Prof. Justin Revenaugh. *Department of Geology and Geophysics, University of Minnesota, Minneapolis.* GEOPHYSICS.

Dr. Roger M. Rowell. *USDA-Forest Service, Forest Products Laboratory, Madison, Wisconsin.* FORESTRY.

Prof. John L. Safko. *Department of Physics and Astronomy, University of South Carolina, Columbia.* CLASSICAL MECHANICS.

Dr. Andrew P. Sage. *Founding Dean Emeritus and First American Bank Professor, University Professor, School of Information Technology and Engineering, George Mason University, Fairfax, Virginia.* CONTROL AND INFORMATION SYSTEMS.

Prof. Ivan K. Schuller. *Department of Physics, University of California, San Diego.* CONDENSED-MATTER PHYSICS.

Richard P. Schulz. *American Electric Power Co., Gahanna, Ohio.* ELECTRICAL POWER ENGINEERING.

Dr. David M. Sherman. *Department of Earth Sciences, University of Bristol, United Kingdom.* MINERALOGY.

Dr. Steven A. Slack. *Associate Vice President for Agricultural Administration, Director, Ohio Agricultural Research and Development Center, and Associate Dean for Research, College of Food, Agricultural, and Environmental Sciences, Ohio State University, Wooster.* PLANT PATHOLOGY.

Prof. Arthur A. Spector. *Department of Biochemistry, University of Iowa, Iowa City.* BIOCHEMISTRY.

Dr. Bruce A. Stanley. *Director, Scientific Programs, Section of Technology Development and Research Resources, Penn State College of Medicine, Hershey, Pennsylvania.* PHYSIOLOGY.

Prof. Anthony P. Stanton. *Carnegie Mellon University, Pittsburgh, Pennsylvania.* GRAPHIC ARTS AND PHOTOGRAPHY.

Dr. Trent Stephens. *Department of Biological Sciences, Idaho State University, Pocatello.* DEVELOPMENTAL BIOLOGY.

Prof. John F. Timoney. *Department of Veterinary Science, University of Kentucky, Lexington.* VETERINARY MEDICINE.

Prof. Sam Treiman. *Deceased; formerly, Department of Physics, Joseph Henry Laboratories, Princeton University, Princeton, New Jersey.* THEORETICAL PHYSICS.

Dr. Bruce A. Voyles. *Professor, Department of Biological Chemistry, Grinnell College, Iowa.* VIROLOGY.

Dr. Sally E. Walker. *Associate Professor of Geology and Marine Science, University of Georgia, Athens.* INVERTEBRATE PALEONTOLOGY.

Prof. Pao K. Wang. *Department of Atmospheric and Oceanic Sciences, University of Wisconsin-Madison.* METEOROLOGY AND CLIMATOLOGY.

Dr. Nicole Y. Weekes. *Pomona College, Claremont, California.* NEUROPSYCHOLOGY.

Prof. Frank M. White. *Department of Mechanical Engineering, University of Rhode Island, Kingston.* FLUID MECHANICS.

Prof. Mary Anne White. *Killam Research Professor in Materials Science, Department of Chemistry, Dalhousie University, Halifax, Nova Scotia, Canada.* MATERIALS SCIENCE AND METALLURGIC ENGINEERING.

Prof. Thomas A. Wikle. *Head, Department of Geography, Oklahoma State University, Stillwater.* PHYSICAL GEOGRAPHY.

Dr. Gary Wnek. *Department of Chemical Engineering, Virginia Commonwealth University, Richmond.* CHEMICAL ENGINEERING.

Dr. James C. Wyant. *University of Arizona Optical Sciences Center, Tucson.* ELECTROMAGNETIC RADIATION AND OPTICS.

Preface

For more than four decades, the *McGraw-Hill Encyclopedia of Science & Technology* has been an indispensable scientific reference work for a broad range of readers, from students to professionals and interested general readers. Found in many thousands of libraries around the world, its 20 volumes authoritatively cover every major field of science. However, the needs of many readers will also be served by a concise work still covering the full breadth of science and technology.

With this in mind, the editors conceived a shorter version of the multivolume work that would retain the authoritativeness, accuracy, clarity, timeliness, quality, and coverage in a convenient, concise format. The result is the *McGraw-Hill Concise Encyclopedia of Science & Technology*, Fifth Edition. To achieve this convenient single volume, the editors extracted the essential text from each article in the parent work while retaining the same proportionality between subjects. The length of each article generally suits the importance and complexity of the subject as well as the current state of knowledge on this topic. The material has been condensed so that it is appropriate to the likely requirements of the reader seeking helpful information without extensive detail. The articles retain the identity of the original authors, all recognized experts, whose affiliations are included in a complete alphabetical listing of Contributors.

The reader will find over 7300 alphabetically arranged entries, many illustrated with images or diagrams. Most include cross references to other articles for background reading or further study. Dual measurement units (U.S. Customary and International System) are used throughout. The Appendix includes useful information complementing the articles. Finally, the Index provides quick access to specific information the reader needs.

This concise reference will fill the need for accurate, current scientific and technical information in a convenient, economical format. It can serve as the starting point for research by anyone seriously interested in science, even professionals seeking information outside their own specialty. It should prove to be a much used and much trusted addition to the reader's bookshelf.

MARK D. LICKER
Publisher

Organization of the Encyclopedia

Alphabetization. The 7300 article titles are sequenced on a word-by-word basis, not letter by letter. Hyphenated words are treated as separate words. In occasional inverted article titles, the comma provides a full stop. The Index is alphabetized on the same principles. Readers can turn directly to the pages for much of their research. An example of sequencing is:

Air
Air brake
Air-cushion vehicle
Air pollution
Air pollution, indoor
Air pressure
Air-traffic control
Airborne radar
Aircraft
Aistopoda

Cross references. Virtually every article has cross references set in Capitals and small capitals. These references offer the user the option of turning to other articles in the volume for related information.

Measurement units. Since some readers prefer the U.S. Customary system while others require the metric or International System of Units (SI), measurements in the Encyclopedia are given in dual units. Insight into the measurement systems is provided by the discussion in the Appendix, which also has handy conversion tables.

Contributors. The authorship of each article is specified at its conclusion, in the form of the contributor's initials for brevity. The contributor's full name and affiliation may be found in the "Contributor Affiliations" section at the back of the volume.

Appendix. Every user should explore the variety of succinct information supplied by the Appendix, which includes measurement tables, mathematical notation, fundamental constants, and scientific notation; and a biographical listing of scientists. For users wishing to go beyond the scope of this Encyclopedia, recommended books and journals are listed in the Bibliographies subsection of the Appendix; the titles are grouped by subject area.

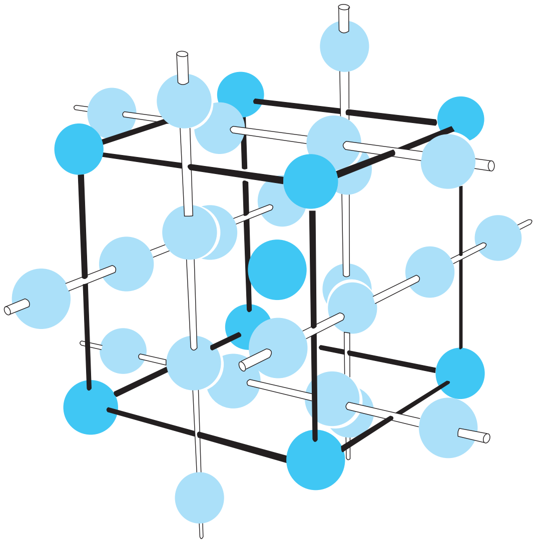
Index. The 30,000-entry Index offers the reader the time-saving convenience of being able to quickly locate specific information in the text, rather than approaching the Encyclopedia via article titles only. This elaborate breakdown of the volume's contents assures both the general reader and the professional of efficient use of the *McGraw-Hill Concise Encyclopedia of Science & Technology*.

A

A15 phases A series of intermetallic compounds which have a particular crystal structure and the chemical formula A_3B, where A represents a transition element and B can be either a transition or a nontransition element. Many A15 compounds exhibit the phenomenon of superconductivity at relatively high temperatures in the neighborhood of 20 K (−424°F) and in high magnetic fields on the order of several tens of teslas (several hundred kilogauss). High-temperature–high-field superconductivity has a number of important technological applications and is a challenging fundamental research area in condensed-matter physics. *See* SUPERCONDUCTIVITY.

The A15 compounds crystallize in a structure in which the unit cell, the repeating unit of the crystal structure, has the overall shape of a cube. The B atoms are located at the corners and in the center of the cube, while the A atoms are arranged in pairs on the cube faces (see illustration). A special characteristic of the A15 crystal structure is that the A atoms form mutually orthogonal linear chains that run throughout the crystal lattice, as shown in the illustration. The extraordinary superconducting properties of the A15 compounds are believed to be primarily associated with these linear chains of transition-element A atoms. *See* CRYSTAL.

Processes have been developed for preparing multifilamentary superconducting wires that consist of numerous filaments of a superconducting A15 compound, such as Nb_3Sn, embedded in a nonsuperconducting copper matrix. Superconducting wires can be used in electric power transmission lines and to wind electrically lossless coils (solenoids) for superconducting electrical machinery (motors and generators) and magnets. Superconducting magnets are employed to produce intense magnetic fields for laboratory research, confinement of high-temperature plasmas in nuclear fusion research, bending beams of charged particles in accelerators, levitation of highspeed trains, mineral separation, and energy storage. *See* SUPERCONDUCTING DEVICES. [M.B.Ma.]



A15 crystal structure of the A_3B intermetallic compounds. The light spheres represent the A atoms; the dark spheres represent the B atoms. The linear chains of A atoms are emphasized.

Aardvark A nocturnal, burrowing, insectivorous mammal of the genus *Orycteropus* in the order Tubulidentata. It averages 6 ft (1.8 m) in length and is covered with short, sparse hair (*see* illustration).

The cape aardvark (*Orycteropus afer*) ranges from Ethiopia to southern Africa.

The aardvark is structurally modified for its diet of ants. The adult lacks canines and incisors; the only teeth are 20 crushing or cheek teeth in a series of 5 upper and 5 lower teeth on both sides of the jaw. These teeth, which do not have roots or enamel, continually grow throughout the life of the animal, have the appearance of tubelike structures of dentine, and are the basis for the ordinal name Tubulidentata. The short, stout, powerful forelimbs terminate in flat claws, which enable the aardvark to burrow rapidly into termite mounds. The head is long and narrow, ending in a tubular snout. The long tubular tongue extends up to 18 in. (45 cm) from the mouth.

Some disagreement exists as to the number of species of *Orycteropus*. The aardvark is edible and economically important for its thick hide which resembles pigskin. *See* ANTEATER; DENTITION; MAMMALIA; TUBULIDENTATA. [C.B.C.]

Abaca One of the strongest of the hard fibers, commercially known as Manila hemp. Abaca is obtained from the leafstalks of a member of the banana family, *Musa textilis*. The plant resembles the fruiting banana, but is a bit shorter in stature, bears small inedible fruits, and has leaves that stand more erect than those of the banana, and that are slightly narrower, more pointed, and 5–7 ft (1.5–2 m) long. The plant was domesticated long ago in the southern Philippines.

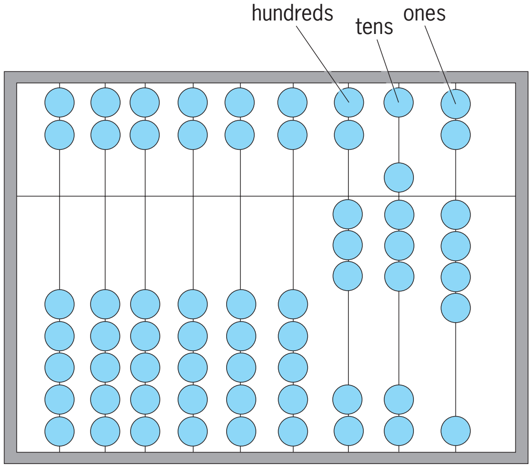
Abaca prefers a warm climate with year-round rainfall, high humidity, and absence of strong winds. Soils must always be moist but the plant does not tolerate waterlogging. Abaca grows best on alluvial soils in the southern Philippines and northern Borneo below 1500 ft (450 m) elevation. The plant is best propagated by rootstalk suckers. There are about 75 varieties grown in the Philippines, grouped into seven categories, each of which varies slightly in height, length, and quality and yield of fiber.

The fiber ranges 6–14 ft (1.8–4.2 m) in strand length, is lustrous, and varies from white to dull yellow. As one of the longest and strongest plant fibers, resistant to fresh and salt water, abaca is favored for marine hawsers and other high-strength ropes. Abaca is also used in sackings, mattings, strong papers, and handicraft art goods.

Abaca is affected by several diseases, of which the chief are bunchy top, mosaic, and wilt. Bunchy top is caused by a virus spread by the banana aphid (*Pentalonia nigronervosa*). Mosaic is also caused by a virus spread by aphids (chiefly *Rhopalosiphum nymphaeae* and *Aphis gossypii*). Abaca wilt is caused by a soil or water-borne fungus, chiefly attacking plant roots. [E.G.N.]

Abacus An early mechanical calculator whose design has evolved through the centuries, with two styles in use today. Both the Chinese and the Japanese styles consist of a frame with a crossbeam. They may be made from many different materials, such as wood or brass. Rods or wires carrying sliding beads extend vertically through the crossbeam. The Chinese *suan pan* has two beads above the beam on each rod and five beads below. Each rod of the Japanese *soroban* carries one bead above and four below.

In working with whole numbers, the rightmost rod represents the ones position, with each rod to the left representing the tens, hundreds, thousands, and so forth, respectively. The beads below the crossbeam represent one of that rod's units (that is, a one, a ten, a hundred, and so forth), and those above represent five. Beads are moved from the outer position toward the crossbeam when used to represent a number (see illustration).

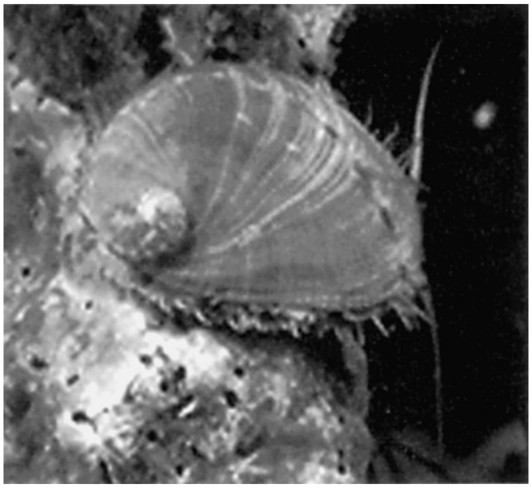


Beads positioned to represent 384 on a Chinese abacus.

The abacus, in contrast to the electronic calculator, is simply an aid to mental computation. A well-developed facility with numbers is required in order to use it effectively. For this reason, it is the calculator of choice for teachers in the Far East. The advent of the electronic calculator, while a boon to the scientific community, may have little impact on shop owners who are comfortable with the abacus. *See* CALCULATORS. [M.K.G.]

Abalone A gastropod mollusk comprising the single genus *Haliotis*, family Haliotidae, also known as ear shell, ormer, or paua. The abalones are cosmopolitan species of temperate and tropical seas. They are active noctumally and feed principally on algae.

The shell is flattened, with an enlarged body whorl and reduced spire, and looks like an ear (see illustration). Characteristically, the shell is perforated by a series of small pores which allow for more direct elimination of water from the mantle cavity.



Typical abalone ear-shaped shell perforated by pores.

Exposed parts of the body are pigmented and show a varying range of colors, such as black, green, or brown. The larvae are pelagic and free-swimming among the plankton in coastal waters for about 2 days, after which they settle down and develop to the adult. *See* CIRCULATION; GASTROPODA; RESPIRATORY PIGMENTS (INVERTEBRATE). [C.B.C.]

Abdomen A major body division of the vertebrate trunk lying posterior to the thorax; and in mammals, bounded anteriorly by the diaphragm and extending to the pelvis. The diaphragm separates the abdominal or peritoneal cavity from the pleural and pericardial cavities of the thorax. In all pulmonate vertebrates (possessing lungs or lunglike organs) other than mammals, the lungs lie in the same cavity with the abdominal viscera, and this cavity is known as the pleuroperitoneal cavity.

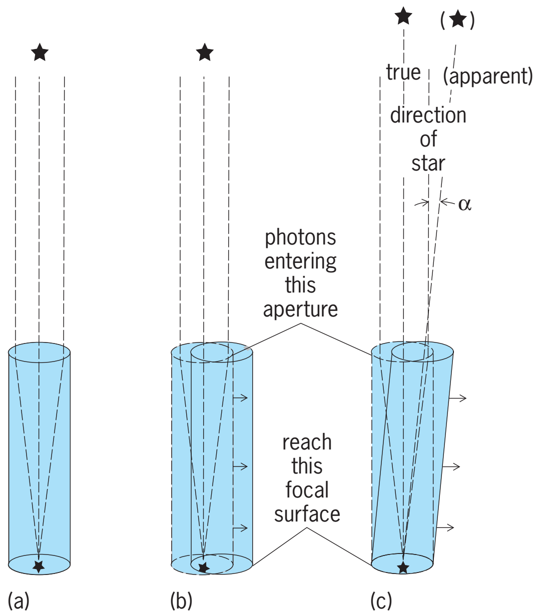
The large coelomic cavity that occupies the abdomen contains the viscera within the peritoneal sac. Connecting sheets of peritoneum from the body wall to the various organs form the mesenteries. Other folds of the peritoneum form the omenta.

The term abdomen is also applied to a similar major body division of arthropods and other animals. [W.J.B.]

Aberration (astronomy) The apparent change in direction of a source of light caused by an observer's component of motion perpendicular to the impinging rays.

To visualize the effect, first imagine a stationary telescope (illustration *a*) aimed at a luminous source such as a star, with photons traveling concentrically down the tube to an image at the center of the focal plane. Next give the telescope a component of motion perpendicular to the incoming rays (illustration *b*). Photons passing the objective require a finite time to travel the length of the tube. During this time the telescope has moved a short distance, causing the photons to reach a spot on the focal plane displaced from the former image position. To return the image to the center, the telescope must be tilted in the direction of motion by an amount sufficient to ensure that the photons once again come concentrically down the tube in its frame of reference (illustration *c*). The necessary tilt angle α is given by $\tan \alpha = vc$, where v is the component of velocity perpendicular to the incoming light and c is the velocity of light. (An analogy illustrating aberration is the experience that, in order for the feet to remain dry while walking through vertically falling rain, it is necessary to tilt an umbrella substantially forward.)

This discovery provided the first direct physical confirmation of the Copernican theory. A second important application of aberration has been its clear-cut demonstration that, as is axiomatic to special relativity, light reaching the Earth has a velocity



Demonstration of aberration, (*a*) Fixed telescope; photons form image at center of focal plane, (*b*) Moving telescope; image is displaced from center, (*c*) Tilted moving telescope is required to restore image to center.

unaffected by the relative motion of the source toward or away from the Earth. *See* Light; Parallax (astronomy). [H.J.S.]

Aberration (optics) A departure of an optical image-forming system from ideal behavior. Ideally, such a system will produce a unique image point corresponding to each object point. In addition, every straight line in the object space will have as its corresponding image a unique straight line. A similar one-to-one correspondence will exist between planes in the two spaces. This type of mapping of object space into image space is called a collinear transformation. When the conditions for a collinear transformation are not met, the departures from that ideal behavior are termed aberrations. They are classified into two general types, monochromatic aberrations and chromatic aberrations. The monochromatic aberrations apply to a single color, or wavelength, of light. The chromatic aberrations are simply the chromatic variation, or variation with wavelength, of the monochromatic aberrations. *See* Chromatic aberration; Geometrical optics; Optical image.

