLOGY.

Foreign genes (transgenes) can be introduced into somatic cells, which grow and differentiate into complete organisms whose sexual reproduction permits both the analysis of the effects of the introduced gene and the development of stocks with desirable characteristics. Transgenic plants have tremendous potential in the development of plants resistant to insects; to viral, fungal, or bacterial disease; and to environmental stress. Transgenic animals are generated in ever-increasing numbers because of their usefulness in studying cell differentiation, morphogenesis, and function. *See* GENE ACTION; GENETIC ENGINEERING; GENETICS. [O.J.M.]

Somatostatin A naturally occurring regulatory peptide that carries out numerous functions in the human body, including the inhibition of growth hormone secretion from the anterior pituitary gland. Somatostatin consists of 14 amino acids; two cysteine residues are joined by a disulfide bond so that the peptide forms a ring structure. A larger variant of this peptide, called somatostatin-28, is produced in some cells and has an additional 14 amino acids attached at the amino-terminal end of normal somatostatin (somatostatin-14).

Somatostatin acts primarily as a negative regulator of a variety of different cell types, blocking processes such as cell secretion, cell growth, and smooth muscle contraction. It is secreted from the hypothalamus into the portal circulation and travels to the anterior pituitary gland, where it inhibits the production and release of both growth hormone and thyroid-stimulating hormone. Many tissues other than the hypothalamus contain somatostatin, suggesting that this peptide has numerous roles.

Each of the functions of somatostatin is initiated by the binding of the peptide to one or more of five different cell-surface receptor proteins, thereby activating one or more intracellular G-proteins and initiating biochemical signaling pathways within the cell. *See* SIGNAL TRANSDUCTION.

Analogs of somatostatin have been synthesized that are smaller, more potent, longer-lasting, and more specific in their biological effects than natural somatostatin. Some of these analogs have become useful as drugs. *See* ENDOCRINE SYSTEM (VERTEBRATE); HORMONE; NEUROSECRETION; PITUITARY GLAND. [W.H.Si.]

Somesthesis A general term for the somatic sensibilities aroused by stimulation of bodily tissues such as the skin, muscles, tendons, joints, and the viscera. Six primary qualities of somatic sensation are commonly recognized: touch-pressure (including temporal variations such as vibration), warmth, coolness, pain, itch, and the position and movement of the joints. These basic sensory qualities exist because each is served by a different set of sensory receptors (the sensory endings of certain peripheral nerve fibers) which differ not only in their sensitivities to different types of stimuli, but also in their connections to structures within the central nervous system.

The somatic sensory pathways are dual in nature. One major part, the lemniscal system, receives input from large-diameter myelinated peripheral nerve fibers (for example, those serving the sense of touch-pressure). The second major somatic pathway is called the anterolateral system. It receives input from small-diameter myelinated and unmyelinated peripheral nerve fibers carrying pain and temperature information. *See* CUTANEOUS SENSATION; PAIN; PROPRIOCEPTION. [R.LaM.]

Sonar A remote sensing technique or device that uses sound waves to detect, locate, and sometimes identify objects in water. The term is an acronym for sound navigation and ranging. There are many applications, using a wide variety of equipment. Naval uses include detection of submarines, sea mines, torpedoes, and swimmers; torpedo guidance; acoustic mines; and navigation. Civilian uses include determining water depth; finding fish; mapping the ocean floor; locating various objects in the ocean, such as pipelines, wellheads, wrecks, and obstacles to navigation; measuring water current profiles; and determining characteristics of ocean bottom sediments. Sound waves rather than electromagnetic waves (for example, radar and light) are used in these applications because their attenuation in seawater is much less. Some marine mammals use sound waves to find food and to navigate. *See* ACOUSTIC TORPEDO; ANTISUBMARINE WARFARE; ECHOLOCATION; MARINE GEOLOGY; MARINE NAVIGATION; UNDERWATER NAVIGATION; UNDERWATER SOUND.

There are two generic types of sonar: active (echolocation) and passive. An active sonar projects a signal (typically a short pulse of sound) into the water in a narrow beam, which propagates at a speed of about 1500 m/s (5000 ft/s). If there is an object (target) in the beam, it reflects a fraction of the sound energy to the sonar, which detects the echo. By measuring the elapsed time between projection and reception, the range to the target can be computed (range = sound speed × travel time ÷ 2).

Direction to the target is determined from the orientation of the sound beam at the time of reception. Passive sonar does not radiate sound but depends on detecting sounds radiated by targets such as submarines and ships. Passive sonar determines direction to a target in the same manner as active sonar, but range determination is more difficult.

In an elementary active pulse sonar, a pulse signal of certain frequency and duration is generated, amplified, and sent to an electroacoustic transducer, which converts the electrical signal into a sound signal, which then radiates into the water. If the transducer is reciprocal in character (typically the case), it also can be used to sense (detect) the returning echoes. The receiver amplifies the weak echoes and measures the range to each target, as well as the orientation of the receiving beam at the time of reception. This information is displayed in some form of range-direction plot.

Most active sonar transducers are mounted on the hulls of submarines or near the keels of surface ships. Sometimes, transducers are towed at a water depth that provides better operation. There are three basic transducer orientations. In the conventional depth sounder, the sound beam is directed downward. Echoes are reflected from the ocean bottom (and from fish that may be in the beam), and the depth of the ocean beneath the sonar can be determined. In the side-scan sonar configuration, the beam is oriented to the side of the ship (normal to the direction of travel) and (usually) slightly downward. As the ship moves forward, a volume of water to the side of the ship is searched. Generally, two sonars are used, one searching to the right and one to the left. Side-scan sonars are well suited to search at a constant speed and along straight lines, such as in mapping the ocean bottom and in general searches of an area. The third, and most popular, sonar configuration involves rotating the sound beam about the vertical axis to search (scan) a sector of the water centered on the sonar platform. *See* ECHO SOUNDER.

The range at which a target can be detected depends on the strength of the projected signal (source level), propagation losses to the target and return, reflection characteristics of the target (target strength), and sensitivity of the receiver. Also, the target echo must be stronger than various masking signals (noise and reverberation), which also are received by the sonar. An important sonar performance characteristic is its ability to locate a target accurately and determine whether an echo is from a single target or from several targets close together. The uncertainty in the direction to the target is approximately the width of the receiving beam.

Passive sonars are used primarily to detect submarines and, to a lesser extent, surface ships. Because passive sonar does not radiate any sound that would reveal its location, it is the primary sensor used by submarines. The major weakness is that it cannot directly measure range to a target. To determine target location, the sonar must take bearings on a target from different locations. Passive sonars depend on detecting noise radiated by targets, a mixture of sounds generated by propellers and hull vibrations (caused by motors, engines, pumps, and hydrodynamic forces). The noise has a continuous spectrum and discrete tones related to rotational speeds of propellers, engines, and so forth. By analysis of the received signals the sonar often can identify the type of target. Most of the radiated energy is in the audible frequency band and decreases in intensity with increasing frequency.

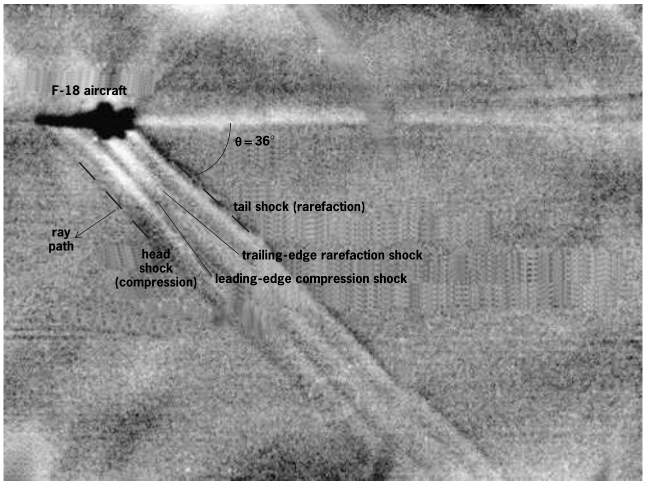
Most passive sonars use large receiving transducer arrays in order to achieve high sensitivity, discriminate against ambient noise, and determine precisely the direction to a target. In submarines, these arrays may be recessed into the structure or mounted on the hull. Submarines also may tow long slender line arrays. A number of very large fixed receiving arrays, placed on the ocean floor with cables running to shore stations, constantly observe strategically important ocean areas. Detection ranges for large passive sonars vary from hundreds of kilometers against noisy targets under good conditions to a very few kilometers against quiet targets.

The sonobuoy consists of a small surface buoy with a hydrophone array suspended beneath the water. Sounds received by the array are telemetered by radio link to an aircraft overhead. (There are also active sonobuoys.) Sonobuoys have relatively short detection ranges and are used primarily in tactical situations. *See* SONOBUOY; ULTRASONICS. [C.M.McK.]

Sonic boom An audible sound wave generated by an object that moves faster than the speed of sound (supersonic object). The sonic boom forms because the air is pushed away faster than the air molecules can move. The displaced air becomes highly compressed and creates a very strong sound wave, referred to as a compressional head shock or bow shock. At the back of the supersonic object the air has to fill the void left as the object moves forward; in this case, the gas becomes rarefied and a rarefractional tail shock develops. These shock waves are the main components of a sonic boom, and they are generated the entire time that an object flies faster than the speed of sound, not just when it breaks the sonic barrier. *See* SHOCK WAVE.

Sonic booms may be natural or generated by human activity. A natural sonic boom is thunder, created when lightning ionizes air, which expands supersonically. Meteors can create sonic booms if they enter the atmosphere at supersonic speeds. Human sources of sonic booms include aircraft, rockets, the space shuttle during reentry, and bullets. *See* METEOR; THUNDER.

Sonic booms are commonly associated with supersonic aircraft. The shock waves associated with sonic booms propagate away from the aircraft in a unique fashion. These waves form a cone, called the Mach cone, that is dragged behind the aircraft. The illustration shows the outline of the Mach cone generated by an F-18 fighter aircraft flying at Mach 1.4. The schlieren photographic technique was used to display the sonic boom, which is normally invisible. The half-angle of the cone is determined solely by the Mach number of the aircraft, $\theta = \arctan(1/M)$, 36° for $M = 1.4$. The shock waves travel along rays that are perpendicular to the Mach cone (see illustration). As the Mach number increases, θ becomes smaller and the sound travels almost directly downward. *See* MACH NUMBER; SCHLIEREN PHOTOGRAPHY; SUPERSONIC FLIGHT.



Schlieren image of the shock waves generated by an F-18 aircraft flying at Mach 1.4. The Mach cone generated by the head and tail shocks can be seen as well as the shocks generated by the leading and trailing edges of the wings. (*NASA Dryden Flight Research Center*)

The typical peak pressure amplitude (or overpressure) of a sonic boom on the ground is about 50–100 pascals. A sonic boom with 50 Pa (1 lbf/ft^2 or 0.007 psi) overpressure will produce no damage to buildings. Booms in the range of 75–100 Pa are considered disturbing by some people. Occasionally there is minor damage to buildings from sonic booms in the range of 100–250 Pa; however, buildings in good condition will be undamaged by overpressures up to 550 Pa. Very low flying aircraft (30 m or 100 ft) can produce sonic booms of 1000–7000 Pa. These pressures are still about five times less than that needed to injure the human ear, but can lead to damage to buildings, such as the breaking of glass windows and the cracking of plaster. Although sonic booms are not dangerous, they can evoke a strong startle response in people and animals. [R.Cl.]

Sonobuoy An expendable device that enables aircraft to detect underwater objects, such as submarines, acoustically. Acoustics is the preferred energy form for use in salt water, because it tends to be the least attenuated by the medium.

A sonobuoy consists of an electronic radio link and antenna connected to a miniature sonar system. It contains the means for its launch from the aircraft, its entry into the water, separation of a floating antenna from the underwater transducer and sonar, and activation of a seawater battery upon entry, as well as a scuttling means for final sinking upon completion of its intended useful life. The short life requires that each component be highly reliable and effective at low cost. The package must also be small and lightweight, since large numbers of packages are to be carried on an aircraft. *See* SONAR.

The simplest sonobuoy is a passive sonar that senses sound with its hydrophone, amplifies and converts it to a radio signal, and transmits the signal from its antenna for analysis, evaluation, and storage in the aircraft. The sonobuoy system may be independently activated by an underwater sound source, usually an explosive device dropped from the aircraft. Two or more simple sonobuoys may be deployed to permit processing of directional information, passively or actively. *See* HYDROPHONE.

Buoys of various types are used as sensors for oceanographic data such as sound speed, geophysical data such as earthquakes, bioacoustic data such as snapping shrimp, and other signal and noise sources. Some have been designed for long-term deployment on station, with provision for storing data until interrogated from an aircraft or a ship. *See* BUOY. [S.L.E.]

Sonochemistry The study of the chemical changes that occur in the presence of sound or ultrasound. Industrial applications of ultrasound include many physical and chemical effects, for example, cleaning, soldering, welding, dispersion, emulsification, disinfection, pasteurization, extraction, flotation of minerals, degassing of liquids, defoaming, and production of gas-liquid sols. *See* SOUND; ULTRASONICS.

When liquids are exposed to intense ultrasound, high-energy chemical reactions occur, often accompanied by the emission of light. There are three classes of such reactions: homogeneous sonochemistry of liquids, heterogeneous sonochemistry of liquid-liquid or liquid-solid systems, and sonocatalysis (which overlaps the first two). In some cases, ultrasonic irradiation can increase reactivity by nearly a millionfold. Especially for liquid-solid reactions, the rate enhancements via ultrasound have proved extremely useful for the synthesis of organic and organometallic compounds. Because cavitation occurs only in liquids, chemical reactions are not generally seen in the ultrasonic irradiation of solids or solid-gas systems.

Ultrasound spans the frequencies of roughly 20 kHz to 10 MHz (human hearing has an upper limit of less than 18 kHz). Ultrasound has acoustic wavelengths of roughly 7.5–0.015 cm which are much larger than molecular dimensions. As a result, the chemical effects of ultrasound are not from direct interaction, but are derived from several different physical mechanisms, depending on the nature of the system. For both sonochemistry and sonoluminescence, the most important of these mechanisms is acoustic cavitation: the formation, growth, and implosive collapse of bubbles in liquids irradiated with high-intensity sound. During the final stages of cavitation, compression of the gas inside the bubbles produces enormous local heating and high pressures. *See* CAVITATION.

When a liquid-solid interface is subjected to ultrasound, cavitation occurs, but a markedly asymmetric bubble collapse occurs, which generates a jet of liquid directed at the surface with velocities greater than 330 ft/s (100 m/s). The impingement of this jet can create a localized erosion (and even melting), responsible for surface pitting and ultrasonic cleaning. Enhanced chemical reactivity of solid surfaces is associated with these processes.

Ultrasonic irradiation of liquid-powder suspensions produces another effect: high-velocity interparticle collisions. Cavitation and the shock waves that it creates in a slurry can accelerate solid particles to high velocities. The resultant collisions are capable of inducing dramatic changes in surface morphology, composition, and reactivity.

The predominant reactions of homogeneous sonochemistry are bond breaking and radical formation. In addition to the initiation or enhancement of chemical reactions, irradiation of liquids with high-intensity ultrasound generates the emission of visible light. The production of such luminescence is a consequence of the localized hot spot created by the implosive collapse of gas- and vapor-filled bubbles during acoustic cavitation. In general, sonoluminescence may be considered a special case of homogeneous sonochemistry. Under conditions where an isolated, single bubble undergoes cavitation, recent studies on the duration of the sonoluminescence flash suggest that a shock wave may be created within the collapsing bubble. *See* CHEMILUMINESCENCE; HOMOGENEOUS CATALYSIS.

A major industrial application of ultrasound is emulsification. The first reported and most studied liquid-liquid heterogeneous systems have involved ultrasonically dispersed mercury. The effect of the ultrasound in this system appears to be due to the large surface area of mercury generated in the emulsion. *See* EMULSION.

The effects of ultrasound on liquid-solid heterogeneous organometallic reactions have been a matter of intense investigation. Various research groups have dealt with extremely reactive metals, such as lithium (Li), magnesium (Mg), or zinc (Zn), as stoichiometric reagents for a variety of common transformations.

Sonochemistry can be used as a synthetic tool for the creation of unusual inorganic materials. Ultrasound has proved extremely useful in the synthesis of a wide range of nanostructured materials, including high-surface-area transition metals, alloys, carbides, oxides, and colloids. Sonochemistry is also proving to have important applications with polymeric materials. Substantial work has been accomplished in the sonochemical initiation of polymerization and in the modification of polymers after synthesis. Sonochemistry has found another recent application in the preparation of unusual biomaterials, notably protein microspheres. The mechanism responsible for microsphere formation is a combination of two acoustic phenomena: emulsification and cavitation. These protein microspheres have a wide range of biomedical applications, including their use as echo contrast agents for sonography, magnetic resonance imaging contrast enhancement, and drug delivery. *See* NANOCHEMISTRY; NANOSTRUCTURE; POLYMER; PROTEIN. [K.S.S.]

Sorghum Sorghum includes many widely cultivated grasses having a variety of names in various countries. Cultivated sorghums in the United States are classified as a single species, *Sorghum bicolor*, although there are many varieties and hybrids. The two major types of sorghum are the grain, or nonsaccharine, type, cultivated for grain production and to a lesser extent for forage, and the sweet, or saccharine, type, used for forage production and for making syrup and sugar.

Grain sorghum is grown in the United States chiefly in the Southwest and the Great Plains. It is a warm-season crop which withstands heat and moisture stress better than most other crops, but extremely high temperatures and extended drought may reduce yields. It is extensively grown in Texas, Kansas, Nebraska, Oklahoma, Missouri, Colorado, and South Dakota. This grain production is fed to cattle, poultry, swine, and sheep primarily. Sorghum is considered nearly equal to corn in feed value.

Sorghums originated in the northeastern quadrant of Africa. Until recent years, practically all grain sorghums of importance introduced into the United States were tall, late maturing, and generally unadapted. Since its introduction into the United States in colonial times, the crop has been altered in many ways, these changes coming as a result of naturally occurring genetic mutations combined with hybridization and selection work of plant breeders. The fact that hybrid grain sorghums with high yield potential could be produced with stems that are short enough for harvesting mechanically made the crop appealing to many farmers. *See* BREEDING (PLANT).

Grain sorghum is difficult to distinguish from corn in its early growth stages, but at later stages it becomes strikingly different. Sorghum plants may tiller (put out new shoots), producing several head-bearing culms from the basal nodes. Secondary culms may also develop from nodal buds along the main stem. The inflorescence (head) varies from a dense to a lax panicle, and the spikelets produce perfect flowers that are subject to both self- and cross-fertilization. Mature grain in different varieties varies in size and color from white to cream, red, and brown. Grain sorghum seeds are small and should not be planted too deep since sorghum lacks the soil-penetrating ability of corn. The seeds are planted either in rows wide enough for tractor cultivation or in narrower rows if cultivation is not intended. [F.R.M.]

Commonly known as sorgo, sweet sorghum was introduced into North America from China in 1850, although its ancestry traces back to Egypt. It is an annual, rather drought-resistant crop. The culms are from 2 to 15 ft (0.6 to 4.6 m) tall, and the hard cortical layer, or shell, encloses a sweet, juicy pith that is interspersed with vascular bundles. At each node both a leaf and a lateral bud alternate on opposite sides; the internodes are alternately grooved on one side. Leaves are smooth with glossy or waxy surfaces and have margins with small, sharp, curved teeth. The leaves fold and roll up during drought. The inflorescence is a panicle of varying size having many primary branches with paired ellipsoidal spikelets containing two florets in each fertile sessile spikelet. The plant is self-pollinated. Seed is planted in cultivated rows and fertilized similarly to corn. The main sorghum-syrup-producing area is in the south-central and southeastern United States. *See* CORTEX (PLANT); PITH. [L.D.B.]

Sound The mechanical excitation of an elastic medium. Originally, sound was considered to be only that which is heard. This admitted questions such as whether or not sound was generated by trees falling where no one could hear. A more mechanistic approach avoids these questions and also allows acoustic disturbances too high in frequency (ultrasonic) to be heard or too low (infrasonic) to be classed as extensions of those events that can be heard.

A source of sound undergoes rapid changes of shape, size, or position that disturb adjacent elements of the surrounding medium, causing them to move about their equilibrium positions. These disturbances in turn are transmitted elastically to neighboring elements. This chain of events propagates to larger and larger distances, constituting a wave traveling through the medium. If the wave contains the appropriate range of frequencies and impinges on the ear, it generates the nerve impulses that are perceived as hearing. *See* HEARING (HUMAN).

Acoustic pressure. A sound wave compresses and dilates the material elements it passes through, generating associated pressure fluctuations. An appropriate sensor (a microphone, for example) placed in the sound field will record a time-varying deviation from the equilibrium pressure found at that point within the fluid. The changing total pressure P measured will vary about the equilibrium pressure P_0 by a small amount called the acoustic pressure, $p = P - P_0$. The SI unit of pressure is the pascal (Pa), equal to 1 newton per square meter (N/m^2). Standard atmospheric pressure (14.7 lb/in.^{2}) is approximately 1 bar = 10^6 dyne/cm^2 = 10^5 Pa. For a typical sound in air, the amplitude of the acoustic pressure may be about 0.1 Pa (one-millionth of an atmosphere); most sounds cause relatively slight perturbations of the total pressure. *See* MICROPHONE; PRESSURE; PRESSURE MEASUREMENT; PRESSURE TRANSDUCER; SOUND PRESSURE.

Plane waves. One of the more basic sound waves is the traveling plane wave. This is a pressure wave progressing through the medium in one direction, say the $+x$ direction, with infinite extent in the y and z directions. A two-dimensional analog is ocean surf advancing toward a very long, straight, and even beach. *See* WAVE (PHYSICS); WAVE EQUATION; WAVE MOTION.

A most important plane wave, called harmonie, is the smoothly oscillating monofrequency plane wave described by Eq. (1). The amplitude of this wave is P. The phase (argument

$$p = P \cos\left[2\pi f\left(t - \frac{x}{c}\right)\right] \qquad (1)$$

of the cosine) increases with time, and at a point in space the cosine will pass through one full cycle for each increase in phase of 2π. The period T required for each cycle must therefore be such that $2\pi fT = 2\pi$, or $T = 1/f$, so that $f = 1/T$ can be identified as the frequency of oscillation of the pressure wave. During this period T, each portion of the waveform has advanced through a distance $\lambda = cT$, and this distance λ must be the wavelength. This gives the fundamental relation (2) between the frequency,

$$\lambda f = c \qquad (2)$$

wavelength, and speed of sound c in any medium. For example, in air at room temperature the speed of sound is 343 m/s (1125 ft/s). A sound of frequency 1 kHz (1000 cycles per second) will have a wavelength of $\lambda = c/f = 343/1000$ m = 0.34 m (1.1 ft). Lower frequencies will have longer wavelengths: a sound of 100 Hz in air has a wavelength of 3.4 m (11 ft). For comparison, in fresh water at room temperature the speed of sound is 1480 m/s (4856 ft/s), and the wavelength of 1-kHz sound is nearly 1.5 m (5 ft), almost five times greater than the wavelength for the same frequency in air.

Description of sound. The characterization of a sound is based primarily on human psychological responses to it. Because of the nature of human perceptions, the correlations between basically subjective evaluations such as loudness, pitch, and timbre and more physical qualities such as energy, frequency, and frequency spectrum are subtle and not necessarily universal.

The strength of a sound wave is described by its intensity. From basic physical principles, the instantaneous rate at which energy is transmitted by a sound wave through unit area is given by the product of acoustic pressure and the component of particle velocity perpendicular to the area. The time average of this quantity is the acoustic intensity. If all quantities are expressed in SI units (pressure amplitude or effective pressure amplitude in Pa, speed of sound in m/s, and density in kg/m^3), then the intensity will be in watts per square meter (W/m^2). *See* SOUND INTENSITY.

Because of the way the strength of a sound is perceived, it has become conventional to specify the intensity of sound in terms of a logarithmic scale with the (dimensionless) unit of the decibel (dB). An individual with unimpaired hearing has a threshold of perception near 10^{-12} W/m^2 between about 2 and 4 kHz, the frequency range of greatest sensitivity. As the intensity of a sound of fixed frequency is increased, the subjective evaluation of loudness also increases, but not proportionally. Rather, the listener tends to judge that every successive doubling of the acoustic intensity corresponds to the same increase in loudness. For sounds lying higher than 4 kHz or lower than 500 Hz, the sensitivity of the ear is appreciably lessened. Sounds at these frequency extremes must have higher threshold intensity levels before they can be perceived, and doubling of the loudness requires smaller changes in the intensity with the result that at higher levels sounds of equal intensities tend to have more similar loudnesses. It is because of this characteristic that reducing the volume of recorded music causes it to sound thin or tinny, lacking both highs and lows of frequency. Since most sound-measuring equipment detects acoustic pressure rather than intensity, it is convenient to define an equivalent scale in terms of the sound pressure level. The intensity level and sound-pressure level are usually taken as identical, but this is not always true. *See* DECIBEL; LOUDNESS.

How “high” sound of a particular frequency appears to be is described by the sense of pitch. A few minutes with a frequency generator and a loudspeaker show that pitch is closely related to the frequency. Higher pitch corresponds to higher frequency, with small influences depending on loudness, duration, and the complexity of the waveform. For the pure tones (monofrequency sounds) encountered mainly in the laboratory, pitch and frequency are not found to be proportional. Doubling the frequency less than doubles the pitch. For the more complex waveforms usually encountered, however, the presence of harmonics favors a proportional relationship between pitch and frequency. *See* PITCH.

Propagation of sound. Plane waves are a considerable simplification of an actual sound field. The sound radiated from a source (such as a loudspeaker, a hand clap, or a voice) must spread outward much like the widening circles from a pebble thrown into a lake. A simple model of this more realistic case is a spherical source vibrating uniformly in all directions with a single frequency of motion. The sound field must be spherically symmetric with an amplitude that decreases with increasing distance from the source, and the fluid elements must have particle velocities that are directed radially.

Not all sources radiate their sound uniformly in all directions. When someone is speaking in an unconfined space, for example an open field, a listener circling the speaker hears the voice most well defined when the speaker is facing the listener. The voice loses definition when the speaker is facing away from the listener. Higher frequencies tend to be more pronounced in front of the speaker, whereas lower frequencies are perceived more or less uniformly around the speaker.

Diffraction. It is possible to hear but not see around the corner of a tall building. However, higher-frequency sound (with shorter wavelength) tends to bend or "spill" less around edges and corners than does sound of lower frequency. The ability of a wave to spread out after traveling through an opening and to bend around obstacles is termed diffraction. This is why it is often difficult to shield a listener from an undesired source of noise, like blocking aircraft or traffic noise from nearby residences. Simply erecting a brick or concrete wall between source and receiver is often an insufficient remedy, because the sounds may diffract around the top of the wall and reach the listeners with sufficient intensity to be distracting or bothersome. *See* ACOUSTIC NOISE; DIFFRACTION.

Rays. Since the speed of sound varies with the local temperature (and pressure, in other than perfect gases), the speed of a sound wave can be a function of position. Different portions of a sound wave may travel with different speeds of sound.

Each small element of a surface of constant phase traces a line in space, defining a ray along which acoustic energy travels. The sound beam can then be viewed as a ray bundle, like a sheaf of wheat, with the rays distributed over the cross-sectional area of the surface of constant phase. As the major lobe spreads with distance, this area increases and the rays are less densely concentrated. The number of rays per unit area transverse to the propagation path measures the energy density of the sound at that point.

It is possible to use the concept of rays to study the propagation of a sound field. The ray paths define the trajectories over which acoustic energy is transported by the traveling wave, and the flux density of the rays measures the intensity to be found at each point in space. This approach, an alternative way to study the propagation of sound, is approximate in nature but has the advantage of being very easy to visualize.

Reflection and transmission. If a sound wave traveling in one fluid strikes a boundary between the first fluid and a second, then there may be reflection and transmission of sound. For most cases, it is sufficient to consider the waves to be planar. The first fluid contains the incident wave of intensity I_i and reflected wave of intensity I_r; the second fluid, from which the sound is reflected, contains the transmitted wave of intensity I_t. The directions of the incident, reflected, and transmitted plane sound waves may be specified by the grazing angles θ_i, θ_r, and θ_t (measured between the respective directions of propagation and the plane of the reflecting surface). *See* REFLECTION OF SOUND.

Absorption. When sound propagates through a medium, there are a number of mechanisms by which the acoustic energy is converted to heat and the sound wave weakened until it is entirely dissipated. This absorption of acoustic energy is characterized by a spatial absorption coefficient for traveling waves. *See* SOUND ABSORPTION. [A.B.Co.]

Sound absorption

The process by which the intensity of sound is diminished by the conversion of the energy of the sound wave into heat. The absorption of sound is an important case of sound attenuation. Regardless of the material through which sound passes, its intensity, measured by the average flow of energy in the wave per unit time per unit area perpendicular to the direction of propagation, decreases with distance from the source. This decrease is called attenuation. In the simple case of a point source of sound radiating into an ideal medium (having no boundaries, turbulent fluctuations, and the like), the intensity decreases inversely as the square of the distance from the source. This relationship exists because the spherical area through which the energy propagates per unit time increases as the square of the propagation distance. This attenuation or loss may be called geometrical attenuation.

In addition to this attenuation due to spreading, there is effective attenuation caused by scattering within the medium. Sound can be reflected and refracted when incident on media of different physical properties, and can be diffracted and scattered as it bends around obstacles. These processes lead to effective attenuation, for example, in a turbulent atmosphere; this is easily observed in practice and can be measured, but is difficult to calculate theoretically with precision. *See* DIFFRACTION; REFLECTION OF SOUND; REFRACTION OF WAVES.

In actual material media, geometrical attenuation and effective attenuation are supplemented by absorption due to the interaction between the sound wave and the physical properties of the propagation medium itself. This interaction dissipates the sound energy by transforming it into heat and hence decreases the intensity of the wave. In all practical cases, the attenuation due to such absorption is exponential in character. *See* SOUND INTENSITY.

The four classical mechanisms of sound absorption in material media are shear viscosity, heat conduction, heat radiation, and diffusion. These attenuation mechanisms are generally grouped together and referred to as classical attenuation or thermoviscous attenuation. *See* CONDUCTION (HEAT); DIFFUSION; HEAT RADIATION; VISCOSITY.

Sound absorption in fluids can be measured in a variety of ways, referred to as mechanical, optical, electrical, and thermal methods. All these methods reduce essentially to a measurement of sound intensity as a function of distance from the source.

The amount of sound that air absorbs increases with audio frequency and decreases with air density, but also depends on temperature and humidity. Sound absorption in air depends heavily on relative humidity. The reason for the strong dependence on relative humidity is molecular relaxation. One can note the presence of two transition regimes in most of the actual absorption curves, representing the relaxation effects of nitrogen and oxygen, the dominant constituents of the atmosphere. *See* ATMOSPHERIC ACOUSTICS.

Sound absorption in water is generally much less than in air. It also rises with frequency, and it strongly depends on the amount of dissolved materials (in particular, salts in seawater), due to chemical relaxation. *See* UNDERWATER SOUND.

The theory of sound attenuation in solids is complicated because of the presence of many mechanisms responsible for it. These include heat conductivity, scattering due to anisotropic material properties, scattering due to grain boundaries, magnetic domain losses in ferromagnetic materials, interstitial diffusion of atoms, and dislocation relaxation processes in metals. In addition, in metals at very low temperature the interaction between the lattice vibrations (phonons) due to sound propagation and the valence of electrons plays an important role, particularly in the superconducting domain. *See* CRYSTAL DEFECTS; DIFFUSION; FERROMAGNETISM; SUPERCONDUCTIVITY. [H.E.Ba.; A.J.Ca.; J.P.C.; R.B.L.]

Sound field enhancement

A system for enhancing the acoustical properties of both indoor and outdoor spaces, particularly for unamplified speech, song, and music. Systems are subdivided into those that primarily change the natural reverberation in the room, increasing its level and decay time (reverberation enhancement systems); and those that essentially replace the natural reverberation (sound field synthesis systems). Both systems may use amplifiers, electroacoustic elements, and signal processing to add sound field components to change the natural acoustics. Sound field enhancement is used to produce variable acoustics, to produce a particular acoustics which is not attainable by passive means, or because a venue has one or all of the following deficiencies: (1) unsuitable ratio between direct, early reflected, and reverberant sound; (2) unsatisfactory early reflection pattern; and (3) short reverberation times. *See* AMPLIFIER.

The purpose of sound field enhancement systems is not to provide higher speech intelligibility or clarity—in contrast to sound reinforcement systems—but to adjust venue characteristics to best suit the program material and venue, and in such a way optimize the subjectively perceived sound quality and enjoyment. *See* SOUND-REINFORCEMENT SYSTEM.

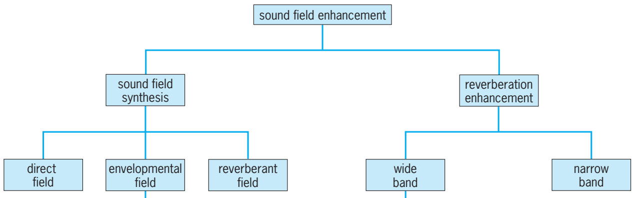
The use of sound field enhancement ranges from systems for homes (surround sound systems and home theater sound systems) to systems for rooms seating thousands of listeners (concert halls, performing arts centers, opera houses, and churches). Outdoor spaces may have elaborate designs to approach the sound quality of indoor spaces (advanced concert pavilions, outdoor concert venues). Systems may be used to improve conditions for both performers and listeners. *See* ARCHITECTURAL ACOUSTICS; REVERBERATION.

Basic elements. A sound field enhancement system may consist of one or more microphones, systems for amplification and electronic signal processing, and one or more loudspeakers. The signal processing equipment may include level controls, equalizers, delays and reverberators, systems for prevention of howl and ringing, as well as frequency dividing networks and crossover networks. *See* EQUALIZER; LOUDSPEAKER; MICROPHONE.

Prerequisites. Many indoor venues have acoustical characteristics unsuitable for communication such as speech, song, or music. Outdoor venues seldom have satisfactory acoustical conditions for unamplified acoustic communication. Satisfactory acoustic conditions include for speech, good speech intelligibility and sound quality; and for music, appropriate loudness, clarity, reverberation envelopment, spaciousness, and other sound quality characteristics for the music to be performed and enjoyed. Rooms with insufficient reverberation are often perceived to be acoustically “dry” or “dead.” Insufficient reverberation usually is due to lack of room volume for the existing sound absorption areas in the room. The reverberation time is essentially proportional to room volume and inversely proportional to sound absorption, as indicated by Sabine’s formula. In these cases, sound field enhancement systems may be used to improve acoustical conditions, by increasing the sound level and reverberation time. Absence of noise is also necessary for good acoustic conditions. *See* ACOUSTIC NOISE; SOUND ABSORPTION.

System design. A simple reverberation enhancement system uses a microphone to pick up the sound signal to be reverberated, amplified, and reradiated in the auditorium. In most cases, reverberation is added to the original signal by electronic digital signal processing. An advanced sound field enhancement system uses several, possibly directional microphones to pick up sound selectively from the stage area. Signal processing and many loudspeakers are used to obtain the desired sound field for the audience and performers. Most performing art centers need variable acoustic conditions that can be changed instantaneously using electronic controls.

Categories. Sound field enhancement systems can be classified according to different criteria. One possible scheme is shown in the illustration. Sound field synthesis systems are designed to provide the necessary sound field components, such as early reflections from side walls and ceiling (the latter are usually called envelopmental sound), and reverberation by using digital filters, which can be designed to imitate a specific desired room response. Reverberation enhancement systems are designed to primarily increase the reverberation time and sound level of the reverberant field, while having negligible influence on the direct sound and the early reflected sound. Reverberation enhancement systems can be further subdivided into regenerative systems, based on the acceptance of unavoidable positive feedback between loudspeakers and microphones to increase the reverberation time; and nonregenerative systems, based on the use of electronic reverberators. Regenerative systems can be designed so as to work over a wide or narrow frequency range; nonregenerative systems are usually wide-frequency-range systems. *See* REFLECTION OF SOUND; SOUND. [M.Kl.]



Classification scheme for sound field enhancement systems.

Sound intensity

A fundamental acoustic quantity which describes the rate of flow of acoustic energy through a unit of area perpendicular to the flow direction. The unit of sound intensity is watt per square meter. The intensity is calculated at a field point (x) as a product of acoustic pressure p and particle velocity u. Generally, both p and u are functions of time, and therefore an instantaneous intensity vector is defined by the equation below.

$$\vec{I}_i(x,t) = p(x,t)\cdot\vec{u}(x,t)$$

The time-variable instantaneous intensity, $\vec{I}_i(x,t)$, which has the same direction as $\vec{u}(x,t)$, is a nonmoving static vector representing the instantaneous power flow through a point (x). *See* POWER; SOUND PRESSURE.

Many acoustic sources are stable at least over some time interval so that both the sound pressure and the particle velocity in the field of such a source can be represented in terms of their frequency spectra.

The applications of sound intensity were fully developed after a reliable technique for intensity measurement was perfected. Sound intensity measurement requires measuring both the sound pressure and the particle velocity. Very precise microphones for sound-pressure measurements are available.

An application of the intensity technique is the measurement of sound power radiated from sources. The knowledge of the radiated power makes it possible to classify, label, and compare the noise emissions from various pieces of equipment and products and to provide a reliable input into environmental design. *See* SOUND. [J.Ti.]

Sound pressure

The incremental variation in the static pressure of a medium when a sound wave is propagated through it. Sound refers to small-amplitude, propagating pressure perturbations in a compressible medium. These pressure disturbances are related to the corresponding density perturbation via the material equation of state, and the manner in which these disturbances propagate is governed by a wave equation. Since a pressure variation with time is easily observed, the science of sound is concerned with small fluctuating pressures and their spectral characteristics. The unit of pressure commonly used in acoustics is the micropascal ($1\ \mu\text{Pa} = 1\ \mu\text{N/m}^2 = 10^{-5}\ \text{dyne/cm}^2 = 10^{-5}\ \mu\text{bar}$). One micropascal is approximately 10^{-11} times the normal atmospheric pressure. *See* PRESSURE; PRESSURE MEASUREMENT; WAVE MOTION.

The instantaneous sound pressure at a point can be harmonic, transient, or a random collection of waves. This pressure is usually measured with an instrument that is sensitive to a particular band of frequencies. A concept widely used in acoustics is “level,” which refers to the logarithm of the ratio of any two field quantities. When the ratio is proportional to a power ratio, the unit for measuring the logarithm of the ratio is called a bel, and the unit for measuring this logarithm multiplied by 10 is called a decibel (dB). The sound intensity, which describes the rate of flow of acoustic energy (acoustic power flow) per unit area, is given by the mean square pressure divided by the acoustic impedance, defined as the product of the medium density and compressional wave speed. *See* DECIBEL; NOISE MEASUREMENT; SOUND; SOUND INTENSITY. [W.M.C.]

Sound recording The technique of entering sound, especially music, on a storage medium for playback at a subsequent time. The storage medium most widely used is magnetic tape. *See* MAGNETIC RECORDING.

Monophonic. In the simplest form of sound recording, a single microphone picks up the composite sound of a musical ensemble, and the microphone's output is recorded on a reel of $^1/_2$-in. (6.4-mm) magnetic tape. This single-track, or monophonic, recording suffers from a lack of dimension, since in playback the entire ensemble will be heard from a single point source: the loudspeaker.

Stereophonic. An improved recording, with left-to-right perspective and an illusion of depth, may be realized by using two microphones which are spaced or angled appropriately and whose outputs are routed to separate tracks on the tape recorder. These two tracks are played back over two loudspeakers, one each on the listener's left and right. Under ideal conditions this stereophonic system will produce an impressive simulation of the actual ensemble. *See* STEREOPHONIC SOUND.

Binaural. In this system, two microphones are placed on either side of a small acoustic baffle in an effort to duplicate the human listening condition. The recording is played back over headphones, so that the microphones are, in effect, an extension of the listener's hearing mechanism.

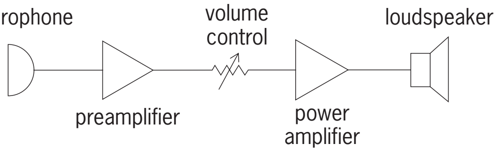
Multitrack. To give the recording engineer more technical control over the recording medium, many recordings are now made using a multiple-microphone technique. In place of the stereo microphone, one or more microphones are located close to each instrument or group of instruments. *See* MICROPHONE.

In the control room the engineer mixes the outputs of all microphones to achieve the desired musical balance. As a logical extension of this technique, the microphone outputs may not be mixed at the time of the recording, but may be routed to 16 or more tracks on a tape recorder, for mixing at a later date.

When many microphones are so used, each instrument in the ensemble is recorded—for all practical purposes—simultaneously. The complex time delay and acoustic relationships within the room are lost in the recording process, and the listener hears the entire ensemble from one perspective only, as though he or she were as close to each instrument as is each microphone. Electronic signal processing devices may not be entirely successful in restoring the missing information, and the listener hears a recording that may be technically well executed, yet lacking the apparent depth and musical cohesiveness of the original. However, the multitrack technique becomes advantageous when it is impractical or impossible to record the entire ensemble at once stereophonically. *See* SOUND-REPRODUCING SYSTEMS. [J.M.Wor.]

Sound-recording studio An enclosure treated acoustically to provide controlled recording of music or speech. Professional sound-recording studios range from small home studios (such as a converted garage or basement) to large facilities using state-of-the-art equipment. They consist of two rooms, the main studio or stage (performance area) and the audio control room. The stage includes one or more microphones, is acoustically isolated to ensure that external sounds do not interfere with the recording, and can be broken up into small booths to separate individual performers. The audio control room contains the mixing console and recording devices. *See* ACOUSTIC NOISE; ARCHITECTURAL ACOUSTICS; SOUND; SOUND RECORDING. [M.Re.; A.Ca.]

Sound-reinforcement system A system that amplifies or enhances the sound of a speaking person, singer, or musical instrument. Sound-reinforcement systems are used to increase the clarity of the original sound as well as to add loudness and reverberation. Those that improve loudness and clarity are often called public address systems, and those that improve reverberation characteristics are called reverberation enhancement systems. Systems for increased loudness are used when listeners are located far from the sound source, as in a large audiorium or outdoors. Systems for increased clarity are used to overcome the effects of unwanted noise or excessive reverberation in a room (such as concert halls and churches with reverberation characteristics designed for music). Reverberation enhancement systems are used to add sound field components, such as reverberation to rooms having unsuitable levels of direct, early reflected sound and reverberant sound or having short reverberation times. *See* ARCHITECTURAL ACOUSTICS; REVERBERATION; SOUND; SOUND FIELD ENHANCEMENT.



Basic sound-reinforcement system.

The basic elements of a sound-reinforcement system are (1) one or more microphones, (2) amplification and electronic signal processing systems, and (3) one or more loudspeakers. The signal processing equipment may include level controls, equalizers or tone controls, systems for prevention of howl and ringing, delays and reverberators, as well as frequency dividing and crossover networks.

The illustration shows the signal flow diagram of a simple system. In the simplest systems, all elements are joined as one physical unit. An example of a simple public address system is the hand-held battery-driven electronic megaphone, consisting of a microphone, a frequency-response-shaping filter, an amplifier, and a horn loudspeaker. Most sound-reinforcement systems, however, are assembled from individual elements to optimize and adapt the system performance for the needs of a particular installation. [D.L.K.; M.Kle.]

Sound-reproducing systems Systems that attempt to reconstruct some or all of the audible dimensions of an acoustic event that occurred elsewhere. A sound-reproducing system includes the functions of capturing sounds with microphones, manipulating those sounds using elaborate electronic mixing consoles and signal processors, and then storing the sounds for reproduction at later times and different places. *See* MICROPHONE.

Certain technical variables are relevant to the reliable reconstruction of audio events. These include frequency range, dynamic range, and linear and nonlinear distortions. Traditionally the audible frequency range has been considered to be 20 Hz to 20 kHz. However, lower frequencies can generate interesting tactile impressions, and it is now argued by some that higher frequencies (even 50 kHz and beyond) add other perceptual nuances. *See* HEARING (HUMAN).

In humans, dynamic range is the range of sound level from the smallest audible sound to the largest sound that can be tolerated. In devices, it is the range from background noise to unacceptable distortion. From the threshold of audibility to the onset of discomfort is about 120 decibels at middle and high frequencies. Microphones are not a limiting factor since the best have dynamic ranges in excess of 130 dB. In the recording studio, dynamics are manipulated by electronic gain compensation, so the ultimate limitation is the storage medium. For example, a 16-bit compact disk (CD) can exceed 100 dB signal-to-noise ratio, while 24-bit digital media can exceed any reasonable need for dynamic range. Background acoustical noise in studios and concert halls sets the lower limit for recordings, just as background noise in homes and cars sets a lower limit for playback. Quiet concert halls and homes are around 25 dB sound pressure level (SPL) at middle and high frequencies. Crescendoes in music and movies approximate 105 dB. *See* ACOUSTIC NOISE;

Compact disk; Decibel; Distortion (electronic circuits); Gain; Loudness; Signal-to-noise ratio; Sound; Sound pressure.

Variations in amplitude and phase as functions of frequency are known as linear distortions, since (ideally) they do not vary with signal level. In practice they often do, and in the process generate nonlinear distortions. In terms of their importance in preserving the timbre of voices and musical instruments, the amplitude versus frequency characteristic, known commonly as the frequency response, is the dominant factor. Humans are very sensitive to variations in frequency response, the amount depending on the bandwidth of the variation. It is convenient to discuss this in terms of the quality factor (Q) of resonances, since most such variations are the result of resonances in loudspeaker transducers or enclosures. *See* Distortion (electronic circuits); Q (electricity); Resonance (acoustics and mechanics); Response; Reverberation.

Nonlinear distortions occur when a device behaves differently at different signal levels. The waveform coming out of a distorting device will be different from the one entering it. The difference in shape, translated into the frequency domain, is revealed as new spectral components. If the input waveform is a single frequency (pure tone), the additional spectral components will be seen to have a harmonic relationship to the input signal. Hence they are called harmonic distortion. If two or more tones are applied to the device, nonlinearities will create harmonics of all of the tones (harmonic distortion) and, in addition, more new spectral components that are sum-and-difference multiples of combinations of the tones. These additional components are called intermodulation distortion.

Perceptually, listeners are aided by a phenomenon called masking, in which loud sounds prevent some less loud sounds from being heard. This means that the music causing the distortion inhibits the ability to hear it. Rough guidelines suggest that, in music, much of the time we can be unaware of distortions measuring in whole percentages, but that occasionally small fractions of a percent can be heard. *See* Masking of sound.

Loudspeakers radiate sound in all directions, so that measurements made at a single point represent only a tiny fraction of the total sound output. In rooms, most of the sound we hear from loudspeakers reaches our ears after reflections from room boundaries and furnishings, meaning that our perceptions may be more influenced by measures of reflected and total sound than by a single measurement, say, on the principal axis. *See* Architectural acoustics; Sound field enhancement.

To be useful, technical measurements must allow us to anticipate how these loudspeakers might sound in rooms. Consequently, it is necessary to measure sounds radiated in many different directions at points distributed on the surface of an imaginary sphere surrounding the loudspeaker. From these data, it is possible to calculate the direct sound from the loudspeaker to the listener, estimates of strong early reflected sounds from room boundaries, and estimates of later reflected or reverberant sounds. It is also possible to calculate measures of total sound output, regardless of the direction of radiation (sound power) and of the uniformity of directivity as a function of frequency. All of these measured quantities are needed in order to fully evaluate the potential for good sound in rooms. *See* Directivity.

Binaural system configurations are sound-reproduction techniques in which a dummy head, equipped with microphones in the ear locations, captures the original performance. Listeners then audition the reproduced performance through headphones, with the left and right ears hearing, ideally, what the dummy head "heard." The system is good, but flawed in that sounds that should be out in front (usually the most important sounds) tend to be perceived to be inside, or close to, the head. Addressing this limitation, systems have been developed that use two loudspeakers, combined with signal processing to cancel the acoustical crosstalk from the right loudspeaker to the left ear, and vice versa. The geometry of the loudspeakers and listener is fixed. In this mode of listening, sounds that should be behind are sometimes displaced forward, but the front hemisphere can be very satisfactorily reproduced. *See* Binaural sound system; Earphones; Virtual acoustics.

Multichannel audio systems began with stereophonic systems using two channels, because in the 1950s the technology was limited to one modulation for each groove wall of a record. Good stereo imaging is possible only for listeners on the axis of symmetry, equidistant from both loudspeakers. *See* Modulation; Stereophonic sound.

Quadraphonic systems appeared in the 1970s, and added two more loudspeakers behind the listeners, mirroring the ones in front. The most common systems exhibited generous interchannel crosstalk or leakage. To hear the proper spatial perspective, the preferred listening location was restricted to front/back as well as left/right symmetry. The failure to agree on a single standard resulted in the system's demise.

For film sound applications, Dolby Surround modified the matrix technology underlying one of the quadraphonic systems, rearranging the four matrixed channels into a left, center, right, and surround configuration. In cinemas, the single, limited-bandwidth, surround channel information is sent to several loudspeakers arranged along the side walls and across the back of the audience area. For home reproduction, the surround channel is split between two loudspeakers placed above and to the sides of the listeners.

Even with the best active (electronically steered) matrix systems, the channels are not truly discrete. Sounds leak into unintended channels where they dilute and distort directional and spatial impressions. Digital recording systems now provide five discrete full-bandwidth channels, plus a low-frequency special effects channel for movies with truly big bass sounds. For homes, 5.1 channels refers to five satellite loudspeakers, operating with a common low-frequency subwoofer. The subwoofer channel is driven through a bass-management system that combines the low frequencies of all channels, usually crossing over at 80–100 Hz so that, with reasonable care in placement, it cannot be localized. [F.T.]

Sourwood A deciduous tree, *Oxydendrum arboreum*, of the heath family, indigenous to the southeastern section of the United States, and found from Pennsylvania to Florida and west to Indiana and Louisiana. It is usually a small or medium-sized tree. The wood is not used commercially. Sourwood is also known as sorrel tree, and it is widely planted as an ornamental. *See* Ericales. [A.H.G./K.P.D.]

South America The southernmost of the New World or Western Hemisphere continents, with three-fourths of it lying within the tropics. South America is approximately 4500 mi (7200 km) long and at its greatest width 3000 mi (4800 km). Its area is estimated to be about 7,000,000 mi^2 (18,000,000 km^2). South America has many unique physical features, such as the Earth's longest north-south mountain range (the Andes), highest waterfall (Angel Falls), highest navigable fresh-water lake (Lake Titicaca), and largest expanse of tropical rainforest (Amazonia). The western side of the continent has a deep subduction trench offshore, whereas the eastern continental shelf is more gently sloping and relatively shallow. *See* Continent.

South America has three distinct regions: the relatively young Andes Mountains located parallel to the western coastline, the older Guiana and Brazilian Highlands located near the eastern margins of the continent, and an extensive lowland plains, which occupies the central portion of the continent. The regions have distinct physiographic and biotic features.

The Andes altitudes often exceed 20,000 ft (6000 m) and perpetual snow tops many of the peaks, even along the Equator. So high are the Andes in the northern half of the continent that few passes lie below 12,000 ft (3600 m). Because of the vast extent of the Andes, a greater proportion of South America than of any other continent lies above 10,000 ft (3000 m). The young, rugged, folded Andean peaks stand in sharp contrast to the old, worn-down mountains of the eastern highlands. Although the Andes appear to be continuous, most geologists believe that they consist of several structural units, more or less joined. They are a single range in southern Chile, two ranges in Bolivia, and dominantly three ranges in Peru, Ecuador, and Colombia.

Except in Bolivia, where they attain their maximum width of 400 mi (640 km), the Andes are seldom more than 200 mi (320 km) wide. The average height of the Andes is estimated to be 13,000 ft (3900 m). However, it is only north of latitude 35°S that the mountains exceed elevations of 10,000 ft (3000 m).

From the southern tip of Cape Horn north to 41°S latitude, the western coastal zone consists of a broad chain of islands where a mountainous strip subsided and the ocean invaded its valleys. This is one of the world's finest examples of a fiorded coast. Nowhere along the Pacific coast is there a true coastal plain. South of Arica, Chile, the bold, precipitous coast is broken by only a few deep streams, the majority of which carry no water for years at a time. Between Arica and Caldera, Chile, there are no natural harbors and almost no protected anchorages. In fact, South America's coastline is the least indented of all the continents except Africa's. *See* FIORD.

The Caribbean coast of Colombia is a lowland formed largely of alluvium, deposited by the Magdalena and Cauca rivers, and bounded by mountains on three sides. In Venezuela, the Central Highlands rise abruptly from the Caribbean, with lowlands around Lake Maracaibo, west of Puerto Cabello, and around the mouth of the Río Tuy of the Port of Guanta. The coastal region of Guyana, Suriname, and French Guiana is a low, swampy alluvial plain 10–30 mi (16–48 km) wide, and as much as 60 mi (96 km) wide along the larger rivers. This coastal plain is being built up by sediments carried by the Amazon to the Atlantic and then deflected westward by the equatorial current and cast upon the shore by the trade winds.

There is no broad coastal plain south of the Amazon and east of the Brazilian Highlands to afford easy access to the interior. The rise from the coastal strip to the interior is quite gradual in northeastern Brazil; but southward, between Bahia and Río Grande do Sul, the steep Serra do Mar is a formidable obstacle to transportation.

Along coastal Uruguay there is a transition between the hilly uplands and plateaus of Brazil and the flat Pampas of Argentina, whereas coastal Argentina as far south as the Río Colorado, in Patagonia, is an almost featureless plain. In Patagonia, steep cliffs rise from the water's edge. Behind these cliffs lies a succession of dry, flat-topped plateaus, surmounted occasionally by hilly land composed of resistant crystalline rocks. Separating southern Patagonia from Tierra del Fuego is the Strait of Magellan, which is 350 mi (560 km) long and 2–20 mi (3–32 km) wide. Threading through numerous islands, the strait is lined on each side with fiords and mountains.

There are three great river systems in South America and a number of important rivers that are not a part of these systems. The largest river system is the Amazon which, with its many tributaries, drains a basin covering 2,700,000 mi^2 (7,000,000 km^2), or about 40% of the continent. The next largest is the system composed of the Paraguay, Paraná, and La Plata rivers, the last being a huge estuary. The third largest river system, located in southern Venezuela, is the Orinoco, which drains 365,000 mi^2 (945,000 km^2) of land, emptying into the Atlantic Ocean along the northeast edge of the continent.

The plants and animals of the South American tropics are classified as Neotropical, defined by the separation of the South American and African continents during the Middle Cretaceous (95 million years ago). The Paraná basalt flow, which caps the Brazilian shield in southern Brazil and adjacent parts of Uruguay and Argentina, as well as western Africa, indicates the previous linkage between the South American and African continents. South America has many biotic environments, including the constantly moist tropical rainforest, seasonally dry deciduous forests and savannas, and high-altitude tundra and glaciated environments.

Amazonia contains the largest extent of tropical rainforest on Earth. It is estimated to encompass up to 20% of the Earth's higher plant species and is a critically important source of fresh water and oxygen. Structurally complex, the rainforest is composed of up to four distinct vertical layers of plants and their associated fauna. The layers often cluster at 10, 20, 98, and 164 ft (3, 6, 30, and 50 m) in height. The lower canopy and forest floor are usually open spaces because of the low intensity of light (around 1%) that reaches the forest floor. Over 75% of Amazonian soils are classified as infertile, acidic, or poorly drained, making them undesirable for agriculture because of nutrient deficiencies. Most of the nutrients in the tropical rainforest are quickly absorbed and stored in plant biomass because the high annual rainfall and associated leaching make it impossible to maintain nutrients in the soils. In addition to the high structural complexity of the tropical rainforest, there is considerable horizontal diversity or patchiness. As many as 300 separate species of trees can be found in a square mile (2.6 km^2) sample tract of rainforest in Brazil. The high complexity and species diversity of the rainforest are the result of long periods of relative stability in these regions. *See* RAINFOREST.

Deciduous forest are found in areas where there is seasonal drought and the trees lose their leaves in order to slow transpiration. The lower slopes of the Andes, central Venezuela, and central Brazil are areas where these formations are found. Conifer forests occur in the higher elevations of the Andes and the higher latitudes of Chile and Argentina. *See* DECIDUOUS PLANTS.

Tropical savannas occupy an extensive range in northern South America through southeastern Venezuela and eastern Colombia. Temperate savannas are found in Paraguay, Uruguay, the Pampas of Argentina, and to the south, Patagonia. Savannas are composed of a combination of grass and tree species. The climate in these areas is often quite hot with high rates of evapotranspiration and a pronounced dry season. Most of the plants and animals of these zones are drought-adapted and fire-adapted. Tall grasses up to 12 ft (3.5 m) are common as are thorny trees of the Acacia (Fabaceae) family. Many birds and mammals are found in these zones, including anteater, armadillo, capybara (the largest rodent on Earth), deer, jaguar, and numerous species of venomous snake, including rattlesnake and bushmaster (*mapanare*). *See* SAVANNA.

South America is unique in having a west-coast desert (the Atacama) that extends almost to the Equator, probably receiving less rain than any on Earth, and an east coast desert located poleward from latitude 40°S (the Patagonian). *See* DESERT.

In Bolivia and Peru the zone from 10,000 to 13,000 ft (3000 to 3900 m), though occasionally to 15,000–16,000 ft (4500 to 4800 m), is known as the *puna*. Here the hot days contrast sharply with the cold nights. Above the *puna*, from timberline to snowline, is the *paramo*, a region of broadleaf herbs and grasses found in the highest elevations of Venezuela, Colombia, and Ecuador. Many of the plant species in these environments are similar to those found at lower elevations; however, they grow closer to the ground in order to conserve heat and moisture. *See* PARAMO; PUNA. [D.A.Sa.; C.L.W.]

South Pole That end of the Earth's rotational axis opposite the North Pole. It is the southernmost point on the Earth and one of the two points through which all meridians pass (the North Pole being the other point). This is the geographic pole and is not the same as the south magnetic pole. The South Pole lies inland from the Ross Sea, within the land mass of Antarctica, at an elevation of about 9200 ft (2800 m).

There is no natural way to determine local Sun time because there is no noon position of the Sun, and shadows point north at all times, there being no other direction from the South Pole. *See* MATHEMATICAL GEOGRAPHY; NORTH POLE. [V.H.E.]

Southeast Asian waters All the seas between Asia and Australia and the Pacific and the Indian oceans. They form a geographical and oceanographical unit because of their special structure and position, and make up an area of 3,450,000 mi^2 (8,940,000 km^2), or about 2.5% of the surface of all oceans.

The surface circulation is completely reversed twice a year by the changing monsoon winds. The subsurface circulation carries chiefly the outrunners of the intermediate waters of the Pacific Ocean into these seas. The tides are mostly of the mixed type. Diurnal tides are found in the Java Sea, in the Gulf of Tonkin, and in the Gulf of Thailand. Semidiurnal tides with high amplitudes occur in the Malacca Straits. *See* INDIAN OCEAN; PACIFIC OCEAN. [K.W.]

The Southeast Asian seas are characterized by the presence of numerous major plate boundaries. In Southeast Asia the plate boundaries are identified, respectively, by young, small ocean basins with their spreading systems and associated high heat flow; deep-sea trenches and their associated earthquake zones and volcanic chains; and major strike-slip faults such as the Philippine Fault (similar to the San Andreas Fault in California). The Southeast Asian seas are thus composed of a mosaic of about 10 small ocean basins whose boundaries are defined mainly by trenches and volcanic arcs. The dimensions of these basins are much smaller than the basins of the major oceans. The major topographic features of the region are believed to represent the surface expression of plate interactions, the scars left behind on the sea floor. *See* PLATE TECTONICS. [D.E.H.]

Soybean *Glycine max*, a legume native to China that has become a major source of vegetable protein and oil for human and animal consumption and for industrial usage. The valued portion of the plant is the seed, which contains about 40% protein and 21% oil. Illinois, Iowa, Arkansas, Missouri, Indiana, Mississippi, Minnesota, Ohio, Louisiana, and Tennessee are the major soybean producers in the United States. *See* FAT AND OIL (FOOD). [W.R.F.]

Space Physically, space is that property of the universe associated with extension in three mutually perpendicular directions. Space, from a newtonian point of view, may contain matter, but space exists apart from matter. Through usage, the term space has come to mean generally outer space or the region beyond Earth. Geophysically, space is that portion of the universe beyond the immediate influence of Earth and its atmosphere. From the point of view of flight, space is that region in which a vehicle cannot obtain oxygen for its engines or rely upon an atmospheric gas for support (either by buoyancy or by aerodynamic effects). Astronomically, space is a part of the space-time continuum by which all events are uniquely located. Relativistically, the space and time variables of uniformly moving (inertial) reference systems are connected by the Lorentz transformations. Gravitationally, one characteristic of space is that all bodies undergo the same acceleration in a gravitational field and therefore that inertial forces are equivalent to gravitational forces. Perceptually, space is sensed indirectly by the objects and events within it. Thus, a survey of space is more a survey of its contents. *See* EUCLIDEAN GEOMETRY; LORENTZ TRANSFORMATIONS; RELATIVITY; SPACE-TIME. [S.F.S.]

Space biology Collectively, the various biological sciences concerned with the study of organisms and their components when exposed to the environment of space (or of a spacecraft beyond the immediate influence of Earth and its atmosphere). Space biology studies include all the biological science disciplines, such as molecular, cellular, developmental, environmental, behavioral, and radiation biology; physiology; medicine; biophysics; and biochemistry. Space biology encompasses both basic and applied sciences, and focuses on using space research to understand and resolve biological problems on Earth, as well as alleviating or preventing the deleterious physiological changes associated with space flight or habitation in non-Earth environments. *See* SPACE.

As crewed space flight developed, medical research focused on the health and well-being of astronauts, which was paramount. This medical research has historically been included in the area of aerospace medicine. From these research efforts, directed at survival of living systems in the space environment, has evolved the broader discipline of space biology, which uses the space environment to gain an understanding of basic biological processes. *See* AEROSPACE MEDICINE.

Space biology considers all of the inherent physical factors of the space environment and their effects on living organisms: (1) factors due to the environment of space, such as radiation and reduced pressure; (2) factors due to the flight dynamics of spacecraft, including acceleration, weightlessness, and vibration; (3) factors due to the environment of the spacecraft, such as air composition, atmospheric pressure, toxic materials, noise, and confinement; and (4) factors due to the environment on nonterrestrial bodies, such as the level of gravity, composition of soil, and temperature extremes. Of these factors, only weightlessness and space radiation are unique to the space environment, but the effects of the other factors must be considered and mimicked in ground-based or flight controls when conducting space biological experiments. In addition, space experiments must take into consideration the physical effects of weightlessness on the environment surrounding and supporting the organisms. For example, neither gases nor liquids behave in a space environment as they do under the conditions found on Earth, as sedimentation, buoyancy, and convection do not occur in a weightless environment. *See* ACCELERATION; WEIGHTLESSNESS. [C.E.Wa.]

Space charge The net electric charge within a given volume. If both positive and negative charges are present, the space charge represents the excess of the total positive charge diffused through the volume in question over the total negative charge. [E.G.R.]

Space communications Communications between a vehicle in outer space and Earth, using high-frequency electromagnetic radiation (radio waves). Provision for such communication is an essential requirement of any space mission. The total communication system ordinarily includes (1) command, the transmission of instructions to the spacecraft; (2) telemetry, the transmission of scientific and applications data from the spacecraft to Earth; and (3) tracking, the determination of the distance (range) from Earth to the spacecraft and its radial velocity (range-rate) toward or away from Earth by the measurement of the round-trip radio transmission time and Doppler frequency shift (magnitude and direction). A specialized but commercially important application, which is excluded from consideration here, is the communications satellite system in which the spacecraft serves solely as a relay station between remote points on Earth. *See* COMMUNICATIONS SATELLITE; DOPPLER EFFECT; MILITARY SATELLITES; SATELLITE (SPACECRAFT); SCIENTIFIC SATELLITES; SPACE FLIGHT; SPACE NAVIGATION AND GUIDANCE; SPACE PROBE; SPACECRAFT GROUND INSTRUMENTATION; TELEMETERING.

Certain characteristic constraints distinguish space communication systems from their terrestrial counterparts. Although only line-of-sight propagation is required, both the transmitter and the receiver are usually in motion. The movement of satellites relative to the rotating Earth, for example, requires geographically dispersed Earth stations to achieve adequate communication with the spacecraft on each orbit.

Because enormous distances are involved (over a billion miles to the planets beyond Jupiter), the signal received on Earth from deep-space probes is so small that local interference, both artificial and natural, has to be drastically reduced. For this purpose, the transmitted frequency has to be sufficiently high, in the gigahertz range, to reduce noise originating in the Milky Way Galaxy (galactic noise background). The receiver site must be remote from technologically advanced population centers to reduce artificial noise, and at a dry location to avoid precipitation attenuation of the radio signal as well as the higher antenna thermal noise associated with higher atmospheric absolute humidity and relatively warm cloud droplets. The receiving antennas must be steerable and large, typically 85 ft (26 m) or at times 210 ft (64 m) in diameter, to enhance the received signal strength relative to the galactic noise background. Special low-noise preamplifiers such as cooled masers are mounted on the Earth receiver antenna feed to reduce the receiver input thermal noise background. Sophisticated digital data processing is required, and the ground-receiver complex includes large high-speed computers and associated processing equipment. *See* MASER; PREAMPLIFIER; RADIO RECEIVER; RADIO TELESCOPE.

The spacecraft communications equipment is constrained by severe power, weight, and space limitations. Typical communications equipment mass ranges from 25 to 220 lb (12 to 100 kg). Another major challenge is reliability, since the equipment must operate for years, sometimes for decades, unattended, in the difficult radiation, vacuum, and thermal environment of space. Highly reliable components and equipment have been developed, and redundancy is employed to eliminate almost all single-point failures. For example, it is not unusual to have as many as three redundant command receivers operating continuously, because without at least one such receiver in operation no command can get through, including a command to switch from a failed command receiver to a backup radio. Power can be saved by putting some or all of the redundant radios on timers, and to switch to a backup receiver if no commands have been received through the primary receiver within a predetermined interval; but the saved power may come at the cost of a possible delay in emergency response initiation.

Spacecraft power is always at a premium, and other techniques must also be used to minimize its consumption by the communication system. The transmitter is a major power consumer, so its efficiency must be maximized. All aspects of data transmission must contribute to error-free (very low bit error rate) reproduction of the telemetry data using no more power or bandwidth than is absolutely essential. Pulse-code modulation is a common technique which helps meet this goal. In general terms, space communication systems are far less forgiving than terrestrial systems and must be designed, constructed, and tested to much higher standards. *See* PULSE MODULATION; SPACE POWER SYSTEMS; SPACE TECHNOLOGY.

The Tracking and Data Relay Satellite System (TDRSS) consists of a series of geostationary spacecraft and an Earth terminal located at White Sands, New Mexico. The purpose of TDRSS is to provide telecommunication services between low-Earth-orbiting (LEO) user spacecraft and user control centers. A principal advantage of the system is the elimination of the need for many of the worldwide ground stations for tracking such spacecraft. The *Tracking and Data Relay Satellite* (*TDRS*) provides no processing of data; rather, it translates received signals in frequency and retransmits them. User orbits are calculated from range and range-rate data obtained through the *TDRS* by using transponders on the user spacecraft. [J.F.Cl.; D.Pl.]

Space flight

The penetration by humans into the reaches of the universe above the terrestrial atmosphere and investigation of these regions by automated, remote-controlled and crewed vehicles.

The purpose of space flight is to provide significant contributions to the physical and mental needs of humanity on a national and global basis. Such contributions fall specifically in the areas of (1) Earth resources of food, forestry, atmospheric environment, energy, minerals, water, and marine life; (2) Earth and space sciences for research; (3) commercial materials processing, manufacturing in space, and public services. More general goals of space flight include expansion of knowledge; exploration of the unknown, providing a driving force for technology advancement and, hence, improved Earth-based productivity; development and occupation of new frontiers with access to extraterrestrial resources and unlimited energy; strengthening of national prestige, self-esteem, and security; and providing opportunity for international cooperation and understanding.

This article focuses on crewed space flight. For discussion of other missions *see* COMMUNICATIONS SATELLITE; METEOROLOGICAL SATELLITES; MILITARY SATELLITES; SATELLITE (SPACECRAFT); SATELLITE NAVIGATION SYSTEMS; SCIENTIFIC SATELLITES; SPACE PROBE.

To conduct crewed space flight, the two leading space-faring nations, the United States and Russia, formerly the Soviet Union, have developed spacecraft systems and the necessary ground facilities, research and development base, operational know-how, planning experience, and management skills. In the United States, crewed space programs are conducted by the National Aeronautics and Space Administration (NASA), a federal agency established in 1958 for the peaceful exploration of space. In Russia, crewed space flights have been under the auspices of the U.S.S.R. Academy of Sciences; they are now the responsibility of the Russian Space Agency (RKA). The first spacecraft with a human on board, the *Vostok 1*, piloted by Yuri A. Gagarin, was launched on April 12, 1961, from the Baikonur Cosmodrome in Kazakhstan and returned after completing one revolution of the Earth. The first American space flight of a human took place 3 weeks later, when NASA launched Alan B. Shepard on May 5 on the *Mercury-Redstone 3* for a 15-min suborbital test flight.

The early spacecraft of both nations were built for only one space flight. The first multiply reusable space vehicle, the space shuttle, was launched by the United States on April 12, 1981.

In November 1987, the 13 member nations of the European Space Agency (ESA) agreed to become the third major power engaging in human space flight. European efforts today focus on a two-pronged program: participation as a partner in the International Space Station (ISS), primarily with the Columbus Orbital Facility (COF), and extension of the Ariane family of expendable launch vehicles with the heavy-lift carrier Ariane 5. By joining the original partnership behind the space station and assigning astronauts to United States space shuttle missions (as did the European Space Agency and Russia), Canada and Japan have also entered the ranks of space-faring nations, while other countries, such as Brazil, are preparing to join. On October 15, 2003, the People's Republic of China launched Yang Liwei on a 21-hour orbital flight aboard the spacecraft *Shenzou 5*.

Crewed spacecraft. A crewed spacecraft is a vehicle capable of sustaining humans above the terrestrial atmosphere. In a more limited sense, the term crewed spacecraft is usually understood to apply to vehicles for transporting and sustaining human crews in space for time periods limited by prestored on-board supplies, as distinct from orbital space stations which support theoretically unlimited habitation of humans in space by autonomous systems, crewed maintenance, and periodic resupply.

The basic requirements of crewed spacecraft are quite different from those of uncrewed space probes and satellites. The presence of humans on board necessitates a life-sustaining environment and the means to return safely to Earth. The major common feature of all crewed spacecraft, therefore, is the atmospheric return element or reentry module. It consists basically of a pressure-tight cabin for the protection, comfort, and assistance of the crew, similar to the cockpits of fighter aircraft, but shaped externally in accordance with the desired airflow and its forces, and surrounded by heat-resistant material, the thermal protection system (TPS), to cope with the high frictional and radiative heating accompanying the energy dissipation phase of the atmospheric return flight to Earth.

The main system that distinguishes crewed spacecraft from other spacecraft is the environmental control and life support system. It provides the crew with a suitably controlled atmosphere. Because all atmospheric supplies must be carried into space, it is essential to recirculate and purify the spacecraft atmosphere to keep the total weight of the vehicle within reasonable limits.

Space suits or pressure suits are mobile spacecraft or chambers that house the astronauts and protect them from the hostile environment of space. They provide atmosphere for breathing, pressurization, and thermal control; protect astronauts from heat, cold, glare, radiation, and micrometeorites; contain a communication link and hygiene equipment; and must have adequate mobility. The suit is worn during launch, docking, and other critical flight phases.

Because of the potential hazards of space flight to personnel, crewed spacecraft must meet stringent requirements of safety and hardware reliability. Reliability is associated with the probability that the spacecraft systems will operate properly for the required length of time and under the specified conditions. To assure survival and return in all foreseeable emergencies, the design of a crew-rated spacecraft includes standby systems (double or triple redundancy) and allows for launch escape, alternative and degraded modes of operation, contingency plans, emergency procedures, and abort trajectories to provide maximum probability of mission success. The priority order of this reliability requirement is (1) crew safety, (2) minimum achievable mission fulfillment, (3) mission data return, and (4) minimal degradation. *See* RELIABILITY, AVAILABILITY, AND MAINTAINABILITY.

Soviet/Russian programs. After the first *Sputnik* launch on October 4, 1957, developments of crewed space flight capability followed in quick succession, leading from the first-generation *Vostok* (East) to the second-generation *Voskhod* (Ascent) and to the third-generation *Soyuz* (Union) spacecraft. Originally engaged in an aggressive program to land a cosmonaut on the Moon before the United States lunar orbit mission of *Apollo 8* in December 1968, the Soviet Union redirected its aims, after four test failures of its N1 heavy-lift launcher, toward the development of permanent human presence in Earth orbit.

The *Vostok*, a single-seater for short-duration missions and ballistic reentry from Earth orbits, consisted of a near-spherical cabin, having three small viewports and external radio antennas. The 7-ft (2-m) sphere of the cabin was attached to a service module. The second-generation *Voskhod*, essentially a greatly modified *Vostok*, was a short-duration multiperson craft and was designed to permit extravehicular activity or spacewalking by one of the crew.

The *Soyuz* design is much heavier, larger, and more advanced in its orbital systems, permitting extended orbital stay times. It consists of three main sections or modules: a descent vehicle, an orbital module, and an instrument-assembly module. The three elements are joined together, with the descent vehicle in the middle. Shortly before atmospheric reentry, the two outer modules are jettisoned.

Soyuz spacecraft carried originally up to three cosmonauts. However, when an accidental explosive decompression of the descent cabin during reentry caused the death of the *Soyuz 11* crew in 1971, the third seat was removed to make room for the necessary additional life-support equipment, and the *Soyuz* thereafter carried only two cosmonauts. An improved version, the *Soyuz T* (for "Transport") was introduced in 1980. A new version, the *Soyuz-TM*, with extended mission duration and new subsystems, replaced this vehicle in February 1987, after a crewless test flight in May 1986.

Between 1971 and 1981, five *Salyut* space stations operated in low Earth orbit successively. The most successful of them, *Salyut 6*, was the first of a "second generation" of such stations. Unlike its predecessors, it had two docking ports, instead of only one. This enabled it to receive visiting crews and resupply ships. Together with other new on-board systems, this feature was the key to missions of considerably extended duration. Its successor, *Salyut 7*, was launched in 1982.

On February 19, 1986, the Soviet Union launched the core vehicle in its *Mir* (Peace) space station complex series. This complex represented a new-generation space station which evolved from the *Salyut* and *Kosmos* series vehicles. The core, an advanced version of *Salyut*, had six docking ports and consisted of four sections. Connected to various docking ports were four laboratory modules, which were launched separately between 1989 and 1996. These modules were dedicated to different scientific and technical disciplines or functions, including technological production with a shop, astrophysics, biological research, and medical research.

In its later years, *Mir* required increasing maintenance and repairs by its crews, particularly after two serious emergencies in 1997. When U.S. support of *Mir* ended at the conclusion of the joint Shuttle/Mir program (ISS Phase 1), further crewed operations of the space station were increasingly difficult and impractical for the Russian Space Agency (RSA). The last crew returned to Earth on August 27, 1999, and the station was deorbited on March 20, 2001. *See* SPACE STATION.

With the successful first test flight, from Baikonur, of the powerful expendable heavy-lift launcher *Energia* on May 15, 1987, the Soviet Union gained a tremendous new launch capability. With its second, and last, flight on November 15, 1988, the *Energia* launched the Soviet space shuttle *Buran* on its only (crewless) orbital test flight. After the collapse of the Soviet Union, the *Energia*/*Buran* programs were terminated.

United States programs. During the first decade after its inception in 1961, the United States crewed space program was conducted in three major phases—Mercury, Gemini, and Apollo.

Mercury was in its basic characteristics similar to the Soviet *Vostok*, but it weighed only about a third as much, as necessitated by the smaller missiles of the United States at that time (the Redstone and Atlas). The one-person *Mercury* capsules used ballistic reentry and were designed to answer the basic questions about humans in space: how they were affected by weightlessness, how they withstood the gravitational forces of boost and entry, how well they could perform in space. *See* WEIGHTLESSNESS.

The second United States step into space was the Gemini Program. With the two-person *Gemini* capsule, for the first time a crewed spacecraft had been given operational maneuverability in space. Its reentry module flew a lifting reentry trajectory for precise landing point control. In addition, its design permitted extravehicular activity by one of the crew.

The third-generation spacecraft, *Apollo*, had five distinct parts: the command module (CM), the service module (SM), the lunar module (LM), the launch escape system (LES), and the spacecraft/lunar module adapter (SLA). The three modules made up the basic spacecraft; the LES and SLA were jettisoned early in the mission after they had outlived their function. The command module served as the control center for the spacecraft and provided living and working quarters for the three-member crew for the entire flight, except for the period when two persons entered the lunar module for the descent to the Moon and return. The command module was the only part of the spacecraft that returned to Earth, flying a lifting trajectory with computer-steered maneuvers. The lunar module carried two astronauts from the orbiting command/service module (CSM) down to the surface of the Moon, provided a base of operations there, and returned the two astronauts to a rendezvous with the command service module in orbit. On the last three lunar landings, *Apollo 15–17*, lunar exploration was supported by the lunar roving vehicle.

A more powerful booster was required to lift the *Apollo* spacecraft to Earth orbit and thence to the Moon. At the Army Ballistic Missile Agency (ABMA) in 1958, a team of engineers under Wernher von Braun set out to prove that vastly more powerful space rockets could be built from existing hardware by clustering engines and tanks. The project evolved into the Saturn Program of NASA. The Saturn 5, which became the Apollo lunar launch vehicle, had the capability to lift 250,000 lb (113 metric tons) into low Earth orbit and to send 100,000 lb (45 metric tons) to the Moon.

In addition to its lunar mission in the Apollo program, the Saturn 5, in a two-stage version, served also—in its last and thirteenth flightz—to launch the first United States space station, *Skylab*.

Skylab. The experimental space station *Skylab* was the largest object placed in space up until that time, and the first crewed project in the U.S. Space Program with the specific purpose of developing the utility of space flight in order to expand and enhance humanity's well-being on Earth. To that end, *Skylab's* equipment included an Earth resources remote sensing instrument and the first crewed solar telescopes in space. A total of three crews of three astronauts each carried out experiments and observations on *Skylab*. *Skylab* was launched uncrewed by Saturn 5 in 1973. The space station underwent repair in orbit, a first for the space program.

Space Transportation System. After the end of the joint American-Soviet space mission, attention began to focus on the routine application of newly acquired know-how systems and experience, specifically in the form of the emerging Space Transportation System (STS), with the ability to transport inexpensively a variety of useful payloads to orbit, as the mainstay and "work horse" of the United States space program. The two major components of the Space Transportation System were the space shuttle and the *Spacelab*.

The space shuttle is a reusable system. It has three major elements: the orbiter, an external tank (ET) containing the liquid propellants to be used by the orbiter main engines for ascent, and two solid-propellant rocket boosters (SRBs) "strapped on" to the external tank. The orbiter and solid rocket booster casings are reusable; the external tank is expended on each launch. *See* SPACE SHUTTLE.

The orbiter *Columbia* made its first orbital flight on April 12–14, 1981. Three additional shuttles were added by the end of 1985. With the launch of the twenty-fifth shuttle mission, *51-L* on January 28, 1986, tragedy struck the American space program. At approximately 11:40 a.m. EST, 73 s after liftoff, the flight of *Challenger*, on its tenth mission, abruptly ended in an explosion triggered by a leak in the right solid rocket booster, killing the seven member crew. Continuation of the United States crewed space program was suspended pending a thorough reassessment of flight safety issues and implementation of necessary improvements. Shuttle flight operations resumed on September 29, 1988.

On February 1, 2003, *Columbia,* on its twenty-eighth flight, was lost with its crew during reentry when it violently disintegrated in the skies over Texas. The Columbia Accident Investigation Board (CAIB) concluded that one of the left wing's leading-edge reinforced-carbon-carbon elements had been punctured during ascent to orbit by a chunk of foam insulation blown off the external tank by the supersonic air stream, rendering the wing unable to withstand reentry heating longer than about eight minutes after entry interface. Further shuttle operations were halted for the duration of the CAIB investigation and subsequent intensive return-to-fight efforts by NASA and its contractors.

The *Spacelab* was a major adjunct of the shuttle. Developed and funded by member nations of the European Space Agency, the large pressurized *Spacelab* module with an external equipment pallet was designed to be the most important payload carrier during the space shuttle era, and was used on numerous shuttle missions between 1983 and 1997. With its large transport capacity (in weight, volume, and power supply), the *Spacelab* was intended to support a wide spectrum of missions is science, applications, and technology by providing versatile and economical laboratory and observation facilities in space for many users. Another objective was to reduce significantly the time from experiment concept to experiment result, compared with previous space practice, and also to reduce the cost of space experimentation. It allowed the direct participation of qualified men and women scientists and engineers to operate their own equipment in orbit.

International Space Station with its solar arrays deployed, photographed from the space shuttle *Endeavour* following undocking on December 9, 2000. (*NASA*)

International Space Station. Interest in the development of a permanent crewed platform in Earth orbit dates back to the very beginnings of human space flight. While the practical realization of the concept was accomplished and proven by the Soviet *Salyut/Mir* and the American *Skylab* programs, the real breakthrough happened on January 29, 1998, when representatives of 16 nations signed a partnership agreement for the joint development and operation of an International Space Station (ISS). The goal of the ISS program is to establish a permanent platform for humans to live and work in space in support of science and technology research, business, education, and exploration. Its objectives are to provide a world-class laboratory complex uniquely located in a microgravity and vacuum environment where long-term scientific research can be carried out to help fight diseases on Earth, unmask fundamental processes leading to new manufacturing processes and products to benefit life on Earth, and observe and understand the Earth's environment and the universe. When completed, the International Space Station (see illustration) will have a mass of about 1,040,000 lb (470 metric tons). It will be 356 ft (108 m) across and 290 ft (108 m) long, with almost an acre (0.4 hectare) of solar panels to provide up to 110 kilowatts of power to six state-of-the-art laboratories.

The on-orbit assembly of the ISS began with the launch of the Functional Cargo Block (FGB) Zarya ("Dawn") on November 20, 1998.

On October 31, 2000, a Soyuz-U carrier lifted off from Baikonur and placed in orbit *Soyuz TM-31*, carrying the first resident crew for the Space Station. Since then, each crew has remained on the station for about six months before rotating with the subsequent crew. Early in 2003, further progress in ISS assembly was halted by the stand-down of space shuttles after the *Columbia* loss. As a consequence of the reduction in resupply missions to the station, crew size was reduced from a three- to a two-person caretaker crew per expedition. [J.V.P.]

Space navigation and guidance

The determination of the position and velocity of a space probe with respect to a target body or a known reference body such as the Earth (navigation) and, based upon this determination, the application of propulsive maneuvers to alter the subsequent path of the probe (guidance).

Space navigation can be viewed as determining the current position and velocity of the probe and then using that determination as the basis of predicting future motion. This determination is made by taking a series of measurements relating to the probe's motion and combining these measurements in such a manner as to make the most accurate estimate of the probe's current position and velocity, taking into account possible small errors or inaccuracies in the measurements themselves. One of the most powerful (and accurate) measurements which can be made is the relative velocity between an Earth tracking station and the space probe itself. This is accomplished by broadcasting an electromagnetic signal which consists of a single tone having a stable frequency to the probe. The probe will receive this signal shifted in frequency in exact proportion to the relative station-probe velocity. This frequency shift is known as the Doppler effect. It is also possible to measure the station-probe distance (or range) using electromagnetic signals.

For missions to the outer planets (Jupiter and beyond) or for a mission to a body such as a comet or asteroid, the position of the target may be sufficiently uncertain as to make a strictly Earth-relative navigation scheme inadequate. Here it is necessary to make measurements that directly involve the target. Typical of these is to obtain optical measurements of the location of the target relative to a star as seen from the probe itself.

In its simplest form, guidance consists of comparing the predicted future motion of the probe against that which is desired, and if these are sufficiently different, executing a propulsive maneuver to modify that future position. Typically, the probe will contain a small rocket motor which can be fired in any desired direction by first rotating the spacecraft away from its cruise orientation and then holding the new attitude fixed while the rocket motor is firing.

Multiplanet missions use an accurate delivery to the first target not only to scientifically explore that planet, but also to use the planet's gravitational attraction to change the course of velocity of the probe advantageously for the next leg of the mission toward the second and subsequent targets. The encounter with a planet becomes in itself a type of guidance correction as the planet changes the path of the probe. *See* GUIDANCE SYSTEMS; SPACE PROBE. [D.W.C.]

Space power systems On-board assemblages of equipment to generate, store, and distribute electrical energy on satellites and spacecraft. A reliable source of electrical power is required for supplying energy to the spacecraft and its payloads during launch and through several years of operational lifetime in a space environment. Present-generation spacecraft fly power systems from tens of watts to several kilowatts. Each of the three fuel cells on the space shuttle delivers 12 kW continuous power and 16 kW peak power. The International Space Station's solar arrays will generate 110 kW total power, with approximately 46 kW available for research activities. *See* SATELLITE (SPACECRAFT); SPACE FLIGHT; SPACE PROBE; SPACE SHUTTLE; SPACE STATION.

With few exceptions, the power systems for United States satellites have used photovoltaic generation for power, batteries for energy storage, and a host of electrical equipment for appropriate regulation, conversion, and distribution. Fuel cells have been limited primarily to use in the crewed space program, supplying power for *Gemini, Apollo*, and the space shuttle. Radioisotope thermoelectric generators (RTGs) have powered, or augmented solar power on, many planetary missions and probes, powered lunar instruments left on the Moon by the *Apollo* missions, and augmented the solar-array battery power system on at least one Earth-orbiting spacecraft. *See* ENERGY STORAGE; FUEL CELL; SOLAR CELL; THERMOELECTRICITY.

Many factors influence the final configuration of a power system. Basic to the initial consideration are the nature of the mission (Earth-orbiting or planetary) and mission lifetime. Other relevant factors include (1) spacecraft and payload requirements with consideration to average and peak power loads; (2) effect of environment such as orbit period, length of time the spacecraft is in sunlight and shadow, radiation particle damage, and space charging; and (3) constraints imposed by the spacecraft such as weight, volume, spacecraft shape and appendages, satellite attitude control, electromagnetic radiation limitations, characteristics of payloads, and thermal dissipation. For spacecraft that are shuttle-launched, additional considerations include compatibility with shuttle payload safety requirements and, in some cases, the retrievability by the shuttle for return to Earth. The weight of the power system ranges from 15 to 25% of the spacecraft weight. [J.C.Mit.]

Space probe An automated, crewless vehicle, the payload of a rocket-launching system, designed for flight missions to other planets, to the Moon, and into interplanetary space, as distinguished from Earth-orbiting satellites (see table).

The space probe is used primarily for scientific purposes, which are stated as the mission objectives. Missions generally fall into three categories according to destination: those to the rocky bodies in the inner solar system, including the Earth-like planets, asteroids, and comets; those to the giant gaseous planets in the outer solar system; and those designed to study solar physics and the properties of interplanetary space. Most spacecraft launched to a planet or other body also study the environment of charged particles and electromagnetic fields in interplanetary space during their cruise phase en route to the destination. *See* ASTEROID; SOLAR SYSTEM.

Missions may also be categorized by complexity. The simplest are flyby spacecraft, which study their target body during a relatively brief encounter period from a distance of hundreds to thousands of miles as they continue past. Next are orbiters, which circle a planet or other body for extended study; some may carry atmospheric descent probes. Even more complex are lander missions, which touch down on a planet or other body for the collection of on-site data; some may bear exploration rovers designed to range beyond the immediate landing site. Finally, the most complex space probes envisaged are sample-return missions, which would collect specimen material from a target body and return it to Earth for detailed study.

Spacecraft subsystems. In the broadest terms, a space probe may be considered a vehicle that transports a payload of sensing instruments to the vicinity of a target body. Thus, the spacecraft must include a number of subsystems to provide power, to communicate with Earth, to maintain and modify attitude and perform maneuvers, to maintain acceptable on-board temperature, and to manage the spacecraft overall. *See* SPACE TECHNOLOGY.

Scientific instruments. The scientific payload may be divided into remote-sensing instruments, such as cameras, and direct-sensing instruments, such as magnetometers or dust detectors. They may be classified as passive instruments, which detect radiance given off by a target body, or active ones, which emit energy such as radar pulses to characterize a target body. *See* REMOTE SENSING.

Power subsystem. Electrical power is required for all spacecraft functions. The total required power ranges from about 300 to 2500 W for current missions, depending on the complexity of the spacecraft. The power subsystem must generate, store, and distribute electrical power. All space probes launched so far have generated power either via solar panels or via radioisotope thermoelectric generators (RTGs). *See* NUCLEAR BATTERY; SOLAR CELL; SPACE POWER SYSTEMS.

Telecommunications subsystem. In order to accomplish its mission, the spacecraft must maintain communications with Earth, such as receiving commands sent from ground controllers, and transmitting scientific data and routine engineering "housekeeping" data. All of these transmissions are made in various segments of the microwave spectrum. The design of the telecommunications subsystem takes into account the volume of data to be transmitted and the distance from Earth at which the spacecraft will operate, dictating such considerations as the size of antennas and the power of the on-board transmitters. *See* MICROWAVE; TELEMETERING.

Advanced planetary probes have carried a dish-shaped high-gain antenna which is the chief antenna used to both transmit and receive. These antennas typically consist of a large parabolic reflector, with a subreflector mounted at the main reflector's focus in a Cassegrain-type configuration. In the interest of redundancy

Important space probes

Name	Launch date	Comments
Luna 1	Jan. 2, 1959	Lunar probe; now in solar orbit; passed within 3278 mi (5275 km) of the Moon
Pioneer 4	Mar. 3, 1959	Cosmic rays; passed 37,300 mi (60,000 km) from Moon
Luna 2	Sept. 2, 1959	Impacted Moon
Luna 3	Oct. 4, 1959	Photographed far side of Moon
Pioneer 5	Mar. 11, 1960	First deep-space probe; magnetic fields and cosmic rays
Mariner 2	Aug. 26, 1962	First planetary flyby; Venus probe
Ranger 7	July 28, 1964	Lunar impact and approach photography
Mariner 4	Nov. 28, 1964	Mars encounter; photography, magnetic fields, cosmic rays
Ranger 8	Feb. 17, 1965	Lunar impact and approach photographs
Ranger 9	Mar. 21, 1965	Lunar impact and Alphonsus; approach photography
Zond 3	July 18, 1965	Photographs from lunar encounter
Pioneer 6	Dec. 16, 1965	Solar orbit
Luna 9	Jan. 31, 1966	First photographs from lunar surface
Luna 10	Mar. 31, 1966	Lunar and interplanetary data
Surveyor 1	May 30, 1966	Soft landing on Moon: environmental data and photography
Lunar Orbiter 1	Aug. 10, 1966	Lunar photographs
Pioneer 7	Aug. 17, 1966	Solar orbit
Luna 11	Aug. 24, 1966	Lunar data
Luna 12	Oct. 22, 1966	Lunar orbital photography and other data
Lunar Orbiter 2	Nov. 6, 1966	Lunar orbital photography
Luna 13	Dec. 21, 1966	Lunar surface photography and soil information
Lunar Orbiter 3	Feb. 5, 1967	Lunar orbital photography
Surveyor 3	Apr. 17, 1967	Lunar surface photography and surface properties
Lunar Orbiter 4	May 4, 1967	Lunar orbital photography
Venera 4	June 12, 1967	Analysis of Venus atmosphere; first instrumented landing on another planet
Mariner 5	June 14, 1967	Venus probe; atmospheric and magnetospheric data
Lunar Orbiter 5	Aug. 1, 1967	Lunar orbital photography
Surveyor 5	Sept. 8, 1967	Lunar surface photography and surface properties, including elemental analysis of surface
Surveyor 6	Nov. 7, 1967	Same as *Surveyor 5*; landing in Sinus Medii
Pioneer 8	Dec. 13, 1967	Solar orbit
Surveyor 7	Jan. 7, 1968	Same as *Surveyor 5*
Zond 5	Sept. 14, 1968	Circled Moon; recovered Sept. 21, 1968
Pioneer 9	Nov. 8, 1968	Solar orbit
Zond 6	Nov. 10, 1968	Circled Moon; recovered Nov. 17, 1968
Venera 5	Jan. 5, 1969	Same as *Venera 4*
Venera 6	Jan. 10, 1969	Same as *Venera 4*
Mariner 6	Feb. 25, 1969	Photography and analysis of surface and atmosphere of Mars
Mariner 7	Mar. 27, 1969	Same as *Mariner 6*
Luna 15	July 14, 1969	Lunar reconnaissance (crashed during attempted lunar landing)
Zond 7	Aug. 8, 1969	Reentered Aug. 14, 1969; third uncrewed circumlunar flight; recovered in the Soviet Union
Venera 7	Aug. 17, 1970	Lander capsule transmitted 23 min from surface of Venus, Dec. 15, 1970
Luna 16	Sept. 12, 1970	Reentered Sept. 24, 1970; uncrewed Moon lander touched down on Sea of Fertility Sept. 20, 1970; returned lunar soil samples
Zond 8	Oct. 20, 1970	Circled Moon; recovered Oct. 27, 1970
Luna 17	Nov. 10, 1970	Landed on Moon Nov. 17, 1970; uncrewed Moon rover
Mars 2	May 19, 1971	First Soviet Mars landing
Mars 3	May 28, 1971	Mars probe
Mariner 9	May 30, 1971	Mars probe
Luna 18	Sept. 2, 1971	Impacted Moon Sept. 11, 1971
Luna 19	Sept. 28, 1971	Lunar photography mission
Luna 20	Feb. 14, 1972	Recovered Feb. 25, 1972; returned lunar sample
Pioneer 10	Mar. 2, 1972	Jupiter encounter; transjovian interplanetary probe
Venera 8	Mar. 27, 1972	Venus landing July 22, 1972
Luna 21	Jan. 8, 1972	Moon landing Jan. 16, 1972, with *Lunikhod* rover
Pioneer 11	Apr. 5, 1973	Jupiter encounter and transjovian interplanetary probe; also Saturn encounter
Mars 4	July 21, 1973	Mars orbiter
Mars 5	July 25, 1973	Mars orbiter
Mars 6	Aug. 5, 1973	Mars lander
Mars 7	Aug. 9, 1973	Mars lander
Mariner 10	Nov. 3, 1973	Venus and Mercury encounter
Luna 22	May 29, 1974	Lunar probe
Helios 1	Dec. 10, 1974	Inner solar system, solar wind exploration
Venera 9	June 8, 1975	Venus probe
Venera 10	June 14, 1975	Venus probe
Viking 1	Aug. 20, 1975	Mars lander and orbiter
Viking 2	Sept. 9, 1975	Mars lander and orbiter
Helios 2	Jan. 15, 1976	Interplanetary; similar objectives to those of *Helios 1*
Luna 24	Aug. 9, 1976	Recovered Aug. 25, 1976; returned lunar sample
Voyager 2	Aug. 20, 1977	Jupiter, Saturn, Uranus, and Neptune encounters; also satellites and ring systems
Voyager 1	Sept. 5, 1977	Same objectives as *Voyager 2* with some orbital differences giving differing encounter trajectories
Pioneer Venus Orbiter	May 20, 1978	Returning atmospheric, surface, and particle and field information
Pioneer Venus Multi-Probe Bus	Aug. 8, 1978	Penetration of Venus atmosphere by four probes; returned atmospheric data
Venera 11	Sept. 8, 1978	Venus lander; returned information on surface properties; detection of lightning and thunderlike sounds
Venera 12	Sept. 14, 1978	Similar mission to *Venera 11*
Venera 13	Oct. 30, 1981	Venus lander
Venera 14	Nov. 4, 1981	Venus lander
Venera 15	June 2, 1983	Venus lander; surface topography
Venera 16	June 7, 1983	Similar mission to *Venera 15*
International Cometary Explorer (ICE)	—	Originally *International Sun-Earth Explorer 3 (ISEE 3)* Earth satellite, redirected using a lunar swingby on Dec. 22, 1983, to encounter with Comet Giacobini-Zinner; plasma and magnetic field

Important space probes ***(cont.)***

Name	Launch date	Comments
Vega 1	Dec. 15, 1984	Venus probe-Halley intercept
Vega 2	Dec. 21, 1984	Venus probe-Halley intercept
Sokigake	Jan. 8, 1985	Halley intercept; precursor to *Suisei*, upgraded to full mission
Giotto	July 2, 1985	Halley intercept
Suisei	Aug. 19, 1985	Halley intercept; plasma and magnetic field measurements
Phobos 1	July 7, 1988	Mars/Phobos probe, lost by command error
Phobos 2	July 12, 1988	Mars/Phobos probe; some data but communications lost
Magellan	May 4, 1989	Venus radar mapper
Galileo	Oct. 18, 1989	Jupiter orbiter and atmospheric probe
Muses	Jan. 24, 1990	Moon orbiter and relay probe; orbiter transmitter malfunctioned
Ulysses	Oct. 6, 1990	Solar polar orbiter
Mars Observer	Sept. 25, 1992	Contact lost 3 days before Mars arrival
Clementine	Jan. 25, 1994	Orbited Moon; thruster malfunction prevented asteroid flyby
Solar and Heliospheric Observatory (SOHO)	Dec. 2, 1995	Orbits L1 libration point to study the Sun
NEAR-Shoemaker	Feb. 17, 1996	Asteroid orbiter
Mars Global Surveyor	Nov. 7, 1996	Mars orbiter
Mars 96	Nov. 16, 1996	Mars orbiter and landers; launch vehicles failed
Mars Pathfinder	Dec. 4, 1996	Mars lander and rover
Advanced Composition Explorer	Aug. 25, 1997	Orbits L1 libration point to study charged particles
Cassini	Oct. 15, 1997	Saturn orbiter/Titan descent probe
Lunar Prospector	Jan. 6, 1998	Lunar orbiter
Nozomi (Planet-B)	July 4, 1998	Mars orbiter; orbit insertion failed
Deep Space 1	Oct. 24, 1998	Test of ion engine and 11 other advanced technologies; asteroid flyby
Mars Climate Orbiter	Dec. 11, 1998	Lost during Mars arrival
Mars Polar Lander	Jan. 3, 1999	Lost during Mars arrival
Stardust	Feb. 7, 1999	Comet flyby, dust sample return
Mars Odyssey	April 7, 2001	Mars orbiter
Wilkinson Microwave Anisotropy Probe	June 30, 2001	Orbits L2 libration point to study cosmic background radiation
Genesis	August 8, 2001	Orbits L1 libration point to collect solar wind samples and return them
Hyabusa (Muses-C)	May 9, 2003	Asteroid sample return mission
Mars Express	June 2, 2003	Mars orbiter and lander; orbiter was successful but *Beagle 2* lander failed
MER-A/Spirit	June 10, 2003	Mars rover
MER-B/Opportunity	July 7, 2003	Mars rover
Spitzer Space Telescope (Space Infrared Telescope Facility)	August 25, 2003	Infrared observatory in Earth-trailing orbit
MESSENGER	August 3, 2004	Mercury orbiter

and in the event that Earth pointing is lost, spacecraft virtually always carry other on-board antennas. These may be low-gain antennas, which typically offer nearly omnidirectional coverage except for blind spots shadowed by the spacecraft body, or medium-gain antennas, which provide a beam width of perhaps 20–30°. *See* ANTENNA (ELECTROMAGNETISM).

Attitude-control subsystem. It would be impossible to navigate the spacecraft successfully or point its scientific instruments or antennas without closely controlling its orientation in space, or attitude. Some spacecraft, particularly earlier ones, have been spin-stabilized; during or shortly after launch, the spacecraft is set spinning at a rate on the order of a few revolutions per minute. Much like a rotating toy top, the spacecraft's orientation is stabilized by the gyroscopic action of its spinning mass. Most planetary spacecraft, however, are three-axis-stabilized, meaning that their attitude is fixed in relation to space. The spacecraft's attitude is maintained and changed via onboard thruster jets or reaction wheels, or a combination of both.

Propulsion subsystem. Most spacecraft are outfitted with a series of thruster jets, each of which produces approximately 0.2–2 pounds-force (1–10 newtons) of thrust. Thrusters are usually fueled with a monopropellant, hydrazine, which decomposes explosively when it contacts an electrically heated metallic catalyst within the thruster. In addition to maintaining the spacecraft's attitude, on-board thrusters are used for trajectory-correction maneuvers. Spacecraft designed to orbit a planet or similar target body must carry a larger propulsion element capable of decelerating the spacecraft into orbit upon arrival. *See* SPACECRAFT PROPULSION.

Thermal control subsystem. In order to minimize the impact of temperature variations on the electronics on board, spacecraft nearly always incorporate some form of thermal control. Mechanical louvers, controlled by bimetallic strips similar to those in terrestrial thermostats, are often used to selectively radiate heat from the interior of the spacecraft into space. Other thermal strategies include painting exterior surfaces. In some cases, spacecraft may also carry one or more active forms of heating to maintain temperature at required minimums.

Command and data subsystem. This designation is given to the main computer that oversees management of spacecraft functions and handling of collected data. Blocks of commands transmitted from Earth are stored in memory in the command and data subsystem and are executed at prescribed times. This subsystem also contains the spacecraft clock in order to accurately pace its activities, as well as all the activities of the spacecraft.

Structure subsystem. The spacecraft's physical structure is considered a subsystem itself for the purposes of planning and design. Usually the heart of this structure is a spacecraft bus, often consisting of a number of bays, which houses the spacecraft's main subsystems. *See* SPACECRAFT STRUCTURE. [F.O.D.]

Space processing Experiments conducted in space in order to take advantage of the reduced gravity in studies of the growth, behavior, and properties of materials. Spacelab, developed by the European Space Agency (ESA), is a laboratory module that flies in the space shuttle payload bay. First launched in 1983 on the *Columbia*, the module has become the workhorse for United States and international science missions emphasizing low gravity. The experiments in fluids, combustion, materials science, and biotechnology conducted on these missions, together with their related ground-based research, have resulted in more than 2200 scientific publications.

Since biotechnology experiments generally have modest space and power requirements, they were able to be accommodated by middeck lockers in other shuttle missions as well as on the *Spacelab* microgravity emphasis missions, which provided them with many more flight opportunities. Even though the microgravity environment on some of these missions was not ideal, biomolecular crystal growth experiments for structural analysis as well as cell and tissue culturing experiments produced many interesting results, some of which could have commercial applications.

There are two compelling reasons for the study of combustion in microgravity. One is the issue of fire safety in the design and operation procedures of orbiting laboratories; the other is to take advantage of the weightless state to study certain combustion phenomena in more detail and to test various models in which convection has been ignored in order to be mathematically tractable. Examples of the latter are a number of droplet combustion experiments in which the burning of free-floating or tethered droplets was studied. The absence of gravity allowed the droplet size to be increased to as much as 5 mm (0.2 in.) so that more detailed observation could be made. The objective is to test theories of droplet combustion and soot formation that are of importance to improving the efficiency of internal combustion engines, gas turbine engines, and home and industrial oil-burning heating systems. *See* COMBUSTION; GAS TURBINE; INTERNAL COMBUSTION ENGINE.

In materials science, the processing of metallic alloys and composites has been carried out in space in order to study their microstructure, thermal properties, and crystal growth. [R.J.N.]

Space shuttle A reusable crewed orbital transportation system. The space shuttle, along with crewless (robotic) expendable launch vehicles including Delta, Atlas, and Titan, make up the United States Space Transportation System (STS). The shuttle has provided the unique capability for in-flight rendezvous and retrieval of faulty or obsolescent satellites, followed by satellite repair, update, and return to orbit or return to Earth for repair and relaunch. The space shuttle also has played an essential continuing role in the construction and provisioning of the International Space Station (ISS) by transporting major components, such as the giant solar-cell arrays and the Canadian computer-driven double-ended robotic arm, from Earth to the ISS and installing them using extended extravehicular activity (EVA, or space walks) by trained ISS resident and shuttle-visiting astronauts. *See* SATELLITE (SPACECRAFT); SPACE STATION.

Early in its history the space shuttle was touted as a low-cost replacement for expendable launch vehicles. Following the *Challenger* shuttle accident in 1986, it became clear that crewless vehicles would have a continuing place in the United States launch vehicle stable, that they have advantages over the shuttle such as lower cost and shorter lead time for tasks within their capability, and that the shuttle fleet would be fully occupied for much of the first decade of the twenty-first century doing complex jobs requiring human presence, in particular associated with the ISS, which no other launch system can do. For such reasons the STS was expanded to include the expendable launch vehicle families in use by the Department of Defense (DOD) and the National Aeronautics and Space Administration (NASA).

The space shuttle orbiter accommodates a crew of four to seven for orbital mission durations up to about 10 days. The space shuttle flight system (see illustration) consists of the orbiter, which includes the three liquid-fueled shuttle main engines; an external fuel tank; and two solid-fuel strap-on booster rockets. The external tank is discarded during each launch. The solid-fuel rocket casings are recovered and reused. The orbiter lands horizontally as an unpowered ("dead stick") aircraft on a long runway at the NASA Kennedy Space Center in Florida or, when conditions for landing these are unacceptable, at the Edwards Air Force Base in California. *See* ROCKET PROPULSION.

Space shuttle lifting off from the Kennedy Space Center.

The shuttle is launched with all three main engines and both strap-on solid-fuel booster rockets burning. The booster rockets are separated 2 min after liftoff at an altitude of 30 mi (48 km), 28 mi (44 km) downrange. Main engine cutoff occurs about 8 min after liftoff, nearly 70 mi (110 km) above the Atlantic Ocean, 890 mi (1430 km) downrange from Kennedy. The external tank is separated from the orbiter shortly after the main engine cutoff, before orbital velocity (speed) is reached, so that the relatively light empty tank can burn up harmlessly during its reentry into the atmosphere above the ocean. Main propulsion for the rest of the mission is provided by the orbital maneuvering system engines, whose first task is to complete insertion of the shuttle into its final, nearly circular path during its first orbit (flight once around Earth) after liftoff.

After the shuttle orbiter completes the orbital phase of its mission and is ready to return to Kennedy, its pilot rotates the spacecraft 180° (tail-first relative to the orbiter's direction of motion) and fires the orbital maneuvering system engines to decrease the space vehicle's speed. This maneuver reduces the orbiter's speed just enough to allow the orbiter to fall into the tenuous outer atmosphere, where atmospheric drag causes the orbit to decay (altitude and velocity decrease) along a spiral path. This reentry slowdown occurs in a precise, computer-controlled manner so that the landing may be made manually, halfway around the Earth, on the desired runway at Kennedy or Edwards. At orbital altitudes, small reaction-control engines (jets) maintain the desired orientation of the orbiter. As the spacecraft-becoming-airplane descends into the denser lower air, its aerodynamic control surfaces gradually take over their normal maintenance of heading, pitch, and roll, and the small jets are turned off. Landing is made at a speed of 220 mi/h (100 m/s). The brakes are helped to bring the vehicle to a stop by a parachute (drag chute) which is deployed from the tail after touchdown of the nose wheel and released well before the vehicle comes to a complete stop.

Major orbiter systems are the environmental control and life support, electric power, hydraulic, avionics and flight control, and the space shuttle main engines. Each system is designed with enough redundancy to permit either continuation of mission operations or a safe return to Earth after any single-element failure. For example, three fuel-cell power plants generate the in-flight electric power. Each fuel cell feeds one of three independent electrical distribution buses. Similarly, three independent hydraulic systems, each powered by an independent auxiliary power unit, operate the aerosurfaces. *See* FUEL CELL; SPACE POWER SYSTEMS.

The avionics system uses five general-purpose computers, four of which operate in a redundant set while the fifth operates independently. These computers perform guidance, navigation, and control calculations, and operate the attitude (orientation) controls and other vehicle systems. They also monitor system performance and can automatically reconfigure redundant systems in the event of a failure during flight-critical mission phases. Each of the three space shuttle main engines has an independent computer for engine control during ascent. *See* DIGITAL COMPUTER; MULTIPROCESSING.

The thermal protection system, which is not redundant, presented a major technical challenge to the orbiter development schedule. This system, unlike those of previous single-use spacecraft, has a design requirement of reuse for 100 missions. Performance requirements also dictate that the system withstand temperatures as high as 3000°F (1650°C) while maintaining the vehicle's structure at no more than 350°F (177°C). *See* ATMOSPHERIC ENTRY.

The key to meeting this challenge was to develop a material possessing an extremely low specific heat capacity and thermal conductivity, together with adequate mechanical strength to withstand the launch and reentry vibration and acceleration. These thermal characteristics must remain stable up to temperatures of at least 3000°F (1650°C). The solution was found in silica ceramic tiles, some 24,000 of which cover most of the orbiter's surface. During the highest thermal load portion of the reentry trajectory (path), the orbiter's wings are level and the nose is elevated well above the flight path. This causes the temperature of the undersurface to be substantially higher than that of the upper surface. For this reason, the undersurface is covered with black borosilicate glass-coated high-temperature tiles. Most of the upper surface of the shuttle is covered with a lower-temperature silica blanket made of two outer layers of woven fabric and an insulating buntinglike center layer stiched together in a quiltlike pattern. Finally, the nose cap and wing leading edges are subject to the highest (stagnation) temperatures, which requires the use of molded reinforced carbon-carbon material.

The first operational shuttle accomplished the first commercial satellite deployments in 1982. In 1984 the first in-orbit satellite repair was accomplished on the *Solar Maximum Mission*'s control system and a primary experiment sensor. Later that same year *Palapa* and *Westar*, two communications satellites in useless orbits, were recovered and returned to Earth on the same space shuttle mission. These repair and recovery missions demonstrated the usefulness of humans in these new space tasks.

Shortly before noon on January 28, 1986, *Challenger* lifted off from Kennedy Space Center on the twenty-fifth shuttle mission. At 72 s into the flight, with no apparent warning from real-time data, the external tank exploded and *Challenger* was destroyed. All seven crew members perished, the first to die in NASA's human space-flight program spanning 25 years and 56 crewed launches. Further flight operations were suspended while a Presidential Commission reviewed the circumstances surrounding the accident, determined its probable cause, and developed recommendations for corrective actions. The cause of the accident was determined to be inadequate design of the solid rocket motor field joint. Deflection of the joint with deformation of the seals at cold temperature allowed hot combustion products to bypass both O-rings, resulting in erosion and subsequent failure of both primary and secondary seals.

In September 1988, a *Tracking and Data Relay Satellite* (*TDRS*) was launched by the first space shuttle to fly after the *Challenger* accident. The initial *TDRS* network was completed 6 months later by the second shuttle launch of a *TDRS*. *See* SPACE COMMUNICATIONS; SPACECRAFT GROUND INSTRUMENTATION.

In the realm of solar system exploration, shuttle launches of *Magellan* to Venus and *Galileo* to Jupiter in 1989 were followed in 1990 by the shuttle launch of *Ulysses* to investigate the magnetic field configuration and variations around the Sun's poles. STS 32 launched the long-awaited Hubble Space Telescope (HST) in 1990; however, this telescope's most important work was not accomplished until later that decade after two shuttle EVA visits—the first to correct a bad case of astigmatism produced by the HST mirror manufacturer, and the second to update the sensors and replace major spacecraft subsystem components that were failing. *See* SATELLITE (ASTRONOMY); SPACE PROBE. [J.F.Cl.]

On February 1, 2003, the space shuttle program suffered a serious setback when the Columbia, on its 28th flight, was lost with its crew of seven during reentry 16 min before the planned landing at Kennedy Space Center, as it violently disintegrated over Texas. The Columbia Accident Investigation Board (CAIB) later concluded that, with crew and ground personnel unaware, one of the left wing's leading-edge reinforced carbon-carbon elements or an associated filler strip of the heat shield had been compromised during ascent to orbit by a piece of debris, possibly a chunk of foam insulation blown off the external tank, rendering the wing unable to withstand reentry heating. Further shuttle operations were halted for the duration of the CAIB investigation. [J.V.P.]

Space station A complex physical structure specifically designed to serve as a multipurpose platform in low Earth orbit. Functioning independently and often without a crew, a space station contains the structures and mechanisms to operate and maintain such support systems as command and data processing, communications and tracking, motion control, electrical power, and thermal and environmental control. Evolving together with technology and increasing in scope and complexity, the space station has a history in which each program was based upon the developments and achievements of its predecessor.

Salyut. The Soviet Union began construction of the world's first space station, called *Salyut*, in 1970. It was the primary Soviet space endeavor for the next 15 years. The design was retained not only through a series of Salyuts that were launched within that decade and later, but also through the development of *Mir*, the most famous, long-lived Russian achievement in space. The Salyuts were cylindrical in shape and contained compartments with specialized functions for operating a space station. The docking compartment was designed to accept the Soyuz spacecraft that transported the cosmonauts. The transfer compartment gave the cosmonauts access to the various work compartments. The work compartments contained the mechanisms that operated and controlled the station, as well as the laboratories in which the cosmonauts performed experiments while they were onboard. *Salyut 1* initially carried a crew of three, but after three cosmonauts died when a valve in the crew compartment of their descent module burst and the air leaked out, the crews were reduced to two cosmonauts, and both crew members were outfitted with pressurized space suits.

Skylab. This program was developed by NASA building on the success of its heavy-lift rocket, the Saturn, which had boosted the Apollo rockets and helped place the first human being on the Moon. *Skylab* weighed just less than 100 tons (90 metric tons). It was launched on May 14, 1973, from the Kennedy Space Center aboard a Saturn 5 rocket. Although the launch was flawless, a shield designed to shade *Skylab's* workshop deployed about a minute after liftoff and was torn away by atmospheric drag. That began a series of problems, most involving overheating, that had to be overcome before *Skylab* was safe for human habitation. Eventually three crews served aboard *Skylab* throughout 1973 for periods of 28, 59, and 84 days, respectively. The single greatest contribution made by each crew was the extravehicular activities that restored *Skylab's* ability to serve as a space station.

Apollo-Soyuz test program. In 1975, during the period of dètente, plans were made for a joint United States-Soviet space venture, known as the Apollo-Soyuz Test Program (ASTP). For the first time, United States astronauts and Soviet cosmonauts became members of each other's flight teams, training together, touring their launch sites, and working in their mission control rooms. For 15 months, they trained and prepared for their historical joint mission in space. In July 1975, the astronauts of *Apollo 18* linked with the cosmonauts of *Soyuz 22*; their docked configuration functioned as a miniature international space station.

Mir. *Mir* was the name of the vehicle for the world's first multipurpose, permanently operating crewed space station. Based upon the Salyut design and configuration, *Mir* essentially was an extension and expansion of the shell of the basic Soviet space vehicle. It would incorporate the standard Salyut/Soyuz/Progress profile. External ports were added for docking of Soyuz vehicles which would carry crew members, and Progress (resupply) vehicles which would bring foodstuffs, drinking water, extra equipment and apparatus, sanitary requisites, medical apparatus, and propellant. These same Progress vehicles would return space "junk" to Earth. Construction was based upon a modular design, permitting the Soviets to replace modules whenever significant improvements in technology made the earlier modules obsolete. Two cylindrical modules formed the basic shape of *Mir* and served as the living and central control compartments for the crews. Additional modules were used for scientific experiments.

The *Mir* core station was a 49-ft (15-m) module. Its launch aboard a Soviet Proton rocket on February 20, 1986, was televised internationally for the first time in Soviet space history. *Mir* was assembled in space and was composed of six modules. In addition to the core, the Kvant-1 module (launched in April 1987) was a 19-ft (6-m) pressurized lab used for astrophysics research. The Kvant-2 module was launched in December 1989, and was used for biological research and for Earth observation. The Kristall module was launched in August 1990, and provided the docking port for the United States space shuttles that visited *Mir*. Between 1994 and 2001, there were nine dockings between space shuttle vehicles and *Mir*. The final two modules, Spektr and Priroda (launched in June 1995 and April 1996, respectively) were remote sensing modules used to study the Earth. *Mir* provided a platform for long-term microgravity research and increased knowledge about living and working in space. By the end of its function in March 2001, the 143-ton (130-metric-ton) *Mir* had spent 15 years in orbit and had orbited the Earth more than 87,600 times with an average orbiting speed of 17,885 mi/h (28,800 km/h). Its superstructure, 109 ft (33 m) long and 90 ft (27 m) wide, burned up upon reentry in to the Earth's atmosphere, and scraps were scattered into the Pacific Ocean just east of New Zealand. *See* Space biology; Space shuttle.

International Space Station. The Soviet successes with *Mir* prompted the United States to respond with what became known as *Space Station Freedom*. Moved from the NASA drawing board in 1993, components of the space station were tested by shuttle crews during a variety of missions. Supporters of this space station advocated such unique opportunities as manufacturing drugs, scientific materials research in microgravity, and studying the health and status of the Earth's environment from outer space. At the direction of President Clinton, the United States transformed the single-nation concept for *Space Station Freedom* into a multinational partnership with the European Space Agency and the Russian Space Agency to create what is now known as the International Space Station (ISS). *See* Space processing.

Sixteen nations have united to build the International Space Station. Dwarfing *Mir*, *Skylab*, the Salyuts, and any ground-based civil engineering project built to date, the International Space Station will include six laboratories built by a consortium of nations. United States space shuttle and Russian Soyuz flights will transport the structures and mechanisms necessary to construct the station.

The first permanent crew of the International Space Station launched from the Baikonur Cosmodrome, on October 31, 2000. In addition to serving as a test bed and springboard for future space exploration, the International Space Station will serve as a research laboratory for innovation in science and technology. Research will focus on such topics as biomedical research and countermeasures to understand and control the effects of space and zero gravity on crew members; biological study of gravity's influence on the evolution, development, and internal processes of plants and animals; biotechnology to develop superior protein crystals for drug development; and fluid physics. Advanced research will be oriented toward topics such as human support technology, materials science, combustion science, and fundamental physics. *See* Space flight; Space technology; Spacecraft structure. [J.J.P.]

Space technology The systematic application of engineering and scientific disciplines to the exploration and utilization of outer space. Space technology developed so that spacecraft and humans could function in this environment that is so different from the Earth's surface. Conditions that humans take for granted do not exist in outer space. Objects do not fall. There is no atmosphere to breathe, to keep people warm in the shade, to transport heat by convection, or to enable the burning of fuels. Stars do not twinkle. Liquids evaporate very quickly and are deposited on nearby surfaces. The solar wind sends electrons to charge the spacecraft, with lightninglike discharges that may damage the craft. Cosmic rays and solar protons damage electronic circuits and human flesh. The vast distances require reliable structures, electronics, mechanisms, and software to enable the craft to perform when it gets to its goal—and all of this with the design requirement that the spacecraft be the smallest and lightest it can be while still operating as reliably as possible.

All spacecraft designs have some common features: structure and materials, electrical power and storage, tracking and guidance, thermal control, and propulsion. The spacecraft structure is designed to survive the forces of launching and ground handling. The structure is made of metals (aluminum, beryllium, magnesium, titanium) or a composite (boron/epoxy, graphite/epoxy). It must also fit the envelope of the launcher. *See* Spacecraft structure.

To maintain temperatures at acceptable limits, various active and passive devices are used: coatings or surfaces with special absorptivities and emissivities, numerous types of thermal insulation, such as multilayer insulation and aerogel, mechanical louvers to vary the heat radiated to space, heat pipes, electrical resistive heaters, or radioisotope heating units.

The location of a spacecraft can be measured by determining its distance from the transit time of radio signals or by measuring the direction of received radio signals, or by both. The direction of a spacecraft can be determined by turning the Earth station antenna to obtain the maximum signal, or by other equivalent and more accurate methods. *See* Space navigation and guidance.

The velocity of a spacecraft is changed by firing thrusters. Solid propellant thrusters are rarely used. Liquid propellant thrusters are either monopropellant or bipropellant. Electric thrusters, such as mercury or cesium ion thrusters, have also been used. Electric thrusters have the highest efficiency (specific impulse) but the lowest thrust. *See* Interplanetary propulsion; Ion propulsion; Propellant; Spacecraft propulsion.

Most spacecraft are spin-stabilized or are three-axis body-stabilized. The former uses the principles of a gyroscope; the latter uses sensors and thrusters to maintain orientation. Some body-stabilized spacecraft (such as astronomical observatories) are fixed in inertial space, while others (such as Earth observatories) have an axis pointed at the Earth and rotate once per orbit. A body-stabilized spacecraft is simpler than a spinner but requires more hardware. The orientation of a spacecraft is measured with Sun sensors (the simplest method), star trackers (the most accurate), and horizon (Earth or other body) or radio-frequency (rf) sensors (usually to determine the direction toward the Earth). Attitude corrections are made by small thrusters or by reaction or momentum wheels; as the motor applies a torque to accelerate or decelerate the rotation, an equal and opposite torque is imparted to the spacecraft.

Primary electrical power is most often provided by solar cells made from a thin section of crystalline silicon protected by a thin glass cover. Excess power from the solar cells is stored in rechargeable batteries so that when power is interrupted during an eclipse, it can be drawn from the batteries. Other sources of power generation include fuel cells, radio isotope thermoelectric generators (RTGs), tethers, and solar dynamic power. Fuel cells have been used on the Apollo and space shuttle programs and produce a considerable amount of power, with drinkable water as a by-product. *See* BATTERY; FUEL CELL; SOLAR CELL; SPACE POWER SYSTEMS.

The status and condition of a spacecraft are determined by telemetry. Temperatures, voltages, switch status, pressures, sensor data, and many other measurements are transformed into voltages, encoded into pulses, and transmitted to Earth. This information is received and decoded at the spacecraft control center. Desired commands are encoded and transmitted from the control center, received by the satellite, and distributed to the appropriate subsystem. Commands are often used to turn equipment on or off, switch to redundant equipment, make necessary adjustments, and fire thrusters and pyrotechnic devices. *See* SPACE COMMUNICATIONS; SPACECRAFT GROUND INSTRUMENTATION; TELEMETERING.

Many spacecraft missions have special requirements and hence necessitate special equipment. Satellites that leave the Earth's gravitational field to travel around the Sun and visit other planets have special requirements due to the greater distances, longer mission times, and variable solar radiation involved.

Spacecraft that return to Earth require special protection for reentry into Earth's atmosphere. In some missions one spacecraft must find, approach, and make contact with another spacecraft. *See* SATELLITE (SPACECRAFT); SPACE PROBE.

Space is distant not only in kilometers but also in difficulty of approach. Large velocity changes are needed to place objects in space, which are then difficult to repair and expensive to replace. Therefore spacecraft must function when they are launched, and continue to function for days, months, or years. The task is similar to that of building a car that will go 125,000 mi (200,000 km) without requiring mechanical repair or refueling. Not only must space technology build a variety of parts for many missions, but it must achieve a reliability far greater than the average. This is accomplished by building inherent reliability into components and adding redundant subsystems, supported by a rigorous test schedule before launch. Efforts are made to reduce the number of single points of failure, that is, components that are essential to mission success and cannot be bypassed or made redundant. [G.D.Gor.]

Space Telescope, Hubble

The Hubble Space Telescope is the largest visible-light observatory ever placed into space. Hubble's orbit, some 612 km (380 mi) above Earth's surface, keeps it above almost all of Earth's atmosphere, at a location where its view of the heavens is much clearer than that of ground-based telescopes. The superior view afforded by Hubble's orbit has made the telescope a unique resource for astronomers worldwide and has led to fundamental discoveries about the size and age of the universe, the birth and death of stars, and the development of galaxies.

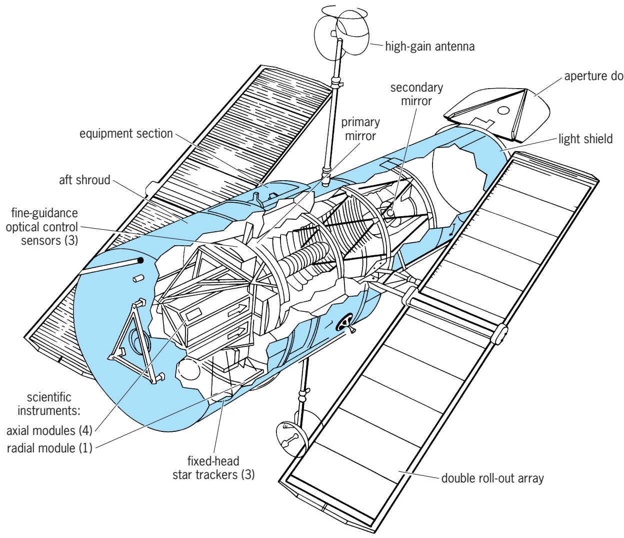


Fig. 1. Diagram of the Hubble Space Telescope.

The spacecraft. The Hubble Space Telescope orbits Earth once every 96 minutes. At its core is a reflecting telescope with a primary mirror 2.4 m (94.5 in.) in diameter (Fig. 1). The primary mirror directs light from astronomical objects to a 30-cm (12-in.) secondary mirror, which then bounces it back through a hole at the center of the primary mirror to the scientific instruments. The optical design is a Ritchey-Chrétien variant of a Cassegrain telescope.

Hubble's optical system enables the telescope to record astronomical images with unprecedented precision in the optical, ultraviolet, and infrared spectral bands. In order to take full advantage of the clearer view above Earth's atmosphere, Hubble's mirrors had to be polished until they were extremely smooth: The largest bumps on Hubble's primary mirror are analogous to the height of a baseball on a surface as wide as the continental United States. A flaw in the overall shape of the primary mirror hampered observations for several years after launch. However, because the primary mirror was so smooth, corrective optics installed in 1993 were able to realize Hubble's expected performance (Fig. 2). Its angular resolution of 0.05 arcsecond at optical wavelengths is equivalent to being able to distinguish two fireflies 1 m (3 ft) apart at a distance of 5000 km (3000 mi). *See* INFRARED ASTRONOMY; TELESCOPE; ULTRAVIOLET ASTRONOMY.

Hubble's complement of scientific instruments handles a wide range of observational tasks. Its cameras can record images of astronomical objects at wavelengths ranging from 115 to 2500 nanometers. Hubble's spectrographs can analyze the spectra of these objects between wavelengths of 115 and 1030 nm. Because these instruments can be removed and replaced, they have been upgraded several times during Hubble's stay in orbit.

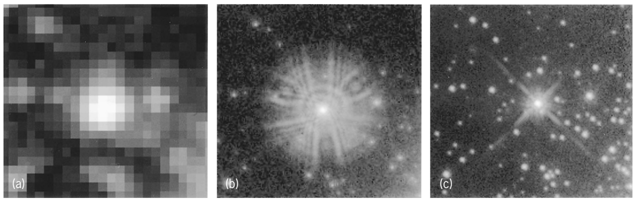

Fig. 2. Comparison of images of a field of stars in the 30 Doradus Nebula. (*a*) Ground-based image obtained under conditions of good seeing. (*b*) Same star field at the same scale taken with the Hubble Space Telescope before the first servicing mission. (*c*) Hubble image after the first servicing mission when the spherical aberration was corrected. (*NASA*)

A diverse assortment of support equipment surrounds the telescope and its scientific instruments.

Highlights of Hubble science. The Hubble Space Telescope's contributions to astronomy are numerous and wide-ranging. The following are a few of the most notable.

Hubble's high resolution has enabled the study of individual Cepheid variable stars in distant galaxies and the measurement of distances to galaxies up to 100 million light-years away. From the distances to these galaxies and the speeds at which they are moving away from each other, astronomers can calculate how long it took for galaxies to reach their current positions. *See* CEPHEIDS; COSMOLOGY; HUBBLE CONSTANT.

Images such as the Hubble Deep Field reveal a multitude of galaxies, some of them over 10 billion light-years away. Many of them appear quite strange and distorted in comparison to present-day galaxies, leading astronomers to believe that disruptive collisions between galaxies were much more common early in time than they are now. *See* GALAXY, EXTERNAL.

Observations of clouds in which stars are currently forming show that brand-new stars are generally surrounded by disks of gas and tiny, solid particles called dust grains. The gas and dust in at least some of these disks are eventually expected to clump into planets similar to those that orbit the Sun. *See* SOLAR SYSTEM; STAR; STELLAR EVOLUTION. [M.V.]

Space-time

A term used to denote the geometry of the physical universe as suggested by the theory of relativity. It is also called space-time continuum. Whereas in Newtonian physics space and time had been considered quite separate entities, A. Einstein and H. Minkowski showed that they are actually intimately intertwined.

Einstein showed that in general two observers, each using the same techniques of observation but being in motion relative to each other, will disagree concerning the simultaneity of distant events. But if they do disagree, they are also unable to compare unequivocally the rates of clocks moving in different ways, or the lengths of scales and measuring rods. Instead, clock rates and scale lengths of different observers and different frames of reference must be established so as to assure the principal observed fact. Each observer, using his or her own clocks and scales, must measure the same speed of propagation of light. This requirement leads to a set of relationships known as the Lorentz transformations. *See* LORENTZ TRANSFORMATIONS.

In accordance with the Lorentz transformations, both the time interval and the spatial distance between two events are relative quantities, depending on the state of motion of the observer who carries out the measurements. There is, however, a new absolute quantity that takes the place of the two former quantities. It is known as the invariant, or proper, space-time interval τ and is defined by Eq. (1), where T is the ordinary time interval, R

$$\tau^2 = T^2 - \frac{1}{c^2}R^2 \qquad (1)$$

the distance between the two events, and c the speed of light in empty space. Whereas T and R are different for different observers, τ has the same value. In the event that Eq. (1) would render τ imaginary, its place may be taken by σ, defined by Eq. (2). If both τ and σ are zero, then a light signal leaving the

$$\sigma^2 = R^2 - c^2T^2 \qquad (2)$$

location of one event while it is taking place will reach the location of the other event precisely at the instant the signal from the latter is coming forth.

The existence of a single invariant interval led the mathematician Minkowski to conceive of the totality of space and time as a single four-dimensional continuum, which is often referred to as the Minkowski universe. In this universe, the history of a single space point in the course of time must be considered as a curve (or line), whereas an event, limited both in space and time, represents a point. So that these geometric concepts in the Minkowski universe may be distinguished from their analogs in ordinary three-dimensional space, they are referred to as world curves (world lines) and world points, respectively. *See* GRAVITATION; RELATIVITY. [P.G.B.]

Spacecraft ground instrumentation

Instrumentation located on the Earth for monitoring, tracking, and communicating with satellites, space probes, and crewed spacecraft. Radars, communication antennas, and optical instruments are classified as ground instrumentation. They are deployed in networks and, to a lesser extent, in ranges. Ranges are relatively narrow chains of ground instruments used to follow the flights of missiles, sounding rockets, and spacecraft ascending to orbit. Some ranges are a few miles long; others, such as the U.S. Air Force's Eastern Test Range, stretch for thousands of miles. Networks, in contrast, are dispersed over wide geographical areas so that their instruments can follow satellites in orbit as the Earth rotates under them at 15° per hour, or space probes on their flights through deep space.

Networks are of two basic kinds: networks supporting satellites in Earth orbit, and networks supporting spacecraft in deep space far from Earth. A third concept was added in the 1980s with the Tracking and Data Relay Satellite System (TDRSS), also called the Space Network (SN). TDRSS replaced most of the ground stations used for Earth orbital support. The *Tracking and Data Relay Satellites* (*TDRS*) are placed in geosynchronous orbits to relay signals to and from other orbiting spacecraft during more than 85% of each orbit, to and from a single ground station.

Ranges and networks have various technical functions:

1. Tracking: determination of the positions and velocities of space probes and satellites through radio and optical means.
2. Telemetry: reception of telemetered signals from scientific instruments and spacecraft housekeeping functions.
3. Voice reception and transmission: provision for communication with the crew of a spacecraft, such as the space shuttle.
4. Command: transmission of coded commands to spacecraft equipment, including scientific instruments.
5. Television reception and transmission: provision for observation of the crew, spacecraft environment, and so on.
6. Ground communications: telemetry, voice, television, command, tracking data, and spacecraft acquisition data transmission between network sites and the central mission control center, and payload information to user facilities.
7. Computing: calculation of orbital elements and radar acquisition data prior to transmission to users; also, computation of the signals that drive visual displays at a mission control center.

See SPACE COMMUNICATIONS; SPACE NAVIGATION AND GUIDANCE; TELEMETERING.

NASA operates two ground-based networks and the TDRSS. The ground-based networks are the Spaceflight Tracking and Data Network (STDN), which tracks, commands, and receives telemetry from United States and foreign satellites in Earth orbit; and the Deep Space Network (DSN), which performs the same functions for all types of spacecraft sent to explore deep space, the Moon, and solar system planets. The TDRSS provides the same support to Earth orbital spacecraft as the STDN. The U.S. Department of Defense operates two classified networks: the Satellite Control Facility (SCF); and the National Range Division Stations, which include those of all United States military ranges. Russia and the European Space Agency (ESA) also maintain similar networks.

The Laser Tracking Network consists of a series of both fixed and mobile laser systems used for ranging to retroreflector-equipped satellites in highly stable orbits. Laser stations obtain ranging data for these satellites by bouncing a highly concentrated pulse of laser light off the retroreflector corner cube installed on the spacecraft exterior. The exact position of the spacecraft in orbit can then be mathematically determined for a given point in time. By comparing several ranging operations, orbital predictions can be interpolated and extrapolated. The resultant data have a variety of applications, such as precise prediction of satellite orbit and measurement of the Earth's gravitational field, polar motion, earth tides, Earth rotation, tectonic plate motion, and crustal motion to accuracies within the centimeter range. The Laser Tracking Network is a multinational cooperative effort with over 30 laser sites located in North and South America, Europe, China, Japan, and Australia. [H.W.Wo.]

Spacecraft propulsion A system that provides control of location and attitude of spacecraft by using rocket engines to generate motion. Spacecraft propulsion systems come in various forms depending on the specific mission requirements. Each exhibits considerable variation in such parameters as thrust, specific impulse, propellant mass and type, pressurization schemes, cost, and materials. All of these variables must be considered in deciding which propulsion system is best suited to a given mission. Typical spacecraft applications include communications satellites, science and technology spacecraft, and Earth-monitoring missions such as weather satellites. Orbital environments range from low-Earth to geosynchronous to interplanetary. *See* ASTRONAUTICAL ENGINEERING; ROCKET PROPULSION; SATELLITE (SPACECRAFT); SPACE FLIGHT; SPACE PROBE; SPECIFIC IMPULSE; THRUST.

The two fundamental variables that define the design of spacecraft propulsion systems are the total velocity change to be imparted to the spacecraft for translational purposes, and the impulse necessary to counteract the various external torques imposed on the spacecraft body. From these, the required quantity of a given propellant combination can be specified. Propellant accounts for almost 60% of the lift-off mass of a communications satellite.

The specific impulse has a significant effect on the total propellant load that a spacecraft must carry to perform its assigned mission. Since a massive satellite must be boosted into space by the use of expensive launch vehicles, such as the space shuttle and Ariane, significant cost savings may be gained if smaller, less expensive launch vehicles may be used. The size of the required launch vehicle is directly proportional to the mass of the payload. Since most of the other components that make up spacecraft are relatively fixed in weight, it is critical to utilize propellant combinations that maximize specific impulse.

For modern spacecraft the choices are either bipropellants, which utilize a liquid oxidizer and a separate liquid fuel; solid propellants, which consist of oxidizer and fuel mixed together; or monopropellants, which are liquid fuels that are easily dissociated by a catalyst into hot, gaseous reaction products. High specific impulse is offered by bipropellants, followed by solid propellants and monopropellants.

Spacecraft attitude control schemes play an important role in defining the detailed characteristics of spacecraft propulsion systems. Essentially, there are three methods for stabilizing a spacecraft: three-axis control, spin control, and gravity gradient. In three-axis systems the body axes are inertially stabilized with reference to the Sun and stars, and utilize rocket engines for control in all six degrees of freedom. Spin-stabilized spacecraft use the inertial properties of a gyroscope to permanently align one of the axes by rotating a major portion of the spacecraft body about this axis. This approach significantly reduces the number of thrusters needed for control. Gravity gradient control is a nonactive technique that relies on the Earth's tidal forces to permanently point a preferred body axis toward the Earth's center. *See* GYROSCOPE; INERTIAL GUIDANCE SYSTEM; SPACECRAFT STRUCTURE.

Translation of a spacecraft, independent of its control technique, requires thrusters aligned parallel to the desired translational axis. Usually, all three axes require translational capability. Combining the two requirements for attitude control and translation results in the minimum number of rocket engines required to perform the mission. These are supplemented with additional thrusters to allow for failures without degrading the performance of the propulsion system. Simplistically, it would be reasonable to assume that the propellant-engine combination with the highest specific impulse would be the preferable choice. However, the ultimate requirement is the lowest possible mass for the entire propulsion system. The complexity of the system is greatly influenced by, and is roughly proportional to, the specific impulse, since bipropellants require more tanks, valves, and so forth than either solid systems or monopropellant systems. This is primarily due to the differences in density between liquids and solids, and the fact that bipropellants require high-pressure gas sources to expel the fluid from the tanks and into the rocket engine chamber. For communications satellites in the lift-off weight range of 3000 lbm (1360 kg), the trade-off between specific impulse and system mass dictates the use of a solid rocket motor for the main-orbit circularizing burn and a monopropellant propulsion system for on-orbit attitude control and translation. Spacecraft launch masses above about 5000 lbm (2268 kg) require the use of all-bipropellant systems. [K.D.]

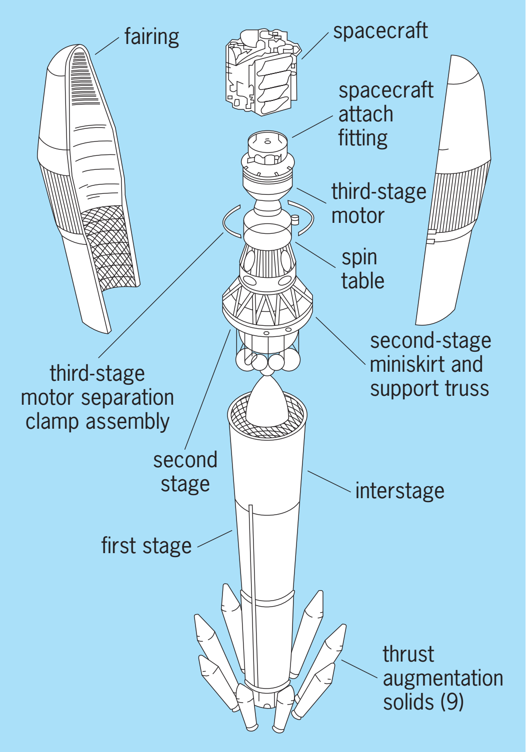
Spacecraft structure The supporting structure for systems capable of leaving the Earth and its atmosphere, performing a useful mission in space, sometimes returning to the Earth and sometimes landing on other bodies. Among the principal technologies that enter into the design of spacecraft structures are aerodynamics, aerothermodynamics, heat transfer, structural mechanics, structural dynamics, materials technology, and systems analysis. In applying these technologies to the structural design of a spacecraft, trade studies are made to arrive at a design which fulfills system requirements at a minimum weight with acceptable reliability and which is capable of being realized in a reasonable period of time.

The structural aspects of space flight can be divided into six broad regions or phases: (1) transportation, handling, and storage; (2) testing; (3) boosting; (4) Earth-orbiting flight; (5) reentry, landing, and recovery on the Earth; (6) interplanetary flight with orbiting of or landing on other planets. Each phase has its own structural design criteria requiring detailed consideration of heat, static loads, dynamic loads, rigidity, vacuum effects, radiation, meteoroids, acoustical loads, atmospheric pressure loads, foreign atmospheric composition, solar pressure, fabrication techniques, magnetic forces, sterilization requirements, accessibility for repair, and interrelation of one effect with the others. Heavy reliance is placed on computer-generated mathematical models and ground testing.

The basic spacecraft structural design considerations apply equally well to both crewed and crewless spacecraft. The degree of reliability of the design required is, however, much greater for crewed missions. Also, the spacecraft structures in the case of crewed missions must include life-support systems and reentry and recovery provisions. In the case of lunar or planetary missions where landing on and leaving the foreign body are required, additional provisions for propulsion, guidance, control, spacecraft sterilization, and life-support systems must be realized, and the structure must be designed to accommodate them.

Testing. To ensure that spacecraft structures will meet mission requirements criteria in general requires testing to levels above the expected environmental conditions by a specific value. The test level must be set to provide for variations in materials, manufacture, and anticipated loads. In cases where structures are required to perform dynamic functions repeatedly, life testing is required to ensure proper operation over a given number of cycles of operation. *See* INSPECTION AND TESTING.

Boost. The purpose of the boost phase is to lift the vehicle above the sensible atmosphere, to accelerate the vehicle to the velocity required, and to place the spacecraft at a point in space, heading in the direction required for the accomplishment of its mission. For space missions, the required velocities range from 26,000 ft/s (8 km/s) for nearly circular Earth orbits to 36,000 ft/s (11 km/s) for interplanetary missions. Achievement of these velocities requires boosters many times the size of the spacecraft itself. Generally, this boosting is accomplished by a chemically powered rocket propulsion system using liquid or solid propellants. Multiple stages are required to reach the velocities for space



Exploded view of typical Delta II 7925 three-stage structure. (*After Commercial Delta II Payload Planners Guide, McDonnell Douglas Commercial Delta Inc., 1990*)

missions. Vertical takeoff requires a thrust or propulsive force that exceeds the weight of the complete flight system by approximately 30%. An example of a multiple-stage booster is the Delta launch vehicle used for the crewless missions (see illustration). The Delta II 7925 vehicle has the capability to place 4000 lb (1800 kg) into a geosynchronous transfer orbit. *See* INTERPLANETARY PROPULSION; PROPELLANT; ROCKET PROPULSION.

Space phase and design considerations. The space phase begins after the boost phase and continues until reentry. In this phase, the structures that were stowed for launch are deployed. Important design considerations include control system interaction, thermally induced stress, and minimization of jitter and creaks.

The spacecraft control system imparts inertial loads throughout the structure. In the zero gravity environment, every change in loading or orientation must be reacted through the structure.

Spacecraft structural design usually requires that part of the principal structure be a pressure vessel. Efficient pressure vessel design is therefore imperative. An important material property, especially in pressure vessel design, is notch sensitivity. Notch sensitivity refers to the material's brittleness under biaxial strain. This apparent brittleness contributed to premature failure of some early boosters. *See* PRESSURE VESSEL.

Meteoric particles may have extremely high velocities relative to the spacecraft (up to 225,000 ft/s or 68 km/s). Orbital debris also include residual particles resulting from human space-flight activities. Collisions involving these bodies and a space station and other long-duration orbiting spacecraft are inevitable. The worst-case effects of such collisions include the degradation of performance and the penetration of pressure vessels, including high-pressure storage tanks and habitable crew modules. An essential parameter in the design of these structures is the mitigation of these effects. *See* METEOR.

Radiation shielding is required for some vehicles, particularly those operating for extended times within the Earth's magnetically trapped radiation belts or during times of high sunspot activity. The shielding may be an integral part of the structure. Computer memories are particularly susceptible to radiation and cosmic-ray activity and must be shielded to survive. Effects of radiation on most metallic structures over periods of 10–20 years is not severe. The durability of composite structures in space is a major concern for long life. Based on available data, the synergistic effects of vacuum, heat, ultraviolet, and proton and electron radiation degrade the mechanical, physical, and optical properties of polymers.

Temperature extremes in the structure and the enclosed environment are controlled by several techniques. Passive control is accomplished by surface coatings and multilayer thermal blankets which control the radiation transfer from the spacecraft to space and vice versa. Because incident solar radiation varies inversely with the square of distance from the Sun, means of adjusting surface conditions are required for interplanetary missions. Heat generated by internal equipment or other sources must be considered in the heat balance design. Other techniques used to actively control spacecraft temperatures are thermal louvers and heat pipes. *See* HEAT PIPE.

Thermal gradients must be considered in spacecraft design, especially when the spacecraft has one surface facing the Sun continuously. In some cases it is desirable to slowly rotate the spacecraft to eliminate such gradients.

Spacecraft structures usually are required to be lightweight and rigid, which results in the selection of high-modulus materials. Titanium and beryllium have low densities and relatively high modulus-density ratios. Alloys of these metals are relatively difficult to fabricate, and therefore their application is quite limited. The more common aluminum, magnesium, and stainless steel alloys are basic spacecraft structural materials. They are easy to fabricate, relatively inexpensive, and in general quite suitable for use in the space environment. Plastics are used in spacecraft structures when radio-frequency or magnetic isolation is required. They are also used in situations where some structural damping is desired.

The modern requirements for low weight, high strength, high stiffness, and low thermal expansion (for precision optical pointing) have prompted the use of composite materials for spacecraft structure. These materials consist of high-strength reinforcement fibers which are supported by a binder material referred to as the matrix. The fibers are typically made of glass, graphite, or carbon, and the matrix is an epoxy resin. *See* COMPOSITE MATERIAL.

Reentry phase. Although the atmospheric layer of the Earth is relatively thin, it is responsible for the reduction of vehicle velocity and the resulting deceleration loads, as well as for the severe heating experienced by reentering vehicles. A body entering the Earth's atmosphere possesses a large amount of energy. This energy must be dissipated in a manner which allows the reentering vehicle to survive. Most of the vehicle's original energy can be transformed into thermal energy in the air surrounding the vehicle, and only part of the original energy is retained in the vehicle as heat. The fraction that appears as heat in the vehicle depends upon the characteristics of the flow around the vehicle. In turn, the flow around the vehicle is a function of its geometry, attitude, velocity, and altitude. *See* ATMOSPHERIC ENTRY.

Spacecraft are seldom designed to reenter the Earth's atmosphere (the space shuttle being an exception), but may be designed to enter extraterrestrial atmospheres. In either case, the structural design is similar.

High-speed reentry causes extreme friction and heat buildup on spacecraft that must be dissipated by using high-temperature ceramic or ablative materials. The space shuttle is covered with special thermal insulating tiles that allow the structural elements to remain cool when the surface reaches 1200°F (650°C), and its leading edges are protected by a carbon-carbon reinforced material that can withstand temperatures as high as 2300°F (1260°C).

Satellites whose orbits decay into the Earth's upper atmosphere become flaming objects as they rapidly descend. Generally, most or all of the satellite is consumed before it reaches the surface, but there are exceptions such as the March 22, 2001, reentry of the Russian space station, *Mir.*

In crewed applications, vehicles employing aerodynamic lift during reentry have several advantages over zero-lift ballistic bodies: (1) The use of lift allows a more gradual descent, thus reducing the deceleration forces on both vehicle and occupants. (2) The vehicle's ability to glide and maneuver within the atmosphere gives it greater accuracy in either hitting a target or landing at a predetermined spot. (3) It can accommodate greater errors of guidance systems because for a given deceleration it can tolerate a greater range of entry angles. (4) Greater temperature control is afforded because aerodynamic lift may be varied to control altitude with velocity.

Structures. Erectable structures take many and varied shapes. They are sometimes relatively simple hinged booms, while on other occasions they become quite large and massive. Many more spacecraft structures are rigid than erectable or inflatable.

The space shuttle or Space Transportation System (STS) can carry 65,000 lb (30,000 kg) of cargo to and from low Earth orbit. *See* Space shuttle.

The International Space Station (ISS) is a cooperative, 16-nation effort. It will include six laboratories and weigh a million pounds when assembled. *See* Communications satellite; Meteorological satellites; Military satellites; Satellite navigation systems; Scientific satellites; Space station. [W.Hai.; P.S.W.]

Spallation reaction A nuclear reaction that can take place when two nuclei collide at very high energy (typically 500 MeV per nucleon and up), in which the involved nuclei are either disintegrated into their constituents (protons and neutrons), light nuclei, and elementary particles, or a large number of nucleons are expelled from the colliding system resulting in a nucleus with a smaller atomic number. This mechanism is clearly different from fusion reactions induced by heavy or light ions with modest kinetic energy (typically 5 MeV per nucleon) where, after formation of a compound nucleus, only a few nucleons are evaporated. A spallation reaction can be compared to a glass that shatters in many pieces when it falls on the ground. The way that the kinetic energy is distributed over the different particles involved in a spallation reaction and the process whereby this results in residues and fluxes of outgoing particles are not well understood. *See* Nuclear fusion.

Spallation reactions take place in interstellar space when energetic cosmic rays (such as high-energy protons) collide with interstellar gas, which contains atoms such as carbon, nitrogen, and oxygen. This leads to the synthesis of light isotopes, such as ^{6}Li, ^{9}Be, ^{10}Be, and ^{11}B, that cannot be produced abundantly in nucleosynthesis scenarios in the big bang or stellar interiors. *See* Big bang theory; Nucleosynthesis.

In terrestrial laboratories spallation reactions are initiated by bombarding targets with accelerated light- or heavy-ion beams, and they are used extensively in basic and applied research, such as the study of the equation of state of nuclear matter, production of energetic neutron beams, and radioactive isotope research. *See* Neutron diffraction; Relativistic heavy-ion collisions; Slow neutron spectroscopy. [P.V.D.]

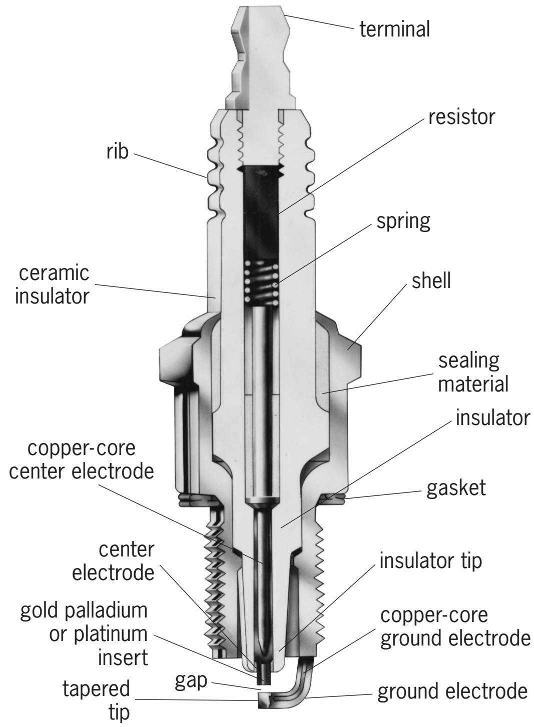
Spark gap The region between two electrodes in which a disruptive electrical spark may take place. The gap should be taken to mean the electrodes as well as the intervening space. Such devices may have many uses. The ignition system in a gasoline engine furnishes a very important example. Another important case is the use of a spark gap as a protective device in electrical equipment. Here, surges in potential may be made to break down such a gap so that expensive equipment will not be damaged. *See* Breakdown potential; Electric spark. [G.H.M.]

Spark knock The sound and related effects produced in spark-ignited internal combustion engines by instantaneous ignition and combustion (autoignition) of the gaseous fuel-air mixture ahead of the advancing flame front.

After spark ignition, a flame travels outward from the spark plug and, under normal combustion, will progressively burn the entire fuel-air charge. The burned gas liberates heat and expands, leading to increased pressure and temperature in the unburned gas ahead of the flame front. The unburned gas may be raised above its autoignition temperature. If the flame front velocity is too small the unburned gas spontaneously ignites and burns instantaneously. The instantaneous combustion results in a very intense pressure wave that produces the audible, high-frequency (pinging) sound known as spark knock. *See* Combustion chamber; Explosive.

Besides sound, spark knock can result in pitting, or erosion, of the combustion chamber, damage to spark plug electrodes, and possible structural damage to the engine. Spark knock also leads to loss of engine efficiency by inducing spark plug preignition, resulting in overly advanced spark timing. Spark knock also causes intense turbulence within the cylinder, aggravating heat loss from the burned gas to the colder cylinder and head surfaces and reducing efficiency. *See* Automotive engine; Combustion; Internal combustion engine. [J.R.As.; D.L.An.]

Spark plug A device that screws into the combustion chamber of an internal combustion engine to provide a pair of electrodes between which an electrical discharge is passed to ignite the combustible mixture. The spark plug consists of an outer steel shell that is electrically grounded to the engine and a ceramic insulator, sealed into the shell, through which a center electrode passes (see illustration). The high-voltage current jumps the gap between the center electrode and the ground electrode fixed to the outer shell.



Cross section of a typical spark plug. (*Champion Spark Plug Co.*)

The electrodes are made of nickel and chrome alloys that resist electrical and chemical corrosion. Some center electrodes have a copper core, while others have a platinum tip. Many spark plugs have a resistor in the center electrode to help prevent radio-frequency interference. The parts exposed to the combustion gases are designed to operate at temperatures hot enough to prevent electrically conducting deposits but cool enough to avoid ignition of the mixture before the spark occurs. *See* Ignition system. [D.L.An.]

Spatangoida An order of exocyclic Euechinoidea in which the posterior ambulacral plates form a shield-shaped area behind the mouth. The plates are arranged in two similar parallel longitudinal series. The apical system is compact. The families are defined mainly by reference to the fascicles, which are ribbonlike bands of minute, close-set uniform ciliated spinules on various parts of the test. The order reached its maximum in the mid-Tertiary, but is still richly represented today in most seas. *See* EUECHINOIDEA. [H.B.F.]

Spearmint Either of two vegetatively propagated, clonal cultivar species (*Mentha spicata* and *M. longifolia*) of mints of the family Lamiaceae (Labiatae). They are grown primarily in Idaho, Indiana, Michigan, Washington, and Wisconsin as a source of essential oil of spearmint.

Principal uses of the oil are in flavoring gum, toothpaste, and candy. Chopped fresh leaves of *M. spicata* preserved in vinegar are used as a condiment served with lamb, especially in England, and dried or freeze-dried leaves of several strains are used in flavoring soups, stews, tea, or sauces. Sprigs of the decorative curly mint *M. crispa* (or *M. spicata var. crispata*) are often used in mixed drinks such as mint juleps. *See* LAMIALES. [M.J.M.]

Special functions Functions which occur often enough to acquire a name. Some of these, such as the exponential, logarithmic, and the various trigonometric functions, are extensively taught in school and occur so frequently that routines for calculating them are built into many pocket calculators. *See* DIFFERENTIATION; LOGARITHM; TRIGONOMETRY.

The more complicated special functions, or higher transcendental functions as they are often called, have been extensively studied by many mathematicians because they arose in the problems which were being studied. Among the more useful functions are the following: the gamma function defined by Eq. (1), which generalizes the factorial; the related beta function defined by Eq. (2), which generalizes the binomial coefficient;

$$\Gamma(x) = \int_0^\infty t^{x-1}e^{-t}dt \qquad (1)$$

$$B(x, y) = \int_0^1 t^{x-1}(1-t)^{y-1}dt \qquad (2)$$

and elliptic integrals, which arose when mathematicians tried to determine the arc length of an ellipse, and their inverses, the elliptic functions. The hypergeometric function and its generalizations includes many of the special functions which occur in mathematical physics, such as Bessel functions, Legendre functions, error functions, and the classical orthogonal polynomials of Jacobi, Laguerre, and Hermite. The zeta function defined by Eq. (3) has many applications in number theory, and it also

$$\zeta(s) = \sum_{n=1}^{\infty} n^{-s} \qquad (3)$$

arises in M. Planck's work on radiation. *See* BESSEL FUNCTIONS; ELLIPTIC FUNCTION AND INTEGRAL; GAMMA FUNCTION; HEAT RADIATION; HYPERGEOMETRIC FUNCTIONS; LEGENDRE FUNCTIONS; NUMBER THEORY; ORTHOGONAL POLYNOMIALS. [R.A.]

Speciation The process by which new species of organisms evolve from preexisting species. It is part of the whole process of organic evolution. The modern period of its study began with the publication of Charles Darwin's and Alfred Russell Wallace's *Theory of Evolution by Natural Selection* in 1858, and Darwin's *On the Origin of Species* in 1859.

Belief in the fixity of species was almost universal before the middle of the nineteenth century. Then it was gradually realized that all species continuously change, or evolve; however, the causative mechanism remained to be discovered. Darwin proposed a mechanism. He argued that (1) within any species population there is always some heritable variation; the individuals differ among themselves in structure, physiology, and behavior; and (2) natural selection acts upon this variation by eliminating the less fit. Thus if two members of an animal population differ from each other in their ability to find a mate, obtain food, escape from predators, resist the ravages of parasites and pathogens, or survive the rigors of the climate, the more successful will be more likely than the less successful to leave descendants. The more successful is said to have greater fitness, to be better adapted, or to be selectively favored. Likewise among plants: one plant individual is fitter than another if its heritable characteristics make it more successful than the other in obtaining light, water, and nutrients, in protecting itself from herbivores and disease organisms, or in surviving adverse climatic conditions. Over the course of time, as the fitter members of a population leave more descendants than the less fit, their characteristics become more common.

This is the process of natural selection, which tends to preserve the well adapted at the expense of the ill adapted in a variable population. The genetic variability that must exist if natural selection is to act is generated by genetic mutations in the broad sense, including chromosomal rearrangements together with point mutations. *See* GENETICS; MUTATION.

If two separate populations of a species live in separate regions, exposed to different environments, natural selection will cause each population to accumulate characters adapting it to its own environment. The two populations will thus diverge from each other and, given time, will become so different that they are no longer interfertile. At this point, speciation has occurred: two species have come into existence in the place of one. This mode of speciation, speciation by splitting, is probably the most common mode. Two other modes are hybrid speciation and phyletic speciation; many biologists do not regard the latter as true speciation.

Many students of evolution are of the opinion that most groups of organisms evolve in accordance with the punctuated equilibrium model rather than by phyletic gradualism. There are two chief arguments for this view. First, it is clear from the fossil record that many species persist without perceptible change over long stretches of time and then suddenly make large quantum jumps to radically new forms. Second, phyletic gradualism seems to be too slow a process to account for the tremendous proliferation of species needed to supply the vast array of living forms that have come into existence since life first appeared on Earth. *See* ANIMAL EVOLUTION; POPULATION GENETICS; SPECIES CONCEPT. [E.C.P.]

Species concept The species is the fundamental unit of organization of the taxonomic system; of interactions between organisms as described by geneticists and ecologists; and of evolution as studied by phylogeneticists. As a category the term species resists definition; thus, a species concept is adopted as a framework within which biologists of various persuasions delineate the taxa with which they work at the species level. However, no universal concept has been accepted by all biologists for two fundamental reasons: (1) Different groups of organisms in nature are organized differently in terms of reproductive mechanisms and patterns; in degrees of differentiation among species in morphological, genetic, physiological, behavioral, biochemical, and other types of characters; and in the modes of speciation that have given rise to the members of the group. (2) The philosophy, training, working methods, and goals of different of biologists affect the manner in which each perceives the coherence or diversity of the biological world in general and that of the group of organisms in question in particular.

According to the taxonomic concept, a species consists of groups of individuals (populations) that are morphologically similar to one another, and differ morphologically from other such groups. There are several important ideas expressed in this concept. First, there is internal cohesiveness; that is, the members of the species share certain characteristics. Second, there is external distinction because other species have different characteristics, and thus species may be distinguished from one another. Third, the characteristics that a species possesses may be easily observed because they are phenotypic; that is, a species may be identified by its appearance.

Difficulty in applying the taxonomic concept arises with certain groups of organisms. Bacteria are often identified by physiological and biochemical tests requiring sophisticated laboratories and equipment; in addition, the mutation rate in bacteria is so high that the various traits used to identify them can change rapidly. In insects, the morphological differences between species may be very slight and easily overlooked. In certain groups of plants, hybridization and polyploidy have led to a continuous range of variation of characters, in which no discontinuities sufficient to distinguish species can be discerned. Critics claim that the purely phenetic approach of the taxonomic concept may not reflect real genetic or breeding relationships. However, this concept provides guidelines by which species may be recognized by ordinary (nonexperimental) means. The composition of a species so recognized can then be subjected to hypothesis testing within the framework of other concepts. *See* BACTERIAL TAXONOMY; TAXONOMIC CATEGORIES.

According to the biological concept, a species is composed of groups of individuals (populations) that normally interbreed with one another. The fundamental ideas expressed by this concept are that the internal cohesiveness of a species is maintained by the exchange of genes through sexual reproduction (gene flow) and that the distinctness of the species is maintained by reproductive isolation (barriers to gene flow) from other groups of populations. If two populations do not exchange genes, they belong to separate species regardless of their morphological similarity.

This concept works well in those groups of organisms that are exclusively outbreeding, such as birds and mammals. However, it is difficult to apply to plants, in which interbreeding between morphologically very distinct species and even genera is common. Also, those organisms that do not reproduce sexually present problems of classification. Even in sexually reproducing organisms, populations that are morphologically identical but reproductively separated by geographic distance (disjuncts) present problems of classification within the framework of the concept. The populations might interbreed if they were in contact, but this can be determined only under artificial conditions and not in nature. However, the development of the biological species concept has contributed greatly to making taxonomy an evolutionary science because of its emphasis on the identification of genetic, rather than the very possibly superficial phenetic, relationship among organisms.

According to the evolutionary concept, a species is a lineage of ancestor-descendant populations that maintains its identity from other such lineages and that has its own evolutionary tendencies and historical fate. The important ideas expressed in this concept are the following. (1) All organisms, regardless of their mode of reproduction, belong to some evolutionary species. (2) Species need be reproductively isolated from one another to the extent that they maintain their distinction from other species. (3) There may or may not be a morphological discontinuity between species but, if there is, it is reasonable to hypothesize that more than one species is present. If there is not, other data such as that on breeding relationships may be used to recognize species.

The evolutionary concept encompasses the taxonomic concept, the biological concept, and other more narrowly defined concepts—for example, the ecological species, the genetic species, and the paleospecies. It is operational in that it provides guidelines for the recognition of species and for testing of hypotheses concerning membership in each species; it also is compatible with the Linnaean taxonomic hierarchy. As it becomes more widely used by working systematists, problems and difficulties with the concept may appear that will require its refinement. However, the evolutionary concept may in the long run be more acceptable to a wider group of biologists than any other yet proposed. *See* TAXONOMY. [M.A.La.]

Specific charge

The ratio of charge to mass expressed as e/m, of a particle. The acceleration of a particle in electromagnetic fields is proportional to its specific charge. Specific charge can be determined by measuring the velocity which the particle acquires in falling through an electric potential; by measuring the frequency of revolution in a magnetic field; or by observing the orbit of the particles in combined electric and magnetic fields. *See* ELEMENTARY PARTICLE. [C.J.G.]

Specific fuel consumption

The ratio of the fuel mass flow of an aircraft engine to its output power, in specified units. Specific fuel consumption (abbreviated sfc or SFC) is a widely used measure of atmospheric engine performance. For reciprocating engines it is usually given in U.S. Customary units of pound-mass per hour per horsepower [(lbm/h)/hp or lbm/(hp·h)], and International System (SI) units of kilograms per hour per kilowatt [(kg/h)/kW]. *See* RECIPROCATING AIRCRAFT ENGINE.

For the gas turbine family of atmospheric aircraft engines, and for ramjets, performance is usually given in terms of thrust specific fuel consumption (abbreviated tsfc or TSFC) expressed as fuel mass flow per unit thrust output with Customary units of pound-mass per hour per pound-force [(lbm/h)/lbf] or SI units of kilograms per hour per newton [(kg/h)/N; 1 N equals approximately 0.225 lbf]. For high-supersonic and hypersonic ramjets, specific fuel consumption is sometimes given in pound-mass per second per pound-force [(lbm/s)/lbf] or kilograms per second per newton [(kg/s)/N]. *See* AIRCRAFT PROPULSION; JET PROPULSION; PROPULSION; RAMJET; TURBINE PROPULSION; TURBOJET. [J.P.L.]

Specific gravity

The specific gravity of a material is defined as the ratio of its density to the density of some standard material, such as water at a specified temperature, for example, 60°F (15°C), or (for gases) air at standard conditions of temperature and pressure. Specific gravity is a convenient concept because it is usually easier to measure than density, and its value is the same in all systems of units. *See* DENSITY. [L.N.]

Specific heat

A measure of the heat required to raise the temperature of a substance. When the heat ΔQ is added to a body of mass m, raising its temperature by ΔT, the ratio C given in Eq. (1) is defined as the heat capacity of the body. The quantity c defined in Eq. (2) is called the specific heat capacity or specific

$$C = \frac{\Delta Q}{\Delta T} \qquad (1)$$

$$c = \frac{C}{m} = \frac{1}{m}\frac{\Delta Q}{\Delta T} \qquad (2)$$

heat. A commonly used unit for heat capacity is joule · kelvin^{-1} ($\mathrm{J \cdot K^{-1}}$); for specific heat capacity, the unit joule · gram^{-1} · K^{-1} ($\mathrm{J \cdot g^{-1} \cdot K^{-1}}$) is often used. Joule should be preferred over the unit calorie = 4.18 J. As a unit of specific heat capacity, $\mathrm{Btu \cdot lb^{-1} \cdot {}^{\circ}F^{-1} = 4.21\ J \cdot g^{-1} \cdot K^{-1}}$ is also still in use in English-language engineering literature. If the heat capacity is referred to the amount of substance in the body, the molar heat capacity c_m results, with the unit $\mathrm{J \cdot mol^{-1} \cdot K^{-1}}$.

If the volume of the body is kept constant as the energy ΔQ is added, the entire energy will go into raising its temperature. If, however, the body is kept at a constant pressure, it will change its volume, usually expanding as it is heated, thus converting some of the heat ΔQ into mechanical energy. Consequently, its temperature increase will be less than if the volume is kept constant. It is therefore necessary to distinguish between these two processes, which are identified with the subscripts V (constant volume) and p (constant pressure): C_V, c_V, and C_p, c_p. For gases at low pressures, which obey the ideal gas law, the molar heat capacities differ by R, the molar gas constant, as given in Eq. (3), where $R = 8.31\ \mathrm{J \cdot mol^{-1} \cdot K^{-1}}$; that is, the expanding gas heats up less.

$$c_p - c_V = R \qquad (3)$$

For solids, the difference between c_p and c_V is of the order of 1% of the specific heat capacities at room temperature. This small difference can often be ignored. *See* CALORIMETRY; CHEMICAL THERMODYNAMICS; HEAT CAPACITY; SPECIFIC HEAT OF SOLIDS; THERMODYNAMIC PROCESSES. [R.O.P.]

Specific impulse The impulse produced by a rocket divided by the mass m_p of propellant consumed. Specific impulse I_{sp} is a widely used measure of performance for chemical, nuclear, and electric rockets. It is usually given in seconds for both U.S. Customary and International System (SI) units.

The impulse produced by a rocket is the thrust force F times its duration t in seconds. The specific impulse is given by the equation below. Its equivalent, specific thrust F_{sp}, that is sometimes

$$I_{sp} = \frac{Ft}{m_p} \qquad (1)$$

used alternatively, is the rocket thrust divided by the propellant mass flow rate $F/\dot{m}_p$. *See* IMPULSE (MECHANICS); THRUST.

Calculation of specific impulse for the various forms of electric rockets involves electrothermal, resistance or arc heating of the propellant or its ionization and acceleration to high jet velocity by electrostatic or electromagnetic body forces. Ions in the exhaust jets of these devices must be neutralized so the spacecraft will not suffer from space charging or other effects from the plumes of the devices' operation. *See* ELECTROTHERMAL PROPULSION; ION PROPULSION; PLASMA PROPULSION; ROCKET PROPULSION; SPACECRAFT PROPULSION. [J.P.L.]

Speckle The generation of a random intensity distribution, called a speckle pattern, when light from a highly coherent source, such as a laser, is scattered by a rough surface or inhomogeneous medium. *See* LASER.

The surfaces of most materials are extremely rough on the scale of an optical wavelength (approximately 5×10^{-7} m). When nearly monochromatic light is reflected from such a surface, the optical wave resulting at any moderately distant point consists of many coherent wavelets, each arising from a different microscopic element of the surface. Since the distances traveled by these various wavelets may differ by several wavelengths if the surface is truly rough, the interference of the wavelets of various phases results in the granular pattern of intensity called speckle. If a surface is imaged with a perfectly corrected optical system, diffraction causes a spread of the light at an image point, so that the intensity at a given image point results from the coherent addition of contributions from many independent surface areas. As long as the diffraction-limited point-spread function of the imaging system is broad by comparison with the microscopic surface variations, many dephased coherent contributions add at each image point to give a speckle pattern.

The basic random interference phenomenon underlying laser speckle exists for sources other than lasers. For example, it explains radar "clutter," results for scattering of x-rays by liquids, and electron scattering by amorphous carbon films. Speckle theory also explains why twinkling may be observed for stars, but not for planets. *See* COHERENCE; DIFFRACTION; INTERFERENCE OF WAVES; TWINKLING STARS.

In metrology, the most obvious application of speckle is to the measurement of surface roughness. If a speckle pattern is produced by coherent light incident on a rough surface, then surely the speckle pattern, or at least the statistics of the speckle pattern, must depend upon the detailed surface properties. An application of growing importance in engineering is the use of speckle patterns in the study of object displacements, vibration, and distortion that arise in nondestructive testing of mechanical components. [J.C.Wy.]

Astronomical speckle interferometry is a technique for obtaining spatial information on astronomical objects at the diffraction-limited resolution of a telescope, despite the presence of atmospheric turbulence. Speckle interferometry techniques have proven to be an invaluable tool for astronomical research, allowing studies of a wide range of scientifically interesting problems. They have been widely used to determine the separation and position angle of binary stars, and for accurate diameter measurements of a large number of stars, planets, and asteroids. Speckle imaging techniques have successfully uncovered details in the morphology of a range of astronomical objects, including the Sun, planets, asteroids, cool giants and supergiants, young stellar objects, the supernova SN1987A in the Large Magellanic Cloud, Seyfert galaxies, and quasars. *See* BINARY STAR; INTERFEROMETRY. [M.Ka.]

Spectral type An indicator of the physical and chemical characteristics of a star, based on study of the star's spectrum. Stars possess a remarkable variety of spectra, some simple, others complex. To understand the natures of the stars, it was first necessary to bring order to the subject and to classify the spectra.

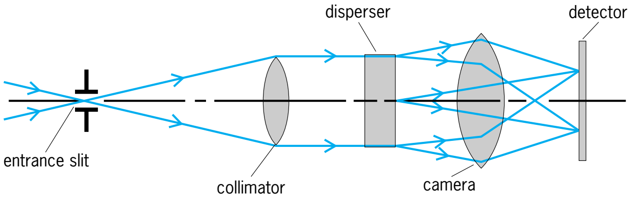
The modern system of classification was initiated about 1890. The spectra were ordered by letter, A through O, largely on the basis of the strengths of the hydrogen lines. Several letters were found to be unnecessary or redundant, and on the basis of continuity of lines other than hydrogen, it was found that B preceded A and O preceded B. The result is the classical spectral sequence, OBAFGKM. The classes were decimalized, setting up the sequence O5, ..., O9, B0, ..., B9, A0, and so forth. (Not all the numbers are used.) The modern standard sequence, called the Harvard sequence after the observatory where it was formulated, runs from O3 to M9. Classes L and T were added to the sequence in 1999.

Class A has the strongest hydrogen lines, B is characterized principally by neutral helium (with weaker hydrogen), and O by ionized helium. Hydrogen weakens notably through F and G, but the metal lines, particularly those of ionized calcium, strengthen. In K, hydrogen becomes quite weak, while the neutral metals grow stronger. The M stars effectively exhibit no hydrogen lines at all but are dominated by molecules, particularly titanium oxide (TiO). L stars are dominated by metallic hydrides and neutral alkali metals, while T is defined as methane. At G, the sequence branches downward into R and N, whose stars are rich in carbon molecules. In class S, the titanium oxide molecular bands of class M are replaced by zirconium oxide (ZrO).

At first appearance, the different spectral types seem to reflect differences in stellar composition. However, within the sequence OBAFGKMLT the elemental abundances are roughly similar. The dramatic variations in spectra are strictly the result of changes in temperature. The different spectra of the R, N, and S stars, however, are caused by true and dramatic variations in the chemical composition, the result of internal thermonuclear processing and convection. *See* STELLAR EVOLUTION.

In the 1940s, W. W. Morgan, P. C. Keenan, and E. Kellman expanded the Harvard sequence to include luminosity. A system of roman numerals is appended to the Harvard class to indicate position on the Hertzsprung-Russell diagram: I for supergiant, II for bright giant, III for giant, IV for subgiant, and V for dwarf or main sequence. *See* ASTRONOMICAL CATALOGS; HERTZSPRUNG-RUSSELL DIAGRAM. [J.B.Ka.]

Spectrograph An optical instrument that consists of an entrance slit, collimator, disperser, camera, and detector and that produces and records a spectrum. A spectrograph is used to extract a variety of information about the conditions that exist where light originates and along the paths of light. It reveals the details that are stored in the light's spectral distribution, whether



Basic optical components of a spectrograph.

this light is from a source in the laboratory or a quasistellar object a billion light-years away.

Spectrograph design takes into account the type of light source to be measured, and the circumstances under which these measurements will be made. Since observational astronomy presents unusual problems in these areas, the design of astronomical spectrographs may also be unique.

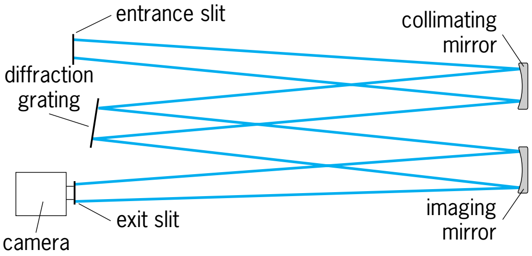
Astronomical spectrographs have the same general features as laboratory spectrographs (see illustration). The width of the entrance slit influences both spectral resolution and the amount of light entering the spectrograph, two of the most important variables in spectroscopy. The collimator makes this light parallel so that the disperser (a grating or prism) may properly disperse it. The camera then focuses the dispersed spectrum onto a detector, which records it for further study.

Laboratory spectrographs usually function properly only in a fixed orientation under controlled environmental conditions. By contrast, most astronomical spectrographs are used on a moving telescope operating at local temperature. Thus, their structures must be mechanically and optically insensitive to orientation and temperature.

The brightness, spectral characteristics, and geometry of laboratory sources may be tailored to experimental requirements and to the capabilities of a spectrograph. Astronomical sources, in the form of images at the focus of a telescope, cannot be manipulated, and their faintness and spectral diversity make unusual and difficult demands on spectrograph performance.

Typical laboratory spectrographs use either concave gratings, which effectively combine the functions of collimator, grating, and camera in one optical element, or plane reflection gratings with spherical reflectors for collimators and cameras. *See* ASTRONOMICAL SPECTROSCOPY. [R.Hi.]

Spectroheliograph A spectrographic instrument that produces mono-chromatic images of the Sun. In a simple form of the instrument, an image of the Sun from a solar telescope is focused on a plane containing the entrance slit of the spectroheliograph (see illustration). The light passing through the slit is collimated by a concave mirror that is tilted such that the light is incident on a plane diffraction grating. Part of the dispersed light from the grating is focused by a second concave mirror, identical to the first mirror, at an exit slit identical to the entrance slit. By symmetry of the optical system, the portion of the solar disk imaged on the entrance slit is reimaged in the plane of the exit slit with the same image scale but in dispersed wavelength. The light imaged along the exit slit then corresponds to the portion of the solar image falling on the entrance slit, but in the light of only a narrow region of the spectrum, as determined by the spectrographic dispersion. The particular wavelength sampled is set by the grating angle. By uniform transverse motion of the instrument such that the entrance slit is scanned across the solar image, the light passing through the exit slit maps out a corresponding monochromatic image of the Sun, which can be recorded photographically with a stationary camera or digitally by sequential readout of a linear array that moves with the exit slit. *See* ASTRONOMICAL SPECTROSCOPY; DIFFRACTION GRATING; SUN. [R.N.Sm.]



Optical configuration of a simple spectroheliograph.

Spectroscopy An analytic technique concerned with the measurement of the interaction (usually the absorption or the emission) of radiant energy with matter, with the instruments necessary to make such measurements, and with the interpretation of the interaction both at the fundamental level and for practical analysis.

A display of such data is called a spectrum, that is, a plot of the intensity of emitted or transmitted radiant energy (or some function of the intensity) versus the energy of that light. Spectra due to the emission of radiant energy are produced as energy is emitted from matter, after some form of excitation, then collimated by passage through a slit, then separated into components of different energy by transmission through a prism (refraction) or by reflection from a ruled grating or a crystalline solid (diffraction), and finally detected. Spectra due to the absorption of radiant energy are produced when radiant energy from a stable source, collimated and separated into its components in a monochromator, passes through the sample whose absorption spectrum is to be measured, and is detected. Instruments which produce spectra are variously called spectroscopes, spectrometers, spectrographs, and spectrophotometers. *See* SPECTRUM.

Interpretation of spectra provides fundamental information on atomic and molecular energy levels, the distribution of species within those levels, the nature of processes involving change from one level to another, molecular geometries, chemical bonding, and interaction of molecules in solution. At the practical level, comparisons of spectra provide a basis for the determination of qualitative chemical composition and chemical structure, and for quantitative chemical analysis.

Origin of spectra. Atoms, ions, and molecules emit or absorb characteristically; only certain energies of these species are possible; the energy of the photon (quantum of radiant energy) emitted or absorbed corresponds to the difference between two permitted values of the energy of the species, or energy levels. (If the flux of photons incident upon the species is great enough, simultaneous absorption of two or more photons may occur.) Thus the energy levels may be studied by observing the differences between them. The absorption of radiant energy is accompanied by the promotion of the species from a lower to a higher energy level; the emission of radiant energy is accompanied by falling from a higher to a lower state; and if both processes occur together, the condition is called resonance.

Instruments. Spectroscopic methods involve a number of instruments designed for specialized applications.

An optical instrument consisting of a slit, collimator lens, prism or grating, and a telescope or objective lens which produces a spectrum for visual observation is called a spectroscope.

If a spectroscope is provided with a photographic camera or other device for recording the spectrum, the instrument is called a spectrograph.

A spectroscope that is provided with a calibrated scale either for measurement of wavelength or for measurement of refractive indices of transparent prism materials is called a spectrometer.

A spectrophotometer consists basically of a radiant-energy source, monochromator, sample holder, and detector. It is used for measurement of radiant flux as a function of wavelength and for measurement of absorption spectra.

An interferometer is an optical device that measures differences of geometric path when two beams travel in the same medium, or the difference of refractive index when the geometric paths are equal. Interferometers are employed for high-resolution measurements and for precise determination of relative wavelengths. *See* INTERFEROMETRY.

Methods and applications. Since the early methods of spectroscopy there has been a proliferation of techniques, often incorporating sophisticated technology.

Acoustic spectroscopy uses modulated radiant energy that is absorbed by a sample. The loss of that excess produces a temperature increase that can be monitored around the sample by using a microphone transducer. This is the optoacoustic effect. *See* PHOTOACOUSTIC SPECTROSCOPY.

In astronomical spectroscopy, the radiant energy emitted by celestial objects is studied by combined spectroscopic and telescopic techniques to obtain information about their chemical composition, temperature, pressure, density, magnetic fields, electric forces, and radial velocity. *See* ASTRONOMICAL SPECTROSCOPY; SPECTROHELIOGRAPH.

Atomic absorption and fluorescence spectroscopy is a branch of electronic spectroscopy that uses line spectra from atomized samples to give quantitative analysis for selected elements at levels down to parts per million, on the average.

Attenuated total reflectance spectroscopy is the study of spectra of substances in thin films or on surfaces obtained by the technique of attenuated total reflectance or by a closely related technique called frustrated multiple internal reflection. In either method the radiant-energy beam penetrates only a few micrometers of the sample. The technique is employed primarily in infrared spectroscopy for qualitative analysis of coatings and of opaque liquids.

Electron spectroscopy includes a number of subdivisions, all of which are associated with electronic energy levels. The outermost or valence levels are studied in photoelectron spectroscopy. Electron impact spectroscopy uses low-energy electrons (0–100 eV).

X-ray photoelectron spectroscopy (XPS), also called electron spectroscopy for chemical analysis (ESCA), and Auger spectroscopy use x-ray photons to remove inner-shell electrons. Ion neutralization spectroscopy uses protons or other charged particles instead of photons. *See* AUGER EFFECT; ELECTRON SPECTROSCOPY; SURFACE AND INTERFACIAL CHEMISTRY; SURFACE PHYSICS.

Fourier transform spectroscopy is a technique that has been applied to infrared spectrometry and nuclear magnetic resonance spectrometry to allow the acquisition of spectra from smaller samples in less time, with high resolution and wavelength accuracy. *See* FOURIER SERIES AND TRANSFORMS.

Gamma-ray spectroscopy employs the techniques of activation analysis and Mössbauer spectroscopy. *See* ACTIVATION ANALYSIS; MÖSSBAUER EFFECT; NEUTRON SPECTROMETRY.

Information on processes which occur on a picosecond time scale can be obtained by making use of the coherent properties of laser radiation, as in coherent anti-Stokes-Raman spectroscopy. Laser fluorescence spectroscopy provides the lowest detection limits for many materials of interest in biochemistry and biotechnology. Ultrafast laser spectroscopy may be used to study some aspects of chemical reactions, such as transition states of elementary reactions and orientations in bimolecular reactions. *See* LASER SPECTROSCOPY.

In mass spectrometry, the source of the spectrometer produces ions, often from a gas, but also in some instruments from a liquid, a solid, or a material absorbed on a surface. The dispersive unit provides either temporal or spatial dispersion of ions according to their mass-to-charge ratio. *See* MASS SPECTROMETRY; SECONDARY ION MASS SPECTROMETRY (SIMS); TIME-OF-FLIGHT SPECTROMETERS.

In multiplex or frequency-modulated spectroscopy, each optical wavelength exiting the spectrometer output is encoded or modulated with an audio frequency that contains the optical wavelength information. Use of a wavelength analyzer then allows recovery of the original optical spectrum.

When a beam of light passes through a sample, a small fraction of the light exits the sample at a different angle. If the wavelength of the scattered light is different than the original wavelength, it is called Raman scattering. Raman spectroscopy is used in structural chemistry and is a valuable tool for surface analysis. A related process, resonance Raman spectroscopy, makes use of the fact that Raman probabilities are greatly increased when the exciting radiation has an energy which approaches the energy of an allowed electronic absorption. *See* RAMAN EFFECT.

In x-ray spectroscopy, the excitation of inner electrons in atoms is manifested as x-ray absorption; emission of a photon as an electron falls from a higher level into the vacancy thus created is x-ray fluorescence. The techniques are used for chemical analysis. *See* X-RAY FLUORESCENCE ANALYSIS; X-RAY SPECTROMETRY. [M.M.Bu.]