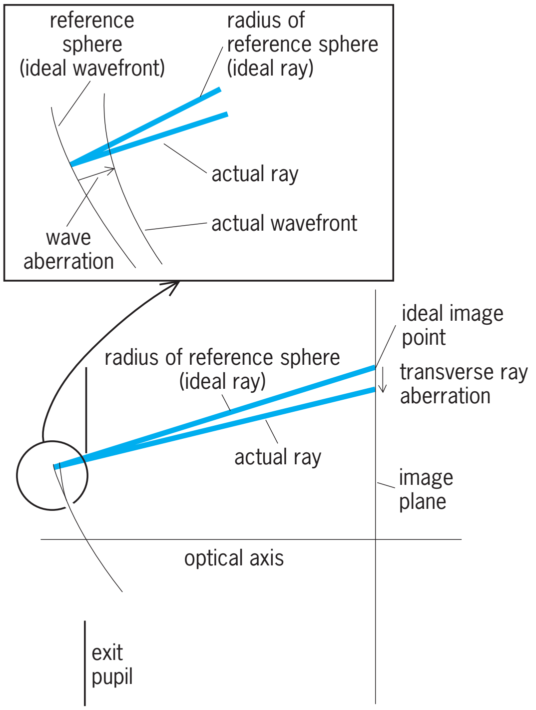


Diagram of the image space of an optical system, showing aberration measures: the wave aberration and the transverse ray aberration.

The monochromatic aberrations can be described in several ways. Wave aberrations are departures of the geometrical wavefront from a reference sphere with its vertex at the center of the exit pupil and its center of curvature located at the ideal image point. The wave aberration is measured along the ray and is a function of the field height and the pupil coordinates of the reference sphere (see illustration).

Transverse ray aberrations are measured by the transverse displacement from the ideal image point to the ray intersection with the ideal image plane. The chief monochromatic aberrations are spherical (aperture) aberrations, coma, astigmatism, curvature of field, and distortion. *See* Chromatic aberration; Geometrical optics; Lens (optics); Optical image; Optical surfaces.

Each surface in an optical system introduces aberrations as the light beam passes through the system. The aberrations of the entire system consist of the sum of the surface contributions, some of which may be positive and others negative. The challenge of optical design is to balance these contributions so that the total aberrations of the system are tolerably small. In a well-corrected system the individual surface contributions are many times larger than the tolerance value, so that the balance is rather delicate, and the optical system must be made with a high degree of precision. *See* Lens (optics); Optical surfaces. [R.V.S.]

Abrasive A material of extreme hardness that is used to shape other materials by a grinding or abrading action. Abrasive materials may be used either as loose grains, as grinding wheels, or as coatings on cloth or paper. They may be formed into ceramic cutting tools that are used for machining metal in the same way that ordinary machine tools are used. Because of their superior hardness and refractory properties, they have advantages in speed of operation, depth of cut, and smoothness of finish.

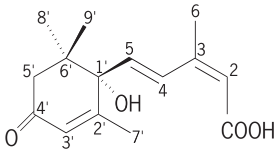
Abrasive products are used for cleaning and machining all types of metal, for grinding and polishing glass, for grinding logs to paper pulp, for cutting metals, glass, and cement, and for manufacturing many miscellaneous products such as brake linings and nonslip floor tile.

The important natural abrasives are diamond, corundum, emery, garnet, feldspar, calcined clay, lime, chalk, and silica, SiO_2, in its many forms—sandstone, sand, flint, and diatomite.

The synthetic abrasive materials are silicon carbide, aluminum oxide, titanium carbide, and boron carbide. The synthesis of diamond puts this material in the category of manufactured abrasives. [J.F.McM.]

Abscisic acid One of the five major plant hormones. It has a number of important functions in plant growth and development. The name abscisic acid (ABA) is derived from the ability of the substance to promote abscission. It is also a potent inhibitor of growth. In this capacity it helps to induce and prolong dormancy of buds. Abscisic acid is a powerful inhibitor of seed germination and has an important role in the closure of stomata. *See* Abscission; Dormancy.

Abscisic acid is distributed throughout the plant body but is found in highest concentrations in leafy tissues, fruits, and seeds. The principal site of ABA synthesis is the chloroplast. Synthesis of ABA increases markedly when the plant is under stress.



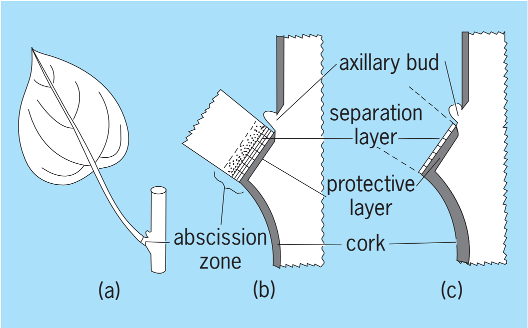
Structural formula for +-abscisic acid.

The chemical structure of ABA is shown in the illustration. ABA is a member of the terpenoid family of chemicals, which includes a number of essential oils, insect hormones, steroids, gibberellins, carotenoids, and natural rubber. It is a weak organic acid, as are two other plant hormones, auxin and gib-berellin. Natural ABA is dextrorotatory, hence the "+" in front of the name. *See* AUXIN; GIBBERELLIN; PLANT HORMONES. [F.T.A.]

Abscission The process whereby a plant sheds one of its parts. Leaves, flowers, seeds, and fruits are parts commonly abscised. Almost any plant part, from very small buds and bracts to branches several inches in diameter, may be abscised by some species. However, other species, including many annual plants, may show little abscission, especially of leaves.

Abscission may be of value to the plant in several ways. It can be a process of self-pruning, removing injured, diseased, or senescent parts. It permits the dispersal of seeds and other reproductive structures. It facilitates the recycling of mineral nutrients to the soil. It functions to maintain homeostasis in the plant, keeping in balance leaves and roots, and vegetative and reproductive parts.

In most plants the process of abscission is restricted to an abscission zone at the base of an organ (see illustration); here separation is brought about by the disintegration of the walls of a special layer of cells, the separation layer. The portion of the abscission zone which remains on the plant commonly develops into a corky protective layer that becomes continuous with the cork of the stem.



Diagrams of the abscission zone of a leaf. (*a*) A leaf with the abscission zone indicated at the base of the petiole. (*b*) The abscission zone layers shortly before abscission and (*c*) the layers after abscission.

Auxin applied experimentally to the distal (organ) side of an abscission zone retards abscission, while auxin applied to the proximal (stem) side accelerates abscission. The gibberellins are growth hormones which influence abscission. When applied to young fruits or to leaves, they tend to promote growth, delay maturation, and thereby indirectly prevent or delay abscission. Abscisic acid has the ability to promote abscission and senescence and to retard growth. Small amounts of ethylene have profound effects on the growth of plants and can distort and reduce growth and promote senescence and abscission. *See* ABSCISIC ACID; AUXIN. [F.T.A.]

Absolute zero The temperature at which an ideal gas would exert no pressure. The Kelvin scale of temperatures is defined in terms of the triple point of water, $T_3 = 273.16^\circ$ (where the solid, liquid, and vapor phases coexist), and absolute zero. Temperature is measured most simply via the constant-volume ideal-gas thermometer, in which a small amount of gas is introduced (in order to limit the effect of interactions between molecules) and then sealed off, and the gas pressure P referenced to its value at the triple point $P(T_3)$ is measured. The ideal-gas law applies if the molecules in a gas exert no forces on one another and if they are not attracted to the walls. Absolute zero is the temperature at which the pressure of a truly ideal gas would vanish. *See* TEMPERATURE MEASUREMENT.

According to classical physics, all motion would cease at absolute zero; however, the quantum-mechanical uncertainty principle requires that there be a small amount of residual motion (zero-point motion) even at absolute zero. *See* KINETIC THEORY OF MATTER; UNCERTAINTY PRINCIPLE.

Temperature can also be defined from the Boltzmann distribution. If a collection of spin-1/2 magnetic ions is placed in a magnetic field, the ratio of the occupancy of the lower to the higher energy state is given by the equation below. Here k is

$$\frac{N_L}{N_H} = \exp\frac{|\Delta E|}{kT}$$

Boltzmann's constant, ΔE is the magnitude of the difference in energy between the states, and T is the Kelvin temperature. Thus, at high temperatures the two states have nearly equal occupation probability, while the lower energy state is progressively favored at lower temperatures. At absolute zero, only the lower energy level is occupied. This relation allows for the possibility of negative temperatures when the population of the higher energy state exceeds that of the lower state. *See* BOLTZMANN CONSTANT; BOLTZMANN STATISTICS.

Negative temperatures notwithstanding, the third law of thermodynamics states that the absolute zero of temperature cannot be attained by any finite number of steps. The lowest (and hottest) temperatures that have been achieved are on the order of a picokelvin (10^{-12} K). These are spin temperatures of nuclei which are out of equilibrium with the lattice vibrations and electrons of a solid. The lowest temperatures to which the electrons have been cooled are on the order of 10 microkelvins in metallic systems. *See* LOW-TEMPERATURE PHYSICS; TEMPERATURE. [J.M.Pa.; D.M.Le.]

Absorption Either the taking up of matter in bulk by other matter, as in the dissolving of a gas by a liquid; or the taking up of energy from radiation by the medium through which the radiation is passing. In the first case, an absorption coefficient is defined as the amount of gas dissolved at standard conditions by a unit volume of the solvent. Absorption in this sense is a volume effect: The absorbed substance permeates the whole of the absorber. In absorption of the second type, attenuation is produced which in many cases follows Lambert's law and adds to the effects of scattering if the latter is present.

Absorption of electromagnetic radiation can occur in several ways. For example, microwaves in a waveguide lose energy to the walls of the guide. For nonperfect conductors, the wave penetrates the guide surface and energy in the wave is transferred to the atoms of the guide. Light is absorbed by atoms of the medium through which it passes, and in some cases this absorption is quite distinctive. Selected frequencies from a heterochromatic source are strongly absorbed, as in the absorption spectrum of the Sun. Electromagnetic radiation can be absorbed by the photoelectric effect, where the light quantum is absorbed and an electron of the absorbing atom is ejected, and also by Compton scattering. Electron-positron pairs may be created by the absorption of a photon of sufficiently high energy. Photons can be absorbed by photoproduction of nuclear and subnuclear particles, analogous to the photoelectric effect.

Sound waves are absorbed at suitable frequencies by particles suspended in the air (wavelength of the order of the particle size), where the sound energy is transformed into vibrational energy of the absorbing particles.

Absorption of energy from a beam of particles can occur by the ionization process, where an electron in the medium through which the beam passes is removed by the beam particles. The finite range of protons and alpha particles in matter is a result of this process. In the case of low-energy electrons, scattering is as important as ionization, so that range is a less well-defined concept. Particles themselves may be absorbed from a beam. For example, in a nuclear reaction an incident particle X is absorbed into nucleus Y, and the result may be that another particle Z, or a photon, or particle X with changed energy comes out. Low-energy positrons are quickly absorbed by annihilating with electrons in matter to yield two gamma rays. [M.H.H.]

In the chemical process industries and in related areas such as petroleum refining and fuels purification, absorption usually means gas absorption. This is a unit operation in which a gas (or vapor) mixture is contacted with a liquid solvent selected to preferentially absorb one, or in some cases more than one, component from the mixture. The purpose is either to recover a desired component from a gas mixture or to rid the mixture of an impurity. In the latter case, the operation is often referred to as scrubbing.

When the operation is employed in reverse, that is, when a gas is utilized to extract a component from a liquid mixture, it is referred to as gas desorption, stripping, or sparging.

In gas absorption, either no further changes occur to the gaseous component once it is absorbed in the liquid solvent, or the absorbed component (solute) will become involved in a chemical reaction with the solvent in the liquid phase. In the former case, the operation is referred to as physical gas absorption, and in the latter case as gas absorption with chemical reaction. *See* GAS ABSORPTION OPERATIONS; UNIT OPERATIONS. [W.F.F.]

Absorption (biology) The net movement (transport) of water and solutes from outside an organism to its interior. The unidirectional flow of materials into an animal from the environment generally takes place across the alimentary tract, the lungs, or the skin, and in each location a specific cell layer called an epithelium regulates the passage of materials.

Absorption across epithelia may occur by several different passive and active processes. Simple diffusion is the net movement of molecules from the apical to basolateral surfaces of an epithelium down chemical and electrical gradients without the requirement of cellular energy sources. Facilitated diffusion across the epithelium is similar to simple diffusion in that energy is not required, but in this process, molecular interaction with protein binding sites (carriers) in one or both membranes must occur to facilitate the transfer. Active molecular transport involves the use of membrane protein carriers as well as cellular energy supplies to move a transported molecule up an electrochemical gradient across the epithelium. Endocytosis and phagocytosis are also examples of active transport because metabolic energy is required, but in these processes whole regions of the cell membrane are used to engulf fluid or particles, rather than to bring about molecular transfer using single-membrane proteins. *See* CELL MEMBRANES; ENDOCYTOSIS; OSMOREGULATORY MECHANISMS; PHAGOCYTOSIS.

Although a wide variety of ions are absorbed by different types of epithelial cells, the mechanisms of Na^+ and Cl^- transport in mammalian small intestine are perhaps best known in detail. Transepithelial transport of these two ions occurs in this tissue by three independent processes: active Na^+ absorption, not coupled directly to the flow of other solutes but accompanied indirectly by the diffusional absorption of Cl^-; coupled NaCl absorption; and cotransport of Na^+ with a wide variety of nutrient molecules. *See* ION TRANSPORT.

Net water transport across the epithelium is coupled to net ion transport in the same direction. Pump sites for Na^+ are believed to be located along the lateral borders of epithelial cells. Energy-dependent Na^+ efflux from the cells to the intercellular spaces creates a local increase in osmotic pressure within these small compartments. An osmotic pressure gradient becomes established here, with greatest solute concentrations located nearest the tight junctions. Water flows into the cell across the brush border membrane and out the lateral membranes in response to the increased osmotic pressure in the paracellular spaces. Once water is in the intercellular compartment, a buildup of hydrostatic pressure forces the transported fluid to the capillary network. [G.A.A.]

Absorption of electromagnetic radiation The process whereby the intensity of a beam of electromagnetic radiation is attenuated in passing through a material medium by conversion of the energy of the radiation to an equivalent amount of energy appearing within the medium; the radiant energy is converted into heat or some other form of molecular energy. A perfectly transparent medium permits the passage of a beam of radiation without any change in intensity other than that caused by the spread or convergence of the beam, and the total radiant energy emergent from such a medium equals that which entered it, whereas the emergent energy from an absorbing medium is less than that which enters, and, in the case of highly opaque media, is reduced practically to zero. No known medium is opaque to all wavelengths of the electromagnetic spectrum; similarly, no material medium is transparent to the whole electromagnetic spectrum. A medium which absorbs a relatively wide range of wavelengths is said to exhibit general absorption, while a medium which absorbs only restricted wavelength regions of no great range exhibits selective absorption for those particular spectral regions. For example, ordinary window glass is transparent to visible light, but shows general absorption for ultraviolet radiation of wavelengths below about 310 nanometers, while colored glasses show selective absorption for specific regions of the visible spectrum. The color of objects which are not self-luminous and which are seen by light reflected or transmitted by the object is usually the result of selective absorption of portions of the visible spectrum. *See* COLOR; ELECTROMAGNETIC RADIATION.

The capacity of a medium to absorb radiation depends on a number of factors, mainly the electronic and nuclear constitution of the atoms and molecules of the medium, the wavelength of the radiation, the thickness of the absorbing layer, and the variables which determine the state of the medium, of which the most important are the temperature and the concentration of the absorbing agent. In special cases, absorption may be influenced by electric or magnetic fields. The state of polarization of the radiation influences the absorption of media containing certain oriented structures, such as crystals of other than cubic symmetry. *See* STARK EFFECT; ZEEMAN EFFECT.

Lambert's law, also called Bouguer's law or the Lambert-Bouguer law, expresses the effect of the thickness of the absorbing medium on the absorption. If I is the intensity to which a monochromatic parallel beam is attenuated after traversing a thickness d of the medium, and I_0 is the intensity of the beam at the surface of incidence (corrected for loss by reflection from this surface), the variation of intensity throughout the medium is expressed by Eq. (1), in which α is a constant for the medium

$$I = I_0 e^{-\alpha d} \tag{1}$$

called the absorption coefficient. This exponential relation can be expressed in an equivalent logarithmic form as in Eq. (2), where

$$\log_{10}(I_0/I) = (\alpha/2.303)d = kd \tag{2}$$

$k = \alpha/2.303$ is called the extinction coefficient for radiation of the wavelength considered. The quantity $\log_{10}(I_0/I)$ is often called the optical density, or the absorbance of the medium.

Beer's law refers to the effect of the concentration of the absorbing medium, that is, the mass of absorbing material per unit of volume, on the absorption. This relation is of prime importance in describing the absorption of solutions of an absorbing solute, since the solute's concentration may be varied over wide limits, or the absorption of gases, the concentration of which depends on the pressure. The effects of thickness d and concentration c on absorption of monochromatic radiation can be combined in a single mathematical expression, given in Eq. (3), in which k' is a constant for a given absorbing substance

$$I = I_0 e^{-k'cd} \tag{3}$$

(at constant wavelength and temperature), independent of the actual concentration of solute in the solution. In logarithms, the relation becomes Eq. (4).

$$\log_{10}(I_0/I) = (k'/2.303)cd = \epsilon cd \tag{4}$$

The values of the constants k' and ϵ in Eqs. (3) and (4) depend on the units of concentration. If the concentration of the solute is expressed in moles per liter, the constant ϵ is called the molar extinction coefficient. Some authors employ the symbol a_M, which is called the molar absorbance index, instead of ϵ.

If Beer's law is adhered to, the molar extinction coefficient does not depend on the concentration of the absorbing solute, but usually changes with the wavelength of the radiation, with the temperature of the solution, and with the solvent.

Absorption of radiation by matter always involves the loss of energy by the radiation and a corresponding gain in energy by the atoms or molecules of the medium. The energy absorbed from radiation appears as increased internal energy, or in increased vibrational and rotational energy of the atoms and molecules of the absorbing medium. As a general rule, translational energy is not directly increased by absorption of radiation, although it may be indirectly increased by degradation of electronic energy or by conversion of rotational or vibrational energy to that of translation by intermolecular collisions.

The energy acquired by matter by absorption of visible or ultraviolet radiation, although primarily used to excite electrons to higher energy states, usually ultimately appears as increased kinetic energy of the molecules, that is, as heat. It may, however, under special circumstances, be reemitted as electromagnetic radiation. Fluorescence is the reemission, as radiant energy, of absorbed radiant energy, normally at wavelengths the same as or longer than those absorbed. The radiant reemission of absorbed radiant energy at wavelengths longer than those absorbed, for a readily observable interval after withdrawal of the exciting radiation, is called phosphorescence. Phosphorescence and fluorescence are special cases of luminescence, which is defined as light emission that cannot be attributed merely to the temperature of the emitting body. *See* FLUORESCENCE; FLUORESCENT LAMP; LUMINESCENCE; PHOSPHORESCENCE. [W.W.]

Abstract algebra

A term used synonymously with modern algebra and general algebra to describe the type of algebra which has been developed since the mid-1920s and has become a basic idiom of contemporary mathematics. In contrast with the earlier algebra, which was highly computational and was confined to the study of specific systems generally based on real and complex numbers, abstract algebra is conceptual and axiomatic and deals with systems which are arbitrary sets of elements of unspecified type, together with certain compositions satisfying prescribed lists of axioms.

A good insight into the difference between the older and the present approach can be obtained by comparing the older matrix theory with the more abstract linear algebra. Both deal with roughly the same portion of mathematics, the former a direct perspective which stresses calculations with matrices, the latter from an axiomatic and geometric viewpoint which treats vector spaces and linear transformations as the basic notions, and matrices as secondary to these. *See* LINEAR ALGEBRA; MATRIX THEORY.

Abstract algebra deals with a number of important algebraic structures, such as groups, rings, and lattices. *See* GROUP THEORY; RING THEORY. [N.J.]

Abstract data type

A mathematical entity consisting of a set of values (the carrier set) and a collection of operations that manipulate them. For example, the Integer abstract data type consists of a carrier set containing the positive and negative whole numbers and 0, and a collection of operations manipulating these values, such as addition, subtraction, multiplication, equality comparison, and order comparison. *See* ABSTRACT ALGEBRA.

Abstraction. To abstract is to ignore some details of a thing in favor of others. Abstraction is important in problem solving because it allows problem solvers to focus on essential details while ignoring the inessential, thus simplifying the problem and bringing to attention those aspects of the problem involved in its solution. Abstract data types are important in computer science because they provide a clear and precise way to specify what data a program must manipulate, and how the program must manipulate its data, without regard to details about how data are represented or how operations are implemented. Once an abstract data type is understood and documented, it serves as a specification that programmers can use to guide their choice of data representation and operation implementation, and as a standard for ensuring program correctness.

A realization of an abstract data type that provides representations of the values of its carrier set and algorithms for its operations is called a data type. Programming languages typically provide several built-in data types, and usually also facilities for programmers to create others. Most programming languages provide a data type realizing the Integer abstract data type, for example. The carrier set of the Integer abstract data type is a collection of whole numbers, so these numbers must be represented in some way. Programs typically use a string of bits of fixed size (often 32 bits) to represent Integer values in base two, with one bit used to represent the sign of the number. Algorithms that manipulate these strings of bits implement the operations of the abstract data type. *See* ALGORITHM; PROGRAMMING LANGUAGES.

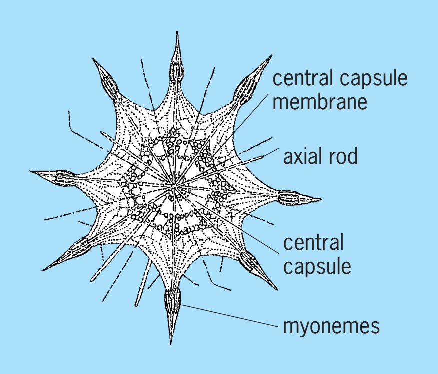
Realizations of abstract data types are rarely perfect. Representations are always finite, while carrier sets of abstract data types are often infinite. Many individual values of some carrier sets (such as real numbers) cannot be precisely represented on digital computers. Nevertheless, abstract data types provide the standard against which the data types realized in programs are judged.

Usefulness. Such specifications of abstract data types provide the basis for their realization in programs. Programmers know which data values need to be represented, which operations need to be implemented, and which constraints must be satisfied. Careful study of program code and the appropriate selection of tests help to ensure that the programs are correct. Finally, specifications of abstract data types can be used to investigate and demonstrate the properties of abstract data types themselves, leading to better understanding of programs and ultimately higher-quality software. *See* COMPUTER PROGRAMMING; SOFTWARE ENGINEERING; SHRINK FIT.

Relation to object-oriented paradigm. A major trend in computer science is the object-oriented paradigm, an approach to program design and implementation using collections of interacting entities called objects. Objects incorporate both data and operations. In this way they mimic things in the real world, which have properties (data) and behaviors (operations). Objects that hold the same kind of data and perform the same operations form a class.

Abstract data values are separated from abstract data type operations. If the values in the carrier set of an abstract data type can be reconceptualized to include not only data values but also abstract data type operations, then the elements of the carrier set become entities that incorporate both data and operations, like objects, and the carrier set itself is very much like a class. The object-oriented paradigm can thus be seen as an outgrowth of the use of abstract data types. *See* OBJECT-ORIENTED PROGRAMMING. [C.Fo.]

Acantharia A subclass of Actinopodea. These marine protozoans are related to the Radiolaria and possess a nonliving, organic capsular wall surrounding a central mass of cytoplasm. The intracapsular cytoplasm is connected to the extra-capsular cytoplasm by fine cytoplasmic strands passing through pores in the capsular wall. Skeletons are typically constructed of celestite (strontium sulfate) instead of silica. The basic structural elements are 20 rods which pass through the capsule to the center in regular arrangement (polar and equatorial; see illustration). An equatorial rod forms an angle of 90° with a polar rod, and other groups are arranged with similar exactness. This type of skeleton may be modified by addition of a latticework, apparently composed of plates, each fused with a skeletal rod. Some genera show a double latticework, concentric with the central capsule.



Acantharia: ***Acanthometra pellucida*.**

Pseudopodia are more or less permanent. Zooxanthellae are of at least two kinds: dinophyceae containing trichocysts in the cytoplasm; and a group of algae characterized, among other things, by numerous discoidal plastids each of which contains an interlamellar pyrenoid.

Myonemes (myophrisks) are significant components of the hydrostatic apparatus and apparently regulate the buoyancy of Acantharia by expanding or contracting portions of the extracapsular cytoplasmic sheath.

Although essentially pelagic, Acantharia may move vertically with the help of their hydrostatic apparatus. Little is known about the ecology or distribution of Acantharia. The Gulf Stream is rich in Acantharia in spring and summer, but rather poor in other seasons.

The taxonomy of Acantharia is under review, but according to one scheme there are two orders: Acanthometrida, and Acanthophractida. *See* ACANTHOMETRIDA; ACANTHOPHRACTIDA; ACTINOPODEA; PROTOZOA; SARCODINA; SARCOMASTIGOPHORA. [O.R.A.]

Acanthite The mineral name applied to the monoclinic form of silver sulfide (Ag_2S) that is stable at room temperature. Two different crystalline structures are assumed in succession as temperature is increased. At a temperature of about 176–178°C (349–352°F), depending on stoichiometry, acanthite transforms rapidly to argentite, which is body-centered cubic, space group $Im3m$. The cell contains two Ag_2S units and has a lattice constant that ranges from 0.4860 nm at 186°C (367°F) to 0.4889 nm at 325°C (617°F). At 586–620°C (1087–1148°F), again depending on stoichiometry, argentite transforms to a face-centered cubic structure. The details of the atomic arrangement in this phase are not known.

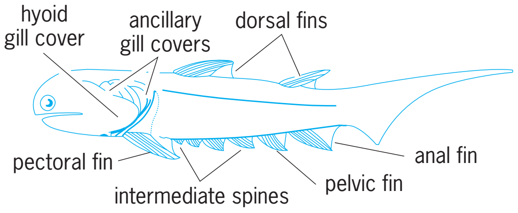
Acanthite is an important silver ore. Notable deposits in the United States include Butte, Montana; Aspen and Leadville, Colorado; and the Comstock Lode in Nevada. The mineral is also common in Mexican mines at Guanajuato. Other major deposits occur in Bolivia, Peru, and Chile. Especially fine crystals have been found in Saxony and in the Harz Mountains in Germany. Silver sulfide is encountered in everyday life as the black tarnish that develops on silver objects. *See* CRYSTAL STRUCTURE. [B.J.Wu.]

Acanthocephala A distinct phylum of helminths, the adults of which are parasitic in the alimentary canal of vertebrates. They are commonly known as the spiny-headed worms. The phylum comprises the orders Archiacanthoceph-ala, Palaeacanthocephala, and Eocanthocephala. Over 500 species have been described from all classes of vertebrates, although more species occur in fish than in birds and mammals and only a relatively few species are found in amphibians and reptiles. The geographical distribution of acanthocephalans is worldwide, but genera and species do not have a uniform distribution because some species are confined to limited geographic areas. Host specificity is well established in some species, whereas others exhibit a wide range of host tolerance. The same species never occurs normally, as an adult, in coldblooded and warm-blooded definitive hosts. More species occur in fish than any other vertebrate; however, Acanthocephala have not been reported from elasmobranch fish. The fact that larval development occurs in arthropods gives support to the postulation that the ancestors of Acanthocephala were parasites of primitive arthropods during or before the Cambrian Period and became parasites of vertebrates as this group arose and utilized arthropods for food. *See* PALAEACANTHOCEPHALA.

Adults of various species show great diversity in size, ranging in length from 0.04 in. (1 mm) in some species found in fish to over 16 in. (400 mm) in some mammalian species.

The body of both males and females has three subdivisions: the proboscis armed with hooks, spines, or both; an unspined neck; and the posterior trunk. The proboscis is the primary organ for attachment to the intestinal wall of the host. In most species the proboscis is capable of introversion into a saclike structure, the proboscis receptacle. The proboscis receptacle and neck can be retracted into the body cavity but without inversion. The body cavity, or pseudocode, contains all the internal organs, the most conspicuous of which are the reproductive organs. There is no vestige of a digestive system in any stage of the life cycle. The reproductive organs of the male consist of a pair of testes and specialized cells, the cement glands. The products of the testes and cement glands are discharged through a penis. Female Acanthocephala are unique in that the ovary exists as a distinct organ only in the very early stages of development and later breaks up to form free-floating egg balls. The eggs are fertilized as they are released from the egg balls and are retained within the ligament sacs until embry-onation is complete. The nervous system is composed of a chief ganglion or brain located within the proboscis receptacle. Two nerve trunks pass through the wall of the proboscis receptacle to innervate the trunk wall. Modified protonephridial organs are found closely adherent to the reproductive system, but in most species specialized excretory organs are completely lacking. [D.V.Mo.]

Acanthodii A subclass of importance, including the earliest known jawed fishes or gnathostomes, first appearing in the Lower Silurian and surviving until the Lower Permian. They were usually small, less than 8 in. (20 cm) in length, though a few may have been as much as 100 in. (250 cm) long. The body was fusiform, the mouth terminal or nearly so, the eyes large, and the nasal capsules small. The tail was heterocercal; there were one or two dorsal fins, and all fins except the caudal had a spine on the anterior edge (see illustration). The scales had



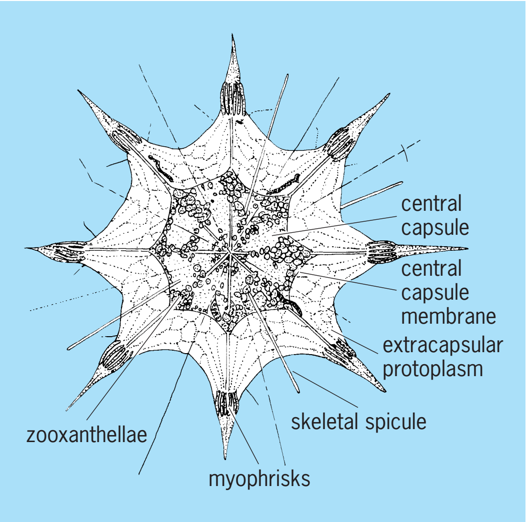
Lateral view of *Climatius reticulatus* (Climatiidae), about 6 in. (15 cm) long.

a square or rhombic crown and typically were nonoverlapping; they grew by periodic additions all around, lacked a pulp chamber, and were composed superficially of dentine or mesodentine and basally of bone, often acellular. Acanthodii are best considered as a subclass of Teleostomi, collateral with Osteichthyes, and can be classified as follows:

- Subclass Acanthodii
  - Order Climatiida
    - Family Climatiidae
    - Family Diplacanthidae
    - ?Family Gyracanthidae
  - Order Ischnacanthida
    - Family Ischnacanthidae
  - Order Acanthodida
    - Family Acanthodidae

See Chondrichthyes; Teleostomi. [R.H.De.]

Acanthometrida An order of Acantharia. These marine protozoans have a skeleton limited to 20 radially arranged rods which extend from the center, forming a characteristic pattern in which angles are quite exact, as in *Acanthometra* (see illustration). The cytoplasm surrounding the spines contains a conical array of contractile microfila-ments (myophrisks or myonemes) that act to expand or contract the gelatinous sheath surrounding the cell, a phenomenon that is apparently responsible for changes in the level of flotation. *See* Acantharia; Actinopodea; Protozoa; Sarcodina; Sarcomastigophora. [O.R.A.]



Acanthometra. (*After L. H. Hyman, The Invertebrates, vol. 1, McGraw-Hill, 1940*).

Acanthophractida An order of Acantharia. In this group of protozoans, skeletons typically include a latticework shell, although the characteristic skeletal rods are recognizable. The latticework may be spherical or ovoid, is fused with the skeletal rods, and is typically concentric with the central capsule. The body is usually covered with a single or double gelatinous sheath through which the skeletal rods emerge. Myonemes extend from the gelatinous sheath to each skeletal rod. These marine forms live mostly below depths of 150–200 ft (45–60 m). The order includes *Colectspis*, *Diploconus*, *Dorotaspis*, and many other genera. *See* Acantharia; Actinopodea; Protozoa; Sarcodina; Sarcomastigophora. [R.P.H.]

Acari A subclass of Arachnida, the mites and ticks; also called Acarina. All are small (0.004–1.2 in. or 0.1–30 mm, most less than 0.08 in. or 2 mm in length), have lost most traces of external body segmentation, and have the mouthparts borne on a discrete body region, the gnathosoma. They are apparently most closely related to Opiliones and Ricinulei.

The chelicerae may be chelate or needlelike. Pedipalps are generally smaller than the walking legs, and are simple or sometimes weakly chelate. Legs may be modified by projections, enlarged claws, heavy spines, or bladelike rows of long setae for crawling, clinging to hosts, transferring spermatophores, or swimming. Mites frequently have one or two simple eyes (ocelli) anterolaterally on the idiosoma (occasionally one anteromedially as well). The ganglia of the central nervous system are coalesced into a single "brain" lying around the esophagus. A simple dorsal heart is present in a few larger forms.

Mites are ubiquitous, occurring from oceanic trenches below 13,200 ft (4000 m) to over 20,800 ft (6300 m) in the Himalayas and suspended above 3300 ft (1000 m) in the atmosphere; there are species in Antarctica. Soil mites show the least specialized adaptations to habitat and are frequently well-sclerotized predators. Inhabitants of stored grains, cheese, and house dust are also relatively unspecialized. The dominant forms inhabiting mosses are heavily sclerotized beetle mites (Oribatidae). Flowering plant associates include spider mites (Tetranychidae) and gall mites (Eriophyidae). Fungivores are usually weakly sclerotized inhabitants of moist or semiaquatic habitats, while the characteristic fresh-water mites include sluggish crawlers, rapid swimmers, and planktonic drifters. Mites associated with invertebrate animals include internal, external, and social parasites as well as inactive phoretic stages on Insecta, Crustacea, Myriapoda, Chelicerata, Mollusca, and Parazoa. A similar diversity of species are parasites or commensals of vertebrates. Some parasitic mites are disease vectors. Over 30,000 species have been described, and it is estimated that as many as 500,000 may exist. *See* Arachnida. [D.B.]

Acceleration The time rate of change of velocity. Since velocity is a directed or vector quantity involving both magnitude and direction, a velocity may change by a change of magnitude (speed) or by a change of direction or both. It follows that acceleration is also a directed, or vector, quantity. If the magnitude of the velocity of a body changes from v_1 ft/s to v_2 ft/s in t seconds, then the average acceleration a has a magnitude given by Eq. (1):

$$a = \frac{\text{velocity change}}{\text{elapsed time}} = \frac{v_2 - v_1}{t_2 - t_1} = \frac{\Delta v}{\Delta t} \tag{1}$$

To designate it fully the direction should be given, as well as the magnitude. *See* Velocity.

Instantaneous acceleration is defined as the limit of the ratio of the velocity change to the elapsed time as the time interval approaches zero. When the acceleration is constant, the average acceleration and the instantaneous acceleration are equal.

Whenever a body is acted upon by an unbalanced force, it will undergo acceleration. If it is moving in a constant direction, the acting force will produce a continuous change in speed. If it is moving with a constant speed, the acting force will produce an acceleration consisting of a continuous change of direction. In the general case, the acting force may produce both a change of speed and a change of direction.

Angular acceleration is a vector quantity representing the rate of change of angular velocity of a body experiencing rotational motion. If, for example, at an instant t_1, a rigid body is rotating about an axis with an angular velocity ω_1, and at a later time t_2, it has an angular velocity ω_2, the average angular acceleration α is given by Eq. (2), in radians per second per second.

$$\overline{\alpha} = \frac{\omega_2 - \omega_1}{t_2 - t_1} = \frac{\Delta\omega}{\Delta t} \qquad (2)$$

The instantaneous angular acceleration is given by $\alpha = d\omega/dt$.
[R.D.Ru.]

When a body moves in a circular path with constant linear speed at each point in its path, it is also being constantly accelerated toward the center of the circle under the action of the force required to constrain it to move in its circular path. This acceleration toward the center of path is called radial acceleration. The component of linear acceleration tangent to the path of a particle subject to an angular acceleration about the axis of rotation is called tangential acceleration. *See* ACCELERATION MEASUREMENT; ROTATIONAL MOTION.
[C.E.H.; R.J.S.]

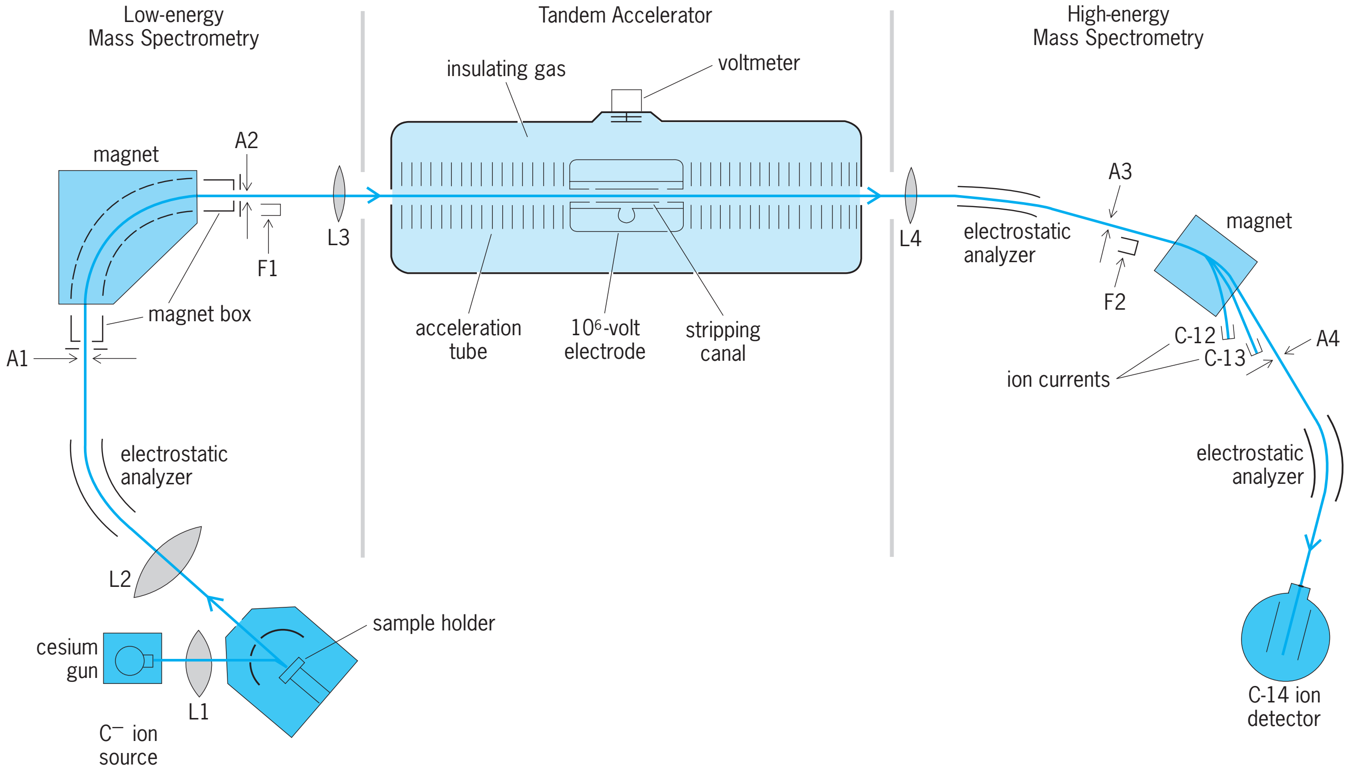
Accelerator mass spectrometry The use of a combination of mass spectrometers and an accelerator to measure the natural abundances of very rare radioactive isotopes. These abundances are frequently lower than parts per trillion. The most important applications of accelerator mass spectrometry are in archeological and geophysical studies, as, for example, in radiocarbon dating by the counting of the rare carbon-14 (radiocarbon; ^{14}C) isotope. *See* DATING METHODS; GEOCHRONOMETRY; PARTICLE ACCELERATOR.