Spectrum

Spectrum The term spectrum is applied to any class of similar entities or properties strictly arrayed in order of increasing or decreasing magnitude. In general, a spectrum is a display or plot of intensity of radiation (particles, photons, or acoustic radiation) as a function of mass, momentum, wavelength, frequency, or some other related quantity. For example, a β-ray spectrum represents the distribution in energy or momentum of negative electrons emitted spontaneously by certain radioactive nuclides, and when radionuclides emit α-particles, they produce an α-particle spectrum of one or more characteristic energies. A mass spectrum is produced when charged particles (ionized atoms or molecules) are passed through a mass spectrograph in which electric and magnetic fields deflect the particles according to their charge-to-mass ratios. The distribution of sound-wave energy over a given range of frequencies is also called a spectrum. *See* MASS SPECTROSCOPE; SOUND.

In the domain of electromagnetic radiation, a spectrum is a series of radiant energies arranged in order of wavelength or of frequency. The entire range of frequencies is subdivided into wide intervals in which the waves have some common characteristic of generation or detection, such as the radio-frequency spectrum, infrared spectrum, visible spectrum, ultraviolet spectrum, and x-ray spectrum.

Spectra are also classified according to their origin or mechanism of excitation, as emission, absorption, continuous, line, and band spectra. An emission spectrum is produced whenever the radiations from an excited light source are dispersed. An absorption spectrum is produced against a background of continuous radiation by interposing matter that reduces the intensity of radiation at certain wavelengths or spectral regions. The energies removed from the continuous spectrum by the interposed absorbing medium are precisely those that would be emitted by the medium if properly excited. A continuous spectrum contains an unbroken sequence of waves or frequencies over a long range. Line spectra are discontinuous spectra characteristic of excited atoms and ions, whereas band spectra are characteristic of molecular gases or chemical compounds. *See* ATOMIC STRUCTURE AND SPECTRA; ELECTROMAGNETIC RADIATION; LINE SPECTRUM; MOLECULAR STRUCTURE AND SPECTRA; SPECTROSCOPY. [W.F.M./W.W.W.]

Spectrum analyzer

Spectrum analyzer An instrument for the analysis and measurement of signals throughout the electromagnetic spectrum. Spectrum analyzers are available for subaudio, audio, and radio-frequency measurements, as well as for microwave and optical signal measurements.

Generally, a spectrum analyzer separates the signal into two components: amplitude (displayed vertically) and frequency (displayed horizontally). On some low-frequency analyzers, phase information can also be displayed. Low-frequency analyzers are sometimes grouped under the heading “harmonic analyzers,” although this term is becoming less common.

On a conventional spectrum analyzer, a screen with a calibrated graticule displays the components of the input signal. The vertical scale displays the amplitude of each component, and the chosen frequency band is displayed horizontally. Components of the signal being analyzed are displayed as vertical lines whose height is proportional to amplitude and whose horizontal displacement equates to frequency. Originally, cathode-ray tubes were used for the display; solid-state displays such as liquid-crystal displays now are used. *See* CATHODE-RAY TUBE; ELECTRONIC DISPLAY.

Early radio-frequency and microwave analyzers were developed to measure the performance of microwave radar transmitters and to analyze signals from single-sideband transmitters. *See* RADAR; SINGLE SIDEBAND.

A typical use for radio-frequency and microwave spectrum analyzers is the measurement of spurious radiation (noise) from electrical machinery and circuits, known as radio-frequency interference (RFI). Other uses include monitoring and surveillance to detect unauthorized or unintended transmissions, such as the civil monitoring of broadcast and communication channels and the detection of electronic warfare signals. Another application is the analysis of radio communication transmitters and receivers, including those used in radio and television broadcasting, satellite systems, and mobile radio and cellular telephone communications. *See* ELECTRICAL INTERFERENCE; ELECTRONIC WARFARE.

Low-frequency spectrum analyzers are used in a variety of applications. The most obvious use is the measurement of distortion and unwanted signals in all types of audio equipment, from recording and broadcast studios to amplifiers used in the home. *See* SOUND RECORDING; SOUND-REPRODUCING SYSTEMS.

Further uses include the analysis of speech waveforms, measurement of vibration and resonances in mechanical equipment and structures, determination of echo delays in seismic signals, investigation of noise such as from aircraft engines or from machinery in factories, analysis of sonar signals used to detect objects underwater, and study of ultrasonic waves to determine the internal structure of objects such as human tissue and metal castings. *See* BIOMEDICAL ULTRASONICS; MECHANICAL VIBRATION; NOISE MEASUREMENT; NONDESTRUCTIVE EVALUATION; SEISMOLOGY; SONAR; ULTRASONICS.

Optical spectrum analyzers use techniques such as a collimating mirror and a diffraction grating or a Michelson interferometer to separate out the light-wave components. They are used for a variety of applications, including measurements on lasers and light-emitting diodes, and for the analysis of optical-fiber equipment used to carry multichannel, digital telephony. *See* DIFFRACTION GRATING; INTERFEROMETRY; LASER; LIGHT-EMITTING DIODE; OPTICAL COMMUNICATIONS; OPTICAL FIBERS. [S.J.Gl.]

Speech A set of audible sounds produced by disturbing the air through the integrated movements of certain groups of anatomical structures. Humans attach symbolic values to these sounds for communication. There are many approaches to the study of speech.

Speech production. The physiology of speech production may be described in terms of respiration, phonation, and articulation. These interacting processes are activated, coordinated, and monitored by acoustical and kinesthetic feedback through the nervous system.

Most of the speech sounds of the major languages of the world are formed during exhalation. Consequently, during speech the period of exhalation is generally much longer than that of inhalation. The aerodynamics of the breath stream influence the rate and mode of the vibration of the vocal folds. This involves interactions between the pressures initiated by thoracic movements and the position and tension of the vocal folds. *See* RESPIRATION.

The phonatory and articulatory mechanisms of speech may be regarded as an acoustical system whose properties are comparable to those of a tube of varying cross-sectional dimensions. At the lower end of the tube, or the vocal tract, is the larynx. It is situated directly above the trachea and is composed of a group of cartilages, tissues, and muscles. The upper end of the vocal tract may terminate at the lips, at the nose, or both. The length of the vocal tract averages 6.5 in. (16 cm) in men and may be increased by either pursing the lips or lowering the larynx.

The larynx is the primary mechanism for phonation, that is, the generation of the glottal tone. The vocal folds consist of connective tissue and muscular fibers which attach anteriorly to the thyroid cartilage and posteriorly to the vocal processes of the arytenoid cartilages. The vibrating edge of the vocal folds measures about 0.92– 1.08 in. (23–27 mm) in men and considerably less in women. The aperture between the vocal folds is known as the glottis. The tension and position of the vocal folds are adjusted by the intrinsic laryngeal muscles, primarily through movement of the two arytenoid cartilages. *See* LARYNX.

When the vocal folds are brought together and there is a balanced air pressure to drive them, they vibrate laterally in opposite directions. During phonation, the vocal folds do not transmit the major portion of the energy to the air. They control the energy by regulating the frequency and amount of air passing through the glottis. Their rate and mode of opening and closing are dependent upon the position and tension of the folds and the pressure and velocity of airflow. The tones are produced by the recurrent puffs of air passing through the glottis and striking into the supralaryngeal cavities.

Speech sounds produced during phonation are called voiced. Almost all of the vowel sounds of the major languages and some of the consonants are voiced. In English, voiced consonants may be illustrated by the initial and final sounds in the following words: “bathe,” “dog,” “man,” “jail.” The speech sounds produced when the vocal folds are apart and are not vibrating are called unvoiced; examples are the consonants in the words “hat,” “cap,” “sash,” “faith.” During whispering all the sounds are unvoiced.

The rate of vibration of the vocal folds is the fundamental frequency of the voice (F0). It correlates well with the perception of pitch. The frequency increases when the vocal folds are made taut. Relative differences in the fundamental frequency of the voice are utilized in all languages to signal some aspects of linguistic information.

Many languages of the world are known as tone languages, because they use the fundamental frequency of the voice to distinguish between words. Chinese is a classic example of a tone language. There are four distinct tones in Chinese speech. Said with a falling fundamental frequency of the voice, *ma* means “to scold.” Said with a rising fundamental frequency, it means “hemp.” With a level fundamental frequency it means “mother,” and with a dipping fundamental frequency it means “horse.” In Chinese, changing a tone has the same kind of effect on the meaning of a word as changing a vowel or consonant in a language such as English.

The activity of the structures above and including the larynx in forming speech sound is known as articulation. It involves some muscles of the pharynx, palate, tongue, and face and of mastication.

The primary types of speech sounds of the major languages may be classified as vowels, nasals, plosives, and fricatives. They may be described in terms of degree and place of constriction along the vocal tract. *See* PHONETICS.

The only source of excitation for vowels is at the glottis. During vowel production the vocal tract is relatively open and the air flows over the center of the tongue, causing a minimum of turbulence. The phonetic value of the vowel is determined by the resonances of the vocal tract, which are in turn determined by the shape and position of the tongue and lips.

The nasal cavities can be coupled onto the resonance system of the vocal tract by lowering the velum and permitting airflow through the nose. Vowels produced with the addition of nasal resonances are known as nasalized vowels. Nasalization may be used to distinguish meanings of words made up of otherwise identical sounds, such as *bas* and *banc* in French. If the oral passage is completely constricted and air flows only through the nose, the resulting sounds are nasal consonants. The three nasal consonants in “meaning” are formed with the constriction successively at the lips, the hard palate, and the soft palate.

Plosives are characterized by the complete interception of airflow at one or more places along the vocal tract. The places of constriction and the manner of the release are the primary determinants of the phonetic properties of the plosives. The words “par,” “bar,” “tar,” and “car” begin with plosives. When the interception is brief and the constriction is not necessarily complete, the sound is classified as a flap. By tensing the articulatory mechanism in proper relation to the airflow, it is possible to set the mechanism into vibrations which quasiperiodically intercept the airflow. These sounds are called trills.

These are produced by a partial constriction along the vocal tract which results in turbulence. Their properties are determined by the place or places of constriction and the shape of the modifying cavities. The fricatives in English may be illustrated by the initial and final consonants in the words “vase,” “this,” “faith,” “hash.”

The ability to produce meaningful speech is dependent in part upon the association areas of the brain. It is through them that the stimuli which enter the brain are interrelated. These areas are connected to motor areas of the brain which send fibers to the motor nuclei of the cranial nerves and hence to the muscles. Three neural pathways are directly concerned with speech production, the pyramidal tract, the extrapyramidal, and the cerebellar motor paths. It is the combined control of these pathways upon nerves arising in the medulla and ending in the muscles of the tongue, lips, and larynx which permits the production of speech. *See* NERVOUS SYSTEM (VERTEBRATE).

Six of the 12 cranial nerves send motor fibers to the muscles that are involved in the production of speech. These nerves are the trigeminal, facial, glossopharyngeal, vagus, spinal accessory, and the hypoglossal. *See* PSYCHOACOUSTICS; PSYCHOLINGUISTICS.

Development. In the early stages of speech development the child’s vocalizations are quite random. The control and voluntary production of speech are dependent upon physical maturation and learning.

It is possible to describe the development of speech in five stages. In the first stage the child makes cries in response to stimuli. These responses are not voluntary but are part of the total bodily expression. The second stage begins between the sixth and seventh week. The child is now aware of the sounds he or she is making and appears to enjoy this activity. During the third stage the child begins to repeat sounds heard coming from himself or herself. This is the first time that the child begins to link speech production to hearing. During the ninth or tenth month the child enters the fourth stage and begins to imitate without comprehension the sounds that others make. The last stage begins between the twelfth and eighteenth month, with the child intentionally employing conventional sound patterns in a meaningful way. The exact time at which each stage may occur varies greatly from child to child.

Speech technology. Speech technology has been developing within three areas. One has to do with identifying a speaker by analyzing a speech sample. Since the idea is analogous to that of identifying an individual by fingerprint analysis, the technique has been called voice print. However, fingerprints have two important advantages over voice prints: (1) they are based on extensive data that have accumulated over several decades of use internationally, whereas no comparable reference exists for voice prints; and (2) it is much easier to alter the characteristics of speech than of fingerprints. Consequently, this area has remained largely dormant. Most courts in the United States, for instance, do not admit voice prints as legal evidence.

The two other areas of speech technology, synthesis and recognition, have seen explosive growth. In many applications where a limited repertoire of speech is required, computer-synthesized speech is used instead of human speakers. A common technology currently used in speech synthesis involves an inventory of pitch-synchronized, prestored human speech. These prestored patterns are selected according to the particular requirements of the application and recombined with some overlap into the desired sentence by computer, almost in real time. The quality of synthesized speech for English is remarkably good, though it is limited at present to neutral, emotionless speech. Many other languages are being synthesized with varying degrees of success.

The recognition of speech by computer is much more difficult than synthesis. Instead of just reproducing the acoustic wave, the computer must understand something of the semantic message that the speech wave contains, in order to recognize pieces of the wave as words in the language. Humans do this easily because they have a great deal of background knowledge about the world, because they are helped by contextual clues not in the speech wave, and because they are extensively trained in the use of speech. Nonetheless, given various constraints, some of the existing systems do remarkably well. These constraints include (1) stable acoustic conditions in which speech is produced, (2) a speaker trained by the system, (3) limited inventory of utterances, and (4) short utterances. The research here is strongly driven by the marketplace, since all sorts of applications can be imagined where spoken commands are required or highly useful. *See* SPEECH DISORDERS. [W.S.Y.W.]

Speech disorders

Speech disorders may be classified according to their causes or symptoms. The major causes are organic, imitative environmental, and psychogenic. Organic disorders may result from disease, impairment, or absence of the organs of speech. Imitative disorders occur when the child imitates defective speech. A speech disorder has a psychogenic origin when there is a psychological basis for its presence. A classification includes disorders of articulation, rhythm, voice, and symbolization.

Disorders of articulation may be so severe that the resultant speech is unintelligible. Specific sounds or groups of sounds may be omitted, added, substituted, or distorted. The following are some examples of this type of disorder: Lalling, involving misarticulated r, l, t, and d sounds, may be caused by poor control of the tongue tip. In lisping, misarticulated sibilant sounds, particularly s and z, are often substituted by the th sound. Delayed speech, involving the absence of many consonants and poor intelligibility, is often caused by slow physical or psychological maturation. Dysarthria, generalized sound substitutions and distortions, is caused by lesions in the peripheral or central nervous system.

Disorders of rhythm are characterized by disruptions of the normal rate of speech. Two common disorders of rhythm are stuttering or stammering and cluttering.

Voice disorders are usually described as defects of pitch, loudness, and voice quality. Improper use of the voice may cause an injury to the vocal folds and intensify an existing voice disorder. Disorders of pitch are characterized as too high, too low, monotonous, and repeated pitch patterns. A high-pitched voice is most often caused by psychological tension. The muscles of the larynx are contracted so that the pitch is raised beyond its normal range. Voice quality disorders are usually described as hoarseness, nasality, denasality, and similar conditions. Hoarseness may be caused by pharyngeal or laryngeal pathologies. Cleft palate speech is a striking example of nasality. Nasal speech may also follow a paralysis of the palatal muscles. The nasal speech results because the palate is unable to aid in achieving nasopharyngeal closure.

Symbolization disorders involve an impairment of language formulation and expression. They may occur without a concomitant impairment of speech production. Common types of these disorders are aphasia and delayed speech. *See* SPEECH. [R.S.T.; W.S.Y.W.]

Speech perception A term broadly used to refer to how an individual understands what others are saying. More narrowly, speech perception is viewed as the way a listener can interpret the sound that a speaker produces as a sequence of discrete linguistic categories such as phonemes, syllables, or words. *See* PHONETICS; PSYCHOLINGUISTICS.

Classical work in the 1950s and 1960s concentrated on uncovering the basic acoustic cues that listeners use to hear the different consonants and vowels of a language. It revealed a surprisingly complex relationship between sound and percept. The same physical sound (such as a noise burst at a particular frequency) can be heard as different speech categories depending on its context (as "k" before "ah," but as "p" before "ee" or "oo"), and the same category can be cued by different sounds in different contexts. Spoken language is thus quite unlike typed or written language, where there is a relatively invariant relationship between the physical stimulus and the perceived category.

The reasons for the complex relationship lie in the way that speech is produced: the sound produced by the mouth is influenced by a number of continuously moving and largely independent articulators. This complex relationship has caused great difficulties in programming computers to recognize speech, and it raises a paradox. Computers readily recognize the printed word but have great difficulty recognizing speech. Human listeners, on the other hand, find speech naturally easy to understand but have to be taught to read (often with difficulty). It is possible that humans are genetically predisposed to acquire the ability to understand speech, using special perceptual mechanisms usually located in the left cerebral hemisphere. *See* HEMISPHERIC LATERALITY.

Building on the classical research, the more recent work has drawn attention to the important contribution that vision makes to normal speech perception; has explored the changing ability of infants to perceive speech and contrasted it with that of animals; and has studied the way that speech sounds are coded by the auditory system and how speech perception breaks down in those with hearing impairment.There has also been substantial research on the perception of words in continuous speech.

Adult listeners are exquisitely sensitive to the differences between sounds that are distinctive in their language. The voicing distinction in English (between "b" and "p") is cued by the relative timing of two different events (stop release and voice onset). At a difference of around 30 milliseconds, listeners hear an abrupt change from one category to another, so that a shift of only 5 ms can change the percept. On the other hand, a similar change around a different absolute value, where both sounds are heard as the same category, would be imperceptible. The term categorical perception refers to this inability to discriminate two sounds that are heard as the same speech category.

Categorical perception can arise for two reasons: it can have a cause that is independent of the listener's language—for instance, the auditory system may be more sensitive to some changes than to others; or it can be acquired as part of the process of learning a particular language. The example described above appears to be language-independent, since similar results have been found in animals such as chinchillas whose auditory systems resemble those of humans. But other examples have a language-specific component. The ability to hear a difference between "r" and "l" is trivially easy for English listeners, but Japanese perform almost at chance unless they are given extensive training. How such language-specific skills are developed has become clearer following intensive research on speech perception in infants.

Newborn infants are able to distinguish many of the sounds that are contrasted by the world's languages. Their pattern of sucking on a blind nipple signals a perceived change in a repeated sound. They are also able to hear the similarities between sounds such as those that are the same vowel but have different pitches. The ability to respond to such a wide range of distinctions changes dramatically in the first year of life. By 12 months, infants no longer respond to some of the distinctions that are outside their native language, while infants from language communities that do make those same distinctions retain the ability. Future experience could reinstate the ability, so it is unlikely that low-level auditory changes have taken place; the distinctions, although still coded by the sensory system, do not readily control the infant's behavior.

Although conductive hearing losses can generally be treated adequately by appropriate amplification of sound, sensorineural hearing loss involves a failure of the frequency-analyzing mechanism in the inner ear that humans cannot yet compensate for. Not only do sounds need to be louder before they can be heard, but they are not so well separated by the ear into different frequencies. Also, the sensorineurally deaf patient tolerates only a limited range of intensities of sound; amplified sounds soon become unbearable (loudness recruitment).

These three consequences of sensorineural hearing loss lead to severe problems in perceiving a complex signal such as speech. Speech consists of many rapidly changing frequency components that normally can be perceptually resolved. The lack of frequency resolution in the sensorineural patient makes it harder for the listener to identify the peaks in the spectrum that distinguish the simplest speech sounds from each other; and the use of frequency-selective automatic gain controls to alleviate the recruitment problem reduces the distinctiveness of different sounds further. These patients may also be less sensitive than people with normal hearing to sounds that change over time, a disability that further impairs speech perception.

Some profoundly deaf patients can identify some isolated words by using multichannel cochlear implants. Sound is filtered into different frequency channels, or different parameters of the speech are automatically extracted, and electrical pulses are then conveyed to different locations in the cochlea by implanted electrodes. The electrical pulses stimulate the auditory nerve directly, bypassing the inactive hair cells of the damaged ear. Such devices cannot reconstruct the rich information that the normal cochlear feeds to the auditory nerve. *See* HEARING (HUMAN); HEARING AID; HEARING IMPAIRMENT; PERCEPTION; PSYCHOACOUSTICS; SPEECH. [C.J.Da.]

Speech recognition In a strict sense, the process of electronically converting a speech waveform (as the acoustic realization of a linguistic expression) into words (as a best-decoded sequence of linguistic units). At times it can be generalized to the process of extracting a linguistic notion from a sequence of sounds, that is, an acoustic event, which may encompass linguistically relevant components, such as words or phrases, as well as irrelevant components, such as ambient noise, extraneous or partial words in an utterance, and so on. Applications of speech recognition include an automatic typewriter that responds to voice, voice-controlled access to information services (such as news and messages), and automated commercial transactions (for example, price inquiry or merchandise order by telephone), to name a few. Sometimes, the concept of speech recognition may include "speech understanding," because the use of a speech recognizer often involves understanding the intended message expressed in the spoken words. Currently, such an understanding process can be performed only in an extremely limited sense, often for the purpose of initiating a particular service action among a few choices. For example, a caller's input utterance "I'd like to borrow money to buy a car" to an automatic call-routing system of a bank would connect the caller to the bank's loan department.

Converting a speech waveform into a sequence of words involves several essential steps. First, a microphone picks up the acoustic signal of the speech to be recognized and converts it into an electrical signal. A modern speech recognition system also requires that the electrical signal be represented digitally by means of an analog-to-digital (A/D) conversion process, so that it can be processed with a digital computer or a microprocessor.

This speech signal is then analyzed (in the analysis block) to produce a representation consisting of salient features of the speech. The most prevalent feature of speech is derived from its short-time spectrum, measured successively over short-time windows of length 20–30 milliseconds overlapping at intervals of 10–20 ms. Each short-time spectrum is transformed into a feature vector, and the temporal sequence of such feature vectors thus forms a speech pattern.

The speech pattern is then compared to a store of phoneme patterns or models through a dynamic programming process in order to generate a hypothesis (or a number of hypotheses) of the phonemic unit sequence. (A phoneme is a basic unit of speech and a phoneme model is a succint representation of the signal that corresponds to a phoneme, usually embedded in an utterance.) A speech signal inherently has substantial variations along many dimensions. First is the speaking rate variation—a speaker cannot produce a word of identical duration at will. Second, articulation variation is also abundant, in terms both of talker-specific characteristics and of the manner in which a phoneme is produced. Third, pronunciation variation occurs among different speakers and in various speaking contexts (for example, some phonemes may be dropped in casual conversation). Dynamic programming is performed to generate the best match while taking these variations into consideration by compressing or stretching the temporal pattern and by probabilistically conjecturing how a phoneme may have been produced. The latter includes the probability that a phoneme may have been omitted or inserted in the utterance. The knowledge of probability (often called a probabilistic model of speech) is obtained via “training,” which computes the statistics of the speech features from a large collection of spoken utterances (of known identity) according to a mathematical formalism.

The hypothesized phoneme sequence is then matched to a stored lexicon to reach a tentative decision on the word identity. The decoded word sequence is further subject to verification according to syntactic constraints and grammatical rules, which in turn define the range of word hypotheses for lexical matching. This process of forming hypotheses about words and matching them to the observed speech pattern, and vice versa, in order to reach a decision according to a certain criterion is generally referred to as the “search.” In limited domain applications in which the number of legitimate expressions is manageably finite, these constraints can be embedded in an integrated dynamic programming process to reduce search errors.

The degree of sophistication of a speech recognition task is largely a function of the size of the vocabulary it has to deal with. A task involving, say, less than 100 words is called small vocabulary recognition and is mostly for command-and-control applications with isolated word utterances as input. There are usually very few grammatical constraints associated with these types of limited tasks. When the vocabulary size grows to 1000 words, it is possible to construct meaningful sentences, although the associated grammatical rules are usually fairly rigid. For dictation, report writing, or other tasks such as newspaper transcription, a speech recognition system with a large vocabulary (on the order of tens of thousands of word entries) is needed. *See* LINGUISTICS; PSYCHOACOUSTICS; SPEECH.

The technology of speech recognition often finds applications in speaker recognition tasks as well. Speaker recognition applications can be classified into two essential modes, speaker identification and speaker verification. The goal of speaker identification is to use a machine to find the identity of a talker, in a known population of talkers, using the speech input. Speaker verification aims to authenticate a claimed identity from the voice signal. [B.H.J.]

Speed The time rate of change of position of a body without regard to direction. It is the numerical magnitude only of a velocity and hence is a scalar quantity. Linear speed is commonly measured in such units as meters per second, miles per hour, or feet per second.

Average linear speed is the ratio of the length of the path traversed by a body to the elapsed time during which the body moved through that path. Instantaneous speed is the limiting value of the foregoing ratio as the elapsed time approaches zero. *See* VELOCITY. [R.D.Ru.]

Speed regulation The change in steady-state speed of a machine, expressed in percent of rated speed, when the machine load is reduced from rated load to zero. The definition of regulation is usually taken to mean the net change in a steady-state characteristic, and does not include any transient deviation or oscillation that may occur prior to reaching the new operation point. This same definition is used for stating the speed regulation of electric motors as well as for certain drive systems, such as steam turbines. [P.M.A.]

Speedometer A device for indicating the speed of a vehicle. There are three types of speedometers in general use: mechanical analog, quartz electric analog, and digital microprocessor.

The mechanical analog speedometer is driven by a cable housed in a casing and connected to a gear at the transmission. This gear is designed for the particular vehicle model, considering the vehicle’s tire size and rear axle ratio. In most cases, the speedometer is designed to convert 1001 revolutions of the drive cable into registering 1 mi on the odometer, which records distance traveled by the vehicle. The speed-indicating portion of the speedometer operates on the magnetic principle. In the speedometer head, the drive cable attaches to a revolving permanent magnet that rotates at the same speed as the cable. Floating on bearings between the upper frame and the revolving permanent magnet is a nonmagnetic movable speed cup. The magnet revolves within the speed cup, producing a rotating magnetic field. The magnetic field is constant, and the amount of speed cup movement is at all times in proportion to the speed of the magnet rotation. A pointer, attached to the speed cup spindle, indicates the speed on the speedometer dial. *See* MAGNETIC FIELD.

The quartz speedometer utilizes an accurate clock signal supplied by a quartz crystal, along with integrated electronic circuitry to process an electrical speed signal. This signal is generated by a permanent-magnet generator mounted in the transmission. This permanent-magnet generator, designed to be used with both quartz and digital speedometers, provides a sinusoidal speed signal that is proportional to vehicle speed at the rate of 4004 pulses per mile (2503 per kilometer).

In the digital microprocessor speedometer, the vehicle speed is monitored by the permanent speed sensor mounted in the transmission. The signal is transmitted to the microprocessor where the counter converts the speed signal to a digital signal and stores it in memory. The timing circuit has the capacity to handle the counter and memory storage in less than 0.25 s. Memory circuit signals are sent to the electronic display circuit, which selects the display numerals representing the vehicle’s speed, according to the number of pulses received from the speed sensor. *See* AUTOMOTIVE TRANSMISSION; ELECTRONIC DISPLAY. [R.A.Gr.]

Spelaeogriphacea A crustacean order within the Malacostraca: Peracarida, erected for a single living species. *Spelaeogriphus lepidops*. This shrimplike animal lives in a stream inside a cave on Table Mountain, South Africa. *Spelaeogriphus* has a slender, flexible body, seven pairs of walking legs, five pairs of swimmerets, and a very long flagellum on each second antenna. A short carapace is fused to the first thoracic segment, covers the second, and forms ventrolateral branchial chambers, within which are cuplike gills, attached to the first thoracic segment. The animals creep over the stream bottom with their walking legs and swim by undulations of the whole trunk. *See* PERACARIDA. [J.H.L.]

Sperm cell The male gamete. The typical sperm of most animals has a head containing the nucleus and acrosome, a middle piece with the mitochondria, and a tail with the 9 + 2 microtubule pattern (see illustration). Sperm, as well as the acrosome shape, varies with the species. The nucleus consists of condensed chromatin (deoxyribonucleic acid, DNA) and histone proteins. The acrosome, which is derived from the Golgi complex, contains hydrolytic enzymes, that is, hyaluronidase capable of lysing the egg coats at fertilization. Actin molecules which aid in the interaction between sperm and egg are found in the area between the acrosome and nucleus. The mitochondria in the middle piece apparently provide the energy necessary for the motility created by the tail. The tail has a central core, or axial filament, made up of nine double tubules and two central tubules. *See* CILIA AND FLAGELLA.

Many groups, including nematodes, myriapods, and crustaceans, have atypical sperm which lack a flagellum and are presumably nonmotile. The sperm of *Ascaris* is round and moves by ameboid means. The crustacean sperm have a large acrosome of several components. In the anomurans a middle with mitochondria and arms filled with microtubules precedes the nucleus. In the true crabs the nucleus forms arms which possess microtubules and also surrounds the many component acrosomes. The nucleus of crustacean sperm does not condense with maturation as it does in typical sperm mentioned above. *See* SPERMATOGENESIS. [G.W.H.]

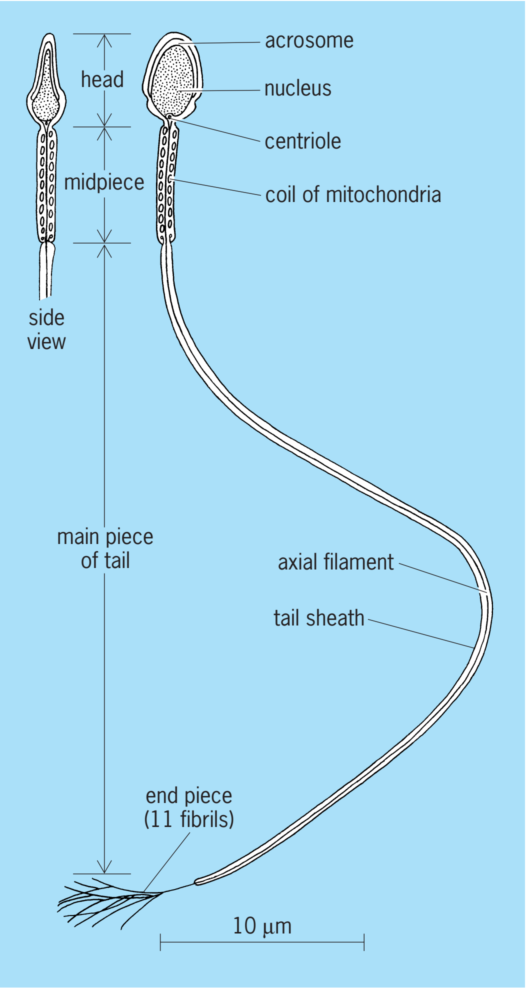


Diagram of a human spermatozoon, based on electron micrographs.

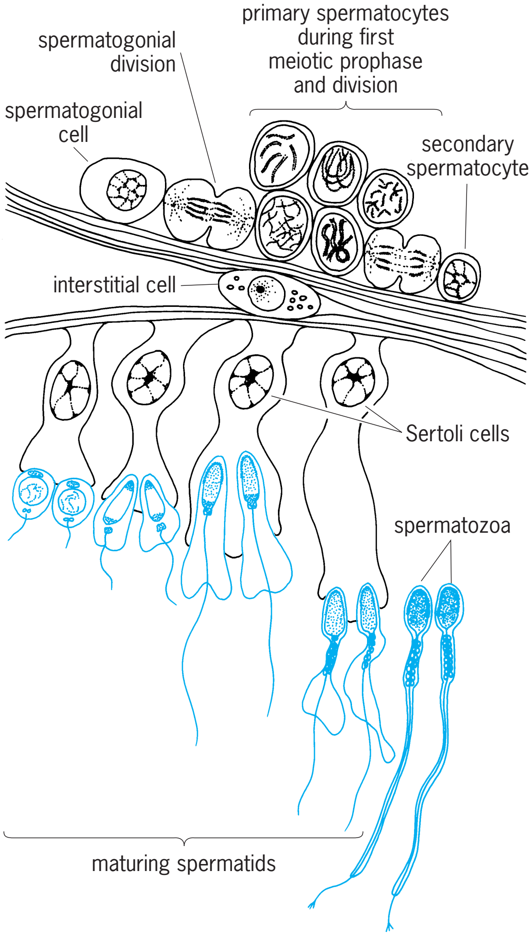
Spermatogenesis The differentiation of spermatogonial cells (primordial germ cells in the testes) into spermatozoa (see illustration).



Cellular events in human spermatogenesis.

Spermatogonial divisions occur continuously throughout the life of mammals; these divisions both maintain the stem cell population (spermatogonial cells) and supply cells which develop into sperm. Clusters of spermatogonia maintain communication through cytoplasmic bridges, and these groups become primary spermatocytes when they synchronously enter the first meiotic prophase. The first meiotic prophase is characterized by a series of remarkable changes in chromosome morphology, which are identical to those seen in the corresponding stage of oogenesis. The secondary spermatocyte produced by this division then undergoes a division in which the chromosomes are not replicated; the resulting spermatids contain half the somatic number of chromosomes. *See* MEIOSIS.

The spermatids become embedded in the cytoplasm of Sertoli cells, and there undergo the distinctive changes which result in formation of spermatozoa. These morphological transformations include the conversion of the Golgi apparatus into the acrosome and progressive condensation of the chromatin in the nucleus. A centriole migrates to a position distal to the nucleus and begins organizing the axial filament which will form the motile tail of the sperm. Mitochondria may fuse to form a nebenkern as is the case for many vertebrates, or there may be less extensive fusion as in mammals. In all cases the resulting structures become located around the axial filament in the midpiece. The cytoplasm of the spermatid is reflected distally away from the nucleus during spermatid maturation; eventually, most of the cytoplasm is sloughed off and discarded.

The Sertoli cells are thought to provide nutrition for the developing sperm, because their cytoplasm contains large stores of glycogen which diminish as spermatids mature. There is no direct evidence for this nutritive function, but some forms of male sterility are associated with the failure to produce normal Sertoli cells. Electron microscopy has revealed distinct plasma membranes surrounding the two cell types at the points of contact, and thus the Sertoli cell-spermatid relationship is not syncytial as once thought.

Spermatogenesis is cyclical to a varying extent depending on the species, and under endocrine control. Spermatogenesis is maintained and regulated by male steroid hormones such as testosterone, which is produced by the interstitial or Leydig cells found in the connective tissue of the testis. Interstitial cells, in turn, are stimulated by luteinizing hormone (LH) which is produced by the pituitary gland. The male testis-regulating hormone was formerly known as interstital cell-stimulating hormone (ICSH), but it is now known to be identical to LH. *See* ENDOCRINE MECHANISMS; GAMETOGENESIS; TESTIS. [S.J.B.]

Sphaeractinoidea An extinct group of fossil marine sponges closely related to modern Sclerospongiae and fossil Stromatoporoidea. They may have appeared as early as Late Carboniferous (Pennsylvania Period) of the Late Paleozoic Era. They were definitely present during the Permian Period at the close of the Paleozoic and flourished during the Mesozoic Era, especially during the Jurassic and Cretaceous, declining rapidly during the late Cretaceous, and may have persisted until Eocene time, during the Cenozoic Era.

Like the stromatoporoids, they have a radial canal system; in vertical thin section the skeleton is calcareous and characterized by a latticelike pattern. The vertical structures are round, short to long rodlike pillars. However, unlike the stromatoporoids, the horizontal component of the reticulum is trabecular or rodlike rather than separated parallel or concentric plates, or they may be thin, flat, or broadly arched cyst plates. *See* SCLEROSPONGIAE; STROMATOPOROIDEA. [J.St.J.]

Sphaerocarpales An order of liverworts in the subclass Marchantiidae, consisting of two families, the terrestrial Sphaerocarpaceae (*Sphaerocarpos* and *Geothallus*) and the aquatic Riellaceae (*Riella*). The plants are characterized by envelopes surrounding each antheridium and archegonium, absence of elaters, poor development of seta, and absence of thickenings in the unilayered wall of an indehiscent capsule.

The rhizoids are smooth, and air chambers and pores are lacking. Oil bodies may be present. The antheridia are separately contained within receptacles on the dorsal surface or at the margins, while the archegonia are separately produced in receptacles dorsally or behind the growing point. The sporophyte consists of a bulbous foot, short or obsolescent seta, and globose indehiscent capsule with a unilayered wall. *See* BRYOPHYTA. [H.C.]

Sphaerularoidea A superfamily of parasitic nematodes in the order Tylenchida. Adult females are hemocoel parasites of insects and mites; a few taxa contain both plant and insect parasites. In general, nematodes belonging to this group have three distinct phases in their life cycles: two free-living and one parasitic. In the free-living phase the female gonad is single, anteriorly directed, and with few developing oocytes and a prominent uterus filled with sperm. In the parasitic phase either the body becomes grossly enlarged and degenerates to a reproductive sac, or the uterus prolapses and gonadal development takes place outside the body. The males are always free-living and not infective. The most interesting taxon is *Sphaerularia bombi*, which prolapses the uterus. When totally prolapsed, the gonad becomes the parasite and the original female a useless appendage. It is not unusual for the prolapsed gonad to attain a volume 15,000 times that of the original female. *See* NEMATA. [A.R.M.]

Sphagnopsida A class of the plant division Bryophyta containing plants commonly called peatmosses. The spongelike plants grow as perennials in soft cushions or lawns in wet habitats (rarely they grow submerged). The class consists of a single genus, *Sphagnum*, of some 200 species. The thallose protonema, fascicled branches, dimorphous leaf cells, and spores developed from amphithecial tissue are characters unique to the class. The plants are ecologically important, owing to the spongelike construction of leaves and outer cells of stems and branches, and the ability, whether living or dead, to create acid conditions by exchanging hydrogen ions for cations in solution. The dried plant parts are used as a mulch in horticultural practice, and as fuel where the plant is abundant. *See* BRYOPHYTA. [H.Cr.]

Sphalerite A mineral, β-ZnS, also called blende. It is the low-temperature form and more common polymorph of ZnS, Pure β-ZnS on heating inverts to wurtzite, α-ZnS, at 1868°F (1020°C).

The mineral is most commonly in coarse to fine, granular, cleavable masses. The luster is resinous to submetallic; the color is white when pure, but is commonly yellow, brown, or black, darkening with increased percentage of iron. There is perfect dodecahedral cleavage; the hardness is $3^1/_2$ on Mohs scale; specific gravity is 4.1 for pure sphalerite.

Sphalerite is a common and widely distributed mineral. It occurs both in veins and in replacement deposits in limestones. As the chief ore mineral of zinc, sphalerite is mined on every continent. The United States is the largest producer, followed by Canada, Mexico, Russia, Australia, Peru, the Congo River area, and Poland. *See* WURTZITE; ZINC. [C.S.Hu.; P.B.M.]

Sphenisciformes The penguins, a small monotypic order of flightless, marine swimming birds found in the southern oceans. Classification schemes that hypothesize a link between penguins and loons have no support in fact.

Penguins are medium-sized to large birds. They are completely flightless, their wings having been modified into stiff, flattened flippers. They stand upright on legs that are far posterior and that terminate in four toes, the anterior three of which are webbed. Penguins swim and dive well, using only their wings for propulsion: their feet are used only for steering. Terrestrial locomotion is by walking, hopping, or sliding on the belly while pushing with the wings. The plumage consists of dense, scalelike feathers that are black dorsally and white ventrally. A distinctive pattern or crest, often yellow, occurs on the head. Penguins are gregarious, breeding in large colonies along the coast. The males and females, which are identical, form strong pair bonds and share in the incubation and care of the downy nestlings. The older young of some species are kept in large groups, or creches. The emperor penguin (*Aptenodytes forsteri*) breeds on the ice pack along the Antarctic coasts during the fall. Incubation of the one or two eggs is the responsibility of the male, which remains on the nest for over 2 months in the winter without eating.

Penguins are found only in the cold southern oceans, on the Antarctic continent and its surrounding islands and northward to Australia, New Zealand, South America, and Africa. One species, the Galápagos penguins (*Spheniscus mendiculus*), is found in the Galápagos Islands, which are on the Equator but are surrounded by the cold Humboldt Current. *See* AVES. [W.J.B.]

Sphenodonta One of the two surviving orders of lepidosaurian reptiles; they are represented today, however, by a single species, *Sphenodon punctatus*. They have a typical diapsid skull, and, also typically, the teeth are fused to the edges of the jaws; their only characteristic specialization is that the upper jaw forms an overhanging beak.

Sphenodon punctatus, the tuatara, is a moderate-sized (about 2–2½ ft or 0.6–0.8 m long) lizardlike reptile which is strictly conserved on a few small islands off the coast of New Zealand. It formerly inhabited the mainland but was hunted to extinction by humans. Among living reptiles the tuatara is unique in having no penis; its "pineal eye," however, is neither unique nor as functional as popularly supposed. By day it lives in shallow burrows, often in association with petrels; at night it emerges to feed on land snails and insects, especially crickets. Courtship behavior terminates with mating (fertilization is internal, despite the lack of penis in the male), after which the female leaves the male and buries her small leathery eggs in a burrow to incubate for 12–13 months. *See* Lepidosauria; Reptilia. [A.J.C.]

Sphenophyllales An extinct group of articulate land plants, common during Late Pennsylvanian and Early Permian times. They are typified by *Sphenophyllum*, a small, branching plant, probably of trailing habit. The long, jointed stems had superposed, longitudinal, surficial ribs between nodes. The vascular system contained a solid xylem core with triangular primary wood. The leaves were wedge-shaped and had toothed, notched, or rounded distal margins. Long, terminal cones, when found detached, contained sporangia and spores. Most species were homosporous (produced spores of a single type). *See* Paleobotany. [S.H.M.]

Sphenophyta One of the major divisions (formerly known as Equisetophyta) of vascular plants that includes both living and fossil representatives. The three principal orders are Pseudoborniales (Devonian), Sphenophyllales (Devonian-Triassic), and Equisetales (Devonian-Recent); the Hyeniales (Devonian) may also be sphenophytes. *See* Equisetales; Hyeniales; Pseudoborniales; Sphenophyllales.

All sphenophytes are characterized by axes with distinct nodes that produce whorls of small leaves or branches; branches often contain longitudinal ribs and furrows. Internally the stems of sphenophytes are characterized by longitudinally oriented canals, some of which functioned in gaseous exchange. Secondary tissues were produced in a few fossil forms. The reproductive organs of this group are loosely arranged strobili or cones consisting of a central axis bearing whorls of modified branches, each terminating in a recurved, thick-walled sporangium. Most sphenophytes produced one type of spore (homospory), although a few fossil forms were heterosporous.

Today all that remains of the sphenophytes is the genus *Equisetum*, commonly called the horsetail or scouring rush. Except in Australia and New Zealand, the members are worldwide in distribution and typically grow in damp habitats along the edges of streams, although some species are adapted to mesic conditions. A few species attain considerable size, but none of these produce secondary tissues. *See* Embryobionta. [T.N.T.]

Sphere Both in euclidean solid geometry and in common usage the word sphere denotes a solid of revolution obtained by revolving a semicircle of radius r about its diameter. Its total volume is $V = {}^4\!/_3\pi r^3$.

However, in analytic geometry, and more generally in modern mathematics, the word sphere denotes a spherical surface that bounds a solid sphere. In this sense a sphere is the locus of all points P in three-dimensional space whose distance from a fixed point O (called the center) is equal to a given number. The word radius may refer either to one of the segments OP, or to their common length r. A plane that intersects a sphere in just one point is called a tangent plane and is perpendicular to the radius drawn from the center of the sphere to that point. A plane that intersects a sphere in more than one point intersects it in a circle. The circle is called a great circle or a small circle of the sphere according to whether the plane does or does not pass through the center of the sphere. If two parallel planes intersect a sphere, the spherical surface between them is called a zone.

Any great circle of a sphere divides it into two hemispheres. A second great circle cuts a hemisphere into two lunes. A third great circle cuts each lune into two spherical triangles. *See* Surface and solid of revolution. [J.S.F.]

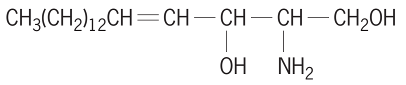
Spherical harmonics A spherical harmonic or solid spherical harmonic of degree n is a homogeneous function, $R_n(x, y, z)$, of degree n which satisfies Laplace's equation below. Here n

$$\Delta R \equiv \frac{{}^2R}{\partial y^2} + \frac{\partial^2 R}{\partial y^2} + \frac{\partial^2 R}{\partial z^2} \equiv 0$$

is any number, and $(x^2 + y^2 + z^2)^{(-n-1)/2}$. $R_n(x, y, z)$ is a spherical harmonic of degree $-n - 1$. There are analogous definitions for spaces of any number of dimensions. In the present article, n is a nonnegative integer and R_n, a polynomial in x, y, z (polynomial spherical harmonic). In terms of spherical coordinates r, τ, π, $R_n(x, y, z) = r^n S_n(\tau, \pi)$, where S_n, a polynomial in $\cos\tau$, $\sin\tau$, $\cos\pi$, $\sin\pi$, is a spherical surface harmonic of degree n. There are $2n + 1$ linearly independent spherical surface harmonics of degree n; any spherical surface harmonic of degree n is a linear combination of these, and conversely any linear combination of spherical surface harmonics of degree n is again a spherical surface harmonic of degree n.

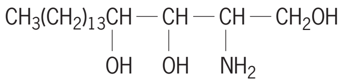
Spherical harmonics occur in potential theory. They occur in connection with Laplace's equation not only in spherical coordinates but also in spheroidal coordinates (spheroidal harmonics) and confocal coordinates (ellipsoidal surface harmonics). In spherical coordinates, spherical surface harmonics occur in connection with Laplace's and Poisson's equations, the wave equation, and the Schrödinger equation. In mathematical physics, spherical harmonics appear in the theories of gravitation, electricity and magnetism, hydrodynamics, and in other fields. [A.Er.]

Sphingolipid Any lipid containing the long-chain amino alcohol sphingosine (structure **1**) or a variation of it, such as dihydrosphingosine, phytosphingosine (structure **2**), or dehydrophytosphingosine. Sphingosine itself is synthesized by condensing a long-chain fatty acid with the amino acid serine.



$CH_3(CH_2)_{12}CH{=}CH{-}CH(OH){-}CH(NH_2){-}CH_2OH$

(1)



$CH_3(CH_2)_{13}CH(OH){-}CH(OH){-}CH(NH_2){-}CH_2OH$

(2)

Sphingosine is converted into a variety of derivatives to form the family of sphingolipids. The simplest form is a ceramide which contains a sphingosine and a fatty acid residue joined by an amide linkage. Ceramide is the basic building block of practically all of the naturally occurring sphingolipids. It can be further modified by the addition of a phosphorylcholine at the primary alcohol group to form sphingomyelin, a ubiquitous phospholipid in the plasma membranes of virtually all cells. Modification of a ceramide by addition of one or more sugars at the primary alcohol group converts it to a glycosphingolipid, which occurs widely in both the plant and animal kingdoms. *See* Glycoside; Lipid.

Sphingolipids participate in diverse cellular functions. A number of inheritable diseases that can cause severe mental retardation and early death occur as the result of a deficiency in one or more of the degradative enzymes, resulting in the accumulation of a particular sphingolipid in tissues. These diseases are collectively called sphingolipidoses and include Niemann-Pick disease, Gaucher disease, Krabbe disease, metachromatic leukodystrophy, and several forms of gangliosidoses, such as

Tay-Sachs disease. Functionally, glycosphingolipids are known to serve as important cell-surface molecules for mediating cell-to-cell recognition, interaction, and adhesion. They also serve as receptors for a variety of bacterial and viral toxins. Many glycosphingolipids can modulate immune responses as well as the function of hormones and growth factors by transmitting signals from the exterior to the interior of the cell. A number of glycolipids are also found to participate in a variety of immunological disorders by serving as autoantigens. Other sphingolipids and their metabolites may serve as second messengers in several signaling pathways that are important to cell survival or programmed cell death (apoptosis). *See* AUTOIMMUNITY; METABOLIC DISORDERS. [R.K.Y.]

Spica A 1st-magnitude star in the constellation Virgo. Spica (α Virginis) is a hot main-sequence star of spectral type B1, effective temperature about 25,000 K (45,000°F), at a distance of 80 parsecs from the Sun (2.59×10^{15} km or 1.61×10^{15} mi). *See* SPECTRAL TYPE.

It is a double-line spectroscopic binary with an orbital period of almost exactly 4 days. The system constitutes an example of an ellipsoidal variable, where the separation between the two stars is so small that powerful tidal forces distort the stars. The changing aspect of the primary as seen from Earth causes light variations with a period equal to the orbital period. The separation between the two stars is only about 3.5 times the radius of the primary. The primary itself is an intrinsic variable of the β Cephei type and is pulsating with a period of about 4 h. *See* BINARY STAR; STAR; VARIABLE STAR. [D.W.L.]

Spice and flavoring Ingredients added to food to provide all or a part of the flavor. Spices are pungent or aromatic substances of vegetable origin used in foods at levels that yield no significant nutritive value. Flavor is the perception of those characteristics of a substance taken orally that affect the senses of taste and olfaction. The term flavoring refers to a substance which may be a single chemical species or a blend of natural or synthetic chemicals whose primary purpose is to provide all or part of the particular flavor effect to any food or other product taken orally. Flavorings are categorized by source: animal, vegetable, mineral, and synthetic. *See* OLFACTION; TASTE.

Other than by source, flavorings can be divided into two groups; one group affects primarily the sense of taste, and the other affects primarily the sense of olfaction. The members of the first group are called seasonings, the members of the second group are called flavors. The same terms can be used to divide flavorings in another way. The term flavors can be applied to those products which provide a characterizing flavor to a food or beverage. The term seasoning can then be applied to those products which modify or enhance the flavor of a food or beverage—spices added to meats, blends added to potato chips, lemon added to apple pie.

In the United States most flavorings are processed. Therefore another classification is by method of manufacture. Chemicals are produced by chemical synthesis or physical isolation and include such substances as vanillin, salt, monosodium glutamate, citric acid, and menthol. Concentrates are powders manufactured by dehydrating vegetables, such as onions and garlic, or concentrated fruit juices. Condiments are single ingredients or blends of flavorful foods, spices, and seasonings, some of which may have been derived by fermentation, enzyme action, roasting, or heating. They are usually designed to be added to prepared food at the table (for example, chutney, vinegar, soy sauce, prepared mustard). Other manufactured flavorings include essential oils, hydrolyzed plant proteins, process flavors, and compounded or blended flavorings. *See* ESSENTIAL OILS.

Spices are natural substances that have been dehydrated and consist of whole or ground aromatic and pungent parts of plants, for example, anise, cinnamon, dill, nutmeg, and pepper. Such spices are also classified as herbs if grown in temperate climates.

Extracts are natural substances produced by extraction from solutions of the sapid constituents of spices and other botanicals in food-grade solvents. They are also available as synthetics. [E.J.M.]

Spilite An aphanitic (microscopically crystalline) to very-fine-grained igneous rock, with more or less altered appearance, resembling basalt but composed of albite or oligoclase, chlorite, epidote, calcite, and actinolite.

In spite of the highly sodic plagioclase, spilites are generally classed with basalts because of the low silica content (about 50%). They also retain many textural and structural features characteristic of basalt.

Spilites are found most frequently as lava flows and more rarely as small dikes and sills. Spilitic lavas typically show pillow structure, in which the rock appears composed of closely packed, elongated, pillow-shaped masses up to a few feet across. Pillows are typical of subaqueous lava flows. Vesicles, commonly filled with various minerals, may give the rock an amygdaloidal structure. *See* AMYGDULE; BASALT; IGNEOUS ROCKS. [W.I.R.]

Spin (quantum mechanics) The intrinsic angular momentum of a particle. It is that part of the angular momentum of a particle which exists even when the particle is at rest, as distinguished from the orbital angular momentum. The total angular momentum of a particle is the sum of its spin and its orbital angular momentum resulting from its translational motion. The general properties of angular momentum in quantum mechanics imply that spin is quantized in half integral multiples of $\hbar$ ($=h/2\pi$, where h is Planck's constant); orbital angular momentum is restricted to half even integral multiples of $\hbar$. A particle is said to have spin $^{3}/_{2}$, meaning that its spin angular momentum is $^{3}/_{2}$. *See* ANGULAR MOMENTUM.

A nucleus, atom, or molecule in a particular energy level, or a particular elementary particle, has a definite spin. The spin is an intrinsic or internal characteristic of a particle, along with its mass, charge, and isotopic spin. *See* QUANTUM MECHANICS; SYMMETRY LAWS (PHYSICS). [C.J.G.]

Spin glass One of a wide variety of materials which contain interacting atomic magnetic moments and also possess some form of disorder, in which the temperature variation of the magnetic susceptibility undergoes an abrupt change in slope, that is, a cusp, at a temperature generally referred to as the freezing temperature. At lower temperatures the spins have no long-range magnetic order, but instead are found to have static or quasistatic orientations which vary randomly over macroscopic distances. The latter state is referred to as spin-glass magnetic order. Spin-glass ordering is usually detected by means of magnetic susceptibility measurements, although additional data are required to demonstrate the absence of long-range order. Closely related susceptibility cusps can also be observed by using neutron diffraction. It is not generally agreed whether spin glasses undergo a phase transition or not. *See* MAGNETIC SUSCEPTIBILITY; NEUTRON DIFFRACTION; PHASE TRANSITIONS. [R.E.W.]

Spin label A molecule which contains an unpaired electron spin which can be detected with electron spin resonance (ESR) spectroscopy. Molecules are labeled when an atom or group of atoms which exhibits some unique physical property is chemically bonded to a molecule of interest. Groups containing unpaired electrons include organic free radicals and a variety of types of transition-metal complexes (such as vanadium, copper, iron, and manganese). Through analysis of ESR spectra, rates of molecular motion whose motion is restrained by surrounding molecules can be determined.

Analysis of the rate and type of motion of a spin label is important for a wide variety of biological problems. The type of label used in these studies is generally a nitroxide free radical. Spin-labeling studies provide a powerful technique for the study of the geometry and dimensions of receptors in enzymes. Spin labels have been used extensively to study the structure of membranes, and can provide important information about the organization and rates of motion in membranes. Spin labels have also been used to study the structure and organization of synthetic polymers and to study phase transitions. *See* CELL MEMBRANES; ELECTRON PARAMAGNETIC RESONANCE (EPR) SPECTROSCOPY; ENZYME. [R.Kr.]

Spinach A cool-season annual of Asiatic origin. *Spinacia oleracea*, belonging to the plant order Caryophyllales. It is grown for its foliage and served as a cooked vegetable or as a salad. New Zealand spinach (*Tetrogonia expansa*) and Mountain spinach (*Atriplex hortense*) are also called spinach but are less commonly grown. Spinach plants are usually dioecious. *See* CARYOPHYLLALES. [H.J.C.]

Spinal cord The portion of the central nervous system within the spinal canal of the vertebral column, that is, the entire central nervous system except the brain. The spinal cord extends from the foramen magnum at the base of the skull to a variable level of the spinal canal; it terminates at the lumbar level in humans and extends well into the caudal region in fishes.

The outer portion of the spinal cord is made up of nerve fibers most of which are oriented longitudinally and carry information between parts of the spinal cord, between spinal cord and brain, and between brain and spinal cord. The outer white matter is divided into dorsal, lateral, and ventral columns. The interior of the spinal cord consists of gray matter and is divided into a dorsal sensory horn (or column) and a ventral motor horn (or column). In the thoracic and lumbar regions of the cord there is also a small lateral horn (or column) which contains preganglionic sympathetic neurons. In the very center of the bilaterally symmetrical spinal cord is a small central canal, containing cerebrospinal fluid. *See* SYMPATHETIC NERVOUS SYSTEM.

Paired spinal nerves enter the spinal canal between each pair of vertebrae and connect with the spinal cord. The number of spinal nerves varies widely in vertebrates; in humans there are 31 pairs (8 cervical, 12 thoracic, 5 lumbar, 5 sacral, and 1 coccygeal). Each spinal nerve divides into a dorsal sensory root and a ventral motor root before entering the spinal cord. The motor neurons of the ventral horn, in addition to receiving synapses from dorsal root axons, also receive synaptic endings from neurons in other parts of the spinal cord and from long axons coming from the brain. The axons of the ventral horn neurons leave the cord through the ventral root of the spinal nerve and run with peripheral nerves to innervate the muscles of the body. With this complex synaptic and fiber organization, the spinal cord can act as the integrating center for spinal reflexes (such as the knee jerk reflex), send sensory information from the brain, and receive information from the brain to initiate or inhibit muscular activity. *See* MOTOR SYSTEMS; NERVOUS SYSTEM (VERTEBRATE); SENSATION. [D.B.W.]

Spinal cord disorders In addition to those disorders common to the brain, the spinal cord is subject to certain lesions because of its position or structure. A few of the more important are mentioned.

Spinal cord injury results from dislocations, fracture, or compression in many cases, but a special form, called spinal shock, may result from a severe blow without actual distortion of adjacent tissue. In this case, there is a temporary paralysis which gradually clears. In direct damage, the cord may be slightly, partially, or completely damaged at one or more levels. Typical motor and sensory losses follow, with a poor prognosis for recovery if the nerve tissue is severely injured.

A fairly common type of potential cord injury is seen in a number of cases of slipped disks, in which the inner, soft part of the vertebral column extrudes into the spinal canal. If this compresses the cord, functional loss of temporary or permanent degree can follow; more often, pressure is exerted on spinal roots so that pain, numbness, and some type of muscle weakness intervene.

Spinal cord tumors are not infrequent and most of these are of two types, the metastatic, from a primary source elsewhere in the body, and the tumors of the meninges or connective tissue related to the cord. The latter include neurofibromas, meningiomas, and gliomas, which occur most often. The signs and symptoms and the extent of damage relate largely to the physical compression of the cord at a particular level. *See* TUMOR.

A few of the more common congenital defects involving the cord include an unclosed neural canal, or spina bifida, and reduplicated or otherwise malformed cords, such as those caught in an external sac of other tissues, the meningomyelocoele.

Inflammations may result from known or unknown agents and in meningitis may involve primarily the coverings; in myelitis, the cord itself. The meningococcus, pneumococcus, streptococcus, tubercle bacillus, and other microorganisms frequently cause meningitis. The most widely known cause of myelitis, of course, is the poliomyelitis virus group.

An ill-defined group of disorders characterized by degeneration of nerve tracts or myelin sheaths of the cord is found more often than one would suspect. In these, some unknown or poorly understood mechanism causes the deterioration of cells and fibers so that function is altered, then lost, and the nervous tissue is either replaced by a scar or a softening of cystlike area remains. Multiple sclerosis, combined degeneration associated with pernicious anemia, Parkinson's disease, postinfectious encephalomyelitis, and syringomyelia are examples. *See* MULTIPLE SCLEROSIS; PARKINSON'S DISEASE; SPINAL CORD. [E.G.St.; N.K.M.]

Spin-density wave The ground state of a metal in which the conduction-electron-spin density has a sinusoidal variation in space, with a wavelength usually incommensurate with the crystal structure. This antiferromagnetic state normally occurs in metals, alloys, and compounds with a transition-metal component. It occurs also, however, in quasi-one-dimensional organic conductors. *See* ANTIFERROMAGNETISM; CRYSTAL STRUCTURE; ELECTRON SPIN; ORGANIC CONDUCTOR.

There are well over 100 materials which, over a temperature range, support a spin-density wave. These include some of the rare-earth elements of the lanthanide series and the 3*d* transition metals, manganese and chromium, the latter being the prototypical itinerant electron antiferromagnet. The occurrence of inelastic neutron-scattering peaks at incommensurate points indicates the existence of spin-density-wave fluctuations in some metals thought to be nonmagnetic (for example, copper and yttrium) when doped with magnetic impurities (manganese and gadolinium, respectively). This behavior suggests that the spin-density-wave instability may be common, even in nontransition metals. *See* RARE-EARTH ELEMENTS; TRANSITION ELEMENTS. [E.F.]

Spinel Any of a family of important AB_2O_4 oxide minerals, where A and B represent cations. Spinel minerals are widely distributed in the earth, in meteorites, and in rocks from the Moon. While the ideal spinel formula is $MgAl_2O_4$, some 30 elements, with valences from 1 to 6, are known to substitute in the A or B cation sites, resulting in well over 150 synthetic compounds having the spinel crystal structure. The term spinel is derived from *spina* (Latin, thorn) in reference to its pointed octahedral, crystal habit, and also to its dendritic snowflake form in rapidly chilled high-temperature slags and lavas.

The named spinel minerals that have so far been recorded in nature are oxides that occur as a matrix of A^{2+} versus B^{3+} cations. Three spinel series evolve from the classification: spinel, magnetite, and chromite. In addition to these spinels, there are other oxide, sulfur (thiospinels), silicate, and rare selenide-bearing spinels, all of which have relatively simple end-member compositions. *See* MAGNETITE.

Aluminous spinels are highly refractory, vary from translucent to transparent, and vary from colorless to green, blue, brown, and black. All other oxide and thiospinels are opaque with metallic lusters. Mohs hardness varies from about 4.5 (linnaeite) to about 8 (spinel). Density is approximately 5 g/cm^3 (3 oz/in.^{3}). Magnetite and maghemite are ferrimagnetic, with high saturation magnetizations and Curie temperatures of 580°C (1076°F) and 675°C (1247°F), respectively. *See* CURIE TEMPERATURE; FERRIMAGNETISM; HARDNESS SCALES.

Spinels are widely employed to deduce the evolutionary history of rocks because compositions are extremely sensitive to environmental conditions of formation. Emery, the abrasive, is magnetite + corundum. Chromite is the chief source of chromium. Iron, titanium and vanadium are derived from magnetite, and zinc is extracted from franklinite. Spinel also occurs as a semiprecious gem, and it is widely employed as a mechanically robust ceramic. The compass used in ancient times was a mixture of magnetite and maghemite; the entire fields of rock magnetism and paleomagnetism as well as the recorded history of the Earth's magnetic field hinge on the magnetic properties of these inverse spinels. Maghemite is widely employed in magnetic recording tapes and magnetic colloids. *See* MINERALOGY; PALEOMAGNETISM; PETROLOGY. [S.E.H.]

Spinicaudata An order of fresh-water branchiopod crustaceans formerly included in the order Conchostraca. The entire body and its appendages are covered by a bivalve carapace up to about 17 mm (0.7 in.) long, hence the name clam shrimp. The carapace is often bilaterally compressed and usually displays several lines of growth. The head cannot be protruded. Reproduction is usually bisexual. All species frequent temporary pools in many parts of the world, but *Cyclestheria* also occurs in permanent waters. *See* BRANCHIOPODA. [G.Fr.]

Spinning (metals) A production technique for shaping and finishing metal. In the spinning of metal, a sheet is rotated and worked by a round-ended tool. The sheet is formed over a mandrel. Spinning may serve to smooth wrinkles in drawn parts, provide a fine finish, or complete a forming operation as in curling an edge of a deep-drawn part. Spun products range from precision reflectors and nose cones to kitchen utensils. *See* SHEET-METAL FORMING. [R.L.Fr.]

Spinning (textiles) The fabrication of yarn (thread) from either discontinuous natural fibers or bulk synthetic polymeric material. In a textile context the term spinning is applied to two different processes leading to the yarns used to make threads, cords, ropes, or woven or knitted textile products.

Natural fibers, such as wool, cotton, or linen, are generally found as short, entangled filaments. Their conversion into yarn is referred to as spinning. After a carding operation on the raw material to disentangle the short filaments, the filaments are drawn (drafted) to promote alignment in an overlapping pattern and then twisted to form, by mechanical interlocking of the discontinuous filaments, a resistant continuous yarn. *See* COTTON; LINEN; WOOL.

The term spinning is also used for the production of monofilaments from synthetic polymers—for example, polyamides or nylons, polyesters, and acrylics—or modified natural polymers, such as cellulose-rayon. Generally the monofilaments are stretched (drawn) to increase their strength by promoting molecular orientation and are wound as yarn which can be used directly for threads, cords, or ropes. Such yarn, however, is often cut into relatively short lengths (staple) and reformed by a process similar to that used for natural fibers into a yarn more suitable, in terms of appearance and feel, for making certain textile products. *See* MANUFACTURED FIBER; NATURAL FIBER; TEXTILE. [J.M.Cha.]

Spiral A term used generically to describe any geometrical entity that winds about a central point or axis while also receding from it. Spiral staircases, helices, and nonplanar loxodromes (curves that intersect those of a given class at a constant angle, for example, rhumb lines, in case the curves are on a sphere whose meridians form the given class) are examples of spirals whose windings do not lie in a plane. *See* HELIX. [L.M.Bl.]

Spiriferida An extinct order of brachiopods, in the subphylum Rhynchonelliformea, that inhabited shallow seas of the Paleozoic and early Mesozoic. It was the most diverse group of spire-bearing brachiopods (those that contain a spirally coiled calcareous structure called the brachidium used to support the lophophore). Spiriferids also possess unequally biconvex valves that are externally smooth or radially ribbed. The valves are generally strophic (straight hinge) with a well-developed interarea commonly limited to the ventral valve. Shells may be punctate (possessing small perforations filled by outer epithelial tissue) or impunctate. Punctate shells arose in stratigraphically younger spiriferids; the presence or absence of punctae serves to distinguish two major taxonomic groups. Spiriferids were sessile, attached, epifaunal suspension feeders. Most had a functional pedicle, used for attachment to the substrate. *See* ARTICULATA (ECHINODERMATA); BRACHIOPODA. [M.E.P.]

Spirometry The measurement, by a form of gas meter, of volumes of gas that can be moved in or out of the lungs. The classical spirometer is a hollow cylinder (bell) closed at its top. With its open end immersed in a larger cylinder filled with water, it is suspended by a chain running over a pulley and attached to a counterweight. The magnitude of a gas volume entering or leaving is proportional to the vertical excursion of the bell. Volume changes can also be determined from measurements of flow, or rate of volume change, that can be sensed and recorded continuously by a transducer that generates an electrical signal. The flow signal can be continuously integrated to yield a volume trace.

The volume of gas moved in or out with each breath is the tidal volume; the maximal possible value is the vital capacity. Even after the most complete expiration, a volume of gas that cannot be measured by the above methods, that is, the residual volume, remains in the lungs. It is usually measured by a gas dilution method or by an instrument that measures blood flow in the lungs. Lung volumes can also be estimated by radiological or optical methods.

At the end of an expiration during normal resting breathing, the muscles of breathing are minimally active. Passive (elastic and gravitational) forces of the lungs balance those of the chest wall. In this state the volume of gas in the lungs is the functional residual capacity or relaxation volume. Displacement from this volume requires energy from natural (breathing muscles) or artificial (mechanical) sources. *See* RESPIRATION. [A.B.O.]

Spirophorida An order of sponges of the class Demospongiae, subclass Tetractinomorpha, with a globular shape and a skeleton of oxeas and triaenes as megascleres, and microspined, contorted, sigmalike microscleres. Members of this order range down to depths of at least 5900 ft (1800 m). *See* DEMOSPONGIAE. [W.D.H.]

Spirotrichia A major subclass of the class Ciliatea which contains those ciliate Protozoa that are typified by conspicuous, compound ciliary structures. The structures are the cirri, which occur on the ventral surface of the body, and the buccal organelles, which include the undulating membrane and the adoral zone of membranelles. This group of ciliates is classified into six orders. (see respective articles):

Subclass Spirotrichia
Order: Heterotrichida
Odontostomatida
Oligotrichida
Tintinnida
Entodiniomorphida
Hypotrichida

The orders in this subclass contain those organisms that are considered to be the most highly evolved ciliates. [J.O.C.]

Spirurida An order of nematodes in which the labial region is usually provided with two lateral labia or pseudolabia; in some taxa there are four or more lips; rarely lips are absent. Because of the variability in lip number, there is variation in the shape of the oral opening, which may be surrounded by teeth. The amphids are most often laterally located; however, in some taxa they may be located immediately posterior to the labia or pseudolabia. The stoma may be cylindrical and elongate or rudimentary. The esophagus is generally divisible into an anterior muscular portion and an elongate swollen posterior glandular region, where the multinucleate glands are located. Eclosion larvae are usually provided with a cephalic spine or hook and a porelike phasmid on the tail.

All known spirurid nematodes utilize an invertebrate in their life cycle; the definitive hosts are mammals, birds, reptiles, and rarely amphibians. The order contains four superfamilies: Spiruroidea, Physalopteroidea, Filarioidea, and Drilonematoidea.

Spiruroidea. The Spiruroidea comprise parasitic nematodes whose life cycle always requires an intermediate host for larvae to the third stage. The definitive hosts are mammals, birds, fishes, reptiles, and rarely amphibians; and spiruroids may be located in the host's digestive tract, eye, or nasal cavity or in the female reproductive system. Morphologically, the lip region is variable in Spiruroidea, ranging from four lips to none. When lips are present, the lateral lips are well developed and are referred to as pseudolabia. The cephalic and cervical region may be ornamented with cordons, collarettes, or cuticular rings. The stoma is always well developed and is often provided with teeth just inside the oral opening. In birds the nematodes are often associated with the gizzard, and the damage caused results in death, generally by starvation. When the muscles of the gizzard are destroyed, seeds pass intact and cannot be digested.

This superfamily contains the largest of all known nematodes, *Placentonema gigantissima*, parasitic in the placenta of sperm whales. Mature females attain a length of 26 ft (8 m) and a diameter of 1 in. (2.5 cm). The adult female has 32 ovaries, which produce great numbers of eggs. [A.R.M.]

Filarioidea. The Filarioidea contain highly specialized parasites of most groups of vertebrates. They are particularly common in amphibians, birds, and mammals. While they cannot be classified as completely harmless, most of the many hundreds of known species are not associated with any recognized disease. A limited number of species produce serious diseases in humans, and a few others produce serious diseases in domestic or wild animals. The filarial parasites of humans are found almost exclusively in the tropics, with some extension into the subtropics.

There are no conspicuous divisions into distinct body regions. Sexual dimorphism is the rule; in common with other nematodes, the female filarioid is at least twice as long as the male, and often the difference is much greater. The adult worms are found in a wide variety of places in the body of the vertebrate host, but each species has its preferred host and preferred location within that host.

All the known filariae require a bloodsucking arthropod intermediate host, usually an insect and commonly a dipteron, in which to complete embryonation. The microfilariae are ingested as the arthropod feeds. After embryonation is completed, the resulting infective larvae gain entrance into the definitive vertebrate in association with the next feeding of the arthropod. *See* NEMATA.

Filariasis. Filariasis is a disease caused by Filarioidea in humans or lower animals. The term is loosely used to indicate mere infection by such organisms. In human medicine, filariasis commonly refers to the disease caused by, or to infection with, one of the mosquito-borne, elephantoid-producing filarioids—most frequently *Wuchereria bancrofti*, less frequently *Brugia malayi*, and more recently *B. timori*. The only specific laboratory aid to diagnosis is the detection and identification of the microfilariae.

Onchocerciasis. This disease is caused by *Onchocerca volvulus* in the subcutaneous lymphatics. It is characterized by subcutaneous nodules which are most conspicuous where the skin lies close over bony structures, via cranium, pelvic girdle, joints, and shoulder blades. When they are on the head, the microfilariae reach the eyes. Ocular disturbances vary from mild transient bleary vision to total and permanent blindness.

Loa loa. The African eye worm, *Loa loa*, is the filarioidean worm most commonly acquired by Caucasian immigrants, including missionaries, in Africa. Transmission is by daytime-feeding sylvan deer-flies, genus *Chrysops*. The only preventive measures are protective clothing, including head nets. Repellents have some value. Fortunately, serious damage is rare even when the worm gets into the eye. The areas of pitting edema known as calabar swellings are painful and diagnostic. They commonly occur on the wrists, hands, arms, or orbital tissues. [G.F.O.]

Splachnales An order of the true mosses (subclass Bryidae), whose members are remarkable perennial plants that grow mainly on nitrogenous substrates, such as dung, and show considerable differentiation of neck tissue below the spore-bearing part of the capsule. The order consists of two families with about eight genera.

The plants are gregarious or dense-tufted, erect, and often forked. The leaves are soft, lanceolate or obovate, sometimes bordered at the margins, and commonly toothed. The single costa may be excurrent or terminate at or below the apex. The setae are elongate and the capsules erect with a noticeably differentiated neck. Stomata are very numerous in the neck, and have two guard cells. A single peristome is usually present, entire or forked with 16 teeth sometimes paired or joined in twos and fours. *See* BRYIDAE; BRYOPHYTA; BRYOPSIDA. [H.Cr.]

Spleen An organ of the circulatory system present in most vertebrates, lying in the abdominal cavity usually in close proximity to the left border of the stomach.

In humans the spleen normally measures about 1 by 3 by 5 in. (2.5 × 7.5 × 12.5 cm) and weighs less than $^1/_2$ lb (230 g). It is a firm organ with an oval shape and is indented on its inner surface to form the hilum, or stalk of attachment to the peritoneum. This mesentery fold also carries the splenic artery and vein to the organ.

The spleen is an important part of the blood-forming, or hematopoietic, system; it is also one of the largest lymphoid organs in the body and as such is involved in the defenses against disease attributed to the reticuloendothelial system. Although the chief functions of the spleen appear to be the production of lymphocytes, the probable formation of antibodies, and the destruction of worn-out red blood cells, other less well-understood activities are known. For example, in some animals it may act as a reservoir for red blood cells, contracting from time to time to return these cells to the bloodstream as they are needed. In the fetus and sometimes in later life, the spleen may be a primary center for the formation of red blood cells. Another function of the spleen is its role in biligenesis. Because the spleen destroys erythrocytes, it is one of the sites where extrahepatic bilirubin is formed. *See* BILIRUBIN; SPLEEN DISORDERS. [W.J.B.]

Spleen disorders The spleen is rarely the site of primary disorders except those of vascular origin, but it is frequently involved in systemic inflammations, metabolic diseases, and generalized blood disorders.

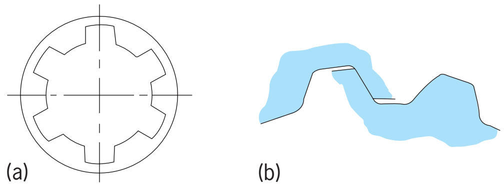
Among vascular disturbances, acute and chronic congestion are prominent, particularly chronic congestion caused by cardiac failure, cirrhosis of the liver, and obstruction of the blood flow from the spleen by thrombi, scarring, or tumor tissue. Obstruction of the splenic artery or its branches by thrombi may result in an infarct caused by either cardiac or blood disease.

Inflammations include acute and chronic forms. The characteristic engorgement of blood often causes a marked enlargement of the organ. Bacteremias frequently produce this enlargement, or splenomegaly, and inflammation, but any severe infectious disease such as diphtheria or pneumonia may do so.

The leukemias, especially when of the lymphocytic or neutrophilic varieties cause some of the most prominent cases of splenomegaly as well as other changes.

Tumors originating in the spleen are rare and usually limited to such benign growths as hemangiomas, lymphangiomas, and fibromas, but malignant lymphomas and lymphosarcomas also occur. Secondary tumors, which originate elsewhere and metastasize to the spleen, are not uncommon, particularly the lymphoma group. *See* SPLEEN. [E.G.St./N.K.M.]

Splines A series of projection and slots used instead of a key to prevent relative rotation of cylindrically fitted machine parts. Splines are several projections machined on the shaft; the shaft fits into a mating bore called a spline fitting. Splines are made in two forms, square and involute, as illustrated. Since there are several projections (integral keys) to share the force in transmitting power, the splines can be shallow, thereby not weakening the shaft as much as a standard key.



Diagrams of (*a*) square spline and (*b*) involute spline profile.

Three classes of fits are used for square splines: sliding (as for gear shifting) under load, sliding when not loaded, and permanent fit. Square splines have been used extensively for machine parts. In the automotive industry, square splines have been replaced generally by involute splines.

Involute splines are used to prevent relative rotation of cylindrically fitted machine parts and have the same functional characteristics as square splines. The involute spline, however, is like an involute gear, and the spline fitting (internal part) is like a mating internal gear. *See* MACHINE KEY. [P.H.B.]

Spodumene The name given to the monoclinic lithium pyroxene $LiAl(SiO_3)_2$. Spodumene commonly occurs as white to yellowish prismatic crystals, often with a "woody" appearance.

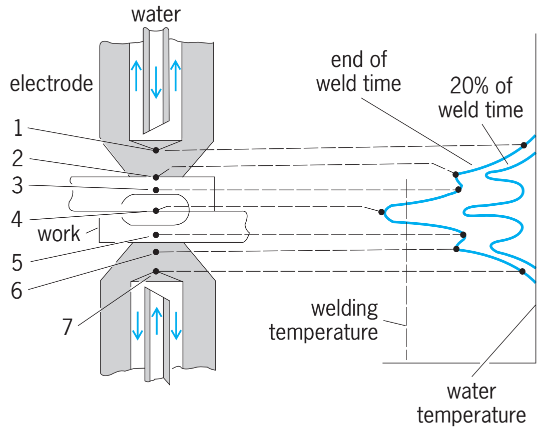
Spodumene is usually found as a constituent in certain granitic pegmatites. The emerald-green variety, hiddenite, and a lilac variety, kunzite, are used as precious stones. Spodumene from pegmatites is used as an ore for lithium. *See* LITHIUM; PYROXENE. [G.W.DeV.]

Spongiomorphida A small extinct order of Triassic and Jurassic marine invertebrate fossils of uncertain biologic affinities. The spongiomorphs had calcareous skeletons composed of small vertical rods called pillars and interconnecting horizontal rods called trabeculae or synapticulae. The pillars consist of upwardly inflected cone-in-cone layers of fibrous calcareous deposits. The trabeculae are formed from thickened zones at the base of the flare of the cones in the pillars. Spongiomorphs were sessile, benthonic, shallow marine organisms associated with calcareous deposits, especially reefs. *See* HYDROZOA. [J.St.J.]

Sporozoa A subphylum of Protozoa, typically with spores. The spores are simple and have no polar filaments. There is a single type of nucleus. There are no cilia or flagella except for flagellated microgametes in some groups. In most Sporozoa there is an alternation of sexual and asexual stages in the life cycle. In the sexual stage, fertilization is by syngamy, that is, the union of male and female gametes. All Sporozoa are parasitic. The subphylum is divided into three classes—Telosporea, Toxoplasmea, and Haplosporea. *See* HAPLOSPOREA; PROTOZOA; TELOSPOREA; TOXOPLASMEA. [N.D.L.]

Sports medicine A branch of medicine concerned with the effects of exercise and sports on the human body, including treatment of injuries. Sports medicine can be divided into three general areas: clinical sports medicine, sports surgery, and the physiology of exercise. Clinical sports medicine includes the prevention and treatment of athletic injuries and the design of exercise and nutrition programs for maintaining peak physical performance. Sports surgery is also concerned with the treatment of injuries from contact (human or object) sports. Exercise physiology, a growing field of sports medicine, involves the study of the body's response to physical stress. It comprises the science of fitness, the preservation of fitness, and the role of fitness in the prevention and treatment of disease. [O.A.]

Spot welding A resistance-welding process in which coalescence is produced by the flow of electric current through the resistance of metals held together under pressure. Usually the upper electrode moves and applies the clamping force. Pressure must be maintained at all times during the heating cycle to prevent flashing at the electrode faces. Electrodes are water-cooled and are made of copper alloys because pure copper is soft and deforms under pressure. The electric current flows through at least seven resistances connected in series for any one weld (see illustration). After the metals have been fused together, the electrodes usually remain in place sufficiently long to cool the weld. *See* RESISTANCE WELDING; WELDING AND CUTTING OF METALS. [E.J.L.]



Distribution of temperature in local (numbered) elements of a spot-welding operation.

Spray flow A special case of a two-phase (gas and liquid) flow in which the liquid phase is the dispersed phase and exists in the form of many droplets. The gas phase is the continuous phase, so abstract continuous lines (or surfaces) can be constructed through the gas at any instant without intersection of the droplets. The droplets and the gas have velocities that can be different, so both phases can move through some fixed volume or chamber and the droplets can move relative to the surrounding gas. *See* GAS; LIQUID; PARTICULATES; TWO-PHASE FLOW.

Spray flows have many applications. Sprays are used to introduce liquid fuel into the combustion chambers of diesel engines, turbojet engines, liquid-propellant rocket engines, and oil-burning furnaces. They are used in agricultural and household applications of insecticides and pesticides, for materials and chemicals processing, for fire extinguishing, for cooling in heat exchangers, for application of medicines, and for application of coatings (including paint and various other types of layered coatings). Common liquids (such as water, fuels, and paints) are used in sprays. It is sometimes useful to spray uncommon liquids such as molten metals. In the various applications, the approximately spherical droplets typically have submillimeter diameters that can be as small as a few micrometers. *See* METAL COATINGS.

Sprays are formed for industrial, commercial, agricultural, and power generation purposes by injection of a liquid stream into a gaseous environment. In addition, sprays can form naturally in a falling or splashing liquid. Injected streams of liquid tend to become unstable when the dynamic pressure (one-half of the gas density times the square of the liquid velocity) is much larger than the coefficient of surface tension divided by the transverse dimension. Typically, the liquid stream disintegrates into ligaments (coarse droplets) and then into many smaller spherical droplets. The breakup (or atomization) process is faster at higher stream velocity, and the final droplet sizes are smaller for higher stream velocities. Spray droplet sizes vary and typically are represented statistically by a distribution function. The number of droplets in a spray can be as high as a few million in a volume smaller than a liter. *See* ATOMIZATION; JET FLOW; SURFACE TENSION. [W.A.Si.]

Spread spectrum communication A means of communicating by purposely spreading the spectrum (frequency extent or bandwidth) of the communication signal well beyond the required bandwidth of the data modulation signal. Spread spectrum signals are typically transmitted by electromagnetic waves in free space, with usage in both nonmilitary and military systems.

Motivation for using spread spectrum signals is based on the following:

1. Spread spectrum systems have the ability to reject hostile as well as unintentional jamming by interfering signals.
2. Spread spectrum signals have a low probability of being intercepted or detected since the power in the transmitted wave is “spread” over a large bandwidth or frequency extent.
3. Since these signals cannot be readily demodulated without knowing the code and its precise timing, a level of message privacy is obtained.
4. The wide bandwidth of the spread spectrum signals provides tolerance to multipath (reflected waves that typically take longer to arrive at the receiver than the direct desired signal so that the two can be distinguished).
5. A high degree of precision in ranging (distance measuring) can be obtained by using one type of spread spectrum signaling called direct sequence, with applications to navigation.
6. Multiple access, or the ability to send many independent signals over the same frequency band, is possible in spread spectrum signaling.

See COMMUNICATIONS SCRAMBLING; ELECTRICAL INTERFERENCE; ELECTRONIC WARFARE; RADIO-WAVE PROPAGATION.

There are four generic types of spread spectrum signals: direct sequence (DS) or pseudonoise (PN), frequency hopping (FH), linear frequency modulation (chirp), and time hopping (TH). The first two methods are much more commonly used today than the other two.

Direct sequence modulation is characterized by phase-modulating a sine wave by an unending string of pseudonoise code chips (symbols of much smaller time duration than a bit). This unending string is typically based on a pseudonoise code that generates an apparently random sequence of code chips that repeats only after the pseudonoise code period. Digital data representing the information to be transmitted are binary phase-shift keyed onto the carrier. Then the pseudonoise code generator also binary phase-shift keys the carrier, and the composite signal is transmitted. *See* PHASE MODULATION.

In a direct-sequence system, the phase of the carrier changes pseudorandomly with the pseudonoise code. In a frequency-hopping system, the frequency of the carrier changes according to a pseudonoise code with a consecutive group of pseudonoise code chips defining a particular frequency. Typically either multiple frequency-shift keying (MFSK) or differential phase-shift keying (DPSK) is used as the data modulation. Multiple frequency-shift keying is a modulation scheme in which one of a number of tones (2, 4, 8, and so forth) is transmitted at a given time according to a group of consecutive data bits (n bits produce 2^n tones). At each hop frequency one of the 2^n tones is selected according to the n bits, and one of 2^n corresponding frequencies, centered about the hop frequency, is transmitted. In conjunction with frequency hopping, multiple frequency-shift keying would imply, at each instant of time, a given carrier frequency that depends on the hop-pseudonoise code sequence and the consecutive group of the most recent n data bits. Differential phase-shift keying is similar to phase-shift keying except that only the differences of the phases (not the actual phases) are encoded and noncoherent techniques (not requiring a carrier loop) can be employed at the receiver.

A device called a frequency synthesizer achieves the actual frequency selection. For example, a 12-bit segment of the pseudonoise code may correspond to one of 2^{12} different frequencies, so that one of approximately 4000 (2^{12}) frequencies is selected each hop time. Frequency synthesizers are used in both the transmitter and the receiver. The transmitter modulates the data by typically using either multiple frequency-shift keying or differential phase-shift keying modulation, which in turn is frequency-hopped by the frequency synthesizer. At the receiver, an acquisition process is utilized to synchronize the receiver frequency synthesizer with the received hopping signal, and then a tracking system maintains synchronism. Finally a bit synchronizer provides timing for the data demodulator which demodulates the original, transmitted data bits.

An important aspect of spread spectrum communications is multiple access. Code-division multiple access (CDMA) is a method by which spread spectrum signals are utilized to allow the use of multiple signals over the same frequency band. The two common types are direct-sequence CDMA (DS/CDMA) systems and frequency-hopped CDMA (FH/CDMA) systems. *See* MULTIPLEXING AND MULTIPLE ACCESS.

Although the early evolution of spread spectrum systems was motivated primarily by military interests, nonmilitary applications have enjoyed considerable development. One important example that has both military and nonmilitary users is the Global Positioning Systems (GPS), which is a direct-sequence, CDMA, spread spectrum system for transmitting the satellite ranging codes. *See* SATELLITE NAVIGATION SYSTEMS.

The space shuttle utilizes a direct-sequence spread spectrum communication system on its forward link. It relays data through the geostationary *Tracking and Data Relay Satellites* (*TDRS*). Another example in the military arena is the Milstar system, which utilizes frequency-hopping spread spectrum communication over a very large bandwidth to achieve considerable immunity from unfriendly jamming signals. *See* MILITARY SATELLITES; SPACE COMMUNICATIONS; SPACE SHUTTLE.

Globalstar is a commercial satellite system that utilizes a CDMA signal structure along with a bent-pipe transponder to provide communications much like a cell phone, except that Globalstar is satellite-based. Currently the handsets are considerably more expensive than cell phones. However, these phones have the advantage that they can be reached beyond the range of cell phones. *See* COMMUNICATIONS SATELLITE.

The main reception source of news stories for radio and newspapers is small spread spectrum ground stations. Another application of code-division multiple access is transmission directly by satellite from a bank's automatic teller machine to that bank's computer facility. A home security system using spread spectrum techniques imposed on the ac power line has been used in Japan. Many cordless telephones utilize direct-sequence spread spectrum techniques. [J.K.H.]

Spring (hydrology) A place where groundwater discharges upon the land surface because the natural flow of groundwater to the place exceeds the flow from it. Springs are ephemeral, discharging intermittently, or permanent, discharging constantly. Springs are usually at mean annual air temperatures. The less the discharge, the more the temperature reflects seasonal temperatures. Spring water usually originates as rain or snow (meteoric water).

Hot-spring water may differ in composition from meteoric water through exchange between the water and rocks. Common minerals consist of component oxides. Oxygen of minerals has more ^{18}O than meteoric water. Upon exchange, the water is enriched in ^{18}O. Most minerals contain little deuterium, so that slight deuterium changes occur. Some hot-spring waters are acid from the oxidation of hydrogen sulfide to sulfate.

Mineral spring waters have high concentrations of solutes and wide ranges in chemistry and temperatures; hot mineral springs may be classified as hot springs as well as mineral springs. Most mineral springs are high either in sodium chloride or sodium bicarbonate (soda springs) or both; other compositions are found, such as a high percentage of calcium sulfate from the solution of gypsum.

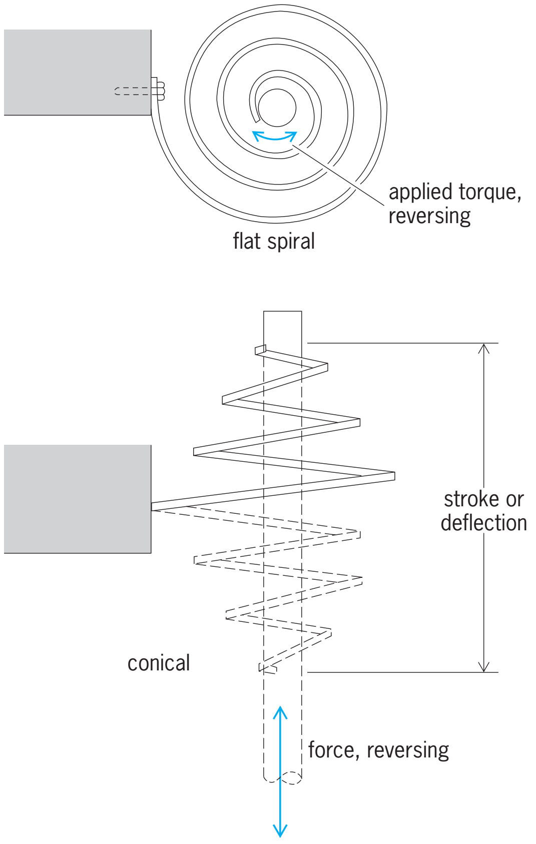
The chemical compositions of spring waters are seldom in chemical equilibrium with the air. Groundwaters whose recharge is through grasslands may contain a thousand times as much CO_2 as would be in equilibrium with air, and those whose recharge is through forests may contain a hundred times as much as would be in equilibrium with air. Sulfate in groundwater may be reduced in the presence of organic matter to H_2S, giving some springs the odor of rotten eggs. *See* GEYSER; GROUND-WATER HYDROLOGY. [I.B.]

Spring (machines) A machine element for storing energy as a function of displacement. Force applied to a spring member causes it to deflect through a certain displacement, thus absorbing energy.

A spring may have any shape and may be made from any elastic material. Even fluids can behave as compression springs and do so in fluid pressure systems. Most mechanical springs take on specific and familiar shapes such as helix, flat, or leaf springs. All mechanical elements behave to some extent as springs because of the elastic properties of engineering materials.

The most frequent use of springs is to supply motive power in a mechanism. Common examples are clock and watch springs, toy motors, and valve springs in auto engines. A special case of the spring as a source of motive power is its use for returning displaced mechanisms to their original positions, as in the door-closing device, the spring on the cam follower for an open cam, and the spring as a counterbalance. Frequently a spring in the form of a block of very elastic material such as rubber absorbs shock in a mechanism. Springs also serve an important function in vibration control. *See* SHOCK ABSORBER; SHOCK ISOLATION.

Springs may be classified into six major types according to their shape. These are flat or leaf, helical, spiral, torsion bar, disk, and constant force springs. A leaf spring is a beam of cantilever design with a deliberately large deflection under a load. The helical spring consists essentially of a bar or wire or uniform cross section wound into a helix. In a spiral spring, the spring bar or wire is wound in an Archimedes spiral in a plane. A spiral spring is unique in that it may be deflected in one of two ways or a combination of both of them (see illustration). A torsion bar spring consists essentially of a shaft or bar of uniform section. The disk spring consists essentially of a disk or washer supported at the outer periphery by one force and an opposing force on the center or hub of the disk. A constant force spring is used when a constant force must be applied regardless of displacement. [L.S.L.]



Spiral spring is unique in responding to torsional or translation forces.

Spruce Evergreen tree belonging to the genus *Picea* of the pine family. The needles are single, usually four-sided, and borne on little peglike projections; the cones are pendulous. Resin ducts in the wood may be seen with a magnifying lens, but they are fewer than in *Pinus*.