The advantage of counting the radioactive atoms themselves rather than their decay products is well illustrated by radiocarbon dating, which requires the measurement of the number of ^{14}C atoms in a sample. The long half-life of 5730 years for ^{14}C implies that only 15 beta-particle emissions per minute are observed from 1 g of contemporary carbon. However, an accelerator mass spectrometer can be used to count the ^{14}C atoms at over 15 per second from a milligram sample of carbon. Consequently, accelerator mass spectrometry can be used to date samples that are a thousand times smaller than those that are dated by using the beta-particle counting method, and the procedure is carried out about 120 times faster.

For the study of many rare radioactive atoms, accelerator mass spectrometry also has the important advantage that there can be no background except for contamination with the species being studied. For example, significant interference with the beta-particle counting of radiocarbon from cosmic rays and natural radioactivity occurs for carbon samples about 25,000 years old. In contrast, accelerator mass spectrometer measurements are affected only by the natural contamination of the sample which becomes serious for samples about 50,000 years old.

Apparatus. The success of accelerator mass spectrometry results from the use of more than one stage of mass spectrometry and at least two stages of ion acceleration. The illustration shows the layout of an ideal accelerator mass spectrometer for radiocarbon studies, divided for convenience into three stages.

The first part of the accelerator mass spectrometer is very similar to a conventional mass spectrometer. In the second stage, a tandem accelerator first accelerates negative ions to the central high-voltage electrode, converts them into positive ions by several successive collisions with gas molecules in a region of higher gas pressure, known as a stripping canal, and then further accelerates the multiply charged positive ions through the same voltage difference back to ground potential. In the third stage, the



Simplified diagram of an accelerator mass spectrometer used for radiocarbon dating. The equipment is divided into three sections. Electric lenses L1–L4 are used to focus the ion beams; apertures A1–A4 and charge collection cups F1 and F2 are used for setting up the equipment.

accelerated ions are analyzed further by the high-energy mass spectrometer.

Distinguishing features. The features that clearly distinguish accelerator mass spectrometry from conventional mass spectrometry are the elimination of molecular ions and isobars from the mass spectrometry.

A tandem accelerator provides a convenient way of completely eliminating molecular ions from the mass spectrometry because ions of a few megaelectronvolts can lose several electrons on passing through the region of higher gas pressure in the stripping canal. Molecules with more than two electrons missing have not been observed, so that accelerator mass spectrometry utilizing charge −3 ions is free of molecular interferences.

The use of a negative-ion source, which is necessary for tandem acceleration, can also ensure the complete separation of atoms of nearly identical mass (isobars). In the case of radiocarbon analysis, the abundant stable ^{14}N ions and the very rare radioactive ^{14}C ions are separated completely because the negative ion of nitrogen is unstable whereas the negative ion of carbon is stable. In other cases, it is possible to count the ions without any background in the ion detectors because of their high energy. In many cases, it is also possible to identify the ion. *See* MASS SPECTROMETRY. [A.E.L.]

Accelerometer A mechanical or electromechanical instrument that measures acceleration. The two general types of accelerometers measure either the components of translational acceleration or angular acceleration.

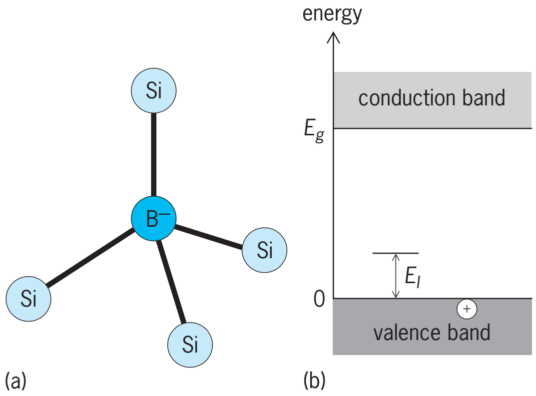
Most translational accelerometers fall into the category of seismic instruments, which means the accelerations are not measured with respect to a reference point. Of the two types of seismic instruments, one measures the attainment of a predefined acceleration level and the other measures acceleration continuously. In one version of the first type of instrument, a seismic mass is suspended from a bar made of brittle material which fails in tension at a predetermined acceleration level.

Continuously measuring seismic instruments are composed of a damped or an undamped spring-supported seismic mass which is mounted by means of the spring to a housing. The seismic mass is restrained to move along a predefined axis. Also provided is some type of sensing device to measure acceleration.

The type of sensing device used to measure the acceleration determines whether the accelerometer is a mechanical or an electromechanical instrument. One type of mechanical accelerometer consists of a liquid-damped cantilever spring-mass system, a shaft attached to the mass, and a small mirror mounted on the shaft. A light beam reflected by the mirror passes through a slit, and its motion is recorded on moving photographic paper. The type of electromechanical sensing device classifies the accelerometer as variable-resistance, variable-inductance, piezoelectric, piezotransistor, or servo type of instrument or transducer.

There are several different types of angular accelerometers. In one type the damping fluid serves as the seismic mass. Under angular acceleration the fluid rotates relative to the housing and causes on two symmetrical vanes a pressure which is a measure of the angular acceleration. Another type of instrument has a fluid-damped symmetrical seismic mass in the form of a disk which is so mounted that it rotates about the normal axis through its center of gravity. The angular deflection of the disk, which is restrained by a spring, is proportional to the angular acceleration. [R.C.Du.; T.I.]

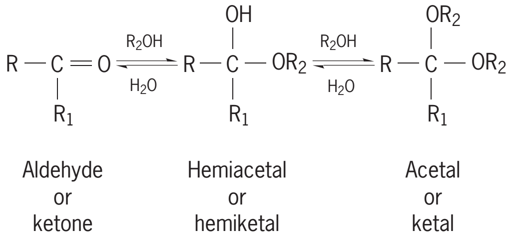
Acceptor atom An impurity atom in a semiconductor which can accept or take up one or more electrons from the crystal and become negatively charged. An atom which substitutes for a regular atom of the material but has one less valence electron may be expected to be an acceptor atom. For example, atoms of boron, aluminum, gallium, or indium are acceptors in germanium and silicon (illus. *a*), and atoms of antimony and bismuth are acceptors in tellurium crystals. Acceptor atoms tend to increase the number of holes (positive charge carriers) in the semiconductor (illus. *b*). The energy gained when an electron is taken up by an acceptor atom from the valence band of the crystal is the ionization energy of the atom. *See* DONOR ATOM; SEMICONDUCTOR. [H.Y.F.; A.K.R.]



Trivalent acceptor atom, boron (B), in the elemental semiconductor silicon (Si). (*a*) Boron atom in a substitutional position, that is, replacing silicon, a tetravalent host atom, by completing the four tetrahedral covalent bonds with its nearest neighbor silicon atoms. This requires an electron to be accepted from the valence band, thus making boron negatively charged. (*b*) Energy diagram showing that the absence of an electron in the valence band is equivalent to a positive charge carrier, a hole, which is bound to boron via Coulomb attraction with an ionization enerzy El · Eg = energy gap separating valence band from conduction band.

Acetal A geminal diether ($R_1 = H$). Ketals, considered a subclass of acetals, are also geminal diethers (R_1 = C, aliphatic or aromatic). Acetals are (1) independent structural units or a part of certain biological and commercial polymers, (2) blocking or protecting groups for complex molecules undergoing selective synthetic transformations, and (3) entry compounds for independent organic chemical reactions. *See* POLYACETAL.

Acetals are easily prepared by the reaction of aldehydes with excess alcohol, under acid-catalyzed conditions. This is usually a two-step process (see reaction below) in which an aldehyde is treated with an alcohol to yield a less stable hemiacetal, which then reacts with additional alcohol to give the acetal. Protonic or Lewis acids are effective catalysts for acetal formation; dehydrating agents, such as calcium chloride and molecular sieves, can also be used for molecules, such as sugars, where acids may cause problems. Less common acetal preparations are Grignard reagent condensation with orthoformates and mercuric-catalyzed additions of alcohols to acetylenes. *See* ALDEHYDE; KETONE; ORGANIC SYNTHESIS. [C.F.B.]



$$\mathrm{R{-}\underset{R_1}{\underset{|}{C}}{=}O \underset{H_2O}{\overset{R_2OH}{\rightleftharpoons}} R{-}\underset{R_1}{\underset{|}{\overset{\overset{OH}{|}}{C}}}{-}OR_2 \underset{H_2O}{\overset{R_2OH}{\rightleftharpoons}} R{-}\underset{R_1}{\underset{|}{\overset{\overset{OR_2}{|}}{C}}}{-}OR_2}$$

Acetic acid A colorless, pungent liquid, CH_3COOH, melting at 16.7°C and boiling at 118.0°C. Acetic acid is the sour principle in vinegar. Concentrated acid is called glacial acetic acid because of its readiness to crystallize at cool temperatures.

Acetic acid is manufactured by three main routes: butane liquid-phase catalytic oxidation in acetic acid solvent, palladium-copper salt-catalyzed oxidation of ethylene in aqueous solution, and methanol carbonylation in the presence of rhodium catalyst. Large quantities of acetic acid are recovered in the manufacture of cellulose acetate and polyvinyl alcohol. Some acetic acid is produced in the oxidation of higher olefins, aromatic hydrocarbons, ketones, and alcohols. *See* Oxidation process; Wood chemicals.

Pure acetic acid is completely miscible with water, ethanol, diethyl ether, and carbon tetrachloride, but is not soluble in carbon disulfide. In a water solution, acetic acid is a typical weakly ionized acid ($Ka = 1.8 \times 10^{-5}$). Acetic acid neutralizes many oxides and hydroxides, and decomposes carbonates to furnish acetate salts, which are used in textile dyeing and finishing, as pigments, and as pesticides; examples are verdigris, white lead, and paris green. *See* Vinegar. [F.W.]

Acetone A chemical compound, CH_3COCH_3. A colorless liquid with an ethereal odor, it is the first member of the homologous series of aliphatic ketones. Its physical properties include boiling point 56.2°C (133.2°F), melting point −94.8°C (−138.6°F), and specific gravity 0.791.

Acetone is used as a solvent for cellulose ethers, cellulose acetate, cellulose nitrate, and other cellulose esters. Cellulose acetate is spun from acetone solution. Lacquers, based on cellulose esters, are used in solution in mixed solvents including acetone. [D.A.S.]

Acetylcholine A naturally occurring quaternary ammonium cation ester, with the formula $CH_3(O)COC_2H_4N(CH)_3^+$, that plays a prominent role in nervous system function. The great importance of acetylcholine derives from its role as a neurotransmitter for cholinergic neurons, which innervate many tissues, including smooth muscle and skeletal muscle, the heart, ganglia, and glands. The effect of stimulating a cholinergic nerve, for example, the contraction of skeletal muscle or the slowing of the heartbeat, results from the release of acetylcholine from the nerve endings.

Acetylcholine is synthesized at axon endings from acetyl coenzyme A and choline by the enzyme choline acetyltransferase, and is stored at each ending in hundreds of thousands of membrane-enclosed synaptic vesicles. When a nerve impulse reaches an axon ending, voltage-gated calcium channels in the axonal membrane open and calcium, which is extremely low inside the cell, enters the nerve ending. The increase in calcium-ion concentration causes hundreds of synaptic vesicles to fuse with the cell membrane and expel acetylcholine into the synaptic cleft (exocytosis). The acetylcholine released at a neuromuscular junction binds reversibly to acetylcholine receptors in the muscle end-plate membrane, a postsynaptic membrane that is separated from the nerve ending by a very short distance. The receptor is a cation channel which opens when two acetylcholine molecules are bound, allowing a sodium current to enter the muscle cell and depolarize the membrane. The resulting impulse indirectly causes the muscle to contract.

Acetylcholine must be rapidly removed from a synapse in order to restore it to its resting state. This is accomplished in part by diffusion but mainly by the enzyme acetylcholinesterase, which hydrolyzes acetylcholine.

Acetylcholinesterase is a very fast enzyme: one enzyme molecule can hydrolyze 10,000 molecules of acetylcholine in 1 s. Any substance that efficiently inhibits acetylcholinesterase will be extremely toxic. [I.B.W.]

Acetylene An organic compound with the formula C_2H_2 or $HC{\equiv}CH$. The first member of the alkynes, acetylene is a gas with a narrow liquid range; the triple point is −81°C (−114°F). The heat of formation (ΔH_f°) is +227 kilojoules/mole, and acetylene is the most endothermic compound per carbon of any hydrocarbon. The compound is thus extremely energy-rich and can decompose with explosive force. At one time acetylene was a basic compound for much chemical manufacturing. It is highly reactive and is a versatile source of other reactive compounds.

The availability of acetylene does not depend on petroleum liquids, since it can be prepared by hydrolysis of calcium carbide (CaC_2), obtained from lime (CaO), and charcoal or coke (C). In modern practice, methane (CH_4) is passed through a zone heated to 1500°C (2732°F) for a few milliseconds, and acetylene is then separated from the hydrogen in the effluent gas.

The main use of acetylene is in the manufacture of compounds derived from butyne-1,4-diol. The latter is obtained by condensation of acetylene with two moles of formaldehyde and is converted to butyrolactone, tetrahydrofuran, and pyrrolidone. Two additional products, vinyl fluoride and vinyl ether, are also based on acetylene.

Because of the very high heat of formation and combustion, an acetylene-oxygen mixture provides a very high temperature flame for welding and metal cutting. For this purpose acetylene is shipped as a solution in acetone, loaded under pressure in cylinders that contain a noncombustible spongy packing. *See* Alkyne. [J.A.Mo.]

Acid and base Two interrelated classes of chemical compounds, the precise definitions of which have varied considerably with the development of chemistry. Some of these controversies are still unresolved.

Acids initially were defined only by their common properties as substances which had a sour taste, dissolved many metals, and reacted with alkalies (or bases) to form salts. For a time it was believed that a common constituent of all acids was the element oxygen, but gradually it became clear that, if there were an essential element, it was hydrogen, not oxygen. This concept of an acid proved to be satisfactory for about 50 years.

Bases initially were defined as those substances which reacted with acids to form salts (they were the "base" of the salt). The alkalies, soda and potash, were the best-known bases, but it soon became clear that there were other bases, notably ammonia and the amines.

When the concept of ionization of chemical compounds in water solution became established, acids were defined as substances which ionized in aqueous solution to give hydrogen ions, H^+, and bases were substances which reacted to give hydroxide ions, OH^-. These definitions are sometimes known as the Arrhenius-Ostwald theory of acids and bases. Their use makes it possible to discuss acid and base equilibria and also the strengths of individual acids and bases.

A powerful and wide-ranging protonic theory of acids and bases was introduced by J. N. Brønsted in 1923 and was rapidly accepted. Somewhat similar ideas were advanced almost simultaneously by T. M. Lowry and the new theory is occasionally called the Brønsted-Lowry theory. The Brønsted definitions of acids and bases are: An acid is a species which can act as a source of protons; a base is a species which can accept protons. Compared to the water (Arrhenius) theory, this represents only a slight change in the definition of an acid but a considerable extension of the term base. In addition to hydroxide ion, the bases now include a wide variety of uncharged species, such as ammonia and the amines, as well as numerous charged species, such as the anions of weak acids. In fact, every acid can generate a base by loss of a proton. Acids and bases which are related in this way are known as conjugate acid-base pairs, and the table lists examples.

As the table shows, strengths of acids and bases are not independent. A very strong Brønsted acid implies a very weak conjugate base and vice versa. A qualitative ordering of acid strength or base strength permits a rough prediction of the extent to which an acid-base reaction will go. The rule is that a strong acid and a strong base will react extensively with each other, whereas a weak acid and a weak base will react together only very slightly.

Studies of catalysis have played a large role in the acceptance of a set of quite different definitions of acids and bases, those due to G. N. Lewis: An acid is a substance which can accept an electron pair from a base; a base is a substance which can donate an electron pair. Bases under the Lewis definition are very similar

Conjugate acid-base pairs

	Acids	Bases	
Strong	H_2SO_4	HSO_4^-	Weak
acids	HCl	Cl^-	bases
↑	H_3O^+	H_2O	↑
	HSO_4^-	SO_4^{2-}	
	$HF_{(aq)}$	F^-	
	CH_3COOH	CH_3COO^-	
	NH_4^+	NH_3	
↓	NCO_3^-	CO_3^{2-}	↓
Weak	H_2O	OH^-	Strong
acids	C_2H_5OH	$C_2H_5O^-$	bases

to those defined by Brönsted, but the Lewis definition for acids is very much broader.

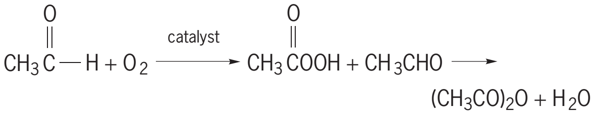
Another comprehensive theory was proposed by M. Usanovich in 1939 and is sometimes known as the positive-negative theory. Acids are defined as substances which form salts with bases, give up cations, and add themselves to anions and free electrons. Bases are similarly defined as substances which give up anions or electrons and add themselves to cations. So far, this theory has had little acceptance, quite possibly because the definitions are too broad to be very useful. *See* HYDROGEN ION. [F.A.L.; R.H.Bo.]

Acid anhydride One of an important class of reactive organic compounds derived from acids via formal intermolecular dehydration.

Anhydrides of straight-chain acids containing from 2 to 12 carbon atoms are liquids with boiling points higher than those of the parent acids. They are relatively insoluble in cold water and are soluble in alcohol, ether, and other common organic solvents. The lower members are pungent, corrosive, and weakly lacrimatory. Anhydrides from acids with more than 12 carbon atoms and cyclic anhydrides from dicarboxylic acids are crystalline solids.

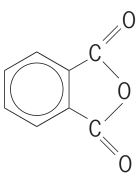
Because the direct intermolecular removal of water from organic acids is not practicable, anhydrides must be prepared by means of indirect processes. A general method involves interaction of an acid salt with an acid chloride.

Acetic anhydride, the most important aliphatic anhydride, is manufactured by air oxidation of acetaldehyde, using as catalysts the acetates of copper and cobalt, shown in reaction (1).

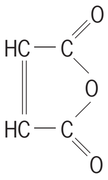


$$CH_3\overset{\overset{O}{\|}}{C}{-}H + O_2 \xrightarrow{\text{catalyst}} CH_3\overset{\overset{O}{\|}}{C}OOH + CH_3CHO \longrightarrow (CH_3CO)_2O + H_2O \quad (1)$$

Cyclic anhydrides are obtained by warming succinic or glutaric acids, either alone, with acetic anhydride, or with acetyl chloride. Under these conditions, adipic acid first forms linear, polymeric anhydride mixtures, from which the monomer is obtained by slow, high-vacuum distillation. Cyclic anhydrides are also formed by simple heat treatment of cis-unsaturated dicarboxylic acids, for example, maleic and glutaconic acids; and of aromatic 1,2-dicarboxylic acids, for example, phthalic acid. Commercially, however, both phthalic (**1**) and maleic (**2**) anhydrides are primary products of manufacture, being formed by vapor-phase, catalytic (vanadium pentoxide), air oxidation of naphthalene and benzene, respectively; at the reaction temperature, the anhydrides form directly.



(1)



(2)

Anhydrides are used in the preparation of esters. Ethyl acetate and butyl acetate (from butyl alcohol and acetic anhydride) are excellent solvents for cellulose nitrate lacquers. Acetates of high-molecular-weight alcohols are used as plasticizers for plastics and resins. Cellulose and acetic anhydride give cellulose acetate, used in acetate rayon and photographic film. The reaction of anhydrides with sodium peroxide forms peroxides (acetyl peroxide is violently explosive), used as catalysts for polymerization reactions and for addition of alkyl halides to alkenes. In Friedel-Crafts reactions, anhydrides react with aromatic compounds, forming ketones such as acetophenone.

Maleic anhydride reacts with many dienes to give hydroaromatics of various complexities (Diels-Alder reaction). Maleic anhydride is used commercially in the manufacture of alkyd resins from polyhydric alcohols. Soil conditioners are produced by basic hydrolysis of the copolymer of maleic anhydride with vinyl acetate.

Phthalic anhydride and alcohols form esters (phthalates) used as plasticizers for plastics and resins. Condensed with phenols and sulfuric acid, phthalic anhydride yields phthaleins, such as phenolphthalein; with *m*-dihydroxybenzenes under the same conditions, xanthene dyes form, for example, fluorescein. Phthalic anhydride is used in manufacturing glyptal resins (from the anhydride and glycerol) and in manufacturing anthraquinone. Heating phthalic anhydride with ammonia gives phthalimide, used in Gabriel's synthesis of primary amines, amino acids, and anthranilic acid (*o*-aminobenzoic acid). With alkaline hydrogen peroxide, phthalic anhydride yields monoperoxyphthalic acid, used along with benzoyl peroxide as polymerization catalysts, and as bleaching agents for oils, fats, and other edibles.

Anhydrides react with water to form the parent acid, with alcohols to give esters, and with ammonia to yield amides; and with primary or secondary amines, they furnish *N*-substituted and *N*,*N*-disubstituted amides, respectively. *See* ACYLATION; DIELS-ALDER REACTION; ESTER. [P.E.F.]

Acid-base indicator A substance that reveals, through characteristic color changes, the degree of acidity or basicity of solutions. Indicators are weak organic acids or bases which exist in more than one structural form (tautomers) of which at least one form is colored. Intense color is desirable so that very little indicator is needed; the indicator itself will thus not affect the acidity of the solution.

Common-acid base indicators

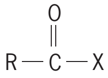
Common name	pH range	Color change (acid to base)	pK
Methyl violet	0–2, 5–6	Yellow to blue violet to violet	
Metacresol purple	1.2–2.8, 7.3–9.0	Red to yellow to purple	1.5
Thymol blue	1.2–2.8, 8.0–9.6	Red to yellow to blue	1.7
Tropeoline 00 (Orange IV)	1.4–3.0	Red to yellow	
Bromphenol blue	3.0–4.6	Yellow to blue	4.1
Methyl orange	2.8–4.0	Orange to yellow	3.4
Bromcresol green	3.8–5.4	Yellow to blue	4.9
Methyl red	4.2–6.3	Red to yellow	5.0
Chlorphenol red	5.0–6.8	Yellow to red	6.2
Bromcresol purple	5.2–6.8	Yellow to purple	6.4
Bromthymol blue	6.0–7.6	Yellow to blue	7.3
Phenol red	6.8–8.4	Yellow to red	8.0
Cresol red	2.0–3.0, 7.2–8.8	Orange to amber to red	8.3
Orthocresolphthalein	8.2–9.8	Colorless to red	
Phenolphthalein	8.4–10.0	Colorless to pink	9.7
Thymolphthalein	10.0–11.0	Colorless to red	9.9
Alizarin yellow GG	10.0–12.0	Yellow to lilac	
Malachite green	11.4–13.0	Green to colorless	

Acid-base indicators are commonly employed to mark the end of an acid-base titration or to measure the existing pH of a solution. Care must be used to compare colors only within the indicator range. A color comparator may also be used, employing standard color filters instead of buffer solutions.

The indicator range is the pH interval of color change of the indicator. In this range there is competition between indicator and added base for the available protons; the color change, for example, yellow to red, is gradual rather than instantaneous. Observers may, therefore, differ in selecting the precise point of change.

The table lists many of the common indicators, their ranges of pH and color change, and pK values. *See* Acid and base; Hydrogen ion; Titration. [A.L.H.]

Acid halide One of a large group of organic substances possessing the halocarbonyl group,



$$R-\overset{\overset{\displaystyle O}{\|}}{C}-X$$

in which X stands for fluorine, chlorine, bromine, or iodine. The terms acyl and aroyl halides refer to aliphatic or aromatic derivatives, respectively.

The great inherent reactivity of acid halides precludes their free existence in nature; all are made by synthetic processes. In general, acid halides have low melting and boiling points and show little tendency toward molecular association. With the exception of the formyl halides (which do not exist), the lower members are pungent, corrosive, lacrimatory liquids that fume in moist air. The higher members are low-melting solids.

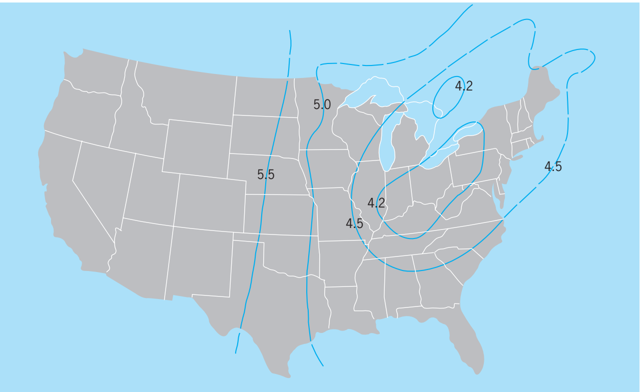
Acid chlorides are prepared by replacement of carboxylic hydroxyl of organic acids by treatment with phosphorus trichloride, phosphorus pentachloride, or thionyl chloride.

Although acid bromides may be prepared by these methods, acid iodides are best prepared from the acid chloride treatment with either CaI_2 or HI, and acid fluorides from the acid chloride by interaction with HF or antimony fluoride.

The reactivity of acid halides centers upon the halocarbonyl group, resulting in substitution of the halogen by appropriate structures. Thus with substances containing active hydrogen atoms (for example, water, primary and secondary alcohols, ammonia, and primary and secondary amines), hydrogen chloride is formed together with acids, esters, amides, and *N*-substi-tuted amides, respectively. [P.E.F.]

Acid rain Precipitation that incorporates anthropogenic acids and acidic materials. The deposition of acidic materials on the Earth's surface occurs in both wet and dry forms as rain, snow, fog, dry particles, and gases. Although 30% or more of the total deposition may be dry, very little information that is specific to this dry form is available. In contrast, there is a large and expanding body of information related to the wet form: acid rain or acid precipitation. Acid precipitation, strictly defined, contains a greater concentration of hydrogen (H^+) than of hydroxyl (OH^-) ions, resulting in a solution pH less than 7. Under this definition, nearly all precipitation is acidic. The phenomenon of acid deposition, however, is generally regarded as being anthropogenic, that is, resulting from human activity.

Theoretically, the natural acidity of precipitation corresponds to a pH of 5.6, which represents the pH of pure water in equilibrium with atmospheric concentrations of carbon dioxide. Atmospheric moisture, however, is not pure, and its interaction with ammonia, oxides of nitrogen and sulfur, and windblown dust results in a pH between 4.9 and 6.5 for most "natural" precipitation. The distribution and magnitude of precipitation pH in the United States (illustration) suggest the impact of anthropogenic rather than natural causes. The areas of highest precipitation acidity (lowest pH) correspond to areas within and downwind of heavy industrialization and urbanization where emissions of sulfur and nitrogen oxides are high. It is with these emissions that the most acidic precipitation is thought to originate.



Distribution of rainfall pH in the eastern United States.

The transport of acidic substances and their precursors, chemical reactions, and deposition are controlled by atmospheric processes. In general, it is convenient to distinguish between physical and chemical processes, but it must be realized that both types may be operating simultaneously in complicated and interdependent ways. The physical processes of transport by atmospheric winds and the formation of clouds and precipitation strongly influence the patterns and rates of acidic deposition, while chemical reactions govern the forms of the compounds deposited.

There are a number of chemical pathways by which the primary pollutants, sulfur dioxide (SO_2) from industry, nitric oxide (NO) from both industry and automobiles, and reactive hydrocarbons mostly from trees, are transformed into acid-producing compounds. Some of these pathways exist solely in the gas phase, while others involve the aqueous phase afforded by the cloud and precipitation. As a general rule, the volatile primary pollutants must first be oxidized to more stable compounds before they are efficiently removed from the atmosphere. Ironically, the most effective oxidizing agents, hydrogen peroxide (H_2O_2) and ozone (O_3), arise from photochemical reactions involving the primary pollutants themselves. *See* Air pollution.

The effect of acid deposition on a particular ecosystem depends largely on its acid sensitivity, its acid neutralization capability, the concentration and composition of acid reaction products, and the amount of acid added to the system. As an example, the major factors influencing the impact of acidic deposition on lakes and streams are (1) the amount of acid deposited; (2) the pathway and travel time from the point of deposition to the lake or stream; (3) the buffering characteristics of the soil through which the acidic solution moves; (4) the nature and amount of acid reaction products in soil drainage and from sediments; and (5) the buffering capacity of the lake or stream.

Acid precipitation may injure trees directly or indirectly through the soil. Foliar effects have been studied extensively, and it is generally accepted that visible damage occurs only after prolonged exposure to precipitation of pH 3 or less (for example, acid fog or clouds). Measurable effects on forest ecosystems will then more likely result indirectly through soil processes than directly through exposure of the forest canopy. Many important declines in the condition of forest trees have been reported in Europe and North America during the period of increasing precipitation acidity. These cases include injury to white pine in the eastern United States, red spruce in the Appalachian Mountains of eastern North America, and many economically important species in central Europe. Since forest trees are continuously stressed by competition for light, water, and nutrients; by disease organisms; by extremes in climate; and by atmospheric pollutants, establishing acid deposition as the cause of these declines is made more difficult. Each of these sources of stress, singly or in combination, produces similar injury. However, a large body of information indicates that accelerated soil acidification resulting from acid deposition is an important predisposing stress that in combination with other stresses has resulted in increased decline and mortality of sensitive tree species and widespread reduction in tree growth. *See* FOREST ECOSYSTEM; TERRESTRIAL ECOSYSTEM.

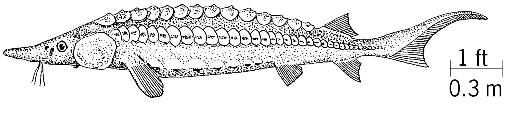
Acidic deposition impacts aquatic ecosystems by harming individual organisms and by disrupting flows of energy and materials through the ecosystem. The effect of acid deposition is commonly assessed by studying aquatic invertebrates and fish. Aquatic invertebrates live in the sediments of lakes and streams and are vitally important to the cycling of energy and material in aquatic ecosystems. These small organisms break down large particulate organic matter for further degradation by microorganisms, and they are an important food source for fish, aquatic birds, and predatory invertebrates.

Currently, there are concerns that acid deposition is causing the loss of fish species, through physiological damage and by reproductive impairment. While fish die from acidification, their numbers and diversity are more likely to decline from a failure to reproduce.The effects of acid deposition on individuals in turn elicit changes in the composition and abundance of communities of aquatic organisms. The degree of change depends on the severity of acidification, and the interaction of other factors, such as metal concentrations and the buffering capacity of the water. The pattern most characteristic of aquatic communities in acidified waters is a loss of species diversity, and an increase in the abundance of a few, acid-tolerant taxa.

Community-level effects may occur indirectly, as a result of changes in the food supply and in predator-prey relations. Reduction in the quality and amount of periphyton may decrease the number of herbivorous invertebrates, which may in turn reduce the number of organisms (predatory invertebrates and fish) that feed upon herbivorous invertebrates. The disappearance of fish may result in profound changes in plant and invertebrate communities. Dominant fish species function as keystone predators, controlling the size distribution, diversity, and numbers of invertebrates. Their reduction alters the interaction within and among different levels of the food web and the stability of the ecosystem as a whole.

The impact of acid deposition on terrestrial and aquatic ecosystems is not uniform. While increases in acid deposition may stress some ecosystems and reduce their stability and productivity, others may be unaffected. The degree and nature of the impact depend on the acid input load, organismal susceptibility, and buffering capacity of the particular ecosystem. *See* BIOGEOCHEMISTRY. [R.R.Sc./D.Lam./H.B.Pi./D.Ge.]

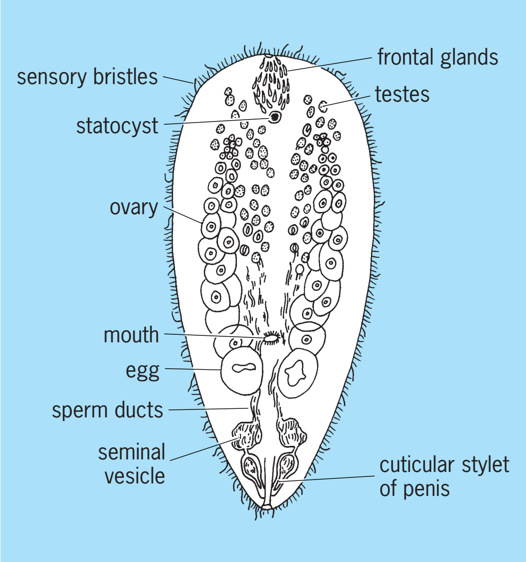
Acipenseriformes An archaic order of actinopterygian fishes, represented by the sturgeons and paddlefishes. The characters include a highly chondrified internal skeleton; fins which are archaic and sharklike in appearance, with more than one ray per pterygiophore; a caudal fin which is strongly hete-rocercal; scales which are reduced and often form five lengthwise series of bony plates; rostrum produced; and weak jaws (see illustration). Fleshy barbels are present on the lower surface of the snout. The cartilaginous skeleton of the acipenseri form fishes was long regarded as primitive, and was taken as indicative of alliance with the Chondrichthyes. Research reveals, however, that this is secondary, and the true relationship is with the typical bony fishes.



Lake sturgeon (*Acipenser fulvescens*).

The Acipenseriformes include three families: the extinct Chondrosteidae; the sturgeon family, Acipenseridae, with 4 Recent genera and about 23 species; and the paddlefish family, Polyodontidae, consisting of two Recent species, *Psephurus gladius* of China and *Polyodort spathula* of the eastern United States. *See* ACTINOPTERYGII; OSTEICHTHYES; STURGEON. [R.M.B.]

Acoela An order of marine Turbellaria, generally regarded as primitive, and lacking protonephridia, oviducts, yolk glands, permanent digestive cavity, and strictly delimited gonads. The nervous system is epidermal in the most primitive representatives, but it is generally submuscular and consists of three to six pairs of longitudinal strands without anterior concentrations recognizable as a brain. The anterior or median ventral mouth opens into a simple pharynx which lacks elaborate musculature and leads directly to the syncytial vacuolated mass of endoderm forming the spongy intestinal tissue and lacking any true lumen.

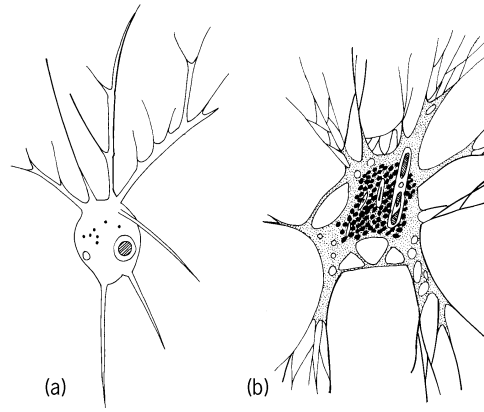


Acoela: *Childia spinosa*.

Eyes are often absent; when present they are of the usual paired turbellarian pigment-cup type, with one to a few pigment and retinal cells. The epidermis, typically, is uniformly ciliated, and locomotion is accomplished by means of rapid, smooth ciliary gliding or swimming.

The acoels (see illustration) are mostly small (one to several millimeters in length). They are virtually worldwide in distribution, living beneath stones, among algae, on the bottom mud, or interstitially, from the littoral zone to deeper waters. A few are pelagic (in tropical and subtropical zones), and others have become symbiotic, living entocommensally in various invertebrates but mainly in echinoderms. *See* COELENTERATA; PLATYHELMINTHES; TURBELLARIA. [J.B.J.]

Aconchulinida An order of the subclass Filosia comprising a small group of naked amebas which form filamentous pseudopodia (filopodia). The genus *Penardia*, possibly the only valid one in the order, includes filopodia-forming amebas with variable shape, an outer zone of clear ectoplasm, and inner cytoplasm often containing many vacuoles and sometimes zoochlorellae (see illustration). Pseudopodia are sometimes extended primarily at the poles of the organism, but also may fuse laterally to form small sheets of clear cytoplasm. A single nucleus and one water-elimination vesicle are characteristic of these amebas. Size of described species ranges from less



Aconchulinida. (*a*) *Penardia cometa.* (*b*) *P. mutabllis.*

than 10 to about 400 micrometers. *See* Filosia; Protozoa; Sarcodina; Sarcomastigophora. [R.P.H.]

Acorales An order of monocotyledonous angiosperms composed of a single genus, Acorus (sweet flag or sweet calamus), with two species widespread in the Northern Hemisphere. Formerly, *Acorus* was included in the aroid family, Araceae, but several lines of evidence, including deoxyribonucleic acid (DNA) sequences, have firmly established it as the first-branching lineage of the monocotyledons. These species are emergent aquatics with peculiar inflorescences, and they are unusual among the monocots in having characters otherwise confined to the magnoliid dicots, such as the anther formation and the presence of ethereal oils. These oils are the basis of the species' frequent use as a medicine to treat toothache and dysentery, and as an ointment in religious ceremonies. *See* Magnoliophyta. [M.W.C.]

Acoustic emission A method of nondestructive testing and materials characterization that uses mechanical waves moving through materials. It is similar to seismology, except in being concerned with the scale of engineering structures, such as aircraft, bridges, and chemical tanks. When a structure is subjected to external force (or stress), a defect (for example, a crack or welding flaw) on the structure is activated and enlarged dynamically, and thus generates waves, which spread through materials at a certain speed. Such waves, known as acoustic emission signals, are detected by sensors attached on the surfaces of the structure. Mechanical vibration due to acoustic emission signals is weak and requires high-sensitivity sensors and electronic amplification before it can be analyzed. *See* Seismology.

In nondestructive testing of structures, acoustic emission signals are typically evaluated in order to know if the failure of a structure is imminent; if cracks and other defects, presumed to be present in any structure, are active; the positions of such active defects; and whether a structure with such defects can be safely operated. In evaluating material behavior and quality, acoustic emission is used to assess how a material responds to mechanical stress, that is, when and how it changes shape permanently and how it proceeds to eventual fracture; how an alloy withstands repeated application of stress (known as fatigue); the level of stress and corrosive environment that lead to failure of a material; and the types of microscopic failure processes that arise in a material under stress. *See* Metal, mechanical properties of; Plastic deformation of metal; Stress and strain.

Acoustic emission signals emanating from their sources contain information about the source, such as the direction and speed of crack opening. For example, the high-speed cracking of brittle materials (such as high-strength steels and ceramics) produces short, fast-varying acoustic emission signals, which are typically plotted against time measured in microseconds. In contrast, slow-growing defects in plastics result in longer, slowly varying signals, which are typically plotted on a time scale of milliseconds. Because of the distortion of waves during the propagation through a complex structure and detection by a sensor, however, much of the information is lost. Thus, the presence of detectable acoustic emission signals is the most important clue in assessing the integrity of the structure.

By detecting one such signal at multiple sensor positions, the location of its source can be determined from the timing of signal arrivals. The basic principle of triangulation is the same as practiced in seismology, except that the differences in signal arrival times are of the order of microseconds to milliseconds. The speed of wave propagation is a material constant, determined by the stiffness and mass density of the propagating medium.

A typical sensor uses a piezoelectric ceramic element, which converts mechanical vibration into an electrical signal, which can be amplified 1000 to 10,000 times. Various electrical measurement techniques are used to characterize and analyze the signals received. It is common to obtain and record several features of acoustic emission signals. These form the basis of real-time analysis and decision-making. In laboratory studies, the entire waveforms are also recorded for detailed analysis after testing. *See* Piezoelectricity. [K.O.]