The white spruce (*P. glauca*), ranging from northern New England to the Lake States and Montana and northward into Alaska, is distinguished by the somewhat bluish cast of its needles, small cylindrical cones, and gray or pale-brown twigs without pubescence (hairs). Red spruce (*P. rubens*) is a similar tree but with greener foliage; smaller, more oval cones; and more or less pubescent twigs. Occurring naturally with white spruce in the northeastern United States and adjacent Canada, red spruce extends southward along the Appalachians into North Carolina. Black spruce (*P. mariana*) ranges from northern New England and Newfoundland to Alaska. However, it occurs sparingly in the Appalachians to West Virginia. The cones are smaller than in the white and red species and are egg-shaped or nearly spherical and persistent. The twigs are pubescent.

Blue spruce (*P. pungens*), also known as Colorado blue spruce, is probably the best known of the western species because of its wide use as an ornamental tree. The twigs are glabrous (without pubescence). Engelmann spruce (*P. engelmanni*) has needles usually of a deep blue-green color, sometimes much like those of the blue spruce but the young twigs are slightly hairy. The cones, although cylindrical, are smaller than in blue spruce. This species is also a Rocky Mountain tree like the blue spruce, but it is more widely distributed from British Columbia to Arizona and also in the mountains of Oregon and Washington. Sitka spruce (*P. sitchensis*) is the largest spruce in the Northern Hemisphere. The leaves have a pungent odor, are considerably flattened, and stand out from the twig in all directions. It ranges from Alaska to northern California. The Norway spruce (*P. abies*), the common spruce of Europe, is much planted in the United States for timber, as well as for ornamental purposes. It can be recognized by the dark-green color of the leaves; glabrous, pendent, short branchlets; and large cones, usually near the top of the tree. *See* PINALES. [A.H.G./K.P.D.]

Sputtering The ejection of material from a solid or liquid surface following the impact of energetic ions, atoms, or molecules. Sputtering is the basis of a large variety of methods for the synthesis and analysis of materials.

Sputtering can be classified according to the mode of energy loss of the incident (primary) particle. Nuclear stopping involves billiard ball-like atomic collisions in which a significant momentum transfer occurs; it dominates for incident ion energies below about 1–2 keV per nucleon. Electronic stopping involves collisions in which little momentum is transferred, but significant electronic excitation is caused in the target; it dominates for energies above about 10 keV per nucleon.

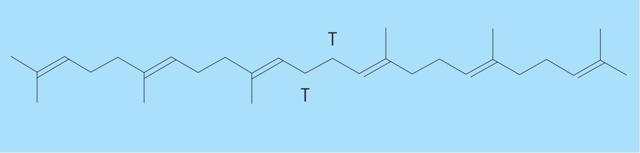
Sputtering has also been classified into physical and chemical sputtering. Physical sputtering involves a transfer of kinetic energy from the incident particle to the surface atoms leading to ejection, while chemical sputtering occurs when the incident species react chemically with the target surface leading to the formation of a volatile reaction product which evaporates thermally from the surface.

Sputtering of complex materials—metal alloys, inorganic and organic compounds and polymers, and minerals—can produce complex results. The relative efficiencies with which different elemental species are ejected following ion impact can differ, giving rise to preferential sputtering. When preferential sputtering occurs, the species sputtered with the lower efficiency accumulates to a higher concentration at the surface. Subsurface collisions of the incident ion cause atomic motion leading to atomic mixing of surface and subsurface layers over the ion penetration depth. Chemical bonds can be broken, and sometimes new bonds can be formed. Sputtering of solids which have multiple phases, or which are polycrystalline, leads to the development of surface roughness due to the differences in sputtering yields between different regions. *See* ION BEAM MIXING.

Sputtering is widely used in the manufacture of semiconductor devices; sputter deposition is used to deposit thin films with a high degree of control by sputtering material from a target onto a substrate; sputter etching is used to remove unwanted films in a reversal of this process. Reactive ion etching is a chemical sputtering process in which chemically active sputtering species form volatile compounds with the target material leading to significantly higher etch rates and great selectivity. For example, fluorine-containing compounds etch silicon rapidly by forming volatile silicon tetrafluoride but do not etch aluminum or other metals used to make electrical interconnections between devices on a semiconductor chip because the metal fluorides are involatile. Sputter etching and reactive ion etching have the useful advantage of being anisotropic—that is, they etch only in one direction so that very fine surface features can be delineated. *See* CRYSTAL GROWTH; GLOW DISCHARGE; INTEGRATED CIRCUITS.

In materials characterization, sputtering is used to remove surface material controllably, allowing in-depth concentration profiles of chemical composition to be determined with a surface-sensitive sampling technique. *See* SURFACE PHYSICS. [P.Wi.]

Squalene A C_{30} triterpenoid hydrocarbon. Squalene is made up of six (*trans*-1,4)-isoprene units linked as two farnesyl (head-to-tail) groups that are joined tail to tail in the center (see illustration).



Structure of squalene; the tail-to-tail joining is indicated by T.

Squalene can be isolated in large quantities from the liver oils of the shark and other elasmobranch fishes, and is a relatively inexpensive compound. Complete hydrogenation of the liver oil gives the saturated hydrocarbon squalane, which is used in lotions and skin lubricants.

The major significance of squalene is its role as a central intermediate metabolite in the biogenesis of all steroids and triterpenoids. *See* STEROID; TERPENE. [J.A.Mo.]

Squall A strong wind with sudden onset and more gradual decline, lasting for several minutes. Wind speeds in squalls commonly reach 30–60 mi/h (13–27 m/s), with a succession of brief gusts of 80–100 mi/h (36–45 m/s) in the more violent squalls. Squalls may be local in nature, as with isolated thunderstorms, or may occur over a wide area in the vicinity of a well-developed cyclone, where the squalls locally reinforce already strong winds. Because of their sudden violent onset, and the heavy rain, snow, or hail showers which often accompany them, squalls cause heavy damage to structures and crops and present severe hazards to transportation.

The most common type of squall is the thundersquall or rain squall associated with heavy convective clouds, frequently of the cumulonimbus type. Such a squall usually sets in shortly before onset of the thunderstorm rain, blowing outward from the storm and generally lasting for only a short time. It is formed when cold air, descending in the core of the thunderstorm rain area, reaches the Earth's surface and spreads out. Particularly in desert areas, the thunderstorm rain may largely or wholly evaporate before reaching the ground, and the squall may be dry, often associated with dust storms. *See* DUST STORM; SQUALL LINE; THUNDERSTORM.

Squalls of a different type result from cold air drainage down steep slopes. The force of the squall is derived from gravity and depends on the descending air which is colder and more dense than the air it replaces. So-called fall winds of this kind are common on mountainous coasts of high latitudes, where cold air forms on elevated plateaus and drains down fiords or deep valleys. Violent squalls also characterize the warm foehn winds of the Alps and the similar chinook winds on the eastern slopes of the Rocky Mountains. *See* CHINOOK; WIND. [C.W.N.; E.Ke.]

Squall line A line of thunderstorms, near whose advancing edge squalls occur along an extensive front. The thundery region, 12–30 mi (20–50 km) wide and up to 1200 mi (2000 km) long, moves at a typical speed of 30 knots (15 m/s) for 6–12 h or more and sweeps a broad area. In the United States, severe squall lines are most common in spring and early summer when northward incursions of maritime tropical air east of the Rockies interact with polar front cyclones. Ranking next to hurricanes in casualities and damage caused, squall lines also supply most of the beneficial rainfall in some regions. *See* FRONT; SQUALL; THUNDERSTORM. [C.W.N.]

Squamata The dominant order of living reptiles composed of the lizards and snakes. The group first appeared in Jurassic times and today is found in all but the coldest regions. Various forms are adapted for arboreal, burrowing, or aquatic lives, but most squamates are fundamentally terrestrial. There are about 4700 Recent species: 2200 lizards and 2500 snakes.

The order is readily distinguished from all known reptiles by its highly modified skull; an enlarged and movable quadrate; and a temporal opening that is lost or reduced in many forms. No other reptiles show these modifications, which allow for great kinesis in the lower jaw since it articulates with the quadrate. In addition, the order is distinct from other living reptile groups because its members have no shells or secondary palates and the males possess paired penes.

Traditionally the Squamata have been divided into two major subgroups, the lizards, suborder Sauria, and the snakes, suborder Serpentes. The latter group is basically a series of limbless lizards, and it is certain that snakes are derived from some saurian ancestor. There are many different legless lizards, and it has been suggested that more than one line has evolved to produce those species currently grouped together as snakes.

Sauria. The majority of saurians are insectivorous, but a few feed on plants while others, notably the Varanidae and allies, feed on larger prey including birds and mammals. The largest living lizard is the Komodo dragon (*Varanus komodoensis*).

The majority of lizards are quadrupedal in locomotion and are usually ambulatory scamperers or scansorial. Some forms are bipedal, at least when in haste. The coloration of each species of lizard is characteristic. Most forms exhibit marked differences in coloration between the sexes, at least during the breeding season, and frequently the young are markedly different from the parents. Color changes occur in rapid fashion among some species, and all are capable of metachrosis or changing color to a certain extent. *See* SEXUAL DIMORPHISM.

There are but two species of venomous lizards, both members of the genus *Heloderma*, in the family Helodermatidae: the Gila monster (*H. suspectum*) and the beaded lizard (*H. horridum*).

The following list indicates the major evolutionary lines and families of lizards. Families indicated by an asterisk contain limbless, snakelike species. All members of the families Pygopodidae, Anelytropsidae, Dibamidae, Amphisbaenidae, Feylinidae, and Anniellidae are snakelike lizards.

Iguania line
  Family: Iguanidae
    Agamidae
    Chamaeleontidae
Gekkota line
  Family: Gekkonidae
    Pygopodidae
Scincomorpha line
  Family: Xantusiidae
    Teiidae
    Lacertidae
    Gerrhosauridae*
    Scincidae*
    Anelytropsidae*
    Dibamidae*
Annulata line
  Family: Amphisbaenidae*
Anguimorpha line
  Family: Anguidae*
    Anniellidae*
    Feyliniidae*
    Xenosauridae
    Helodermatidae
    Varanidae
    Lanthonotidae

Serpentes. Snakes are basically specialized, limbless lizards which probably evolved from burrowing forms but have now returned from subterranean habitats to occupy terrestrial, arboreal, and aquatic situations. The following characteristics are typical of all serpents. There is no temporal arch so that the lower jaw and quadrate are very loosely attached to the skull. This gives the jaw even greater motility than is the case in lizards. The body is elongate with 100–200 or more vertebrae, and the internal organs are elongate and reduced. A spectacle covers the eye.

The largest living snake is the Indian python (*Python reticulatus*), which reaches 30 ft (9 m) in length and a weight of 250 lb (113 kg). The largest venomous snake is the king cobra (*Ophiophagus hannah*), of southern Asia, which is known to attain a length of 18 ft (5.5 m).

The senses of snakes are fundamentally similar to those of all terrestrial vertebrates. Great dependence is placed upon olfaction and the Jacobson's organs (olfactory canals in the nasal mucosa). The tongue of all snakes is elongate and deeply bifurcated. When not in use it can be retracted into a sheath located just anterior to the glottis, but it is protrusible and is constantly being projected to pick up samples for the Jacobson's organs from the surrounding environment. Snakes are deaf to airborne sounds and receive auditory stimuli only through the substratum via the bones of the head. The eyes are greatly modified from those in lizards, and there is no color vision. Some groups are totally blind and have vestigial eyes covered by scales or skin.

Four basic patterns of locomotion are found in snakes, and several may be used by a particular individual at different times. The most familiar type is curvilinear. Snakes using rectilinear locomotion move forward in a straight line, without any lateral undulations, by producing wavelike movements in the belly plates. Laterolinear locomotion, or sidewinding, is used primarily on smooth or yielding surfaces and is very complex. Concertina locomotion movement resembles the expansion and contraction of that musical instrument.

The vast majority of living snakes are harmless to humans, although a number are capable of inflicting serious injury with their venomous bites. The venom apparatus has evolved principally as a method of obtaining food, but it is also advantageous as a defense against attackers. Fangs are teeth modified for the injection of venom into the victim, and the venom glands are modified salivary glands connected to the grooved fangs by a duct. Special muscles are present in all proglyphous snakes to force the venom into the wound. The venom itself is a complex substance containing a number of enzymes. Certain of these enzymes attack the blood, others in the nervous system, and some are spreaders.

The following list indicates the major groups of living snakes.

Family: Typhlopidae
  Leptotyphlopidae
  Aniliidae
  Boidae
  Colubridae
  Elapidae
  Hydrophiida
  Viperidae
  Crotalidae

[J.M.S.]

Squash The common name for edible fruits of several species of the genus *Cucurbita: C. pepo, C. moschata, C. maxima*, and *C. mixta*. Those species originated in the Americas but are now grown in most countries around the world. Within squash there is tremendous variation in size, shape, color, and usage.

The most clearly defined group is summer squash, fruit of any species of *Cucurbita* eaten as a vegetable when immature. It is most commonly *C. pepo*. Fruit color may be white, yellow, or light or dark green, and the green may be solid or striped. Shapes may be flattened disks as in Pattypan, cylindrical as in Zucchini and Cocozelle, or with necks as in the straightneck and crookneck types. Summer squash has mild flavor, high water content, and relatively low nutritional value.

Winter squash is fruit of *Cucurbita* eaten when mature and derives its name from its ability to be stored for several weeks or months before consumption. Varieties of winter squash are found in all four species. The Table Queen group, synonymous with Acorn, is *C. pepo*, Butternut belongs to *C. moschata*, Green-striped Cushaw is *C. mixta*, while *C. maxima* has the widest range of types, including Buttercup, Hubbards, and Delicious of various colors, Banana, and Boston Marrow. Flesh color varies from light yellow to dark orange, and the edible portion ranges from thin to very thick. [H.M.M.]

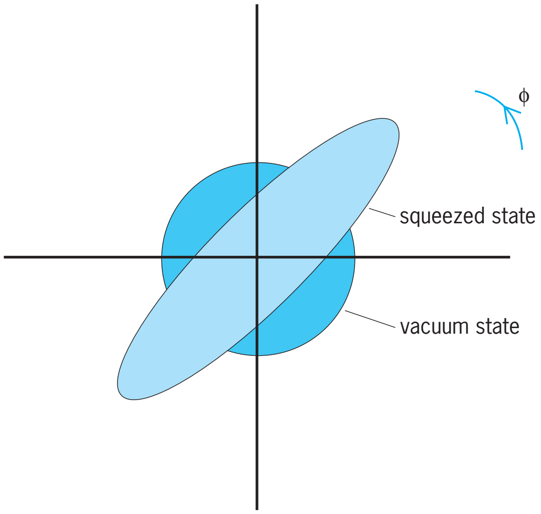
Squeezed quantum states Quantum states for which certain variables can be measured more accurately than is normally possible.

All matter and radiation fluctuate. Much random fluctuation derives from environmental influence, but even if all these influences are removed, there remains the intrinsic uncertainty prescribed by the laws of quantum physics. The position and momentum of a particle, or the electric and magnetic components of an electromagnetic field, are conjugate variables that cannot simultaneously possess definite values (Heisenberg uncertainty principle). It is possible, however, to have the position of a particle more and more accurately specified at the expense of increasing momentum uncertainty; the same applies to electromagnetic field amplitudes. This freedom underlies the phenomenon of squeezing or the possibility of having squeezed quantum states. With squeezed states, the inherent quantum fluctuation may be partly circumvented by focusing on the less noisy variable, thus permitting more precise measurement or information transfer than is otherwise possible. *See* Uncertainty principle.

According to quantum electrodynamics, the vacuum is filled with a free electromagnetic field in its ground state that consists of fluctuating field components with significant noise energy. If ϕ is a phase angle and $a(\phi)$ and $a[\phi + (\pi/2)]$ are two quadrature components of the field (for example, the electric and magnetic field amplitudes), the vacuum mean-square field fluctuation is given by Eq. (1), independently of the phase angle.

$$\langle \Delta a^2(\phi) \rangle = \frac{1}{4} \qquad (1)$$

Equation (1) is normalized to a photon; the corresponding equivalent noise temperature at optical frequencies is thousands of kelvins. Equation (1) also gives the general fluctuation of an arbitrary coherent state, which is the quantum state of ordinary lasers. Further environment-induced randomness is introduced in addition to Eq. (1) for other conventional light sources, including light-emitting diodes. *See* Coherence; Electrical noise; Laser; Quantum electrodynamics.



Field-amplitude fluctuation $\langle \Delta a^3(\phi) \rangle$as a function of phase angle ϕ. The noise circle of the vacuum state, Eq. (1) in the text, is squeezed to an ellipse according to Eq. (3).

In a squeezed state, the quadrature fluctuation is reduced below Eq. (1) for some ϕ, as given in Eq. (2). At that point,

$$\langle \Delta a^2(\phi) \rangle < \frac{1}{4} \qquad (2)$$

squeezing, that is, reduction of field fluctuation below the coherent state level, occurs. The fluctuation of the conjugate quadrature is correspondingly increased to preserve the uncertainty relation, Eq. (3). In a two-photon coherent state, or squeezed state

$$\langle \Delta a^2(\phi) \rangle \left\langle \Delta a^2 \left(\phi + \frac{\pi}{2} \right) \right\rangle \geq \frac{1}{16} \qquad (3)$$

in the narrow sense, Eq. (3) is satisfied with equality. As seen in the illustration, the designation "squeezed state" is partly derived from the fact that the noise circle of Eq. (1) is squeezed to an ellipse when Eq. (3) is satisfied with equality.

Squeezed light can be generated by a variety of processes, especially nonlinear optical processes. The first successful experimental demonstration of squeezing, in 1985, involved a four-wave mixing process in an atomic beam of sodium atoms.

Squeezing was first studied in connection with optical communication, although it is evident that reduced quantum fluctuation might find applications in precision measurements. *See* Nonlinear optics; Optical communications. [H.P.Yu.]

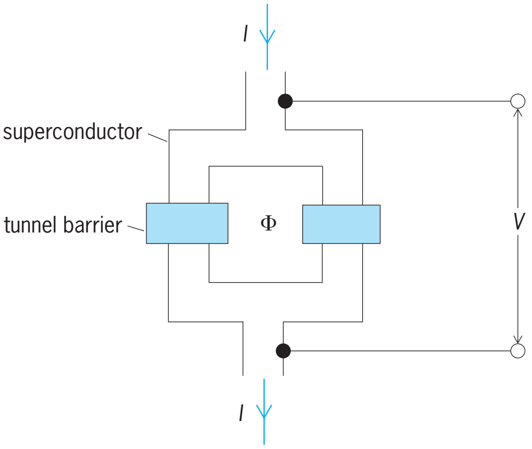
Squid The common name applied to cephalopods of the order Teuthoidea. They are marine mollusks that inhabit the oceans of the world. Squids are characterized by having eight arms and two longer tentacles around the mouth; an elongated, tapered, usually streamlined body; an internal rod- or blade-like shield (gladius); and fins on the body (mantle). The arms have two (infrequently four or six) rows of suckers and occasionally clawlike hooks, and the tentacles have terminal clubs with suckers, hooks, or both. The muscular, elastic tentacles are contractile, not retractile into pockets like those of cuttlefishes (Sepioidea). *See* Sepioidea.

Squids have an exceptionally well-developed brain and organs of the central nervous system that approach in complexity and function those of fishes and even some birds and mammals. Squids are active, powerful swimmers, driven by jet propulsion as water taken into the mantle cavity is forcefully expelled through the funnel. Prey, normally shrimps, fishes, or other squids, are captured with the two tentacles and held with the arms while the beaks cut off bites that the radula and tongue shove down the throat. *See* Nervous system (invertebrate).

Two groups (suborders) of squids are recognized: Myopsida and Oegopsida. *See* Cephalopoda; Coleoidea; Teuthoidea. [C.F.E.R.]

SQUID An acronym for superconducting quantum interference device, which actually refers to two different types of device, the dc SQUID and the rf SQUID.

The dc SQUID consists of two Josephson tunnel junctions connected in parallel on a superconducting loop (see illustration). A small applied current flows through the junctions as a supercurrent, without developing a voltage, by means of Cooper pairs of electrons tunneling through the barriers. However, when the applied current exceeds a certain critical value, a voltage is generated. When a magnetic field is applied so that a magnetic flux threads the loop, the critical value oscillates as the magnetic flux is changed, with a period of one flux quantum, weber, where h is Planck's constant and e is the electron charge. The oscillations arise from the interference of the two waves describing the Cooper pairs at the two junctions, in a way that is closely analogous to the interference between two coherent electromagnetic waves. *See* Interference of waves; Josephson effect; Superconductivity.



Direct-current (dc) SQUID with enclosed magnetic flux Φ. I = applied current; V = generated voltage.

The rf SQUID consists of a single junction interrupting a superconducting loop. In operation, it is coupled to the inductor of an *LC*-tank circuit excited at its resonant frequency by a radiofrequency (rf) current. The rf voltage across the tank circuit oscillates as a function of the magnetic flux in the loop, again with a period of one flux quantum. Although SQUIDs were for many years operated while immersed in liquid helium, ceramic superconductors with high transition temperatures make possible devices operating in liquid nitrogen at 77 K.

SQUIDs have important device applications. Usually with the addition of a superconducting input circuit known as a flux transformer, both dc and rf SQUIDs are used as magnetometers to detect tiny changes in magnetic field. The output of the SQUID is amplified by electronic circuitry at room temperature and fed back to the SQUID so as to cancel any applied flux. This makes it possible to detect changes in flux as small as 10^{-6} of one flux quantum with SQUIDs based on low-transition-temperature superconductors, corresponding to magnetic field changes of the order of 1 femtotesla in a 1-hertz bandwidth. Suitable modifications to the input circuit enable the SQUID to measure other physical quantities, including voltages, displacement, or magnetic susceptibility. SQUIDs are also used for logic and switching elements in experimental digital circuits and high-speed analog-to-digital converters. *See* ANALOG-TO-DIGITAL CONVERTER; INTEGRATED CIRCUITS; MAGNETOMETER; SUPERCONDUCTING DEVICES. [J.Cl.]

SS 433 A remarkable stellar object with unique properties: it shows evidence of ejection of two narrow streams of cool gas traveling in oppositely directed beams from a central object at a velocity of almost one-quarter the speed of light—the beams executing a repeating, rotating pattern about the central object once every 164 days.

One peculiar characteristic of SS 443 is that the spectrum possesses not only a set of emission lines due to hydrogen and helium, but two further sets of lines, one displaced to longer (redder) wavelengths from the familiar lines, and the second displaced to shorter (bluer) wavelengths. These displacements can be understood in terms of the Doppler effect. In addition, the wavelengths of the lines change every night in a smoothly progressing pattern, indicating that the velocity of the emitting regions is also changing.

Especially intriguing is the observation that on a given night the average velocity of the approaching and receding beams is not zero, but rather a large positive value, about 7500 mi/s (12,000 km/s), despite the fact that SS 433 is approximately stationary with respect to the Earth. This proves to be a direct consequence of Einstein's special theory of relativity. An outside observer perceives a change in measured times and lengths of a system moving at very large velocity. The beam velocity in SS 433 is large enough that special relativity is important. *See* RELATIVITY.

There has been much speculation as to the type of star present in SS 443, with many astronomers now agreeing that the enormous velocities in the beams require a highly collapsed, compact star with a strong gravitational field. A neutron star, the same end point of stellar evolution responsible for pulsars, or possibly a black hole could satisfy this requirement. *See* BINARY STAR; BLACK HOLE; NEUTRON STAR; PULSAR. [B.M.]

Stability augmentation The alteration of the inherent behavior of a system. As an example, ships tend to exhibit significant rolling motions at sea. To dampen these rolling motions, a roll stabilization (feedback) system can be used. Such a system consists of a set of vanes (that is, small wings) extending outward from the hull, below the waterline. By varying the vane incidence angle relative to the hull, a hydrodynamic lift is generated on the vane. The vanes are driven by a feedback system so that the rolling motions are opposed by creating positive lift on one side of the hull and negative lift on the other side.

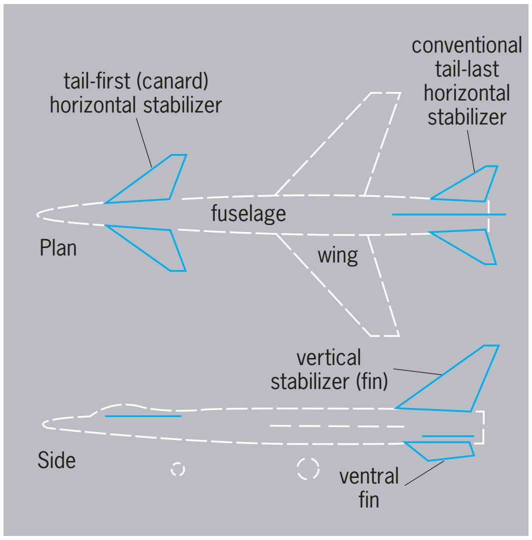
As a second example, nearly all satellites require some form of stability augmentation to help in keeping the antennas or sensors aligned with receiving equipment on Earth. The stability augmentation is effected by thrusters which receive their commands from a feedback system. *See* SPACECRAFT PROPULSION.

As a third example, stability augmentation systems are used on aircraft. This is usually achieved by a system which controls one or more flight-control surfaces (or engines) automatically without inputs from the pilot. The inherent stability and response behavior of many modern airplanes tends toward low damping or even instability. The physical reasons have to do with the configuration of the airplane and the combination of flight speed and altitude at which the airplane is operated. Several modern fighters and even some transports are intentionally designed with no or little inherent stability. There are a number of reasons for such a design condition. In the case of fighters, excellent maneuverability in combat is essential. By making a fighter intentionally inherently unstable, it is easy to design the control system so that load factors in pull-ups or in turns can be built up rapidly. In the case of transports, the motivation to design for little or no inherent stability is to lower the size of the tail and thereby achieve a reduction in drag and weight. *See* AIRPLANE; MILITARY AIRCRAFT.

The control exercised by the stability augmentation system contrasts with that exercised by the pilot. The pilot may be connected with the flight-control surface via a direct mechanical link. Alternatively, in many modern airplanes the pilot cockpit control movement is sensed by a position transducer. The output of the position transducer in turn is sent, via a computer-amplifier combination, to a hydraulic actuator, referred to as a servo, which drives the flight-control surface. Command signals which come from the pilot or from the stability augmentation system are sent by wire (fly-by-wire) or by optical conduit (fly-by-light) to the electromagnetic valve. A valve distributes high-pressure hydraulic fluid either to the left or to the right of the piston so that the piston is forced to move. The piston in turn moves the flight-control surface. *See* FLIGHT CONTROLS.

With the introduction of fast in-flight digital computers, it has become possible to equip airplanes with so-called full flight envelop protection systems. Such systems are designed to refuse any pilot input which might get the airplane into a flight condition from which recovery is no longer possible. Such systems can easily be arranged to prevent a pilot from rolling a commercial airplane too much or to prevent the pilot from stalling the airplane. Such systems can also be arranged so that loads acting on the wing or tail do not approach dangerously high levels. In that case the system is referred to as a load-alleviation system. [J.Ro.]

Stabilizer (aircraft) The horizontal or vertical aerodynamic wing surfaces that provide aircraft stability and longitudinal balance in flight. Horizontal and vertical stabilizers (fins) are similar to the aircraft wing in structural design and function of providing lift at angle of attack to the wind. However, stabilizers are not required to supply lift to overcome aircraft weight during flight, and when the wing-fuselage center of pressure is behind the aircraft center of gravity, the aerodynamic load on the horizontal stabilizer may be downward. Various stabilizer arrangements are shown in the illustration. *See* Flight controls. [M.J.A.]



Various stabilizer arrangements.

Stabilizer (chemistry) Any substance that tends to maintain the physical and chemical properties of a material. Degradation, that is, irreversible changes in chemical composition or structure, is responsible for the premature failure of materials. Stabilizers are used to extend the useful life of materials as well as to maintain their critical properties above the design specifications. Oxygen and water are the principal degradants, but ultraviolet radiation also can have a significant effect (photodegradation).

A wide variety of additives has been developed to stabilize polymers against degradation. Stabilizers are available that inhibit thermal oxidation, burning, photodegradation, and ozone deterioration of elastomers. Research in the chemistry of the low-temperature oxidation of natural rubber has revealed that hydrocarbon polymers oxidize by a free-radical chain mechanism. In pure, low-molecular-weight hydrocarbons, an added initiator is required to produce the first radicals. In contrast, initiation of polymer oxidation occurs in the complex molecules of elastomers through impurities already present, for example, hydroperoxides. *See* Chain reaction (chemistry); Free radical.

Stabilization of hydrocarbon polymers can be accomplished with preventative or chain-breaking antioxidants. Preventative antioxidants stabilize by reducing the number of radicals formed in the initiation stage. Where hydroperoxides are responsible for initiation, the induced decomposition of these reactive intermediates into nonradical products provides effective stabilization. Suppressing the catalytic effects of metallic impurities that increase the rate of radical formation can also provide stabilization. Chain-breaking antioxidants interrupt the oxidative chain by providing labile hydrogens to compete with the polymer in reaction with the propagating radicals. The by-product of this reaction is a radical which is not capable of continuing the oxidative chain.

Stabilization of polymers against photooxidation, the principal component of outdoor weathering, is accomplished by addition of ultraviolet absorbers, and radical scavengers. Ultraviolet absorbers absorb and harmlessly dissipate damaging radiation. Another class of additives, known as hindered-amine light stabilizers, function by scavenging destructive radicals. *See* Antioxidant; Carbon black; Inhibitor (chemistry); Photodegradation. [W.L.H.]

Stain (microbiology) Any colored, organic compound, usually called dye, used to stain tissues, cells, cell components, or cell contents. The dye may be natural or synthetic. The object stained is called the substrate. The small size and transparency of microorganisms make them difficult to see even with the aid of a high-power microscope. Staining facilitates the observation of a substrate by introducing differences in optical density or in light absorption between the substrate and its surround or between different parts of the same substrate. In electron microscopy, and sometimes in light microscopy (as in the silver impregnation technique of staining flagella or capsules), staining is accomplished by depositing on the substrate ultraphotoscopic particles of a metal such as chromium or gold (the so-called shadowing process); or staining is done by treating the substrate with solutions of metallic compounds such as uranyl acetate or phosphotungstic acid. Stains may be classified according to their molecular structure. They may also be classified according to their chemical behavior into acid, basic, neutral, and indifferent. This classification is of more practical value to the biologist. *See* Electron microscope; Medical bacteriology. [J.P.Tr.]

Stainless steel The generic name commonly used for that entire group of iron-base alloys which exhibit phenomenal resistance to rusting and corrosion because of chromium (Cr) content. Contents of Cr exceeding 10%, with carbon (C) held suitably low, make iron effectively rustproof.

Other alloy elements, notably nickel (Ni) and molybdenum (Mo), can also be added to the basic stainless composition to produce both variety and improvement of properties. Over 100 different stainless steels are produced commercially, about half as standardized grades. Some are more properly classed as stainless irons since they do not harden as steel; others are true steels to which corrosion resistance becomes an added feature. Still others that are neither properly steels nor irons introduce totally new classes of materials, from both mechanical and chemical standpoints. *See* Alloy; Steel. [C.A.Z.]

Stalactites and stalagmites Stalactites, stalagmites, dripstone, and flowstone are travertine deposits in limestone caverns, formed by the evaporation of waters bearing calcium carbonate. Stalactites grow down from the roofs of caves and tend to be long and thin, with hollow cores. The water moves down the core and precipitates at the bottom, slowly extending the length while keeping the core open for more water to move down.

Stalagmites grow from the floor up and are commonly found beneath stalactites; they are formed from the evaporation of the same drip of water that forms the stalactite. Stalagmites are thicker and shorter than stalactites and have no central hollow core. *See* Cave; Limestone. [R.Si.]

Stall-warning indicator A device that determines the critical angle of attack for a given aircraft, at which point the drag coefficient overpowers the lift coefficient and the aircraft will no longer sustain itself in steady-state condition (level flight or climb/descent). The indicator usually operates from vane sensors, airflow pressure sensors, tabs on the leading edge of the wings, and computing devices which include accelerometers, airspeed detectors, and vertical gyros. [J.W.A.]

Standard An accepted reference sample which is used for establishing a unit for the measurement of physical quantities. A physical quantity is specified by a numerical factor and a unit; for example, a mass might be expressed as 8 g, a length as 6 cm, and a time interval as 2 min. Here the gram is a mass unit defined in terms of the international kilogram, which serves as the primary standard of mass. The centimeter is defined in terms of the international meter, which is the primary standard of length and is defined as the length of path traveled by light in a vacuum during a time interval of 1/299,792,458 of a second. In similar fashion, the minute is a time interval defined as 60 s, where the second is the international standard of time and is defined as the duration of 9 192 631 770 periods of the radiation corresponding to the transition between the two hyperfine energy levels of the ground state of the cesium-133 atom.

The National Institute of Standards and Technology in the United States and comparable laboratories in other countries are responsible for maintaining accurate secondary standards for various physical quantities. *See* ELECTRICAL UNITS AND STANDARDS; LIGHT; METRIC SYSTEM; PHYSICAL MEASUREMENT; TIME. [D.Wi.]

Standard model The theory that explains the three major interactions of elementary particle physics—the strong interaction responsible for nuclear forces, the weak interaction responsible for radioactive decay, and the electromagnetic interaction—in terms of a common physical picture. The model for this picture is quantum electrodynamics, the fundamental theory underlying electromagnetism. In that theory, electrons, viewed as structureless elementary constituents of matter, interact with photons, structureless elementary particles of light. The standard model extends quantum electrodynamics to explain all three interactions of subnuclear physics in terms of similar basic constituents. *See* ELECTRON; ELECTROWEAK INTERACTION; ELEMENTARY PARTICLE; LIGHT; PHOTON; QUANTUM CHROMODYNAMICS; QUANTUM ELECTRODYNAMICS; STRONG NUCLEAR INTERACTIONS; WEAK NUCLEAR INTERACTIONS. [M.E.Pe.]

Staphylococcus A genus of bacteria containing at least 28 species that are collectively referred to as staphylococci. Their usual habitat is animal skin and mucosal surfaces. Although the genus is known for the ability of some species to cause infectious diseases, many species rarely cause infections. Pathogenic staphylococci are usually opportunists and cause illness only in compromised hosts. *Staphylococcus aureus*, the most pathogenic species, is usually identified by its ability to produce coagulase (proteins that affect fibrinogen of the blood-clotting cascade). Since most other species of staphylococci do not produce coagulase, it is useful to divide staphylococci into coagulase-positive and coagulase-negative species. Coagulase-negative staphylococci are not highly virulent but are an important cause of infections in certain high-risk groups. Although *Staphylococcus* infections were once readily treatable with antibiotics, some strains have acquired genes making them resistant to multiple antimicrobial agents. *See* BACTERIA; DRUG RESISTANCE; MEDICAL BACTERIOLOGY.

Staphylococcus cells are spherical with a diameter of 0.5–1.5 micrometers. Clumps of staphylococci resemble bunches of grapes when viewed with a microscope, owing to cell division in multiple planes. The staphylococci have a gram-positive cell composition, with a unique peptidoglycan structure that is highly cross-linked with bridges of amino acids. *See* STAIN (MICROBIOLOGY).

Most species are facultative anaerobes. Within a single species, there is a high degree of strain variation in nutritional requirements. Staphylococci are quite resistant to desiccation and high-osmotic conditions. These properties facilitate their survival in the environment, growth in food, and communicability.

In addition to genetic information on the chromosome, pathogenic staphylococci often contain accessory elements such as plasmids, bacteriophages, pathogenicity islands (DNA clusters containing genes associated with pathogenesis), and transposons. These elements harbor genes that encode toxins or resistance to antimicrobial agents and may be transferred to other strains. Genes involved in virulence, especially those coding for exotoxins and surface-binding proteins, are coordinately or simultaneously regulated by loci on the chromosome. *See* BACTERIAL GENETICS; BACTERIOPHAGE; PLASMID; TRANSPOSONS.

Most *Staphylococcus aureus* infections develop into a pyogenic (pus-forming) lesion caused by acute inflammation. Inflammation helps eliminate the bacteria but also damages tissue at the site of infection. Typical pyogenic lesions are abscesses with purulent centers containing leukocytes, fluid, and bacteria. Pyogenic infections can occur anywhere in the body. Blood infections (septicemia) can disseminate the organism throughout the body and abscesses can form internally.

Certain strains of *S. aureus* produce exotoxins that mediate two illnesses, toxic shock syndrome and staphylococcal scalded skin syndrome. In both diseases, exotoxins are produced during an infection, diffuse from the site of infection, and are carried by the blood (toxemia) to other sites of the body, causing symptoms to develop at sites distant from the infection. Toxic shock syndrome is an acute life-threatening illness mediated by staphylococcal superantigen exotoxins. Staphylococcal scalded skin syndrome, also known as Ritter's disease, refers to several staphylococcal toxigenic infections. It is characterized by dermatologic abnormalities caused by two related exotoxins, the type A and B exfoliative (epidermolytic) toxins. *See* CELLULAR IMMUNOLOGY; TOXIC SHOCK SYNDROME.

Staphylococcal food poisoning is not an infection, but an intoxication that results from ingestion of staphylococcal enterotoxins in food. The enterotoxins are produced when food contaminated with *S. aureus* is improperly stored under conditions that allow the bacteria to grow. Although contamination can originate from animals or the environment, food preparers with poor hygiene are the usual source. Effective methods for preventing staphylococcal food poisoning are aimed at eliminating contamination through common hygiene practices, such as wearing gloves, and proper food storage to minimize toxin production. *See* FOOD POISONING.

Coagulase-positive staphylococci are the most important *Staphylococcus* pathogens for animals. Certain diseases of pets and farm animals are very prominent. *Staphylococcus aureus* is the leading cause of infectious mastitis in dairy animals. [G.Boh.]

Star A self-luminous body that during its life generates (or will generate) energy and support by thermonuclear fusion.

Names. Over 6000 stars can be seen with the unaided eye. The brightest carry proper names from ancient times, most of Arabic origin. A more general system names stars within constellations by Greek letters roughly in accord with apparent brightness, followed by the Latin genitive of the constellation name (for example, Vega, in Lyra, is also Alpha Lyrae). More generally yet, brighter stars carry numbers in easterly order within a constellation (Vega also 3 Lyrae). All naked-eye stars also have HR (Harvard Revised) numbers assigned in order east of the vernal equinox. A variety of catalogs list millions of telescopic stars. *See* ASTRONOMICAL CATALOGS; CONSTELLATION.

Magnitudes and colors. About 130 B.C., Hipparchus assigned naked-eye stars to six brightness groups or "apparent magnitudes" (m), with first magnitude the brightest. This scheme is now quantified as a logarithmic system such that five magnitudes correspond to a factor of 100 in brightness, rendering first magnitude 2.512··· times brighter than second, and so on.

Stars assume subtle colors from red to blue-white, reflecting different spectral energy distributions that result from temperatures ranging from under 2000 K (3100°F) to over 100,000 K (180,000°F). The magnitude of a star therefore depends on the detector's color sensitivity. Numerous magnitude systems range from the ultraviolet into the infrared, though the apparent visual magnitude ($m_v = V$) is still standard. The differences among the systems allow measures of stellar color and temperature. *See* Color index; Magnitude (astronomy).

Distances. The fundamental means of finding stellar distances is parallax. As the Earth moves in orbit around the Sun, a nearby star will appear to shift its location against the background. The parallax (*p* in arcseconds) is defined as one half the total shift, and is the angle subtended by the Earth's orbital radius as seen from the star. Distance in parsecs (pc) is 1/pc, where 1 pc = 206,265 AU = 3.26 light-years. (A light-year is the distance that a ray of light will travel in a year.) The nearest star, a telescopic companion to Alpha Centauri, is 1.29 pc = 4.22 light-years away. *See* Light-year; Parallax (astronomy); Parsec.

Distribution and motions. All the unaided-eye stars and 200 billion more are collected into the Milky Way Galaxy (or simply, the Galaxy), 98% concentrated into a thin disk over 100,000 light-years across. From the Sun, inside the disk and 27,000 light-years from the Galaxy's center in Sagittarius, the disk appears as the Milky Way. Surrounding the disk is a vast but sparsely populated halo.

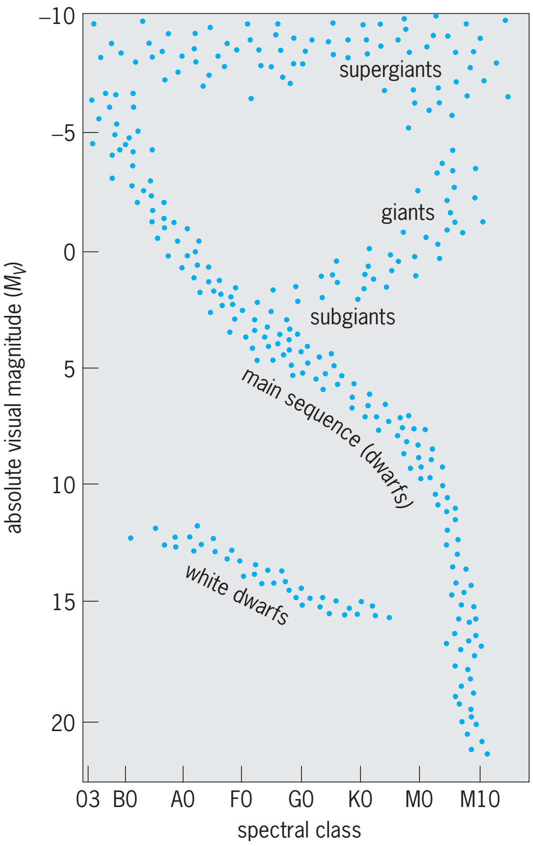
Angular proper motions across the line depend on velocities across the line of sight and distances. Statistical analysis of these motions shows the Sun to be moving through the local stars at a speed of 20 km/s (12 mi/s), roughly toward Vega. From radial velocities of sources outside the Galaxy, it is found that the Sun moves in a roughly circular orbit at 220 km/s (137 mi/s), which when combined with the space motions of other stars allows their galactic orbits to be determined. Stars in the disk have closely circular orbits; those in the halo have elliptical ones. *See* Doppler effect; Milky Way Galaxy.

Absolute magnitudes. The apparent visual magnitude of a star depends on its intrinsic visual luminosity and on the inverse square of the distance. Knowledge of the distance allows the determination of the true visual luminosity, expressed as the absolute visual magnitude, M_v. This quantity is defined as the apparent visual magnitude that the star would have at a distance of 10 pc. Absolute visual magnitudes range from $M_v = -10$ to $+20$ (a factor of 10^{12}). The Sun's absolute visual magnitude is in the middle of this range, +4.83.

Spectral classes. Stars exhibit a variety of absorption-line spectra. The absorptions, narrow cuts in the spectra, are produced by atoms, ions, and molecules in the stars' thin, semitransparent outer layers, or atmospheres. Over a century ago, Edward C. Pickering lettered them according to the strengths of their hydrogen lines. After he and his assistants dropped some letters and rearranged others for greater continuity, they arrived at the standard spectral sequence, OBAFGKM, which was later decimalized (the Sun is in class G2). Classes L and T were added in 1999. Since the sequence correlates with color, it must also correlate with temperature, which ranges from 55,000 K (100,000°F) for hot class O, through about 6000 K (10,000°F) for solar-type class G, to under 2000 K (3100°F) for class L, and below 1000 K (1300°F) for class T (all of which are brown dwarf substars).

The majority of stars in the galactic disk have chemical compositions like that of the Sun. Differences in spectra result primarily from changes in molecular and ionic composition and in the efficiencies of absorption, all of which correlate with temperature. *See* Astronomical spectroscopy; Spectral type.

Hertzsprung-Russell diagram. Shortly after the invention of the spectral sequence, H. N. Russell and E. Hertzsprung showed that luminosity correlates with spectral class. A graph of absolute visual (or bolometric) magnitude (luminosity increasing upward) plotted against spectral class (or temperature, decreasing toward the right) is called the Hertzsprung-Russell (HR) diagram (see illustration). The majority of stars lie in a band in which luminosity climbs up and to the left with temperature (with the Sun in the middle). But another band begins near the location of the Sun and proceeds up and to the right (to lower temperature), luminosities increasing to thousands solar as temperature drops to class M. To be bright and cool, such stars must have large radiating areas and radii. To distinguish between the bands, the larger stars are called giants, while those of the main band are termed dwarfs (or main-sequence stars). Yet brighter stars to the cool side of the main sequence, with luminosities approaching 10^6 solar, are called supergiants. In between the giants and the dwarfs lie a few subgiants. At the top, superior to the supergiants, are the very rare hypergiants. *See* Dwarf star; Giant star; Subgiant star; Supergiant star.



Hertzsprung-Russell (HR) diagram, showing the positions of the major kinds of stars.

In the lower left corner of the diagram, beneath the main sequence, are stars so dim that they must be very small. Since the first ones found were hot and white, they became known as white dwarfs in spite of their actual temperatures or colors. White dwarfs must be positioned on the HR diagram according to their temperatures (rather than their spectral classes). *See* White dwarf star.

Stars in the galactic halo are deficient in heavy elements. Low metal content makes halo dwarfs bluer than those of the standard main sequence, shifting them to the left and seemingly downward on the HR diagram, where they are known as subdwarfs. *See* Stellar population.

Double and multiple stars. Most stars are members of some sort of community, from doubles through multiples (double-doubles, and so forth) to clusters, which themselves contain doubles. Separations between components of double stars range from thousands of astronomical units (with orbital periods of a million years) to stars that touch each other (and orbit in hours). *See* Binary star.

Masses and main-sequence properties. Observations of hundreds of binary stars show that mass (*M*) increases upward along the main sequence from about 8% solar at cool class M to over 20 solar in the cooler end of class O. Extrapolation by theory suggests masses of 120 solar at the extreme hot end (class O3) of the main sequence. Fainter than the Sun, luminosity is proportional to M^3; brighter than solar, luminosity goes as M^4. This mass-luminosity relation is the result of higher internal temperatures and pressures in more massive stars caused by gravitational compression. *See* MASS-LUMINOSITY RELATION.

As internal temperature climbs above the 8×10^6 K limit, hydrogen fuses to helium via the proton-proton cycle at an ever-increasing rate. Above about 15×10^6 K (27×10^6 °F), so does fusion by the carbon cycle, in which carbon acts as a nuclear catalyst. *See* CARBON-NITROGEN-OXYGEN CYCLES.

The onset of carbon-cycle dominance coincides with a change in stellar structure. The Sun has a radiatively stable core surrounded by an envelope whose outer parts are in a state of convection that helps produce a magnetic field and magnetic sunspots. Hotter dwarfs have shallower convection layers, and above class F, envelope convection disappears, the cores becoming convective. The convective layers of cooler dwarfs deepen, until below about 0.3 solar mass (class M4), convection takes over completely and the stars are thoroughly mixed. *See* CONVECTION (HEAT).

Below a lower mass limit of 8% solar, internal temperatures and densities are not great enough to allow the proton-proton chain to operate. Such stars, called brown dwarfs, glow dimly and redly from gravitational contraction and from the fusion of natural deuterium (^{2}H) into helium. *See* BROWN DWARF.

Clusters. Doubles and multiples are highly structured. Clusters are not, the member stars orbiting a common center of mass. Open clusters are fairly small collections in which a few hundred or a thousand stars are scattered across a few tens of light-years. About 150 globular clusters occupy the Galaxy's halo, the poorest about as good as a rich open cluster, the best containing over a million stars within a volume 100 light-years across.

The HR diagrams of clusters are radically different from the HR diagrams of the general stellar field. Those of open clusters differ among themselves in having various portions of the upper main sequence removed. The effect is related to the cluster's age, since high-mass stars die first. Globular clusters, which lack an upper main sequence and are therefore all old, contain a distinctive "horizontal branch" composed of modest giants.

Variable stars. Dwarfs are generally stable. Giants and supergiants, however, can have structures that allow them to pulsate. Cepheids (named after the star Delta Cephei) are F and G supergiants and bright giants that occupy a somewhat vertical instability strip in the middle of the HR diagram. They vary regularly by about a magnitude over periods ranging from 1 to 50 days. The pulsation is driven by a deep layer of gas in which helium is becoming ionized. Larger and more luminous Cepheids take longer to pulsate. Once this period-luminosity relationship is calibrated through parallax and main-sequence cluster fitting, the period of a Cepheid gives its absolute magnitude, which in turn gives its distance. Cepheids are vital in finding distances to other galaxies. *See* CEPHEIDS; HUBBLE CONSTANT.

Miras (after the star Mira, Omicron Ceti), or long-period variables, are luminous giants that can vary visually by more than 10 magnitudes over periods that range from 50 to 1000 days, the pulsations again driven by deep ionization layers. *See* MIRA.

Duplicity produces its own set of intrinsic variations. If the members of a binary system are close enough together, one of them can transfer mass to the other, and instabilities in the transfer process cause the binary to flicker. If one companion is a white dwarf, infalling compressed hydrogen can erupt in a thermonuclear runaway, producing a sudden nova that can reach absolute magnitude −10. If the white dwarf gains enough matter such that it exceeds its allowed limit (the Chandrasekhar limit) of 1.4 solar masses, it can even explode as a supernova. *See* CATACLYSMIC VARIABLE; NOVA; VARIABLE STAR.

Off the HR diagram. Various kinds of stars are not placeable on the classical HR diagram. The most common examples are the central stars of planetary nebulae, which are complex shells and rings of ionized gas that surround hot blue stars. *See* PLANETARY NEBULA.

Even hotter neutron stars are found associated with the exploded remains of supernovae (supernova remnants). Only 25 or so kilometers (15 mi) across, the visible ones spin rapidly, and are highly magnetic, with fields 10^{12} times the strength of Earth's field. Radiation beamed from tilted, wobbling magnetic axes can strike the Earth to produce seeming pulses of radiation. *See* NEUTRON STAR; PULSAR.

Evolution. The different kinds of stars can be linked through theories of stellar evolution. Stars are born by the gravitational collapse of dense knots within cold dusty molecular clouds found only in the Galaxy's disk. When the new stars are hot enough inside to initiate fusion, their contraction halts and they settle onto the main sequence. The higher the stellar mass, the greater the internal compression and temperature, and the more luminous the star. But the higher the internal temperature, the greater the rate at which hydrogen is fused, and the shorter the star's life. *See* MOLECULAR CLOUD; PROTOSTAR; STELLAR EVOLUTION. [J.B.Ka.]

Star clouds

Large groupings of stars with dimensions of 1000 to several thousand light-years. Star clouds are not stable clusterings of stars or even groups of a common origin, such as stellar associations. Instead, they are large areas where the stellar density is higher than average in a galaxy. They are nevertheless physical entities in that they result from large-scale star formation events or series of events that are to some extent limited in size by the characteristics of the galactic environment.

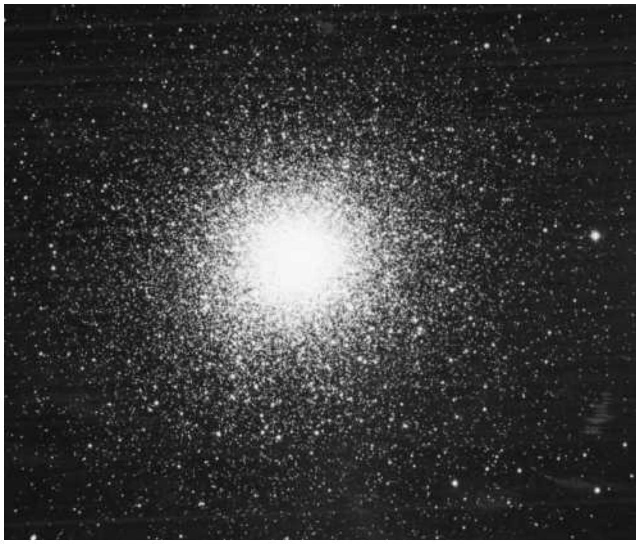
Large star clouds are found commonly in the spiral arms of galaxies such as the Milky Way Galaxy and the Andromeda Galaxy (M31), but are not found in smaller, dwarf galaxies or in very old galaxies. Conspicuous star clouds in the Milky Way Galaxy are found in the constellations Carina, Cygnus, Sagittarius, and Scutum. *See* ANDROMEDA GALAXY; MILKY WAY GALAXY; STAR. [P.Hod.]

Star clusters

Groups of stars held together by mutual gravitational attraction. There are two basic morphological types: open clusters and globular clusters. Typical densities of field stars near the Sun are 0.1 star per cubic parsec. (One parsec equals 1.9×10^{13} mi or 3.1×10^{13} km.) Open clusters, with dozens to thousands of stars, have central densities of 0.3 to 10 stars per cubic parsec, and are often elongated or amorphous in shape. Globular clusters, with a thousand to several million stars, and central densities of a few hundred to over 100,000 stars per cubic parsec, are generally spherical (see illustration). Associations are even looser assemblages, with a few hundred stars and central densities lower than the field. They are often recognized because of unusually large numbers of special types of stars. OB associations are dominated by hot, luminous, young O and B stars. T associations are dominated by young T Tauri variable stars. *See* SPECTRAL TYPE; T TAURI STAR.

Star clusters are important because, within each cluster, member stars probably are at the same distance from the Sun, and have the same age and the same initial chemical composition. Stars with larger masses begin life hotter and brighter than lower-mass stars and end their lives earlier. Most stars within clusters lie along a band in the luminosity-temperature plane (where temperature is measured by spectral type or color). In older clusters, this main-sequence band terminates at fainter and cooler levels. Ages derived from such observations provide a chronology of which clusters formed first. Differences observed among stars away from the main sequence, such as in luminosity and temperature or in chemical composition, reflect changes to the stars during the ends of their lives and provide laboratories for the study of stellar evolution. *See* HERTZSPRUNG-RUSSELL DIAGRAM; MILKY WAY GALAXY; STELLAR EVOLUTION.

Open clusters, once called galactic clusters, are found mostly along the band of Milky Way, and are rarely found more than 1000 parsecs from the plane. A dozen are visible to the naked eye, such as Ursa Major, the Hyades (the horns of Taurus), and the Pleiades. Over a thousand are cataloged, and the Milky Way



Great globular cluster in Hercules, Messier 13. Photographed with 200-in. (500-cm) telescope. (*California Institute of Technology, Palomar Observatory*)

probably contains tens of thousands, most hidden by interstellar obscuration. *See* Hyades; Pleiades.

The youngest clusters may be hidden within dark dust clouds opaque to optical light. Infrared methods can reveal such embedded clusters, which have ages of less than 10^6 years. The oldest open clusters may reach 10^{10} years. Few old clusters are known, partly because of the dissolution of clusters with time. *See* Infrared astronomy.

Generally more distant, more massive, older, and more deficient in heavy elements than open clusters, globular clusters are dispersed all over the sky, but with a strong concentration in the direction of the galactic center (Sagittarius). In 1917, H. Shapley estimated distances to globulars to infer the distance to the galactic center. A total of 158 globular clusters are known, some of which are visible to the unaided eye.

The nearest globular lies about 2000 parsecs away, while the most distant one in the Milky Way Galaxy lies over 100,000 parsecs from the Sun. There seem to be two chemically distinct classes of globular clusters: metal-deficient clusters, typically 30 times poorer in heavy elements than the Sun; and metal-rich clusters, typically about 3 times more deficient. The metal-deficient globulars have very high velocities relative to the Sun, and so do not belong to the disk of the Milky Way; they are found in a spherical distribution around the galactic center. The more metal-rich globulars have motions characteristic of disk stars and clusters, and are found within a few kiloparsecs of the plane. All globular clusters in the Milky Way are very old, typically about 1.4×10^{10} years. *See* Star. [B.W.Ca.]

Star tracker A device that automatically measures the angular separation of stellar observations with respect to a reference platform. It is also referred to as an astrotracker.

By using the star tracker in conjunction with a precise time reference (chronometer) and a dead-reckoning device consisting of gyroscopes and accelerometers (inertial navigator), a digital computer can correct many of the inertial navigator errors so that precise, autonomous (free from any radio position aids), terrestrial navigation can be achieved. The major errors corrected by the star tracker are introduced by the inertial navigator's gyroscopes that result in attitude deviations. In this configuration, called a stellar inertial system, very high precision aircraft autonomous navigation is achieved. Since the availability of radio position aids poses no problem for commercial aircraft, stellar inertial navigation technology is applied only on military vehicles. These navigation devices are used when radio position aids, such as Loran and the Global Positioning System (GPS), may be unavailable. *See* Chronometer; Electronic warfare; Inertial guidance system.

Star trackers are also used for both military and nonmilitary applications on space probes, space-based interceptors, and satellites. In these applications the precise attitude capabilities of these devices provide the fiducial precision reference for pointing of the vehicle and Earth or planet sensors. On space missions, star trackers are the only sensor presently available that can provide arc-second attitude accuracy. *See* Space navigation and guidance.

A gimbaled stellar inertial system is mounted on the stable element of an inertial navigator. The tracking system measures the telescope azimuth rotation angle and elevation angle to the acquired star with respect to a stable inertial reference. The tracker is programmed to observe different, widely angular separated stars in order to achieve accurate operation. The deviation of the measured stellar observations from their ideal stellar positions is utilized to enhance the performance of the inertial navigator.

The preponderance of modern systems do not contain gimbals. These systems are completely strapped down (that is, with no moving parts) and observe stars at random as the stars come into the rigid, fixed star tracker's field of view. These systems, based on their knowledge of the telescope's location and direction, know which stars should be in the field of view and where their images are located on the star tracker's optical detector. In order to make a three-axis attitude correction, there should be a least two stellar observations ideally separated by 90°. Smaller angular separations lead to a dilution of attitude correction precision. The multiple measurements need not be performed simultaneously since the star tracker corrects the attitude of each axis based on the stellar observations available. Thus, these strapdown startracker systems consist of either multiple telescopes with moderate fields of view or a single telescope with a very wide field of view for proper operation. *See* Celestial navigation.

The preponderance of star-tracker photodetectors used to measure the stellar irradiance are solid-state, silicon semiconductor photosensors. These devices have their peak responsivity in the near-infrared region (0.6–1.0 micrometer). Imaging focal-plane arrays have up to a million photosensors on a single semiconductor silicon chip arranged in a rectangular grid matrix. Each of the individual photosensors on the focal-plane array is called a pixel. The devices are similar to the photosensors found in home video-camera recorders. *See* Charge-coupled devices.

[S.Le.]

Starburst galaxy A galaxy that is observed to be undergoing an unusually high rate of formation of stars. It is often defined as a galaxy that, if it continues to form stars at the currently observed rate, will exhaust its supply of star-forming material, the interstellar gas and dust, in a time period that is very short compared to the age of the universe. For a typical starburst galaxy, this gas exhaustion time scale is less than 10^8 years, that is, less than 1% of the age of the universe. Such galaxies must be undergoing a passing burst of star formation.

The term starburst usually also implies that the burst of star formation is occurring in the nuclear regions of the galaxy, because the term was coined to describe a sample of luminous spiral galaxies with bright, pointlike nuclei. However, related objects meet the definition of short gas-exhaustion time scale but exhibit more widespread star formation. These include the nearest, best-studied starburst galaxy, M82.

There are several theories as to why starbursts occur. One likely cause is the interaction between two galaxies as they pass close to, or collide with, one another. The tidal forces generated result in shock-wave compression of the interstellar material and star formation in the compressed clouds. Many star-burst galaxies show evidence of interactions, including distorted appearance and long, wispy tails of material. Not all starbursts can be due to interactions, however, since some display no evidence for any recent disturbance. Other mechanisms that are thought responsible for high star-formation rates in galaxies are very strong spiral density waves and central bar instabilities. *See* GALAXY, EXTERNAL. [C.J.L.]

Starch A carbohydrate that occurs as discrete, partially crystalline granules in the seeds, roots (tubers), stems (pith), leaves, fruits, and pollen grains of higher plants. Starch functions as the main storage or reserve form of carbohydrate; it is second in abundance only to cellulose, a major structural component of plants. Cereal grains, tuber and root crops, and legumes (seeds) have long been used as major sources of carbohydrate in human diets. *See* CELLULOSE.

Starch is isolated commercially from the following sources: cereal grain seeds [maize (corn), wheat, rice, sorghum], roots and tubers [potato, sweet potato, tapioca (cassava), arrowroot], and stems and pith (sago). Cereal grains are often steeped first to loosen the starch granules in the endosperm matrix, followed by wet grinding or milling. Roots and tubers are ground to give a suspension containing starch granules. Then follows screening or sieving, washing, centrifuging, dewatering, and drying.

Starch, a polymer of glucose, is an alpha-glucan, predominantly containing alpha-1,4-glucosidic linkages with a relatively small amount of alpha-1,6-glucosidic linkages forming branch points. Two major polymeric components are present: amylose and amylopectin. Normally a white powder of 98–99.5% purity, starch is insoluble in cold water, ethanol, and most common solvents. *See* GLUCOSE.

Starches are involved in important roles in foods, either naturally occurring in an ingredient or added to achieve a desired functional characteristic. Often the desired functional characteristic (thickening; gelling; adhesive; binding; improving acid, heat, and shear stability) cannot be achieved by using a native starch. Starches may be altered physically, chemically, or enzymatically to produce modified starches with improved functional properties.

The paper, textile, adhesive, chemical, pharmaceutical, and polymer industries use starch and starch derivatives. Organic acids and organic solvents for use as chemical intermediates, enzymes, hormones, antibiotics, and vaccines are industrially produced from starch. *See* CARBOHYDRATE. [D.R.L.]

Stark effect The effect of an electric field on spectrum lines. The electric field may be externally applied; but in many cases it is an internal field caused by the presence of neighboring ions or atoms in a gas, liquid, or solid. Discovered in 1913 by J. Stark, the effect is most easily studied in the spectra of hydrogen and helium, by observing the light from the cathode dark space of an electric discharge. Because of the large potential drop across this region, the lines are split into several components. For observation perpendicular to the field, the light of these components is linearly polarized.

The linear Stark effect exhibits large, nearly symmetrical patterns. The interpretation of the linear Stark effect was one of the first successes of the quantum theory. According to this theory, the effect of the electric field on the electron orbit is to split each energy level of the principal quantum number n into $2n - 1$ equidistant levels, of separation proportional to the field strength. *See* ATOMIC STRUCTURE AND SPECTRA.

The quadratic Stark effect occurs in lines resulting from the lower energy states of many-electron atoms. The quadratic Stark effect is basic to the explanation of the formation of molecules from atoms, of dielectric constants, and of the broadening of spectral lines.

The intermolecular Stark effect is produced by the action of the electric field from surrounding atoms or ions on the emitting atom. The intermolecular effect causes a shifting and broadening of spectrum lines. The molecules being in motion, these fields are inhomogeneous in space and also in time. Hence the line is not split into resolved components but is merely widened. [F.A.J./W.W.W.]

The quantum-confined Stark effect is the Stark effect observed in structures in which the hydrogenic system is confined in a layer of thickness much less than its normal diameter. This is not practical with atoms, but the effect is observed with excitons in semiconductor quantum-well heterostructures. It is important that quantum-confined Stark shifts can be much larger than the binding energy of the hydrogenic system. The resulting shifts of the exciton optical absorption lines can be used to make optical beam modulators and self-electrooptic-effect optical switching devices. *See* ARTIFICIALLY LAYERED STRUCTURES; ELECTROOPTICS; EXCITON; OPTICAL MODULATORS; SEMICONDUCTOR HETEROSTRUCTURES. [D.A.B.M.]

Static A hissing, crackling, or other sudden sharp noise that tends to interfere with the reception, utilization, or enjoyment of desired signals or sounds. Perhaps the commonest form of static is that heard in ordinary broadcast receivers during electrical storms. Interference in radio receivers caused by improperly operating electric devices in the vicinity is sometimes also called static. *See* SFERICS.

The crackling sounds heard when long-playing plastic phonograph records are played are also called static. These sounds are caused by sudden deflection of the phonograph needle by dust particles, which are attracted by the grooves of the record by surface electric charges caused by friction on dry days. Static appears as momentary white specks in a television picture. *See* ELECTRICAL INTERFERENCE; ELECTRICAL NOISE. [J.Mar.]

Static electricity Electric charge at rest, generally produced by friction or electrostatic induction. Triboelectrification is the process whereby charge transfer between dissimilar materials, at least one of which must have a high electrical resistivity, occurs due to rubbing or mere contact. *See* ELECTRIC CHARGE; ELECTRICAL RESISTIVITY.

In modern industry, highly insulating synthetic materials, such as plastic powders and insulating liquids, are used in large quantities in an ever-increasing number of applications. Such materials charge up readily, and large quantities of electrical energy may develop with an attendant risk of incendiary discharges. When, for example, powder is pneumatically transported along pipes, charge levels of up to about 100 microcoulombs per kilogram can develop and potentials of thousands of volts are generated within powder layers and the powder cloud. Energetic sparking from charged powder may initiate an explosion of the powder cloud. Similar problems occur when insulating liquids, such as certain fuels, are pumped along pipes, and it is essential that strict grounding procedures are followed during the refueling of aircraft, ships, and other large vehicles.

The capacity of a person for retaining charge depends upon stature, but is typically about 150 picofarads. Even the simple operations of removing items of clothing or sliding off a chair can lead to body discharges to ground of about 0.1 μC, which are energetic enough to ignite a mixture of natural gas and air. Human body capacitance is sufficiently high that, if poorly conducting shoes are worn, body potential may rise to 15,000 V or so above ground during industrial operations such as emptying bags of powder. Sparking may then occur with energy exceeding the minimum ignition energy of powder or fumes, so initiating a fire or explosion. Conducting footware should be used to prevent charge accumulation on personnel in industrial situations where triboelectrification may occur. *See* CAPACITANCE.

In the microelectronics industry, extremely low-energy discharges, arising from body potentials of only a few tens of volts, can damage microelectronics systems or corrupt computer data. During the handling of some sensitive semiconductor devices, it is imperative that operators work on metallic grounded surfaces and are themselves permanently attached to ground by conducting wrist straps. *See* ELECTROSTATICS. [A.G.B.]

Static var compensator A thyristor-controlled (hence static) generator of reactive power, either lagging or leading, or both. The word var stands for volt ampere reactive, or reactive power. The device is also called a static reactive compensator.

Need for reactive compensation. Reactive power is the product of voltage times current where the voltage and current are 90° out of phase with one another. Thus, reactive power flows one way for one-quarter of a cycle, the other way for the next quarter of a cycle, and so on (in contrast to the real power, or active power, which flows in one direction only). This back-and-forth flow results in no net power being delivered by the generator to the load. However, current associated with reactive power does flow through the conductor and creates extra losses. *See* ALTERNATING CURRENT; ELECTRIC POWER MEASUREMENT; VOLTAMPERE.

Most loads draw lagging reactive power, which causes electric power system voltage to sag. On the other hand, under light loads, the capacitance of high-voltage lines can create excessive leading reactive power, causing the voltage at some locations to rise above the nominal value. Finally, it is prudent to keep reactive power flows to a minimum in order to allow the lines to carry more active power.

Mechanical versus static compensation. Utilities frequently install capacitors connected from line to ground to compensate for lagging reactive power and reactors connected from line to ground to compensate for leading reactive power. These reactors and capacitors are switched in and out with mechanical switches based on the level of line loading as it varies throughout the day. However, frequent operation of these mechanical switches may reduce their reliability. *See* CAPACITOR; REACTOR (ELECTRICITY).

It is desirable to have a controllable source of reactive power (leading or lagging); and the static var compensator, controlled with static switches, called thyristors, for higher reliability, fulfills this function. It is more expensive than mechanically switched capacitors and reactors (due to the cost of thyristor valves and associated equipment), and hence its use is based on an economic trade-off of benefits versus cost. *See* SEMICONDUCTOR RECTIFIER. [N.G.H.]

Statics The branch of mechanics that describes bodies which are acted upon by balanced forces and torques so that they remain at rest or in uniform motion. This includes point particles, rigid bodies, fluids, and deformable solids in general. Static point particles, however, are not very interesting, and special branches of mechanics are devoted to fluids and deformable solids. For example, hydrostatics is the study of static fluids, and elasticity and plasticity are two branches devoted to deformable bodies. Therefore this article will be limited to the discussion of the statics of rigid bodies in two- and three-space dimensions. *See* BUOYANCY; ELASTICITY; HYDROSTATICS; MECHANICS.

In statics the bodies being studied are in equilibrium. The equilibrium conditions are very similar in the planar, or two-dimensional, and the three-dimensional rigid body statics. These are that the vector sum of all forces acting upon the body must be zero; and the resultant of all torques about any point must be zero. Thus it is necessary to understand the vector sums of forces and torques.

In studying statics problems, two principles, superposition and transmissibility, are used repeatedly on force vectors. They are applicable to all vectors, but specifically to forces and torques (first moments of forces). The principle of superposition of vectors is that the sum of any two vectors is another vector. The principle of transmissibility of a force applied to a rigid body is that the same mechanical effect is produced by any shift of the application of the force along its line of action. To use the superposition principle to add two vectors, the principle of transmissibility is used to move some vectors along their line of action in order to add to their components.

The moment of a force about a directed line is a signed number whose value can be obtained by applying these two rules: (1) The moment of a force about a line parallel to the force is zero. (2) The moment of a force about a line normal to a plane containing the force is the product of the magnitude of the force and the least distance from the line to the line of the force. *See* EQUILIBRIUM OF FORCES; FORCE; TORQUE. [B.DeF.]

Statistical mechanics That branch of physics which endeavors to explain the macroscopic properties of a system on the basis of the properties of the microscopic constituents of the system. Usually the number of constituents is very large. All the characteristics of the constituents and their interactions are presumed known; it is the task of statistical mechanics (often called statistical physics) to deduce from this information the behavior of the system as a whole.

Scope. Elements of statistical mechanical methods are present in many widely separated areas in physics. For instance, the classical Boltzmann problem is an attempt to explain the thermodynamic behavior of gases on the basis of classical mechanics applied to the system of molecules.

Statistical mechanics gives more than an explanation of already known phenomena. By using statistical methods, it often becomes possible to obtain expressions for empirically observed parameters, such as viscosity coefficients, heat conduction coefficients, and virial coefficients, in terms of the forces between molecules. Statistical considerations also play a significant role in the description of the electric and magnetic properties of materials. *See* BOLTZMANN STATISTICS; INTERMOLECULAR FORCES; KINETIC THEORY OF MATTER.

If the problem of molecular structure is attacked by statistical methods, the contributions of internal rotation and vibration to thermodynamic properties, such as heat capacity and entropy, can be calculated for models of various proposed structures. Comparison with the known properties often permits the selection of the correct molecular structure.

Perhaps the most dramatic examples of phenomena requiring statistical treatment are the cooperative phenomena or phase transitions. In these processes, such as the condensation of a gas, the transition from a paramagnetic to a ferromagnetic state, or the change from one crystallographic form to another, a sudden and marked change of the whole system takes place. *See* PHASE TRANSITIONS.

Statistical considerations of quite a different kind occur in the discussion of problems such as the diffusion of neutrons through matter. In this case, the probability of the various events which affect the neutron are known, such as the capture probability and scattering cross section. The problem here is to describe the physical situation after a large number of these individual events. The procedures used in the solution of these problems are very similar to, and in some instances taken over from, kinetic considerations. Similar problems occur in the theory of cosmic-ray showers.

It happens in both low-energy and high-energy nuclear physics that a considerable amount of energy is suddenly liberated. An incident particle may be captured by a nucleus, or a high-energy proton may collide with another proton. In either case, there is a large number of ways (a large number of degrees of freedom) in which this energy may be utilized. To survey the resulting processes, one can again invoke statistical considerations. *See* SCATTERING EXPERIMENTS (NUCLEI).

Of considerable importance in statistical physics are the random processes, also called stochastic processes or sometimes fluctuation phenomena. The brownian motion, the motion of a particle moving in an irregular manner under the influence of molecular bombardment, affords a typical example. The stochastic processes are in a sense intermediate between purely statistical processes, where the existence of fluctuations may safely be neglected, and the purely atomistic phenomena, where each particle requires its individual description. *See* BROWNIAN MOVEMENT; STOCHASTIC PROCESS.

All statistical considerations involve, directly or indirectly, ideas from the theory of probability of widely different levels of sophistication. The use of probability notions is, in fact, the distinguishing feature of all statistical considerations. *See* PROBABILITY; STATISTICS.

Methods. For a system of N particles, each of the mass m, contained in a volume V, the positions of the particles may be labeled x_1, y_1, z_1, . . . , x_N, y_N, z_N, their cartesian velocities v_{x1}, . . . , v_{zN}, and their momenta P_{x1}, . . . , P_{zN}. This simplest statistical description concentrates on a discussion of the distribution function $f(x,y,z;v_x,v_y,v_z;t)$. The quantity $f(x,y,z;v_x,v_y,v_z;t) \cdot (dx dy dz dv_x dv_y dv_z)$ gives the (probable) number of particles of the system in those positional and velocity ranges where x lies between x and $x + dx$; v_x between v_x and $v_x + dv_x$, and so on. These ranges are finite.

Observations made on a system always require a finite time; during this time the microscopic details of the system will generally change considerably as the phase point moves. The result of a measurement of a quantity Q will therefore yield the time average, as in Eq. (1). The integral is along the trajectory in phase

$$\overline{Q}_t = \frac{1}{t}\int_0^t Q\,dt \tag{1}$$

space; Q depends on the variables x_1, . . . , P_{zN}, and t. To evaluate the integral, the trajectory must be known, which requires the solution of the complete mechanical problem.

Ensembles. J. Willard Gibbs first suggested that instead of calculating a time average for a single dynamical system, a collection of systems, all similar to the original one, should instead be considered. Such an ensemble of systems is to be constructed in harmony with the available knowledge of the single system, and may be represented by an assembly of points in the phase space, each point representing a single system. If, for example, the energy of a system is precisely known, but nothing else, the appropriate representative example would be a uniform distribution of ensemble points over the energy surface, and no ensemble points elsewhere. An ensemble is characterized by a density function $\rho(x_1, \ldots, z_N;\, p_{x1}, \ldots, p_{zN}; t) \equiv p(x,p,t)$. The significance of this function is that the number of ensemble systems dN_e contained in the volume element $dx_1 \ldots dz_N;\ dp_x \ldots dp_{zN}$ of the phase space (this volume element will be called $d\Gamma$) at time t is as given in Eq. (2).

$$\rho(x,p,t)\ d\Gamma = dN_e \tag{2}$$

The ensemble average of any quantity Q is given by Eq. (3).

$$\overline{Q}_{\text{ens}} = \frac{\int Q\rho\,d\Gamma}{\int \rho\,d\Gamma} \tag{3}$$

The basic idea now is to replace the time average of an individual system by the ensemble average, at a fixed time, of the representative ensemble. Stated formally, the quantity $\overline{Q}_t$ defined by Eq. (1), in which no statistics is involved, is identified with $\overline{Q}_{\text{ens}}$ defined by Eq. (3), in which probability assumptions are explicitly made.

Relation to thermodynamics. It is certainly reasonable to assume that the appropriate ensemble for a thermodynamic equilibrium state must be described by a density function which is independent of the time, since all the macroscopic averages which are to be computed as ensemble averages are time-independent.

The so-called microcanonical ensemble is defined by Eq. (4*a*), where c is a constant, for the energy E between E_0 and $E_0 + \Delta E$; for other energies Eq. (4*b*) holds. By using Eq. (3), any micro-

$$\rho(p,x) = c \tag{4a}$$

$$\rho(p,x) = 0 \tag{4b}$$

canonical average may be calculated. The calculations, which involve integrations over volumes bounded by two energy surfaces, are not trivial. Still, many of the results of classical Boltzmann statistics may be obtained in this way. For applications and for the interpretation of thermodynamics, the canonical ensembles is much more preferable. This ensemble describes a system which is not isolated but which is in thermal contact with a heat reservoir.

There is yet another ensemble which is extremely useful and which is particularly suitable for quantum-mechanical applications. Much work in statistical mechanics is based on the use of this so-called grand canonical ensemble. The grand ensemble describes a collection of systems; the number of particles in each system is no longer the same, but varies from system to system. The density function $p(N,p,x)\, d\Gamma_N$ gives the probability that there will be in the ensemble a system having N particles, and that this system, in its $6N$-dimensional phase space Γ_N, will be in the region of phase space $d\Gamma_N$. [M.Dr.]

Statistics The field of knowledge concerned with collecting, analyzing, and presenting data. Not only workers in the physical, biological, and social sciences, but also engineers, business managers, government officials, market analysts, and many others regularly use statistical methods in their work. The methods range from simple counting to complex mathematical systems designed to extract the maximum amount of information from very extensive data.

In an important sense statistics may be regarded as a field of application of probability theory. The common problem faced by any worker who must collect, analyze, and present data is that of random variation which prevents repetition of exactly the same result when a measurement is repeated. Statistical methods are employed to assess the magnitude of random variation, to minimize it, to balance it out, to remove it by calculation procedures, and to analyze it by suitably arranged patterns of observation. The theory of probability is concerned with the properties of random variables and hence furnishes the basis for developing techniques for controlling them. *See* PROBABILITY.

Viewing statistics from another direction, it is the science of deriving information about populations by observing only samples of those populations. A population is any well-specified collection of elements. Thus, one may refer to the population of adults in the continental United States viewing television screens at 8:14 P.M. on August 6, 1970. Populations may be finite or infinite. An element of a univariate population is characterized by the value of a random variable which measures some single attribute of interest in the population. Thus, one may be interested in whether or not individuals of the television audience were or were not viewing program *A*; with each individual one may associate a random variable; let it be *X*, which takes on the value of 1 if the individual is watching *A* and 0 if he or she is not. If one were interested in a second characteristic of the elements of the television audience (such as age), one would be dealing with a bivariate population; a third characteristic (such as economic status) would make it a trivariate or, less specifically, a multivariate population.

Distributions. In a univariate population, the population distribution is a curve (function of the random variable which characterizes the elements of the population) from which one can determine the proportion of the population which has elements in a certain range of the random variable. For example, the curve of Fig. 1 provides the distribution of annual incomes of family units in the United States in 1954. The total area under the curve is 1. The area under the curve between any two vertical lines gives the proportion of the families having annual incomes between the two values marked on the horizontal scale by the two vertical lines.

The distribution is also referred to as the distribution function, the density function, the frequency function, or the probability density.

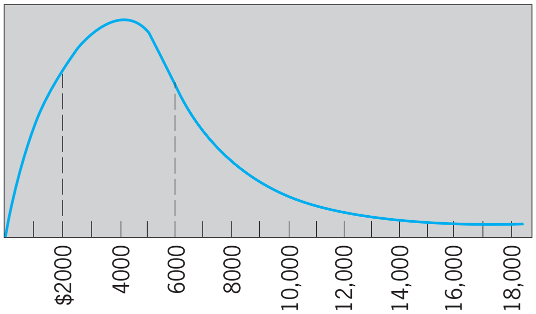


Fig. 1. Distribution of incomes.

The total area under the distribution curve to the left of each point can also be plotted to give a curve which starts at zero and reaches unity as the variable becomes large; the resulting curve is sometimes called the cumulative distribution function, the probability distribution, or simply the distribution. The cumulative form of the curve of Fig. 1 is shown in Fig. 2; the height of the curve at any point on the horizontal scale equals the area to the left of that point under the curve of Fig. 1 and is the proportion of the population having incomes less than the value at that point. The distribution (in either frequency or cumulative form) gives complete information about the way the characterizing variable is spread through the population.

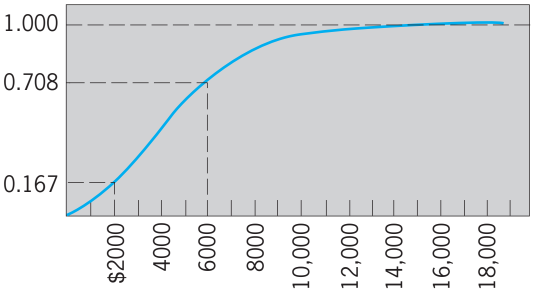

Fig. 2. Cumulative distribution of incomes.

Population parameters. Populations (or population distributions) are often specified incompletely by certain population parameters. Some of these parameters are location parameters or measures of central tendency; a second class of important parameters consists of measures of dispersion or scale parameters.

The most widely used location parameters are the mean, the median, and the mode. The mean is the average over all the population of the values of the random variable. It is often represented by the Greek letter μ. In mathematical terms, if x is the random variable, $f(x)$ the frequency function for a given population, and $F(x)$ its cumulative form, then the mean is as shown in Eq. (1).

$$\mu = \int_{-\infty}^{\infty} xf(x)dx = \int_{-\infty}^{\infty} xdF(x) \qquad (1)$$

The median, often designated by Med, M, or X_{50}, is a number such that, at most, one-half the values of the variable associated with the elements of the population fall above or below it. The mode is the most frequent value of the random variable; if the frequency function has a unique maximum value, the mode is the value of the random variable at which the frequency function reaches its maximum. Location parameters are numbers near the center of the range over which the random variable of the population varies.

The extent to which a population is scattered on either side of its center is roughly indicated by measures of dispersion such as the standard deviation, the mean deviation, the interquartile range, the range, and sometimes others. The standard deviation is the square root of the mean square of the deviations from the mean; it is usually denoted by the Greek letter σ; σ^2 is called the variance and is expressed by Eq. (2).

$$\begin{aligned}\sigma^2 &= \textstyle\int_{-\infty}^{\infty}(x-\mu)^2 f(x)dx \\ &= \textstyle\int_{-\infty}^{\infty}(x-\mu)^2 dF(x) \qquad (2)\end{aligned}$$

The mean deviation, shown in Eq. (3), is the average over the population of the deviations from the mean, all taken to be positive.

$$\begin{aligned}\text{Mean deviation} &= \textstyle\int_{-\infty}^{\infty}|x-\mu|\,f(x)dx \\ &= \textstyle\int_{-\infty}^{\infty}|x-\mu|dF(x) \qquad (3)\end{aligned}$$

The interquartile range (often denoted by Q) is the difference $X_{.75} - X_{.25}$, where $X_{.75}$ is the value of the random variable such that one-quarter of the population has values larger than $X_{.75}$, and $X_{.25}$ is the number such that one-quarter of the population has values smaller than $X_{.25}$. The three numbers, $X_{.25}$, $X_{.50}$, $X_{.75}$, are called quartiles; these divide the population into quarters. The range is the difference between the largest and the smallest of the population elements.

Sampling. If one examines every element of a population and records the value of the random variable for each, complete information is obtained about the distribution of the random variable in the population, and there is no statistical problem. It is usually impossible or uneconomical to make a complete enumeration (or census) of a population, and one must therefore be content to examine only a part or sample of the population. On the basis of the sample, one draws conclusions about the entire population; the conclusions thus drawn are not certain in the sense that they would likely have been somewhat different if a different sample of the population had been examined. The problem of drawing valid conclusions from samples and of specifying their range of uncertainty is known as the problem of statistical inference.

Simple random sampling is a method of selecting a sample of n elements out of a population of N elements so that all such samples have an equal probability of being drawn. This may be done by selecting a first element at random from the population, then a second element at random from the remaining population, and so on until the n elements are selected.

The observations of a sample, besides providing estimates of population parameters, can also be used to obtain an estimate of the population's frequency function. This estimate is determined by dividing the range of the sample observations into several intervals of equal length L and counting the number of observations occurring in each interval; these numbers are then divided by nL to determine fractions giving the relative density of the sample occurring in each interval; then on a sheet of graph paper one lays out the intervals on a horizontal axis and plots horizontal lines above each interval at a height equal to the fraction corresponding to the interval; finally the successive plotted horizontal lines are connected by vertical lines to form a broken line curve known as a histogram (Fig. 3).

When a population can be regarded as being made up of several nonoverlapping subpopulations, one may draw a sample from it by drawing a simple random sample from each

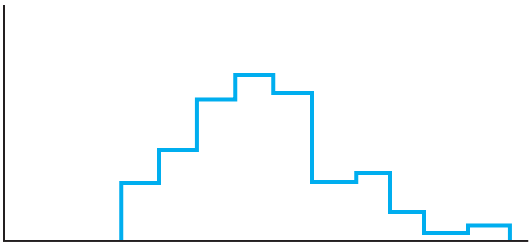

Fig. 3. Histogram.

subpopulation (or stratum); this procedure is called stratified random sampling. Systematic sampling may be regarded as a sampling of units at regular intervals in the population, for example, every tenth unit. When the elements of a population are in mutually exclusive groups called the primary units of the population, then a sample of these primary units might be made, and then, from those selected, a sample of the individual elements would be made. This procedure is called two-stage sampling or subsampling. Multistage sampling can involve more than two stages of sampling.

Many important sampling distributions are derived for random samples drawn from a normal or Gaussian distribution, which is a bell-shaped symmetrical distribution centered at its mean μ.

Estimation. In making an estimate of the value of a parameter of a population from a sample, a function (called the estimator) of the observations is used. For example, for estimating the mean of a normal population the mean of the sample observations is usually taken as the estimator. Another estimator is the average of the two most extreme observations. In fact, there is an infinitude of estimators. The problem of estimation is to find a "good" estimator.

A good estimator may be regarded as one which results in a distribution of estimates concentrated near the true value of the parameter and which can be applied without excessive effort.

Tests of hypotheses. Besides estimation of parameters, another major area of statistical inference is the testing of hypotheses. A hypothesis is merely an assertion that a population has a specific property. The test consists of drawing a sample from the population and determining whether or not it is consistent with the assertion. Very often the hypothesis is a statement about the mean of a population; that it has a given value, that it is the same as that of another population, that it exceeds that of another population by at least 10 units, and the like. Thus, one may be comparing a new blend of gasoline with a current blend, a new drug with a standard one, a new manufacturing process with an existing one.

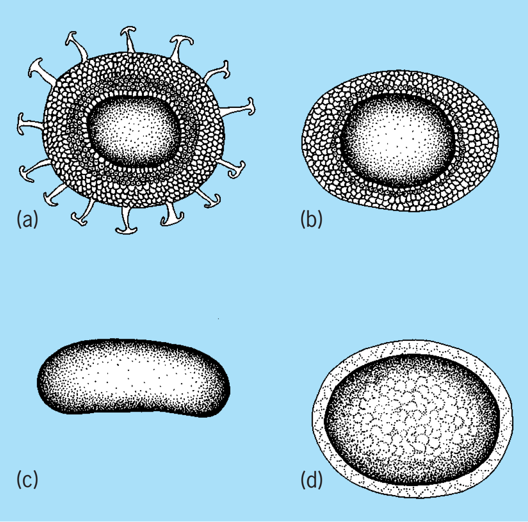
Experimental design. An experiment is performed to obtain information about the relations between several variables. For example, one may study the effect of storage temperature and duration of storage on the flavor of a frozen food. Three variables (flavor, temperature, and duration) are involved; one (flavor) is called the subject of the experiment; the other two are called factors which influence the subject. Sometimes the factors have intrinsic value in themselves; sometimes they are merely nuisance variables which must be taken into account because it is impossible to perform the experiment without them.

There exist in the statistical literature great numbers of specific experimental designs. These are patterns for making experimental observations; the actual construction of the designs requires quite advanced mathematics based on group theory, finite geometries, and combinatorial analysis. The mathematical problem is to find a pattern from which it is possible to extract the desired information and yet minimize the number of observations.

Regression and correlation. The regression problem is that of estimating certain unknown constants or parameters occurring in a function which relates several variables; the variables may be random or not. By far the most easily handled cases are those in which the function is linear in the unknown parameters, and it is worth considerable effort to transform the function to that form if at all possible. *See* ANALYSIS OF VARIANCE; DISTRIBUTION (PROBABILITY). [A.M.M.]

Statoblasts

Chitin-encapsulated bodies, resistant to freezing and a limited amount of desiccation. They serve as a special means of asexual reproduction in the Phylactolaemata, a class of fresh-water Bryozoa. They are 0.01–0.06 in. (0.26–1.5 mm) long, and their shape and structure are important to the taxonomy of the group.



Some types of statoblasts. (*a*) Spinoblast of *Pectinatella magnifica*. (*b*) Floatoblast of *Plumatella repens*. (*c*) Piptoblast or sessoblast of *Fredericella sultana*. (*d*) Sessoblast of *Stolella indica*.

Statoblasts are classified as follows: sessoblasts, those which attach to zooecial tubes (structures of the outer layer or zooecial of an individual in the colony) or the substratum; floatoblasts and spinoblasts, both of which have a float of "air" cells and therefore are free-floating; and piptoblasts, which are free but have no float (see illustration).

These bodies are produced in enormous quantities from spring to autumn. They develop by organization of masses of peritoneal cells and epidermal cells that bulge into the coelom. Each mass then secretes protective upper and lower chitinous valves, the rims of which often project peripherally. Statoblasts are therefore somewhat disk-shaped.

These bodies remain dormant for variable periods of time and serve to tide species over adverse ecological conditions, such as freezing or drying, which kill the colony. During this time they may be dispersed over considerable distances, being carried by animals, floating vegetation, or the action of water currents. When environmental conditions become favorable, which is usually in the spring, statoblasts germinate and a zooid develops from the mass of cells lying between the two valves. Statoblasts of *Lophopodella* have germinated after 50 months of drying. *See* BRYOZOA. [S.P.P]

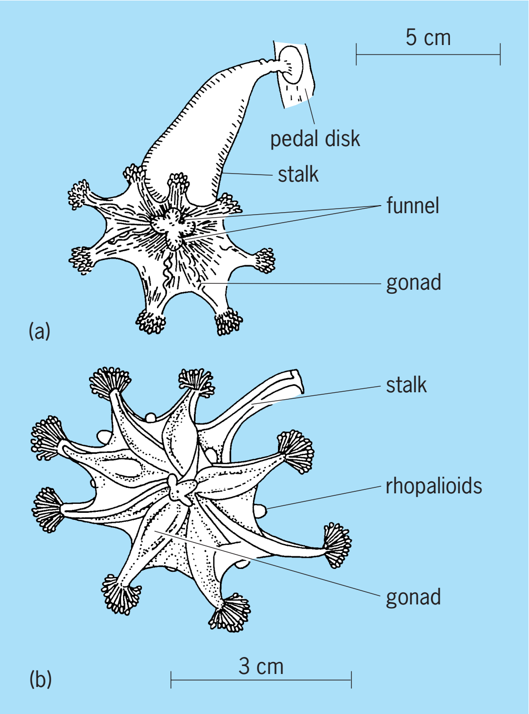
Staurolite

A nesosilicate mineral occurring in metamorphic rocks. The chemical formula of staurolite may be written as $A_4B_4C_{18}D_4T_8O_{40}X_8$, where A = Fe^{2+}, Mg; B = Fe^{2+}, Zn, Co, Mg, Li, Al, Fe^{3+}, Mn^{2+}; C = Al, Fe^{3+}, Cr, V, Ti; D = Al, Mg; T = Si, Al; X = OH, F, O. Staurolite occurs as well-formed, often-twinned, prismatic crystals. It is brown-black, reddish brown, or light brown in color and has a vitreous to dull luster. Light color and dull luster can result from abundant quartz inclusions. There is no cleavage, specific gravity is 3.65–3.75, and hardness is 7–7.5 (Mohs scale). *See* HARDNESS SCALES.

Typical minerals occurring with staurolite are quartz, micas (muscovite and biotite), garnet (almandine), tourmaline, and kyanite, sillimanite, or andalusite. Staurolite is common where pelitic schists reach medium-grade metamorphism. Examples are the Swiss and Italian Alps (notable at Saint Gotthard, Switzerland), and all the New England states, Virginia, the Carolinas, Georgia, New Mexico, Nevada, and Idaho. *See* METAMORPHISM; SILICATE MINERALS. [F.C.Ha.]