Acoustic holography The recording of sound waves in a two-dimensional pattern (the hologram) and the use of the hologram to reconstruct the entire sound field throughout a three-dimensional region of space. Acoustical holography is an outgrowth of optical holography, invented by Dennis Gabor in 1948. The wave nature of both light and sound make holography possible. Acoustical holography involves reconstruction of the sound field that arises due to radiation of sound at a boundary, such as the vibrating body of a violin, the fuselage of an aircraft, or the surface of a submarine. Both acoustical holography and optical holography rely on the acquisition of an interferogram, a two-dimensional recording at a single frequency of the phase and amplitude of an acoustic or electromagnetic field, usually in a plane. Gabor called this interferogram a hologram. *See* Holography; Inverse scattering theory.

Two distinct forms of acoustical holography exist. In farfield acoustical holography (FAH), the hologram is recorded far removed from the source. This form of acoustical holography is characterized by the fact that the resolution of the reconstruction is limited to a half-wavelength. This resolution restriction is removed, however, when the hologram is recorded in the acoustic nearfield, an important characteristic of nearfield acoustical holography (NAH), invented by E. G. Williams and J. D. Maynard in 1980.

Nearfield acoustical holography has been used in the automotive industry to study interior noise and tire noise, in musical acoustics to study vibration and radiation of violin-family instruments, and in the aircraft industry to study interior cabin noise and fuselage vibrations. Applications are also found in underwater acoustics, especially in studies of vibration, radiation, and scattering from ships and submarines. *See* Acoustic noise; Musical acoustics; Underwater sound.

Typically, temporal acoustic data are acquired by measurement of the acoustic pressure with a single microphone or hydrophone, which scans an imaginary two-dimensional surface. In some cases, an array of microphones is used and the pressure is measured instantaneously by the array.The measured data are processed in a computer to reconstruct the pressure at the surface of the object as well as the vibration of the surface. The measured time data are Fourier-transformed into the frequency domain, creating a set of holograms, one for each frequency bin in the transform. In the inversion process, each hologram is broken up into a set of waves or modes whose propagation characteristics are known from basic principles. Each wave or mode is then back-propagated to the source surface by multiplication by the known inverse propagator, and the field is then recomposed by addition of all these waves or modes. *See* FOURIER SERIES AND TRANSFORMS. [E.G.Wi.]

Acoustic impedance At a given surface, the complex ratio of effective sound pressure averaged over the surface to the effective flux (volume velocity or particle velocity multiplied by the surface area) through it. The unit is the $\mathrm{N \cdot s/m^5}$ (newton-second/meter^5), or the mks acoustic ohm. In the cgs system the unit is the $\mathrm{dyn \cdot s/cm^5}$ (dyne-second/centimeter^5). *See* SOUND PRESSURE.

Specific acoustic impedance is the complex ratio of the effective sound pressure at a point to the effective particle velocity at a point. The unit is the $\mathrm{N \cdot s/m^3}$, or the mks rayl. In the cgs system the unit is the $\mathrm{dyn \cdot s/cm^3}$, or the rayl. The difference between specific acoustic impedance and acoustic impedance is in the specification of impedance at a point, as compared to the average over a surface.

Characteristic acoustic impedance is the ratio of effective sound pressure at a point to the particle velocity at that point in a free, progressive wave. This ratio is equal to the product of the density of the medium times the speed of sound in the medium. The characteristic impedance of a sound wave is analogous to the characteristic electrical impedance of an infinitely long, dissipationless transmission line. It is common in acoustical analyses to represent specific acoustic impedances in terms of their ratio to the characteristic impedance of air.

Acoustic impedance, being a complex quantity, can have real and imaginary components analogous to those in an electrical impedance. In applying this analogy, the real part of the acoustic impedance is termed acoustic resistance, and the imaginary part is termed acoustic reactance. *See* ELECTRICAL IMPEDANCE. [W.J.G.]

Acoustic interferometer An instrument that is sensitive to the interference of two or more acoustic waves. It provides information on acoustic wavelengths that is useful in determining the velocity and absorption of sound in samples of gases, liquids, and materials, and it yields information on the nonlinear properties of solids.

In its simplest form, an acoustic interferometer for use in liquids has a fixed piezoelectric crystal (acting as a transmitter) tuned to the frequency of interest and a parallel reflector at a variable distance from it. Driven by an oscillating electrical voltage, the piezoelectric crystal generates a sound wave, which in turn is reflected by the reflector. The acoustic pressure amplitude on the front face of the crystal depends on the velocity amplitude at the face and the distance to the reflecting surface. The amplitude ratio (radiation impedance) of the acoustic pressure to the velocity and the relative phase shift between the two oscillating quantities depend solely on the distance to the reflecting surface. If the reflector acts as a rigid surface, this amplitude ratio is ideally zero whenever the net round-trip distance between the crystal and the reflector is an odd number of half-wavelengths because the reflected wave is then exactly out of phase with the incident wave at the crystal's location. The crystal then draws the maximum current since the oscillations are unimpeded. *See* ACOUSTIC IMPEDANCE; PIEZOELECTRICITY; WAVE MOTION; WAVELENGTH.

During operation, the current drawn by the crystal is monitored as the reflector is gradually moved away from the crystal. Whenever the reflector position is such that the crystal is at a pressure antinode (place of maximum pressure in a standing wave), there is a strong dip in the current drawn due to the relatively high radiation impedance presented by the standing wave to the crystal face. Consecutive antinodes are a half-wavelength apart. For a given frequency f, a measured distance L between the location of any one antinode and that of its nth successor yields the wavelength $2L/n$ and the speed of sound $c = 2Lf/n$. An acoustic interferometer based on this principle can achieve a precision of 0.01%. Since the current drawn by the crystal is relatively insensitive to the frequency for a given radiation impedance, the sound speed can also be determined by keeping the distance between the crystal and the reflector fixed and gradually sweeping the frequency.

The pressure nodes and antinodes correspond to the local maxima and minima, respectively, in the current drawn. The peak of the current amplitude decreases with the distance traversed by the reflector. If the separation distance is sufficiently large that the exponential decrease associated with absorption dominates any spreading losses, the absorption coefficient for the medium can be derived by measurement of the ratios of current amplitudes at two successive points where the current drawn is a local maximum. *See* SOUND; SOUND ABSORPTION; ULTRASONICS. [G.S.K.W.; A.D.P.; S.I.M.]

Acoustic levitation The use of intense acoustic waves to hold a body that is immersed in a fluid medium against the force of gravity without obvious mechanical support.

Levitation can occur in the presence of fluid flow, including the back-and-forth fluid flow produced by the passage of an acoustic wave. Such acoustically generated forces are extremely small in common experience. But intense acoustic waves are nonlinear in their basic character and, therefore, may exert a net acoustic radiation pressure on an object sufficient to balance the gravitational force and thus levitate it. *See* ACOUSTIC RADIATION PRESSURE.

The applications of acoustic levitation in air or other gas include an acoustic positioning module that has been carried in the space shuttle and used in fundamental studies of the oscillation and fission of spinning drops. An acoustic levitation furnace has been designed to study the possibility of containerless solidification of molten materials. *See* SPACE PROCESSING.

Applications of the levitation of objects in liquids have included measurements of the ultimate tensile strengths of liquids, mechanical characterization of superheated and supercooled liquids, the measurement of properties of biological materials (including human red blood cells and lipids from the porpoise dome), the study of shape oscillations and interfacial tension of levitated drops, and the evaporation of charged drop arrays levitated electroacoustically. *See* SOUND. [R.E.A.]

Acoustic microscope An instrument that utilizes focused acoustic waves to produce images of surface and subsurface features in materials, and to measure elastic properties on a microscopic scale. It has been used to image and measure local elastic properties in metals, ceramics, semiconductor integrated circuits, polymeric materials, and biological materials including individual cells. The development of scanning probe microscopy has led to a new type of acoustic microscope capable of imaging elastic properties at nanometer resolution. [S.Sa.]

Acoustic mine A mine that either passively listens to a target's sound noises or periodically interrogates its environment by actively emitting acoustic pulses that may return echoes if prospective targets come within range. A mine is an underwater weapon consisting of a shell case containing high explosives. Mines can be planted by airplanes, surface ships, or submarines. There are three types: drifting mines, moored mines held at a given depth by a cable anchored to the bottom, and bottom mines, which rest on the sea floor. A mine can be activated by various means, such as by contact with a target, by sensing a target's magnetic field, by listening to the acoustic noises from a target, by sensing the excess pressure field from a target passing above it, by reception of acoustic echoes that a target may return to the mine's sonar after it has sent out its interrogating pings, or by a combination of these. *See* SONAR. [G.C.G.]

Acoustic noise Unwanted sound. Noise control is the process of obtaining an acceptable noise environment for people in different situations. Understanding noise and its control requires a knowledge of the major sources of noise, sound propagation, human response to noise, and the physics of methods of controlling noise. The continuing increase in noise levels from many different human activities in industrialized societies has led to the term noise pollution.

Noise as an unwanted by-product of an industrialized society affects not only the operators of machines and vehicles, but also other occupants of buildings in which machines are installed, passengers of vehicles, and most importantly the communities in which machines, factories, and vehicles are operated. [M.J.Cr.]

Acoustic radiation pressure The net pressure exerted on a surface or interface by an acoustic wave. One might presume that the back-and-forth oscillation of fluid caused by the passage of an acoustic wave will not exert any net force on an object, and this is true for sound waves normally encountered. Intense sound waves, however, can exert net forces in one direction of sufficient magnitude (proportional to the sound intensity) to balance gravitational forces and thus levitate an object in air.

Forces due to acoustic radiation pressure have been used to calibrate acoustic transmitters, to deform and break up liquids, to collect like objects or to separate particles (including biological cells) based on mechanical properties, and to position objects in a sound field, sometimes levitating the sample so that independent studies of the object's properties can be performed. Single bubble sonoluminescence phenomena depend on acoustic radiation forces to maintain a bubble in a zone while its substantial radial oscillations take place. *See* ACOUSTIC LEVITATION; SOUND; SONOCHEMISTRY; ULTRASONICS. [R.E.A.]

Acoustic radiometer A device to measure the acoustic power or intensity of a sound beam by means of the force or torque that the beam exerts on an inserted object or interface. The underlying theory involves the concept of radiation pressure. Such pressure occurs, for example, when a plane sound wave is partially reflected at an interface between two materials, with the nonlinear interaction between the incident and reflected waves giving rise to a steady pressure on the interface. If a narrow beam is incident on the interface and the transmitted wave is fully absorbed by the second material, the magnitude of the radiation force F (area integral of radiation pressure) equals a constant times W/c, where W is the power of the sound beam and c is the sound speed.

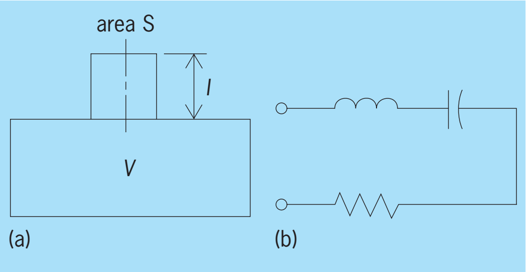
A modern acoustic radiometer, used to measure the total power of an ultrasonic sound beam in water and other liquids, employs a vane suspended in the fluid in such a manner that its displacement in a direction normal to its face is proportional to the net force pushing on its front face. The vane is ideally of dimensions somewhat larger than the incident beam's diameter, so that the encountered force is associated with the entire incident beam. To eliminate the possibility of sound being reflected toward the transmitting transducer, the vane is oriented at 45° to the incident sound beam. The vane's horizontal displacement is made to be proportional to the imposed force by fastening the vane at one end of a long pendulum whose rotation from the vertical is opposed by the effect of gravity, such that the apparent spring constant for displacement in a direction at 45° to the face is approximately Mg/L, where M is the apparent mass of the vane (corrected for the presence of water), g is the acceleration of gravity, and L is the length of the pendulum. A nonlinear acoustics theory for such a circumstance yields a proportionality relation between the net horizontal radiation force on the vane and the acoustic power associated with the incident beam. Because the deflection of the vane is proportional to the radiation force, the acoustic power can be determined. *See* BUOYANCY; PENDULUM.

The concept of the vane device evolved from that of the Rayleigh disk, which was a circular disk that could rotate about its diameter and whose deflection from a nominal 45° orientation was opposed by a torsional spring. The Rayleigh disk was taken to have a radius much smaller than the wavelength, and its use ideally yielded a measurement of the local acoustic intensity that would have existed at the center of the disk were the disk not present. *See* ACOUSTIC RADIATION PRESSURE; SOUND; SOUND INTENSITY; SOUND PRESSURE. [A.D.P.; S.I.Ma.]

Acoustic resonator A device consisting of a combination of elements having mass and compliance whose acoustical reactances cancel at a given frequency. Resonators are often used as a means of eliminating an undesirable frequency component in an acoustical system. In other instances resonators are used to produce an increase in the sound pressure in an acoustic field at a particular frequency.

Resonators are useful most often in the control of low-frequency sound. They are of particular value in reducing the noise from sources having constant frequency excitation.

Resonators have also found considerable application in architectural acoustics. It is often difficult to obtain adequate control of reverberation time at low frequencies in a large studio or auditorium using conventional acoustical materials. A number of designs for these spaces have included the construction of resonators behind walls or in the ceiling to obtain increased low-frequency absorption and thus provide more satisfactory reverberation characteristics. *See* ARCHITECTURAL ACOUSTICS.



Helmholtz resonator. (*a*) Acoustical unit. (*b*) Electrica analog.

The Helmholtz resonator (see illustration) is the simplest and most often utilized acoustical resonator. The unit consists of a straight tube of length l and cross-sectional area S, connected to a closed volume V. This combination is directly analogous to the simple series LC electrical circuit. *See* ACOUSTIC IMPEDANCE; MUFFLER. [W.J.G.]

Acoustic signal processing A discipline that deals generally with the extraction of information from acoustic signals in the presence of noise and uncertainty. Acoustic signal processing has expanded from the improvement of music and speech sounds and a tool to search for oil and submarines to include medical instrumentation; techniques for efficient transmission, storage, and presentation of music and speech; and machine speech recognition. Undersea processing has expanded to studying underwater weather and long-term global ocean temperature changes, mammal tracking at long ranges, and monitoring of hot vents. These techniques stem from the rapid advances in computer science, especially the development of large, inexpensive memories and ever-increasing processing speeds.

Sound can be said to be low and slow compared to computers. The audio frequencies are low, spanning roughly the range from 15 to 25,000 hertz, with seismic frequencies below this range and frequencies relevant to medical ultrasonics above. All of these frequencies are well within the limits of analog-to-digital input samplers and digital-to-analog output converters that form the bridges between continuous-time physical waveforms and the streams of digits handled by a computer. The speed of sound is slow, about 335 m/s (1100 ft/s) in air and 1500 m/s (5000 ft/s) in water, compared to light and radio waves at 3×10^8 m/s (10^9 ft/s), the upper limit for electrical signals in computer circuits. A computer can carry out thousands of elementary computations between input samples. *See* Analog-to-digital converter; Digital-to-analog converter; Sound.

Signal processors "think" in two domains. One domain is the pictures of waveforms, the sound pressure as it changes in time. This time-domain picture is $s(t)$; t is time, and s might be the sound pressure or a microphone voltage. The other picture is the complex magnitude at every important frequency during an interval of time. This frequency-domain or spectrum picture is $S(f \mid T_n)$; f is the frequency in hertz, and T_n is the nth time interval. J. Fourier (1768–1830) formalized his series version of this picture and showed that $s(t)$ could be calculated from $S(f)$, and vice versa. Mathematicians have developed other versions of spectral transforms, each with its special area of application. *See* Fourier series and transforms; Integral transform.

Each domain picture provides the same information, but sometimes it is easier to think, or compute, using one domain rather than the other. The computer version used is the DFT (discrete Fourier transform). Transforms were formerly time-consuming computations; for N points in one domain the time needed was proportional to N squared. In the 1960s a layered algorithm was developed to speed up the DFT. The emphasis is on sample sizes which are integer powers of 2. These fast Fourier transforms have had a major impact on spectral processing.

One example of acoustic signal processing for biomedical purposes is its use in restoring hearing. The cochlea in the inner ear is nature's time-domain-to-frequency-domain transformer, exciting a line of nerve endings in response to something like the short-time spectrum of the input. For people in whom this natural mechanism is dysfunctional but the cochlear nerve is intact, a technology is developing based on modest DFT analysis of sound near an ear, feeding perhaps 32 channels to an implanted microconnector in the cochlear nerve bundle. *See* Hearing (human); Hearing aid; Physiological acoustics.

One of the most difficult signal processing areas is machine recognition of spoken speech. Vocabulary size and number of speakers are key parameters. The fundamental problems are: (1) words are not spoken separately, but in streams of connected sound, (2) a phrase is seldom said the same way every time, (3) the vocabulary is enormous, and (4) there is a huge variety of speaker accents and rhythms. The signal processing must segment an utterance into phonemes, words, or phrases; pick out key features; or compare the whole segment with a library for likely matches. [T.G.Bi.]

Acoustic torpedo An autonomous undersea vehicle that can be launched from submarines, surface ships, or aircraft to attack enemy submarines and surface ships. Its main components are a guidance and control system, a power plant to provide propulsive and electrical energy, a propulsor to control speed and direction, and a warhead. The launching platform performs the function of determining the approximate location of the target and launching the torpedo in the proper direction. The torpedo typically utilizes an acoustic sensor in its nose and is controlled by an on-board computer. During its operation, the torpedo searches the volume of the ocean determined by the launch platform. It progresses through the following phases: detection (an object is present), classification (the object is a target of interest), homing (steer at the object), and detonation of the warhead. *See* Guidance systems; Homing. [F.W.Sy.]

Acoustics The science of sound, which in its most general form endeavors to describe and interpret the phenomena associated with motional disturbances from equilibrium of elastic media. An elastic medium is one such that if any part of it is displaced from its original position with respect to the rest, as for example by an impact, it will return to its original state when the disturbing influence is removed. Acoustics was originally limited to the human experience produced by the stimulation of the human ear by sound incident from the surrounding air. Modern acoustics, however, deals with all sorts of sounds which have no relation to the human ear, for example, seismological disturbances and ultrasonics.

Basic acoustics may be divided into three branches, namely, production, transmission, and detection of sound. Any change of stress or pressure producing a local change in density or a local displacement from equilibrium in an elastic medium can serve as a source of sound. Transmission of sound takes place through an elastic medium by means of wave motion. The most important sound waves are harmonic waves, defined as waves for which the propagated disturbance at any point in its path varies sinusoidally with time with a definite frequency or number of complete cycles per second (the unit being the hertz). Acoustics deals with waves of all frequencies, but not all frequencies are audible by human beings, for whom the average range of audibility extends from 20 to 20,000 Hz. Sound below 20 Hz is referred to as infrasonic, and that above 20,000 Hz is called ultrasonic.

The detection of sound is made possible by the incidence of transmitted sound energy on an appropriate acoustic transducer, such as the ear. For modern applied acoustics, transducers such as the microphone, based on the piezoelectric effect, are widely used. Generally speaking, any transducer used as a source of sound is also available as a detector, though the sensitivity varies considerably with the type. [R.B.L.]

Acoustooptics The field of science and technology that is concerned with the diffraction of visible or infrared light (usually from a laser) by high-frequency sound in the frequency range of 50–2000 MHz. The term "acousto" is a historical misnomer; sound in this frequency range should properly be called ultrasonic. Such sound cannot be supported by air, but propagates as a mechanical wave disturbance in amorphous or crystalline solids, with a sound velocity ranging from 0.6 to 6 km/s (0.4 to 4 mi/s) and a wavelength from 3 to 100 μm. *See* Laser; Ultrasonics.

The sound wave causes a displacement of the solid's molecules either in the direction of propagation (longitudinal wave) or perpendicular to it (shear wave). In either case, it sets up a corresponding wave of refractive-index variation through local dilatation or distortion of the solid medium. It is this wave that diffracts the light by acting as a three-dimensional grating, analogous to x-diffraction in crystals. The fact that the grating is moving is responsible for shifting the frequency of the diffracted light through the Doppler effect. *See* Diffraction grating; Doppler effect; Refraction of waves; Wave motion; X-ray diffraction.

Since the 1960s, acoustooptics has moved from a scientific curiosity to a relevant technology. This evolution was initially driven by the need for fast modulation and deflection of light beams, and later by demands for more general optical processing. It was made possible by the invention of lasers, the development of efficient ultrasonic transducers, and the formulation of realistic models of sound-light interaction. *See* Transducer. [A.K.]

Acquired immune deficiency syndrome (AIDS) A viral disease of humans caused by the human immunodeficiency virus (HIV), which attacks and compromises the body's immune system. Individuals infected with HIV proceed through a spectrum of stages that ultimately lead to the critical end point, acquired immune deficiency syndrome. The disease is characterized by a profound progressive irreversible depletion of T-helper-inducer lymphocytes (CD4+ lymphocytes), which leads to the onset of multiple and recurrent opportunistic infections by other viruses, fungi, bacteria, and protozoa, as well as various tumors (Kaposi's sarcoma, lymphomas). HIV infection is transmitted by sexual intercourse (heterosexual and homosexual), by blood and blood products, and perinatally from infected mother to child (prepartum, intrapartum, and postpartum via breast milk).

Since retroviruses such as HIV-1 integrate their genetic material into that of the host cell, infection is generally lifelong and cannot be eliminated easily. Therefore, medical efforts have been directed toward preventing the spread of virus from infected individuals. *See* RETROVIRUS.

Approximately 50–70% of individuals with HIV infection experience an acute mononucleosis-like syndrome approximately 3–6 weeks following primary infection. In the acute HIV syndrome, symptoms include fever, pharyngitis, lymphadenopathy, headache, arthralgias, myalgias, lethargy, anorexia, nausea, and erythematous maculopapular rash. These symptoms usually persist for 1–2 weeks and gradually subside as an immune response to HIV is generated.

Although the length of time from initial infection to development of the clinical disease varies greatly from individual to individual, a median time of approximately 10 years has been documented for homosexual or bisexual men, depending somewhat on the mode of infection. Intravenous drug users experience a more aggressive course than homosexual men and hemophiliacs because their immune systems have already been compromised.

As HIV replication continues, the immunologic function of the HIV-infected individual declines throughout the period of clinical latency. At some point during that decline (usually after the CD4+ lymphocyte count has fallen below 500 cells per microliter), the individual begins to develop signs and symptoms of clinical illness, and sometimes may demonstrate generalized symptoms of lymphadenopathy, oral lesions, herpes zoster, and thrombocytopenia.

Secondary opportunistic infections are a late complication of HIV infection, usually occurring in individuals with less than 200 CD4+ lymphocytes per microliter. They are characteristically caused by opportunistic organisms such as *Pneumocystis carinii* and cytomegalovirus that do not ordinarily cause disease in individuals with a normally functioning immune system. However, the spectrum of serious secondary infections that may be associated with HIV infection also includes common bacterial pathogens, such as *Streptococcus pneumoniae*. Secondary opportunistic infections are the leading cause of morbidity and mortality in persons with HIV infection. Tuberculosis has also become a major problem for HIV-infected individuals. Therefore, HIV-infected individuals are administered protective vaccines (pneumococcal) as well as prophylactic regimens for the prevention of infections with *P. carinii, Mycobacterium tuberculosis*, and *M. avium* complex. *See* OPPORTUNISTIC INFECTIONS; PNEUMOCOCCUS; STREPTOCOCCUS; TUBERCULOSIS.

Antiretroviral treatment with deoxyribonucleic acid (DNA) precursor analogs—for example, azidothymidine (AZT), dideoxyinosine (ddI), and dideoxycytidine (ddC)—has been shown to inhibit HIV infection by misincorporating the DNA precursor analogs into viral DNA by the viral DNA polymerase. Nevertheless, these agents are not curative and do not completely eradicate the HIV infection. [A.M.Ma.; E.P.Go.]

Acquired immunological tolerance An induced state in which antigens originally regarded as foreign become regarded as self by the immune system. Tolerance can be induced (tolerization) in all of the cells of the immune system, including T cells (also known as T lymphocytes), the antibody-forming B cells (also known as B lymphocytes), and natural killer cells. Artificially induced immunological tolerance can be helpful in a number of clinical settings. Inducing self-tolerance in the immune system could be an approach to curing autoimmune diseases.

Tolerization can also be used to facilate organ transplantation. Despite improvements in immunosuppressive drug therapy, teaching the immune system to regard a set of foreign antigens presented by the organ graft as self (that is, tolerance induction) has become an important goal for several reasons: (1) It would eliminate the need for chronic immunosuppressive therapy, which is associated with lifelong increased risks of infection and malignancy, and other side effects. (2) It would prevent chronic rejection (a major problem even with immunosuppressive therapy), which often leads to late graft loss. (3) It presents a less toxic alternative to the unacceptably high levels of nonspecific immunosuppressive therapy that would likely be required to prevent rejection of xenografts (grafts from a donor of another species). *See* TRANSPLANTATION BIOLOGY.

Many strategies for inducing immunological tolerance involve reproducing the mechanisms involved in natural central tolerance—the phenomenon by which self-tolerance is maintained among immature lymphocytes developing in the central lymphoid organs. For developing T cells, tolerance occurs in the thymus, the central organ for T cell development. For B cells, development occurs in the bone marrow, and an encounter with self antigens can induce tolerance there among the immature cells.

The transplantation of bone marrow or other sources of hematopoietic (blood cell-producing) stem cells provides a very powerful means of inducing T cell central tolerance. The clinical potential of bone marrow or other types of hematopoietic cell transplantation for the induction of transplantation tolerance in humans has not yet been realized.

Peripheral tolerance comprises mechanisms to prevent immune responses among mature lymphocytes in the peripheral tissues. One major mechanism of T cell and B cell peripheral tolerance is anergy, in which the cells cannot be fully activated by encounter with the antigens that their receptors recognize. Numerous methods of inducing T and B cell anergy have been described.

Another major mechanism of peripheral tolerance is suppression, in which both B cells and T cells may be rendered tolerant of a specific antigen through the activity of substances or cells that actively suppress the lymphocyte's function. Numerous means of inducing B cell and T cell suppression have been described, and convincing evidence implicates cells with the ability to suppress T cell alloresponses (immune responses to alloantigens) in transplantation models. *See* IMMUNOSUPPRESSION. [M.Sy.]

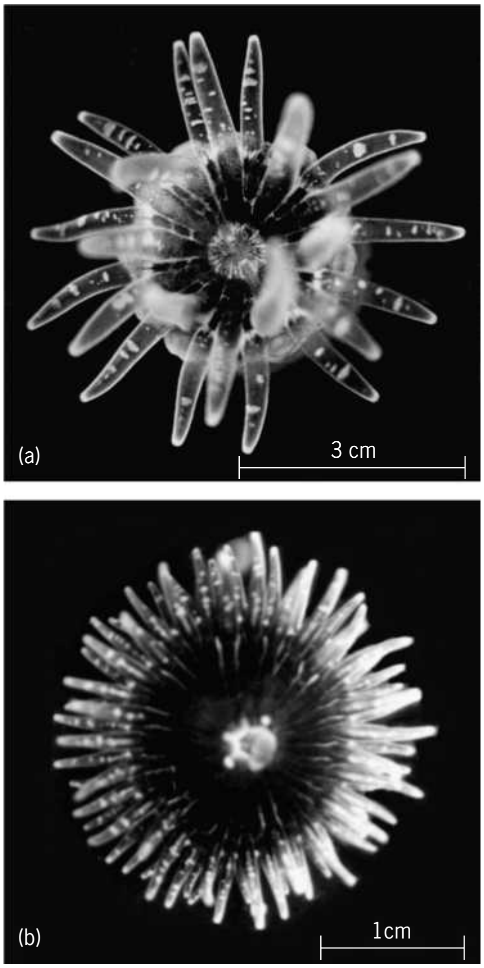
Acrothoracica An order of the subclass Cirripedia. All members burrow into shells of mollusks and thoracican barnacles, echinoderm tests, polyzoans, dead coral, and limestone. The normal three pairs of cirriped mouthparts are present: mandibles, maxillules, and maxillae. Four to six pairs of cirri occur, often greatly reduced in size, the first pair close to the oral appendages and the remainder packed together at the posterior end of the body. The sexes are separate; dwarf males are found on the mantle or wall of the burrow of the female. Naupliar larval stages may be omitted, but a cypris larva always occurs in the life cycle. Three families, about eight genera, and 40 species are recognized. *See* CIRRIPEDIA. [H.G.St.]

Acrylonitrile An explosive, poisonous, flammable liquid, boiling at 171°F (77.3°C), partly soluble in water. It may be regarded as vinyl cyanide, and its systematic name is 2-propenonitrile. Acrylonitrile is prepared by ammoxidation of propylene over various sorts of catalysts, chiefly metallic oxides.

Most of the acrylonitrile produced is consumed in the manufacture of acrylic and modacrylic fibers. Substantial quantities are used in acrylonitrile-butadiene-styrene (ABS) resins, in nitrile elastomers, and in the synthesis of adiponitrile by electrodimerization. Smaller amounts of acrylonitrile are used in cyanoethylation reactions, in the synthesis of drugs, dyestuffs, and pesticides, and as co-monomers with vinyl acetate, vinylpyridine, and similar monomers.

Acrylonitrile undergoes spontaneous polymerization, often with explosive force. It polymerizes violently in the presence of suitable alkaline substances. *See* NITRILE; POLYMERIZATION. [F.W.]

Actiniaria An order of the Zoantharia known as the sea anemones, which are the most widely distributed of the anthozoans. Usually they are solitary animals which live under the low-tide mark attached to some solid object by a basal expansion or pedal disk. They feed on various prey such as copepods, mollusks, annelids, crustaceans, and fish. The burrowing species lack a pedal disk and bury their elongated bodies in the soft sediment of the oceans.



Actiniaria: *Anthopleura* sp. (*a*) Young, (*b*) Adult.

The freely retractile, skeletonless polyp has a cylindrical body, with a thick, tough, rough column wall often bearing rugae, verrucae, tubercles, or suckers (see illustration). The body is often encrusted with sand grains, pebbles, and other detritus. Some species have smooth, thin walls. Nematocysts discharge a toxic substance; however, the human skin is seldom affected by this. The colors of anemones vary with species and many variations occur even among the same species. The tentacles increase in number regularly and are arranged in several cycles. There are 6 primary, 6 secondary, 12 tertiary, 24 quaternary, and so forth in the hexamerous type. The musculature is the most highly developed in the coelenterates.

Most actinians are dioecious. Developing larvae pass through the *Edwardsia* stage then the *Halcampoides* stage. Longitudinal fission frequently occurs as well as budding. Sometimes new individuals result from laceration. *See* COELENTERATA; ZOANTHARIA. [K.At.]

Actinide elements The series of elements beginning with actinium (atomic number 89) and including thorium, protactinium, uranium, and the transuranium elements through the element lawrencium (atomic number 103). These elements have a strong chemical resemblance to the lanthanide, or rare-earth, elements of atomic numbers 57 to 71. Their atomic numbers, names, and chemical symbols are: 89, actinium (Ac), the prototype element, sometimes not included as an actual member of the actinide series; 90, thorium (Th); 91, protactinium (Pa); 92, uranium (U); 93, neptunium (Np); 94, plutonium (Pu); 95, americium (Am); 96, curium (Cm); 97, berkelium (Bk); 98, californium (Cf); 99, einsteinium (Es); 100, fermium (Fm); 101, mendelevium (Md); 102, nobelium (No); 103, lawrencium (Lr). Except for thorium and uranium, the actinide elements are not present in nature in appreciable quantities. The transuranium elements were discovered and investigated as a result of their synthesis in nuclear reactions. All are radioactive and except for thorium and uranium, weighable amounts must be handled with special precautions.

Most actinide elements have the following in common: trivalent cations which form complex ions and organic chelates; soluble sulfates, nitrates, halides, perchlorates, and sulfides; and acid-insoluble fluorides and oxalates. *See* ACTINIUM; LAWRENCIUM; PERIODIC TABLE; PROTACTINIUM; THORIUM; TRANSURANIUM ELEMENTS; URANIUM. [G.T.S.]

Actinium A chemical element, Ac, atomic number 89, and atomic weight 227.0. Actinium was discovered by A. Debierne in 1899. Milligram quantities of the element are available by irradiation of radium in a nuclear reactor. Actinium-227 is a beta-emitting element whose half-life is 22 years. Six other radioisotopes with half-lives ranging from 10 days to less than 1 minute have been identified.

The relationship of actinium to the element lanthanum, the prototype rare earth, is striking. In every case, the actnium compound can be prepared by the method used to form the corresponding lanthanum compound with which it is isomorphous in the solid, anhydrous state. *See* ACTINIDE ELEMENTS; LANTHANUM; NUCLEAR REACTION; RADIOACTIVITY. [S.F.]

Actinobacillus A genus of gram-negative, immotile and nonspore-forming, oval to rod-shaped, often pleomorphic bacteria which occur as parasites or pathogens in mammals (including humans), birds, and reptiles. They are facultatively aerobic, capable of fermenting carbohydrates (without production of gas) and of reducing nitrates. The genomic DNA contains between 40 and 47 mol % guanine plus cytosine. The actinobacillus group shares many biological properties with the genus *Pasteurella*. *See* PASTEURELLA.

Actinobacillus (*Pasteurella*) *ureae* and *A. hominis* occur in the respiratory tract of healthy humans and may be involved in the pathogenesis of sinusitis, bronchopneumonia, pleural empyema, and meningitis. *Actinobacillus actinomycetemcomitans* occurs in the human oral microflora, and together with anaerobic or capnophilic organisms may cause endocarditis and suppurative lesions in the upper alimentary tract. Actinobacilli are susceptible to most antibiotics of the β-lactam family, aminoglycosides, tetracyclines, chloramphenicol, and many other antibacterial chemotherapeutics. *See* ANTIBIOTIC; MEDICAL BACTERIOLOGY. [W.Ma.]

Actinomycetes A heterogeneous collection of bacteria that form branching filaments. The actinomycetes encompass two different groups of filamentous bacteria: the actinomycetes per se and the nocardia/streptomycete complex. Historically, the actinomycetes were called the ray fungi and were thought to be related to the true fungi, such as bread molds, because they formed mats (mycelia) of branching filaments (hyphae). However, unlike the true fungi, the actinomycetes have thin hyphae (0.5–1.5 micrometers in diameter) with genetic material coiled inside as free DNA. The cell wall of the hyphae is made up of a cross-linked polymer containing short chains of amino acids and long chains of amino sugars. In general, actinomycetes do not have membrane-bound cell organelles. Actinomycetes are susceptible to a wide range of antibiotics that are used to treat bacterial diseases, such as penicillin and tetracycline. *See* AMINO SUGAR; ANTIBIOTIC.

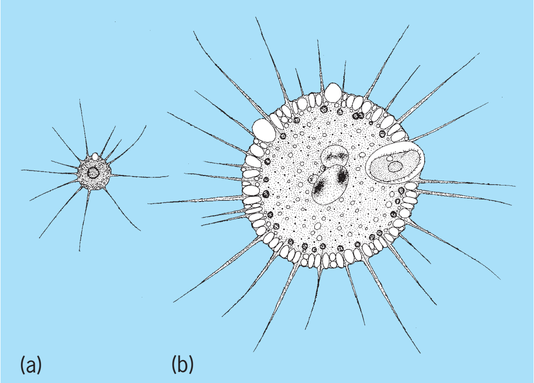
Members of the genus *Actinomyces* are most often found in the mouth and gastrointestinal tract of humans and other animals. *Actinomyces* do not require oxygen for growth and are sometimes referred to as anaerobic bacteria. It is actually the requirement for elevated levels of carbon dioxide rather than the negative effect of oxygen that characterizes *Actinomyces*. When displaced from their normal sites within the mouth or gastrointestinal tract, *Actinomyces* may cause diseases in humans, such as lung abscesses, appendicitis, and lumpy jaw, which is also seen in cattle. Serious ulcers of the cornea of the eye have been caused by contact lens contaminated with saliva containing *Actinomyces*.

The nocardia/streptomycete complex constitutes a continuous spectrum of organisms from those most like true bacteria to those that are superficially most like fungi. The nocardiae represent the transition, having members that resemble the bacteria that cause diphtheria (*Corynebacterium*) and tuberculosis (*Mycobacterium*). Members of the genus *Nocardia* require oxygen for growth, are found in soil and water, and have the ability to use a wide range of organic material as a source of energy. A few species of *Nocardia* cause disease in humans. Nocardiae inhaled from the soil may cause a disease of the lungs similar to tuberculosis. A few species produce clinically useful antibiotics. The streptomycetes have long branching filaments and two types of mycelia. The cell walls are typical bacterial cell walls and do not contain the fatty acids found in nocardiae and mycobacteria. Streptomycetes require oxygen for growth, are found in soil and water, and have the ability to utilize a wide range of organic materials as nutrients. The streptomycetes are particularly important in degradation of dead plant materials in soil; the aroma of fresh soil and newly dug potatoes is actually due to streptomycetes. Streptomycetes do not produce disease in humans or animals and are best known for producing many clinically useful antibiotics, including streptomycin, tetracycline, and cephalosporin. There are many other genera of actinomycetes, defined on the bases of morphology, chemical composition of cell walls, or unique roles in nature. *See* BACTERIA; DIPHTHERIA; MEDICAL BACTERIOLOGY; SOIL MICROBIOLOGY; TUBERCULOSIS. [S.G.B.]

Actinomyxida An order of the protozoan class Myxosporidea (subphylum Cnidospora) characterized by the production of trivalved spores with three polar capsules and one to many sporoplasms. The spore membrane may be extended into anchor-shaped processes, which may have bifurcate tips. These parasites are found in the body cavity or in the intestinal lining of fresh-water annelids and in marine worms of the phylum Sipunculoidea. The life cycle for most species is not well known. *See* CNIDOSPORA; MYXOSPORIDEA; PROTOZOA. [R.F.N.]

Actinophage Any of a number of bacteriophages that infect and lyse bacteria of the order Actinomycetales. Actinophages of particular interest are those that include in their host range any organisms of the genus *Streptomyces*, the source of most of the therapeutically useful antibiotics. Contamination of a culture with a specific actinophage may result in lysis and destruction of the bacteria, which obviously halts antibiotic production. The problem of phage contamination is often solved by the isolation and use of a phage-resistant mutant of the antibiotic-producing bacterium. *See* BACTERIOPHAGE. [L.B.]

Actinophryida An order of Heliozoia. In these protozoans, a centroplast, a highly organized test, and a capsule are lacking (see illustration). The organisms may be uninucleate, as in *Actinophrys*, or multinucleate, as in *Actinosphaerium* (fresh water) and *Camptonema* (marine). The outer cytoplasm is usually highly vacuolated. In uninucleate genera the nucleus is approximately central. Axopodia are present, and their axial filaments end near the nucleus in uninucleate types. *See* ACTINOPODEA; HELIOZOIA; PROTOZOA; SARCODINA. [R.P.H.]



Actinophryida: (*a*) *Actinosphaerium eichorni.* (*b*) *Actinophrys pontica.* (*After P. P. Hall, Protozoology, Prentice-Hall, 1953*)

Actinopodea A class of Sarcodina. Some of these protozoans have more or less permanent pseudopodia, composed of axial filaments surrounded by a cytoplasmic envelope (axopodia); others have delicate and often radially arranged filopodia (filamentous pseudopodia) or filoreticulopodia (filamentous branched pseudopodia) without axial filaments. Although some are stalked and sessile, most are floating types. There are four subclasses: Radiolaria, Acantharia, Heliozoia, and Proteomyxidia. *See* ACANTHARIA; HELIOZOIA; PROTEOMYXIDIA; RADIOLARIA; SARCODINA. [R.P.H.]

Actinopterygii A group of bony fishes, also known as actinops or ray-finned fishes, containing about half of all vertebrate species and about 96% of all living “fishes” (a nonmonophyletic group derived from more than one lineage when tetrapods are excluded). Living Actinopterygii comprise Polypteriformes (bichirs and reedfish), Acipenseriformes (sturgeons and paddlefishes), Lepisosteiformes (gars), Amiiformes (bowfins), and Teleostei (teleosts). Actinops are characterized by the presence of a single dorsal fin, an enclosed sensory canal in the dentary bone, a specialized tissue called ganoin, and several other anatomical characters. About 40% of living actinopterygian species live exclusively or almost exclusively in fresh water. The rest inhabit mostly marine, brackish, or combination environments.