Stauromedusae

An order of the class Scyphozoa, usually found in circumpolar regions. The egg develops into a



Stauromedusae. (*a*) *Lucernaria*. (*b*) *Haliclystus*. (*After L. H. Hyman, The Invertebrates, vol. 1, McGraw-Hill, 1940*)

planula which can only creep since it lacks cilia. The planula changes into a polyp that metamorphoses directly into a combined polyp and medusa form. The medusa is composed of a cuplike bell called a calyx (medusan part) and a stem or stalk (polyp part) which terminates in a pedal disk (see illustration). The calyx is eight-sided and has eight groups of short, capped tentacles and eight sensory bodies, called anchors, on its margin. The mouth, situated at the center of the calyx, has four thin lips and leads to the stomach in which gastral filaments are arranged in a row on either side of each interradius. Though sessile, the medusa can move in a leechlike fashion by alternate attachment and release of the pedal disk, using the substratum as an anchor. *See* Scyphozoa. [T.U.]

Steam Water vapor, or water in its gaseous state. Steam is the most widely used working fluid in external combustion engine cycles, where it will utilize practically any source of heat, that is, coal, oil, gas, nuclear fuel (uranium and thorium), waste fuel, and waste heat. It is also extensively used as a thermal transport fluid in the process industries and in the comfort heating and cooling of space. The universality of its availability and its highly acceptable, well-defined physical and chemical properties also contribute to the usefulness of steam.

The temperature at which steam forms depends on the pressure in the boiler. The steam formed in the boiler (and conversely steam condensed in a condenser) is in temperature equilibrium with the water. Under these conditions, with steam and water in contact and at the same temperature, the steam is termed saturated. Steam can be entirely vapor when it is 100% dry, or it can carry entrained moisture and be wet. After the steam is removed from contact with the liquid phase, the steam can be further heated without changing its pressure. If initially wet, the additional heat will first dry it and then raise it above its saturation temperature. This is a sensible heat addition, and the steam is said to be superheated. Superheated steam at temperatures well above the boiling temperature for the existing steam pressure follows closely the laws of a perfect gas. Chiefly because of its availability, but also because of its nontoxicity, steam is widely used as the working medium in thermodynamic processes. It has a uniquely high latent heat of vaporization. Steam has a specific heat about twice that of air and comparable to that of ammonia. The specific heat of steam is relatively high so that it can carry more thermal energy at practical temperatures than can other usable gases. *See* Boiler; Boyle's law; Charles' law; Dalton's law; Entropy; Steam engine; Steam-generating unit; Steam heating; Steam turbine; Thermodynamic cycle; Thermodynamic principles; Water. [T.Ba.]

Steam condenser A heat-transfer device used for condensing steam to water by removal of the latent heat of steam and its subsequent absorption in a heat-receiving fluid, usually water, but on occasion air or a process fluid. Steam condensers may be classified as contact or surface condensers.

In the contact condenser, the condensing takes place in a chamber in which the steam and cooling water mix. The direct contact surface is provided by sprays, baffles, or void-effecting fill. In the surface condenser, the condensing takes place separated from the cooling water or other heat-receiving fluid (or heat sink). A metal wall, or walls, provides the means for separation and forms the condensing surface.

Both contact and surface condensers are used for process systems and for power generation serving engines and turbines. Modern practice has confined the use of contact condensers almost entirely to such process systems as those involving vacuum pans, evaporators, or dryers, and to condensing and dehumidification processes inherent in vacuum-producing equipment such as steam jet ejectors and vacuum pumps. The steam surface condenser is used chiefly in power generation but is also used in process systems, especially in those in which condensate recovery is important. Air-cooled surface condensers are used in process systems and in power generation when the availability of cooling water is limited. *See* Steam; Steam turbine; Vapor condenser. [J.F.Se.]

Steam electric generator An alternating-current (ac) synchronous generator driven by a steam turbine for 50- or 60-Hz electrical generating systems. *See* Steam turbine.

The synchronous generator is a relatively simple machine made of two basic parts: a stator (stationary) and a rotor (rotating). The stator consists of a cylindrical steel frame. Inside the frame, a cylindrical iron core made of thin insulated laminations is mounted on a support system. The iron core has equally spaced axial slots on its inside diameter, and wound within the core slots is a stator winding. The stator winding copper is electrically insulated from the core. The rotor consists of a forged solid steel shaft. Wound into axial slots on the outside diameter of the shaft is a copper rotor winding that is held in the slots with wedges. Retaining rings support the winding at the rotor body ends. The rotor winding, commonly called the field, is electrically insulated from the shaft and is arranged in pole pairs (always an even number) to form the magnetic field which produces the flux. The rotor shaft (supported by bearings) is coupled to a steam turbine, and rotates inside the stator core. *See* Electric rotating machinery; Windings in electric machinery.

The stator winding (armature) is connected to the ac electrical transmission system through the bushings and output terminals. The rotor winding (field) is connected to the generator's excitation system. The excitation system provides the direct-current (dc) field power to the rotor winding via carbon brushes riding on a rotating collector ring mounted on the generator rotor. The synchronous generator's output voltage amplitude and frequency must remain constant for proper operation of electrical load devices. During operation, the excitation system's voltage regulator monitors the generator's output voltage and current. The voltage regulator controls the rotor winding dc voltage to maintain a constant generator stator output ac voltage, while allowing the stator current to vary with changes in load. Field windings typically operate at voltages between 125 and 575 V dc. The synchronous generator's output frequency is directly proportional to the speed of the rotor, and the speed of the generator rotor is held constant by a speed governor system associated with the steam turbine. *See* Alternating-current generator; Generator.

Synchronous generators range in size from a few kilovoltamperes to 1,650,000 kVA. 60-Hz steam-driven synchronous generators operate at speeds of either 3600 or 1800 rpm; for 50-Hz synchronous generators these speeds would be 3000 or 1500 rpm. These two- and four-pole generators are called cylindrical rotor units. For comparison, water (hydro)-driven and air-driven synchronous generators operate at lower speeds, some as low as 62 rpm (116 poles). The stator output voltage of large (generally greater than 100,000 kVA) units ranges 13,800–27,000 V. *See* Electric power generation; Hydroelectric generator.

There are five sources of heat loss in a synchronous generator: stator winding resistance, rotor winding resistance, core, windage and friction, and stray losses. Removing the heat associated with these losses is the major challenge to the machine designer. The cooling requirements for the stator windings, rotor windings, and core increase proportionally to the cube of the machine size. The early synchronous generators were air-cooled. Later, air-to-water coolers were required to remove the heat. [J.R.Mi.]

Steam engine A machine for converting the heat energy in steam to mechanical energy of a moving mechanism, for example, a shaft. The steam engine can utilize any source of heat in the form of steam from a boiler. Most modern machine elements had their origin in the steam engine: cylinders, pistons, piston rings, valves and valve gear crossheads, wrist pins, connecting rods, crankshafts, governors, and reversing gears. *See* Boiler; Steam.

The 20th century saw the practical end of the steam engine. The steam turbine replaced the steam engine as the major prime mover for electric generating stations. The internal combustion engine, especially the high-speed automotive types which burn volatile (gasoline) or nonvolatile (diesel) liquid fuel, has completely displaced the steam locomotive with the diesel locomotive and marine steam engines with the motorship and motorboat. Because of the steam engine's weight and speed limitations, it was also excluded from the aviation field. *See* Diesel engine; Gas turbine; Internal combustion engine; Steam turbine.

A typical steam reciprocating engine consists of a cylinder fitted with a piston (Fig. 1). A connecting rod and crankshaft convert the piston's to-and-fro motion into rotary motion. A flywheel tends to maintain a constant-output angular velocity in the presence of the cyclically changing steam pressure on the piston face. A D slide valve admits high-pressure steam to the cylinder and allows the spent steam to escape (Fig. 2). The power developed by the engine depends upon the pressure and quantity of steam admitted per unit time to the cylinder.

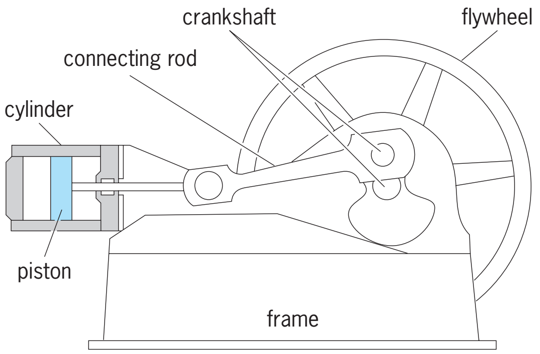


Fig. 1. Principal parts of horizontal steam engine.

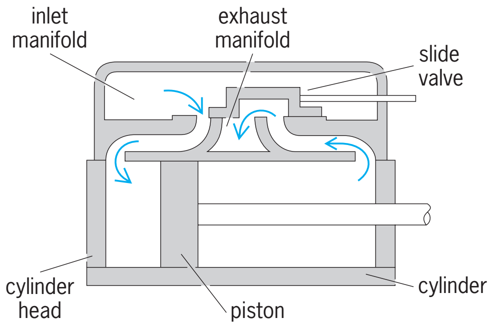

Fig. 2. Single-ported slide valve on counterflow double-acting cylinder.

Engines are classified as single- or double-acting, and as horizontal (Fig. 1) or vertical depending on the direction of piston motion. If the steam does not fully expand in one cylinder, it can be exhausted into a second, larger cylinder to expand further and give up a greater part of its initial energy. Thus, an engine can be compounded for double or triple expansion.

Steam engines can also be classed by functions, and are built to optimize the characteristics most desired in each application. Stationary engines drive electric generators, in which constant speed is important, or pumps and compressors, in which constant torque is important. [T.Ba.]

Steam-generating furnace An enclosed space provided for the combustion of fuel to generate steam. The closure confines the products of combustion and is capable of withstanding the high temperatures developed and the pressures used. Its dimensions and geometry are adapted to the rate of heat release, to the type of fuel, and to the method of firing so as to promote complete burning of the combustible and suitable disposal of ash. In water-cooled furnaces the heat absorbed materially affects the temperature of gases at the furnace outlet and contributes directly to the generation of steam. *See* Furnace construction; Steam; Steam-generating unit. [G.W.K.]

Steam-generating unit The wide diversity of parts, appurtenances, and functions needed to release and utilize a source of heat for the practical production of steam at pressures to 5000 lb/in.^{2} (34 megapascals) and temperatures to 1100°F (600°C), often referred to as a steam boiler for brevity. *See* Steam.

The essential steps of the steam-generating process include (1) a furnace for the combustion of fuel, or a nuclear reactor for the release of heat by fission, or a waste heat system; (2) a pressure vessel in which feedwater is raised to the boiling temperature, evaporated into steam, and generally superheated beyond the saturation temperature; and (3) in many modern central station units, a reheat section or sections for resuperheating steam after it has been partially expanded in a turbine. This aggregation of functions requires a wide assortment of components, which may be variously employed in the interests, primarily, of capacity and efficiency in the steam-production process. The selection, design, operation, and maintenance of these components constitute a complex process. *See* Boiler; Reheating; Superheater. [T.Ba.]

Steam heating A heating system that uses steam generated from a boiler. The steam heating system conveys steam through pipes to heat exchangers, such as radiators, convectors, baseboard units, radiant panels, or fan-driven heaters, and returns the resulting condensed water to the boiler. Such systems normally operate at pressure not exceeding 15 lb/in.^{2} gage or 103 kilopascals gage, and in many designs the condensed steam returns to the boiler by gravity because of the static head of water in the return piping. With utilization of available operating and safety control devices, these systems can be designed to operate automatically with minimal maintenance and attention.

In a one-pipe steam heating system, a single main serves the dual purpose of supplying steam to the heat exchanger and conveying condensate from it. Ordinarily, there is but one connection to the radiator or heat exchanger, and this connection serves as both the supply and return. A two-pipe system is provided with two connections from each heat exchanger, and in this system steam and condensate flow in separate mains and branches.

Another source for steam for heating is from a high-temperature water source (350–450°F or 180–230°C) using a high-pressure water to low-pressure steam heat exchanger. *See* Boiler; Comfort heating; Oil burner; Steam-generating furnace. [J.W.J.]

Steam jet ejector A steam-actuated device for pumping compressible fluids, usually from subatmospheric suction pressure to atmospheric discharge pressure. A steam jet ejector is most frequently used for maintaining vacuum in process equipment in which evaporation or condensation takes place. Because of its simplicity, compactness, reliability, and generally low first cost, it is often preferred to a mechanical vacuum pump for removing air from condensers serving steam turbines, especially for marine service.

Two or more stages may be arranged in series, depending upon the total compression ratio required. Two or more sets of series stages may be arranged in parallel to accommodate variations in capacity. Vapor condensers are usually interposed between the compression stages of multistage steam jet ejectors to condense and remove a significant portion of the motive steam and other condensable vapors. [J.F.Se.]

Steam separator A device for separating a mixture of the liquid and vapor phases of water. Steam separators are used in most boilers and may also be used in saturated steam lines to separate and remove the moisture formed because of heat loss.

Steam separators have many forms and may be as fundamental as a simple baffle that utilizes inertia caused by a change of direction. Most modern, high-capacity boilers use a combination of cyclone separators and steam dryers. Cyclone separators slice the steam-water mixture into thin streams so that the steam bubbles need travel only short distances through the mixture to become disengaged, and then they whirl the mixture in a circular path, creating a centrifugal force many times greater than the force of gravity. Steam dryers remove small droplets of water from the steam by providing a series of changes in direction and a large surface area to intercept the droplets. *See* Boiler feedwater; Steam; Steam turbine. [E.E.Co.]

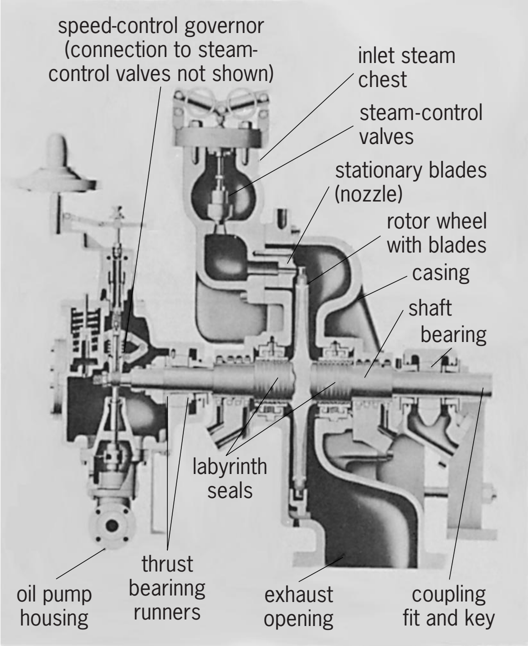
Steam temperature control Means for regulating the operation of a steam-generating unit to produce steam at the required temperature. The temperature of steam is affected by the change in the relative heat absorption as load varies, by changes in ash or slag deposits on the heat-absorbing surface, by changes in fuel, by changes in the proportioning of fuel and combustion air, or by changes in feedwater temperature. Low steam temperature lowers the efficiency of the thermal cycle. However, high steam temperature, which increases thermal efficiency, is restricted by the strength and durability of materials used in superheaters. Control of steam temperature is, therefore, a matter of primary concern in the design of modern steam-generating units.

Steam temperature can be controlled by one or more of several methods. These include (1) the damper control of gases to the superheater, to the reheater, or to both, thus changing the heat input; (2) the recirculation of low-temperature flue gas to the furnace, thus changing the relative amounts of heat absorbed in the furnace and in the superheater, reheater, or both; (3) the selective use of burners at different elevations in the furnace or the use of tilting burners, thus changing the location of the combustion zone with respect to the furnace heat-absorbing surface; (4) the attemperation, or controlled cooling, of the steam by the injection of spray water or by the passage of a portion of the steam through a heat exchanger submerged in the boiler water; (5) the control of the firing rate in divided furnaces; and (6) the control of the firing rate relative to the pumping rate of the feedwater to forced-flow once-through boilers. Generally, these various controls are adjusted automatically. *See* Steam-generating unit. [G.W.K.]

Steam turbine A machine for generating mechanical power in rotary motion from the energy of steam at temperature and pressure above that of an available sink. By far the most widely used and most powerful turbines are those driven by steam. Until the 1960s essentially all steam used in turbine cycles was raised in boilers burning fossil fuels (coal, oil, and gas) or, in minor quantities, certain waste products. However, modern turbine technology includes nuclear steam plants as well as production of steam supplies from other sources. *See* Nuclear reactor.

The illustration shows a small, simple mechanical-drive turbine of a few horsepower. It illustrates the essential parts for all steam turbines regardless of rating or complexity: (1) a casing, or shell, usually divided at the horizontal center line, with the halves bolted together for ease of assembly and disassembly; it contains the stationary blade system; (2) a rotor carrying the moving buckets (blades or vanes) either on wheels or drums, with bearing journals on the ends of the rotor; (3) a set of bearings attached to the casing to support the shaft; (4) a governor and valve system for regulating the speed and power of the turbine by controlling the steam flow, and an oil system for lubrication of the bearings and, on all but the smallest machines, for operating the control valves by a relay system connected with the governor; (5) a coupling to connect with the driven machine; and (6) pipe connections to the steam supply at the inlet and to an exhaust system at the outlet of the casing or shell.

Steam turbines are ideal prime movers for driving machines requiring rotational mechanical input power. They can deliver constant or variable speed and are capable of close speed control. Drive applications include centrifugal pumps, compressors, ship propellers, and, most important, electric generators.



Cutaway of small, single-stage steam turbine. (***General Electric Co.***)

Steam turbines are classified (1) by mechanical arrangement, as single-casing, cross-compound (more than one shaft side by side), or tandem-compound (more than one casing with a single shaft); (2) by steam flow direction (axial for most, but radial for a few); (3) by steam cycle, whether condensing, noncon-densing, automatic extraction, reheat, fossil fuel, or nuclear; and (4) by number of exhaust flows of a condensing unit, as single, double, triple flow, and so on. Units with as many as eight exhaust flows are in use. *See* TURBINE. [F.G.B.]

Steel Any of a great number of alloys that contain the element iron as the major component and small amounts of carbon as the major alloying element. These alloys are more properly referred to as carbon steels. Small amounts, generally on the order of a few percent, of other elements such as manganese, silicon, chromium, molybdenum, and nickel may also be present in carbon steels. However, when large amounts of alloying elements are added to iron to achieve special properties, other designations are used to describe the alloys. For example, large amounts of chromium, over 12%, are added to produce the important groups of alloys known as stainless steels. *See* STAINLESS STEEL.

Low-carbon steels, sometimes referred to as mild steels, usually contain less than 0.25% carbon. These steels are easily hot-worked and are produced in large tonnages for beams and other structural applications. The relatively low strength and high ductility of the low-carbon steels make it possible also to cold-work these steels. Cold-rolled low-carbon steels are extensively used for sheet applications in the appliance and automotive industries. Cold-rolled steels have excellent surface finishes, and both hot- and cold-worked mild steels are readily welded.

Medium-carbon steels contain between 0.25 and 0.70% carbon, and are most frequently used in the heat-treated condition for machine components that require high strength and good fatigue resistance.

Steels containing more than 0.7% carbon are in a special category because of their high hardness and low toughness. This combination of properties makes the high-carbon steels ideal for bearing applications where wear resistance is important and the compressive loading minimizes brittle fracture that might develop on tensile loading. [G.Kr.]

Steel manufacture A sequence of operations in which pig iron and scrap steel are processed to remove impurities and are separated into the refined metal and slag.

Reduction of iron ores by carbonaceous fuel directly to a steel composition was practiced in ancient times, but liquid processing was unknown until development of the crucible process, in which iron ore, coal, and flux materials were melted in a crucible to produce small quantities of liquid steel. Modern steelmaking processes began with the invention of the airblown converter by H. Bessemer in 1856. The Thomas process was developed in 1878; it modified the Bessemer process to permit treatment of high-phosphorus pig iron. The Siemens-Martin process, also known as the open-hearth process, was developed at about the same time. The open-hearth process utilizes regenerative heat transfer to preheat air used with a burner; it can generate sufficient heat to refine solid steel scrap and pig iron in a reverberatory furnace. After World War II, various oxygen steelmaking processes were developed.

Steelmaking can be divided into acid and basic processes depending upon whether the slag is high in silica (acid) or high in lime (basic). The furnace lining in contact with the slag should be a compatible material. A silica or siliceous material is used in acid processes, and a basic material such as burned dolomite or magnesite is used in basic processes. Carbon, manganese, and silicon, the principal impurities in pig iron, are easily oxidized and separated; the manganese and silicon oxides go into the slag, and the carbon is removed as carbon monoxide and carbon dioxide in the off-gases. Phosphorus is also oxidized but does not separate from the metal unless the slag is basic. Removal of sulfur occurs to some extent by absorption in a basic slag. Thus, the basic steelmaking processes are more versatile in terms of the raw materials they can handle, and have become the predominant steelmaking processes.

A typical pig iron charged to the steelmaking process might contain roughly 4% carbon, 1% manganese, and 1% silicon. The phosphorus and sulfur levels in the pig iron vary. The composition of the steel tapped from the steelmaking furnace generally ranges from 0.04 to 0.80% carbon, 0.06 to 0.30% manganese, 0.01 to 0.05% phosphorus, and 0.01 to 0.05% sulfur, with negligible amounts of silicon.

Electric arc furnace technology began late in the nineteenth century with the original design of P. L. T. Heroult. The three-graphite electrode furnace with a swinging roof for top charging and a rocker base for tilting to tap the finished molten steel has been continuously improved and developed further. *See* ELECTRIC FURNACE.

The rapid development of steelmaking technology using the electric arc furnace, not only for alloy and stainless steels but especially for carbon steel production, has increased its share of production capacity to about 20% of the steel industry.

Remelting and refining of special alloys are carried out in duplex or secondary processes; the principal ones are argon-oxygen decarburization, electroslag refining, vacuum arc remelting, and vacuum induction melting. *See* ELECTROMETALLURGY; VACUUM METALLURGY.

Ladle metallurgy was used first to produce high-quality steels, but has been extended to producing many grades of steel because of the economic advantages of higher productivity. The purpose of these ladle treatments is to produce clean steel; introduce reactive additions, such as calcium or rare earths; add alloying additions, as for microalloyed steels, with high recovery; and increase furnace utilization, allowing higher-productivity smelting operations of the blast furnace, and melting and refining operations in steelmaking. Ladle treatments in steel production generally are classified as synthetic slag systems; gas stirring or purging; direct immersion of reactants, such as rare earths; lance injection of reactants; and wire feeding of reactants. These are often used in combination to produce synergistic effects, for example, synthetic slag and gas stirring for desulfurization followed by direct immersion, injection, or wire feeding for inclusion shape control. *See* METAL CASTING; PYROMETALLURGY; REFRACTORY; STAINLESS STEEL; STEEL. [R.D.Pe]

Stellar evolution The large-scale, systematic, and irreversible changes with time of the structure and composition of a star.

Star formation. Stars are born from compact knots within dark molecular clouds that are refrigerated by dust that blocks heating starlight. If the random knots, compressed by supernovae or other means, are dense enough, they can contract under their own gravity. Conservation of angular momentum demands that as they collapse they must spin faster. *See* ANGULAR MOMENTUM; MOLECULAR CLOUD.

High-speed particles (cosmic rays) from exploding stars partially ionize the dusty knots. The ions grab onto the weak magnetic field of the Galaxy and, as a result of their physical interaction with neutral atoms and molecules, provide the initial means to slow the rotation. If the rotation is still too fast, the contracting body may split into a double (or more complex) star, whereupon the angular momentum goes into orbital motion. A contracting protostar still rotates progressively faster until the part of its mass not accreted by the star itself is spun out into a dusty disk, from which planets might later accumulate. From the disk shoot powerful molecular flows that slow the star still more. *See* PROTOSTAR.

When the protostar's interior reaches about 10^6 K (1.8×10^6 °F), it can fuse its internal deuterium. That and convection, which brings in fresh deuterium from outside the nuclear-burning zone, bring some stability, and a star can now be said to be born. Stars like the Sun shrink at constant temperature until deuterium fusion dies down. Then they heat at roughly constant luminosity until the full proton-proton chain begins, which provides the stars' luminosity and stops the contraction. The stars settle onto the zero-age main sequence. The whole process takes only 10 or so million years.

Early evolution. The main sequence is that zone on the Hertzsprung-Russell (HR) diagram in which stars are stabilized against gravitational contraction by fusion. The higher the stellar mass, the greater the internal compression and temperature, and the more luminous the star. Hydrogen fusion is highly sensitive to temperature, a small increase in stellar mass meaning a much higher fusion rate. Although greater mass means a greater nuclear-burning core mass and therefore a larger fuel supply, the increased fusion rate is more than offsetting and thereby shortens stellar life. While the new Sun was destined to survive on the main sequence for 10^{10} years, a 0.1-solar-mass star will live there for 10^{13} years, while a 100-solar-mass star will exhaust its core hydrogen in only 2.5×10^6 years.

The main sequence is divided into three parts. Below 0.8 solar mass (roughly class G8), no star has ever had time to evolve. Between 0.8 solar mass and around 10 solar masses (classes G8 to B1), the stars die as white dwarfs. Above it (classes O and B0), they explode. Binary stars contribute further to the richness of stellar phenomena.

Intermediate mass evolution. Main-sequence life lasts until the core hydrogen is almost gone, at which time hydrogen fusion rather suddenly shuts down. With no support, the now-quiet helium core can contract more rapidly under gravity's force. It heats, causing hydrogen fusion to spread into a thick enclosing shell that runs on the carbon cycle. With a new (though temporary) energy source, the star first dims some while it expands and cools at the surface, changing its spectrum to class K. The transition takes only a few hundred million years or less, leaving few stars in the middle of the HR diagram, the lower masses appearing as F, G, and K subgiants.

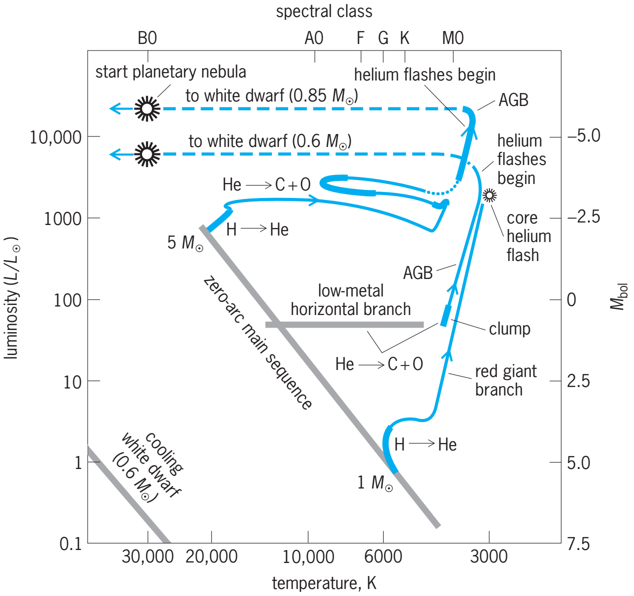
As core contraction proceeds beyond the rightward transition in the HR diagram, stars from about 1 to 5 solar masses (still fusing hydrogen in a shell) suddenly and dramatically increase their luminosities. The future Sun will eventually grow 1000 times brighter than it is today, and a 5-solar-mass star (which begins at about 600 solar luminosities) will reach nearly 3000 solar. At the same time, the stars swell to become red giants. While the core (roughly half a solar mass) of the future Sun shrinks to the size of Earth, the radius will expand to that of Mercury's orbit, or even beyond. When the core temperature climbs to 10^8 K, helium nuclei (alpha particles) begin fusing to unstable beryllium (^{8}Be), which quickly decays back to alpha particles, setting up an equilibrium. The tiny amount of ^{8}Be present reacts with additional alpha particles to create helium via the triple alpha process:

$$^4\text{He} + {}^4\text{He} \leftrightarrow {}^8\text{Be} + \text{gamma ray}$$

$$^8\text{Be} + {}^4\text{He} \rightarrow {}^{12}\text{C} + \text{gamma ray}$$

Fusion with additional helium nuclei creates oxygen and even neon. *See* NUCLEOSYNTHESIS.

The star, now stabilized by a helium-burning core that is surrounded by a hydrogen-fusing shell, retreats about halfway down the red giant branch. The numerous lower-mass stars reside in the class K "red giant clump" (see illustration). Low-mass metal-deficient globular cluster stars spread out from the clump toward higher temperatures to create the distinctive horizontal branch. Energy-generating fusion reactions will try to proceed toward iron (the most stable of all nuclei). Some 80% of the energy is generated in hydrogen burning, so (discounting further burning modes) the helium-burning stage lasts only around 20% of the main-sequence lifetime. Above 5 solar masses, evolution proceeds similarly, but instead of settling into a distinct location on the HR diagram, the stars loop to the blue (higher temperatures) where they fuse helium as class G, F, and A giants. *See* GIANT STAR.



Hertzsprung-Russell diagram of evolution of intermediate-mass stars. These stars evolve from the main sequence to become giants that stabilize during helium fusion in a "clump." When helium fusion is done, they brighten again as AGB stars, lose their envelopes, and evolve to the left to produce planetary nebulae, finally at lower left becoming white dwarfs. (*After J. B. Kaler, Stars, W. H. Freeman, 1992, 1993, from work of I. Iben, Jr.*)

Asymptotic giant branch (AGB). When the helium has fused to carbon and oxygen, the core again contracts. Helium fusion spreads outward into a shell, and for the second time the star climbs the HR diagram's giant branch. Since the second climb is roughly asymptotic to the first, the second climb creates the asymptotic giant branch. The shrinking carbon-oxygen core is now surrounded by a shell of fusing helium, while the old hydrogen-fusing shell expands, cools, and shuts down. Eventually, however, the helium shell runs out of fuel, and the hydrogen shell reignites. Hydrogen burning feeds fresh helium into the space between it and the carbon core, and when there is enough of it, helium burning reignites explosively in a helium flash (or thermal pulse) that can affect the star's surface. The flash squelches hydrogen fusion, and the whole process starts again, helium flashes coming at progressively shorter intervals. AGB stars become larger and brighter than before, passing into the cool end of class M, where they eventually become unstable enough to pulsate as long-period variables (Miras). The Sun will become 5000 times brighter than now and will reach out to the Earth's orbit. *See* MIRA; VARIABLE STAR.

Mass loss and planetary nebulae. During the giant stages, stellar winds greatly increase. Mira pulsations cause shock waves that help drive mass from the stellar surfaces, where the cooled gas becomes ever richer in molecules, some even condensing into dust grains. High luminosity pushes the dust outward, and the dust couples with the gas, resulting in slow (10 km/s or 6 mi/s) thick winds tens of millions of times stronger than the solar wind (up to 10^{-5} solar mass per year). Because stars are in this state for hundreds of thousands of years, they will lose much of themselves back into space—the Sun about half of its mass, a 10-solar-mass star over 80%.

So much mass is lost that an evolving star becomes stripped nearly to its fusion zone, which is protected from the outside by a low-mass hydrogen envelope. As the inner region becomes exposed, the wind diminishes in mass but increases in speed and temperature. Hammering at the surrounding dusty, molecule-filled shroud of lost mass, the high-speed wind compresses the inner edge into a thick ring. Eaten away from the top by the wind and from below by fusion, the stellar envelope shrinks, slowly exposing the hot shell-core structure beneath. When the stripped star's surface reaches 25,000 K (45,000°F), the dense ring that its high-speed wind had previously created is ionized. Subsequent recapture of electrons by ions, along with collisional excitation of heavy atoms, causes the shell to glow, and a planetary nebula is born. *See* PLANETARY NEBULA.

The star inside first heats at constant luminosity to over 100,000 K (180,000°F), the luminosity and final temperature depending on the old core's mass (which ranges from around 0.5 to nearly 1.4 solar masses, the Chandrasekhar limit, above which white dwarfs cannot exist). As residual nuclear fusion shuts down, the star cools and dims at constant radius to become a white dwarf. *See* WHITE DWARF STAR.

High-mass evolution. As the mass of a star increases, so does the mass of the core. The Sun will turn into a white dwarf of around 0.6 solar mass. At 10 solar masses, the core reaches the Chandrasekhar limit, and the star cannot become a white dwarf. At first, high-mass evolution proceeds similarly to that of stars of lower mass. As high-mass stars use their core hydrogen, they too migrate to the right on the HR diagram, becoming not so much brighter but larger, cooling at their surfaces and turning into supergiants. Though almost all these supergiants vary to some extent, the most massive become unstable and undergo huge eruptions.

While intermediate-star fusion stops at carbon and oxygen, supergiants continue onward. The carbon-oxygen core shrinks and heats to the point that carbon fusion can begin, and then carbon and oxygen convert to a more complex mix dominated by oxygen, neon, and magnesium. Helium fusion now continues in a surrounding shell that is nested in one that is fusing hydrogen. Once carbon burning has run its course, the unsupported oxygen-neon-magnesium core shrinks and heats, and now it is carbon burning's turn to move outward into a shell. When hot enough, the oxygen-neon-magnesium mix fires up to burn to one dominated by silicon and sulfur. Continuing the process, the developed silicon and sulfur core finally becomes hot enough to fuse to iron, the silicon-burning core wrapped in oxygen-neon-magnesium, helium, and hydrogen-burning shells.

Supernova. Each nuclear fusion stage generates less energy, and since each takes on the role of supporting the star, each lasts a shorter period of time. While hydrogen fusion takes millions of years, the iron core is created from silicon fusion in a matter of weeks. Iron cannot fuse and produce energy. The core, about 1.5 solar masses and the size of Earth, suddenly collapses at a speed a good fraction that of light. The iron atoms are broken back to neutrons and protons. Under crushing densities, free electrons merge with protons to make yet more neutrons. When the collapsing neutron core hits nuclear densities of 10^{14} g/cm^3 (10^{14} times the density of water), it violently bounces, and the rebound tears away all the outer layers. From the outside, the observer sees the explosion as a type II supernova that can reach an absolute magnitude of −18.

The debris of the explosion, the supernova remnant, highly enriched in iron and other heavy elements, expands for centuries into space. Exposed by the explosion is the compact hot neutron star. Only 25 km (15 mi) across, it is stabilized by the pressure of neutron degeneracy. Radiation beams out along a tilted, wobbling magnetic axis, and if Earth is in its path, a "pulse" of radiation is observed, the neutron star now a "pulsar." *See* NEUTRON STAR; PULSAR.

Beyond the Chandrasekhar limit of 1.4 solar masses, electron degeneracy pressure cannot stabilize a white dwarf, and it must collapse. Neutron stars are similarly limited to around 3 solar masses. Stars at the upper end of the main sequence are expected to create iron cores that exceed even this limiting mass. The dense remains cannot stabilize, and they too must therefore collapse. When such a collapsing star passes a critical radius at which the escape velocity is about that of light, it becomes invisible and a black hole is born. About half a dozen black hole candidates are recognized in binary systems in which the black hole affects the companion. *See* BLACK HOLE. [J.B.Ka.]

Stellar magnetic field

A magnetic field, far stronger than the Earth's magnetic field, which is possessed by many stars. Magnetic fields are important throughout the life cycle of a star. Initially, magnetic fields regulate how quickly interstellar clouds collapse into protostars. Later in the star formation process, circumstellar disk material flows along magnetic field lines, either accreting onto the star or flowing rapidly out along the rotation axis. Outflowing material (stellar winds) carries away angular momentum, slowing rotation at a rate that depends on stellar magnetic field strength. On the Sun, dark sunspots, prominences, flares, and other forms of surface activity are seen in regions where there are strong magnetic fields. There is some evidence that long-term variations in solar activity may affect the Earth's climate. Turbulence in the solar atmosphere drives magnetic waves which heat a tenuous corona (seen during eclipses) to millions of degrees. About 10% of hotter stars (with temperatures of about 10,000 K) with stable atmospheres are Ap stars, which have stronger magnetic fields that control the surface distribution of exotic elements. Even after stars end their internal fusion cycle and become compact remnants, magnetic fields channel accreting material from binary companions, occasionally producing spectacular novae. Despite the enormous gravity around pulsars, magnetic forces far exceed gravitational forces, creating intense electromagnetic beams that spin down (slow the rotation of) the pulsar. *See* BINARY STAR; CATACLYSMIC VARIABLE; NOVA; PROTOSTAR; PULSAR; SOLAR MAGNETIC FIELD; STAR; STELLAR EVOLUTION. [J.A.Va.]

Stellar population

One of the categories into which stars may be classified, based on their place in the evolution of the galaxy containing them. The stellar component of the Milky Way Galaxy consists of three populations: the thin disk, the thick disk, and the halo.

The thin disk, originally referred to as population I, is the youngest component of the galactic stellar population. Still actively forming massive stars from molecular clouds, it is confined to within about 0.35 kiloparsec of the plane. (1 kpc equals 3300 light-years or 3.1×10^{16} km or 1.9×10^{16} mi.) All of the stars have metallicities lying between about one-fifth and twice the solar value, and star formation appears to have remained constant in this population for about the past 8×10^9 years. One reason for the relatively small thickness of the disk is the low velocity dispersion of the component stars; their motion is completely dominated by the differential rotation of the disk. These stars are found associated with H II regions and OB associations as well as open clusters. *See* INTERSTELLAR MATTER; MOLECULAR CLOUD; SUPERNOVA.

The thick disk is an older population, approximately 9–10 × 10^9 years, roughly corresponding to the range between what was once called population II and population I. Its metallicity lies between about one-tenth and one-third of the solar value. The stars in this population are distributed over greater distances from the plane, up to 1.5 kpc, and have correspondingly larger velocity dispersion. This population also includes globular clusters and subdwarfs that overlap at the lowest end of the abundances with the properties of the halo globulars, although the system of old disk globulars is distributed differently than those of the halo.

Lying around the disk and the nuclear spheroidal bulge, there is a halo, roughly corresponding to the original population II, that extends to considerable distances from the plane, some as distant as 30 kpc. This population has an age of order 10–15 × 10^9 years. The stars in this region have very large velocity dispersions and do not appear to participate in the differential rotation as much as other stars. Their metallicities are all lower than about one-twentieth that of the Sun and may extend down to 10^{-3} of the solar value. The most metal-poor globular clusters belong to this population. This stellar halo is not the same as the dark matter halo, but is probably embedded within it. *See* MILKY WAY GALAXY; STAR. [S.N.S.]

Stellar rotation The spinning of stars, due to their angular momentum. Stars do not necessarily rotate as solid bodies, and their angular momentum may be distributed nonuniformly, depending on radius or latitude. However, it is impossible to resolve the surfaces of stars, or see their interiors, and the limited ability to observe them means that their rotation is generally expressed as a single number, $v_{eq} \sin i$. In this measured quantity, v_{eq} is the star's equatorial rotational velocity (in kilometers per second), and i is the angle between the star's rotation axis and the line of sight to the star. In other words, $v_{eq} \sin i$ is the component of a star's rotation that is projected onto the line of sight between the star and the observer. Measurements of $v_{eq} \sin i$ in stars range from as little as 1 km s^{-1} (0.6 mi s^{-1}) up to 400 km s^{-1} (250 mi s^{-1}) or more. A more physically useful measure of rotation is Ω, a star's angular velocity, or P_{rot}, the rotation period (the inverse of Ω). In some cases it is possible to measure P_{rot} directly. *See* ANGULAR MOMENTUM; STAR.

A $v_{eq} \sin i$ value is determined from the breadth of absorption lines in the star's spectrum. The Doppler effect causes the lines to be broadened because one limb of the star is receding and the other approaching. *See* DOPPLER EFFECT.

Late-type stars (cooler than about 6500 K or 11,200°F) exhibit spots on their surfaces analogous to sunspots, and these can be large enough to produce observable changes in the light of the star. In such cases it is possible to measure P_{rot} directly and, in a few instances, changes in P_{rot} have led to estimates of differential rotation (the dependence of Ω on latitude).

There is a broad trend in which typical rotation rates decline with the mass of the star in going down the main sequence. There is an especially prominent break in rotation such that stars with masses below about 1.2 times the solar mass have very low rotation rates, due to their intrinsic structure.

The early-type stars (types O, B, A, and early-F) typically have $v_{eq} \sin i$ values of 50 km s^{-1} (30 mi s^{-1}) or more. The high $v_{eq} \sin i$ values (200 km s^{-1} or 125 mi s^{-1} and more) are seen only in the main-sequence O stars.

Late-type stars are cooler than about 6500 K (11,200°F) and have spectral types of late-F, G, K, or M. The key property of late-type stars that determines much of their phenomenology is the presence of a convective envelope. In such stars, rotation (especially differential rotation) interacts with the convection to produce complex motions in the electrically conductive plasma of the star. These circulatory patterns enable the star to regenerate a seed magnetic field, the so-called dynamo mechanism. The magnetic field can grip an ionized wind beyond the star's surface, leading to gradual angular momentum loss, a process that is seen occurring on the Sun. More rapidly rotating stars produce stronger magnetic fields. *See* MAGNETISM; STELLAR MAGNETIC FIELD.

In this scenario, late-type main-sequence stars spin down over their lifetimes, and that is observed to occur because steadily declining rotation rates can be seen among stars in clusters of increasing age. Moreover, stars that are born together but with different rotation rates will tend to end up with the same P_{rot} because the faster-rotating star will lose angular momentum more quickly. Young stars tend to rotate rapidly because they have not had time to lose the angular momentum with which they formed, while old low-mass stars rotate slowly.

The Sun is a very slowly rotating star ($v_{eq} \sin i = 1.8$ km s^{-1} or 1.1 mi s^{-1}). Over its 4.5-billion-year main-sequence lifetime, it has gradually lost angular momentum to get to the rate that is seen today. Helioseismological studies of the Sun's interior show it to rotate as a solid body, so if it ever had a rapidly rotating core, it does no longer. *See* HELIOSEISMOLOGY; SUN. [D.So.]

Stem The organ of vascular plants that usually develops branches and bears leaves and flowers. On woody stems a branch that is the current season's growth from a bud is called a twig. The stems of some species produce adventitious roots. *See* ROOT (BOTANY).

General characteristics. While most stems are erect, aerial structures, some remain underground, others creep over or lie prostrate on the surface of the ground, and still others are so short and inconspicuous that the plants are said to be stemless, or acaulescent. When stems lie flattened immediately above but not on the ground, with tips curved upward, they are said to be decumbent, as in juniper. If stems lie flat on the ground but do not root at the nodes (joints), the stem is called procumbent or prostrate, as in purslane. If a stem creeps along the ground, rooting at the nodes, it is said to be repent or creeping, as in ground ivy.

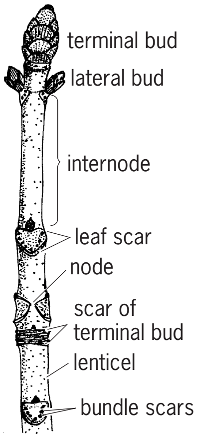
Most stems are cylindrical and tapering, appearing circular in cross section; others may be quadrangular or triangular.

Herbaceous stems (annuals and herbaceous perennials) die to the ground after blooming or at the end of the growing season. They usually contain little woody tissue. Woody stems (perennials) have considerable woody supporting tissue and live from year to year. A woody plant with no main stem or trunk, but usually with several stems developed from a common base at or near the ground, is known as a shrub. [N.A.]

External features. A shoot or branch usually consists of a stem, or axis, and leafy appendages. Stems have several distinguishing features. They arise either from the epicotyl of the embryo in a seed or from buds. The stem bears both leaves and buds at nodes, which are separated by leafless regions or internodes, and sometimes roots and flowers (see illustration).

The nodes are the regions of the primary stem where leaves and buds arise. The number of leaves at a node is usually specific for each plant species. In deciduous plants which are leafless during winter, the place of former attachment of a leaf is marked by the leaf scar. The scar is formed in part by the abscission zone formed at the base of the leaf petiole. The stem regions between nodes are called internodes. Internode length varies greatly among species, in different parts of the same stem, and under different growing conditions.

Lenticels are small, slightly raised or ridged regions of the stem surface that are composed of loosely arranged masses of cells in the bark. Their intercellular spaces are continuous with those in



Winter woody twig (horse chestnut) showing apical dominance. (*After E. W. Sinnott and K. S. Wilson, Botany: Principles and Problems, 5th ed., McGraw-Hill, 1955*)

the interior of the stem, therefore permitting gas exchange similar to the stomata that are present before bark initiation.

There are three major types of stem branching: dichoto-mous, monopodial, and sympodial. Dichotomy occurs by a division of the apical meristem to form two new axes. If the terminal bud of an axis continues to grow and lateral buds grow out as branches, the branching is called monopodial. If the apical bud terminates growth in a flower or dies back and one or more axillary buds grow out, the branching is called sympodial. Often only one bud develops so that what appears to be single axis is in fact composed of a series of lateral branches arranged in linear sequence.

The large and conspicuous stems of trees and shrubs assume a wide variety of distinctive forms. Columnar stems are basically unbranched and form a terminal leaf cluster, as in palms, or lack obvious leaves, as in cacti. Branching stems have been classified either as excurrent, when there is a central trunk and a conical leaf crown, as in firs and other conifers, or as decur-rent (or deliquescent), when the trunk quickly divides up into many separate axes so that the crown lacks a central trunk, as in elm. *See* TREE. [J.B.F.]

Internal features. The stem is composed of the three fundamental tissue systems that are found also in all other plant organs: the dermal (skin) system, consisting of epidermis in young stems and peridem in older stems of many species; the vascular (conducting) system, consisting of xylem (water conduction) and phloem (food conduction); and the fundamental or ground tissue system, consisting of parenchyma and sclerenchyma tissues in which the vascular tissues are embedded. The arrangement of the vascular tissues varies in stems of different groups of plants, but frequently these tissues form a hollow cylinder enclosing a region of ground tissue called pith and separated from the dermal tissue by another region of ground tissue called cortex. *See* CORTEX (PLANT); EPIDERMIS (PLANT); PARENCHYMA; PHLOEM; PITH; SCLERENCHYMA; XYLEM.

Part of the growth of the stem results from the activity of the apical meristem located at the tip of the shoot. The derivatives of this meristem are the primary tissues; epidermis, primary vascular tissues, and the ground tissues of the cortex and pith. In many species, especially those having woody stems, secondary tissues are added to the primary. These tissues are derived from the lateral meristems, oriented parallel with the sides of the stem: cork cambium (phellogen), which gives rise to the secondary protective tissue periderm, which consists of phellum (cork), phellogen (cork cambium), and phelloderm (secondary cortex) and which replaces the epidermis; and vascular cambium, which is inserted between the primary xylem and phloem and forms secondary xylem (wood) and phloem. *See* APICAL MERISTEM; LATERAL MERISTEM.

The vascular tissues and the closely associated ground tissues—pericycle (on the outer boundary of vascular region), interfascicular regions (medullary or pith rays), and frequently also the pith—may be treated as a unit called the stele. The variations in the arrangement of the vascular tissues serve as a basis for distinguishing the stelar types. The word stele means column and thus characterizes the system of vascular and associated ground tissues as a column. This column is enclosed within the cortex, which is not part of the stele. *See* PERICYCLE. [J.E.Gu.]

Stem cells

Cells that have the ability to self-replicate and give rise to specialized cells. Stem cells can be found at different stages of fetal development and are present in a wide range of adult tissues. Many of the terms used to distinguish stem cells are based on their origins and the cell types of their progeny.

There are three basic types of stem cells. Totipotent stem cells, meaning their potential is total, have the capacity to give rise to every cell type of the body and to form an entire organism. Pluripotent stem cells, such as embryonic stem cells, are capable of generating virtually all cell types of the body but are unable to form a functioning organism. Multipotent stem cells can give rise only to a limited number of cell types. For example, adult stem cells, also called organ- or tissue-specific stem cells, are multipotent stem cells found in specialized organs and tissues after birth. Their primary function is to replenish cells lost from normal turnover or disease in the specific organs and tissues in which they are found.

Totipotent stem cells occur at the earliest stage of embryonic development. The union of sperm and egg creates a single totipotent cell. This cell divides into identical cells in the first hours after fertilization. All these cells have the potential to develop into a fetus when they are placed into the uterus. The first differentiation of totipotent cells forms a hollow sphere of cells called the blastocyst, which has an outer layer of cells and an inner cell mass inside the sphere. The outer layer of cells will form the placenta and other supporting tissues during fetal development, whereas cells of the inner cell mass go on to form all three primary germ layers: ectoderm, mesoderm, and endoderm. The three germ layers are the embryonic source of all types of cells and tissues of the body. Embryonic stem cells are derived from the inner cell mass of the blastocyst. They retain the capacity to give rise to cells of all three germ layers. However, embryonic stem cells cannot form a complete organism because they are unable to generate the entire spectrum of cells and structures required for fetal development. Thus, embryonic stem cells are pluripotent, not totipotent, stem cells.

Embryonic germ (EG) cells differ from embryonic stem cells in the tissue sources from which they are derived, but appear to be similar to embryonic stem cells in their pluripotency. Human embryonic germ cell lines are established from the cultures of the primordial germ cells obtained from the gonadal ridge of late-stage embryos, a specific part that normally develops into the testes or the ovaries. Embryonic germ cells in culture, like cultured embryonic stem cells, form embryoid bodies, which are dense, multilayered cell aggregates consisting of partially differentiated cells. The embryoid body-derived cells have high growth potential. The cell lines generated from cultures of the embryoid body cells can give rise to cells of all three embryonic germ layers, indicating that embryonic germ cells may represent another source of pluripotent stem cells.

Much of the knowledge about embryonic development and stem cells has been accumulated from basic research on mouse embryonic stem cells. Since 1998, however, research teams have succeeded in growing human embryonic stem cells in culture. Human embryonic stem cell lines have been established from the inner cell mass of human blastocysts that were produced through in vitro fertilization procedures. The techniques for growing human embryonic stem cells are similar to those used for growth of mouse embryonic stem cells. However, human embryonic stem cells must be grown on a mouse embryonic fibroblast feeder layer or in media conditioned by mouse embryonic fibroblasts. Human embryonic stem cell lines can be maintained in culture to generate indefinite numbers of identical stem cells for research. As with mouse embryonic stem cells, culture conditions have been designed to direct differentiation into specific cell types (for example, neural and hematopoietic cells).

Adult stem cells occur in mature tissues. Like all stem cells, adult stem cells can self-replicate. Their ability to self-renew can last throughout the lifetime of individual organisms. But unlike embryonic stem cells, it is usually difficult to expand adult stem cells in culture. Adult stem cells reside in specific organs and tissues, but account for a very small number of the cells in tissues. They are responsible for maintaining a stable state of the specialized tissues. To replace lost cells, stem cells typically generate intermediate cells called precursor or progenitor cells, which are no longer capable of self-renewal. However, they continue undergoing cell divisions, coupled with maturation, to yield fully specialized cells. Such stem cells have been identified in many types of adult tissues, including bone marrow, blood, skin, gastrointestinal tract, dental pulp, retina of the eye, skeletal muscle, liver, pancreas, and brain. Adult stem cells are usually designated according to their source and their potential. Adult stem cells are multipotent because their potential is normally limited according to their source and their potential. Adult stem cells are multipotent because their potential is normally limited to one or more lineages of specialized cells. However, a special multipotent stem cell that can be found in bone marrow, called the mesenchymal stem cell, can produce all cell types of bone, cartilage, fat, blood, and connective tissues.

Blood stem cells, or hematopoietic stem cells, are the most studied type of adult stem cells. The concept of hematopoietic stem cells is not new, since it has been long realized that mature blood cells are constantly lost and destroyed. Billions of new blood cells are produced each day to make up the loss. This process of blood cell generation called hematopoiesis, occurs largely in the bone marrow. Another emerging source of blood stem cells is human umbilical cord blood. Similar to bone marrow, umbilical cord blood can be used as a source material of stem cells for transplant therapy. However, because of the limited number of stem cells in umbilical cord blood, most of the procedures are performed for young children of relatively low body weight.

Neural stem cells, the multipotent stem cells that generate nerve cells, are a new focus in stem cell research. Active cellular turnover does not occur in the adult nervous system as it does in renewing tissues such as blood or skin. Because of this observation, it had been a dogma that the adult brain and spinal cord were unable to regenerate new nerve cells. However, since the early 1990s, neural stem cells have been isolated from the adult brain as well as fetal brain tissues. Stem cells in the adult brain are found in the areas called the subventricular zone and the ventricle zone. Another location of brain stem cells occurs in the hippocampus, a special structure of the cerebral cortex related to memory function. Stem cells isolated from these areas are able to divide and to give rise to nerve cells (neurons) and neuron-supporting cell types in culture.

Stem cell plasticity refers to the phenomenon of adult stem cells from one tissue generating the specialized cells of another tissue. The long-standing concept of adult organ-specific stem cells is that they are restricted to producing the cell types of their specific tissues. However, a series of studies have challenged the concept of tissue restriction of adult stem cells. Although the stem cells appear able to cross their tissue-specific boundaries, crossing occurs generally at a low frequency and mostly only under conditions of host organ damage. The finding of stem cell plasticity carries significant implications for potential cell therapy. For example, if differentiation can be redirected, stem cells of abundant source and easy access, such as blood stem cells in bone marrow or umbilical cord blood, could be used to substitute stem cells in tissues that are difficult to isolate, such as heart and nervous system tissue. *See* CELL DIFFERENTIATION; EMBRYOLOGY; EMBRYONIC DIFFERENTIATION; GERM LAYERS; HEMATOPOIESIS; REGENERATION (BIOLOGY); TRANSPLANTATION BIOLOGY. [C.Wa.]

Stenolaemata An exclusively marine class of Bryozoa. The Stenolaemata include several thousand species distributed among five orders: Cystoporata, Trepostomata, Cryptostomata, Fenestrata, and Cyclostomata. First appearing late in the Early Ordovician, stenolaemates expanded quickly to dominate bryozoan assemblages until the mid-Cretaceous. *See* BRYOZOA; CRYPTOSTOMATA; CYCLOSTOMATA (BRYOZOA); CYSTOPORATA; TREPOSTOMATA.

Stenolaemate colonies vary greatly in size and shape. Many Paleozoic through mid-Mesozoic forms were large and massive, but more recent representatives are commonly small and delicate. Colonies are encrusting, erect, or free-living. Some erect forms have single or regularly spaced, flexible cuticular joints; segments between joints and all other entire colonies are rigidly calcified and enclosed within a thin cuticular membrane. Living stenolaemate colonies are made up of individual feeding units called zooids with lophophores (rings of tentacles) that are circular in basal outline. Zooidal body cavities are enclosed within tubular or prismatic zooecia (skeletons of individual zooids), gradually expanding from their proximal ends. Zooecia typically are relatively thin-walled in colony interiors (endozone) and relatively thick-walled in outer regions (exozone).

Individual colonies are hermaphroditic. Colonies grow by asexual budding. [F.K.McK.]

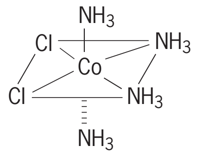
Stenurida A Paleozoic order of the subphylum Asterozoa, order Ophiuroidea, comprising the brittle stars. Stenurids have a double row of plates (ambulacra) that abut across the arm axis either directly opposite one another or slightly offset. In contrast, modern ophiuroids have a single series of axial arm plates termed vertebrae. In stenurids, as in modern ophiuroids, lateral plates are present at the sides of ambulacrals, and prominent lateral spines are typical. Stenurids lack the dorsal and ventral arm shields that are found in most ophiuroids. The content of the order is poorly established, and fewer than 10 genera are known.

The relationship among ophiuroids, asteroids, and all other echinoderms provide an enduring problem in invertebrate evolution. Developmental and other studies based on modern organisms imply that asteroids and ophiuroids are not closely related within the echinoderms. Stenurid morphology, in contrast suggests a close common ancestry for the two. *See* ECHINODERMATA; OPHIUROIDEA. [D.B.B.]

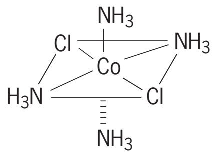
Stepping motor An electromagnetic incremental-motion actuator which converts digital pulse inputs to analog output motion. The device is also termed a step motor. When energized in a programmed manner by a voltage and current input, usually dc, a step motor can index in angular or linear increments. With proper control, the output steps are always equal in number to the input command pulses. Each pulse advances the rotor shaft one step increment and latches it magnetically at the precise point to which it is stepped. Advances in digital computers and particularly microcomputers revolutionized the controls of step motors. These motors are found in many industrial control systems, and large numbers are used in computer peripheral equipment, such as printers, tape drives, capstan drives, and memory-access mechanisms. Step motors are also used in numerical control systems, machine-tool controls, process control, and many systems in the aerospace industry. *See* COMPUTER GRAPHICS; COMPUTER NUMERICAL CONTROL; COMPUTER PERIPHERAL DEVICES; CONTROL SYSTEMS; DIGITAL-TO-ANALOG CONVERTER; PROCESS CONTROL.

There are many types of step motors. Most of the widely used ones can be classified as variable-reluctance, permanent-magnet, or hybrid permanent-magnet types. A variable-reluctance step motor is simple to construct and has low efficiency. The permanent-magnet types are more complex to construct and have a higher efficiency. [B.C.K.]

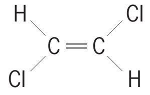
Stereochemistry The study of the three-dimensional arrangement of atoms or groups within molecules and the properties which follow from such arrangement. Molecules that have identical molecular structures but differ in the relative spatial arrangement of component parts are stereoisomers. Inorganic and organic compounds exhibit stereoisomerism. Examples are structures (**1**)–(**8**).



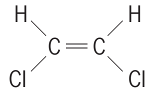
(1)



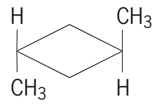
(2)



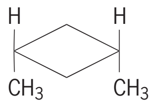
(3)



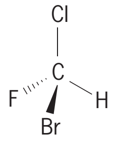
(4)



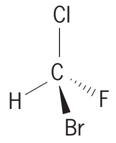
(5)



(6)



(7)



(8)

The nature of the stereochemistry of a molecule is determined by its symmetry. The symmetry elements to be considered are: planes of symmetry, axes of symmetry, centers of symmetry, and reflection or mirror symmetry. Two types of stereoisomers are known. Those such as (**7**) and (**8**), which are devoid of reflection symmetry—which cannot be superimposed on their image in a mirror—are called enantiomers. All other stereoisomers, such as the pairs (**1**)–(**2**), (**3**)–(**4**), and (**5**)–(**6**), are called diastereomers. The configuration of a stereoisomer designates the relative position of the atoms associated with a specific structure. The structures of stereoisomers (**1**) and (**2**) differ only in configuration. The same is true for (**3**) and (**4**), (**5**) and (**6**), and (**7**) and (**8**). *See* Enantiomer. [S.H.W.]

Stereophonic radio transmission

Stereophonic radio transmission The transmission of stereophonic audio signals over radio using either amplitude-modulation (AM) or frequency-modulation (FM) techniques. *See* Stereophonic sound.

To be commercially acceptable, the signal transmitted by a stereo broadcast station should be decipherable by either a stereo receiver or a monophonic receiver. For the monophonic receiver to correctly receive a stereo broadcast, some component of that broadcast must be a single signal that includes information from both the left and the right channel. This is called the $L + R$ signal. A monophonic receiver simply demodulates the $L + R$ signal and delivers it to the listener.

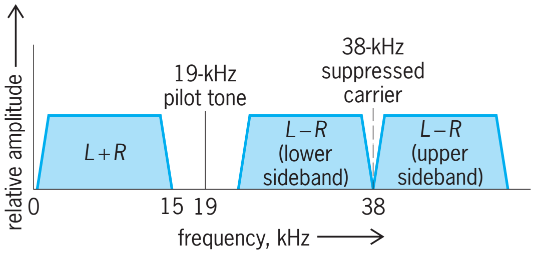
The stereo receiver must use the $L + R$ signal and other transmitted information to demodulate separate L and R signals. For this, stereo broadcasts include an $L - R$ signal. In the stereo receiver, after detection of the $L + R$ and $L - R$ signals, the L and R signals are separated as shown in Eqs. (1) and (2).

$$(L + R) + (L - R) = 2L \qquad (1)$$

$$(L + R) - (L - R) = 2R \qquad (2)$$

The subtraction used in Eq. (2) is realized through phase shifting and addition. Shifting the phase of a signal by 180° inverts the signal. Thus, $(L - R)$ put through a 180° phase shift is $-(L - R)$.

In FM stereo transmissions, the $L + R$ signal is directly frequency-modulated onto the radio-frequency carrier, assuring compatibility (see illustration). The $L - R$ signal is used to amplitude-modulate a 38-kHz hypersonic subcarrier. The 38-kHz carrier is suppressed, creating a double-sideband (DSB), suppressed-carrier AM signal at 38 kHz. This hypersonic signal is then frequency-modulated onto the radio-frequency carrier. A 19-kHz pilot signal is also transmitted to indicate that the broadcast is stereo and to provide an accurate frequency reference for demodulation of the 38-kHz $L - R$ signal. *See* Amplitude modulation; Frequency modulation.



Baseband spectrum of an FM stereo signal. This audio and supersonic spectrum is frequency-modulated onto a radio-frequency carrier.

In the FM stereo receiver, the entire baseband signal that has been frequency-modulated onto a radio-frequency carrier ($L + R$, pilot, and double-sideband $L - R$) is first detected with an FM discriminator. The $L + R$ signal is isolated by a low-pass filter. The pilot tone is doubled and mixed with the double-sideband suppressed-carrier $L - R$ signal, so that the $L - R$ signal can be demodulated by an AM envelope detector. The $L + R$ and $L - R$ audio signals are then passed through a network that implements the functions expressed in Eqs. (1) and (2). The resulting left- and right-channel audio signals are amplified and presented to the listener. *See* Amplitude-modulation detector; Electric filter; Frequency-modulation detector; Frequency-modulation radio.

There are five AM stereo modulation systems permitted by the Federal Communications Commission. Several of these mutually incompatible systems are in use. The most widely used system, installed at around one-third of the AM stereo broadcast stations in the United States, is the Compatible Quadrature Amplitude Modulation (C-QUAM) system, which uses two radio-frequency carriers 90° out of phase. One of these carriers is modulated with the $L + R$ signal, and the other is modulated with the $L - R$ signal. The carriers are then added to create a single signal and limited to remove amplitude variations. The resulting radio-frequency signal is amplitude-modulated with the $L + R$ signal. This last step provides compatibility with monophonic AM receivers. A 25-Hz pilot tone is provided for identification of stereo transmissions. A C-QUAM receiver uses a standard AM detector to demodulate the $L + R$ signal. The $L - R$ signal is demodulated by a sophisticated synchronous FM detector. *See* Phase modulation; Radio receiver. [J.War.]

Stereophonic sound

Stereophonic sound A system of sound recording or transmission in which two or more microphone channels are connected to corresponding loudspeakers in the listening room in order to create a sound field at the listener's ears which is perceived to be very much like that in the original space. Binaural is a special form of stereophonic sound in which two microphones replace the ears of a dummy head and are connected through an amplifier/recorder system to a pair of headphones worn by the listener. Quadraphonic is a special case of stereo in which four channels and loudspeakers are employed. *See* Binaural sound; Quadraphonic sound system.

There are three basic microphone techniques for stereophonic pickup: coincident, spaced apart, and individual instrument (also called close milking). The techniques are sometimes combined.

The coincident technique employs two microphones located very close together, often enclosed in the same case. Usually the two microphones will have cardioid pickup patterns, or one will be a cardioid and the other a figure-eight. The coincident technique relies only on differences in sound intensity to determine position of the phantom images. *See* MICROPHONE.

By placing the microphones several feet apart, it is possible to provide a good pickup of a large group without moving the microphones as far into the reverberant field. The spaced-apart technique provides both time and intensity cues.

Beginning in the late 1960s it became common for most popular music to be recorded in an acoustically dead studio using a large number of microphones, each located close to one instrument or small group of instruments. By proportionally mixing the microphone outputs between the two stereo channels, it is possible to provide the intensity cues necessary for perceiving phantom images. No time cues are produced. *See* SOUND RECORDING; SOUND-REPRODUCING SYSTEMS. [R.Bro.]

Stereoscopy The phenomenon of simultaneous vision with two eyes, producing a visual experience of the third dimension, that is, a vivid perception of the relative distances of objects in space. In this experience the observer seems to see the space between the objects located at different distances from the eyes.

Stereopsis, or stereoscopic vision, is believed to have an innate origin in the anatomic and physiologic structures of the retinas of the eyes and the visual cortex. It is present in normal binocular vision because the two eyes view objects in space from two points, so that the retinal image patterns of the same object points in space are slightly different in the two eyes. The stereoscope, with which different pictures can be presented to each eye, demonstrates the fundamental difference between stereoscopic perception of depth and the conception of depth and distance from the monocular view. *See* VISION. [K.N.O.]

Stereospecific catalyst Stereospecific polymerization catalysts lead to the formation of stereoregular (tactic) polymers, that is, polymers where the centers of steric isomerism in the main chain are arranged in a regular fashion with respect to their configurations. Three factors determine the tacticity of a polymeric chain during its formation: (1) the kind of monomer approach to the growing chain end, (2) the kind of attack of the growing chain end on the double bond (cis or trans opening), and (3) the configuration in the initiation step. In addition to a regular head-to-tail configuration and absence of branching, reactions have to be assumed. The kind of monomer approach is strongly affected by electrical and stereochemical forces, and therefore changes in monomer structure and environment greatly influence polymer tacticity. The intermediate radical or ion can be assumed to have a planar or near-planar structure, and in an uncomplexed form it should be able to rotate freely around its axis with cis and trans addition being equally possible. Upon addition of the next monomer this carbon changes into a tetrahedral structure, thereby creating two isomeric forms, isotactic or syndiotactic. *See* ASYMMETRIC SYNTHESIS; CATALYSIS; POLYMERIZATION; STEREOCHEMISTRY. [A.Sc.]

Steric effect (chemistry) The influence of the spatial configuration of reacting substances upon the rate, nature, and extent of reaction. The sizes and shapes of atoms and molecules, the electrical charge distribution, and the geometry of bond angles influence the courses of chemical reactions. The steric course of organochemical reactions is greatly dependent on the mode of bond cleavage and formation, the environment of the reaction site, and the nature of the reaction conditions (reagents, reaction time, and temperature). The effect of steric factors is best understood in ionic reactions in solution. *See* STEREOCHEMISTRY. [E.W.]

Sterilization An act of destroying all forms of life on and in an object. A substance is sterile, from a microbiological point of view, when it is free of all living microorganisms. Sterilization is used principally to prevent spoilage of food and other substances and to prevent the transmission of diseases by destroying microbes that may cause them in humans and animals. Microorganisms can be killed either by physical agents, such as heat and irradiation, or by chemical substances.

Heat sterilization is the most common method of sterilizing bacteriological media, foods, hospital supplies, and many other substances. Either moist heat (hot water or steam) or dry heat can be employed, depending upon the nature of the substance to be sterilized. Moist heat is also used in pasteurization, which is not considered a true sterilization technique because all microorganisms are not killed; only certain pathogenic organisms and other undesirable bacteria are destroyed. *See* PASTEURIZATION.

Many kinds of radiations are lethal, not only to microorganisms but to other forms of life. These radiations include both high-energy particles as well as portions of the electromagnetic spectrum. *See* RADIATION BIOLOGY.

Filtration sterilization is the physical removal of microorganisms from liquids by filtering through materials having relatively small pores. Sterilization by filtration is employed with liquid that may be destroyed by heat, such as blood serum, enzyme solutions, antibiotics, and some bacteriological media and medium constituents. Examples of such filters are the Berkefeld filter (diatomaceous earth), Pasteur-Chamberland filter (porcelain), Seitz filter (asbestos pad), and the sintered glass filter.

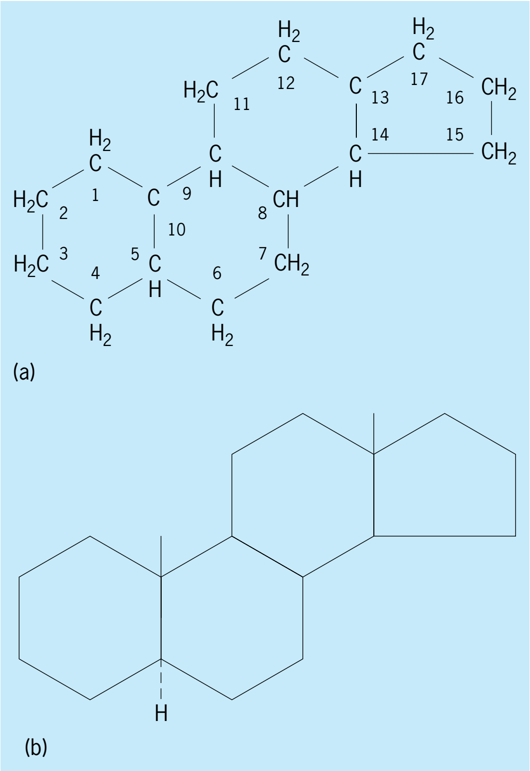
Chemicals are used to sterilize solutions, air, or the surfaces of solids. Such chemicals are called bactericidal substances. In lower concentrations they become bacteriostatic rather than bactericidal; that is, they prevent the growth of bacteria but may not kill them. Other terms having similar meanings are employed. A disinfectant is a chemical that kills the vegetative cells of pathogenic microorganisms but not necessarily the endospores of spore-forming pathogens. An antiseptic is a chemical applied to living tissue that prevents or retards the growth of microorganisms, especially pathogenic bacteria, but which does not necessarily kill them.

The desirable features sought in a chemical sterilizer are toxicity to microorganisms but nontoxicity to humans and animals, stability, solubility, inability to react with extraneous organic materials, penetrative capacity, detergent capacity, noncorrosiveness, and minimal undesirable staining effects. Rarely does one chemical combine all these desirable features. Among chemicals that have been found useful as sterilizing agents are the phenols, alcohols, chlorine compounds, iodine, heavy metals and metal complexes, dyes, and synthetic detergents, including the quaternary ammonium compounds. [C.F.N.]

Steroid Any of a group of organic compounds belonging to the general class of biochemicals called lipids, which are easily soluble in organic solvents and slightly soluble in water. Additional members of the lipid class include fatty acids, phospholipids, and triacylglycerides. The unique structural characteristic of steroids is a four-fused ring system. Members of the steroid family are ubiquitous, occurring, for example, in plants, yeast, protozoa, and higher forms of life. Steroids exhibit a variety of biological functions, from participation in cell membrane structure to regulation of physiological events. Naturally occurring steroids and their synthetic analogs are used extensively in medical practice.

Each steroid contains three fused cyclohexane (six-carbon) rings plus a fourth cyclopentane ring (see illustration). Naturally occurring steroids have an oxygen-containing group at carbon-3. Shorthand formulas for steroids indicate the presence of double bonds, as well as the structure and position of oxygen-containing or other organic groups.

The most abundant steroid in mammalian cells is cholesterol. The levels and locations of planar cholesterol molecules,



Steroid skeleton. (*a*) Structure and numbering. (*b*) Shorthand formulation; the lines attached to the rings represent methyl groups.

embedded in the phospholipid bilayers that form cell and organelle membranes, are known to influence the structure and function of the membranes. A second major function of cholesterol is to serve as a precursor of steroids acting as physiological regulators (such as the steroid hormones). Enzyme systems present in a hormone-secreting gland convert cholesterol to the hormone specific for that gland. For example, the ovary produces estrogens (such as estradiol and progesterone); the testis produces androgens (such as testosterone); the adrenal cortex produces hormones that regulate metabolism (such as cortisol) and sodium ion transport (such as aldosterone). A third major function of cholesterol is to serve as a precursor of the bile acids. These detergentlike molecules are produced in the liver and stored in the gall bladder until needed to assist in the absorption of dietary fat and fat-soluble vitamins and in the digestion of dietary fat by intestinal enzymes. *See* CELL MEMBRANES; CHOLESTEROL; STEROL.

Some examples of diseases treated with naturally occurring or synthetic steroids are allergic reactions, arthritis, some malignancies, and diseases resulting from hormone deficiencies or abnormal production. In addition, synthetic steroids that mimic an action of progesterone are widely used oral contraceptive agents. Other synthetic steroids are designed to mimic the stimulation of protein synthesis and muscle-building action of naturally occurring androgens. *See* HORMONE; LIPID. [M.E.D.]

Sterol Any of a group of naturally occurring or synthetic organic compounds with a steroid ring structure, having a hydroxyl (—OH) group, usually attached to carbon-3. This hydroxyl group is often esterified with a fatty acid (for example, cholesterol ester). The hydrocarbon chain of the fatty-acid substituent varies in length, usually from 16 to 20 carbon atoms, and can be saturated or unsaturated. Sterols commonly contain one or more double bonds in the ring structure and also a variety of substituents attached to the rings. Sterols and their fatty-acid esters are essentially water insoluble. For transport in an aqueous milieu (for example, the bloodstream of mammals), sterols and other lipids are bound to specific proteins, forming lipoprotein particles. These particles are classified based on their composition and density. One lipoprotein class is abnormally high in the blood of humans prone to heart attacks.

Sterols are widely distributed in nature. Modifications of the steroid ring structure are made by specific enzyme systems, producing the sterol characteristic for each species, such as ergosterol in yeast. The major regulatory step in the sterol biosynthetic pathway occurs early in the process. Drugs that lower blood cholesterol levels in humans are designed to inhibit this regulatory enzyme. In addition to their conversion to sterols, several intermediates in the pathway are precursors of other important biological compounds, including chlorophyll in plants, vitamins A, D, E, and K, and regulators of membrane functions and metabolic pathways.

A universal role of sterols is to function as part of membrane structures. In addition, some insects require sterols in their diets. Cholesterol also serves as a precursor of steroid hormones (estrogens, androgens, glucocorticoids, and mineralocorticoids) and bile acids. *See* CHOLESTEROL; STEROID. [M.E.D.]

Stibnite A mineral with composition Sb_2S_3 (antimony trisulfide), the chief ore of antimony. It crystallizes in slender, prismatic, vertically striated crystals which may be curved or bent. It is often in bladed, granular, or massive aggregates. The hardness is 2 on Mohs scale and the specific gravity 4.5–4.6. The luster is metallic and the color lead-gray to black. It is one of few minerals that fuses easily in the match flame (525°C or 977°F).

Stibnite has been found in various mining districts in Germany, Romania, France, Bolivia, Peru, and Mexico. In the United States the Yellow Pine mine at Stibnite, Idaho, is the largest producer. Other deposits are in Nevada and California. The finest crystals have come from the island of Shikoku, Japan. *See* ANTIMONY. [C.S.Hu.]

Stichosomida An order of nematodes composed of taxa that are parasitic in either vertebrates or invertebrates. The most distinguishing characteristic is the modification of the posterior esophagus into a stichosome, a series of glands exterior to the esophagus proper. The stichosome may be in one or two rows. The early larval stages possess a protrusible stylet that is absent in the adults. Amphids are postlabial.

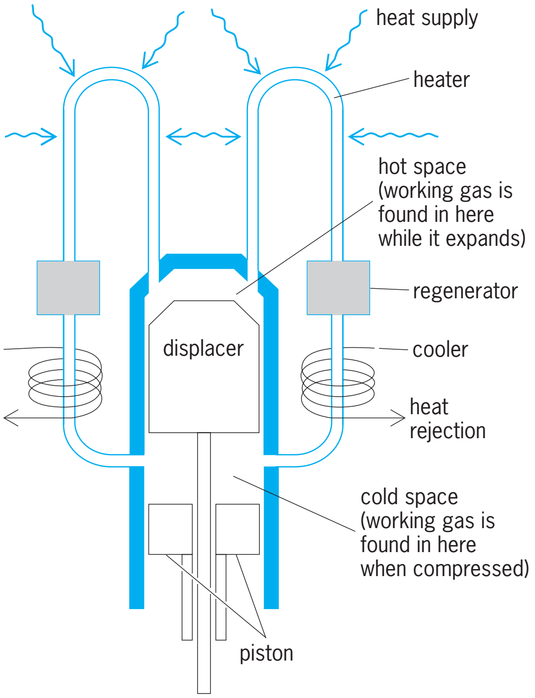
There are three stichosomid superfamilies: Trichocephaloidea parasitize vertebrates. In Mermithoidea, adult worms are free living, but their larvae are parasitic in a variety of insects, arachnids, and pulmonate snails. Echinomermelloidea parasitize marine invertebrates; the superfamily comprises three families: Echinomermellidae, Marimemithidae, and Benthimermithidae. *See* NEMATA. [A.R.M.]

Stickleback Any fish which is a member of the family Gasterosteidae in the order Gasterosteiformes. They have a variable number of free spines in front of the dorsal fin. These small, fresh-water and marine fishes are found in cold and temperate waters of the Northern Hemisphere. All species are of some economic importance since they feed largely on mosquito larvae. *See* GASTEROSTEIFORMES. [C.B.C.]

Stilbite A mineral belonging to the zeolite family of silicates. It crystallizes in sheaflike aggregates of thin tabular crystals. There is perfect cleavage parallel to the side pinacoid, and here the mineral has a pearly luster; elsewhere the luster is vitreous. The color is usually white but may be brown, red, or yellow. Hardness is $3^1/_2$–4 on Mohs scale; specific gravity is 2.1–2.2. *See* ZEOLITE.

Stilbite is found in Iceland, India, Scotland, Nova Scotia, and in the United States at Bergen Hill, New Jersey, and the Lake Superior copper district in Michigan. [C.S.Hu.]

Stirling engine An engine in which work is performed by the expansion of a gas at high temperature to which heat is supplied through a wall. Like the internal combustion engine, a Stirling engine provides work by means of a cycle in which a piston compresses gas at a low temperature and allows it to expand at a high temperature. In the former case the heat is provided by the internal combustion of fuel in the cylinder, but in the Stirling engine the heat (obtained from externally burning fuel) is supplied to the gas through the wall of the cylinder (see illustration).



Principle of Stirling engine, displacer type.

The rapid changes desired in the gas temperature are achieved by means of a second piston in the cylinder, called a displacer, which in moving up and down transfers the gas back and forth between two spaces, one at a fixed high temperature and the other at a fixed low temperature. When the displacer is raised, the gas will flow from the hot space via the heater and cooler tubes into the cold space. When it is moved downward, the gas will return to the hot space along the same path. During the first transfer stroke the gas has to yield up a large amount of heat to the cooler; an equal quantity of heat has to be taken up from the heater during the second stroke. *See* Internal combustion engine. [R.J.M.]

Stishovite Naturally occurring stishovite, SiO_2, is a mineral formed under very high pressure with the silicon atom in sixfold, or octahedral, coordination instead of the usual fourfold, or tetrahedral, coordination. The presence of stishovite indicates formation pressures in excess of 10^6 lb/in.^{2} (7.5 gigapascals). The possibility of the existence of stishovite at great depths strongly influences the interpretations of geophysicists and solid-state physicists regarding the phase transitions of mineral matter, as well as the interpretation of seismic data in the study of such regions of the interior of the Earth. *See* Silica minerals.

Stishovite occurs in submicrometer size in very small amounts (less than 1% of the rock) in samples of Coconino sandstones from the Meteor Crater of Arizona, which contains up to 10% of coesite, the other high-pressure polymorph of silica. Because of its extremely fine grain size and because of the sparsity of this mineral in the rock, positive identification of the mineral is possible only by the x-ray diffraction method after chemical concentration. *See* Coesite; Meteorite.

The specific gravity of stishovite, calculated from the x-ray data, is 4.28, compared with the value of 4.35 for the synthetic material. It is 46% denser than coesite and much denser than other modifications of silica. *See* Rutile. [E.C.T.C.]

Stochastic control theory A branch of control theory which aims at predicting and minimizing the magnitudes and limits of the random deviations of a control system through optimizing the design of the controller. Such deviations occur when random noise and disturbance processes are present in a control system, so that the system does not follow its prescribed course but deviates from the latter by a randomly varying amount.

In contrast to deterministic signals, random signals cannot be described as given functions of time such as a step, a ramp, or a sine wave. The exact function is unknown to the system designer; only some of its average properties are known.

A random signal may be generated by one of nature's processes, for instance, radar noise and wind- or wave-induced forces and moments on a radar antenna or a ship. Alternatively, it may be generated by human intelligence, for instance, the bearing of a zigzagging aircraft, or the contour to be followed by a duplicating machine.

One outstanding experimental fact about nature's random processes is that these signals are very closely Gaussian. The word "Gaussian" is a mathematical concept which describes one or more signals, $i_1, i_2, \ldots, i_n$ having the following properties:

1. The amplitude of each signal is normally distributed.
2. The joint distribution function of any number of signals at the same or different times taken from the set is a multivariate normal distribution. This experimental fact is not surprising in view of the fact that a random process of nature is usually the sum total of the effects of a large number of independent contributing factors. For instance, thermal noise is due to the thermal motions of billions of electrons and atoms. An ocean-wave height at any particular time and place is the sum of wind-generated waves at previous times over a large area. *See* Distribution (probability); Electrical noise; Stochastic process.

The underlying mechanism that generates a random process can usually be described in physical or mathematical terms. For instance, the underlying mechanism that generates shot-effect noise is thermionic emission. If the generating mechanism does not change with time, any measured average property of the random process is independent of the time of measurement aside from statistical fluctuations, and the random process is called stationary. If the generating mechanism does change, the random process is called nonstationary. *See* Control systems. [S.S.L.C.]

Stochastic process A physical stochastic process is any process governed by probabilistic laws. Examples are (1) development of a population as controlled by Mendelian genetics; (2) Brownian motion of microscopic particles subjected to molecular impacts or, on a different scale, the motion of stars in space; (3) succession of plays in a gambling house; and (4) passage of cars by a specified highway point.

In each case, a probabilistic system is evolving; that is, its state is changing with time. Thus the state at time t depends on chance: It is a random variable $x(t)$. The parameter set of values of t involved is usually (and will always be in this article) either an interval (continuous parameter stochastic process) or a set of integers (discrete parameter stochastic process). Some authors, however, apply the term stochastic process only to the continuous parameter case.

If the state of the system is described by a single number, $x(t)$ is numerical-valued. In other cases, $x(t)$ may be vector-valued or even more complicated. For the numerical case, as the state changes, its values determine a function of time, the sample function, and the probability laws governing the process determine the probabilities assigned to the various possible properties of sample functions.

A mathematical stochastic process is a mathematical structure inspired by the concept of a physical stochastic process, and studied because it is a mathematical model of a physical stochastic process or because of its intrinsic mathematical interest and its applications both in and outside the field of probability. The mathematical stochastic process is defined simply as a family of random variables. That is, a parameter set is specified, and to each parameter point t a random variable $x(t)$ is specified. If one recalls that a random variable is itself a function, if one denotes a point of the domain of the random variable $x(t)$ by ω, and if one denotes the value of this random variable at ω by $x(t, \omega)$, it results that the stochastic process is completely specified by the function of the pair (t, ω) just defined, together with the assignment of probabilities. If t is fixed, this function of two variables defines a function of ω, namely, the random variable denoted by $x(t)$. If ω is fixed, this function of two variables defines a function of t, a sample function of the process.

Probabilities are ordinarily assigned to a stochastic process by assigning joint probability distributions to its random variables. These joint distributions, together with the probabilities derived from them, can be interpreted as probabilities of properties of sample functions. For example, if t_0 is a parameter value, the probability that a sample function is positive at time t_0 is the probability that the random variable $x(t_0)$ has a positive value. The fundamental theorem at this level is that, to any self-consistent assignment of joint probability distributions, there corresponds a stochastic process.

Stationary processes are the stochastic processes for which the joint distribution of any finite number of the random variables is unaffected by translations of the parameter; that is, the distribution of $x(t_1 + h), \ldots, x(t_n + h)$ does not depend on h. *See* PROBABILITY.

A Markov process is a process for which, if the present is given, the future and past are independent of each other. More precisely, if $t_1 < \cdots < t_n$ are parameter values, and $1 < j < n$, then the sets of random variables $[x(t_1), \ldots, x(t_{j-1})]$ and $[x(t_{j+1}), \ldots, x(t_n)]$ are mutually independent for given $x(t_j)$. Equivalently, the conditioned probability distribution of $x(t_n)$ *for* given $x(t_{n1}), \ldots, x(t_{n-1})$ depends only on the specified value of $x(t_{n-1})$ and is in fact the conditional probability distribution of $x(t_n)$, given $x(t_{n-1})$. An important and simple example is the Markov chain, in which the number of states is finite or denumerably infinite.

A martingale is a stochastic process with the property that, if $t_1 < \cdots < t_n$ are parameter values, the expected value of $x(t_n)$ for given $x(t_1), \ldots, x(t_{n-1})$ is equal to $x(t_{n-1})$. That is, the expected future value, given present and past values, is equal to the present value. The interpretation that a martingale can be thought of as the fortune of a player after the successive plays of a fair gambling game is obvious.

A process with independent increments is a continuous-parameter process with the property that, if $t_1, < \cdots < t_n$ are parameter values, the successive increments in $x(t_2) - x(t_1), \ldots, x(t_n) - x(t_{n-1})$ are mutually independent. If $y(t) = x(t) - x(t_0)$, where t_0 is fixed, the $y(t)$ process is then a Markov process. *See* GAME THEORY; INFORMATION THEORY; LINEAR PROGRAMMING; OPERATIONS RESEARCH. [J.L.D.]

Stoichiometry All chemical measurements, such as the measurements of atomic and molecular weights and sizes, gas volumes, vapor densities, deviation from the gas laws, and the structure of molecules. In determining the relative weights of the atoms, scientists have relied upon combining ratios, specific heats, and measurements of gas volumes. All such measurements, and the calculations that relate them to each other, constitute the field of stoichiometry. Since measurements are expressed in mathematical terms, stoichiometry can be considered to be the mathematics of general chemistry.

In a general usage, the term stoichiometry refers to the relationships between the measured quantitites of substances or of energy involved in a chemical reaction; the calculations of these quantities include the assumption of the validity of the laws of definite proportions and of conservation of matter and energy. *See* CONSERVATION OF ENERGY; CONSERVATION OF MASS.

A typical stoichiometric problem involves predicting the weight of reactant needed to produce a desired amount of a product in a chemical reaction. For example, phosphorus can be extracted from calcium phosphate, $Ca_3(PO_4)_2$, by a certain process with a 90% yield (some calcium phosphate fails to react or some phosphorus is lost). In a specific problem, it might be necessary to determine the mass of calcium phosphate required to prepare 16.12 lb of phosphorus by this process. The balanced equation for the preparation is shown in reaction (1). In this reaction,

$$2Ca_3(PO_4)_2 + 10C + 6SiO_2 \rightarrow 6CaSiO_3 + 10CO + P_4 \qquad (1)$$

2 moles of calcium phosphate are required to produce 1 mole of phosphorus. Two moles of calcium phosphate have a mass of 620 lb, and 1 mole of phosphorus as P_4 has a mass of 124 lb. Using these relationships, calculation (2) is made. Since the yield

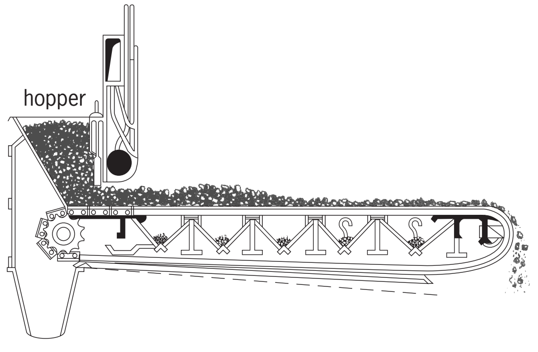
$$\begin{aligned}\frac{2\text{ moles }Ca_3(PO_4)}{1\text{ mole }P_4} &= \frac{620\text{ lb }Ca_3(PO_4)_2}{124\text{ lb }P_4}\\ &= \frac{X\text{ lb }Ca_3(PO_4)_2}{16.12\text{ lb }P_4} \qquad (2)\\ X &= 80.6\text{ lb}\end{aligned}$$

of phosphorus is only 90%, extra $Ca_3(PO_4)_2$ must be used: 88.1 lb is the mass of calcium phosphate required to yield 16.12 lb of phosphorus by this process.

Calculations of this sort are important in chemical engineering processes, in which amounts and yields of products must be known. The same reasoning is used in calculations of energy generated or required. In this case, the energy involved in the reaction of a known weight of the material in question must be known or determined.

The calculations discussed involve compounds in which the ratio of atoms is generally simple. For a discussion of compounds in which the relative number of atoms cannot be expressed as ratios of small whole numbers, *see* NONSTOICHIOMETRIC COMPOUNDS [J.C.Ba.]

Stoker A mechanical means for feeding coal into, and for burning coal in, a furnace. There are three basic types of stokers. Chain or traveling-grate stokers have a moving grate on which the coal burns; they carry the coal from a hopper into the furnace and move the ash out (see illustration). Spreader stokers mechanically or pneumatically distribute the coal from a hopper at the furnace front wall and move it onto the grate which usually moves continuously to dispose of the ash after the coal is burned. Underfeed stokers are arranged to force fresh coal



Chain grate stoker.

from the hopper to the bottom of the burning coal bed, usually by means of a screw conveyor. The ash is forced off the edges of the retort peripherally to the ashpit or is removed by hand. [G.W.K.]

Stokes' theorem The assertion that under certain light restrictions the surface integral of $(\Delta\,\mathfrak{F} \times \mathfrak{F}\,) \cdot \mathbf{v}$ over a surface patch S is equal to the line integral of $\mathfrak{F} \cdot \tau$ taken around C, the boundary curve of S, provided the sense of transcription of C is right-handed relative to $\mathbf{v}$. This can be expresed as

$$\iint (\nabla \times \mathfrak{F}) \cdot \mathbf{v}\, dS = \int \mathfrak{F} \cdot \tau\, ds$$

Here $\mathfrak{F}$ is a vector function, $\mathbf{v}$ is one of the two unit normals to the two-sided surface S, s is arc length measured positively in the sense which is right-handed relative to $\mathbf{v}$, and τ is the unit tangent vector to C in the sense of increasing s. *See* CALCULUS OF VECTORS. [H.V.C.]

Stolonifera An order of the Alcyonaria which lacks coenenchyme. They form either simple or rather complex colonies. The polyp has a cylindrical body with a retractile oral portion which can withdraw into a solid anthostele or calyx protected by many calcareous spicules. The base of the mature polyp is attached to a creeping stolon which is a ribbonlike network or thin flat mat from which daughter polyps arise. Daughter polyps never bud from the wall of the primary polyp. Each polyp is connected by solenial tubes of the stolons, or by transverse platforms. *See* ALCYONARIA. [K.At.]

Stomach The tubular or saccular abdominal organ of the digestive system adapted for temporary food storage and preliminary stages of food breakdown.

In some primitive vertebrates the stomach may be little more than a simple tube quite similar to other portions of the gastrointestinal tract. In other forms the stomach is a distinct, and frequently large, saclike structure of variable shape. Carnivorous forms typically have a better-developed stomach than herbivores, probably reflecting the larger but less numerous feedings characteristic of the former, but exceptions are numerous.

In birds the stomach consists of a proventriculus and a gizzard. The former is well supplied with glands which secrete softening and digestive enzymes; the latter is a strong, muscular grinding organ whose action is often enhanced by the ingestion of small stones.

Mammals have stomachs which vary considerably in structure. Although a single chamber is most common, some mammals, such as cows and their relatives (ruminants), have as many as four. These chambers may have developed either from modifications of the posterior portions of the esophagus or from alterations of the stomach itself.

The human stomach is located beneath the diaphragm, through which the posterior, terminal end of the esophagus passes. The stomach appears as a dilated tube continuous with the distal end of the esophagus. The upper curvature of the stomach is usually above and to the left of the esophageal orifice. This expanded anterior portion is the fundus and is commonly filled with air or gas. The body (corpus) of the stomach is directed toward the attenuated right extremity or pyloric region and is subject to variations in size and shape, depending upon functional activities, habits, disease, and volume of the contents. The pyloric walls are marked by the heavy sphincter muscle which controls the passage of chyme (a semiliquid fluid produced by the mechanical and chemical changes of preliminary digestion) into the duodenum.

The stomach of vertebrates is lined by a mucous membrane that is usually thrown into longitudinal folds called rugae. Most of the surface is covered with mucus-secreting epithelial cells, but scattered throughout the lining are many small glandular pits which are lined with one or more types of secretory cells. *See* DIGESTIVE SYSTEM. [T.S.P.]

Stomatopoda The only order of the superorder Hoplocarida belonging to the subclass Malacostraca of the class Crustacea. This order of the mantis shrimps contains four families: Lysioquillidae, Bathysquillidae, Squillidae, and Gonodactylidae. Stomatopoda are among the larger Crustacea; the size of an adult ranges from about 0.5 in. (12 mm) to over 12 in. (300 mm).

The bodies of stomatopods are narrow and elongate, almost eruciform. Only part of the cephalic and thoracic somites are fused and covered by the dorsal shield, the carapace. Those cephalic somites which bear the antennulae and the eyes are free and visible anterior to the carapace, and the last four thoracic somites are similarly exposed. The tail fan consists of a well-developed, sometimes peculiarly sculptured or deformed, median plate, the telson, and the two uropods. Anteriorly, the carapace bears a flattened movable plate, the rostrum. The eyes are large, stalked, and movable. Of eight pairs of thoracic appendages the first is narrow, slender, and hairy, probably being used for cleaning purposes. The second thoracic leg is very strong and heavy. It has become a large raptorial claw that shows a great resemblance to that of the praying mantis, and for this reason the Stomatopoda are often given the name mantis shrimps.

The Stomatopoda are marine animals rarely found in brackish water. Most species are confined to tropical and subtropical areas, though some occur in the boreal and antiboreal regions. The majority of stomatopods live in the littoral and sublittoral zones, but a few species have been found in greater depths, down to 2500 ft (760 m). *See* MALACOSTRACA. [L.B.Ho.]

Stone and stone products The term stone is applied to rock that is cut, shaped, broken, crushed, and otherwise physically modified for commercial use. The two main divisions are dimension stone and crushed stone. Other descriptive terms may be used, for example, building stone, roofing stone, or precious stone. *See* GEM; ROCK.

The term dimension stone is applied to blocks that are cut and milled to specified sizes, shapes, and surface finishes. The principal uses are for building and ornamental applications. Granites, limestones, sandstones, and marbles are widely used; basalts, diabases, and other dark igneous rocks are used less extensively. Soapstone is used to some extent. Rock suitable for use as dimension stone must be obtainable in large, sound blocks, free from incipient cracks, seams, and blemishes, and must be without mineral grains that might cause stains as a result of weathering. It must have an attractive color, and generally a uniform texture.

Slate differs from other dimension stone because it can be split into thin sheets of any desired thickness. Commercial slate must be uniform in quality and texture and reasonably free from knots, streaks, or other imperfections, and have good splitting properties. Roofing slates are important products of most slate quarries. However, the roofing-slate industry has declined considerably because of competition from other types of roofing. Slate is also used for milled products such as blackboards, electrical panels, window and door sills and caps, baseboards, stair treads, and floor tile. *See* SLATE.

Nearly all the principal types of stone—granite, diabase, basalt, limestone, dolomite, sandstone, and marble—may be used as sources of commercial crushed stone; limestone is by far the most important. Crushed stone is made from sound, hard stone, free from surface alteration by weathering. Stone that breaks in chunky, more or less cubical fragments is preferred. Commercial stone should be free from certain deleterious impurities, such as opalescent quartz, and free from clay or silt. Crushed stone is used principally as concrete aggregate, as road stone, or as railway ballast. Other uses for limestone are as a fluxing material to remove impurities from ores smelted in metallurgical furnaces, in the manufacture of alkali chemicals, calcium carbide, glass, paper, paint, and sugar, and for filter beds and for making mineral wool. [R.L.B.]

Storage tank A container for storing liquids or gases. A tank may be constructed of ferrous or nonferrous metals or alloys, reinforced concrete, wood, or filament-wound plastics, depending upon its use. Tanks resting on the ground have flat bottoms: those supported on towers have either flat or curved bottoms. Standpipes, which are usually cylindrical shells of steel or reinforced concrete resting on the ground, are frequently of great height and comparatively small diameter. They are built to contain water for a distribution system, and height is required to maintain pressure in the system. Tanks for other liquids and for gases, where storage is more important than pressure, are generally lower and of greater diameter. [C.M.A.]

Storm An atmospheric disturbance involving perturbations of the prevailing pressure and wind fields on scales ranging from tornadoes (0.6 mi or 1 km across) to extratropical cyclones (1.2–1900 mi or 2–3000 km across); also, the associated weather (rain storm, blizzard, and the like). Storms influence human activity in such matters as agriculture, transportation, building construction, water impoundment and flood control, and the generation, transmission, and consumption of electric energy. *See* WIND.

The form assumed by a storm depends on the nature of its environment, especially the large-scale flow patterns and the horizontal and vertical variation of temperature; thus the storms most characteristic of a given region vary according to latitude, physiographic features, and season. Extratropical cyclones and anticyclones are the chief disturbances over roughly half the Earth's surface. Their circulations control the embedded smaller-scale storms. Large-scale disturbances of the tropics differ fundamentally from those of extratropical latitudes. *See* HURRICANE; SQUALL; THUNDERSTORM; TORNADO; TROPICAL METEOROLOGY.

Cyclones form mainly in close proximity to the jet stream, that is, in strongly baroclinic regions where there is a large increase of wind with height. Weather patterns in cyclones are highly variable, depending on moisture content and thermodynamic stability of air masses drawn into their circulations. Warm and occluded fronts, east of and extending into the cyclone center, are regions of gradual upgliding motions, with widespread cloud and precipitation but usually no pronounced concentration of stormy conditions. Extensive cloudiness also is often present in the warm sector. Passage of the cold front is marked by a sudden wind shift, often with the onset of gusty conditions, with a pronounced tendency for clearing because of general subsidence behind the front. Showers may be present in the cold air if it is moist and unstable because of heating from the surface. Thunderstorms, with accompanying squalls and heavy rain, are often set off by sudden lifting of warm, moist air at or near the cold front, and these frequently move eastward into the warm sector. *See* CYCLONE; JET STREAM; WEATHER.

Extratropical cyclones alternate with high-pressure systems or anticyclones, whose circulation is generally opposite to that of the cyclone. The circulations of highs are not so intense as in well-developed cyclones, and winds are weak near their centers. In low levels the air spirals outward from a high; descent in upper levels results in warming and drying aloft. Anticyclones fall into two main categories, the warm "subtropical" and the cold "polar" highs.

Between the scales of ordinary air turbulence and of cyclones, there exist a variety of circulations over a middle-scale or mesoscale range, loosely defined as from about one-half up to a few hundred miles. Alternatively, these are sometimes referred to as subsynoptic-scale disturbances because their dimensions are so small that they elude adequate description by the ordinary synoptic network of surface weather stations. Thus their detection often depends upon observation by indirect sensing systems. *See* METEOROLOGICAL SATELLITES; RADAR METEOROLOGY; STORM DETECTION. [C.W.N.]

Storm detection Identifying storm formation, monitoring subsequent storm evolution, and assessing the potential for destruction of life and property through application of various methods and techniques. Doppler radars, satellite-borne instruments, lightning detection networks, and surface observing networks are used to detect the genesis of storms, to diagnose their nature, and to issue warnings when a threat to life and property exists. *See* STORM.

Radar surveillance. Radars emit pulses of electromagnetic radiation that are broadcast in a beam, whose angular resolution is about 1° with a range resolution of about 0.5 km (0.3 mi). The radar beam may intercept precipitation particles in a storm that reflect a fraction of the transmitted energy to the transmitter site (generally called reflectivity or the scatter cross section per unit volume). As the transmitter sweeps out a volume by rotating and tilting the transmitting antenna, the reflectivity pattern of the precipitation particles embodied in the storm is defined. Doppler radars also can measure the velocities of precipitation particles along the beam (radial velocity). Reflectivity and velocity patterns of the storm hydrometeors then make it possible to diagnose horizontal and vertical circulations that may arise within the storm, and to estimate the type and severity of weather elements attending the storm, such as rainfall, hail, damaging winds, and tornadoes. *See* DOPPLER RADAR; PRECIPITATION (METEOROLOGY); RADAR; RADAR METEOROLOGY; WIND.

Satellite surveillance. Since the early 1960s, meteorological data from satellites have had an increasing impact on storm detection and monitoring. In December 1966 the first geostationary *Applications Technology Satellite (ATS 1)* allowed forecasters in the United States to observe storms in animation. A Geostationary Operational Environmental Satellite (GOES) program was initiated within the National Oceanic and Atmospheric Administration (NOAA) with the launch of *GOES 1* in October 1975. The visible and infrared spin scan radiometer (VISSR) provided imagery, which significantly advanced the ability of meteorologists to detect and observe storms by providing frequent-interval visible and infrared imagery of the Earth surface, cloud cover, and atmospheric moisture patterns.

The first of NOAA's next generation of geostationary satellites, *GOES 8* was launched in the spring of 1994. *GOES 8* introduced improved capabilities to detect and observe storms. The *GOES 8* system includes no conflict between imaging and sounding operation, multispectral imaging with improved resolution and better signal-to-noise in the infrared bands, and more accurate temperature and moisture soundings of the storm environment. The Earth's atmosphere is observed nearly continuously.

Derived-product images showing fog and stratus areas from *GOES 8* are created by combining direct satellite measurements, such as by subtracting brightness temperatures at two different wavelengths. *GOES 8* shows the fog and stratus much more clearly because of its improved resolution. This capability enables forecasters to detect boundaries between rain-cooled areas having fog or low clouds, and clear areas. Such boundaries are frequently associated with future thunderstorm development. The sounder on *GOES 8* is capable of fully supporting routine forecasting operations. This advanced sounding capability consists of better vertical resolution in both temperature and moisture, and improved coverage of soundings in and around cloudy weather systems. *See* CLOUD; FOG; METEOROLOGICAL SATELLITES; SATELLITE METEOROLOGY.

Surface observing systems. Larger convective storm systems such as squall lines and mesoscale convective systems can be detected (but not fully described) by the temperature, moisture, wind, and pressure patterns observed by appropriate surface instrumentation. Automatic observing systems provide frequent data on pressure, temperature, humidity, wind, cloud base, and most precipitation types, intensity, and accumulation. Analyses of these data, combined with improved conceptual models of convective storm systems, enable forecasters to detect and monitor the intense mesoscale fluctuations in pressure and winds that often accompany the passage of convective weather systems such as bow echoes, derechos (strong, straight-line winds), and squall lines. A bow echo is a specific radar reflectivity pattern associated with a line of thunderstorms. The middle portion of the thunderstorm line is observed to move faster than the adjacent portions, causing the line of storms to assume a bowed-out configuration. Other analyses of these mesoscale data fields aid the forecaster in detecting favorable areas for thunderstorm cell regeneration, which may produce slowly moving mesoscale convective storms attended by heavy rains and flash floods. *See* SQUALL LINE; WEATHER OBSERVATIONS.

Cloud-to-ground lightning detectors. Lightning location stations provide forecasters with the location, polarity, peak current, and number of strokes in a flash to ground within seconds of the flash occurrence. Useful applications have emerged with regard to the detection and tracking of thunderstorms, squall lines, other mesoscale convective systems, and the weather activity that accompany these phenomena, such as tornadoes and hail. *See* LIGHTNING; MESOMETEOROLOGY; SFERICS; THUNDERSTORM; WEATHER FORECASTING AND PREDICTION. [C.F.Ch.]

Storm electricity Processes responsible for the separation of positive and negative electric charges in the atmosphere during storms, including the spectacular manifestation of this charge separation: lightning discharges. Cloud electrification is almost invariably associated with convective activity and with the formation of precipitation in the form of liquid water (rain) and ice particles (graupel and hail). The most vigorous convection and active lightning occurs in the summertime, when the energy source for convection, water vapor, is most prevalent. Winter snowstorms can also be strongly electrified, but they produce far less lightning than summer storms. Electrified storm clouds occasionally occur in complete isolation; more commonly they are found in convective clusters or in lines that may extend horizontally for hundreds of kilometers. *See* PRECIPITATION (METEOROLOGY).

Measurements of electric field at the ground and from instrumented balloons within thunderclouds have disclosed an electrostatic structure that appears to be fairly systematic throughout the world. The measurements show that the principal variations in charge occur in the vertical and are affected by the temperature of the cloud. The charge structure within a thundercloud is tripolar, with a region of dominant negative charge sandwiched between an upper region of positive charge and a subsidiary lower region of positive charge. In addition to the charge accumulations described within the cloud, electrical measurements disclose the existence of charge-screening layers at the upper cloud boundary and a layer of positive charge near the Earth's surface beneath the cloud. These secondary charge accumulations arising from charge migration outside the cloud are caused by electrostatic forces of attraction set up by the charges within the cloud.

Large differences of electric potential are associated with the distribution of charge maintained by active thunderclouds. These large differences in potential are maintained by charging currents that result from the motions of air and particles. The charging currents range from milliamperes in small clouds that are not producing lightning to several amperes for large storms with high rates of lightning. *See* CLOUD PHYSICS.

In response to charge separation within a thundercloud, the electric field increases to a value of approximately 10^6 V/m (300,000 V/ft) at which point dielectric breakdown occurs and lightning is initiated. Most lightning extends through the cloud at speeds of 10,000–100,000 m/s (22,000–220,000 mi/h). The peak temperature of lightning, which is a highly ionized plasma, may exceed 30,000 K (54,000°F). The acoustic disturbance caused by the sudden heating of the atmosphere by lightning is thunder. *See* LIGHTNING; THUNDER.

Meteorologists have shown a growing interest in the large-scale display of real-time lightning activity, since lightning is one of the most sensitive indicators of convective activity. Research has expanded into relationships between lightning characteristics and the meteorological evolution of different types of storms. The discovery of the sensitive dependence of local lightning activity on the temperature of surface air has led to research focused on the use of the global electrical circuit as a diagnostic for global temperature change. *See* ATMOSPHERIC ELECTRICITY; STORM DETECTION; THUNDERSTORM. [E.Wi.]

Storm surge An anomalous rise in water elevations caused by severe storms approaching the coast. A storm surge can be succinctly described as a large wave that moves with the storm that caused it. The surge is intensified in the nearshore, shallower regions where the surface stress caused by the strong onshore winds pile up water against the coast, generating an opposing pressure head in the offshore direction. However, there are so many other forces at play in the dynamics of the storm surge phenomenon, such as bottom friction, Earth's rotation, inertia, and interaction with the coastal geometry, that a simple static model cannot explain all the complexities involved. Scientists and engineers have dedicated many years in the development and application of sophisticated computer models to accurately predict the effects of storm surges.

The intensity and dimension of the storm causing a surge, and thus the severity of the ensuing surge elevations, depend on the origin and atmospheric characteristics of the storm itself. Hurricanes and severe extratropical storms are the cause of most significant surges. In general, hurricanes are more frequent in low to middle latitudes, and extratropical storms are more frequent in middle to high latitudes. *See* HURRICANE; STORM. [S.R.S.]

Straight-line mechanism A mechanism that produces a straight-line (or nearly so) output motion from an input element that rotates, oscillates, or moves in a straight line. Common machine elements, such as linkages, gears, and cams, are often used in ingenious ways to produce the required controlled motion. The more elegant designs use the properties of special points on one of the links of a four-bar linkage. *See* MECHANISM.

Four-bar linkages that generate approximate straight lines are not new. In 1784 James Watt applied the concept to the vertical-cylinder beam engine. By selecting the appropriate link lengths, the designer can easily develop a mechanism with a high-quality approximate straight line. Contemporary kinematicians have contributed to more comprehensive studies of the properties of the mechanisms that generate approximate straight lines. The work not only describes the various classical mechanisms, but also provides design information on the quality (the amount of deviation from a straight line) and the length of the straight-line output. *See* FOUR-BAR LINKAGE; LINKAGE (MECHANISM).

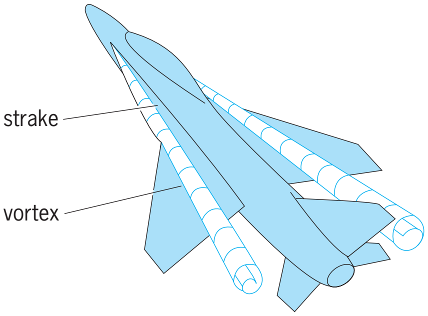
Gears can also be used to generate straight-line motions. The most common combination would be a rack-and-pinion gear. *See* GEAR.

Cam mechanisms are generally not classified as straight-line motion generators, but translating followers easily fall into the classical definition. *See* CAM MECHANISM. [J.A.Sm.]

Strain gage A device which measures mechanical deformation (strain). Normally it is attached to a structural element, and uses the change of electrical resistance of a wire or semiconductor under tension. Capacity, inductance, and reluctance are also used.

The strain gage converts a small mechanical motion to an electrical signal by virtue of the fact that when a metal (wire or foil) or semiconductor is stretched, its resistance is increased. The change in resistance is a measure of the mechanical motion. In addition to their use in strain measurement, these gages are used in sensors for measuring the load on a mechanical member, forces due to acceleration on a mass, or stress on a diaphragm or bellows. *See* Strain. [J.H.Z.]

Strake The slender forward extension of the inboard region of the wing of a combat aircraft used to provide increased lift in the high angle-of-attack maneuvering condition. In contrast to the normal attached-flow design principles, these strakes are built to allow the flow to separate along the leading edge in the high angle-of-attack range and to roll up into strong leading-edge vortices. The illustration shows a typical strake installation and the vortices generated. These are highly stable, and their strong swirling motion creates a lower pressure area on the strake upper surface, resulting in a large incremental increase in lift force known as vortex lift. This vortex lift increases rapidly in the high angle-of-attack range and is less susceptible to the normal stalling characteristics encountered with conventional lifting surfaces. *See* Airfoil; Subsonic flight; Vortex; Wing. [E.C.Po.]



Strake and resulting vortex flow.

Strand line The line that marks the separation of land and water along the margin of a pond, lake, sea, or ocean; also called the shoreline. The strand line is very dynamic. It changes with the tides, storms, and seasons, and as long-term sea-level changes take place. The sediments on the beach respond to these changes, as do the organisms that live in this dynamic environment. On a beach organisms move with the tides, and on a rocky coast they tend to be organized relative to the strand line because of special limitations or adaptations to exposure.

Geologists who study ancient coastal environments commonly try to establish where the strand line might be in the rock strata. This can sometimes be determined by a combination of the nature and geometry of individual laminations in the rock, by identifying sedimentary structures that occur at or near the strand line. The most indicative of these structures are swash marks, which are very thin accumulations of sand grains that mark the landward uprush of a wave on the beach. *See* Facies (geology); Paleogeography; Stratigraphy. [R.A.D.]

Strange particles Bound states of quarks, in which at least one of these constituents is of the strange (s) type. Strange quarks are heavier than the up (u) and down (d) quarks, which form the neutrons and protons in the atomic nucleus. Neutrons (udd) and protons (uud) are the lightest examples of a family of particles composed of three quarks, known as baryons. These and other composite particles which interact dominantly through the strong (nuclear) force are known as hadrons. The first strange hadron discovered (in cosmic rays in 1947) was named the lambda baryon, Λ; it is made of the three-quark combination uds. A baryon containing a strange quark is also called a hyperon. Although strange particles interact through the strong (nuclear) force, the strange quark itself can decay only by conversion to a quark of different type (such as u or d) through the weak interaction. For this reason, strange particles have very long lifetimes, of the order of 10^{-10} s, compared to the lifetimes of the order of 10^{-23} s for particles which decay directly through the strong interaction. This long lifetime was the origin of the term strange particles. *See* Baryon; Hadron; Neutron; Proton; Strong nuclear interactions.

In addition to strange baryons, strange mesons occur. The lightest of these are the kaons ($K^+ = u\bar{s}$ and $K^0 = d\bar{s}$) and the antikaons ($\bar{K}^0 = s\bar{d}$ and $\bar{K}^- = s\bar{u}$). Kaons and their antiparticles have been very important in the study of the weak interaction and in the detection of the very weak *CP* violation, which causes a slow transition between neutral kaons and neutral antikaons. *See* Elementary particle; Meson; Quarks. [T.Bar.]

Strangles A highly contagious disease of the upper respiratory tract of horses and other members of the family Equidae, characterized by inflammation of the pharynx and abscess formation in lymph nodes. This disease occurs in horses of all ages throughout the world. The causative agent is *Streptococcus equi*, a clonal pathogen apparently derived from an ancestral strain of *S. zooepidemicus*. It is an obligate parasite of horses, donkeys, and mules. *See* Streptococcus.

Strangles is most common and most severe in young horses, and is very prevalent on breeding farms. The causative agent has been reported to survive for 7 weeks in pus but dies in a week or two on pasture. Transmission is either direct by nose or mouth contact or aerosol, or indirect by flies, drinking buckets, pasture, and feed. The disease is highly contagious under conditions of crowding, exposure to severe climatic conditions such as rain and cold, and prolonged transportation. Carrier animals, although of rare occurrence, are critical in maintenance of the streptococcus and in initiation of outbreaks.

The mean incubation period is about 10 days, with a range of 3–14 days. The animal becomes quieter, has fever of 39–40.5°C (102–105°F), nasal discharge, loss of appetite, and swelling of one or more lymph nodes of the mouth. Pressure of a lymph node on the airway may cause respiratory difficulty. Abscesses in affected lymph nodes rupture in 7–14 days, and rapid clinical improvement and recovery then ensues. Recovery is associated with formation of protective antibodies in the nasopharynx and in the serum. *See* Antibody.

Streptococcus equi is easily demonstrated in smears of pus from abscesses and in culture of pus or nasal swabs on colistin–nalidixic acid blood agar. Acutely affected animals also show elevated white blood cell counts and elevated fibrinogen.

Commercially available vaccines are injected in a schedule of two or three primary inoculations followed by annual boosters. However, the clinical attack rate may be reduced by only 50%, a level of protection much lower than that following the naturally occurring disease. *See* Immunity.

Procaine penicillin G is the antibiotic of choice and quickly brings about reduction of fever and lymph node enlargement. *See* Biologicals. [J.F.T.]

Stratigraphy A discipline involving the description and interpretation of layered sediments and rocks, and especially their correlation and dating. Correlation is a procedure for determining the relative age of one deposit with respect to another. The term “dating” refers to any technique employed to obtain a numerical age, for example, by making use of the decay of radioactive isotopes found in some minerals in sedimentary rocks or, more commonly, in associated igneous rocks. To a large extent, layered rocks are ones that accumulated through sedimentary processes beneath the sea, within lakes, or by the action of rivers, the wind, or glaciers; but in places such deposits contain significant amounts of volcanic material emplaced as lava flows or as ash ejected from volcanoes during explosive eruptions. *See* Dating methods; Igneous rocks; Rock age determination; Sedimentary rocks.

Sedimentary successions are locally many thousands of meters thick owing to subsidence of the Earth’s crust over millions of years. Sedimentary basins therefore provide the best available record of Earth history over nearly 4 billion years. That record includes information about surficial processes and the varying environment at the Earth's surface, and about climate, changing sea level, the history of life, variations in ocean chemistry, and reversals of the Earth's magnetic field. Sediments also provide a record of crustal deformation (folding and faulting) and of large-scale horizontal motions of the Earth's lithospheric plates (continental drift). Stratigraphy applies not only to strata that have remained flat-lying and little altered since their time of deposition, but also to rocks that may have been strongly deformed or recrystallized (metamorphosed) at great depths within the Earth's crust, and subsequently exposed at the Earth's surface as a result of uplift and erosion. As long as original depositional layers can be identified, some form of stratigraphy can be undertaken. *See* BASIN; CONTINENTAL DRIFT; FAULT AND FAULT STRUCTURES; SEDIMENTOLOGY.

An important idea first articulated by the Danish naturalist Nicolaus Steno in 1669 is that in any succession of strata the oldest layer must have accumulated at the bottom, and successively younger layers above. It is not necessary to rely on the present orientation of layers to determine their relative ages because most sediments and sedimentary rocks contain numerous features, such as current-deposited ripples, minor erosion surfaces, or fossils of organisms in growth position, that have a well-defined polarity with respect to the up direction at the time of deposition (so-called geopetal indicators). This principle of superposition therefore applies equally well to tilted and even overturned strata. Only where a succession is cut by a fault is a simple interpretation of stratigraphic relations not necessarily possible, and in some cases older rocks may overlie younger rocks structurally. *See* DEPOSITIONAL SYSTEMS AND ENVIRONMENTS.

The very existence of layers with well-defined boundaries implies that the sedimentary record is fundamentally discontinuous. Discontinuities are present in the stratigraphic record at a broad range of scales, from that of a single layer or bed to physical surfaces that can be traced laterally for many hundreds of kilometers. Large-scale surfaces of erosion or nondeposition are known as unconformities, and they can be identified on the basis of both physical and paleontological criteria. *See* PALEONTOLOGY; UNCONFORMITY.

Most stratal discontinuities possess time-stratigraphic significance because strata below a discontinuity tend to be everywhere older than strata above. To the extent that unconformities can be recognized and traced widely within a sedimentary basin, it is possible to analyze sedimentary rocks in a genetic framework, that is, with reference to the way they accumulated. This is the basis for the modern discipline of sequence stratigraphy, so named because intervals bounded by unconformities have come to be called sequences.

Traditional stratigraphic analysis has focused on variations in the intrinsic character or properties of sediments and rocks—properties such as composition, texture, and included fossils (lithostratigraphy and biostratigraphy)—and on the lateral tracing of distinctive marker beds such as those composed of ash from a single volcanic eruption (tephrostratigraphy). The techniques of magnetostratigraphy and chemostratigraphy are also based on intrinsic characteristics, although these techniques require sophisticated laboratory analysis. Sequence stratigraphy attempts to integrate these approaches in the context of stratal geometry, thereby providing a unifying framework in which to investigate the time relations between sediment and rock bodies as well as to measure their numerical ages (chronostratigraphy and geochronology). Seismic stratigraphy is a variant of the technique of sequence stratigraphy in which unconformities are identified and traced in seismic reflection profiles on the basis of reflection geometry. *See* GEOCHRONOMETRY; SEISMIC STRATIGRAPHY; SEISMOLOGY.

Conventional stratigraphy currently recognizes two kinds of stratigraphic unit: material units, distinguished on the basis of some specified property or properties or physical limits; and temporal or time-related units. A common example of a material unit is the formation, a lithostratigraphic unit defined on the basis of lithic characteristics and position within a stratigraphic succession. Each formation is referred to a section or locality where it is well developed (a type section), and assigned an appropriate geographic name combined with the word formation or a descriptive lithic term such as limestone, sandstone, or shale (for example, Tapeats Sandstone). Some formations are divisible into two or more smaller-scale units called members and beds. In other cases, formations of similar lithic character or related genesis are combined into composite units called groups and supergroups.

Sequence stratigraphy differs from conventional stratigraphy in two important respects. The first is that basic units (sequences) are defined on the basis of bounding unconformities and correlative conformities rather than material characteristics or age. The second is that sequence stratigraphy is fundamentally not a system for stratigraphic classification, but a procedure for determining how sediments accumulate. *See* SEQUENCE STRATIGRAPHY.

[N.C.B.]

Stratosphere The atmospheric layer that is immediately above the troposphere and contains most of the Earth's ozone. Here temperature increases upward because of absorption of solar ultraviolet light by ozone. Since ozone is created in sunlight from oxygen, a by-product of photosynthesis, the stratosphere exists because of life on Earth. In turn, the ozone layer allows life to thrive by absorbing harmful solar ultraviolet radiation. The mixing ratio of ozone is largest (10 parts per million by volume) near an altitude of 30 km (18 mi) over the Equator. The distribution of ozone is controlled by solar radiation, temperature, wind, reactive trace chemicals, and volcanic aerosols. *See* ATMOSPHERE; TROPOSPHERE.

The heating that results from absorption of ultraviolet radiation by ozone causes temperatures generally to increase from the bottom of the stratosphere (tropopause) to the top (stratopause) near 50 km (30 mi), reaching 280 K (45°F) over the summer pole. This temperature inversion limits vertical mixing, so that air typically spends months to years in the stratosphere. *See* TEMPERATURE INVERSION; TROPOPAUSE.

The lower stratosphere contains a layer of small liquid droplets. Typically less than 1 micrometer in diameter, they are made primarily of sulfuric acid and water. Occasional large volcanic eruptions maintain this aerosol layer by injecting sulfur dioxide into the stratosphere, which is converted to sulfuric acid and incorporated into droplets. Enhanced aerosol amounts from an eruption can last several years. By reflecting sunlight, the aerosol layer can alter the climate at the Earth's surface. By absorbing upwelling infrared radiation from the Earth's surface, the aerosol layer can warm the stratosphere. The aerosols also provide surfaces for a special set of chemical reactions that affect the ozone layer. Liquid droplets and frozen particles generally convert chlorine-bearing compounds to forms that can destroy ozone. They also tend to take up nitric acid and water and to fall slowly, thereby removing nitrogen and water from the stratosphere. The eruption of Mount Pinatubo (Philippines) in June 1991 is believed to have disturbed the Earth system for several years, raising stratospheric temperatures by more than 1 K (1.8°F) and reducing global surface temperatures by about 0.5 K (0.9°F). *See* AEROSOL.

Ozone production is balanced by losses due to reactions with chemicals in the nitrogen, chlorine, hydrogen, and bromine families. Reaction rates are governed by temperature, which depends on amounts of radiatively important species such as carbon dioxide. Human activities are increasing the amounts of these molecules and are thereby affecting the ozone layer. Evidence for anthropogenic ozone loss has been found in the Antarctic lower stratosphere. Near polar stratospheric clouds, chlorine and bromine compounds are converted to species that, when the Sun comes up in the southern spring, are broken apart by ultraviolet radiation and rapidly destroy ozone. This sudden loss of ozone is known as the anthropogenic Antarctic ozone hole. *See* STRATOSPHERIC OZONE. [M.H.H.]

Stratospheric ozone While ozone is found in trace quantities throughout the atmosphere, the largest concentrations are located in the lower stratosphere in a layer between 9 and 18 mi (15 and 30 km). Atmospheric ozone plays a critical role for the biosphere by absorbing the ultraviolet radiation with wavelength (λ) 240–320 nanometers. This radiation is lethal to simple unicellular organisms (algae, bacteria, protozoa) and to the surface cells of higher plants and animals. It also damages the genetic material of cells and is responsible for sunburn in human skin. The incidence of skin cancer has been statistically correlated with the observed surface intensity of ultraviolet wavelength 290–320 nm, which is not totally absorbed by the ozone layer. *See* OZONE; STRATOSPHERE; ULTRAVIOLET RADIATION (BIOLOGY).

Ozone also plays an important role in photochemical smog and in the purging of trace species from the lower atmosphere. Furthermore, it heats the upper atmosphere by absorbing solar ultraviolet and visible radiation ($\lambda < 710$ nm) and thermal infrared radiation ($\lambda \simeq 9.6$ micrometers). As a consequence, the temperature increases steadily from about -60°F (220 K) at the tropopause (5–10 mi or 8–16 km altitude) to about 45°F (280 K) at the stratopause (30 mi or 50 km altitude). This ozone heating provides the major energy source for driving the circulation of the upper stratosphere and mesosphere. *See* ATMOSPHERIC GENERAL CIRCULATION; TROPOPAUSE.

Above about 19 mi (30 km), molecular oxygen (O_2) is dissociated to free oxygen atoms (O) during the daytime by ultraviolet photons, ($h\nu$), as shown in reaction (1). The oxygen atoms produced then form ozone (O_3) by reaction (2), where M is an

$$O_2 + h\nu \rightarrow O + O \qquad \lambda < 242 \text{ nm} \tag{1}$$

$$O + O_2 + M \rightarrow O_3 + M \tag{2}$$

arbitrary molecule required to conserve energy and momentum in the reaction. Ozone has a short lifetime during the day because of photodissociation, as shown in reaction (3). However,

$$O_3 + h\nu \rightarrow O_2 + O \qquad \lambda < 710 \text{ nm} \tag{3}$$

except above 54 mi (90 km), where O_2 begins to become a minor component of the atmosphere, reaction (3) does not lead to a net destruction of ozone. Instead the O is almost exclusively converted back to O_3 by reaction (2). If the odd oxygen concentration is defined as the sum of the O_3 and O concentrations, then odd oxygen is produced by reaction (1). It can be seen that reactions (2) and (3) do not affect the odd oxygen concentrations but merely define the ratio of O to O_3. Because the rate of reaction (2) decreases with altitude while that for reaction (3) increases, most of the odd oxygen below 36 mi (60 km) is in the form of O_3 while above 36 mi (60 km) it is in the form of O. The reaction that is responsible for a small fraction of the odd oxygen removal rate is shown as reaction (4). A significant fraction

$$O + O_3 \rightarrow O_2 + O_2 \tag{4}$$

of the removal is caused by the presence of chemical radicals [such as nitric oxide (NO), chlorine (Cl), bromine (Br), hydrogen (H), or hydroxyl (OH)], which serve to catalyze reaction (4) (see illustration).

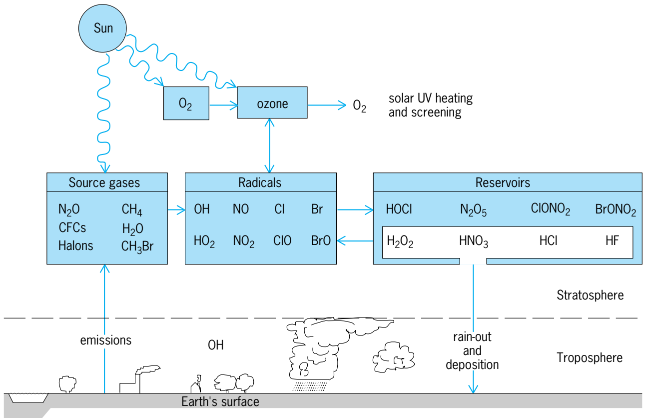
The discovery in the mid-1980s of an ozone hole over Antarctica, which could not be explained by the classic theory of ozone and had not been predicted by earlier chemical models, led to many speculations concerning the causes of this event, which can be observed each year in September and October. As suggested by experimental and observational evidence, heterogeneous reactions on the surface of liquid or solid particles that produce Cl_2, HOCl, and $ClNO_2$ gas, and the subsequent rapid photolysis of these molecules, produces chlorine radicals (Cl, ClO) which in turn lead to the destruction of ozone in the lower stratosphere by a catalytic cycle [reactions (5)–(7)]. Solar radia-

$$Cl + O_3 \rightarrow ClO + O_2 \tag{5}$$

$$ClO + ClO \rightarrow Cl_2O_2 \tag{6}$$

$$Cl_2O_2 + h\nu \rightarrow 2Cl + O_2 \tag{7}$$

tion is needed for these processes to occur.



Principal chemical cycles in the stratosphere. The destruction of ozone is affected by the presence of radicals which are produced by photolysis or oxidation of source gases. Chemical reservoirs are relatively stable but are removed from the stratosphere by transport toward the troposphere and rainout.

Sites on which the reactions producing Cl_2, HOCl, and $ClNO_2$ can occur are provided by the surface of ice crystals in polar stratospheric clouds (PSCs). These clouds are formed between 8 and 14 mi (12 and 22 km) when the temperature drops below approximately -123°F (187 K). Other types of particles are observed at temperatures above the frost point of -123°F (187 K). These particles provide additional surface area for these reactions to occur. Clouds are observed at high latitudes in winter. Because the winter temperatures are typically 20–30°F (10–15 K) colder in the Antarctic than in the Arctic, their frequency of occurrence is highest in the Southern Hemisphere. Thus, the formation of the springtime ozone hole over Antarctica is explained by the activation of chlorine and the catalytic destruction of O_3 which takes place during September, when the polar regions are sunlit but the air is still cold and isolated from midlatitude air by a strong polar vortex. Satellite observations made since the 1970s suggest that total ozone in the Arctic has been abnormally low during the 1990s, probably in relation to the exceptionally cold winter tempratures in the Arctic lower stratosphere recorded during that decade. [G.P.B.; R.G.Pr.]

Strawberry Low-growing perennials, spreading by stolons, with fruit consisting of a fleshy receptacle, and "seeds" in pits or nearly superficial on the receptacle. The strawberry in the United States is derived from two species: *Fragaria chihensis*, which grows along the Pacific Coast of North and South America, and *F. uirginiana*, the eastern meadow strawberry, both members of the order Resales. *See* ROSALES.

The strawberry is the most universally grown of the small fruits, both in the home garden and in commercial plantings. Home garden production is possible in nearly all of the states, provided water can be supplied where rainfall is insufficient. Commercial production is important in probably three-fourths of the states. The following states are large producers: Oregon, California, Tennessee, Michigan, Louisiana, Washington, Arkansas, Kentucky, and New York. *See* FRUIT. [J.H.C.]

Stream function In fluid mechanics, a mathematical idea which satisfies identically, and therefore eliminates completely, the equation of mass conservation. If the flow field consists of only two space coordinates, for example, x and y, a single and very useful stream function $\psi(x, y)$ will arise. If there are three space coordinates, such as (x, y, z), multiple stream functions are needed, and the idea becomes much less useful and is much less widely employed.

The stream function not only is mathematically useful but also has a vivid physical meaning. Lines of constant ψ are streamlines of the flow; that is, they are everywhere parallel to the local velocity vector. No flow can exist normal to a streamline; thus, selected ψ lines can be interpreted as solid boundaries of the flow.

Further, ψ is also quantitatively useful. In plane flow, for any two points in the flow field, the difference in their stream function values represents the volume flow between the points. *See* CREEPING FLOW; FLUID FLOW. [F.M.W.]

Stream gaging The measurement of water discharge in streams. Discharge is the rate of movement of the stream's water volume. It is the product of water velocity times cross-sectional area of the stream channel. Several techniques have been developed for measuring stream discharge; selection of the gaging method usually depends on the size of the stream. The most accurate methods for measuring stream discharge make use of in-stream structures through which the water can be routed, such as flumes and weirs.

A flume is a constructed channel that constricts the flow through a control section, the exact dimensions of which are known. Through careful hydraulic design and calibration by laboratory experiments, stream discharge through a flume can be determined by simply measuring the water depth (stage) in the inlet or constricted sections. Appropriate formulas relate stage to discharge for the type of flume used.

A weir is used in conjunction with a dam in the streambed. The weir itself is usually a steel plate attached to the dam that has a triangular, rectangular, or trapezoidal notch over which the water flows. Hydraulic design and experimentation has led to calibration curves and appropriate formulas for many different weir designs. To calculate stream discharge through a weir, only the water stage in the reservoir created by the dam needs to be measured. Stream discharge can be calculated by using the appropriate formula that relates stage to discharge for the type of weir used. *See* HYDROLOGY; SURFACE WATER. [T.C.Wi.]

Stream pollution Biological, or bacteriological, pollution in a stream indicated by the presence of the coliform group of organisms. While nonpathogenic itself, this group is a measure of the potential presence of contaminating organisms. Because of temperature, food supply, and predators, the environment provided by natural bodies of water is not favorable to the growth of pathogenic and coliform organisms. Physical factors, such as flocculation and sedimentation, also help remove bacteria. Any combination of these factors provides the basis for the biological self-purification capacity of natural water bodies.

Nonpolluted natural waters are usually saturated with dissolved oxygen. They may even be supersaturated because of the oxygen released by green water plants under the influence of sunlight. When an organic waste is discharged into a stream, the dissolved oxygen is utilized by the bacteria in their metabolic processes to oxidize the organic matter. The oxygen is replaced by reaeration through the water surface exposed to the atmosphere. This replenishment permits the bacteria to continue the oxidative process in an aerobic environment. In this state, reasonably clean appearance, freedom from odors, and normal animal and plant life are maintained.

An increase in the concentration of organic matter stimulates the growth of bacteria and increases the rates of oxidation and oxygen utilization. If the concentration of the organic pollutant is so great that the bacteria use oxygen more rapidly than it can be replaced, only anaerobic bacteria can survive and the stabilization of organic matter is accomplished in the absence of oxygen. Under these conditions, the water becomes unsightly and malodorous, and the normal flora and fauna are destroyed. Furthermore, anaerobic decomposition proceeds at a slower rate than aerobic. For maintenance of satisfactory conditions, minimal dissolved oxygen concentrations in receiving streams are of primary importance.

Municipal sewage and industrial wastes affect the oxygen content of a stream. Cooling water, used in some industrial processes, is characterized by high temperatures, which reduce the capacity of water to hold oxygen in solution. Municipal sewage requires oxygen for its stabilization by bacteria. Oxygen is utilized more rapidly than it is replaced by reaeration, resulting in the death of the normal aquatic life. Further downstream, as the oxygen demands are satisfied, reaeration replenishes the oxygen supply.

Polluted waters are deprived of oxygen by the exertion of the biochemical oxygen demand, which is defined as the quantity of oxygen required by the bacteria to oxidize the organic matter. Factors such as the turbulence of the stream flow, biological growths on the stream bed, insufficient nutrients, and inadequate bacteria in the river water influence the rate of oxidation in the stream as well as the removal of organic matter.

When a significant portion of the waste is in the suspended state, settling of the solids in a slow-moving stream is probable. The organic fraction of the sludge deposits decomposes anaerobically, except for the thin surface layer which is subjected to aerobic decomposition due to the dissolved oxygen in the overlying waters. In warm weather, when the anaerobic decomposition proceeds at a more rapid rate, gaseous end products, usually carbon dioxide and methane, rise through the supernatant waters. The evolution of the gas bubbles may raise sludge particles to the water surface. Although this phenomenon may occur while the water contains some dissolved oxygen, the more intense action during the summer usually results in depletion of dissolved oxygen.

Water may absorb oxygen from the atmosphere when the oxygen in solution falls below saturation. Dissolved oxygen for receiving waters is also derived from two other sources: that in the receiving water and the waste flow at the point of discharge, and that given off by green plants.

Unpolluted water maintains in solution the maximum quantity of dissolved oxygen. The saturation value is a function of temperature and the concentration of dissolved substances, such as chlorides. When oxygen is removed from solution, the deficiency is made up by the atmospheric oxygen, which is absorbed at the water surface and passes into solution. The oxygen balance in a stream is determined by the concentration of organic matter and its rate of oxidation, and by the dissolved oxygen concentration and the rate of reaeration. *See* ESTUARINE OCEANOGRAPHY; FRESHWATER ECOSYSTEM; SEWAGE DISPOSAL; WATER POLLUTION. [D.J.O.]

Stream transport and deposition The sediment debris load of streams is a natural corollary to the degradation of the landscape by weathering and erosion. Eroded material reaches stream channels through rills and minor tributaries, being carried by the transporting power of running water and by mass movement, that is, by slippage, slides, or creep. The size represented may vary from clay to boulders. At any place in the stream system the material furnished from places upstream either is carried away or, if there is insufficient transporting ability, is accumulated as a depositional feature. The accumulation of deposited debris tends toward increased ease of movement, and this tends eventually to bring into balance the transporting ability of the stream and the debris load to be transported. [L.B.L.]

Streaming potential The potential which is produced when a liquid is forced to flow through a capillary or a porous solid. The streaming potential is one of four related electrokinetic phenomena which depend upon the presence of an electrical double layer at a solid-liquid interface. This electrical double layer is made up of ions of one charge type which are fixed to the surface of the solid and an equal number of mobile ions of the opposite charge which are distributed through the neighboring region of the liquid phase. In such a system the movement of liquid over the surface of the solid produces an electric current, because the flow of liquid causes a displacement of the mobile counterions with respect to the fixed charges on the solid surface. The applied potential necessary to reduce the net flow of electricity to zero is the streaming potential. [Q.V.W.]

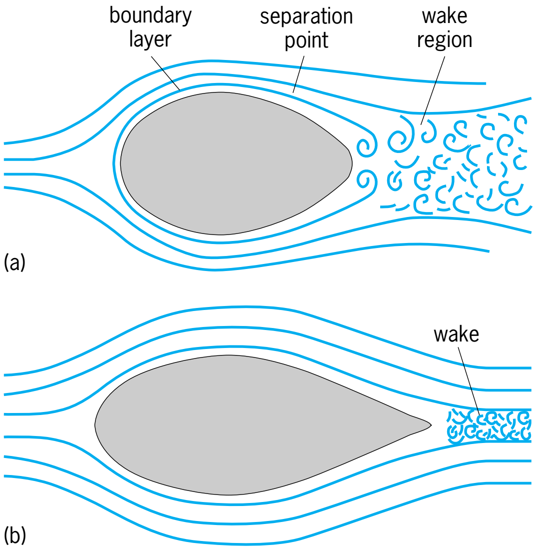
Streamlining The contouring of a body to reduce its resistance (drag) to motion through a fluid.

For fluids with relatively low viscosity such as water and air, effects of viscous friction are confined to a thin layer of fluid on the surface termed the boundary layer. Under the influence of an increasing pressure, the flow within the boundary layer tends to reverse and flow in an upstream direction. Viscosity tends to cause the flow to separate from the body surface with consequent formation of a region of swirling or eddy flow (termed the body wake; illus. *a*). This eddy formation leads to a reduction in the downstream pressure on the body and hence gives rise to a force opposite to the body motion, known as pressure drag. *See* WAKE FLOW.

In general, streamlining in subsonic flow involves the contouring of the body in such a manner that the wake is reduced and hence the pressure drag is reduced. The contouring should provide for gradual deceleration to avoid flow separation, that is, reduced adverse pressure gradients. These considerations lead to the following general rules for subsonic streamlining: The forward portion of the body should be well rounded, and the body should curve back gradually from the forward section to a tapering aftersection with the avoidance of sharp corners along the body surface. These conditions are well illustrated by teardrop shapes (illus. *b*).

At supersonic speeds the airflow can accommodate sudden changes in direction by being compressed or expanded. Where this change in direction occurs at the nose of the body, a compression wave is created, the strength of which depends upon the magnitude of the change in flow direction. Lowering the body-induced flow angle weakens this compression shock wave. When the flow changes direction again at the midpoint of the body, the air will expand to follow the shape of the body. This change in direction creates expansion waves. At the tail of the body the direction changes again, creating another compression or shock wave. At each of these shock waves, changes in pressure, density, and velocity occur, and in this process energy is lost. This loss results in a retarding force known as wave drag. *See* SHOCK WAVE.

Bodies which are streamlined for supersonic speeds are characterized by a sharp nose and small flow deflection angles. Because the intensity of the shock wave and the drag level is dependent upon the magnitude of the change in flow direction, the width or thickness of the body should be minimal. *See* BOUNDARY-LAYER FLOW. [A.G.H.; D.M.Bu.]



Flow about bodies in uniform subsonic flow. (*a*) Blunt body. (*b*) Streamlined body.

Strength of materials A branch of applied mechanics concerned with the behavior of materials under load, relationships between externally applied loads and internal resisting forces, and associated deformations. Knowledge of the properties of materials and analysis of the forces involved are fundamental to the investigation and design of structures and machine elements. *See* MACHINE DESIGN; STRUCTURAL MATERIALS.

Investigation of the resistance of a member, dealing with internal forces, is called free-body analysis. Determination of the distribution and intensity of the internal forces and the associated deformations is called stress analysis. *See* STRESS AND STRAIN.

A material offers resistance to external load only insofar as the component elements can furnish cohesive strength, resistance to compaction, and resistance to sliding. The relations developed in strength of materials analysis evaluate the tensile, compressive, and shear stresses that a material is called upon to resist. The most important factors in determining the suitability of a structural or machine element for a particular application are strength and stiffness. *See* SHEAR. [J.B.S.]

Strepsiptera An order of twisted-wing insects that spend most of their life cycle as internal parasitoids of other insects. The adult male is only a few millimeters in wing span, is free living, and has only one pair of full flight wings (the posterior, or metathoracic, pair). The front (mesothoracic) wings are reduced to narrow, clublike organs that may function as halteres, or flight balancers. The male eyes are coarsely faceted and berrylike, and the antennae have four to seven segments, with some segments having finger- or bladelike extensions. Most adult females are immobile, blind, and larviform, and live inside the insect host. Rarely, the female is free living, with legs and eyes but no wings. More than 600 species of Strepsiptera are known, many of them not yet formally described and named. The order's relationship to other insect orders remains uncertain.

Both male and female begin larval life as mobile first-stage organisms with eyes and three pairs of functional legs. These triunguloids eventually attack the immature or adult forms of the host and enter their bodies, where they molt to an apodous instar. Two subsequent molts result in the divergence of the sexes and the differentiation of a hardened forebody that eventually protrudes through the host integument; the molted larval integuments are not shed but are incorporated in the general puparial wall arid the neotenous adult female capsule. Males (and some adult females) emerge from the puparium and begin the search for a mate, probably through the mediation of airborne pheromones.

Strepsiptera are found worldwide in temperate and tropical habitats. They parasitize insects, mostly of orders Hemiptera and Hymenoptera, but also some cockroaches, mantids, orthopterans, flies, and silverfish. Their effect on the host is variable, ranging from reproductive failure to death. *See* ENDOPTERYGOTA; PHEROMONE. [W.L.Bro.]

Streptococcus A large genus of spherical or ovoid bacteria that are characteristically arranged in pairs or in chains resembling strings of beads. Many of the streptococci that constitute part of the normal flora of the mouth, throat, intestine, and skin are harmless commensal forms; other streptococci are highly pathogenic. The cells are gram-positive and can grow either anaerobically or aerobically, although they cannot utilize oxygen for metabolic reactions. Glucose and other carbohydrates serve as sources of carbon and energy for growth. All members of the genus lack the enzyme catalase. Streptococci can be isolated from humans and other animals.

Streptococcus pyogenes is well known for its participation in many serious infections. It is a common cause of throat infection, which may be followed by more serious complications such as rheumatic fever, glomerulonephritis, and scarlet fever. Other beta-hemolytic streptococci participate in similar types of infection, but they are usually not associated with rheumatic fever and glomerulonephritis. Group B streptococci, which are usually beta-hemolytic, cause serious infections in newborns (such as meningitis) as well as in adults. Among the alpha-hemolytic and nonhemolytic streptococci, *S. pneumoniae* is an important cause of pneumonia and other respiratory infections. Vaccines that protect against infection by the most prevalent capsular serotypes are available. The viridans streptococci comprise a number of species commonly isolated from the mouth and throat. Although normally of low virulence, these streptococci are capable of causing serious infections (endocarditis, abcesses). *See* Pneumonia. [K.Ru.]

Streptothricosis An acute or chronic infection of the epidermis, caused by the bacterium *Dermatophilus congolensis*. which results in an oozing dermatitis with scab formation. Streptothricosis includes dermatophilosis, mycotic dermatitis, lumpy wool, strawberry foot-rot, and cutaneous streptothricosis—diseases having a worldwide distribution and affecting a wide variety of species, including humans.

The infectious form of the bacterium is a coccoid, motile zoospore that is released when the skin becomes wet. Thus, the disease is closely associated with rainy seasons and wet summers. Zoospores lodge on the skin of susceptible animals and germinate by producing filaments which penetrate to the living epidermis, where the organism proliferates by branching mycelial growth.

Early cutaneous lesion of dermatophilosis in cattle reveals small vesicles, papules, and pus formation under hair plaques. An oozing dermatitis then appears as the disease progresses and exudates coalesce to form scabs, which change to hard crusts firmly adherent to the skin. The crusts enlarge and harden, and are often devoid of hair. Lesions occur on most areas of sheep, but the characteristic lesions in the wooled areas occur as numerous hard masses of crust or scab scattered irregularly over the back, flanks, and upper surface of the neck. Lesion resolution has been found to correlate with the presence of immunoglobulin A–containing plasma cells in the dermis and with the antibody levels to *D. congolensis* at the skin surface of infected sheep and cattle.

No single treatment is considered specific for dermatophilosis. Some observers claim that topical agents are successful for sheep and cattle. A number of systemic antibiotics are effective in treating the disease. A combination of streptomycin and penicillin has given good therapeutic results in both bovine and equine infections. [S.S.S.]

Stress (psychology) Generally, environmental events of a challenging sort as well as the body's response to such events. Of particular interest has been the relationship between stress and the body's adaptation to it on the one hand and the body's susceptibility to disease on the other. Both outcomes involve behavioral and brain changes as well as psychosomatic events, that is, changes in body function arising from the ability of the brain to control such function through neural output as well as hormones. One problem is that both environmental events and bodily responses have been referred to interchangeably as stress. It is preferable to refer to the former as the stressor and the latter as the stress response. The stress response consists of a cascade of neural and hormonal events that have short- and long-lasting consequences for brain and body alike. A more serious issue is how an event is determined to be a stressor. One view is to define a stressor as an environmental event causing a negative outcome, such as a disease. Another approach is to view stressors as virtually any challenge to homeostasis and to regard disease processes as a failure of the normal operation of adapative mechanisms, which are part of the stress response. With either view, it is necessary to include psychological stressors, such as fear, that contain implied threats to homeostasis and that evoke psychosomatic reactions. These are reactions that involve changes in neural and hormonal output caused by psychological stress. Psychosomatic reactions may lead to adaptive responses, or they may exacerbate disease processes. Whether the emphasis is on adaptation or disease, it is essential to understand the processes in the brain that are activated by stressors and that influence functions in the body. *See* Homeostasis; Psychosomatic disorders.

Among the many neurotransmitter systems activated by stress is noradrenaline, produced by neurons with cell bodies in the brainstem that have vast projections up to the forebrain and down the spinal cord. Stressful experiences activate the noradrenergic system and promote release of noradrenaline; severe stress leads to depletion of noradrenaline in brain areas such as the hypothalamus. This release and depletion of noradrenaline stores results in changes at two levels of neuronal function: phosphorylation is triggered by the second-messenger cyclic AMP and occurs in the presynaptic and postsynaptic sites where noradrenaline is released and where it also acts; synthesis of new protein is induced via actions on the genome. Both processes enhance the ability of the brain to form noradrenaline when the organism is once again confronted with a stressful situation. Other neurotransmitter systems may also show similar adaptive changes in response to stressors. *See* Noradrenergic system.

Stress also activates the neurally mediated discharge of adrenaline from the adrenal medulla and of hypothalamic hormones that initiate the neuroendocrine cascade, culminating in glucocorticoid release from the adrenal cortex. Thus, the activity of neurons triggered by stressful experiences, physical trauma, fear, or anger leads to hormone secretion that has effects throughout the body. Virtually every organ of the body is affected by stress hormones. The hypothalamic hormone (corticotrophin-releasing hormone) that triggers the neuroendocrine cascade directly stimulates the pituitary to secrete ACTH. In response to certain stressors, the hypothalamus also secretes vasopressin and oxytocin, which act synergistically with corticotrophin-releasing hormone on the pituitary to potentiate the secretion of ACTH. Various stressors differ in their ability to promote output of vasopressin and oxytocin, but all stressors stimulate release of corticotrophin-releasing hormone. Other hormones involved in the stress response include prolactin and thyroid hormone; the metabolic hormones insulin, epinephrine, and glucagon; and the endogenous opiates endorphin and enkephalin. *See* Endorphins.

Of all the hormones in the endocrine cascade initiated by stress, the glucocorticoids are the most important because of their widespread effects throughout the body and in the brain. The brain contains target cells for adrenal glucocorticoids secreted in stress, and receptors in these cells are proteins that interact with the genome to affect expression of genetic information. Thus, the impact of stress-induced activation of the endocrine cascade that culminates in glucocorticoid release is the feedback of glucocorticoids on target brain cells. The effect is to alter the structure and function of the brain cells over a period of time ranging from hours to days.

In the case of noradrenaline, glucocorticoids have several types of feedback effects that modify how the noradrenergic system responds to stress. Glucocorticoids inhibit noradrenaline release, and they reduce the second-messenger response of brain structures such as the cerebral cortex to noradrenaline. Glucocorticoid feedback also affects the serotonin system, facilitating serotonin formation during stress but at the same time altering the levels of several types of serotonin receptors in different brain regions, which has the net effect of shifting the balance within the serotonergic system. Taken together, evidence points to a role of glucocorticoid secretion in leading to restoration of homeostatic balance by counteracting the acute neural events such as increased activity of noradrenaline and serotonin, which are turned on by stressful experiences. Other neurotransmitter systems may also respond to glucocorticoid action. Moreover, the other hormones activated by stress have effects on the brain and body that must be considered. *See* SEROTONIN.

In general, stress hormones are protective and adaptive in the immediate aftermath of stress, and the organism is more vulnerable to many conditions without them. However, the same hormones can promote damage and accelerate pathophysiological changes, such as bone mineral loss, obesity, and cognitive impairment, when they are overproduced or not turned off. This wear-and-tear on the body has been called allostatic load. It is based upon the notion that allostasis is the active process of maintaining stability, or homeostasis, through change, and allostatic load is the almost inevitable cost to the body of doing so.

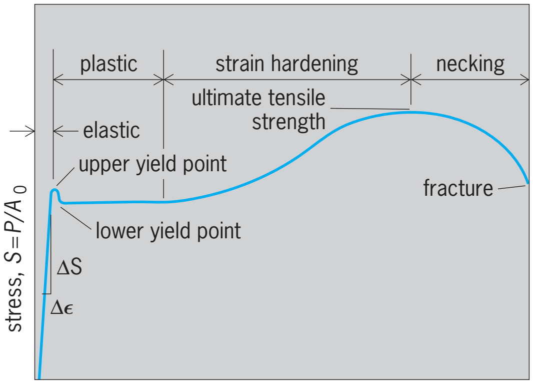
Stress hormone actions have important effects outside the brain on such systems as the immune response. Glucocorticoids and catecholamines from sympathetic nerves and the adrenal medulla participate in the mobilization and enhancement of immune function in the aftermath of acute stress. These effects improve the body's defense against pathogens but can exacerbate autoimmune reactions. When they are secreted chronically, the stress-related hormones are generally immunosuppressive; such effects can be beneficial in the case of an autoimmune disease but may compromise defense against a virus or bacterial infections. At the same time, glucocorticoids are important agents for containing the acute-phase response to an infection or autoimmune disturbance. In the absence of such containment, the organism may die because of the excessive inflammatory response. *See* IMMUNOLOGY.

Besides affecting the immune response, stressors are believed to exacerbate endogenous depressive illness in susceptible individuals. Major depressive illness frequently results in elevated levels of cortisol in the blood. It is not clear whether the elevated cortisol is a cause or strictly a result of the brain changes involved in depressive illness. *See* AFFECTIVE DISORDERS. [B.McE.]

Stress and strain

Related terms defining the intensity of internal reactive forces in a deformed body and associated unit changes of dimension, shape, or volume caused by externally applied forces. Stress is a measure of the internal reaction between elementary particles of a material in resisting separation, compaction, or sliding that tend to be induced by external forces. Total internal resisting forces are resultants of continuously distributed normal and parallel forces that are of varying magnitude and direction and are acting on elementary areas throughout the material. These forces may be distributed uniformly or nonuniformly. Stresses are identified as tensile, compressive, or shearing, according to the straining action.

Strain is a measure of deformation such as (1) linear strain, the change of length per unit of linear dimensions; (2) shear strain, the angular rotation in radians of an element undergoing change of shape by shearing forces; or (3) volumetric strain, the change of volume per unit of volume. The strains associated with stress are characteristic of the material. Strains completely recoverable on removal of stress are called elastic strains. Above a critical stress, both elastic and plastic strains exist, and that part remaining after unloading represents plastic deformation called inelastic strain. Inelastic strain reflects internal changes in the crystalline structure of the metal. Increase of resistance to continued plastic deformation due to more favorable rearrangement of the atomic structure is strain hardening.



Stress-strain diagram for a low-carbon steel. ΔS = change in stress; $\Delta\epsilon$ = change in strain; P = force; A_0 = area of cross section.

A stress-strain diagram is a graphical representation of simultaneous values of stress and strain observed in tests and indicates material properties associated with both elastic and inelastic behavior (see illustration). It indicates significant values of stress-accompanying changes produced in the internal structure. *See* ELASTICITY; STRENGTH OF MATERIALS. [J.B.S.]

Strigiformes

The owls, an order of nocturnal, worldwide predacious birds that are probably most closely related to the goatsuckers. The strigiforms are arranged in four families: Ogygoptyngidae (fossil), Protostrigidae (fossil), Tytonidae (barn owls; 11 species), and Strigidae (typical owls; 135 species). The bay owls (*Phodilus*), occurring in southern Asia and Africa, are somewhat intermediate between the Tytonidae and the Strigidae and are sometimes placed in a separate family; here they are treated as a subfamily, Phodilinae, of the Tytonidae.

Owls are small to medium in size, with soft plumage of somber colors. The large head has a facial disk that covers the feathered parabolic reflectors of the bird's acute directional hearing system. The eyes are large and capable of sight in very dim light, and the bill is strong and hooked. The wings are long and rounded, and the flight feathers are fringed for silent flight. The ulna has a unique bony arch on the shaft. Their strong legs are short to medium in length and terminate in strong feet. Owls are excellent fliers but walk poorly. Of the four toes on each foot, two point forward and two backward and bear strong claws. Prey is detected by acute night vision or by directional hearing; owls can locate and catch their prey in total darkness. Owls are generally nonmigratory and solitary, but some species live in small flocks. Courtship takes place at night with a male hooting to a female, which answers. A strong pair bond exists between the monogamous male and female, which usually build their nest in a tree cavity. Some species nest on the ground, on cliff ledges, or in abandoned crow or hawk nests. The clutch of up to seven eggs is incubated by both sexes, and after hatching, the young stay in the nest and are cared for by both parents. *See* AVES. [W.J.B.]

Stripping

The removal of volatile component from a liquid by vaporization. The stripping operation is an important step in many industrial processes which employ absorption to purify gases and to recover valuable components from the vapor phase. In such processes, the rich solution from the absorption step must be stripped in order to permit recovery of the absorbed solute and recycle of the solvent. *See* GAS ABSORPTION OPERATIONS.

Stripping may be accomplished by pressure reduction, the application of heat, or the use of an inert gas (stripping vapor). Many processes employ a combination of all three; that is, after absorption at elevated pressure, the solvent is flashed to atmospheric pressure, heated, and admitted into a stripping column which is provided with a bottom heater (reboiler). Solvent vapor generated in the rebolier or inert gas injected at the bottom of the column serves as stripping vapor which rises countercurrently to the downflowing solvent. When steam is used as stripping vapor for a system not miscible with water, the process is called steam stripping.

In addition to its use in conjunction with gas absorption, the term stripping is also used quite generally in technical fields to denote the removal of one or more components from a mixed system. Such usage covers (1) the distillation operation which takes place in a distilling column in the zone below the feed point, (2) the extraction of one or more components from a liquid by contact with a solvent liquid, (3) the removal of organic or metal coatings from solid surfaces, and (4) the removal of color from dyed fabrics. *See* Distillation; Electroplating of metals; Solvent extraction. [A.L.K.]

Stroboscope An instrument for observing moving bodies by making them visible intermittently and thereby giving them the optical illusion of being stationary. A stroboscope may operate by illuminating the object with brilliant flashes of light or by imposing an intermittent shutter between the viewer and the object.

Stroboscopes are used to measure the speed of rotation or frequency of vibration of a mechanical part or system. They have the advantage over other instruments of not loading or disturbing the equipment under test. Mechanical equipment may be observed under actual operating conditions with the aid of stroboscopes. Parasitic oscillations, flaws, and unwanted distortion at high speeds are readily detected.

The flashing-light stroboscopes employ gas discharge tubes to provide a brilliant light source of very short duration. Tubes may vary from neon glow lamps, when very little light output is required, to special stroboscope tubes capable of producing flashes of several hundred thousand candlepower with a duration of only a few millionths of a second. *See* Neon glow lamp; Vapor lamp. [A.R.E.]

Stroboscopic photography Stroboscopic or “strobe” photography generally refers to pictures of both single and multiple exposure taken by flashes of light from electrical discharges. Originally the term referred to multiple-exposed photographs made with a Stroboscopic disk as a shutter. One essential feature of modern Stroboscopic photography is a short exposure time, usually much shorter than can be obtained by a mechanical shutter.

High-speed photography with Stroboscopic light has proved to be one of the most powerful research tools for observing fast motions in engineering and in science. Likewise, the electrical system of producing flashes of light in xenon-filled flash lamps is of great utility for studio, candid, and press photography. *See* Photography; Stroboscope. [H.E.E.]

Stromatolite A laminated, microbial structure in carbonate rocks (limestone and dolomite). Stromatolites are the oldest macroscopic evidence of life on Earth, at least 2.5 billion years old, and they are still forming in the seas. During the 1.5 billion years of Earth history before marine invertebrates appeared, stromatolites were the most obvious evidence of life, and they occur sporadically throughout the remainder of the geologic record. In Missouri and Africa, stromatolite reefs have major accumulations of lead, zinc, or copper; and in Montana, New Mexico, and Oman, stromatolites occur within oil and gas reservoirs. For geologists, the shapes of stromatolites are useful indications of their environmental conditions, and variations in form and microstructure of the laminations may be age-diagnostic in those most ancient sedimentary rocks that lack invertebrate fossils. *See* Dolomite; Limestone; Reef.

Stromatolites are readily recognizable in outcrops by their characteristic convex-upward laminated structure. Individual, crescent-shaped laminations, which are generally about a millimeter thick, are grouped together to produce an enormous range of shapes and sizes.

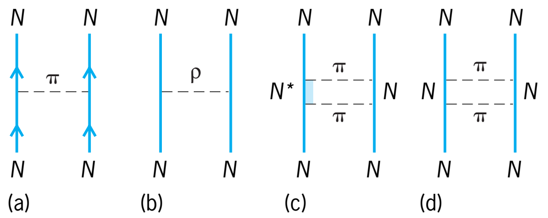
The tiny, filamentous cyanobacteria (blue-green algae) that make present-day stromatolites, and similar filaments associated with the oldest stromatolites known, are considered one of the most successful organisms on Earth. Living stromatolites in the Bahamas and Western Australia possess laminations that record the episodic trapping and binding of sediment particles by the microbial mat. In the modern oceans, stromatolites develop almost exclusively in extreme marine conditions that exclude or deter browsing invertebrates and fish from destroying the microbial mats and inhibit colonization by competing algae. *See* Algae; Cyanobacteria. [R.Gi.]

Stromatoporoidea An extinct order thought to be sponges because of its close similarity to the class Sclerospongiae. Generally accepted stromatoporoids first appeared at the beginning of the Middle Ordovician and died out at the end of the Devonian. The Stromatoporoidea are worldwide in distribution, most commonly associated with bedded limestones and fossil reefs.

The stromatoporoid skeleton is called a coenosteum, which begins development as a thin, encrusting layer of irregular rods and plates called the peritheca. Most coenostea are hemispherical, or thick laminar or lens-shaped structures. However, some stromatoporoids are thin and irregularly undulatory and others are cylindrical, cone-shaped, branching, or anastomosing. *See* Sclerospongiae. [J.St.J.]

Strong nuclear interactions One of the fundamental physical interactions, which acts between a pair of hadrons. Hadrons include the nucleons, that is, neutrons and protons; the strange baryons, such as lambda (Λ) and sigma (Σ); the mesons, such as pion (π) and rho (ρ); and the strange meson, kaon (K). The nature of the interaction is determined principally through observations of the collision of a hadron pair. From this it is found that the interaction has a short range of about 10^{-15} m (10^{-13} in.) and is by far the dominant force within this range, being much larger than the electromagnetic interaction, which is next in magnitude. The strong interaction conserves parity and is time-reversal-invariant. *See* Baryon; Hadron; Meson; Nucleon; Parity (quantum mechanics); Strange particles; Symmetry laws (physics); Time reversal invariance.

The interaction between baryons for distances greater than 10^{-15} m arises from the exchange of mesons. At relatively large distances, single-pion exchange dominates (illus. *a*). At shorter separation distances, the two-pion systems such as the ρ become important (illus. *b*). The interaction between the strange baryons, and between the strange baryons and the nucleons, is moderated by kaon exchange. To summarize this description, the interaction between baryons in the SU(3) multiplet is the consequence of the exchange of SU(3) spin 0 and spin 1 bosons. In a second



Interaction between nucleons (*a*) from exchange of single pion, (*b*) from exchange of ρ-meson, a two-pion system, (*c*) from exchange of two separate pions with formation of excited state of nucleon, and (*d*) without formation of excited state.

approximation, the exchange of two pions (illus. *c, d*), or more generally, the exchange of two members of the SU(3) spin 0 and spin 1 multiplet, is responsible for a component of the strong nuclear interaction. *See* Unitary symmetry.

The range of the interaction generated by these exchanges can be calculated by using the formula below, where m is the mass

$$\text{Range} = \frac{\hbar}{mc}$$

of the exchanged particles, $\hbar$ is Planck's constant divided by 2π, and c is the speed of light. According to the above equation, the range of the interaction developed when a single pion is exchanged (illus. 1*a*) is equal to 1.4×10^{-15} m (5.5×10^{-14} in.), while that due to two-pion exchange (illus. 1*d*) is 0.7×10^{-15} m (2.8×10^{-14} in.).

At short separation distances the quark-gluon structure of the baryons must be taken into account. The interaction must be considered as a property of the six-quark-plus-gluon system. The decisive elements are the Pauli principle obeyed by the quarks, and the mismatch between the six-quark wave function and the two-baryon wave function. Thus, at short distances the interaction is effectively repulsive or more generally independent of the kinetic energy of the baryons at infinite separations. *See* Elementary particle; Exclusion principle; Fundamental interactions; Gluons; Quarks. [H.F.]

Strongylida An order of nematodes in which the cephalic region may be adorned with three or six labia or the labia may be replaced by a corona radiata. All strongylid nematodes are parasitic. The order embraces eight superfamilies: Strongyloidea, Diaphanocephaloidea, Ancylostomatoidea, Trichostrongyloidea, Metastrongyloidea, Cosmocercoidea, Oxyuroidea, and Heterakoidea.

Strongyloidea. The Strongyloidea contain important parasites of reptiles, birds, and mammals. The early larval stages may be free-living microbivores, but the adults are always parasitic. Three species are important parasites of horses, *Strongylus vulgaris, S. equinus*, and *S. edentatus*. All three undergo direct life cycles; that is, infestations are acquired by ingestion of contaminated food.

Trichostrongyloidea. The Trichostrongyloidea comprise obligate parasites of all vertebrates but fishes. Normally they are intestinal parasites, but some are found in the lungs. The species are important parasites of sheep, cattle, and goats. The adult females lay eggs in the intestinal tract, which are passed out with the feces. In the presence of oxygen the eggs hatch in a few days. When the larvae are ingested by an appropriate host, their protective sheath is lost, and they proceed through the fourth larval stage to adulthood in the intestinal tract, where they may enter the mucosa. No migration takes place outside the gastrointestinal tract.

Metastrongyloidea. The Metastrongyloidea comprise obligate parasites of terrestrial and marine mammals, found commonly in the respiratory tract. In their life cycle they utilize both paratenic and intermediate hosts, among them a variety of invertebrates, including earthworms and mollusks. Two important species are *Metastrongylus apri* (swine lungworm) and *Angiostrongylus cantonensis* (rodent lungworm).

Heterakoidea. The Heterakoidea are capable of parasitizing almost any warm-blooded vertebrate as well as reptiles and amphibians. The species *Ascaridia galli* is the largest known nematode parasite of poultry; males are 2–3 in. (50–76 mm) long, and females 3–4.5 in. (75–116 mm). [A.R.M.]

Oxyuroidea. The Oxyuroidea constitute a large group of the phylum Nemata. Hosts include terrestrial mammals, birds, reptiles, amphibians, fishes, insects, and other arthropods.

The species are small to medium sized and thin bodied. With one exception, known life cycles are direct. Typically the eggs pass out of the host's alimentary tract onto the ground, where they become fully embryonated and infective. Normally the infective egg does not hatch until a susceptible animal ingests it. The cecum and colon of the host are the typical locations of these parasites. Larvae in all stages of development and adults occur in the gut.

The human pinworm, *Enterobius vermicularis*, is probably the most contagious of all helminthic diseases. It is estimated that 10% of the world's population suffer from this parasite, the majority being children. Indeed, incidence among schoolchildren in the cool regions of the world often approaches 100%. Infection occurs when eggs are inhaled or ingested. The most common method of transmission is from anus to mouth. Because of the aerial transmission, this disease is highly contagious. Though the infection is seldom serious, the behavioral symptoms are disturbing: nail biting, teeth grinding, anal scratching, insomnia, nightmares, and even convulsions. Several medical treatments are available, but there is often the danger of reinfestation from contaminated objects within the household or institution. *See* Nemata. [J.T.L.]

Strontianite The mineral form of strontium carbonate, usually with some calcium replacing strontium. It characteristically occurs in veins with barite or celestite or as masses in certain sedimentary rocks. Strontianite is normally prismatic, but it may also be massive. It may be colorless or gray with yellow, green, or brownish tints. The hardness is $3\frac{1}{2}$ on Mohs scale, and the specific gravity of 3.76. It occurs at Strontian, Scotland, and in Germany, Austria, Mexico, and India and, in the United States, in the Strontium Hills of Calfornia. *See* Carbonate minerals; Strontium. [R.I.Ha.]

Strontium A chemical element, Sr, atomic number 38, and atomic weight 87.62. Strontium is the least abundant of the alkaline-earth metals. The crust of the Earth is 0.042% strontium, making this element as abundant as chlorine and sulfur. The main ores are celestite, $SrSO_4$, and strontianite, $SrCO_3$. *See* Alkaline-earth metals; Periodic table; Strontianite.

Strontium nitrate is used in pyrotechnics, railroad flares, and tracer bullet formulations. Strontium hydroxide forms soaps and greases with a number of organic acids which are structurally stable, resistant to oxidation and breakdown over a wide temperature range.

Properties of strontium

Property	Value
Atomic number	38
Atomic weight	87.62
Isotopes (stable)	84, 86, 87, 88, 90
Boiling point, °C	1638(?)
Melting point, °C	704(?)
Density, g/cm3 at 20°C	2.6

Strontium is divalent in all its compounds which are, aside from the hydroxide, fluoride, and sulfate, quite soluble. Strontium is a weaker complex former than calcium, giving a few weak oxy complexes with tartrates, citrates, and so on. Some physical properties of the element are given in the table. [R.F.R.]

Strophanthus A genus of woody climbers of the dogbane family (Apocynaceae), natives of tropical Asia and Africa. They are the source of arrow poisons. The dried, greenish, ripe seeds of *Strophanthus hispidus* and *S. kombe* contain the glucoside strophanthin, which is much used in treating heart ailments. Strophanthin acts directly on heart muscle, increasing muscular force. It causes the heart to beat more regularly and decreases the pulse rate. Strophanthin is a precursor of cortisone, which is used in the treatment of arthritis. *See* Gentianales. [P.D.St.; E.L.C.]

Strophomenida An extinct order of brachiopods, in the subphylum Rhynchonelliformea, that inhabited shallow shelf seas of the Paleozoic Era. It contains the greatest taxonomic diversity of all rhynchonelliform brachiopod orders, and its members exhibit a diverse range of morphologies and modes of life.

Strophomenida contains four suborders: Strophomenidina, Chonetidina, Productidina, and Strophalosiidina. A fifth suborder, Orthotetidina, shares characteristics with both strophomenids and primitive orthids. Strophomenids are distinguished from all other articulate brachiopods by their concavo-convex or plano-convex lateral profiles and the lack of a functional pedicle in adults. They also possess strophic (straight) hinge lines and variable ornamentation from fine-ribbed early Paleozoic forms to more elaborate spine-bearing late Paleozoic forms. Adult strophomenids were mostly free-living, sessile, epifaunal suspension feeders. The concavo-convex lateral profile and elaborate spines were adaptations for living on soft substrates. *See* BRACHIOPODA; RHYNCHONELLIFORMEA. [M.E.P.]

Structural analysis A detailed evaluation intended to assure that, for any structure, the deformations will be sufficiently below allowable values that structural failure will not occur. The deformations may be elastic (fully recoverable) or inelastic (permanent). They may be small, with an associated structural failure that is cosmetic; for example, the deflection of a beam supporting a ceiling may cause cracking of the plaster. They may be large, with an associated structural failure that is catastrophic; for example, the buckling of a column or the fracture of a tension member causes complete collapse of the structure.

Structural analysis may be performed by tests on the actual structure, on a physical model of the structure to some scale, or through the use of a mathematical model. Tests on an actual structure are performed in those cases where many similar structures will be produced, for example, automobile frames, or where the cost of a test is justified by the importance and difficulty of the project, for example, a lunar lander. Physical models are sometimes used where subassemblages of major structures are to be investigated. The vast majority of analyses, however, are on mathematical models, particularly in the field of structural engineering which is concerned with large structures such as bridges, buildings, and dams. *See* BRIDGE; BUILDINGS; DAM; STRUCTURE (ENGINEERING).

The advent of the digital computer made it possible to create mathematical models of great sophistication, and almost all complex structures are now so analyzed. Programs of such generality have been written as to permit the analysis of any structure. These programs permit the model of the structure to be two- or three-dimensional, elastic or inelastic, and determine the response to forces that are static or dynamic. Most of the programs utilize the stiffness method, in which the stiffnesses of the individual elements are assembled into a stiffness matrix for the entire structure, and analysis is performed in which all behavior is assumed to be linearly elastic. *See* DIGITAL COMPUTER; ELASTICITY.

The structural engineer's function continues to require training and experience in conceptualizing the structure, choosing the appropriate model, estimating the loads that will be of importance, coding the information for the program, and interpreting the results. The analyst usually enters the process after the conceptualization. Most structures consist of assemblies of members connected at joints. While all real members transmit axial, torsional, and bending actions, the majority of buildings and bridges are analyzed as trusses, beams, and frames with either axial or bending forces predominant. *See* BEAM; ENGINEERING DESIGN; STRESS AND STRAIN; STRUCTURAL DESIGN; TRUSS.

Whether the model selected is detailed or simplified, one extremely important part of the analysis consists of the estimate of the loads to be resisted. For bridges and buildings, the primary vertical loads are gravity loads. These include the weight of the structure itself, and such appurtenances as will be permanent in nature. These are referred to as dead loads. The loads to be carried, the live loads, may consist of concentrated loads (heavy objects occupying little space, for example, a printing press), or loads distributed over relatively large areas (such as floor and deck coverings). Horizontal loads on buildings are produced by wind and by the inertia forces created during earthquakes. In seismic analysis, computers are used to simulate the dynamic characteristics of the structure. The accelerations actually measured during earthquakes are then used to determine the response of the structure. *See* LOADS, DYNAMIC; LOADS, TRANSVERSE; SEISMIC RISK. [G.D.B.R.]

Structural chemistry Much of chemistry is explainable in terms of the structures of chemical compounds. The understanding of these structures hinges very strongly on understanding the electronic configurations of the elements. The union of atoms, and therefore the formation of compounds from the elements, is associated with interactions among the extranuclear electrons of the individual atoms. Electronic interactions among atoms may occur in two ways: Electrons may be transferred from one atom to another, or they may be shared by two (or more) atoms. The first type of interaction is called electrovalence and results in the formation of electrically charged monatomic ions. The second, covalence, leads to the formation of molecules and complex ions. *See* CHEMICAL BONDING. [D.H.B.]

In considering structures more complex than those derived from simple monoatomic ions, the logical step is to consider single polyhedral aggregates of atoms. In its most precise sense, structure is used to denote a knowledge of the bonding distances and angles between atoms in chemical compounds and, in turn, the geometrical arrangements which they form. These atomic arrangements and the associated distances and angles serve uniquely as "fingerprints" of these atom spatial configurations, and depend very much on the electronic configurations around atoms. The chemical combination of neutral atoms to produce uncharged species results in molecule formation, whereas the similar combination of atoms or ions possessing a net charge results in the formation of complex ions. A basic understanding of the species formed involves the concept of the coordination polyhedron, which allows a simple classification of the structures of many polyatomic molecules and ions. This type of classification is particularly useful because it conveniently explains the packing together of simple chemical molecules or ions in terms of highly symmetrical polyhedra. There is an obvious connection between polyhedra and the structures found in crystalline solids formed from them. Crystal formation often involves the linking of convex polyhedra by the sharing of corners, edges, or faces, ultimately forming space-filling assemblies in which all faces of each polyhedron are in contact with faces of other polyhedra. The most important simple polyhedrons are the tetrahedron, the trigonal bipyramid, the octahedron, the pentagonal bipyramid, and the cube. The most commonly observed of these polyhedral configurations are the tetrahedron (four faces) and the octahedron (six faces).

The simplest correlative device which accurately summarizes a very large number of structures and enables the chemist to predict, with a good chance of success, the geometric array of the atoms in a compound of known composition, is based on an extreme electrostatic model. This model, or theory, represents the bonds in a purely formal way. The central atom is considered to be a positive ion having a charge equal to its oxidation state. The groups attached to the central atom (the ligands) are then treated either as negative ions or as neutral dipolar molecules. The principal justification for this approach lies in its successful correlation of a vast amount of information.

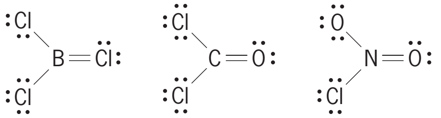
A number of significant observations can be made with regard to these formulations. There are series of ions, or ions and molecules, having the same type of composition, differing only in the nature of the central ion and the net charge on the aggregate. Examples are found in the series: NO_3^-, CO_3^{2-}, BO_3^{3-}, ClO_3^-, SO_3^{2-}, PO_3^{3-}; ClO_4^-, SO_4^{2-}, PO_4^{3-}, SiO_4^{4-}; AlF_6^{3-}, SiF_6^{2-}, PF_6^-. The numbers of atomic nuclei and of electrons are the same for all the members of each series; consequently, these are called isoelectronic series. Not only are the several chemical entities in such series isoelectronic, but they are usually identical in geometrical structure (isostructural).

It may also be observed that corresponding ions from a given vertical family of the periodic table commonly vary in coordination number. A useful example is found in N^{5+} and P^{5+} which form NO_3^- and PO_4^{3-}, respectively. In addition, some neutral molecules expand their coordination numbers to form stable anionic halo complexes, whereas others do not. Thus, SiF_4 reacts with fluoride ion to form SiF_6^{2-}, whereas CF_4 does not form a similar complex ion. The most satisfactory explanation of these and many related observations is conveniently formulated in terms of the electrostatic model chosen here.

The necessary condition for stability of the coordination polyhedron MA_n requires that the anions A are each in contact with the central atom M. As a consequence of this condition, the limit of stability of the structure arises in those cases where the anions are also mutually in contact. Larger ligands, or anions, would not be in contact with the central ion. This relationship is usually summarized in terms of the limiting ratio of the radius of the cation, r_M, to that of the anion, r_A, below which the anions would no longer be in contact with the cation.

According to the valence-bond theory, the principal requirements for the formation of a covalent bond are a pair of electrons and suitably oriented electron orbitals on each of the atoms being bonded. The geometry of the atoms in the resulting coordination polyhedron is correlated with the orientation of the orbitals on the central atom. The orbitals used depend on the energies of the electrons in them. In general, the order of increasing energy of the electron orbitals is $(n-1)d < ns < np < nd$. It is concluded that a nontransition atom having one valence electron will form a covalent bond utilizing an *s* orbital. In those cases where an unshared pair of electrons may be assigned to the *ns* orbital, as many as three equivalent bonds may be formed by utilizing the three *np* orbitals of the central atom. Because of the orientation of these *p* orbitals with respect to each other, the three resulting bonds should be at 90° to each other. This expectation is nearly realized in PH_3. In order to account for four or six equivalent bonds, or for that matter in order to account for all the remaining polyhedral and polygonal structures, except the angular structure for a coordination number of 2 (with two unshared pairs of electrons on the central atom), an additional assumption is necessary. It is assumed that *s* and *p*, *s* and *d*, or *s*, *p*, and *d* orbitals, are replaced by new orbitals, called hybridized orbitals. These hybridized orbitals are derived from the original orbitals (mathematically) in such a way that the required number of equivalent bonds may be formed. In the simplest case, it is shown that *s* and *p* may be combined to form two equivalent *sp* hybridized orbitals directed at 180° to each other. Other sets of hybridized orbitals have been shown to be appropriate to describe the bonding in other structures. *See* LIGAND FIELD THEORY.

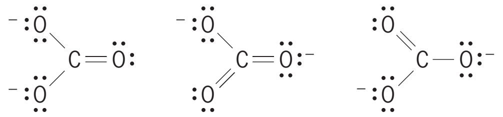
Among inert-gas ions of the first row of eight elements in the periodic table, there are four orbitals available for covalent bond formation, one 2*s* and three 2*p*. Consequently, a maximum of four bonds may be formed. This is in general agreement with the existence of the tetrahedron as the limiting coordination polyhedron among these elements, for example, BeF_4^{2-}, BF_4^-, CCl_4, NH_4^+. Although only Li^+ deviates from this pattern, having a coordination number of 6 in its crystalline halides, these compounds are best treated as simple electrovalent salts. In keeping with the limitation of only four orbitals, the formation of double or triple bonds between atoms of these elements reduces the coordination number of the central atom. Thus, the highest coordination number of a first-row element forming one double bond is 3. This is illustrated by the structures below.



In these and similar examples, the geometric array is determined by the formation of three single bonds utilizing sp^2 hybridized orbitals on the central atom and *p* orbitals on the ligand. In general, the bonds determining the geometry of a molecule or ion (in this way) are called σ bonds. The double bond results from the superposition of a second bond, a π bond, between two atoms. In this example the formation of a π bond reduces the number of σ bonds from four to three, thus changing the geometries of the corresponding molecules or ions from tetrahedral to trigonal planar.

The formation of a second π bond (a triple bond or two double bonds) reduces the coordination number of the atom in question still further, resulting in the linear *sp* set of hybridized orbitals being utilized in σ-bond formation. *See* VALENCE.

With regard to the nature of doubly bonded compounds, another problem arises when such structures are viewed from the standpoint of valence-bond theory. In the species BCl_3, $COCl_2$, NO_2Cl, and many similar substances, nonequivalent bonds are predicted. The doubly bonded oxygen should be closer to the central carbon atom than the singly bonded ones. This is not found to be true experimentally so long as the similar atoms are otherwise equivalent. There is only one observable C—O distance in carbonate, one N—O distance in nitrate, and so on. To account for such facts as these, the concept of resonance must be introduced. If the π bond exists, it must exist equally between the central atom and all the equivalent oxygen atoms. The resonance method of describing this situation is to say that one of the pictorial structures is inadequate to describe the substance properly, but that enough pictorial structures (resonance structures) should be considered to permute the double bond about all the equivalent bonds. The true structure is assumed to be something intermediate to all the resonance structures and more stable than any of them because it exists in preference to any one of them. The resonance structures for CO_3^{2-} are the following:



See CONJUGATION AND HYPERCONJUGATION; RESONANCE (MOLECULAR STRUCTURE).

The classic homologous series of compounds in organic chemistry provide useful examples involving the condensation of polyhedrons containing the same central element in the individual units. The general formula, $C_nH_{2n} + 2$, represents a large number of compounds extending from the lowest member, methane, CH_4, to polyethylene, a plastic of economic importance in which *n* is a very large number. Two ways exist for the linking together of these tetrahedrons. This gives rise to two molecular forms, both of which are stable, well-known compounds. It is

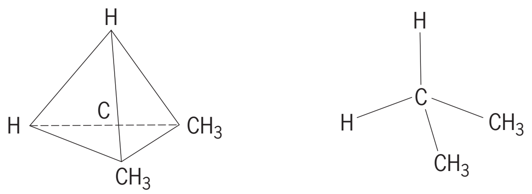


Fig. 1. Geometric structure of propane.

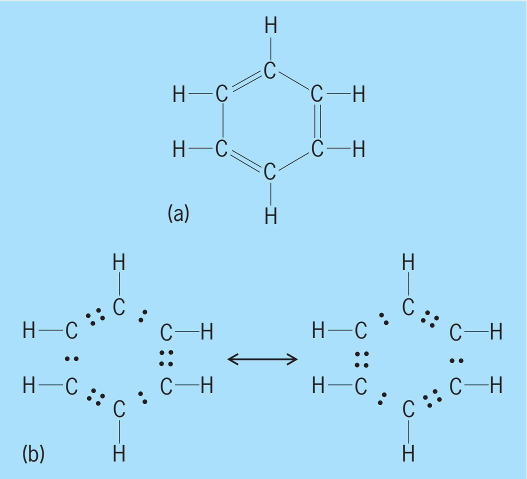

Fig. 3. Benzene molecule. (*a*) Structural formula. (*b*) Two forms in resonance.

an essential part of these structures that each —C link is linear (because it is merely a σ-bond); however, when two carbon atoms are linked to a third, the C—C—C angle is essentially determined by the bond angle of the central carbon atom (that is, the other carbons may be treated as ligands to the first (Fig. 1). The other familiar homologous series of organic chemistry differ from the saturated hydrocarbons in having at least one unique coordination polyhedron of a different type. The olefins contain two doubly bonded, or unsaturated, carbon atoms, whose polyhedral structures are trigonal planar, and the remainder of the carbons are tetrahedral. As in the case of the aliphatic hydrocarbons, the olefins exhibit an isomerism which is associated with the branching of the chain structure. In addition, the presence of two linked trigonal planar carbon atoms and the fact that the polyhedrons cannot rotate about the double bond give rise to a different kind of isomerism, called cis-trans isomerism (Fig. 2). *See* BOND ANGLE AND DISTANCE.

The existence of a predicted isomerism provides one of the most important confirmations of the theories of chemical structure. In general, the polyhedral view of molecular structure, as described here, has been thoroughly verified by the discovery of the many types of predicted isomerism. The first really convincing proof of the tetrahedral structures of saturated carbon atoms involved optical isomerism. *See* OPTICAL ACTIVITY.

The aromatic hydrocarbons are characterized by cyclic arrangements of trigonal planar carbon atoms (Fig. 3*a*). The highly symmetrical nature of the benzene molecule is not fully represented by such a structure. The figure indicates the presence of three double and three single bonds in the ring. It has been shown that the C—C bonds are all the same and, consequently, the true structure of the substance must be represented by two resonance structures which interchange the single and double bonds (Fig. 3*b*). *See* BENZENE. [J.M.Wi.]

Structural connections Methods of joining the individual members of a structure to form a complete assembly. The connections furnish supporting reactions and transfer loads from one member to another. Loads are transferred by fasteners (rivets, bolts) or welding supplemented by suitable arrangements of plates, angles, or other structural shapes. When the end of a member must be free to rotate, a pinned connection is used.

The suitability of a connection depends on its deformational characteristics as well as its strength. Rotational flexibility or complete rigidity must be provided according to the degree of end restraint assumed in the design. A rigid connection maintains the original angles between connected members virtually unchanged after loading. Flexible or nonrestraining connections permit rotation approximately equal to that at the ends of a simply supported beam. Intermediate degrees of restraint are called semirigid.

A commonly used form of connection for rolled-beam sections, called a web connection, consists of two angles which are attached to opposite sides of a member and which are in turn connected to the web of a supporting beam, girder, column, or framing at right angles. A shelf angle may be added to facilitate erection (Fig. 1).

A bracket or seat on which the end of the beam rests is a seat connection; it is intended to furnish the end reaction of the supported beam. Two general types are used: The unstiffened seat provides bearing for the beam by a projecting plate or angle leg which offers resistance only by its own flexural strength (Fig. 2); the stiffened seat is supported by a vertical plate or angle which transfers the reaction force to the supporting member without flexural distortion of the outstanding seat.

When the action line of a transferred force does not pass through the centroid of the connecting fastener group or welds, the connection is subjected to rotational moment which produces additional shearing stresses in the connectors. The load transmitted by diagonal bracing to a supporting column flange through a gusset plate is eccentric with reference to the connecting fastener group.

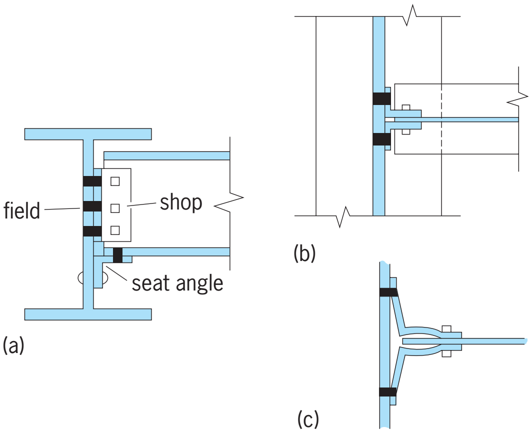

Fig. 1. Riveted or bolted web connections. (*a*) Beam-to-ginder, elevation view. (*b*) Plan view. (*c*) Bending of angle legs.

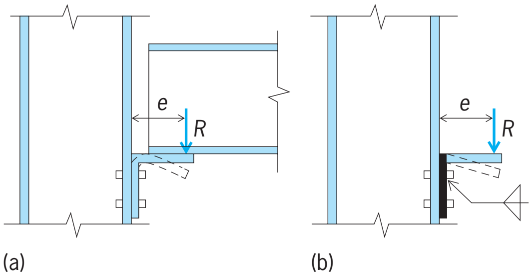

Fig. 2. Unstiffened seat connections. (*a*) Fastened angle seat. (*b*) Welded angle seat. *R* = reaction load; *e* = distance to reaction from column face.

In beam-to-column connections and stiffened seat connections or when members transfer loads to columns by a gusset plate or a bracket, the fasteners are subjected to tension forces caused by the eccentric connection. Although there are initial tensions in the fasteners, the final tension is not appreciably greater than the initial tension.

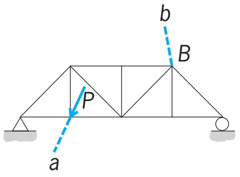
Rigidity and moment resistance are necessary at the ends of beams forming part of a continuous framework which must resist lateral and vertical loads. Wind pressures tend to distort a building frame, producing bending in the beams and columns which must be suitably connected to transfer moment and shear. The resisting moment can be furnished by various forms of angle T for fasteners or welded or bracket connections.

Where appreciably angular change between members is expected, and in special cases where a hinge support without moment resistance is desired, connections are pinned. Many bridge trusses and large girder spans have pin supports. *See* Bolt; Joint (structures); Rivet. [J.B.S.]

Structural deflections The deformations or movements of a structure and its components, such as beams and trusses, from their original positions. It is as important for the designer to determine deflections and strains as it is to know the stresses caused by loads. *See* Stress and strain.

Deflections may be computed by any of several methods. Generally the computation is based on the assumption that stress is proportional to strain. As a result, deflection equations involve the modulus of elasticity E, which is a measure of the stiffness of a material.

The relation between deflections at different parts of a structure is indicated by Maxwell's law of reciprocal deflections. This states that if a load P is applied at any point A in any direction a and causes a shift of another point B in direction b, the same load applied at B in direction b will cause an equal shift of A in direction a (see illustration). The law is used in a number of ways such as in simplifying deflection calculations, checking the accuracy of computations, and producing influence lines. *See* Structural analysis.



Example of Maxwell's law of reciprocal deflections.

Beam and truss deflections usually are computed by similar methods, except that integration is used for equations and summation for trusses. Beam deflection equations involve bending moments and moments of inertia. Truss deflection equations are based on the stresses and cross-sectional areas of chords and web members. Deflections may also be determined graphically. *See* Beam; Truss. [J.B.S.]

Structural design The selection of materials and member type, size, and configuration to carry loads in a safe and serviceable fashion. In general, structural design implies the engineering of stationary objects such as buildings and bridges, or objects that may be mobile but have a rigid shape such as ship hulls and aircraft frames. Devices with parts planned to move with relation to each other (linkages) are generally assigned to the area of mechanical design.

Structural design involves at least five distinct phases of work: project requirements, materials, structural scheme, analysis, and design. For unusual structures or materials a sixth phase, testing, should be included. These phases do not proceed in a rigid progression, since different materials can be most effective in different schemes, testing can result in changes to a design, and a final design is often reached by starting with a rough estimated design, then looping through several cycles of analysis and redesign. Often, several alternative designs will prove quite close in cost, strength, and serviceability. The structural engineer, owner, or end user would then make a selection based on other considerations.

Before starting design, the structural engineer must determine the criteria for acceptable performance. The loads or forces to be resisted must be provided. For specialized structures this may be given directly, as when supporting a known piece of machinery, or a crane of known capacity. For conventional buildings, building codes adopted on a municipal, county, or state level provide minimum design requirements for live loads (occupants and furnishings, snow on roofs, and so on). The engineer will calculate dead loads (structure and known, permanent intallations) during the design process. For the structure to be serviceable or useful, deflections must also be kept within limits, since it is possible for safe structures to be uncomfortably "bouncy." Very tight deflection limits are set on supports for machinery, since beam sag can cause driveshafts to bend, bearings to burn out, parts to misalign, and overhead cranes to stall. Beam stiffness also affects floor "bounciness," which can be annoying if not controlled. In addition, lateral deflection, sway, or drift of tall buildings is often held within approximately height/500 (1/500 of the building height) to minimize the likelihood of motion discomfort in occupants of upper floors on windy days. *See* Loads, dynamic; Loads, transverse.

Technological advances have created many novel materials such as carbon fiber- and boron fiber-reinforced composites, which have excellent strength, stiffness, and strenth-to-weight properties. However, because of the high cost and difficult or unusual fabrication techniques required, glass-reinforced composites such as fiberglass are more common, but are limited to lightly loaded applications. The main materials used in structural design are more prosaic and include steel, aluminum, reinforced concrete, wood, and masonry. *See* Composite material; Masonry; Precast concrete; Prestressed concrete; Reinforced concrete; Structural materials.

In an actual structure, various forces are experienced by structural members, including tension, compression, flexure (bending), shear, and torsion (twist). However, the structural scheme selected will influence which of these forces occurs most frequently, and this will influence the process of material selection. *See* Shear; Torsion.

Analysis of structures is required to ensure stability (static equilibrium), find the member forces to be resisted, and determine deflections. It requires that member configuration, approximate member sizes, and material properties be known or assumed. Aspects of analysis include: equilibrium; stress, strain, and elastic modulus; linearity; plasticity; and curvature and plane sections. Various methods are used to complete the analysis.

Once a structure has been analyzed (by using geometry alone if the analysis is determinate, or geometry plus assumed member sizes and materials if indeterminate), final design can proceed. Deflections and allowable stresses or ultimate strength must be checked against criteria provided either by the owner or by the governing building codes. Safety at working loads must be calculated. Several methods are available, and the choice depends on the types of materials that will be used. Once a satisfactory scheme has been analyzed and designed to be within project criteria, the information must be presented for fabrication and construction. This is commonly done through drawings, which indicate all basic dimensions, materials, member sizes, the anticipated loads used in design, and anticipated forces to be carried through connections. [R.L.T.; L.M.J.]

Structural geology The branch of geology that deals with study and interpretation of deformation of the Earth's crust. Deformation brings about changes in size (dilation), shape (distortion), position (translation), or orientation (rotation). Evidence for the changes caused by deformation are commonly implanted into geologic bodies in the form of recognizable structures, such as faults and joints, folds and cleavage, and foliation and lineation. The geologic record of structures and structural relations is best developed and most complicated in mountain belts, the most intensely deformed parts of the Earth's crust. *See* MOUNTAIN SYSTEMS.

The discipline of structural geology harnesses three interrelated strategies of analysis: descriptive analysis, kinematic analysis, and dynamic analysis. Descriptive analysis is concerned with recognizing and describing structures and measuring their orientations. Kinematic analysis focuses on interpreting the deformational movements responsible for the structures. Dynamic analysis interprets deformational movements in terms of forces, stresses, and mechanics. The ultimate goal of these interdependent approaches is to interpret the physical evolution of crustal structures, that is, tectonic analysis. A major emphasis in modern structural geology is strain analysis, the quantitative analysis of changes in size and shape of geologic bodies, regardless of scale.

There are many significant practical applications of structural geology. An understanding of the descriptive and geometric properties of folds and faults, as well as mechanisms of folding and faulting, is of vital interest to exploration geologists in the petroleum industry. Ore deposits commonly are structurally controlled, or structurally disturbed, and for these reasons detailed structural geologic mapping is an essential component of mining exploration. Other applications of structural geology include the evaluation of proposals for the disposal of radioactive waste in the subsurface, and the targeting of safe sites for dams, hospitals, and the like in regions marked by active faulting. *See* FAULT AND FAULT STRUCTURES; FOLD AND FOLD SYSTEMS; ORE AND MINERAL DEPOSITS; PETROLEUM GEOLOGY. [G.H.D.]

Structural materials

Construction materials which, because of their ability to withstand external forces, are considered in the design of a structural framework.

Brick is the oldest of all artificial building materials. It is classified as face brick, common brick, and glazed brick. Face brick is used on the exterior of a wall and varies in color, texture, and mechanical perfection. Common brick consists of the kiln run of brick and is used behind whatever facing material is employed providing necessary wall thickness and additional structural strength. Glazed brick is employed largely for interiors where beauty, ease of cleaning, and sanitation are primary considerations. *See* BRICK.

Structural clay tiles are burned-clay masonry units having interior hollow spaces termed cells. Such tile is widely used because of its strength, light weight, and insulating and fire-protection qualities. *See* TILE.

Architectural terra-cotta is a burned-clay material used for decorative purposes. The shapes are molded either by hand in plaster-of-paris molds or by machine, using the stiff-mud process.

Building stones generally used are limestone, sandstone, granite, and marble. Until the advent of steel and concrete, stone was the most important building material. Its principal use now is as a decorative material because of its beauty, dignity, and durability. *See* GRANITE; LIMESTONE; MARBLE; SANDSTONE; STONE AND STONE PRODUCTS.

Concrete is a mixture of cement, mineral aggregate, and water, which, if combined in proper proportions, form a plastic mixture capable of being placed in forms and of hardening through the hydration of the cement. *See* CONCRETE; PRESTRESSED CONCRETE; REINFORCED CONCRETE.

The cellular structure of wood is largely responsible for its basic characteristics, unique among the common structural materials. When cut into lumber, a tree provides a wide range of material which is classified according to use as yard lumber, factory or shop lumber, and structural lumber. Laminated lumber is used for beams, columns, arch ribs, chord members, and other structural members. Plywood is generally used as a replacement for sheathing, or as form lumber for reinforced concrete structures. *See* LUMBER; PLYWOOD; WOOD ANATOMY; WOOD PRODUCTS.

Important structural metals are the structural steels, steel castings, aluminum alloys, magnesium alloys, and cast and wrought iron. Steel castings are used for rocker bearings under the ends of large bridges. Shoes and bearing plates are usually cast in carbon steel, but rollers are often cast in stainless steel. Aluminum alloys are strong, lightweight, and resistant to corrosion. The alloys most frequently used are comparable with the structural steels in strength. Magnesium alloys are produced as extruded shapes, rolled plate, and forgings. The principal structural applications are in aircraft, truck bodies, and portable scaffolding. Gray cast iron is used as a structural material for columns and column bases, bearing plates, stair treads, and railings. Malleable cast iron has few structural applications. Wrought iron is used extensively because of its ability to resist corrosion. It is used for blast plates to protect bridges, for solid decks to support ballasted roadways, and for trash racks for dams. *See* ALUMINUM; CAST IRON; MAGNESIUM ALLOYS; STEEL; STRUCTURAL STEEL; WROUGHT IRON. [C.M.A.]

Composite materials are engineered materials that contain a load-bearing material housed in a relatively weak protective matrix. A composite material results when two or more materials, each having its own, usually different characteristics, are combined, producing a material with properties superior to its components. The matrix material (metallic, ceramic, or polymeric) bonds together the reinforcing materials (whiskers, laminated fibers, or woven fabric) and distributes the loading between them. *See* COMPOSITE MATERIAL; CRYSTAL WHISKERS.

Fiber-reinforced polymers (FRP) are a broad group of composite materials made of fibers embedded in a polymeric matrix. Compared to metals, they generally have relatively high strength-to-weight ratios and excellent corrosion resistance. They can be formed into virtually any shape and size. Glass is by far the most used fiber in FRP (glass-FRP), although carbon fiber (carbon-FRP) is finding greater application. Although complete FRP shapes and structures are possible, the most promising application of FRP in civil engineering is for repairing structures or infrastructure. FRP can be used to repair beams, walls, slabs, and columns. *See* POLYMERIC COMPOSITE. [M.Sc.]

Structural petrology

The study of the structural aspects of rocks, as distinct from the purely chemical and mineralogical studies that are generally emphasized in other branches of petrology. The term was originally used synonymously with petrofabric analysis, but is sometimes restricted to denote the analysis of only microscopic structural and textural features. *See* PETROFABRIC ANALYSIS; PETROGRAPHY. [J.M.Ch.]

Structural plate

A simple rolled steel section used as an isolated structural element, as a support of other structural elements, or as part of other structural elements. When isolated plates are extremely thick, their design is controlled by shear; plates of moderate thickness are controlled by bending (with some torsion), and very thin plates carry their loads principally by tensile membrane action. Although stresses of all types exist in all plates, it is usually sufficient to deal with only the most significant. Bending is the most common design criterion.

Plates are commonly used as cover plates on wide-flange beams, as the flanges and webs of plate girders, and as the sides of tube-shaped beams and columns. In all these cases, serious consideration must be given to the fact that the plate may buckle when compressed. Fortunately, the plates have edge supports in the direction of the stress, so they function as panels rather than as beams. Their ratios of length to width are large enough that the resistance to local buckling of the plate element depends upon its width-thickness ratio, practically independent of its length. (The length of the overall section is still significant in determining the member's capacity.) *See* BEAM; COLUMN; JOINT (STRUCTURES); LOADS, TRANSVERSE; STRUCTURAL STEEL. [G.D.Br.]

Structural steel Steel used in engineering structures, usually manufactured by either the open-hearth or the electric-furnace process. The exception is carbon-steel plates and shapes whose thickness is $^7/_{16}$ in. (11 mm) or less and which are used in structures subject to static loads only. These products may be made from acid-Bessemer steel. The physical properties and chemical composition are governed by standard specifications of the American Society for Testing and Materials (ASTM). Structural steel can be fabricated into numerous shapes for various construction purposes. *See* STEEL. [W.G.B.]

Structure (engineering) An arrangement of designed components that provides strength and stiffness to a built artifact such as a building, bridge, dam, automobile, airplane, or missile. The artifact itself is often referred to as a structure, even though its primary function is not to support but, for example, to house people, contain water, or transport goods. *See* AIRPLANE; AUTOMOBILE; BRIDGE; BUILDINGS; DAM.

The primary requirements for structures are safety, strength, economy, stiffness, durability, robustness, esthetics, and ductility. The safety of the structure is paramount, and it is achieved by adhering to rules of design contained in standards and codes, as well as in exercising strict quality control over all phases of planning, design, and construction. The structure is designed to be strong enough to support loads due to its own weight, to human activity, and to the environment (such as wind, snow, earthquakes, ice, or floods). The ability to support loads during its intended lifetime ensures that the rate of failure is insignificant for practical purposes. The design should provide an economical structure within the constraints of all other requirements. The structure is designed to be stiff so that under everyday conditions of loading and usage it will not deflect or vibrate to an extent that is annoying to the occupants or detrimental to its function. The materials and details of construction have durability, such that the structure will not corrode, deteriorate, or break under the effects of weathering and normal usage during its lifetime. A structure should be robust enough to withstand intentional or unintentional misuse (for example, fire, gas explosion, or collision with a vehicle) without totally collapsing. A structural design takes into consideration the community's esthetic sensibilities. Ductility is necessary to absorb the energy imparted to the structure from dynamic loads such as earthquakes and blasts. *See* CONSTRUCTION ENGINEERING; ENGINEERING DESIGN.

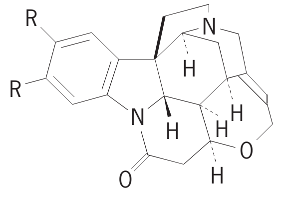
Common structural materials are wood, masonry, steel, reinforced concrete, aluminum, and fiber-reinforced composites. Structures are classified into the categories of frames, plates, and shells, frequently incorporating combinations of these. Frames consist of "stick" members arranged to form the skeleton on which the remainder of the structure is placed. Plated structures include roof and floor slabs, vertical shear walls in a multistory building, or girders in a bridge. Shells are often used as water or gas containers, in roofs of arenas, or in vehicles that transport gases and liquids. The connections between the various elements of a structure are made by bolting, welding or riveting. *See* COMPOSITE MATERIAL; CONCRETE; STEEL; STRUCTURAL MATERIALS. [T.V.G.]

Struthioniformes A small order of weak-flying, partridgelike birds and giant flightless ratite birds found in the southern continents. Their relationship to other birds is unknown. The struthioniforms are characterized by a palaeognathous palate which provides freedom of movement between segments of the palate and the jaw. For this reason they are frequently placed in a separate superorder, the Palaeognathae. However, that distinction places too much emphasis on their separation from other birds. Contrary to common opinion, no evidence supports the concept that the palaeognathous birds are primitive among living birds.

The order Struthioniformes can be divided into three suborders, Lithornithi, Tinami, and Struthioni, each of which includes both fossil and extant representatives.

The struthioniforms are medium-sized to giant birds. The ostriches are the largest extant birds, but some of the moas, elephant birds, and dromornithids were even larger. The head is small; a medium flattened bill is a common feature except in the kiwis, which have a long bill used for probing into the ground for worms. The wings are reduced in all forms except the lithionithids and tinamous, which can still fly, and the plumage is soft. Their legs are strong, and all forms run well. The struthioniforms eat a variety of foods, especially large fruits and other large food items. Breeding is polygamous, with two or more females laying eggs in a single nest. The males are responsible for incubation, and they assume the major or sole role in caring for the downy young, which leave the nest after hatching. *See* AVES; RATITES. [W.J.B.]

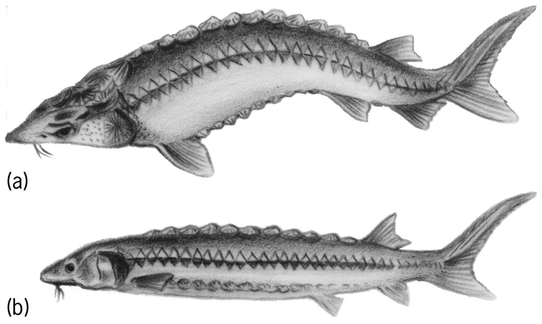
Strychnine alkaloids Alkaloid substances derived from the seeds and bark of plants of the genus *Strychnos* (family Loganiaceae). This genus serves as the source of poisonous, nitrogen-containing plant materials, such as strychnine (see structure; R = H). The seeds of the Asian species of *Strychnos* contain 2–3% alkaloids, of which about half is strychnine and the rest is closely related materials; for example, brucine (see structure; R = OCH_3) is a more highly oxygenated relative. Strychnine and brucine are isolated by extraction of basified plant residue with chloroform and then, from the chloroform solution, by dilute sulfuric acid. Precipitation from the dilute acid is accomplished with ammonium hydroxide. Strychnine is separated from brucine by fractional crystallization from ethanol. *See* CRYSTALLIZATION; STRYCHNOS.



At one time strychnine was used as a tonic and a central nervous system stimulant, but because of its high toxicity (5 mg/kg is a lethal dose in the rat) and the availability of more effective substances, it no longer has a place in human medicine. [D.D.]

Strychnos A genus of tropical trees and shrubs belonging to the Logania family (Loganiaceae). *Strychnos nux-vomica*, a native of India and Ceylon, is the source of strychnine. The alkaloid, strychnine, has been used medicinally in the treatment of certain nervous disorders and paralysis. Curare, used by the Indians to poison arrows, is obtained from *S. toxifera* and *S. castelnaei* in Guiana and Amazonas and from *S. tieute* in the Sunda Islands. Curare paralyzes the motor nerve endings in striated muscles and is used in medical practice in cases in which a state of extreme muscular relaxation or even immobility is desirable. It has become an important drug in the field of anesthesiology. *See* GENTIANALES; STRYCHNINE ALKALOIDS. [P.D.St.; E.L.C.]

Sturgeon Any of 10 species of large fish which comprise the family Acipenseridae in the order Acipenseriformes. These fish are found in North Temperate Zone waters, where they are almost exclusively bottom-living and feed on organisms such as mollusks, worms, and larvae. The body has five rows of bony plates, of which one is situated dorsally, two laterally, and two ventrally. The snout is elongate and there are four barbels on its lower surface; the mouth is ventrally located, and in the adult



Two species of sturgeons found in United States coastal waters. (*a*) Atlantic sturgeon (*Acipenser oxyrhynchus*). (*b*) Short-nosed sturgeon (*A. brevirostrus*).

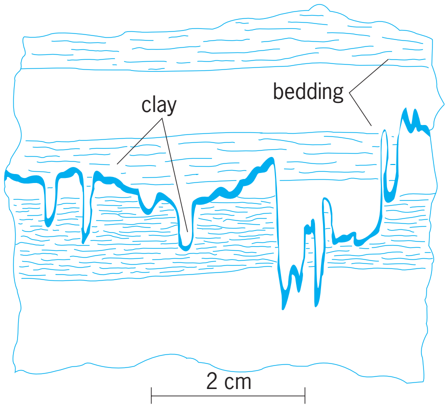
the jaws lack teeth (see illustration). The skeleton is mainly cartilaginous.

Sturgeons are known primarily for the roe, which is processed as caviar. A single female can produce millions of eggs, which may be removed from dead fish or stripped from living fish. The smoked flesh of the sturgeon is a delicacy. *See* ACIPENSERIFORMES. [C.B.C.]

Stylasterina An order of the class Hydrozoa of the phylum Coelenterata, including several brightly colored branching or encrusting "corals" of warm seas. (True corals belong to a different class, the Anthozoa). The calcareous skeleton is covered by living tissue and is penetrated by ramifying tubes. Nutritive polyps, the gastrozooids, lie in cups on one surface or along certain edges of the skeletal substance. A spine, or style, at the base of each cup gives the order its name.

Some authorities combine the Stylasterina with the Milleporina in a single order, the Hydrocorallina. *See* ANTHOZOA; HYDROZOA. [S.Cr.]

Stylolites Irregular surfaces occurring in certain rocks, mostly parallel to bedding planes, in which small toothlike projections on one side of the surface fit into cavities of like shape on the other side (see illustration). Stylolites are most common in limestones and dolomites but are also present in many other kinds of rock, including sandstones, gypsum beds, and cherts. *See* DOLOMITE; LIMESTONE; SEDIMENTARY ROCKS. [R.Si.]



Stylolite in limestone.

Stylommatophora A superorder of the molluscan subclass Pulmonata containing about 20,500 species that are grouped into 56 families. Nearly all land snails without an operculum are stylommatophorans. They have eyespots on the tips of a pair of retractile tentacles, hermaphroditic reproduction with partial fusion of the male and female system, and, normally, a second pair of retractile tentacles that function as chemoreceptors. All are air-breathing and most are truly terrestrial. Three orders, based on excretory structures, are recognized. The more primitive Orthurethra and Mesurethra have less efficient water conservation devices than do the more specialized members of the order Sigmurethra, in which a closed ureter functions in water conservation. The latter specialization apparently is a prerequisite for evolution toward a sluglike structure, since all 16 families with slugs or sluglike taxa belong to the Sigmurethra. *See* PULMONATA. [G.A.S.]

Styrene A colorless, liquid hydrocarbon with the formula $C_6H_5CH{=}CH_2$. It boils at 145.2°C (293.4°F) and freezes at −30.6°C (−23.1°F). The ethylenic linkage of styrene readily undergoes addition reactions and under the influence of light, heat, or catalysts undergoes self-addition or polymerization to yield polystyrene.

The majority of the styrene used is converted into polystyrene, but other thermoplastic or even thermosetting resins are prepared from styrene by copolymerization with suitable comonomers. A smaller quantity of styrene goes into the manufacture of elastomers or synthetic rubbers.

Styrene is a skin irritant. Prolonged breathing of air containing more than 400 ppm of styrene vapor may be injurious to health. *See* POLYMERIZATION; POLYSTYRENE RESIN. [C.K.B.]

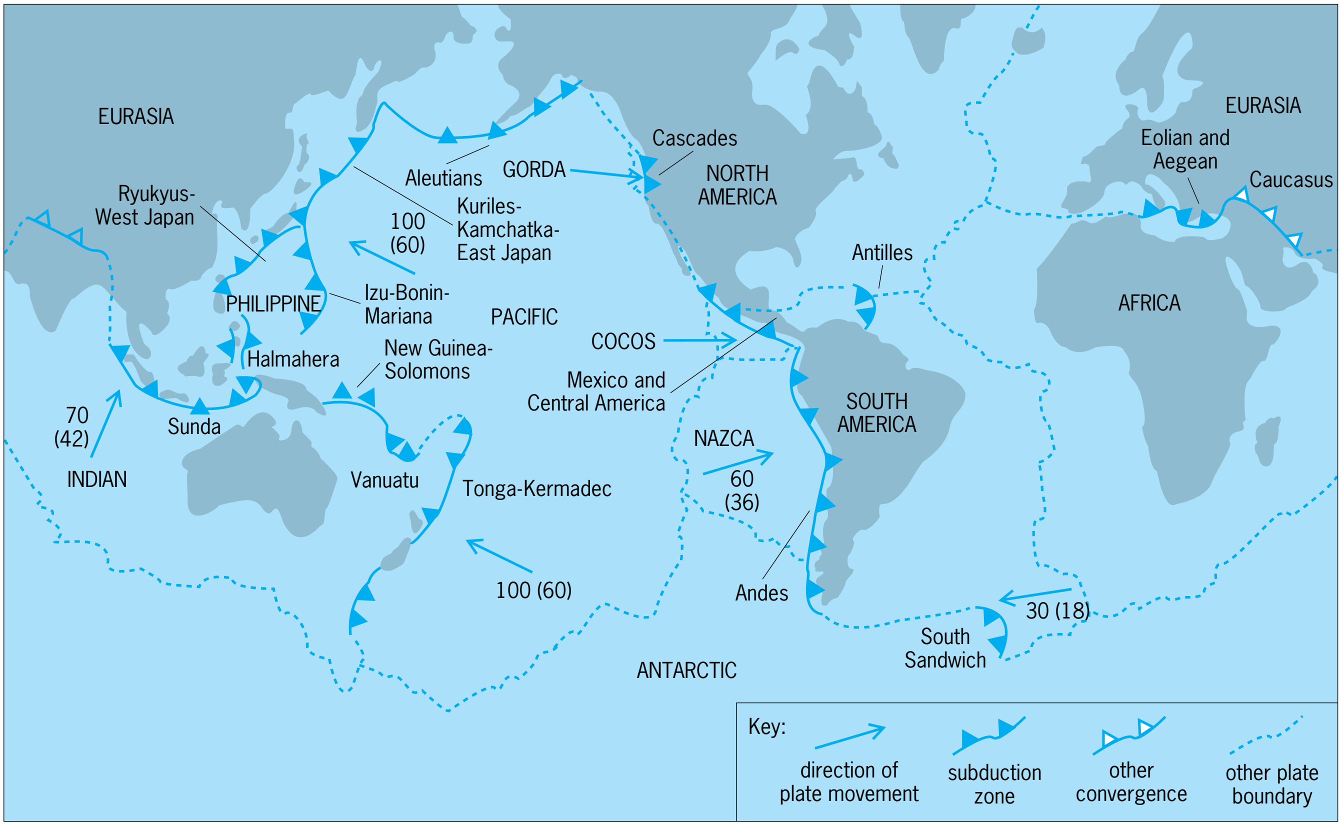
Subduction zones Regions where portions of the Earth's tectonic plates are diving beneath other plates, into the Earth's interior. Subduction zones are defined by deep oceanic trenches, lines of volcanoes parallel to the trenches, and zones of large earthquakes that extend from the trenches landward.

Plate tectonic theory recognizes that the Earth's surface is composed of a mosaic of interacting lithospheric plates, with the lithosphere consisting of the crust (continental or oceanic) and associated underlying mantle, for a total thickness of about 100 km (60 mi). Oceanic lithosphere is created by sea-floor spreading at mid-ocean ridges (divergent, or accretionary, plate boundaries) and destroyed at subduction zones (at convergent, or destructive, plate boundaries). At subduction zones, the oceanic lithosphere dives beneath another plate, which may be either oceanic or continental. Part of the material on the subducted plate is recycled back to the surface (by being scraped off the subducting plate and accreted to the overriding plate, or by melting and rising as magma), and the remainder is mixed back into the Earth's deeper mantle. This process balances the creation of lithosphere that occurs at the mid-ocean ridge system. The convergence of two plates occurs at rates of 1–10 cm/yr (0.4–4 in./yr) or 10–100 km (6–60 mi) per million years (see illustration).

During subduction, stress and phase changes in the upper part of the cold descending plate produce large earthquakes in the upper portion of the plate, in a narrow band called the Wadati-Benioff zone that can extend as deep as 700 km (420 mi). The plate is heated as it descends, and the resulting release of water leads to melting of the overlying mantle. This melt rises to produce the linear volcanic chains that are one of the most striking features of subduction zones. *See* LITHOSPHERE.

Subduction zones can be divided in two ways, based either on the nature of the crust in the overriding plate or on the age of the subducting plate. The first classification yields two broad categories: those beneath an oceanic plate, as in the Mariana or Tonga trenches, and those beneath a continental plate, as along the west coast of South America (see illustration). The first type is known as an intraoceanic convergent margin, and the second is known as an Andean-type convergent margin. *See* MID-OCEANIC RIDGE; PLATE TECTONICS.

Active volcanoes are highly visible features of subduction zones. The volcanoes that have developed above subduction zones in East Asia, Australasia, and the western Americas surround the Pacific Ocean in a so-called Ring of Fire. At



Principal subduction zones. Plate names are in all-capitals. Numbers at arrows indicate velocity of plate movement in kilometers (miles) per million years. (*After J. Gill, Orogenic Andesites and Plate Tectonics, Springer-Verlag, 1981*)

intraoceanic convergent margins, volcanoes may be the only component above sea level, leading to the name "island arc." The more general term "volcanic arc" refers to volcanoes built on either oceanic or continental crust. *See* VOLCANO.

An eventual consequence of subduction is orogeny, or mountain building. Subduction zones are constantly building new crust by the production of volcanic material or the accretion of oceanic sediments. However, the development of the greatest mountain ranges—the Alps or the Himalayas—occurs not during "normal" subduction but during the death of a subduction zone, when it becomes clogged with a large continent or volcanic arc. *See* OROGENY. [R.J.Ste.; S.H.B.]

Subgiant star An evolving star of luminosity class IV. Such a star is brighter than the main-sequence dwarfs and fainter than the true giants in its spectral class, lying between the two on the Hertzsprung-Russell diagram. The classic subgiants fall in a small region from class F to K (with effective temperatures ranging from 7000 to 4000 K or 12,000 to 7000°F). In class G they lie at absolute visual magnitude +3 with luminosities about five times the solar luminosity. Classic subgiants have masses around 1.3 times that of the Sun and violate the mass-luminosity relation as too bright for their masses. The concept is extended to the hot part of the Hertzsprung-Russell diagram from class F to O, in which the distinctions between subgiants and neighboring dwarfs and giants are much smaller, only a magnitude or less.

Main-sequence dwarfs run on the fusion of hydrogen to helium in their cores. The subgiant stage begins when the core hydrogen mass fraction drops to around 0.1, and then continues as the fraction goes to zero and the star evolves toward, but not onto, the red-giant branch with a contracting helium core. *See* DWARF STAR; GIANT STAR; HERTZSPRUNG-RUSSELL DIAGRAM; SPECTRAL TYPE; STAR; STELLAR EVOLUTION. [J.B.Ka.]

Sublimation The process by which solids are transformed directly to the vapor state without passing through the liquid phase. Sublimation is of considerable importance in the purification of certain substances such as iodine, naphthalene, and sulfur.

Sublimation is a universal phenomenon exhibited by all solids at temperatures below their triple points. For example, it is a common experience to observe the disappearance of snow from the ground even though the temperature is below the freezing point and liquid water is never present. The rate of disappearance is low, of course, because the vapor pressure of ice is low below its triple point. Sublimation is a scientifically and technically useful phenomenon, therefore, only when the vapor pressure of the solid phase is high enough for the rate of vaporization to be rapid. *See* PHASE EQUILIBRIUM; TRIPLE POINT; VAPOR PRESSURE. [N.H.N.]

Submarine A ship which can operate completely submerged in the water. The term formerly applied to any ship capable of operating completely underwater, but now usually describes a ship built for military purposes. The term "submersible" usually is applied to small, underwater vehicles that are built for research, rescue, commercial work, or pleasure.

By the end of World War II, antisubmarine warfare had progressed significantly by exploiting the limited underwater endurance and speed of the diesel-electric designs of that era. The application of nuclear power to submarines after World War II reestablished the near-invulnerability of the submarine to antisubmarine warfare from surface ships and aircraft. Nuclear power depends on nuclear fission rather than the oxidation of fossil fuels and thus requires no oxygen source as do diesel engines, allowing the submarine to operate submerged for very long periods. However, advances in submarine technology and nonnuclear propulsion cause the nonnuclear submarine to remain highly attractive to the navies of many nations. *See* SHIP NUCLEAR PROPULSION.

Submarines can be classified by their primary military missions. Attack submarines are fast, long-range ships equipped with torpedo tubes or cruise missile launch tubes. They carry sensitive underwater sound receivers and transmitters (sonar) used to detect enemy submarines. They may be armed with torpedoes of various kinds, cruise missiles, mines, and equipment for deployment of small units of clandestine troops.

Ballistic-missile submarines carry long-range missiles fitted with nuclear warheads that can be launched while submerged. The submarine can remain submerged and undetected for many days and, on command, launch missiles on any target within range. The missiles are stowed in and launched from vertical tubes. *See* MISSILE.

Experimental submarines are occasionally built to test new designs of hull shape, deeper depth capability, power plants, or controls.

Submersibles are usually small, deep-diving vehicles. Their use is for exploration and study of the ocean depths, development of equipment, rescue, or commercial work. Some designs take advantage of the forces of gravity and buoyancy for vertical motion. Other designs use vertically oriented propellers to propel the craft up and down. Movement is restricted to short distances and slow speed because of small size and small battery capacity. *See* UNDERWATER VEHICLE.

Compared with surface ships, the submarine has features that enable it to submerge and resist great sea pressure. Submarines have a pressure hull and a nonpressure hull. The pressure hull is the watertight, pressure-proof envelope in which equipment operates and the officers and crew live. In certain areas of the submarine there is a nonpressure hull of lighter structure, forming the main ballast tanks. A nonwatertight superstructure provides a smooth, fair envelope to cover pipes, valves, and fittings on top of the hull. Above the superstructure the fairwater similarly encloses the bridge, the periscope, and multiple mast supports. *See* PERISCOPE; SHIP DESIGN.

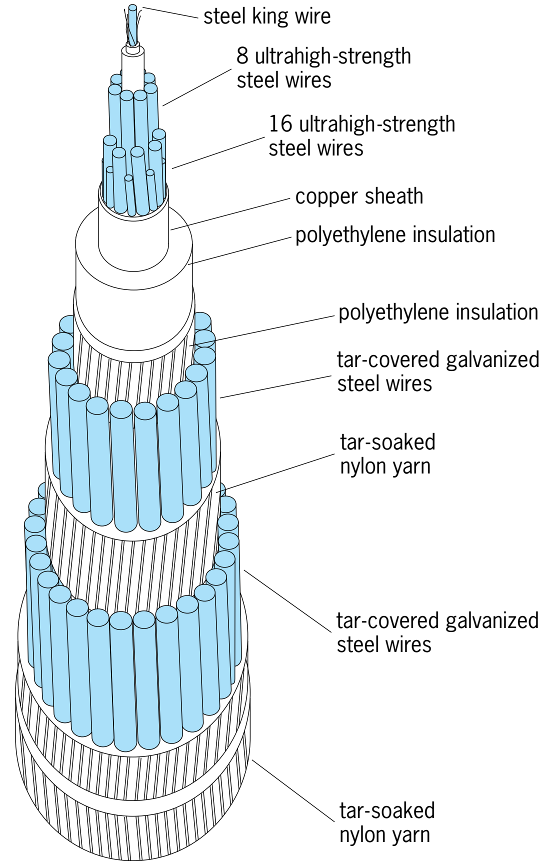
The principal means of detecting the presence of a submerged submarine is to listen for sounds which may have been generated on board or by its movement through the water. Very small amounts of acoustic energy can be detected by sophisticated sonars. Therefore, modern submarines are designed with multiple features to greatly reduce the amount of noise they generate.

[M.S.F.; J.H.W.]

Submarine cable A cable, primarily for communications, laid on the ocean floor to provide international links. This term is sometimes applied to power cables in water, but these are not usually of great length.

Coaxial cables with 1840 circuits (each having 3-kHz bandwidth) are used extensively for shorter cables. Cables using digital transmission over optical fibers (lightguide transmission) offer a significant cost-per-channel advantage over coaxial systems. Voice signals are transmitted by laser-generated digital light pulses over single-mode fiber pairs. *See* COAXIAL CABLE; COMMUNICATIONS CABLE; MULTIPLEXING AND MULTIPLE ACCESS; TRANSMISSION LINES.

SL280 digital lightguide transatlantic submarine cables utilize semiconductor laser diodes operating at a wavelength of 1.3-micrometers and carries 280 megabits per second on six hair-thin fibers, of which two pairs are active and the third is available as standby. Each fiber is a glass strand 125 μm in diameter, plastic-coated to 250 μm, and embedded in an elastomer that is part of the unit fiber structure. The fibers are helically wrapped around a central kingwire for strength during manufacture and an outer sheath of nylon to ensure dimensional stability. This structure is then helically wrapped with steel armor wires for strength, ensheathed in a copper conductor, and coated with a final protective layer of polyethylene insulation (see illustration).



Cutaway view of double-armored SL cable.

The fiber-optic digital repeaters regenerate the signal in its original form, unlike the earlier analog repeaters which were signal amplifiers. The repeaters detect the optical signal entering the repeater, transform it into an electrical signal and amplify it, regenerate it by putting it through a high-speed clocked decision circuit, and then convert the regenerated electrical signal into an optical one by using a 1.3-μm laser transmitter. Transmission rates of 560 megabits per second are provided in the subsequent SL560 design, utilizing lasers operating at 1.5 μm.

Virtually all analog (coaxial) submarine cable systems were configured as a single line from one landing point to another. Traffic requirements, however, are not identical for all countries, and it was realized to be advantageous to implement a tree configuration, where the various branches go to different countries. Digital fiber-optic technology makes branching possible by dedicating certain fiber pairs to certain subsystems.

With the increased volume and capacity of fiber-optic systems, customers and system owners cannot afford or support the potential loss of business and revenue associated with a cable failure. To reduce this risk, many systems employ a ring-network design architecture. These systems use a self-healing loop network with built-in backup and redundancy, which provide fiber-on-fiber restoration and connectivity. In the unlikely event of a cable failure of any nature, communications traffic can be shifted from one fiber cable to another so that digital voice, data, or video communications can continue without disruption. *See* LASER; OPTICAL COMMUNICATIONS; OPTICAL FIBERS; PULSE MODULATION.

[G.J.S.]

Submarine canyon A steep-sided valley developed on the sea floor of the continental slope. Submarine canyons serve as major conduits for sediment transport from land and the continental shelf to the deep sea. Modern canyons are relatively narrow, deeply incised, steeply walled, often sinuous valleys with predominantly V-shaped cross sections. Most canyons originate near the continental-shelf break, and generally extend to the base of the continental slope. Canyons often occur off the mouths of large rivers, such as the Hudson River or the Mississippi River, although many other canyons, such as the Bering Canyon in the southern Bering Sea, are developed along structural trends. *See* CONTINENTAL MARGIN.

Modern submarine canyons vary considerably in their dimensions. The average lengths of canyons has been estimated to be about 34 mi (55 km); although the Bering Canyon is more than 680 mi (1100 km) long and is the world's longest submarine canyon. The shortest canyons are those off the Hawaiian Islands, and average about 6 mi (10 km) in length. Submarine canyons are characterized by relatively steep gradients. The average slope of canyon floors is 309 ft/mi (58 m/km). In general, shorter canyons tend to have higher gradients. For example, shorter canyons of the Hawaiian group have an average gradient of 766 ft/mi (144 m/km), whereas the Bering Canyon has a slope of only 42 ft/mi (7.9 m/km).

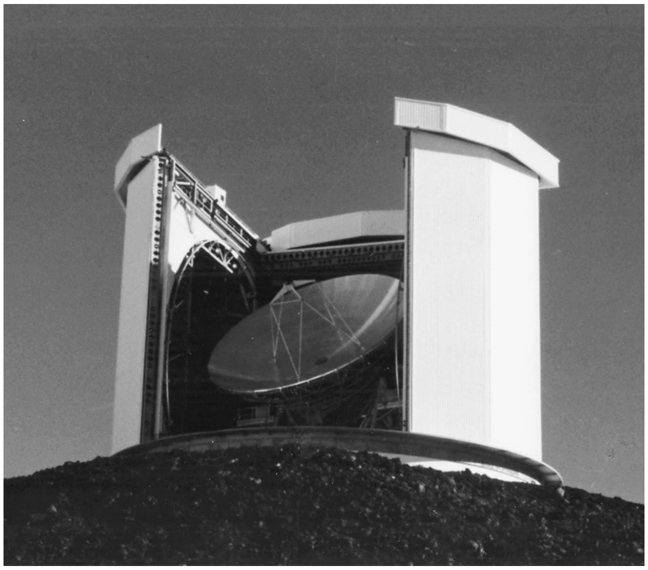
In comparison to modern canyons, dimensions of ancient canyons are considerably smaller. Deposits of ancient canyons are good hydrocarbon reservoirs. This is because submarine canyons and channels are often filled with sand that has the potential to hold oil and gas. Examples of hydrocarbon-bearing canyon-channel reservoirs are present in the subsurface in California, Louisiana, and Texas.

Physical and biological processes that are common in submarine canyons are mass wasting, turbidity currents, bottom currents, and bioerosion, mass wasting and turbidity currents being the more important. Mass wasting is a general term used for the failure, dislodgement, and downslope movement of sediment under the influence of gravity. Common examples of mass wasting are slides, slumps, and debris flows. Major slumping events can lead to formation of submarine canyons. The Mississippi Canyon in the Gulf of Mexico is believed to have been formed by retrogressive slumping during the late Pleistocene fall in sea level and has been partially infilled during the Holocene rise in sea level. Turbidity currents are one of the most important erosional and depositional processes in submarine canyons. There is considerable evidence to suggest that turbidity currents flow at velocities of 11–110 in./s (28–280 cm/s) in submarine canyons. Therefore, turbidity currents play a major role in the erosion of canyons. *See* DEPOSITIONAL SYSTEMS AND ENVIRONMENTS; MARINE GEOLOGY; MARINE SEDIMENTS; MASS WASTING; TURBIDITY CURRENT.

[G.Sh.]

Submillimeter astronomy Investigation of the universe by probing the electromagnetic spectrum at wavelengths from approximately 0.3 to 1.0 millimeter: the submillimeter waveband. This waveband is bounded at longer wavelengths by the millimeter waveband (1–10 mm), and at shorter wavelengths by the far-infrared waveband (20–300 micrometers). Astronomical objects with temperatures between about 10 kelvins and several hundred kelvins, typically in the interstellar medium of galaxies, emit radiation strongly in the submillimeter waveband. *See* ELECTROMAGNETIC RADIATION.

The submillimeter waveband is one of the last parts of the electromagnetic spectrum to be investigated. This is due both to the technical challenge of making sensitive detectors, which must be held at temperatures close to absolute zero, and to the effects of the Earth's atmosphere. Atmospheric molecules, primarily water vapor, both absorb (dim) the signal from astronomical sources and emit their own radiation that acts to mask the astronomical signals. The effects are most severe at the shortest wavelengths, and only high mountain sites and air or space-borne platforms can be used for submillimeter astronomy. From high mountains, observations are possible in only three atmospheric windows, at wavelengths of about 0.35, 0.45, and 0.85 mm. Radiation of 0.85 mm penetrates down to about 2 km (1.2 mi) above sea level; while on the driest nights, only about one-half of photons with wavelengths of 0.35 or 0.45 μm that enter the upper atmosphere can be detected at the 4200-m (14,000-ft) summit of Mauna Kea, Hawaii.



James Clerk Maxwell Telescope, 49-ft-diameter (15-m) submillimeter telescope situated at Mauna Kea, Hawaii.

Several submillimeter telescopes operate on high mountain tops, including the 15-m (49-ft) James Clerk Maxwell Telescope (JCMT; see illustration) and the 10.4-m (34-ft) Caltech Submillimeter Observatory (CSO) telescope, both on Mauna Kea, and the 15-m (49-ft) Swedish-ESO Submillimeter Telescope (SEST) in Chile. These telescopes look like satellite antennas, but their surfaces are smooth and precisely shaped to an accuracy of order 10 μm. These ground-based telescopes are subject to more atmospheric absorption than airborne and space telescopes; but because they have larger apertures, they can collect more radiation, boosting their sensitivity. *See* TELESCOPE.

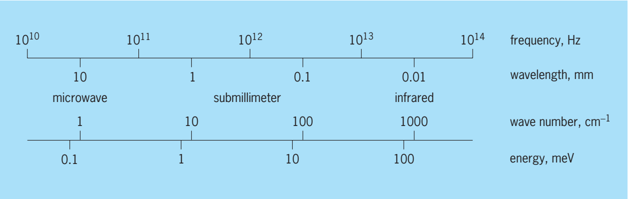
In 2005 the Stratospheric Observatory for Infrared Astronomy (SOFIA), a 2.5-m-aperture (8.2-ft) telescope in a 747 aircraft, was expected to be operating. Like the former Kuiper Airborne Observatory (KAO), SOFIA will fly at up to 14 km (9 mi) altitude. Stratospheric balloons, flying at altitudes of about 40 km (25 mi), can also be used to carry submillimeter telescopes; an example is the BOOMERANG cosmic microwave background experiment reported in 2000. *See* INFRARED ASTRONOMY.

The signals from several submillimeter telescopes can be combined together in an interferometer to provide a telescope with resolution as fine as one with an aperture as large as the greatest separation between the individual telescopes. Examples of this type of telescope are the Smithsonian Millimeter Array (SMA) on Mauna Kea, and the United States-Europe-Japan Atacama Large Millimeter Array (ALMA) under development in Chile. *See* RADIO TELESCOPE.

Submillimeter observations are used by astronomers with a wide range of interests to study matter in the universe at temperatures of about 10–100 K and the cosmic microwave background radiation. Interstellar chemistry in clouds of gas and dust, the formation of protostars embedded in stellar nurseries within the Milky Way, the properties of the interstellar medium in even the most distant galaxies, and the evolution of galaxies are all studied in the submillimeter waveband. Submillimeter observations are especially important for observations of regions that are rich in dust and gas. These are opaque to visible and infrared light, but submillimeter light can still escape, allowing these regions to be studied.

[A.Bl.]

Submillimeter-wave technology The generation, detection, and application of radiation in the submillimeter-wave region of the electromagnetic spectrum. In practical terms, this region corresponds to wavelengths between about 30 micrometers and 3 millimeters (see illustration). At its extremes the region overlaps with the microwave and infrared, and a unique feature is that the distinct propagation methods of these adjacent regions, guided-wave and free-space propagation, are used throughout it. *See* Electromagnetic radiation; Infrared radiation; Microwave.



Electromagnetic spectrum in and near the submillimeter-wave region, showing its frequency, wavelength, wave number, and photon energy equivalents.

Widespread use of the submillimeter-wave region did not occur until two revolutionary developments in the late 1950s and early 1960s: (1) the practical realization of Fourier transform spectroscopy, which led to significant improvements in the quality of broad band submillimeter-wave spectroscopy; and (2) the discovery of two reasonably intense submillimeter-wave laser sources, the hydrogen cyanide and the water-vapor electrically excited lasers. *See* Infrared spectroscopy; Laser.

Radiation sources. The main application of incoherent radiation sources is as broad band sources in Fourier transform spectrometers. The two most commonly used sources are the mercury-vapor lamp and the globar. *See* Mercury-vapor lamp; Microwave tube.

There are several categories of coherent submillimeter-wave radiation sources: (1) nonrelativistic electron-beam tubes such as klystrons, extended interaction oscillators, orotrons, ledatrons, and carcinotrons or backward-wave oscillators, which oscillate with varying amounts of tunability and output power; (2) relativistic electron-beam devices such as gyrotrons, free-electron lasers, and synchrotrons; and (3) solid-state devices such as Gunn and IMPATT oscillators. With the exception of the free-electron laser, these are long-wave devices. The final category, gas lasers, covers the entire submillimeter-wave region. *See* Gyrotron; Klystron; Microwave solid-state devices; Synchrotron radiation.

Detectors. Most submillimeter-wave detectors are either thermal, rectifying, or photon detectors. The first respond to heat generated by absorbed radiation, the second by rectification of radiation-field-induced currents, the third by absorption of individual photons. They are commonly used in direct and heterodyne detection systems. Thermal detectors include room-temperature thermopile, Golay cell, and pyroelectric detectors, while more sensitive semiconductor bolometers operate at liquid-helium temperatures. Rectifying devices include metal-semiconductor and metal-metal point contacts and Schottky barrier diodes, all room-temperature devices, and Josephson-type devices operated at about 4.2 K (−452°F). Submillimeter-wave photon detectors are based on semiconductors and rely on the absorption of a photon changing the free-carrier density or mobility and hence the conductivity of the detector. *See* Bolometer; Pyroelectricity; Radiometry; Superconducting devices.

Atmospheric transparency. Between the visible and microwave regions the atmosphere is effectively opaque, with the exception of two windows in the near-infrared and three in the submillimeter-wave region, at 94, 140, and 220 GHz. The significant feature of the submillimeter-wave windows is that the levels of attenuation involved are not as seriously increased by adverse atmospheric conditions as those of the near-infrared. This makes them attractive for many applications. The attenuation associated with these windows is, nonetheless, quite high and means that ground-level low-frequency submillimeter-wave systems have a relatively limited range. This can be advantageous for some applications.

Applications. In the past, applications of radiation in the submillimeter-wave region were distributed evenly over the region and largely concerned research activities. Now, however, as a result of developments toward integrated, inexpensive transmitter and receiver systems, applications include many radar- and telecommunications-related activities centered on the 94-GHz atmospheric window. These applications are mainly military, but spin-offs into the civil area are expected.

Photon energies in the submillimeter-wave region correspond to activation energies of many physical, chemical, and bioloical phenomena, and the spectroscopic techniques of this region have been widely applied to their study. Other spectroscopic applications have concerned the development of radiometric methods to meet the requirements of fusion plasma diagnostics and astronomy. *See* Submillimeter astronomy.

The submillimeter-wave region has been extensively used for fundamental frequency metrology, relating the frequencies of submillimeter-wave gas lasers directly back to the primary frequency standard. Important consequences have been the definition of the speed of light as a fixed quantity and the redefinition of the meter as a unit derived from it. *See* Light; Physical measurement.

The submillimeter-wave region impinges on fusion plasma research in two ways. First, in machines such as tokamaks it provides a way of studying the spatial and temporal evolution of the electron temperature. The second application is electron cyclotron heating, in which electron heating by microwave radiation at the electron cyclotron frequency has been demonstrated. High-power gyrotron oscillators are generally used as the radiation sources. *See* Nuclear fusion; Plasma (physics); Plasma diagnostics.

In the study and applications of fast electromagnetic pulse propagation, a number of novel techniques for the submillimeter-wave region have been developed. The generation and detection of such pulses can be done with ultrashort optical pulses driving photoconductive switches, or by all-electronic systems based on nonlinear transmission lines. The submillimeter-wave radiation used in these systems is variously known as T waves or terahertz waves. *See* Optical pulses.

[J.R.Bi.]

Subsonic flight Movement of a vehicle through the atmosphere at a speed appreciably below that of sound waves. Subsonic flight extends from zero (hovering) to a speed approximately 85% of sonic speed corresponding to the ambient temperature. At higher vehicle velocities the local velocity of air passing over the vehicle surface may exceed sonic speed, and true subsonic flight no longer exists.

Vehicle type may range from a small helicopter, which operates at all times in the lower range of the velocity scale, to an intercontinental ballistic missile, which is operative throughout this and other velocity regimes, but is in subsonic flight for only a few seconds. The design of each is affected by the same principles of subsonic aerodynamics. Subsonic flow of a fluid such as air may be subdivided into a range of velocities in which the flow may be considered incompressible without appreciable error (below a velocity of approximately 300 mi/h or 135 m/s), and a higher range in which the compressible nature of the fluid becomes significant. In both cases the viscosity of the fluid is important. The theories which apply to compressible, inviscid fluids may be used almost without modification in some low-subsonic problems, and in other cases the results offered by these theories may be modified to account for the effects of viscosity and compressibility. *See* COMPRESSIBLE FLOW; TRANSONIC FLIGHT; VISCOSITY.

A typical subsonic wing cross section (airfoil) has a rounded front portion (leading edge) and a sharp rear portion (trailing edge). Air approaching the leading edge comes to rest at some point on the leading edge, with flow above this point proceeding around the upper airfoil surface to the trailing edge, and flow below passing along the lower surface to the same point, where the flow again theoretically has zero velocity. The two points of zero local velocity are known as stagnation points. If the path from front to rear stagnation point is longer along the upper surface than along the lower surface, the mean velocity of flow along the upper surface must be greater than that along the lower surface. Thus, in accordance with the principle of conservation of energy, the mean static pressure must be less on the upper surface than on the lower surface. This pressure difference, applied to the surface area with proper regard to force direction, gives a net lifting force. Lift is defined as a force perpendicular to the direction of fluid flow relative to the body, or more clearly, perpendicular to the free-stream velocity vector. *See* AIRFOIL; BERNOULLI'S THEOREM.

The wing, as the lifting device, whether fixed, as in the airplane, or rotating, as in the helicopter, is probably the most important aerodynamic part of an aircraft. However, stability and control characteristics of the subsonic airplane depend on the complete structure. Control is the ability of the airplane to rotate about any of the three mutually perpendicular axes meeting at its center of gravity. Static stability is the tendency of the airplane to return to its original flight attitude when disturbed by a moment about any of the axes. [J.E.Ma.]

Substitution reaction One of a class of chemical reactions in which one atom or group (of atoms) replaces another atom or group in the structure of a molecule or ion. Usually, the new group takes the same structural position that was occupied by the group replaced.

Substitution reactions involve the attack of a reagent, which is the source of the new atom or group, on the substrate, the molecule or ion in which the replacement occurs. They involve the formation of a new bond and the breaking of an old bond. Substitution reactions are classified according to the nature of the reagent (electrophilic, nucleophilic, or radical) and according to the nature of the site of substitution (saturated carbon atom or aromatic carbon atom). *See* ELECTROPHLIC AND NUCLEOPHILIC REAGENTS.

Systematic names for substitution reactions are composed of the parts: name of group introduced + de + name of group replaced + ation, with suitable elision or change of vowels for euphony. Thus, the replacement of bromine by a methoxy group is called methoxydebromination. *See* ORGANIC REACTION MECHANISM. [J.F.B.]

Subsynchronous resonance The resonance between a series-capacitor-compensated electric system and the mechanical spring-mass system of a turbine-generator at subsynchronous frequencies. Beginning about 1950, series capacitors were installed in long alternating-current transmission lines [250 km (150 mi) or more] to cancel part of the inherent inductive reactance of the line. Until 1971, up to 70% of the 60-Hz inductive reactance was canceled by series capacitors in some long lines with little concern for side effects. (If 70% of a line's inductive reactance is canceled, the line is said to have 70% series compensation.) In 1970, and again in 1971, a turbine-generator at the Mohave Power Plant in southern Nevada experienced shaft damage that required several months of repairs on each occasion, following switching events that placed the turbine-generator radial on a series-compensated transmission line. The shaft damage was due to torsional oscillations between the two ends of the generator-exciter shaft. Shortly after the second event, it was determined that the torsional oscillations were caused by torsional interaction, which is a type of subsynchronous resonance. There have been no reported occurrences of two other types of subsynchronous resonance, the induction generator effect and torque amplification. *See* ALTERNATING-CURRENT CIRCUIT THEORY; ALTERNATING-CURRENT GENERATOR; TRANSMISSION LINES; TURBINE.

It has been clearly established that subsynchronous resonance can be controlled with the use of countermeasures, thus making it possible to benefit from the distinct advantages of series capacitors. About a dozen countermeasures have been successfully applied such that there has been no reported subsynchronous resonance event since 1971. Subsynchronous resonance countermeasures protect turbine-generator shafts from harmful torsional oscillations by one of two methods. First, the turbine-generator can be tripped when a subsynchronous resonance condition is detected. This limits the number of torsional oscillations experienced by the turbine-generator shafts. This type of countermeasure is relatively inexpensive but is not acceptable if the anticipated subsynchronous resonance conditions are expected to occur frequently. Generally, such a countermeasure will not be applied as the sole subsynchronous resonance protection if it is expected to cause a turbine-generator to be tripped more than once every 10 years. Three types of tripping countermeasures are applied: torsional motion relay, armature current relay, and the generator tripping logic scheme. The second method of protection does not involve turbine-generator tripping, but eliminates or limits harmful torsional oscillations. *See* ELECTRIC POWER SYSTEMS. [R.G.F.]

Subtraction One of the four fundamental operations of arithmetic and algebra. Subtraction is often regarded as an operation inverse to addition, that is, if a and b are numbers, the number $a - b$ is defined as that number which added to b gives a. The more modern viewpoint eliminates subtraction completely by considering the number $a - b$ as the sum of a and that number (denoted by $-b$) which added to b gives 0. The number symbolized by $-b$ is called the inverse of b (with respect to addition). Every real number has a unique inverse (the number 0 is its own inverse). In this sense "subtraction" may be performed on objects of many different kinds, and the original numerical operation greatly extended. *See* ADDITION; ALGEBRA; DIVISION; MULTIPLICATION; NUMBER THEORY. [L.M.Bl.]

Subway engineering The branch of transportation engineering that deals with feasibility study, planning, design, construction, and operation of subway (underground railway) systems. In addition to providing rapid and comfortable service, subways consume less energy per passenger carried in comparison with other modes of transportation such as automobiles and buses. They have been adopted in many cities as a primary mode of transportation to reduce traffic congestion and air pollution.

Subways are designed for short trips with frequent stops, compared to above-ground, intercity railways. Many factors considered in the planning process of subway systems are quite similar to those for railway systems. Subway system planning starts with a corridor study, which includes a forecast of ridership and revenues, an estimation of construction and operational costs, and a projection of the potential benefits from land development. *See* RAILROAD ENGINEERING; TRANSPORTATION ENGINEERING.

All subway systems have three major types of structures: stations, tunnels, and depots. The most important task in planning a new subway system or a new subway line is to locate stations and depots and to determine the track alignment. Subway lines are normally located within the right-of-way of public roads and as far away as possible from private properties and sites of importance. Because stations and entrances are usually located in densely populated areas, land acquisition is often a major problem. One solution is to integrate entrances into nearby developments such as parks, department stores, and public buildings, which lessens the visual impact of the entrances and reduces their impediment to pedestrian flow.

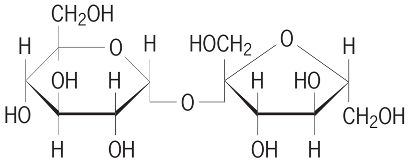
Design of the permanent works includes structural and architectural elements and electrical and mechanical facilities. There are two types of structures: stations and tunnels. For stations, space optimization and passenger flow are important. The major elements in a typical station are rails, platform, staircases, and escalators. For handicapped passengers, provisions should be made for the movement of wheelchairs in elevators and at fare gates, and special tiles should be available to guide the blind to platforms.

In both stations and tunnels, ventilation is essential for the comfort of the passengers and for removing smoke during a fire. Sufficient staircases are required for passengers to escape from the station platform to a point of safety in case of a fire. The electrical and mechanical facilities include the rolling stock, signaling, communication, power supply, automated fare collection, and environmental control (air-conditioning) systems. Corrosion has caused problems to structures in some subways; therefore, corrosion-resistant coatings may be required. To minimize noise and vibration from running trains, floating slabs can be used under rails or building foundations in sections of routes crossing densely populated areas and in commercial districts where vibration and secondary airborne noise inside buildings are unacceptable. *See* Ventilation.

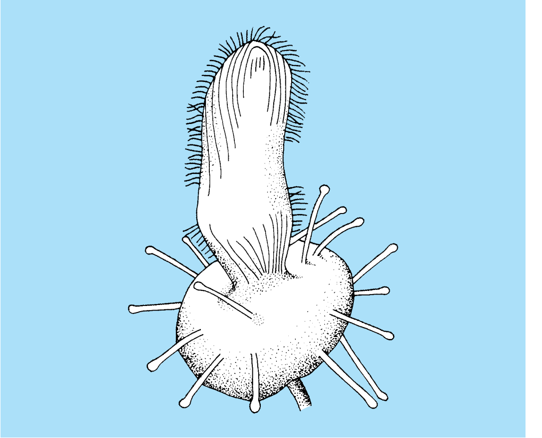
Underground stations are normally constructed by using an open-cut method. For open cuts in soft ground, the sides of the pits are normally retained by wall members and braced using struts. The pits are fitted with decks for maintaining traffic at the surface. For new lines that pass under existing lines, it is not possible to have open cuts. In such cases, stations have to be constructed using mining methods (underground excavation). *See* Tunnel.

Many modern subway systems are fully automated and require only a minimal staff. Train movements are monitored and regulated by computers in a control center. Therefore, engineering is limited to the function and maintenance of the electrical and mechanical facilities. The electrical and mechanical devices requiring constant care include the rolling stock, signaling, communication and broadcasting systems, power supply, elevators and escalators, automated fare collection, and environmental control systems. Also included are depot facilities, and station and tunnel service facilities. *See* Electric distribution systems; Railroad control systems. [Z.C.M.; R.N.Hw.]

Sucrose An oligosaccharide, α-D-glucopyranosyl-β-D-fructofuranoside, also known as saccharose, cane sugar, or beet sugar. The structure is shown below. Sucrose is very soluble in water and crystallizes from the medium in the anhydrous form. The sugar occurs universally throughout the plant kingdom in fruits, seeds, flowers, and roots of plants. Honey consists principally of sucrose and its hydrolysis products. Sugarcane and sugarbeets are the chief sources for the preparation of sucrose on a large scale. Another source of commercial interest is the sap of maple trees. *See* Oligosaccharide; Sugarbeet; Sugarcane. [W.Z.H.]



Suctoria A small specialized subclass of the protozoan class Ciliatea whose members were long considered entirely separate from the "true" ciliates. The sole order of this subclass is Suctorida. These forms show a number of highly specialized features. Most conspicuous are their tentacles, often numerous, which serve as mouths. These multiple organelles of ingestion fasten to the pellicle of prey organisms, generally passing ciliates. By forces not entirely understood, the tentacles are used to suck out the prey's protoplasm to provide sustenance for the suctorian. Nearly all species are stalked, and the sedentary, mature forms are devoid of any external ciliature. Young larval forms are produced by both endogenous and exogenous budding. These forms bear locomotor cilia and serve, as in the case of species of the Peritrichia, for dissemination (see illustration). *See* Ciliatea; Peritrichia. [J.O.C.]



Endogenous budding in the suctorian *Podophrya*, a species which measure 10–28 micrometers.

Sudangrass An annual, warm-season grass of tropical origin said to have been grown in Egypt since early times, though its value was first recognized in Sudan only in 1909. In that same year it was introduced into the United States as a replacement for johnsongrass, which had become a noxious weed in many southern states. Sudangrass (*Sorghum bicolor* var. *sudanense*, also called *S. sudanense* and *S. vulgare* var. *sudanense*) and its hybrids are commonly used as pasture, greenchop, silage, or hay. They fill an important need in many regions of the United States, because they produce high-quality forage for cattle and sheep during the summer, when other pasture is in short supply or of low quality. Many of the varieties and hybrids produce forage until frost. *See* Grass. [M.R.G.]

Sudden infant death syndrome (SIDS) The sudden and unexpected death of an apparently normal infant that remains unexplained after an adequate autopsy. Of a group of apparently healthy infants dying suddenly and unexpectedly, 15% will usually manifest pathologic evidence of a disease process which is sufficient to explain the death. The remaining 85% are unexplained and are classified as SIDS. In spite of the probable heterogeneity of diseases in SIDS cases, the consistent and distinctive characteristics of these infant deaths support the notion that many, if not the majority, represent a single disease process.

The incidence of SIDS in the United States is about 2.0 cases per 1000 live births, which makes SIDS the leading cause of death between the ages of 1 month and 1 year. Most SIDS deaths occur at 2–4 months of age, and about 90% occur by 6 months. SIDS is more common in males, prematurely born infants, multiple births, and the economically disadvantaged. SIDS is also increased in infants of teen-age or smoking mothers and in infants who have a history of a severe apparent life-threatening event, usually accompanied by marked cyanosis or pallor and limpness, and absence of breathing. SIDS also occurs more frequently during winter months. The rate among Native Americans is greater than among Blacks, which is greater than among Caucasians; Asians have the lowest rate. While there is slight familial clustering of SIDS, there is probably not a genetic predisposition to SIDS.

The cause of SIDS is unknown; leading hypotheses include respiratory, cardiac, and metabolic mechanisms. Much attention has been focused on the "apnea hypothesis," implicating a primary respiratory arrest due to chronic or transient insufficiency or irregularity of breathing. An imbalance between sympathetic and parasympathetic influences on cardiac activity, leading to potentially fatal cardiac arrhythmias, is a popular cardiac hypothesis.

While there is still no proof that SIDS can be prevented, electronic cardiorespiratory monitors have been prescribed for many infants in high-risk categories for SIDS. Home monitors are recommended only for infants at very high risk for SIDS. *See* Congenital anomalies; Human genetics. [A.St.; K.Wi.; J.G.Br.]

Sugar Usually, sucrose, the common sugar of commerce. This sugar is a disaccharide, $C_{12}H_{22}O_{11}$, which is split, as shown in the reaction below, by hydrolysis into two monosaccharides,

$$\underset{\text{Sucrose}}{C_{12}H_{22}O_{11}} + \underset{\text{Water}}{H_2O} \rightarrow \underset{\text{Glucose}}{C_6H_{12}O_6} + \underset{\text{Fructose}}{C_6H_{12}O_6}$$

or simple sugars: glucose (dextrose) and fructose (levulose). Sucrose rotates the plane of polarized light to the right, as does glucose, but fructose is so strongly levorotatory that it overcomes the effect of glucose. Thus mixtures of equal amounts of glucose and fructose are levorotatory. The hydrolytic reaction is called inversion of sugar, and the product is invert sugar or, simply, invert. *See* Carbohydrate; Optical activity.

Sucrose is widely distributed in nature, having been found in all green plants that have been carefully examined for its presence. The total quantity of all sugars formed each year has been estimated at a colossal 4×10^{11} tons (3.6×10^{11} metric tons). In spite of its availability in all green plants, sucrose is obtained commercially in substantial amounts from only two plants: sugarcane, which supplies about 56% of the world total, and the sugarbeet, which provides 44%.

Cane sugar manufacture. The manufacture of cane sugar is usually done in two series of operations. First, raw sugar of about 98% purity is produced at a location adjacent to the cane fields. The raw sugar is then shipped to refineries, where a purity that is close to 100% is achieved.

Raw cane sugar. The production of raw cane sugar begins with growing the cane in tropical or subtropical areas. The cane is harvested after a season varying from 7 months in subtropical areas to 12–22 months in the tropics. The cane stalks are harvested either mechanically or by heavy hand knives. The trend is toward mechanization. The stalks are transported to a mill by oxcart, rail, or truck. *See* Sugarcane.

At the mill the stalks are crushed and macerated between heavy grooved iron rollers while being sprayed countercurrently with water to dilute the residual juice. The expressed juice contains 95% or more of the sucrose present. The fibrous residue, or bagasse, is usually burned under the boilers, although increasing amounts are being made into paper, insulating board, and hardboard as well as furfural, which is a chemical intermediate for the synthesis of furan and tetrahydrofuran.

Cane juice. The cane juice is treated with lime to bring its pH to about 8.2. This pH prevents the inversion reaction, which is favored by heat and acid and would lower the yield of crystallizable sugar. The juice is then heated to facilitate the precipitation of impurities, which are removed by continuous filtration.

The purified juice is concentrated by multiple-stage vacuum evaporation (usually four or five stages) and, when sufficiently concentrated, is boiled to grain or seeded with sucrose crystals in a single-stage vacuum pan. Usually three successive crops of crystals are grown, cooled, and centrifuged. The final mother liquor, which is resistant to further crystallization, is called blackstrap molasses. It is used principally as a feed for cattle. Relatively small amounts are still fermented to produce industrial alcohol and rum.

Raw cane sugar refining. The refining of raw sugar begins with dissolution of the molasses which remains in a thin film on the crystals in spite of the centrifugation. This step, called affination, brings the purity from about 98 to about 99%. The crystals are dissolved in hot water and percolated through bone char columns to remove color by adsorption. The sucrose is finally concentrated by vacuum evaporation, crystallized by seeding, centrifuged, and dried.

A major step forward has been the use of bone char in a continuous countercurrent manner (Grosvenor patent). The bone char is washed, dried, and burned to remove impurities; it is reused until it wears out mechanically and is discarded as fines. Even the fines have value as fertilizer because of their high calcium phosphate content.

Bone char has been replaced in some refineries by granular carbon derived from coal or wood waste. It is used in columns and regenerated by a process similar to the one used for bone char, which unlike granular carbon is primarily calcium phosphate. Granular carbon is frequently used in combination with decolorizing resins to reduce the color of process liquors coming from the carbon columns. Pulverized activated vegetable carbon is used in a few instances to remove color from raw sugar liquors, but its use is declining. Ion-exchange resins are used to remove ash from raw sugar liquors, especially when the liquor is to be converted directly into refined liquid sugar without going through the crystallization step first. *See* Ion exchange.

Beet sugar. In the United States, sugarbeets are grown under contract by farmers from seed supplied by a beet sugar company. Because sugarbeets, like the other temperate-zone crops, thrive best under crop rotation, they are not well adapted to one-crop agriculture. *See* Sugarbeet.

Beet processing. When beets are delivered to a factory, they are washed and sliced, and the slices are extracted countercurrently with hot water to remove the sucrose. The resulting solution is purified by repeatedly precipitating calcium carbonate, calcium sulfite, or both, in it. Colloidal impurities are entangled in the growing crystals of precipitate and removed by continuous filtration. The resulting solution is nearly colorless, and the sucrose is concentrated by multiple-effect vacuum evaporation. The syrup is seeded, cooled, and centrifuged, and the beet sugar crystals are washed with water and dried.

Beet molasses differs from cane molasses in having a much lower content of invert sugar. It is, therefore, relatively stable to the action of alkali and, in the United States, is usually treated with calcium oxide to yield a precipitate of calcium sucrate. This is a mixture of loose chemical aggregates of sucrose and calcium oxide which are relatively insoluble in water. The precipitate is filtered, washed, and added to the incoming crude sugar syrup, where it furnishes calcium for the precipitations of calcium carbonate and sulfite referred to above, which remove impurities. Carbon dioxide in the form of flue gas is the other reagent, and sulfur dioxide from burning sulfur is used to produce sulfite. Ion exclusion processes have been developed for recovery of sucrose from beet molasses.

Beet residue use. The beet tops and extracted slices, as well as the molasses, are valuable as feeds. More feed for cattle and other ruminants can be produced per acre-year from beets than from any other crop widely grown in the United States. This is independent of the food energy in the crystallized sucrose, which exceeds that available from any other temperate-zone plant. It is for these reasons that the densely populated countries of Europe have expanded their beet sugar production, in spite of the ready availability of cane sugar from the tropics.

The increased use of nitrogenous fertilizer has resulted in augmenting the protein content of the molasses and other beet byproducts.

Nutritional value. Sucrose has, in the past, been attacked by some nutritionists on the ground that it provides only "empty calories," without protein, minerals, or vitamins. This argument lost much of its force when it was shown that all the vitamins and minerals recommended by the National Research Council can be obtained by consuming any of a great variety of foods in amounts that yield a total of only one-half of the caloric requirements of an average person. The wide use by the public of vitamin supplements has caused some nutritionists to express an opposite worry over excessive vitamin consumption.

In addition to the charges that it provides empty calories, sugar has been blamed for such health problems as diabetes mellitus, coronary heart disease, dental caries, and obesity. These charges and the scientific evidence associated with them have been extensively reviewed by a special committee of the Federation of American Societies for Experimental Biology. A report of the committee findings, published by the Food and Drug Administration in 1976, includes the following: Sucrose is a contributor to the formation of dental caries when used at levels and in the manner prevailing in 1976; otherwise, there is no clear evidence in the available information that demonstrates a hazard to the public when sucrose is used at those levels.

Other sources of sugars. In Hawaii, the pineapple industry recovers both sucrose and citric acid from the rinds. The residue is fed to cattle. The total quantity of sucrose obtained from waste fruits is statistically negligible. On the other hand, a substantial fraction of the total sucrose consumed is that naturally present in a large number of fruits, vegetables, and nuts. *See* SUCROSE; SUGAR CROPS.

Lactose. Cow's milk, on a dry basis, is about 38% lactose or milk sugar. When milk is converted into cheese, the lactose remains in the whey, from which it may easily be isolated and purified. Lactose is a disaccharide which is split by hydrolysis into glucose and galactose. Lactose is about one-tenth as soluble in water as sucrose and it is one-sixth to one-half as sweet, depending on the concentration. Some of the major uses for lactose are as a direct-compression vehicle for the manufacture of pharmaceutical tablets and as a diluent for pharmaceuticals and synthetic sweeteners. *See* CHEESE; LACTOSE.

Starch. Starches can be hydrolyzed either by dilute acid or by enzymes. The product of acid hydrolysis varies with time and conditions but contains glucose, maltose, maltotriose, maltotetrose, and other sugars up to the dextrins. Only glucose, a monosaccharide, is readily isolated. Crystallized as the monohydrate, it is used in foods as a sweetener. *See* CORN; GLUCOSE.

Syrups high in maltose, a disaccharide, can be obtained by the action of amylases on starch. This hydrolysis has been of great importance for thousands of years in splitting starches for alcoholic fermentation. As yet, there is no large-scale production of pure maltose. *See* MALTOSE.

A major type of syrup was developed from starch hydrolyzates by the mid-1980s. An enzyme that isomerizes dextrose (glucose) was commercially developed to manufacture hydrolyzed starch syrups (corn syrups) containing varying amounts of fructose (levulose). The enzyme isomerizes dextrose into fructose theoretically to a 50-50 mixture of dextrose and fructose. In practice, the isomerization is allowed to progress until a syrup containing (on a solids basis) approximately 50% dextrose, 42% fructose, and 8% higher saccharide is achieved. Syrups containing more than 42% fructose (solid basis) can be made by subjecting the 42% fructose syrup to an ion-exclusion process that separates dextrose and fructose. The fructose-rich fraction from the separation is converted into a finished product, and the dextrose-rich fraction is returned to the isomerization process. Commercially produced syrups contain 42% or 55% fructose. The combined processes are also used to manufacture commercial fructose. The high-fructose corn syrups are competitive with sucrose and invert sugar in a variety of food products. The most widely used application for 55% high-fructose corn syrup is in soft drinks, displacing sucrose and invert sugar. *See* FRUCTOSE; STARCH.

Maple sugar. Before America was settled by Europeans, Indians were collecting and concentrating the juice of the hard maple (*Acer saccharum*), making maple syrup. The practice was copied by the new settlers, and production of maple syrup has been an industry ever since in the regions where hard maples are common, principally the northeastern United States.

The maple flavor does not exist in the sap but is developed by heating it. By additional heating at about 250°F (120°C), a flavor four or five times more intense can be developed. Maple syrup so produced is of special value for adding flavor to the less expensive products of the sucrose industry. Maple sugar is sucrose of about 95–98% purity; the characteristic flavor makes up only a small percent. Fairly satisfactory imitation maple flavors are available.

Honey. Honey is a form of relatively pure invert sugar dissolved in water to form a concentrated solution. However, honey also contains flavors derived from the nectar of the flowers from which it was obtained by the bee. Nutritionally, it is nearly equivalent in invert sugar but contains an excess of fructose over glucose. The sucrose found in the flowers is inverted by the enzyme honey invertase. Tupelo honey is remarkable in containing about twice as much fructose as glucose, and hence has little tendency to deposit glucose crystals.

The ready availability of the food energy in honey was known to athletes in ancient Greece. Only in recent times has it been discovered that, paradoxically, the energy of sucrose is still more quickly available. The flavors of various honeys run a wide gamut. That from the Mount Hymettus region, which is flavored by wild thyme, has been known and treasured since the poems of Homer.

Molasses. Virtually all molasses is distributed in the form of a concentrated viscous solution, but it can be reduced to a powder by means of spray-drying. It can then be handled without an investment by the consumer in tanks, pipes, and pumps. Unfortunately, later contact with moisture converts the dried molasses to a gummy mass. The availability of vaporproof bags (for example, those lined with polyethylene) has provided one solution to this problem. There are also various additives which, when mixed with molasses, reduce its tendency to pick up moisture. So far, dried molasses has made little headway against the practice of handling concentrated solutions.

Syrups. Syrups are relatively concentrated, somewhat viscous, solutions of various sugars, frequently in admixture to hinder crystallization. Large amounts of sucrose have been distributed in the form of high-purity syrups. These syrups consist of sucrose, invert sugar, or both. In some instances syrups include mixtures with dextrose and various corn syrups. The so-called liquid sugars are important for several reasons: the requirement for the use of syrups in a number of food processes (conversion of granular sucrose to a syrup was eliminated at the point of use); economy of handling, being moved with pumps, pipes, tank trucks, and tank cars; the high degree of sanitation inherent in the storage and distribution of sugar within the plant in a closed system, including the elimination of dust from the dumping of bags; and the availability of a combination of sugars with differing characteristics in a single product.

The quantity of sucrose distributed in syrup form has been reduced drastically because of the inroads made by high-fructose corn syrups, which have a composition somewhat comparable to that of invert sugar. These products are available only as syrups. They do not have taste characteristics identical to sucrose and invert sugar syrups, but lower prices catalyze their substitution for sucrose.

It is the aim of the sugar refiner and the beet processor to eliminate color and all flavors other than sweetness. The manufacture of table syrups, which are widely used on waffles and pancakes, aims at a broader spectrum of flavor. Corn syrup, which is somewhat lacking in sweetness, ordinarily has about 15% sucrose added. The high viscosity of the corn syrup, resulting from the content of dextrins, tends to hinder crystallization and is an advantage in the manufacture of certain candies.

Some sugar refiners manufacture so-called refiners' syrups for use in the manufacture of foods and table syrups. In addition to these syrups, a group of products generally referred to as cane syrup and edible molasses are manufactured from cane juice. Cane syrup is concentrated whole cane juice, while edible molasses is concentrated cane juice from which some sugar has been removed by crystallization. These syrups and molasses contain both sucrose and invert sugar, and have a relatively dark color and a distinctive flavor. They also contain many of the nonsugars found in sugarcane juice. They are used principally by food processors, but substantial amounts are packaged for home use. Sorghum syrup is made by extracting juice from the stalk of sweet sorghum and evaporating the juice to syrup consistency. It is a dark, pungently flavored product that is not widely distributed. *See* FOOD ENGINEERING; FOOD MANUFACTURING; SUGAR CROPS. [H.B.H; Ch.B.B.]

Sugarbeet The plant *Beta vulgaris*, developed in modern times to fill the need for a sugar crop that could be grown in temperate climates. The sugarbeet was the source of only 5% of the world's commercial sugar in 1840, but by 1890 it supplied almost 50%, and since about 1920 this has dropped to about 40% with 60% derived from sugarcane. European countries produce most of their sugar from sugarbeet, with some countries having surplus sugar for export. *See* SUGARCANE.

The sugarbeet, fodder beet, garden beet, and leaf beet (Swiss chard) are cultivars of *B. vulgaris* and are genetically related. In addition to *B. vulgaris*, which includes all cultivated forms of beet, there are 12 species of wild beet in the Mediterranean and Middle Eastern regions. These wild beets are of interest in sugarbeet improvement as sources of disease resistance. Most varieties of sugarbeet in the United States are hybrid. [D.Ste.]

Sugarcane *Saccharum officinarum*, a member of the grass family. This crop originated in New Guinea about 15,000–8000 B.C., and was later moved by primitive peoples westward into Southeast Asia and India and eastward into Polynesia. Most current commercial varieties are interspecific hybrids involving primarily two or more of the following species: *S. officinarum*, *S. robustum*, and *S. spontaneum*.

Sugar is generally removed from sugarcane in large factories by either milling or diffusion. Milling crushes the stalks as they pass between a series of large metal rollers separating the fiber (bagasse) from the juice laden with sugar. The diffusion process separates sugar from finely cut stalks by dissolving it in hot water or hot juice. Processing of the juice is completed by clarification to remove nonsugar components, by evaporation to remove water, and by removal of molasses in high-speed centrifuges to produce centrifugal sugar. Bagasse and molasses are the principal by-products from processing sugarcane. [R.E.Co.]

Sulfide phase equilibria The chemistry of the sulfides is rather simple inasmuch as most sulfide minerals involve only two major elements, although some involve three, and a few four. Understanding of the phase relations among these minerals is important both to the geologist, whose task it is to locate and exploit ore deposits, and to the metallurgist, whose task it is to extract the metals from the ores for industrial use.

Sulfide ore deposits are the most important sources of numerous metals such as lead, zinc, copper, nickel, cobalt, and molybdenum. In addition, sulfide ores provide substantial amounts of noble metals such as platinum, gold, and silver, and of other industrially important elements such as cadmium, rhenium, and selenium. Although iron sulfides usually are the most common minerals in such deposits, most commercial iron is mined from iron oxide ores and most sulfur from elemental sulfur deposits.

Common sulfide minerals

Mineral name	Chemical formula
Pyrite	FeS_2
Pyrrhotites (three or more varieties)	$Fe_{1-x}S$
Covellite	CuS
Digenite	Cu_9S_5
Chalcocite	Cu_2S
Bornite	Cu_5FeS_4
Chalcopyrite	$CuFeS_2$
Cubanite	$CuFe_2S_3$
Galena	PbS
Sphalerite and wurtzite	ZnS
Metacinnabar and cinnabar	HgS
Argentite and acanthite	Ag_2S
Molybdenite	MoS_2
Millerite	NiS
Pentlandite	$(Fe,Ni)_9S_8$

Some of the more common sulfide minerals are listed in the table. The first eight sulfide minerals listed may be plotted in the ternary system copper-iron-sulfur. Similarly, the first two and the last two minerals may be plotted in the ternary system iron-nickel-sulfur. Thus, by studying in detail the phase equilibria in two ternary systems a great deal of information can be obtained about many of the common sulfides occurring in ore deposits. However, before the ternary systems can be explored in a systematic way, the binary systems bounding the ternaries have to be studied in detail. Similarly, it is necessary that the four bounding ternary systems be fully understood before a quaternary system can be systematically investigated. Thus, it is seen that before a systematic study of, for example, the immensely important quaternary system copper-iron-nickel-sulfur can proceed, much preliminary information is required. The prerequisite data include complete knowledge of the four ternary systems Cu-Fe-S, Cu-Fe-Ni, Fe-Ni-S, and Cu-Ni-S. In turn, the phase relations in these ternary systems cannot be systematically studied before the six binary systems Fe-Cu, Fe-Ni, Cu-Ni, Fe-S, Cu-S, and Ni-S have been thoroughly explored. *See* PHASE EQUILIBRIUM.

The enormous differences in the vapor pressures over the different phases occurring in sulfide systems add complications to the diagrammatic representation. For instance, in the Fe-S system the vapor pressure over pure iron is about 10^{-25} atm (10^{-20} pascal) at 450°C (840°F), whereas that over pure sulfur is a little more than 1 atm (10^5 pascals) at the same temperature. A complete diagrammatic representation of the relations in such a system, therefore, requires coordinates for composition and temperature, as well as for pressure. In a two-component system, such as the Fe-S system, such a representation is feasible because only three coordinates are necessary. However, in ternary (where such diagrams involve four-dimensional space) and in multicomponent systems, this type of diagrammatic representation is not possible. For this reason it is customary to use composition and temperature coordinates only for the diagrammatic representation of sulfide systems. The relations as shown in such diagrams in reality represent a projection from composition-temperature-pressure space onto a two-dimensional composition-temperature plane or onto a three-dimensional prism, depending upon whether the system contains two or three components.

Pyrite or pyrrhotite, or both, occur almost ubiquitously, not only in ore deposits but in nearly all kinds of rocks. Of the binary systems mentioned above, therefore, the iron-sulfur system is of the most importance to the economic geologist. *See* PYRITE. [G.Kul.]

Sulfonamide One of the group of organosulfur compounds, RSO_2NH_2. Many sulfonamides, which are the amides of sulfonic acids, have the marked ability to halt the growth of bacteria. The therapeutic drugs of this group are known as sulfa drugs. *See* ORGANOSULFUR COMPOUND.

The antibacterial spectrum of sulfonamides comprises a wide variety of gram-positive and gram-negative bacteria, including staphylococci, streptococci, meningococci, and gonococci, as well as the gangrene, tetanus, coli, dysentery, and cholera bacilli. They have only slight activity against *Mycobacterium tuberculosis*, while certain closely related sulfones are quite active against

M. leprae. The use of sulfonmethoxine has proved to be effective in the treatment of chloroquine-resistant malaria. The relative potency of sulfonamides against the different microorganisms varies, and their action is bacteriostatic rather than bactericidal.

The antibacterial effect, both in patients and in test tube cultures, is antagonized by *p*-aminobenzoic acid (PABA) and PABA-containing natural or synthetic products, such as folic acid and procaine. Accordingly, the mode of action of sulfonamides is considered to be an antimetabolite activity, dependent upon the inhibition of enzyme systems involving the essential PABA. *See* BACILLARY DYSENTERY; CHOLERA; LEPROSY; MALARIA; MENINGOCOCCUS; STAPHYLOCOCCUS; STREPTOCOCCUS; TETANUS; TUBERCULOSIS.

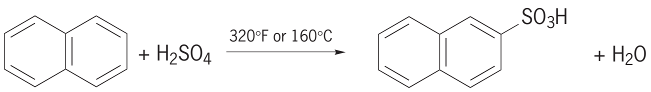
Bacterial resistance has developed to all known sulfonamides, and many sulfonamide-resistant strains are encountered among the gram-positive and gram-negative bacteria. The emergence of resistance to sulfonamides, however, seems less rapid and less widespread than resistance to most antibiotics.

Sulfonamides are used today mostly as auxiliary drugs or in combination with antibiotics. In certain infectious diseases, however (for instance, in meningococcal infections and most infections of the urinary tract), sulfonamides deserve preference over antibiotics. *See* ANTIMICROBIAL AGENTS; DRUG RESISTANCE.

[R.L.M.; E.Gru.]

Sulfonation and sulfation Sulfonation is a chemical reaction in which a sulfonic acid group, —SO_3H, is introduced into the structure of a molecule or ion in place of a hydrogen atom. Sulfation involves the attachment of the —OSO_2OH group to carbon, yielding an acid sulfate, $ROSO_2OH$, or of the —SO_4— group between two carbons, forming the sulfate, $ROSO_2OR$.

Sulfonation of aromatic compounds is the most important type of sulfonation. This is accomplished by treating the aromatic compound with sulfuric acid, as in the reaction below. The product of sulfonation is a sulfonic acid.



Napthalene

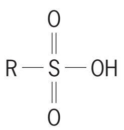
β-Napthalenesulfonic acid

Sulfonation may also be defined as any chemical process by which the sulfonic acid group, —SO_2OH, or the corresponding salt or sulfonyl halide group, for example, —SO_2Cl, is introduced into an organic compound. These groups may be bonded to either a carbon or a nitrogen atom. The latter compounds are designated *N*-sulfonates or sulfamates.

Most sulfonates are employed as such in acid or salt form for applications where the strongly polar hydrophilic —SO_2OH group confers needed properties on a comparatively hydrophobic nonpolar organic molecule. Some sulfonates, such as methanesulfonic and toluenesulfonic acids, are used as catalysts. The major quantity of sulfonates and sulfates is both marketed and used in salt form. This category includes detergents; emulsifying, demulsifying, wetting, and solubilizing agents; lubricant additives; and rust inhibitors. *See* ORGANOSULFUR COMPOUND; SUBSTITUTION REACTION.

[P.H.G./R.S.K.]

Sulfonic acid A derivative of sulfuric acid ($HOSO_2OH$) in which an OH has been replaced by a carbon group, as shown in the structure below. Sulfonic acids are strongly acidic,



$$R-\overset{\overset{\displaystyle O}{\|}}{\underset{\underset{\displaystyle O}{\|}}{S}}-OH$$

water-soluble, nonvolatile, and hygroscopic; they do not act as oxidizing agents and are typically highly stable compounds. Sulfonic acids rarely occur naturally. An exception, taurine, $NH_2CH_2CH_2SO_3H$, occurs in bile.

The aliphatic sulfonic acids are generally made by oxidation of thiols. Several have unique properties. For example, trifluoromethanesulfonic acid, CF_3SO_3H, is such a strong acid that it will protonate sulfuric acid. A compound derived from natural camphor, 10-camphorsulfonic acid, is used extensively in the optical resolution of amines.

Aromatic sulfonic acids are much more important than those of the aliphatic series. Aromatic sulfonic acids are produced by sulfonation of aromatic compounds with sulfuric acid or fuming sulfuric acid. Sulfonation of aromatic hydrocarbons is a reversible process; treatment of an aromatic sulfonic acid with superheated steam removes the —SO_3H group. This process can be used in purifying aromatic hydrocarbons. Aromatic sulfonic acids and their derivatives, especially metal salts, are important industrial chemicals. *See* SULFURIC ACID.

The most extensive use of the sulfonation reaction is in the production of detergents. The most widely used synthetic detergents are sodium salts of straight-chain alkylbenzenesulfonic acids. *See* DETERGENT.

Sulfonated polymers, particularly sulfonated polystyrenes, act as ion-exchange resins which have important applications in water softening, ion-exchange chromatography, and metal separation technology. Both sulfonated polymers and simple aromatic sulfonic acids, particularly *p*-toluenesulfonic acid, are frequently used as acid catalysts in organic reactions such as esterification and hydrolysis. *See* HOMOGENEOUS CATALYSIS; ION EXCHANGE.

The sulfonic group, in either acid or salt form, is capable of making many substances water soluble, increasing their usefulness. This application is particularly significant in the dying industry, in which a majority of the dyes are complex sodium sulfonates. Many acid-base indicators are soluble due to the presence of a sodium sulfonate moiety. Some pigments used in the paint and ink industry are insoluble metal salts or complexes of sulfonic acid derivatives. Most of the brighteners used in detergents compounded for laundering are sulfonic acid derivatives of heterocyclic compounds. *See* ACID-BASE INDICATOR; DETERGENT; DYE; INK; ORGANOSULFUR COMPOUND; PAINT.

[C.R.J.]

Sulfur A chemical element, S, atomic number 16, and atomic weight 32.064. The atomic weight reflects the fact that sulfur is composed of the isotopes ^{32}S (95.1%), ^{33}S (0.74%), ^{34}S (4.2%), and ^{36}S (0.016%). The ratios of the various isotopes vary slightly but measurably according to the history of the sample. By virtue of its position in the periodic table, sulfur is classified as a main-group element. *See* PERIODIC TABLE.

The chemistry of sulfur is more complex than that of any other elemental substance, because sulfur itself exists in the largest variety of structural forms. At room temperature, all the stable forms of sulfur are molecular; that is, the individual atoms aggregate into discrete molecules, which in turn pack together to form the solid material. In contrast, other elements near sulfur in the periodic table normally exist as polymers (silicon, phosphorus, arsenic, selenium, tellurium) or as diatomic molecules (oxygen, nitrogen, chlorine). Selenium and phosphorus can exist as molecular solids, but the stable forms of these elements are polymeric.

At room temperature the most stable form of sulfur is the cyclic molecule S_8. The molecule adopts a crownlike structure, consisting of two interconnected layers of four sulfur atoms each. The S—S bond distances are 0.206 nanometer and the S—S—S bond angles are 108°. Three allotropes are known for cyclo-S_8. The most common form is orthorhombic α-sulfur, which has a density of 2.069 g/cm^3 (1.200 oz/in.^{3}) and a hardness of 2.5 on the Mohs scale. It is an excellent electrical insulator, with a room temperature conductivity of 10^{18} ohm^{-1} cm^{-1}. Sublimed sulfur and "flowers" of sulfur are generally composed of α-S_8. Sulfur is quite soluble in carbon disulfide (CS_2; 35.5/100 g or 1.23 oz/3.52 oz at 25°C or 77°F), poorly soluble in alcohols, and practically insoluble in water. At 95.3°C (203°F), sulfur changes into the monoclinic β allotrope. This form of sulfur also consists of cyclic S_8 molecules, but it has a slightly lower density at 1.94–2.01 g/cm^3 (1.12–1.16 oz/in.^{3}). A third allotrope containing S_8 is triclinic γ-sulfur. The β and γ allotropes of sulfur slowly revert to the α form at room temperature. Crystals of sulfur are yellow and have an absorption maximum in the ultraviolet at 285 nm, which shifts to higher energy as the temperature decreases. At low temperatures, S_8 is colorless. Even at room temperature, however, finely powdered sulfur can appear to be nearly white.

The best-studied system is α-S_8, which converts to the β form at 90°C (194°F), which then melts at 120°C (248°F) to give a golden yellow liquid. If this melt is quickly recooled, it refreezes at 120°C (248°F), thus indicating that it consists primarily of S_8 molecules. If the melt is maintained longer at 120°C (248°F), then the freezing point is lowered about 5°C (9°F), indicating the formation of about 5% of other rings and some polymer. At 159.4°C (318.9°F), the melt suddenly assumes a red-brown color. Over the range 159.4–195°C (318.9–383°F), the viscosity of the melt increases 10,000-fold before gradually decreasing again. This behavior is very unusual, since the viscosity of most liquids decreases with increasing temperature. The strong temperature dependence of the viscosity is due to the polymerization and eventual depolymerization of sulfur. Polymeric sulfur retains its elastomeric character even after being cooled to room temperature. There are several polymeric forms of sulfur, but all of them revert to α-S_8 after a few hours.

Sublimination of S_8 occurs when it is maintained in a vacuum at a temperature below its melting point. It vaporizes at 444.61°C (832.30°F). Below 600°C (1110°F), the predominant species in the gas are S_8 followed by S_7 and S_6. Above 720°C (1328°F), violet S_2 is the major species.

Principal inorganic compounds. Hydrogen sulfide (H_2S) is the most important compound that contains only sulfur and hydrogen. It is a gas at room temperature with a boiling point of -61.8°C (-79.2°F) and a freezing point of -82.9°C (-117°F). The low boiling point of hydrogen sulfide is attributed to the weakness of intermolecular S···H hydrogen bonding; the O···H hydrogen bond is much stronger, as evidenced by the high boiling point of water. Gaseous hydrogen sulfide is 1.19 times more dense than air, and air-H_2S mixtures are explosive. Hydrogen sulfide has a strong odor similar to that of rotten eggs; its odor is detectable at concentrations below 1 microgram/m^3. At high concentrations, H_2S has a paralyzing effect on the olfactory system, which is very hazardous because H_2S is even more toxic than carbon monoxide (CO).

The most common compound that contains only carbon and sulfur is carbon disulfide (CS_2). Carbon disulfide molecules are linear, consisting of two sulfur atoms connected to a central carbon atom. Carbon disulfide is a toxic, highly flammable, and volatile liquid that melts at -111°C (-168°F) and boils at 46°C (115°F). Commercial carbon disulfide has a strong unpleasant odor due to impurities. It is manufactured from methane and elemental sulfur and is used for the production of carbon tetrachloride, rayon, and cellophane. Structurally related to carbon disulfide is carbonyl sulfide (SCO), which forms from carbon monoxide and elemental sulfur. The chlorination of CS_2 gives Cl_3CSCl, which can be reduced by H_2S to thiophosphene, $CSCl_2$. Thiophosgene ($CSCl_2$) [boiling point 73°C or 163°F] is a planar molecule with the carbon at the center of a triangle defined by the sulfur and two chlorine atoms. Thiocyanate, the linear anion NCS^-, is prepared by the reaction of cyanide (—CN) with elemental sulfur.

Several sulfur oxides exist, but the dioxide and trioxide are of preeminent importance. Sulfur dioxide (SO_2) is a colorless gas that boils at -10.02°C (113.97°F) and freezes at -75.46°C (-103.8°F). The density of liquid sulfur dioxide at -10°C (14°F) is 1.46 g/cm^3 (0.84 oz/in.^{3}). Liquid sulfur dioxide is an excellent solvent. The sulfur dioxide molecule is bent, with an O—S—O angle of 119°.

Sulfur trioxide (SO_3) is a planar molecule that is a liquid at room temperature that exists in equilibrium with a cyclic trimeric structure known as β-SO_3. When β-SO_3, actually S_3O_9, is treated with traces of water, it converts to either of two polymeric forms referred to as γ- and α-sulfur trioxide. These are fibrous materials, proposed to have the formula $(SO_3)_xH_2$, where x is in the thousands. Sulfur trioxide is prepared by the oxidation of sulfur dioxide, although at very high temperatures this reaction reverses. Exposure of sulfur trioxide to water yields sulfuric acid (H_2SO_4); exposure of SO_3 to sulfuric acid yields disulfuric acid ($H_2S_2O_7$). *See* Sulfuric acid.

Chlorine and sulfur react to give a family of compounds with the general formula S_xCl_2, several members of which have been obtained in pure form. The structures of these compounds are based on an atom or chain of sulfur atoms terminated with Cl. Sulfur monochloride (S_2Cl_2), also known as sulfur monochloride, is the most widely available of the series. It is a yellow oil that boils at 138°C (280°F), and reacts with chlorine in the presence of iron(III) chloride ($FeCl_3$) catalyst to give sulfur dichloride (SC_2), which is a red volatile liquid with a boiling point of 59°C (138°F). Treatment of sulfur dichloride with sodium fluoride (NaF) gives SF_4.

Thionyl chloride ($OSCl_2$) is a colorless reactive compound with a boiling point of 76°C (169°F); it is used to convert hydroxy compounds to chlorides. Important applications include the preparation of anhydrous metal halides and alkyl halides. Sulfuryl chloride (O_2SCl_2; boiling point 69°C or 156°F) is used as a source of chlorine.

Organosulfur compounds. This family of compounds contains carbon, hydrogen, and sulfur, and it is a particularly vast area of sulfur chemistry. Thiols, also known as mercaptans, feature the linkage C—S—H. Mercaptans are foul-smelling compounds. They are the sulfur analogs of alcohols, but they are more volatile. They can be prepared by the action of hydrogen sulfide (H_2S) on olefins. Deprotonation of thiols gives thiolate anions, which form stable compounds with many heavy metals. Thiols and especially thiolates can be oxidized to form disulfides (persulfides), which have the connectivity of C—S—S—C. The organic persulfides are also related to organic polysulfides, which have chains of sulfur atoms terminated with carbon. The introduction of such mono-, di-, and polysulfide linkages is the basis of the vulcanization process, which imparts desirable mechanical properties to natural or synthetic polyolefin rubbers. This is accomplished by heating the polymer with sulfur in the presence of a zinc catalyst. *See* Rubber.

Thioethers, also known as organic sulfides, feature the connectivity C—S—C and are often prepared from the reaction of thiolates and alkyl halides. Like mercaptans, thioethers often have strong unpleasant odors, but they are also responsible for the pleasant odors of many foods and perfumes. They are intentionally introduced at trace levels in order to impart an odor to gaseous hydrocarbon fuels. The reaction of alkyl dihalides and sodium polysulfides affords organic polysulfide polymers known as thiokols.

There are many organic sulfur oxides; prominent are sulfonic acids (RSO_3H), which are the organic derivatives of sulfuric acid. These compounds are prepared by the oxidation of thiols as well as by treatment of benzene derivatives with sulfuric acid, for example, benzene sulfonic acid. Most detergents are salts of sulfonic acids. *See* Detergent.

Biochemistry. Sulfur is required for life. Typical organisms contain 2% sulfur dry weight. Three amino acids contain sulfur, as do many prosthetic groups in enzymes. Some noteworthy sulfur compounds include the disulfide lipoic acid, the thioethers biotin and thiamine (vitamin B_1), and the thiol coenzyme A. Sulfide ions, S^{2-}, are found incorporated in metalloproteins and metalloenzymes such as the ferredoxins, nitrogenases, and hydrogenases. *See* Amino acids; Enzyme; Protein.

Many bacterial species obtain energy by the oxidations of sulfides. Bacteria of the genus *Thiobacillus* couple the conversion of carbon dioxide (CO_2) to carbohydrates to the aerobic oxidation of mineral sulfides to sulfuric acid. This activity can be turned to good use for leaching low-grade mineral ores. Often, however, the sulfuric acid runoff (such as in mines or sewers) has negative environmental consequences. The purple and green bacteria as well as the blue-green algae are remarkable because they are photosynthetic but anaerobic; they oxidize sulfide, not water (as do most photosynthetic organisms). Depending on the species, the sulfur produced in this energy-producing pathway can accumulate inside or outside the cell wall. *See* BACTERIAL PHYSIOLOGY AND METABOLISM; PHOTOSYNTHESIS.

Minerals. Sulfide minerals are among the most important ores for several metals. These compounds are two- or three-dimensional polymers containing interconnected metal cations and sulfide S^{2-} or persulfido $S_2{}^{2-}$ anions. In general, metal sulfides are darkly colored, often black, and they are not soluble in water. They can sometimes be decomposed by using strong acids, with liberation of hydrogen sulfide. Certain sulfides will also dissolve in the presence of excess sulfide or polysulfide ions.

Pyrites (FeS_2), also known as iron pyrites or fool's gold, are the most common sulfide minerals and can be obtained as very large crystals that have a golden luster. Sphalerite (zinc blende; ZnS) and galena (PbS) are major sources of zinc and lead. Orange cinnabar (HgS) and yellow greenockite (CdS) are the major ores for mercury and cadmium, respectively. Molybdenite (MoS_2) is the major ore of molybdenum.

The sulfur content of fossil fuels results from the sulfur in the ancient organisms as well as from subsequent incorporation of mineral sulfur into the hydrocarbon matrix. Gaseous fossil fuels are often contaminated with hydrogen sulfide, which is an increasingly important source of sulfur. Organic derivatives containing the C—S—C linkage are primarily responsible for the sulfur content of petroleum and coal. The so-called organic sulfur in petroleum can be removed by hydrodesulfurization catalysis, involving reaction with hydrogen over a molybdenum catalyst, to give hydrocarbons and hydrogen sulfide. [T.B.R.]

Sulfuric acid

A strong mineral acid with the chemical formula H_2SO_4. It is a colorless, oily liquid, sometimes called oil of vitriol or vitriolic acid. The pure acid has a density of 1.834 at 25°C (77°F) and freezes at 10.5°C (50.90°F). It is an important industrial commodity, used extensively in petroleum refining and in the manufacture of fertilizers, paints, pigments, dyes, and explosives.

Sulfuric acid is produced on a large scale by two commercial processes, the contact process and the lead-chamber process. In the contact process, sulfur dioxide, SO_2, is converted to sulfur trioxide, SO_3, by reaction with oxygen in the presence of a catalyst. Sulfuric acid is produced by the reaction of the sulfur trioxide with water. The lead-chamber process depends upon the oxidation of sulfur dioxide by nitric acid in the presence of water, the reaction being carried out in large lead rooms.

Sulfuric acid reacts vigorously with water to form several hydrates. The concentrated acid, therefore, acts as an efficient drying agent, taking up moisture from the air and even abstracting the elements of water from such compounds as sugar and starch. The concentrated acid also acts as a strong oxidizing agent. It reacts with most metals upon heating to produce sulfur dioxide. *See* SULFUR. [F.J.J.]

Sum rules

Formulas in quantum mechanics for transitions between energy levels, in which the sum of the transition strengths is expressed in a simple form. Sum rules are used to describe the properties of many physical systems, including solids, atoms, atomic nuclei, and nuclear constituents such as protons and neutrons. The sum rules are derived from quite general principles, and are useful in situations where the behavior of individual energy levels is too complex to describe by a precise quantum-mechanical theory. *See* ENERGY LEVEL (QUANTUM MECHANICS).

In general, sum rules are derived by using Heisenberg's quantum-mechanical algebra to construct operator equalities, which are then applied to particles or the energy levels of a system. *See* QUANTUM MECHANICS. [G.F.Be.]

Sun

The star around which the Earth revolves, and the planet's source of light and heat, hence life. The Sun is a globe of gas, 1.4×10^6 km (8.65×10^5 mi) in diameter with a mass 333,000 times the Earth, held together by its own gravity. The surface temperature of the Sun is about 6000 K (10,000°F); since solids and liquids do not exist at these temperatures, the Sun is entirely gaseous. Almost all the gas is in atomic form, although a few molecules exist in the coolest surface regions, such as sunspots.

The Sun is a typical member of the spectral class dG2, stars of surface temperature 6000 K. The d stands for a dwarf, a normal star of that class. *See* SPECTRAL TYPE.

Solar structure. The interior of the Sun can be studied only by inference from the observed properties of the entire star. The great mass of the Sun presses down on the center, requiring a gas with a central density of near 90 g/cm^3 and 2×10^7 K (3.6×10^{6} °F) temperature to support it. At these huge temperatures and densities, nuclear reactions take place. The radiation produced flows outward till it is radiated into space by the surface (photosphere) at 6000 K (10,000°F).

Energy production. The energy of the Sun is produced by the conversion of hydrogen into helium. For each hydrogen atom converted, one neutrino is produced. These neutrinos are detected, but less than the expected number. *See* NEUTRINO; SOLAR NEUTRINOS.

The material at the center of the Sun is so dense that a few millimeters are opaque, so the photons created by nuclear reactions are continually absorbed and reemitted and thus make their way to the surface by a random walk. The atoms in the center of the Sun are entirely stripped of their electrons by the high temperatures, and most of the absorption is by continuum processes, such as the scattering of light by electrons. Because there are so many absorption and emission processes along the way, it can take as long as a million years to complete the random walk to the surface.

Convection. In the outer regions of the solar interior, the temperature is low enough for ions and even neutral atoms to form and, as a result, atomic absorption becomes very important. The high opacity makes it very difficult for the radiation to continue outward, so steep temperature gradients are established that result in convective currents. Most of the outer envelope of the Sun is in such convective equilibrium. These large-scale mass motions are responsible for the complex phenomena observed at the surface. *See* CONVECTION (HEAT).

Radiation. Electromagnetic energy is produced by the Sun in essentially all wavelengths. However, more than 95% of the energy is concentrated in the relatively narrow band between 290 and 2500 nm and is accessible to routine observation from ground stations on Earth. The maximum radiation is in the green region, and the eyes of human beings have naturally evolved to be sensitive to this range of the spectrum. The total radiation is called the solar constant. It is not exactly constant but varies slightly (±0.1%) with the solar cycle. The ultraviolet flux, however, varies by substantial factors depending on the exact wavelength, and this affects the Earth's upper atmosphere. *See* ELECTROMAGNETIC RADIATION; SOLAR CONSTANT.

Atmosphere. Although the Sun is gaseous, it can be seen only to the point at which the density is so high that the material is opaque. This layer, the visible surface of the Sun, is termed the photosphere. Light from father down reaches the Earth by repeated absorption and emission by the atoms, but the deepest layers cannot be seen directly. The surface is actually not sharp, but the Sun is so far away that the smallest distance that can be resolved with the best telescope is about 300 km (200 mi). Since the density e-folding height (scale height) is less than 200 km (120 mi), the edge appears sharp. *See* PHOTOSPHERE.

Above the photosphere the atmosphere is transparent, and its density falls off much more slowly because magnetic fields support the ionized particles. The atmosphere can be seen by using a narrow-band filter or a spectrograph to pick out the isolated wavelengths absorbed by the atmospheric gases. In the upper photosphere it is cooler, and the lines are dark. If the light is imaged in the strongest lines, such as those of hydrogen, a region higher still is seen, called the chromosphere. The light from this region is dominated by the red hydrogen alpha (level 2 → 3 transition) line, which gives it a rosy color seen at a solar eclipse. The chromosphere is a rapidly fluctuating region of jets and waves coming up from the surface. When all the convected energy coming up from below reaches the surface, it is concentrated in the thin material and produces considerable activity. Where the magnetic field is stronger, these waves are absorbed, and raise the temperature to 7000–8000 K (12,000–14,000°F). The scale height of the chromosphere is 1000 km (600 mi) or more, so there no longer is a sharp edge. *See* CHROMOSPHERE; ECLIPSE.

When the Moon obscures the Sun at a total solar eclipse, the vast extended atmosphere of the Sun called the corona can be seen. The corona is a million times fainter than the photosphere, so it is visible only when seen against the dark sky of an eclipse or with very special instruments. Its density is low, but its temperature is high (more than 10^6 K or 1.8×10^6°F). The hot gas evaporating out from the corona flows steadily to the Earth and farther in the solar wind. *See* SOLAR CORONA; SOLAR WIND.

Coronal holes. Early coronal observations showed that the corona was occasionally absent over certain regions. In particular, at sunspot minimum it was quite weak over the poles. X-ray pictures revealed great bands of the solar surface essentially devoid of corona for many months. These proved to be regions where the local magnetic fields were connected to quite distant places, so the fields actually reached out to heights from which the solar wind could sweep the gas outward. Analysis of solar wind data showed that equatorial coronal holes were associated with high-velocity streams in the solar wind, and recurrent geomagnetic storms were associated with the return of these holes. Thus the relative intensity of the corona over sunspot regions is partly due to their strong, closed magnetic fields which trap the coronal gas.

Solar activity. There are a number of transient phenomena known collectively as solar activity. These are all connected with sunspots.

Sunspots. Sunspots were discovered around 1610. Heinrich Schwabe announced in 1843 that their number rose and fell with a 10-year period. Subsequent study of the old records revealed an 11-year period since the original discovery.

The number of sunspots peaks soon after the beginning of each cycle and decays to a minimum in 11 years. The first spots of a number cycle always occur at higher latitudes, between 20° and 35°, and the latitude of occurrence decreases as the cycle unfolds (Spörer's law). Almost no spots are observed outside the latitude range of 5–35°. The great majority are small and last a few days, but some last for two rotations. In 1908, George Ellery Hale discovered that sunspots had strong magnetic fields. Each spot group contains positive and negative magnetic polarity (monopoles are forbidden by Maxwell's laws). Hale found that the polarities were mirrored, with the same polarity generally leading in one hemisphere and following in the other. He found that with each new number cycle the lead polarity switches, so that the complete magnetic cycle lasts 22 years. But each new number cycle starts a few years before the end of the previous one, so the average duration of a half-cycle is nearly 14 years. *See* MAGNETISM.

The darkness of sunspots (Fig. 1) is probably due to the intense magnetic fields (3000 gauss or 0.3 tesla), which cool the surface by suppressing the normal convective energy flow from below. It takes several days for the darkening to occur.

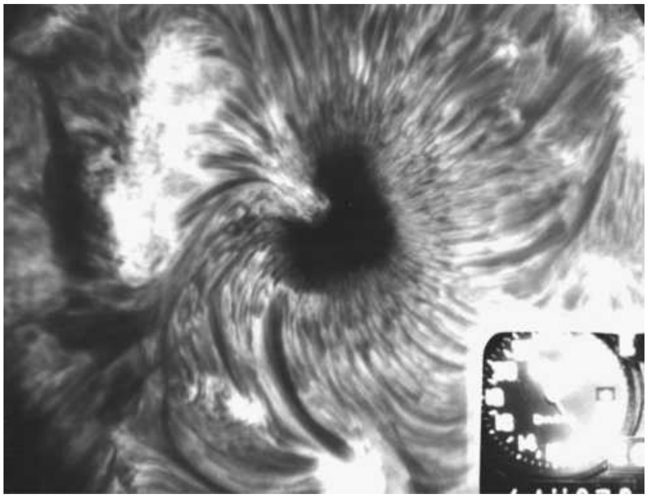


Fig. 1. Large symmetric sunspot photographed in Hα light. Clock indicates time of photograph. (*Big Bear Solar Observatory*)

Although the sunspot is cool, its neighborhood is the scene of the hottest and most intense activity, generally referred to as an active region. Magnetic energy is continually released there. The corona above an active region is hot and dense, roughly three times hotter and denser than in quiet regions.

Prominences. The term "prominence" is used for any cloud of cool gas in the corona, where it appears bright against the sky. Because these clouds absorb the chromospheric light and scatter it, they appear dark against the solar disk in Hα and other strong lines. In continuous light they are transparent. At the limb we see the chromospheric light they scatter against the dark sky. Since they are much denser than the corona, something must hold them up against gravity. Prominences are found only in regions of horizontal magnetic fields that support them. Thus filaments on the disk, which may last for weeks, are good markers of the magnetic boundaries. When the magnetic structure changes, prominences become unstable and erupt, always upward. They also may be ejected by solar flares or appear as graceful loops raining from the corona after flares. Erupting prominences are probably the source of coronal mass ejections, in which a bubble of coronal material erupts outward at several hundred kilometers per second and flows out into interplanetary space.

Plages. Just as prominences occur when the magnetic field changes from one sign to the other, plages occur whenever the magnetic field is vertical and relatively strong but not strong enough to form a sunspot. They are bright regions in any strong spectrum line, because the chromosphere is heated there. In a typical active region, the preceding magnetic field is clumped in a sunspot and the following field spread out in a plage. In Hα light, the plage is seen to be connected to the sunspot by dark fibrils outlining the lines of force.

Flares. The most spectacular activity associated with sunspots is the solar flare (Fig. 2). A flare is defined as an abrupt increase in the Hα emission from the sunspot region. The brightness of the flare may be up to eight times that of the chromosphere; the rise time is seldom longer than a few minutes. The Hα brightening results from heating of the chromosphere at the foot points of the magnetic field by a tremendous energy release in the atmosphere. While flares are usually visible only in chromospheric lines, the foot points of big flares can be seen in white light. From the foot points, a cloud of hot material, up to 3×10^7 K (5.4×10^7°F) arises and concentrates at the arch tops. This cloud condenses out in an array of loop prominences. An active sunspot

Fig. 2. The great "sea horse" flare of August 7, 1972, late in the flare, photographed in the blue wing of the Hα line. The neutral line between two bright strands is crossed by an arcade of bright loop prominences raining down from the corona. (*Big Bear Solar Observatory*)

group produces a hierarchy of flares, a few big and many small ones.

Flares are often associated with the eruption of filaments. A few minutes after the eruption begins, there is an abrupt acceleration and a storm of energetic particles is produced, heating the corona to flare brightness.

The flare produces a huge stream of solar energetic particles (SEP) as well as shock waves. A huge magnetohydrodynamic shock wave flies out at about 1000 km/s (600 mi/s) and continues into interplanetary space, often reaching the Earth. The wave produces a huge radio burst in the meter-wavelength range as it excites the coronal layers. The energetic nuclei produce gamma-ray lines from nuclear reactions as they penetrate to the photosphere. If they are sufficiently numerous, they heat the photosphere faster than it can reemit energy and a white light flare is observed, usually in the form of bright transient flashes at the foot points of the flare loops. The particles reach the Earth in a great particle storm. [H.Zi.]

Sun dog A bright spot of light that sometimes appears on either side of the Sun, the same distance above the horizon as the Sun, and separated from it by an angle of about 22° (see illustration). For higher Sun elevations, the angle increases slightly. These spots are known by many common names: sun dogs, mock suns, false suns, or the 22° parhelia. They usually show a red edge on the side closest to the Sun. On some occasions the entire spectrum of colors can be spread out in the sun-dog spot but, commonly, the red edge is followed by an orange or yellow band that merges into a diffuse white region. The effects result from the refraction by sunlight through small, flat, hexagonal-shaped ice crystals falling through the air such that their flat faces are oriented nearly horizontally. *See* HALO; METEOROLOGICAL OPTICS. [R.Gr.]

Sun dogs on either side of the Sun. Also visible are the 22° halo and the parhelic circle. (*Courtesy of Robert Greenler*)

Sundew Any plant of the genus *Drosera* (90 species) of the family Droseraceae. Sundews are small, herbaceous, insectivorous plants that grow on all the continents, especially Australia. Numerous glandular hairs (tentacles) on the leaf secrete a viscous fluid which traps a visiting insect. The tentacles then bend inward about the victim, bringing it into contact with the surface of the leaf where it is digested. The droplets secreted by the glands on the leaves glitter like dewdrops in the morning sunlight; hence, the name, sundew. *See* INSECTIVOROUS PLANTS; NEPENTHALES; SECRETORY STRUCTURES (PLANT). [P.D.St./E.L.C.]

Sundial An instrument for telling time by the Sun. It is composed of a style that casts a shadow and a dial plate, which is the surface upon which hour lines are marked and upon which the shadow falls. The style lies parallel to Earth's axis. The construction of the hour lines is based on the assumption that the apparent motion of the Sun is always on the celestial equator. The most widely used form is the horizontal dial that indicates local apparent time (Sun time). Other forms of the sundial indicate local mean time, and standard time. *See* TIME. [R.N.M.]

Sunfish A name given to certain members of the freshwater family Centrarchidae as well as to members of the marine family Molidae. There are two species of oceanic sunfishes in the genus *Mola*; both are large, stout, deep-bodied fishes with rough skin and are found in warm seas, where they are frequently seen near the surface. These fishes appear to be tailless.

The fresh-water sunfishes are grouped together with the crappies. The warmouth sunfish (*Chaenobryttus gulosus*) is the only species found in the United States, where it occurs in the Mississippi River drainage and in streams along the Atlantic coast. It differs from other sunfishes in having teeth on the tongue.

The crappies are game fish of considerable importance. Crappies are a favorite species for pond culture. They can be readily transplanted and, under favorable conditions, multiply prodigiously. *See* PERCIFORMES. [C.B.C.]

Sunflower *Helianthus annuus*, the most widely distributed of the 50 native North American species of this genus of the family Compositae. It is an extremely variable species, with two main divisions. The first involves wild weedy plants found along roadways and other recently disturbed areas; the second, domesticated plants grown in fields and gardens. *See* ASTERALES.

Within the domestic type there are two categories of plants: the ornamental, which has a few branches with larger heads than the wild, and the crop type, which has only a single stem and the largest head of all sunflowers (see illustration). Crop types are either oil or nonoil. Plant breeders have modified the plant for adaptation to modern, large-scale farming and have increased the oil content of the seeds. The present worldwide interest in growing sunflowers as a crop is due to the increased yield of the new commercially available oilseed hybrids.

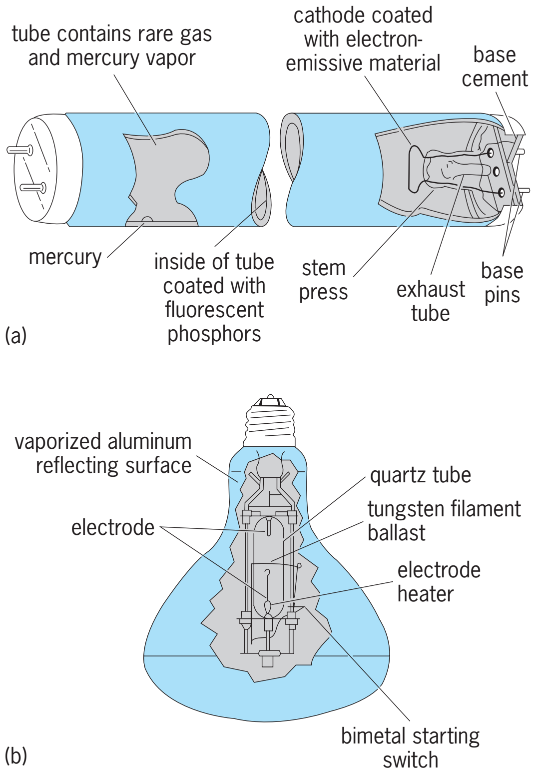
Sunflowers are grown on all the continents and in many countries throughout the world. Russia is the major producer, followed by Argentina, the United States, and Canada. Sunflower oil (sunoil) is the second most important vegetable crop oil. It is

Maturing sunflower. (*U.S. Department of Agriculture*)

a high-quality oil and is high in linoleic fatty acid. The oil is used in cooking, salad dressing, mayonnaise, margarine, and soap. [B.H.B.]

Sunlamp A special form of mercury arc discharge lamp designed to produce ultraviolet radiation. These lamps also produce some radiant energy in the visible region of the spectrum, thus having a light output as well as an ultraviolet output. The lamps are principally used for producing a skin tan on the human body. The less common uses include therapeutically producing vitamin D in the body for the treatment of rickets and causing fluorescence or photochemical reactions.

Sunlamps have ultraviolet radiation at wavelengths above 280 nanometers. The lower limit is set by the fact that the quartz and high-silica glass used for lamp envelopes do not transmit below 280 nm. The two lamps designed for tanning are the FS-40 and the RS. The FS-40 tubular fluorescent lamp (illus. *a*) operates with a low-pressure mercury arc that causes a special chemical phosphor coating inside the tube to radiate ultraviolet energy. The RS sunlamp (illus. *b*) is a reflector unit containing a high-pressure mercury arc tube for generating ultraviolet energy plus a tungsten filament (similar to incandescent lamp filaments) in series with the arc tube to serve as a ballast. *See* MERCURY-VAPOR LAMP; ULTRAVIOLET LAMP. [G.R.P.]



Structure of sunlamps. (*a*) FS-40. (*b*) RS.

Superacid An acid which has an extremely great proton-donating ability. It has proved convenient to define a superacid somewhat arbitrarily as an acid, or more generally, an acidic medium, which has a proton-donating ability equal to or greater than that of anhydrous (100%) sulfuric acid.

Superacids belong to the general class of proton or Brönsted acids. A proton acid is defined as any species which can act as a source of protons and which will therefore protonate a suitable base, as in reaction (1).

$$\mathrm{HA} + \mathrm{B} \rightleftharpoons \mathrm{BH}^+ + \mathrm{A}^- \qquad (1)$$

The strengths of acids are often compared by measuring the extent of their ionization in water, that is, the extent to which they can protonate the base water, as in reaction (2).

$$\mathrm{HA} + \mathrm{H_2O} \rightleftharpoons \mathrm{H_3O}^+ + \mathrm{A}^- \qquad (2)$$

However, all strong acids are fully ionized in dilute aqueous solution, and they therefore appear to have the same strength. Their strengths are said to be reduced or leveled to that of the hydronium ion (H_3O^+), which is the most highly acidic species that can exist in water. In any case, many of the superacids react with and are destroyed by water. For these reasons, the strengths of superacids cannot be measured by the conventional means of utilizing their aqueous solutions. The acidities of superacids can, however, be conveniently measured in terms of the Hammett acidity function. *See* ACID AND BASE.

The Hammett acidity function is a method of measuring acidity based on the determination of the ionization ratios of suitable weak bases (indicators), usually by means of the change in absorption spectrum that occurs on protonation of the base, although the nuclear magnetic resonance (NMR) spectrum has also been used. The Hammett acidity function (H_0) is defined by Eq. (3), where $K_{\mathrm{BH+}}$ is the dissociation constant of the acid

$$\mathrm{H_0} = \mathrm{p}K_{\mathrm{BH+}} - \log \frac{[\mathrm{BH}^+]}{[\mathrm{B}]} \qquad (3)$$

form of the indicator and $[BH^+]/[B]$ is the ionization ratio of the indicator. Hammett acidity function (H_0) values for a number of superacids are given in the table. In each case the value refers to the 100% (anhydrous) acid. Each of the superacids in the table

Hammett acidity function values for several superacids

Superacid	Formula	$-H_0$
Sulfuric acid	H_2SO_4	11.9
Chlorosulfuric acid	HSO_3Cl	13.8
Trifluoromethane sulfonic acid	HSO_3CF_3	14.0
Disulfuric acid	$H_2S_2O_7$	14.4
Fluorosulfuric acid	HSO_3F	15.1
Hydrogen fluoride	HF	15.1

is a liquid at room temperature, and each forms the basis of a solvent system. *See* IONIC EQUILIBRIUM; SOLUTION. [R.J.Gi.]

Supercharger An air pump or blower in the intake system of an internal combustion engine. Its purpose is to increase the air-charge weight and therefore the power output from an engine of a given size. In an aircraft engine, the supercharger counteracts the power loss that results from the decrease of atmospheric pressure with increase of altitude. Various types of pumps and compressors may be used as superchargers, which are either mechanically driven by the engine crankshaft or powered by the engine exhaust gas. *See* COMPRESSOR; PUMP; TURBOCHARGER.

Some production automobile engines use a spiral-type supercharger, while others use a pressure-wave supercharger. However, automotive, marine, and stationary engines generally use a positive-displacement Roots blower driven from the engine crankshaft. *See* INTERNAL COMBUSTION ENGINE.

In a supercharged diesel engine, the increased air charge allows the engine to burn more fuel and produce greater power without creating excessive pressure inside the cylinder. Supercharging the diesel engine makes ignition of the fuel easier without requiring a fuel of better quality. *See* DIESEL ENGINE.

To enable a reciprocating aircraft engine to develop its rated sea-level power at altitude, a supercharger must be used to increase the pressure and weight of the intake air charge. Centrifugal compressors are generally used because of their relatively small size for a given capacity, and are driven either by a gear drive from the crankshaft or by the engine exhaust gas. With gear drive, a lower ratio is commonly used at low and medium altitudes, with a change to a higher ratio at high altitudes. *See* AIRCRAFT ENGINE. [J.A.B.; D.L.An.]

Supercomputer A computer which, among existing general-purpose computers at any given time, is superlative, often in several senses: highest computation rate, largest memory, or highest cost. Predominantly, the term refers to the fastest "number crunchers," that is, machines designed to perform numerical calculations at the highest speed that the latest electronic device technology and the state of the art of computer architecture allow.

The demand for the ability to execute arithmetic operations at the highest possible rate originated in computer applications areas collectively referred to as scientific computing. Large-scale numerical simulations of physical processes are often needed in fields such as physics, structural mechanics, meteorology, and aerodynamics. A common technique is to compute an approximate numerical solution to a set of partial differential equations which mathematically describe the physical process of interest but are too complex to be solved by formal mathematical methods. This solution is obtained by first superimposing a grid on a region of space, with a set of numerical values attached to each grid point. Large-scale scientific computations of this type often require hundreds of thousands of grid points with 10 or more values attached to each point, with 10 to 500 arithmetic operations necessary to compute each updated value, and hundreds of thousands of time steps over which the computation must be repeated before a steady-state solution is reached. *See* COMPUTATIONAL FLUID DYNAMICS; NUMERICAL ANALYSIS; SIMULATION.

Two lines of technological advancement have significantly contributed to what roughly amounts to a doubling of the fastest computers' speeds every year since the early 1950s—the steady improvement in electronic device technology and the accumulation of improvements in the architectural designs of digital computers.

Computers incorporate very large-scale integrated (VLSI) circuits with tens of millions of transistors per chip for both logic and memory components. A variety of types of integrated circuitry is used in contemporary supercomputers. Several use high-speed complementary metallic oxide semiconductor (CMOS) technology. Throughout most of the history of digital computing, supercomputers generally used the highest-performance switching circuitry available at the time—which was usually the most exotic and expensive. However, many supercomputers now use the conventional, inexpensive device technology of commodity microprocessors and rely on massive parallelism for their speed. *See* COMPUTER STORAGE TECHNOLOGY; CONCURRENT PROCESSING; INTEGRATED CIRCUITS; LOGIC CIRCUITS ; SEMICONDUCTOR MEMORIES.

Increases in computing speed which are purely due to the architectural structure of a computer can largely be attributed to the introduction of some form of parallelism into the machine's design: two or more operations which were performed one after the other in previous computers can now be performed simultaneously. *See* COMPUTER SYSTEMS ARCHITECTURE.

Pipelining is a technique which allows several operations to be in progress in the central processing unit at once. The first form of pipelining used was instruction pipelining. Since each instruction must have the same basic sequence of steps performed, namely instruction fetch, instruction decode, operand fetch, and execution, it is feasible to construct an instruction pipeline, where each of these steps happens at a separate stage of the pipeline. The efficiency of the instruction pipeline depends on the likelihood that the program being executed allows a steady stream of instructions to be fetched from contiguous locations in memory.

The central processing unit nearly always has a much faster cycle time than the memory. This implies that the central processing unit is capable of processing data items faster than a memory unit can provide them. Interleaved memory is an organization of memory units which at least partially relieves this problem.

Parallelism within arithmetic and logical circuitry has been introduced in several ways. Adders, multipliers, and dividers now operate in bit-parallel mode, while the earliest machines performed bit-serial arithmetic. Independently operating parallel functional units within the central processing unit can each perform an arithmetic operation such as add, multiply, or shift. Array processing is a form of parallelism in which the instruction execution portion of a central processing unit is replicated several times and connected to its own memory device as well as to a common instruction interpretation and control unit. In this way, a single instruction can be executed at the same time on each of several execution units, each on a different set of operands. This kind of architecture is often referred to as single-instruction stream, multiple-data stream (SIMD).

Vector processing is the term applied to a form of pipelined arithmetic units which are specialized for performing arithmetic operations on vectors, which are uniform, linear arrays of data values. It can be thought of as a type of SIMD processing, since a single instruction invokes the execution of the same operation on every element of the array. *See* COMPUTER PROGRAMMING; PROGRAMMING LANGUAGES.

A central processing unit can contain multiple sets of the instruction execution hardware for either scalar or vector instructions. The task of scheduling instructions which can correctly execute in parallel with one another is generally the responsibility of the compiler or special scheduling hardware in the central processing unit. Instruction-level parallelism is almost never visible to the application programmer.

Multiprocessing is a form of parallelism that has complete central processing units operating in parallel, each fetching and executing instructions independently from the others. This type of computer organization is called multiple-instruction stream, multiple-data stream (MIMD). *See* MULTIPROCESSING. [D.W.M.]

Superconducting devices Devices that perform functions in the superconducting state that would be difficult or impossible to perform at room temperature, or that contain components which perform such functions. The superconducting state involves a loss of electrical resistance and occurs in many metals and alloys at temperatures near absolute zero. An enormous impetus was provided by the discovery in 1986 of a new class of ceramic, high-transition-temperature (T_c)

superconductors, which has resulted in a new superconducting technology at liquid nitrogen temperature. Superconducting devices may be conveniently divided into two categories: small-scale thin-film devices, and large-scale devices which employ zero-resistance superconducting windings made of type II superconducting materials. *See* SUPERCONDUCTIVITY.

Small-scale devices. A variety of thin-film devices offer higher performance than their nonsuperconducting counterparts. The prediction and discovery in the early 1960s of the Josephson effects introduced novel opportunities for ultrasensitive detectors, high-speed switching elements, and new physical standards. Niobium-based devices, patterned on silicon wafers using photolithographic techniques taken over from the semiconductor industry, have reached a high level of development, and a variety of such devices are commercially available. These devices operate at or below 4.2 K (−452°F), the temperature of liquid helium boiling under atmospheric pressure. *See* LIQUID HELIUM.

The discovery of the high-transition-temperature superconductors has enabled the operation of devices in liquid nitrogen at 77 K (−321°F). Not only is liquid nitrogen much cheaper and more readily available than liquid helium, but it also boils away much more slowly, enabling the use of simpler and more compact dewars or simpler, relatively inexpensive refrigerators. Of the new ceramic superconductors, only $YBa_2Cu_3O_{7-x}$ (YBCO) has been developed in thin-film form to the point of practical applications, and several devices are available. Intensive materials research has resulted in techniques, notably laser-ablation and radio-frequency sputtering, for the epitaxial growth of high-quality films with their crystalline planes parallel to the surface of the substrate. Most of the successful Josephson-junction devices have been formed at the interface between two grains of YBCO. These so-called grain-boundary junctions are made by depositing the film either on a bicrystal in which the two halves of the substrate have a carefully engineered in-plane misalignment of the crystal axes, or across a step-edge patterned in the substrate. *See* CRYOGENICS; GRAIN BOUNDARIES.

Two types of superconducting quantum interference device (SQUID) detect changes in magnetic flux: the dc SQUID and the rf SQUID. The dc SQUID, which operates with a dc bias current, consists of two Josephson junctions incorporated into a superconducting loop. The maximum dc supercurrent, known as the critical current, and the current-voltage (I-V) characteristic of the SQUID oscillate when the magnetic field applied to the device is changed. The oscillations are periodic in the magnetic flux Φ threading the loop with a period of one flux quantum, $\Phi_0 = h/2e \approx 2.07 \times 10^{-15}$ weber, where h is Planck's constant and e is the magnitude of the charge of the electron. Thus, when the SQUID is biased with a constant current, the voltage is periodic in the flux. The SQUID is almost invariably operated in a flux-locked loop. A change in the applied flux gives rise to a corresponding current in the coil that produces an equal and opposite flux in the SQUID. The SQUID is thus the null detector in a feedback circuit, and the output voltage is linearly proportional to the applied flux. *See* JOSEPHSON EFFECT; SQUID.

The rf SQUID consists of a single Josephson junction incorporated into a superconducting loop and operates with an rf bias. The SQUID is coupled to the inductor of an *LC*-resonant circuit excited at its resonant frequency, typically 30 MHz. The characteristics of rf voltage across the tank circuit versus the rf current depends on applied flux. With proper adjustment of the rf current, the amplitude of the rf voltage across the tank circuit oscillates as a function of applied flux. The rf SQUID is also usually operated in a feedback mode.

SQUIDs are mostly used in conjunction with an input circuit. For example, magnetometers are made by connecting a superconducting pickup loop to the input coil to form a flux transformer. A magnetic field applied to the pickup loop induces a persistent current in the transformer and hence a magnetic flux in the SQUID. These magnetometers have found application in geophysics, for example, in magnetotellurics. *See* GEOPHYSICAL EXPLORATION; MAGNETOMETER.

Low-transition-temperature SQUIDs are widely used to measure the magnetic susceptibility of tiny samples over a wide temperature range. Another application is a highly sensitive voltmeter, used in measurements of the Hall effect and of thermoelectricity. Low-transition-temperature SQUIDs are used as ultrasensitive detectors of nuclear magnetic and nuclear quadrupole resonance, and as transducers for gravitational-wave antennas. So-called scanning SQUIDs are used to obtain magnetic images of objects ranging from single-flux quanta trapped in superconductors to subsurface damage in two metallic sheets riveted together. *See* HALL EFFECT; MAGNETIC SUSCEPTIBILITY; NUCLEAR MAGNETIC RESONANCE (NMR); NUCLEAR QUADRUPOLE RESONANCE; THERMOELECTRICITY; VOLTMETER.

Perhaps the single largest area of application is biomagnetism, notably to image magnetic sources in the human brain or heart. In these studies an array of magnetometers or gradiometers is placed close to the subject, both generally being in a magnetically shielded room. The fluctuating magnetic signals recorded by the various channels are analyzed to locate their source. These techniques have been used, for example, to pinpoint the origin of focal epilepsy and to determine the function of the brain surrounding a tumor prior to its surgical removal. *See* BIOMAGNETISM.

The most sensitive detector available for millimeter and submillimeter electromagnetic radiation is the superconductor-insulator-superconductor (SIS) quasiparticle mixer. In this tunnel junction, usually niobium–aluminum oxide–niobium, the Josephson supercurrent is quenched and only single electron tunneling occurs. The current-voltage characteristic exhibits a very sharp onset of current at a voltage $2\Delta/e$, where Δ is the superconducting energy gap. The mixer is biased near this onset where the characteristics are highly nonlinear and used to mix the signal frequency with the frequency of a local oscillator to produce an intermediate frequency that is coupled out into a low-noise amplifier. These mixers are useful at frequencies up to about 750 GHz (wavelengths down to 400 micrometers). Such receivers are of great importance in radio astronomy, notably for airborne, balloon-based, or high-altitude, ground-based telescopes operating above most of the atmospheric water vapor. *See* RADIO ASTRONOMY.

The advent of high-transition-temperature superconductors stimulated major efforts to develop passive radio-frequency and microwave components that take advantage of the low electrical losses offered by these materials compared with normal conductors in liquid nitrogen. The implementation of thin-film YBCO receiver coils has improved the signal-to-noise ratio of nuclear magnetic resonance (NMR) spectrometers by a factor of 3 compared to that achievable with conventional coils. This improvement enables the data acquisition time to be reduced by an order of magnitude. These coils also have potential applications in low-frequency magnetic resonance imaging (MRI). High-transition-temperature bandpass filters have application in cellular communications. *See* ELECTRIC FILTER; MOBILE RADIO. [J.Cl.]

Large-scale devices. Large-scale applications of superconductivity comprise medical, energy, transportation, high-energy physics, and other miscellaneous applications such as high-gradient magnetic separation. When strong magnetic fields are needed, superconducting magnets offer several advantages over conventional copper or aluminum electromagnets. Most important is lower electric power costs because once the system is energized only the refrigeration requires power input, generally only 5–10% that of an equivalent-field resistive magnet. Relatively high magnetic fields achievable in unusual configurations and in smaller total volumes reduce the costs of expensive force-containment structures. *See* MAGNET.

Niobium-titanium (NbTi) has been used most widely for large-scale applications, followed by the A15 compounds, which include niobium-tin (Nb_3Sn), niobium-aluminum (Nb-Al), niobium-germanium (Nb-Ge), and vanadium-gallium (Va_3Ga). Niobium-germanium held the record for the highest critical field (23 K; −418.5°F) until the announcement of high-temperature ceramic superconductors. *See* A15 phases.

Significant advances have been made in high-temperature superconducting wire development. Small coils have been wound that operate at 20 K (−410°F). Current leads are in limited commercial use. Considerable development remains necessary to use these materials in very large applications.

MRI dominates superconducting magnet systems applications. Most of the MRI systems are in use in hospitals and clinics, and incorporate superconducting magnets. *See* Medical imaging.

Some of the largest-scale superconducting magnet systems are those considered for energy-related applications. These include magnetic confinement fusion, superconducting magnetic energy storage, magnetohydrodynamic electrical power generation, and superconducting generators. *See* Magnetohydrodynamic power generator; Nuclear fusion.

In superconducting magnetic energy storage superconducting magnets are charged during off-peak hours when electricity demand is low, and then discharged to add electricity to the grid at times of peak demand. The largest systems would require large land areas, for example, an 1100-m-diameter (3600-ft) site for a 5000-MWh system. However, intermediate-size systems are viable. A 6-T peak-field solenoidal magnet system designed for the Alaskan power network stores 1800 megajoules (0.5 MWh). High-purity-aluminum-stabilized niobium-titanium alloy conductor carrying 16 kiloamperes current is used for the magnet winding.

Superconducting magnets have potential applications for transportation, such as magnetically levitated vehicles. In addition, superconducting magnets are used in particle accelerators and particle detectors. *See* Magnetic levitation; Particle accelerator; Particle detector. [A.M.Da.]

Superconductivity A phenomenon occurring in many electrical conductors, in which the electrons responsible for conduction undergo a collective transition into an ordered state with many unique and remarkable properties. These include the vanishing of resistance to the flow of electric current, the appearance of a large diamagnetism and other unusual magnetic effects, substantial alteration of many thermal properties, and the occurrence of quantum effects otherwise observable only at the atomic and subatomic level.

Superconductivity was discovered by H. Kamerlingh Onnes in Leiden in 1911 while studying the temperature dependence of the electrical resistance of mercury within a few degrees of absolute zero. He observed that the resistance dropped sharply to an unmeasurably small value at a temperature of 4.2 K (−452°F). The temperature at which the transition occurs is called the transition or critical temperature, T_c. The vanishingly small resistance (very high conductivity) below T_c suggested the name given the phenomenon.

In 1933 W. Meissner and R. Ochsenfeld discovered that a metal cooled into the superconducting state in a moderate magnetic field expels the field from its interior. This discovery demonstrated that superconductivity involves more than simply very high or infinite electrical conductivity, remarkable as that alone is. *See* Meissner effect.

In 1957, J. Bardeen, L. N. Cooper, and J. R. Schrieffer reported the first successful microscopic theory of superconductivity. The Bardeen-Cooper-Schrieffer (BCS) theory describes how the electrons in a conductor form the ordered superconducting state. The BCS theory still stands as the basic explanation of superconductivity, even though extensive theoretical work has embellished it.

There are a number of practical applications of superconductivity. Powerful superconducting electromagnets guide elementary particles in particle accelerators, and they also provide the magnetic field needed for magnetic resonance imaging. Ultrasensitive superconducting circuits are used in medical studies of the human heart and brain and for a wide variety of physical science experiments. A completely superconducting prototype computer has even been built. *See* Medical imaging; Particle accelerator; Superconducting devices.

Transition temperatures. It was realized from the start that practical applications of superconductivity could become much more widespread if a high-temperature superconductor, that is, one with a high T_c, could be found. For instance, the only practical way to cool superconductors with transition temperatures below 20 K (−424°F) is to use liquid helium, which boils at a temperature of 4.2 K (−452°F) and which is rather expensive. On the other hand, a superconductor with a transition temperature of 100 K (−280°F) could be cooled with liquid nitrogen, which boils at 77 K (−321°F) and which is roughly 500 times less expensive than liquid helium. Another advantage of a high-T_c material is that, since many of the other superconducting properties are proportional to T_c, such a material would have enhanced properties. In 1986 the discovery of transition temperatures possibly as high as 30 K (−406°F) was reported in a compound containing barium, lanthanum, copper, and oxygen. In 1987 a compound of yttrium, barium, copper, and oxygen was shown to be superconducting above 90 K (−298°F). In 1988 researchers showed that a bismuth, strontium, calcium, copper, and oxygen compound was superconducting below 110 K (−262°F), and transition temperatures as high as 135 K (−216°F) were found in a mercury, thallium, barium, calcium, copper, and oxygen compound.

Occurrence. Some 29 metallic elements are known to be superconductors in their normal form, and another 17 become superconducting under pressure or when prepared in the form of thin films. The number of known superconducting compounds and alloys runs into the thousands. Superconductivity is thus a rather common characteristic of metallic conductors. The phenomenon also spans an extremely large temperature range. Rhodium is the element with the lowest transition temperature (370 μK), while $Hg_{0.2}Tl_{0.8}Ca_2Ba_2Cu_3O$ is the compound with the highest (135 K or −216°F).

Despite the existence of a successful microscopic theory of superconductivity, there are no completely reliable rules for predicting whether a metal will be a superconductor. Certain trends and correlations are apparent among the known superconductors, however—some with obvious bases in the theory—and these provide empirical guidelines in the search for new superconductors. Superconductors with relatively high transition temperatures tend to be rather poor conductors in the normal state.

The ordered superconducting state appears to be incompatible with any long-range-ordered magnetic state: Usually the ferromagnetic or antiferromagnetic metals are not superconducting. The presence of nonmagnetic impurities in a superconductor usually has very little effect on the superconductivity, but the presence of impurity atoms which have localized magnetic moments can markedly depress the transition temperature even in concentrations as low as a few parts per million. *See* Antiferromagnetism; Ferromagnetism.

Some semiconductors with very high densities of charge carriers are superconducting, and others such as silicon and germanium have high-pressure metallic phases which are superconducting. Many elements which are not themselves superconducting form compounds which are.

Certain organic conductors are superconducting. For instance, brominated polymeric chains of sulfur and nitrogen, known as $(SNBr_{0.4})_x$, are superconducting below 0.36 K. Other more complicated organic materials have T_c values near 10 K (−442°F). *See* Organic conductor.

Although nearly all the classes of crystal structure are represented among superconductors, certain structures appear to be especially conducive to high-temperature superconductivity. The so-called A15 structure, shared by a series of intermetallic compounds based on niobium, produced several superconductors with T_c values above 15 K (−433°F) as well as the record holder, NbGe, at 23 K (−418°F). Indeed, the robust applications of superconductivity that depend on the ability to carry high current in the presence of high magnetic fields still exclusively use two members of this class: NbTi with $T_c = 8$ K (−445°F), and Nb_3Sn with $T_c = 18.1$ K (−427°F). *See* A15 PHASES.

After 1986 the focus of superconductivity research abruptly shifted to the copper-oxide-based planar structures, due to their significantly higher transition temperatures. Basically there are three classes of these superconductors, all of which share the common feature that they contain one or more conducting planes of copper and oxygen atoms. The first class is designated by the chemical formula $La_{2-x}A_xCuO_4$, where the A atom can be barium, strontium, or calcium. Superconductivity was originally discovered in the barium-doped system, and systematic study of the substitutions of strontium, calcium, and so forth have produced transition temperatures as high as 40 K (−388°F).

The second class of copper-oxide superconductor is designated by the chemical formula $Y_1Ba_2Cu_3O_{7-\delta}$, with $\delta < 1.0$. Here, single sheets of copper and oxygen atoms straddle the rare-earth yttrium ion and chains of copper and oxygen atoms thread among the barium ions. The transition temperature, 92 K (−294°F), is quite insensitive to replacement of yttrium by many other rare-earth ions. *See* RARE-EARTH ELEMENTS.

The third class is the most complicated. These compounds contain either single thallium-oxygen layers, represented by the chemical formula $Tl_1Ca_{n-1}Ba_2Cu_nO_{2n+3}$, where n refers to the number of copper-oxygen planes, or double thallium-oxygen layers, represented by the chemical formula $Tl_2Ca_{n-1}Ba_2Cu_nO_{2n+4}$. The number of copper-oxygen planes may be varied, and as many as three planes have been included in the structure. Thallium may be replaced by bismuth, thus generating a second family of superconductors. In all of these compounds, the transition temperature appears to increase with the number of planes, but T_c decreases for larger values of n.

The spherical molecule comprising 60 carbon atoms (C_{60}), known as a buckyball, can be alloyed with various alkaline atoms which contribute electrons for conduction. By varying the number of conductors in C_{60}, it is possible to boost T_c to a maximum value of 52 K (−366°F). *See* FULLERENE.

Superconductivity was discovered in magnesium diboride (MgB_2) in January 2001 in Japan. This material may be a good alternative for some of the applications envisioned for high-T_c superconductivity, since this compound has T_c of 39 K (−389°F), is relatively easy to make, and consists of only two elements.

Magnetic properties. The existence of the Meissner-Ochsenfeld effect, the exclusion of a magnetic field from the interior of a superconductor, is direct evidence that the superconducting state is not simply one of infinite electrical conductivity. Instead, it is a true thermodynamic equilibrium state, a new phase which has lower free energy than the normal state at temperatures below the transition temperature and which somehow requires the absence of magnetic flux.

The exclusion of magnetic flux by a superconductor costs some magnetic energy. So long as this cost is less than the condensation energy gained by going from the normal to the superconducting phase, the superconductor will remain completely superconducting in an applied magnetic field. If the applied field becomes too large, the cost in magnetic energy will outweigh the gain in condensation energy, and the superconductor will become partially or totally normal. The manner in which this occurs depends on the geometry and the material of the superconductor. The geometry which produces the simplest behavior is that of a very long cylinder with field applied parallel to its axis. Two distinct types of behavior may then occur, depending on the type of superconductor—type I or type II.

Below a critical field H_c which increases as the temperature decreases below T_c, the magnetic flux is excluded from a type I superconductor, which is said to be perfectly diamagnetic. For a type II superconductor, there are two critical fields, the lower critical field H_{c1} and the upper critical field H_{c2}. In applied fields less than H_{c1}, the superconductor completely excludes the field, just as a type I superconductor does below H_c. At fields just above H_{c1}, however, flux begins to penetrate the superconductor, not in a uniform way, but as individual, isolated microscopic filaments called fluxoids or vortices. Each fluxoid consists of a normal core in which the magnetic field is large, surrounded by a superconducting region in which flows a vortex of persistent supercurrent which maintains the field in the core. *See* DIAMAGNETISM.

Thermal properties. The appearance of the superconducting state is accompanied by rather drastic changes in both the thermodynamic equilibrium and thermal transport properties of a superconductor.

The heat capacity of a superconducting material is quite different in the normal and superconducting states. In the normal state (produced at temperatures below the transition temperature by applying a magnetic field greater than the critical field), the heat capacity is determined primarily by the normal electrons (with a small contribution from the thermal vibrations of the crystal lattice) and is nearly proportional to the temperature. In zero applied magnetic field, there appears a discontinuity in the heat capacity at the transition temperature. At temperatures just below the transition temperature, the heat capacity is larger than in the normal state. It decreases more rapidly with decreasing temperature, however, and at temperatures well below the transition temperature varies exponentially as $e^{-\Delta/kT}$, where Δ is a constant and k is Boltzmann's constant. Such an exponential temperature dependence is a hallmark of a system with a gap Δ in the spectrum of allowed energy states. Heat capacity measurements provided the first indications of such a gap in superconductors, and one of the key features of the macroscopic BCS theory is its prediction of just such a gap. *See* SPECIFIC HEAT OF SOLIDS.

Ordinarily a large electrical conductivity is accompanied by a large thermal conductivity, as in the case of copper, used in electrical wiring and cooking pans. However, the thermal conductivity of a pure superconductor is less in the superconducting state than in the normal state, and at very low temperatures approaches zero. Crudely speaking, the explanation for the association of infinite electrical conductivity with vanishing thermal conductivity is that the transport of heat requires the transport of disorder (entropy). The superconducting state is one of perfect order (zero entropy), and so there is no disorder to transport and therefore no thermal conductivity. *See* ENTROPY; THERMAL CONDUCTION IN SOLIDS.

Two-fluid model. C. J. Gorter and H. B. G. Casimir introduced in 1934 a phenomenological theory of superconductivity based on the assumption that in the superconducting state there are two components of the conduction electron "fluid" (hence the name given this theory, the two-fluid model). One, called the superfluid component, is an ordered condensed state with zero entropy; hence it is incapable of transporting heat. It does not interact with the background crystal lattice, its imperfections, or the other conduction electron component and exhibits no resistance to flow. The other component, the normal component, is composed of electrons which behave exactly as they do in the normal state. It is further assumed that the superconducting transition is a reversible thermodynamic phase transition between two thermodynamically stable phases, the normal state and the superconducting state, similar to the transition between the liquid and vapor phases of any substance. The validity of this assumption is strongly supported by the existence of the Meissner-Ochsenfeld effect and by other experimental evidence. This assumption permits the application of all the powerful and general machinery of the theory of equilibrium thermodynamics. The results tie together the observed thermodynamic properties of superconductors in a very satisfying way.

Microscopic (BCS) theory. The key to the basic interaction between electrons which gives rise to superconductivity was provided by the isotope effect. It is an interaction mediated by the background crystal lattice and can crudely be pictured as follows: An electron tends to create a slight distortion of the elastic lattice as it moves, because of the Coulomb attraction between the negatively charged electron and the positively charged lattice. If the distortion persists for a brief time (the lattice may ring like a struck bell), a second passing electron will see the distortion and be affected by it. Under certain circumstances, this can give rise to a weak indirect attractive interaction between the two electrons which may more than compensate their Coulomb repulsion.

The first forward step was taken by Cooper in 1956, when he showed that two electrons with an attractive interaction can bind together to form a "bound pair" (often called a Cooper pair) if they are in the presence of a high-density fluid of other electrons, no matter how weak the interaction is. The two partners of a Cooper pair have opposite momenta and spin angular momenta. Then, in 1957, Bardeen, Cooper, and Schrieffer showed how to construct a wave function in which all of the electrons (at least, all of the important ones) are paired. Once this wave function is adjusted to minimize the free energy, it can be used as the basis for a complete microscopic theory of superconductivity.

The successes of the BCS theory and its subsequent elaborations are manifold. One of its key features is the prediction of an energy gap. Excitations called quasiparticles (which are something like normal electrons) can be created out of the superconducting ground state by breaking up pairs, but only at the expense of a minimum energy of Δ per excitation; Δ is called the gap parameter. The original BCS theory predicted that Δ is related to T_c by $\Delta = 1.76kT_c$ at $T = 0$ for all superconductors. This turns out to be nearly true, and where deviations occur they are understood in terms of modifications of the BCS theory. The manifestations of the energy gap in the low-temperature heat capacity and in electromagnetic absorption provide strong confirmation of the theory. [D.N.L.; R.J.So.; M.O.]

Supercontinent

The six major continents today are Africa, Antarctica, Australia, Eurasia, North America, and South America. Prior to the formation of the Atlantic, Indian, and Southern ocean basins over the past 180 million years by the process known as sea-floor spreading, the continents were assembled in one supercontinent called Pangea (literally "all Earth"). Pangea came together by the collision, about 300 million years ago (Ma), of two smaller masses of continental rock, Laurasia and Gondwanaland. Laurasia comprised the combined continents of ancient North America (known as Laurentia), Europe, and Asia. Africa, Antarctica, Australia, India, and South America made up Gondwanaland (this name comes from a region in southern India). The term "supercontinent" is also applied to Laurasia and Gondwanaland; hence it is used in referring to a continental mass significantly bigger than any of today's continents. A supercontinent may therefore incorporate almost all of the Earth's continental rocks, as did Pangea, but that is not implied by the word. *See* CONTINENT; CONTINENTS, EVOLUTION OF.

Laurasia, Gondwanaland, and Pangea are the earliest supercontinental entities whose former existence can be proven. Evidence of older rifted continental margins, for example surrounding Laurentia and on the Pacific margins of South America, Antarctica, and Australia, point to the existence of older supercontinents. The hypothetical Rodinia (literally "the mother of all continents") may have existed 800–1000 Ma, and Pannotia (meaning "the all-southern supercontinent") fleetingly around 550 Ma. Both are believed to have included most of the Earth's continental material. There may have been still earlier supercontinents, because large-scale continents, at least the size of southern Africa or Western Australia, existed as early as 2500 Ma at the end of Archean times. *See* ARCHEAN; CONTINENTAL MARGIN.

The amalgamation and fragmentation of supercontinents are the largest-scale manifestation of tectonic forces within the Earth. The cause of such events is highly controversial. *See* PLATE TECTONICS. [I.W.O.D.]

Supercritical fields

Static fields that are strong enough to cause the normal vacuum, which is devoid of real particles, to break down into a new vacuum in which real particles exist. This phenomenon has not yet been observed for electric fields, but it is predicted for these fields as well as others such as gravitational fields and the gluon field of quantum chromodynamics.

Vacuum decay in quantum electrodynamics. The original motivation for developing the new concept of a charged vacuum arose in the late 1960s in connection with attempts to understand the atomic structure of superheavy nuclei expected to be produced by heavy-ion linear accelerators. *See* PARTICLE ACCELERATOR.

The best starting point for discussing this concept is to consider the binding energy of atomic electrons as the charge Z of a heavy nucleus is increased. If the nucleus is assumed to be a point charge, the total energy E of the $1s_{1/2}$ level drops to 0 when $Z = 137$. This so-called $Z = 137$ catastrophe had been well known, but it was argued loosely that it disappears when the finite size of the nucleus is taken into account. However, in 1969 it was shown that the problem is not removed but merely postponed, and reappears around $Z = 173$. Any level $E(nj)$ can be traced down to a binding energy of twice the electronic rest mass if the nuclear charge is further increased. At the corresponding charge number, called Z_{cr}, the state dives into the negative-energy continuum of the Dirac equation (the so-called Dirac sea). The overcritical state acquires a width and is spread over the continuum. *See* ANTIMATTER; RELATIVISTIC QUANTUM THEORY.

When Z exceeds Z_{cr} a K-shell electron is bound by more than twice its rest mass, so that it becomes energetically favorable to create an electron-positron pair. The electron becomes bound in the $1s_{1/2}$ orbital and the positron escapes. The overcritical vacuum state is therefore said to be charged. *See* POSITRON.

Clearly, the charged vacuum is a new ground state of space and matter. The normal, undercritical, electrically neutral vacuum is no longer stable in overcritical fields: it decays spontaneously into the new stable but charged vacuum. Thus the standard definition of the vacuum, as a region of space without real particles, is no longer valid in very strong external fields. The vacuum is better defined as the energetically deepest and most stable state that a region of space can have while being penetrated by certain fields.

Superheavy quasimolecules. Inasmuch as the formation of a superheavy atom of $Z > 173$ is very unlikely, a new idea is necessary to test these predictions experimentally. That idea, based on the concept of nuclear molecules, was put forward in 1969: a superheavy quasimolecule forms temporarily during the slow collision of two heavy ions. It is sufficient to form the quasimolecule for a very short instant of time, comparable to the time scale for atomic processes to evolve in a heavy atom, which is typically of the order 10^{-18} to 10^{-20}. Suppose a uranium ion is shot at another uranium ion at an energy corresponding to their Coulomb barrier, and the two, moving slowly (compared to the K-shell electron velocity) on Rutherford hyperbolic trajectories, are close to each other (compared to the K-shell electron orbit radius). Then the atomic electrons move in the combined Coulomb potential of the two nuclei, thereby experiencing a field corresponding to their combined charge of 184. This happens because the ionic velocity (of the order of $c/10$) is much smaller than the orbital electron velocity (of the order of c), so that there is time for the electronic molecular orbits to be established, that is, to adjust to the varying distance between the charge centers, while the two ions are in the vicinity of each other. *See* QUASIATOM.

Giant nuclear systems. The energy spectrum for positrons created in, for example, a uranium-curium collision consists of three components: the induced, the direct, and the spontaneous, which add up to a smooth spectrum. The presence of the spontaneous component leads only to 5–10% deviations for normal nuclear collisions along Rutherford trajectories. This situation raises the question as to whether there is any way to get a clear qualitative signature for spontaneous positron production. Suppose that the two colliding ions, when they come close to each other, stick together for a certain time Δt before separating again. The longer the sticking, the better is the static approximation. For Δt very long, a very sharp line should be observed in the positron spectrum with a width corresponding to the natural lifetime of the resonant positron-emitting state. The observation of such a sharp line will indicate not only the spontaneous decay of the vacuum but also the formation of giant nuclear systems ($Z > 180$). *See* Linewidth; Nuclear molecule.

Search for spontaneous positron emission. The search for spontaneous positron emission in heavy-ion collisions began in 1976. Of special interest are peak structures in the positron energy distribution. However, the issue of spontaneous positron production in strong fields remains open. If line structures have been observed at all, they are most likely due to nuclear conversion processes. The observation of vacuum decay very much depends on the existence of sufficiently long-lived (at least 10^{-20} s) giant nuclear molecular systems. Therefore, the investigation of nuclear properties of heavy nuclei encountering heavy nuclei at the Coulomb barrier is a primary task.

Other field theories. The idea of overcriticality also has applications in other field theories, such as those of pion fields, gluon fields (quantum chromodynamics), and gravitational fields (general relativity).

A heavy meson may be modeled as an ellipsoidal bag, with a heavy quark Q and antiquark $\bar{Q}$ located at the foci of the ellipsoid. The color-electric or glue-electric field lines do not penetrate the bag surface. The Dirac equation may be solved for light quarks q and antiquarks $\bar{q}$ in this field of force. In the spherical case the potential is zero, and the solutions with different charges degenerate. As the source charges Q and $\bar{Q}$ are pulled apart, the wave functions start to localize. At a critical deformation of the bag, positive and negative energy states cross; that is, overrcriticality is reached and the color field is strong enough that the so-called perturbative vacuum inside the bag rearranges so that the wave functions are pulled to opposite sides and the color charges of the heavy quarks are completely shielded. Hence two new mesons of types $\bar{Q}q$ and $Q\bar{q}$ appear; the original meson fissions. *See* Gluons; Quantum chromodynamics; Quarks. [W.Gr.]

Supercritical fluid Any fluid at a temperature and a pressure above its critical point; also, a fluid above its critical temperature regardless of pressure. Below the critical point the fluid can coexist in both gas and liquid phases, but above the critical point there can be only one phase. Supercritical fluids are of interest because their properties are intermediate between those of gases and liquids, and are readily adjustable. *See* Critical phenomena; Phase equilibrium.

In a given supercritical fluid the thermodynamic and transport properties are a function of density, which depends strongly on the fluid's pressure and temperature. The density may be adjusted from a gaslike value of 0.1 g/ml to a liquidlike value as high as 1.2 g/ml. Furthermore, as conditions approach the critical point, the effect of temperature and pressure on density becomes much more significant. Increasing the density of supercritical carbon dioxide from 0.2 to 0.5 g/ml, for example, requires raising the pressure from 85 to 140 atm (8.6 to 14.2 megapascals) at 158°F (70°C), but at 95°F (35°C) the required change is only from 65 to 80 atm (6.6 to 8.1 MPa).

For a given fluid, the logarithm of the solubility of a solute is approximately proportional to the solvent density at constant temperature. Therefore, a small increase in pressure, which causes a large increase in the density, can raise the solubility a few orders of magnitude. While almost all of a supercritical fluid's properties vary with density, some of these properties are more like those of a liquid while others are more like those of a gas. *See* Supercritical-fluid chromatography.

In most supercritical-fluid applications the fluid's critical temperature is less than 392°F (200°C) and its critical pressure is less than 80 atm (8.1 MPa). High critical temperatures require operating temperatures that can damage the desired product, while high critical pressures result in excessive compression costs. In addition to these pure fluids, mixed solvents can be used to improve the solvent strength. [K.Jo.; R.Len.]

Spercritical-fluid chromatography Any separation technique in which a supercritical fluid is used as the mobile phase. For any fluid, a phase diagram can be constructed to show the regions of temperature and pressure at which gases and liquids, gases and solids, and liquids and solids can coexist. For the gas-liquid equilibrium, there is a certain temperature and pressure, known as the critical temperature and pressure, below which a gas and a liquid can coexist but above which only a single phase (known as a supercritical fluid) can form.

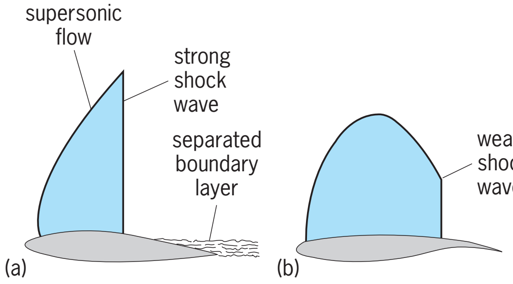
For example, the density of supercritical fluids is usually between 0.25 and 1.2 g/ml and is strongly pressure-dependent. Their solvent strength increases with density, so that molecules that are retained on the column can often be eluted simply by increasing the pressure under which the fluid is compressed.

Diffusion coefficients of solutes in supercritical fluids are tenfold greater than the corresponding values in liquid solvents (although about three orders of magnitude less than the corresponding values in gases). The high diffusivity of solutes in supercritical fluids decreases their resistance to mass transfer in a chromatographic column and hence allows separations to be made either very quickly or at high resolution. Molecules can be separated in a few minutes or less by using packed columns of the type used for high-performance liquid chromatography (HPLC). *See* Diffusion in gases and liquids.

Despite the relatively large number of separations made using packed-column supercritical-fluid chromatography that have been described since 1962, supercritical-fluid chromatography became popular only in the late 1980s with the commercial introduction of capillary (open-tubular) supercritical-fluid chromatographs. While supercritical-fluid chromatography may never be as widely used as gas chromatography or high-performance liquid chromatography, it provides a useful complement to these chromatographies. *See* Chemical separation techniques; Chromatography; Fluids; Gas chromatography; Liquid chromatography. [P.R.G.]

Supercritical wing A wing with special streamwise sections, or airfoils, which provide substantial delays in the onset of the adverse aerodynamic effects which usually occur at high subsonic flight speeds.

When the speed of an aircraft approaches the speed of sound, the local airflow about the airplane, particularly above the upper surface of the wing, may exceed the speed of sound. Such a condition is called supercritical flow. On previous aircraft, this supercritical flow resulted in the onset of a strong local shock wave above the upper surface of the wing (illus. *a*). This local



Comparison of airflow about airfoils. (*a*) Conventional airfoils, Mach number = 0.7. (*b*) Supercritical airfoils. Mach number = 0.8.

wave caused an abrupt increase in the pressure on the surface of the wing, which may cause the surface boundary-layer flow to separate from the surface, with a resulting severe increase in the turbulence of the flow. The increased turbulence leads to a severe increase in drag and loss in lift, with a resulting decrease in flight efficiency. The severe turbulence also caused buffet or shaking of the aircraft and substantially changed its stability or flying qualities. *See* Aerodynamic force; Aerodynamic wave drag; Low-pressure gas flow; Shock wave; Transonic flight.

Supercritical airfoils are shaped to substantially reduce the strength of the shock wave and to delay the associated boundary-layer separation (illus. *b*). Since the airfoil shape allows efficient flight at supercritical flight speeds, a wing of such design is called a supercritical wing. *See* Airplane; Wing. [R.T.Wh.]

Superfluidity The frictionless flow of liquid helium at low temperature; also, the flow of electric current without resistance in certain solids at low temperature (superconductivity).

Both helium isotopes have a superfluid transition, but the detailed properties of their superfluid states differ considerably because they obey different statistics. ^{4}He, with an intrinsic spin of 0, is subject to Bose-Einstein statistics, and ^{3}He, with a spin of $^1/_2$, to Fermi-Dirac statistics. There are two distinct superfluid states in ^{3}He called A and B.

The term “superfluidity” usually implies He II or the A and B phases of ^{3}He, but the basic similarity between these and the “fluid” consisting of pairs of electrons in superconductors is sufficiently strong to designate the latter as a charged superfluid. Besides flow without resistance, superfluid helium and superconducting electrons display quantized circulating flow patterns in the form of microscopic vortices. *See* Bose-Einstein statistics; Liquid helium; Quantized vortices; Second sound; Superconductivity. [L.J.C.]

Supergiant star A member of a class of evolved stars that occupy the top of the Hertzsprung-Russell diagram to the right of the main sequence. The absolute visual magnitudes (M_V) of supergiants range approximately between −4 and −10, and they are the largest and brightest stars. They are recognized by their spectroscopic characteristics. For example, those in class A have narrow hydrogen lines. Supergiants are subdivided into classes Ib (M_V about −5) and Ia (M_V about −7). A “hypergiant class zero” was later added near $M_V = -10$; the use of transition class Ia-0 at absolute visual magnitudes near −9 is now common. Red supergiants are the largest of all stars, and at maximum can reach diameters approaching that of the orbit of Saturn.

In an evolutionary sense, supergiants are stars above about 10 solar masses and absolute visual magnitude −6 that began main-sequence life hotter than class B1 and cannot evolve to become white dwarfs. As progeny of O stars, supergiants are exceedingly rare. Supergiant masses allow further burning of carbon and oxygen to oxygen, neon, and magnesium; thence to silicon and sulfur; and thence to iron. The iron cores collapse to produce type II supernovae, the condensed remnants at the centers becoming either neutron stars or, from the most massive stars, black holes. *See* Astronomical spectroscopy; Black hole; Hertzsprung-Russell diagram; Neutron star; Spectral type; Star; Stellar evolution; Supernova. [J.B.Ka.]

Supergranulation A system of convective cells, with typical diameters of 20,000 km (12,000 mi), that cover the Sun’s surface. Solar convection cells are invisible in ordinary photographs.

High-resolution photographs of the Sun’s visible surface reveal the granulation, a closely packed cellular grid having bright (hot) centers surrounded by dark (cool) lanes. Granules have lifetimes of 10–30 minutes and average diameters of 1000 km (620 mi). In the 1930s, L. Biermann suggested that, in the outer 30% of the Sun, heat from the Sun’s interior is transported to the surface by convection, just like hot rising bubbles in a pot of boiling soup heated from below. The granules are the boiling bubbles (plumes) of this convective process. Theorists in the 1950s proposed that the bubble sizes are approximately equal to the local scale height H (the distance in which density or pressure changes by a factor $e \approx 2.7$). Since H varies from about 1000 km (620 mi) at the Sun’s surface to 100,000 km (62,000 mi) at the base of the convection zone, a very large range of plume sizes was hypothesized. *See* Convection (heat).

In 1959, R. Leighton modified the spectroheliograph to image the Sun using the Doppler and Zeeman effects. Images of line-of-sight (approaching and receding) gas motions (Dopplergrams) and of magnetic fields (magnetograms) could be obtained. The Dopplergrams showed a new cell structure with area 400 times that of the granulation, having a mainly horizontal flow pattern. Lifetimes of most supergranules are 1–2 days, but observations in 1998 with the Michelson Doppler Imager (MDI) on the *Solar and Heliospheric Observatory* (*SOHO*) spacecraft showed that some live longer than 4 days. The cells form an irregular polygonal structure, with most of the down-flow occurring at the polygon vertices. The supergranules fit neatly within an essentially identical network (grid) structure seen in magnetograms. The kinetic energy of the supergranular motions at the Sun’s surface exceeds the magnetic field’s ability to resist such motions, and thus the magnetic field is dragged forcibly to the supergranule boundaries until the two patterns coincide. This magnetic field, in turn, causes local heating of the upper solar atmosphere (chromosphere), producing a similar chromospheric network pattern seen in high-temperature spectral lines. *See* Doppler effect; Fraunhofer lines; Solar magnetic field; Spectrograph; Spectroheliograph; Sun; Zeeman effect. [G.W.Si.]

Supergravity A theory that attempts to unify gravitation with the other fundamental interactions. The first, and only, completely successful unified theory was constructed by James Clerk Maxwell, in which the up-to-then unrelated electric and magnetic phenomena were unified in his electrodynamics. *See* Fundamental interactions; Maxwell’s equations.

Electroweak theory. The second stage of unification concerns the unification of electromagnetic and weak interactions, using Maxwell’s theory as a guide. This was accomplished making use of the nonabelian gauge theories invented by C. N. Yang and R. L. Mills, and of spontaneous symmetry breaking. The symmetry of Maxwell’s theory is very similar to spatial rotations about an axis, rotating the vector potentials while leaving the electric and magnetic fields unchanged. It is a local invariance because the rotations about a fixed axis can be made by different amounts at different points in space-time. Thus, Maxwell’s theory is invariant under a one-parameter group of transformations U(1). In Yang-Mills theory this local invariance was generalized to theories with larger symmetry groups such as the three-dimensional rotation group $\mathrm{SO}(3) \simeq \mathrm{SU}(2)$ which has three parameters. The number of parameters of the local symmetry (gauge) group is also equal to the number of 4-vector potentials in the gauge theory based on that group. A detailed analysis of weak and electromagnetic forces shows that their description requires four 4-vector potentials (gauge fields), so that the gauge group must be a four-parameter group. In fact, it is the product $\mathrm{SU}(2) \cdot \mathrm{U}(1)$. *See* Electroweak interaction; Gauge theory; Group theory; Symmetry breaking.

Grand unified theories. In the third stage of unification, electroweak and strong forces are regarded as different components of a more general force which mediates the interactions of particles in a grand unified model. Strong forces are responsible for the interactions of hadrons and for keeping quarks confined inside hadrons. They are described by eight massless 4-vector potentials (gluons), the corresponding eight-parameter group being SU(3). This local symmetry is called color, and the corresponding theory quantum chromodynamics (QCD). The combination $\mathrm{SU}(3) \cdot \mathrm{SU}(2) \cdot \mathrm{SU}(1)$ has strong experimental support, and has come to be known as the standard model. Thus the gauge group of any grand unified model must include the standard model as a subsymmetry. The most dramatic prediction of these theories is the decay of protons. *See* GLUONS; GRAND UNIFICATION THEORIES; PROTON; QUANTUM CHROMODYNAMICS; QUARKS; STANDARD MODEL.

Supersymmetry and supergravity theories. A still higher and more ambitious stage of unification deals with the possibility of combining grand unified and gravity theories into a superunified theory, also known as supergravity. To achieve this, use is made of the dual role played by local internal symmetry groups. On the one hand, they describe the behavior of forces. On the other hand, they classify the elementary particles (fields) of the theory into multiplets: spin-zero fields in one multiplet, spin-1/2 fields in another multiplet, and so forth, but never fermions and bosons in a single irreducible multiplet of internal symmetry. This last restriction used to be a major obstacle on the way to superunification. This is because, of all the elementary particles, only the quanta of the gravitational field (gravitons) have spin 2, so that a multiplet of elementary particles including the graviton must of necessity involve particles of different spin. But then by an internal symmetry transformation, which is by definition distinct from space-time (Lorentz) transformations, it is possible to "rotate" particles of different spin into one another, thus altering their space-time transformation properties. This apparent paradox can be circumvented if both the internal symmetry and Lorentz transformations are part of a larger (supersymmetric) transformation group which also includes the spin-changing transformations. The irreducible multiplets of such supergroups naturally contain both fermions and bosons. This is how supersymmetry makes its appearance in supergravity theories. *See* GRAVITON; LORENTZ TRANSFORMATIONS; RELATIVITY; SUPERSYMMETRY; SYMMETRY LAWS (PHYSICS).

Effective theory. If supergravity models are regarded not as fundamental theories but as effective theories describing the low-energy behavior of superstring theories, it is possible to make a strong case for their usefulness. In that case, since supergravity is no longer a fundamental theory, it is no longer crucial that supergravity satisfy very stringent physical requirements such as renormalizability. In its role as an effective theory, supergravity has been used in a number of problems in particle physics. *See* ELEMENTARY PARTICLE; QUANTUM FIELD THEORY; SUPERSTRING THEORY. [F.M.]

Superheater A component of a steam-generating unit in which steam, after it has left the boiler drum, is heated above its saturation temperature. The amount of superheat added to the steam is influenced by the location, arrangement, and amount of superheater surface installed, as well as the rating of the boiler. The superheater may consist of one or more stages of tube banks arranged to effectively transfer heat from the products of combustion. *See* STEAM-GENERATING UNIT. [G.W.K.]

Superluminal motion Proper motion of an astronomical object apparently exceeding the velocity of light, *c*. This phenomenon is relatively common in the nuclei of quasars, many of which exhibit systematic changes in images of their radio-frequency emission over periods of months to years. In some cases, features in the image appear to separate at a speed inferred to be more than 10 times the speed of light, given the great distance of the quasars from Earth.

Superluminal motion was one of the most exciting discoveries to emerge from a technique in radio astronomy first developed in the late 1960s and called very long baseline interferometry (VLBI). This method involves the tape recording of radio signals from large antennas at up to 10–15 locations across the Earth, and the combination of these signals in a computer to form a radio image of the quasar at extremely high resolution (less than 0.001 arcsecond). *See* QUASAR; RADIO ASTRONOMY; RADIO TELESCOPE.

Superluminal motion is seen mostly in quasars but also in some other active galactic nuclei. This rapid motion is confined to within a few tens of parsecs of the nucleus, whose power source is believed to be a massive black hole. At least 30 examples of superluminal motion are now known. Most show apparent speeds less than 10*c*, but examples of speeds above 20*c* have been found. A very few objects in the Milky Way Galaxy also show superluminal motion. An example is GRS 1915 + 105, a relativistic jet source, which emits strongly in the x-ray as well as in the radio spectrum. Because the object is within the Milky Way Galaxy, its apparent speed of 1.25*c* is detectable in less than a day. *See* GALAXY, EXTERNAL; X-RAY ASTRONOMY.

Announcement of the discovery of superluminal motion in 1972 caused widespread concern because of the apparent violation of Albert Einstein's special theory of relativity, even though the basic explanation still favored now was in fact predicted some years before the announcement. Many explanations were proposed (besides Einstein's theory being incorrect), but only the relativistic jet model has stood the test of time. Superluminal motion is explained in this model as primarily a geometric effect. A feature (perhaps a cloud of relativistic plasma) moves away from the nucleus of the quasar at high (relativistic) speed (but less than *c*) at a small angle to the line of sight to the Earth. Radio waves from the moving feature arrive only slightly later than waves from the nucleus, whereas the feature took a much longer time to reach its current position. The motion appears superluminal because the speed is calculated using this much shorter time interval. As the speed approaches *c* and the angle to the line of sight decreases, the apparent speed can be arbitrarily large. In this explanation, no material speeds faster than *c* are required, so there is no conflict with special relativity. *See* RELATIVITY. [S.C.U.]

Supermassive stars Hypothetical objects with masses exceeding 60 solar masses, the mass of the largest known ordinary stars (1 solar mass equals 4.4×10^{30} lbm or 2×10^{30} kg). The term is most often used in connection with objects larger than 10^4 solar masses that might be the energy source in quasars and active galaxies. These objects probably do not exist. However, their nonexistence is one of the major assumptions that makes the case for giant black holes, rather than supermassive stars, being the central engines of quasars. *See* BLACK HOLE; QUASAR; STAR. [H.L.Sh.]

Supermultiplet A generalization of the concept of a multiplet. A multiplet is a set of quantum-mechanical states, each of which has the same value of some fundamental quantum number and differs from the other members of the set by another quantum number which takes values from a range of numbers dictated by the fundamental quantum number. The number of states in the set is called the multiplicity or dimension of the multiplet. The concept was originally introduced to describe the set of states in a nonrelativistic quantum-mechanical system with the same value of the orbital angular momentum, L, and different values of the projection of the angular momentum on an axis, M. The values that M can take are the integers between $-L$ and L, $2L + 1$ in all. This is the dimension of the multiplet. If the hamiltonian operator describing the system is rotationally invariant, all states of the multiplet have the same energy. A supermultiplet is a generalization of the concept of multiplet to the case when there are several quantum numbers that describe the quantum-mechanical states. *See* ANGULAR MOMENTUM; SYMMETRY LAWS (PHYSICS).

Both concepts, multiplet and supermultiplet, acquire a precise mathematical meaning by the use of the theory of group transformations. A multiplet is an irreducible representation of a group, G. The quantum number called fundamental in the paragraph above labels the representation of the group. The other quantum number labels the representation of a subgroup G' of G. For angular momentum, the group G is the rotation group, called special orthogonal group in three dimensions, SO(3), and its subgroup G' is the group of special orthogonal transformations in two dimensions, SO(2). A supermultiplet is a generalization to the case in which the group G is not a group of rank one but has larger rank. A group of rank one has only one quantum number to label its representations. The concept of a multiplet or supermultiplet is particularly useful in the classification of states of physical systems. *See* GROUP THEORY; NONRELATIVISTIC QUANTUM THEORY; QUANTUM MECHANICS; QUANTUM NUMBERS.

The term supermultiplet was first used by E. P. Wigner in 1932 in order to classify the quantum-mechanical states of light atomic nuclei. The constituents of these are protons, p, and neutrons, n. Each proton and neutron has an intrinsic spin, S, of $^1/_2$ in units of $\hbar$, which is Planck's constant divided by 2π. The projection of the intrinsic spin on an axis, S_z, is then $S_z = {}^1/_2$ or $-{}^1/_2$ (spin up or down). In addition to having the same spin, the proton and neutron have essentially the same mass but differ in that the proton is charged whereas the neutron is not. They can thus be regarded as different charge states of the same particle, a nucleon. The distinction can be made formal by introducing a quantum number called isotopic spin, T, which has the value $^1/_2$. The two charge orientations, T_z, are taken to be $^1/_2$ for the proton and $-{}^1/_2$ for the neutron. There are thus four constituents of nuclei, protons and neutrons with spin up and down, that is, $p\uparrow$, $p\downarrow$, $n\uparrow$, and $n\downarrow$. The set of transformations among these constituents forms a group called SU(4), the special unitary group in four dimensions. This is the group G for Wigner's theory. The representations of SU(4), that is, Wigner supermultiplets, are characterized by three quantum numbers (λ_1, λ_2, λ_3) with $\lambda_1 \geq \lambda_2 \geq \lambda_3$. *See* I-SPIN; NUCLEAR STRUCTURE. [F.I.]

Supernova The catastrophic, explosive death of a star, accompanied by the sudden, transient brightening of the star to an optical luminosity comparable to that of an entire galaxy.

A supernova shines typically for several weeks to several months with a luminosity between 2×10^8 and 5×10^9 times that of the Sun, then gradually fades away. Each explosion ejects from one to several tens of solar masses at speeds ranging from thousands to tens of thousands of kilometers per second. The total kinetic energy, 10^{44} joules (2.5×10^{28} megatons of high explosive), is about 100 times the total light output, making supernovae some of the highest-energy explosions in the universe. Unlike its fainter relative, the nova, a supernova does not recur for the same object. *See* NOVA.

Supernovas may be grouped according to either their observational characteristics or their explosion mechanism. Basically, type I supernovae have no hydrogen in their spectrum; type II supernovae do. Two mechanisms are involved: thermonuclear explosion in white dwarfs and gravitational collapse in massive stars. Type I supernovae of different subclasses can occur by either mechanism, but it is thought that most type II supernovae are powered by gravitational collapse.

During the last thousand years, there have been approximately seven supernovae visible to the unaided eye, in 1006, 1054, 1181, 1408, 1572, 1604, and 1987. SN 1006 may have been as bright as the quarter moon. The first six of these occurred in the Earth's vicinity of the Milky Way Galaxy. But the last, and only, naked-eye supernova since the invention of modern instrumentation occurred in the Large Magellanic Cloud, a small satellite galaxy of the Milky Way about 160,000 light-years away. Supernovae are discovered in other galaxies at a rate of about 150 per year. Most supernovae in the Milky Way Galaxy are obscured by dust, but various arguments suggest that about two type II supernovae per century and one type Ia every other century occur in the Milky Way Galaxy. *See* MAGELLANIC CLOUDS; MILKY WAY GALAXY.

Type Ia supernovae. Type Ia supernovae may be regarded as nature's largest thermonuclear bombs. They occur when an accreting white dwarf, composed of carbon and oxygen, grows to a mass 1.38 times that of the Sun, almost the critical mass that can be supported by electron degeneracy pressure, and ignites carbon fusion near its center. Ignition occurs when carbon fusion at the center releases energy faster than neutrinos can carry it away. Because the pressure is insensitive to the temperature, a nuclear runaway occurs. Fusion releases energy, which raises the temperature, which makes fusion go faster, but the gas cannot expand and cool. The nuclear runaway spreads in about 1 second through the star. The energy released by this nuclear burning is more than enough to completely blow the white dwarf apart with high velocity. Nothing remains—no neutron star, no black hole, and no burst of neutrino emission. *See* BINARY STAR; THERMONUCLEAR REACTION.