The fossil record indicates that actinopterygians are at least as old as the Late Silurian (about 420 million years before present). Fossil actinopterygians are speciose and extremely abundant, making up the majority of vertebrate fossils that are known by complete skeletons. Many major radiations of early actinopterygians, such as pycnodonts, semionotiforms, and palaeonisciforms, have been extinct for tens of millions of years. Other early actinopterygian groups, such as the Cheirolepiformes, have been extinct for hundreds of millions of years. Based on the fossil record, the most major differentiation of the group began in the late Mesozoic. *See* AMIIFORMES; POLYPTERIFORMES; SEMIONOTIFORMES. [L.G.]

Action Any one of a number of related integral quantities which serve as the basis for general formulations of the dynamics of both classical and quantum-mechanical systems. The term has been associated with four quantities: the fundamental action S, for general paths of a dynamical system; the classical action S_C, for the actual path; the modified action S', for paths restricted to a particular energy; and action variables, for periodic motions.

A dynamical system can be described in terms of some number N of coordinate degrees of freedom that specify its configuration. As the vector q whose components are the degrees of freedom $q_1, q_2, \ldots, q_N$ varies with time t, it traces a path $q(t)$ in an N-dimensional space. The fundamental action S is the integral of the lagrangian of the system taken along any path $q(t)$, actual or virtual, starting from a specified configuration q_1 at a specified time t_1, and ending similarly at configuration q_2 and time t_2. The value of this action $S[q(t)]$ depends on the particular path $q(t)$. The actual path $q_C(t)$ which is traversed when the system moves according to newtonian classical mechanics gives an extremum value of S, usually a minimum, relative to the other paths. This is Hamilton's least-action principle. The extremum value depends only on the end points and is called the classical action $S_C(q_1, q_2; t_1, t_2)$.

An important variant of Hamilton's principle applies when the virtual paths $q(t)$ are restricted to motions all of the same energy E, but no longer to a specific time interval, $t_1 - t_2$. The modified action $S' = S - E(t_1 - t_2)$ obeys a modified least-action principle, usually called Maupertuis' principle, namely, that the classical path gives again an extremal value of S' relative to all paths of that energy. Maupertuis' principle is closely related to Fermat's principle of least time in classical optics for the path of light rays of a definite frequency through a region of inhomogeneous refractive index. *See* HAMILTON'S PRINCIPLE; MINIMAL PRINCIPLES.

In quantum mechanics, as originally formulated by E. Schrödinger, the state of particles is described by wave functions which obey the Schrödinger wave equation. States of definite energy in, say, atoms are described by stationary wave functions, which do not move in space. Nonstationary wave functions describe transitory processes such as the scattering of particles, in which the state changes. Both stationary and nonstationary state wave functions are determined, in principle, once the Schrödinger wave propagator (also called the Green function) between any two points q_1 and q_2 is known. In a fundamental restatement of quantum mechanics, R. Feynman showed that all paths from q_1 to q_2, including the virtual paths, contribute to the wave propagator. Each path contributes a complex phase-term $\exp i\,(\phi[q(t)])$, where the phase ϕ is proportional to the action for that path. The resulting sum over paths, appropriately defined, is the path integral (or functional integral) representation of the Schrödinger wave propagator. The path integral has become the general starting point for most formulations of quantum theories of particles and fields. The classical path $q_C(t)$ of least action now plays the role in the wave function as being the path of stationary phase. *See* PROPAGATOR (FIELD THEORY). [B.G.]

Activated carbon A powdered, granular, or pelleted form of amorphous carbon characterized by very large surface area per unit volume because of an enormous number of fine pores. Activated carbon is capable of collecting gases, liquids, or dissolved substances on the surface of its pores.

Adsorption on activated carbon is selective, favoring nonpolar over polar substances. Compared with other commercial adsorbents, activated carbon has a broad spectrum of adsorptive activity, excellent physical and chemical stability, and ease of production from readily available, frequently waste materials. *See* ADSORPTION.

Almost any carbonaceous raw material can be used for the manufacture of activated carbon. Wood, peat, and lignite are commonly used for the decolorizing materials. Bone char made by calcining bones is used in large quantity for sugar refining. Nut shells (particularly coconut), coal, petroleum coke, and other residues in either granular, briqueted, or pelleted form are used for adsorbent products.

Activation is the process of treating the carbon to open an enormous number of pores in the 1.2- to 20-nanometer-diameter range (gas-adsorbent carbon) or up to 100-nm-diameter range (decolorizing carbons). After activation, the carbon has the large surface area (500–1500 m^2/g) responsible for the adsorption phenomena. Carbons that have not been subjected previously to high temperatures are easiest to activate. Selective oxidation of the base carbon with steam, carbon dioxide, flue gas, or air is one method of developing the pore structure. Other methods require the mixing of chemicals, such as metal chlorides (particularly zinc chloride) or sulfides or phosphates, potassium sulfide, potassium thiocyanate, or phosphoric acid, with the carbonaceous matter, followed by calcining and washing the residue. *See* CARBON; CHARCOAL. [H.B.A.]

Activation analysis A technique in which a neutron, charged particle, or gamma photon is captured by a stable nuclide to produce a different, radioactive nuclide which is then measured. The technique is specific, highly sensitive, and applicable to almost every element in the periodic table.

In neutron activation analysis (NAA), the most widely used form of activation analysis, the sample to be analyzed is placed in a nuclear reactor where it is exposed to a flux of thermal neutrons. Some of these neutrons are captured by isotopes of elements in the sample; this results in the formation of a nuclide with the same atomic number, but with one more mass unit of weight. A prompt gamma ray is immediately emitted by the new nuclide.

Measurement of the induced radioactivities is the key to activation analysis. This is usually obtained from the gamma-ray spectra of the induced radionuclides. Gamma rays from radioactive isotopes have unique, discrete energies, and a device that converts such rays into electronic signals that can be amplified and displayed as a function of energy is a gamma-ray spectrometer. It consists of a detector [germanium doped with lithium, GeLi, or sodium iodide doped with thallium, NaI(Tl)] and associated electronics.

Activation analysis can also be performed with charged particles (protons or He^{3+} ions, for example), but because fluxes of such particles are usually lower than reactor neutron fluxes and cross sections are much smaller, charged-particle methods are usually reserved for special samples. Charged particles penetrate only a short distance into samples, which is another disadvantage. A variant called proton-induced x-ray emission (PIXE) has been highly successful in analyzing air particulates on filters.

Activation analysis has been applied to a variety of samples. It is particularly useful for small (1 mg or less) samples, and one irradiation can provide information on 30 or more elements. Samples such as small amounts of pollutants, fly ash, very pure experimental alloys, and biological tissue have been successfully studied by neutron activation analysis. Of particular interest has been its use in forensic studies; paint, glass, tape, and other specimens of physical evidence have been assayed for legal purposes. In addition, the method has been used for authentication of art objects and paintings where only a small sample is available. *See* FORENSIC CHEMISTRY; NUCLEAR REACTION; PARTICLE DETECTOR; RADIOISOTOPE. [W.S.L.]

Active sound control The modification of sound fields by using additional sound transmitted from loudspeakers. The signals from the loudspeakers are controlled electronically by using digital signal processing techniques.

The physical principle underlying the active control of sound is interference. That is, the sound pressure fluctuations produced at a given point in space by two sources of sound simply add together at each point in time. Thus if a secondary source of sound is made to produce the opposite pressure fluctuation to a given primary source at a given point in space, the net result will be silence at that point. *See* INTERFERENCE OF WAVES.

The developments in modern electronics during the latter part of the twentieth century enabled the practical implementation of the active control of sound with much greater ease than was possible before. A detection microphone is first used to sense the primary sound. The electrical signal from this microphone is passed through an analog low-pass filter, then sampled and converted into digital format. This resulting sequence of numbers is then passed through a digital filter prior to being converted back into an analog signal and fed to the loudspeaker comprising the secondary source. The value of the output from the digital filter at a given time is typically calculated from both the current and a number of previous values of the input sequence. These values are multiplied by a series of numbers comprising the filter coefficients before being added together to produce the output value at that particular time. These arithmetic operations can be carried out extremely fast on a special-purpose microprocessor that is used to implement the digital filter. An error microphone is then used to sense the degree of interference between the primary and secondary sound. *See* DIGITAL FILTER; MICROPROCESSOR.

The coefficients of the digital filter are chosen to ensure that the waveform of the sound radiated from the loudspeaker is aligned in time in order to be (as far as possible) opposite to the waveform produced at the error microphone by the primary source. When the waveform of the primary sound is unpredictable, it is important to ensure that the time taken to process and transmit the secondary sound is sufficiently short that it arrives soon enough at the error microphone to cancel the primary sound. This basic approach to the problem is often referred to as feed-forward active control, since it makes use of the advanced warning of the arrival of unwanted sound. This is provided by the finite time required for sound to propagate from the detection microphone to the error microphone.

Some physical limitations of the technique can be overcome simply by increasing the number of secondary sources used to control the field. For example, if 10 loudspeakers are used to control a pure-tone sound field, it is possible in principle to produce 10 points of silence in the field. Of course, depending upon the geometrical arrangement and the acoustical environment of the primary and secondary sources, increases in level may well be produced at other positions. Another strategy is to drive the secondary sources in order to minimize the sound level at a number of error microphones which is larger than the number of secondary sources. Under these circumstances it is possible to produce widespread reductions in sound level. All that is required is the detection of the frequency of the primary source; this reference signal is then sampled and passed through a digital filter associated with each secondary source. (This signal is uncorrupted by feedback from the secondary source outputs.) The coefficients of these filters are then adjusted adaptively in response to the signals sampled at the error microphones by using a multichannel generalization of a common algorithm. This ensures the minimization of the sum of the squared outputs from the error microphones and thus the suppression of the sound field.

Many acoustic waveforms of practical interest are highly unpredictable. Examples include the waveforms of the noise generated inside an automobile due to the airflow past the passenger cabin and the vibrations generated by the contact of the tires with the road. In addition, there may be multiple primary sources of such unwanted sound. In these cases it becomes more difficult to find reference signals that give a prior indication of the acoustic pressure fluctuations well before their arrival at the ears of the occupants. However, it is possible to find the optimal matrix of digital filters that ensures the minimization of the sum of the time-averaged signals from a number of error microphones. *See* ACOUSTIC NOISE; ADAPTIVE SIGNAL PROCESSING; CONTROL SYSTEMS; SOUND. [P.A.N.]

Activity (thermodynamics) The activity of a substance is a thermodynamic property that is related to the chemical potential of that substance. Activities are closely related to measures of concentration, such as partial pressures and mole fractions. The conditions that hold in chemical reaction equilibrium and in phase equilibrium can be expressed in terms of activities of the species involved.

The activity a_i of chemical species i in a phase (a homogeneous portion) of a thermodynamic system is defined by Eq. (1), where

$$a_i \equiv \exp[(\mu_i - \mu_i^\circ)/RT] \qquad (1)$$

μ_i is the chemical potential of i in that phase, μ_i° is the chemical potential of i in its standard state, R is the gas constant, and T is the absolute temperature. Equation (1) shows that the activity a_i depends on the choice of standard state for species i. Since μ_i is an intensive quantity that depends on the temperature, pressure, and composition of the phase, a_i is an intensive function of these variables. a_i is dimensionless. When $\mu_i = \mu_i^\circ$, then $a_i = 1$. The degree of departure of a_i from 1 measures the degree of departure of the chemical potential from its standard-state value. The chemical potential is defined by $\mu_i \equiv \partial G/\partial n_i$, where G is the Gibbs energy of the phase, n_i is the number of moles of substance i in the phase, and the partial derivative is taken at constant temperature, pressure, and amounts of all substances except i. *See* FREE ENERGY.

From Eq. (1), it follows that μ_i is given by Eq. (2). The chemical potentials μ_i are key thermodynamic quantities of a phase,

$$\mu_i = \mu_i^\circ + RT \ln a_i \qquad (2)$$

since all thermodynamic properties of the phase can be found if the chemical potentials in the phase are known as functions of temperature, pressure, and composition. Activities are more convenient to work with than chemical potentials, because the chemical potential of a substance in a phase goes to minus infinity as the amount of that substance in the phase goes to zero; also, one can determine only a value of μ_i relative to its value in some other state, whereas one can determine the actual value of each a_i. [I.N.L.]

Acylation A process in which a hydrogen atom in an organic compound is replaced by an acyl group (R—CO, where R = an organic group). The reaction involves substitution by a nucleophile (electron donor) at the electrophilic carbonyl group (C═O) of a carboxylic acid derivative. The substitution usually proceeds by an addition-elimination sequence. Two common reagents, with the general formula RCOX, that bring about acylation are acid halides (X = Cl, Br) and anhydrides (X = OCOR). There are also other acylating reagents. The carboxylic acid (X = OH) itself can function as an acylating agent when it is protonated by a strong acid catalyst as in the direct esterification of an alcohol. Typical nucleophiles in the acylation reaction are alcohols (ROH) or phenols (ArOH), both of which give rise to esters, and ammonia or amines (RNH_2), which give amides. *See* ACID ANHYDRIDE; ACID HALIDE; AMIDE; AMINE. [J.A.Mo.]

Adaptation (biology) A characteristic of an organism that makes it fit for its environment or for its particular way of life. For example, the Arctic fox (*Alopex lagopus*) is well adapted for living in a very cold climate. Appropriately, it has much thicker fur than similar-sized mammals from warmer places; measurement of heat flow through fur samples demonstrates that the Arctic fox and other arctic mammals have much better heat insulation than tropical species. Consequently, Arctic foxes do not have to raise their metabolic rates as much as tropical mammals do at low temperatures. The insulation is so effective that Arctic foxes can maintain their normal deep body temperatures of 100°F (38°C) even when the temperature of the environment falls to −112°F (−80°C). Thus, thick fur is obviously an adaptation to life in a cold environment. *See* THERMOREGULATION.

In contrast to that clear example, it is often hard to be sure of the effectiveness of what seems to be an adaptation. For example, the scombrid fishes (tunnies and mackerel) seem to be adapted to fast, economical swimming. The body has an almost ideal streamlined shape. However, some other less streamlined-looking fishes are equally fast for their sizes. There are no measurements of the energy cost of scombrid swimming, but measurements on other species show no clear relationship between energy cost and streamlining.

Evolution by natural selection tends to increase fitness, making organisms better adapted to their environment and way of life. It might be inferred that this would ultimately lead to perfect adaptation, but this is not so. It must be remembered that evolution proceeds by small steps. For example, squids do not swim as well as fish. The squid would be better adapted for swimming if it evolved a fishlike tail instead of its jet propulsion mechanism, but evolution cannot make that change because it would involve moving down from the lesser adaptive summit before climbing the higher one. [R.M.Al.]

Adaptive control A special type of nonlinear control system which can alter its parameters to adapt to a changing environment. The changes in environment can represent variations in process dynamics or changes in the characteristics of the disturbances. *See* NONLINEAR CONTROL THEORY.

A normal feedback control system can handle moderate variations in process dynamics. The presence of such variations is, in fact, one reason for introducing feedback. There are, however, many situations where the changes in process dynamics are so large that a constant linear feedback controller will not work satisfactorily. For example, the dynamics of a supersonic aircraft change drastically with Mach number and dynamic pressure, and a flight control system with constant parameters will not work well. *See* FLIGHT CONTROLS.

Adaptive control is also useful for industrial process control. Since delay and holdup times depend on production, it is desirable to retune the regulators when there is a change in production. Adaptive control can also be used to compensate for changes due to aging and wear. *See* PROCESS CONTROL. [K.J.A.]

Adaptive management An approach to management of natural resources that emphasizes how little is known about the dynamics of ecosystems and that as more is learned management will evolve and improve. Natural systems are very complex and dynamic, and human observations about natural processes are fragmentary and inaccurate. As a result, the best way to use the available resources in a sustainable manner remains to be determined. Furthermore, much of the variability that affects natural populations is unpredictable and beyond human control. This combination of ignorance and unpredictability means that the ways in which ecosystems respond to human interventions are unknown and can be described only in probabilistic terms. Nonetheless, management decisions need to be made. Adaptive management proceeds despite this uncertainty by treating human interventions in natural systems as large-scale experiments from which more may be learned, leading to improved management in the future.

A key first step in the development of an adaptive management program is the assessment of the problem. During this stage, existing knowledge and interdisciplinary experience is synthesized and formally integrated by developing a dynamic model of the system. This modeling exercise helps to identify key information gaps and to postulate hypotheses about possible system responses to human intervention consistent with available information. Different management policies have to be screened in order to narrow down the alternatives to a few plausible candidates.

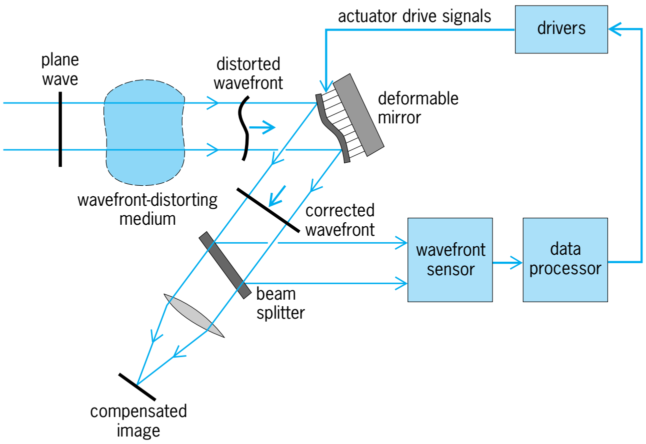
The second stage involves the formal design of a management and monitoring program. To the extent that new information can result in improved future management, adaptive management programs may include large-scale experiments deliberately designed to accelerate learning. Some management actions may be more effective than others at filling the relevant information gaps. In cases where spatial replication is possible (such as small lakes, patches of forest, and reefs), policies that provide contrasts between different management units will be much more informative about the system dynamics than those that apply the same rule everywhere. There are other barriers to the implementation of large-scale management experiments. Experiments usually have associated costs; thus, in order to be worthwhile, benefits derived from learning must overcompensate short-term sacrifices. Choices may be also restricted by social concerns or biological constraints, or they may have unacceptably high associated risks.

Once a plan for action has been chosen, the next stage is to implement the program in the field. This is one of the most difficult steps, because it involves a concerted and sustained effort from all sectors involved in the use, assessment, and management of the natural resources. Beyond the implementation of specific initial actions, putting in place an adaptive management program involves a long-term commitment to monitoring the compliance of the plan, evaluating the effects of management interventions, and adjusting management accordingly.

No matter how thorough and complete the initial assessment and design may have been, systems may always respond in manners that could not be foreseen at the planning stage. Ecosystems exhibit long-term, persistent changes at the scale of decades and centuries; thus, recent experience is not necessarily a good basis for predicting future behavior. The effects of global climatic change on the dynamics of ecosystems, which are to a large extent unpredictable, will pose many such management challenges. Adaptive management programs have to include a stage of evaluation and adjustment. Outcomes of past management decisions must be compared with initial forecasts, models have to be refined to reflect new understanding, and management programs have to be revised accordingly. New information may suggest new uncertainties and innovative management approaches, leading to another cycle of assessment, design, implementation, and evaluation. [A.M.Pa.]

Adaptive optics The science of optical systems in which a controllable optical element, usually a deformable mirror, is used to optimize the performance of the system, for example, to maintain a sharply focused image in the presence of wavefront aberrations. A distinction is made between active optics, in which optical components are modified or adjusted by external control to compensate slowly changing disturbances, and adaptive optics, which applies to closed-loop feedback systems employing sensors and data processors, operating at much higher frequencies. *See* CONTROL SYSTEMS.

In a typical adaptive optics system (see illustration) the distorted light beam to be compensated is reflected from the



Typical adaptive optics system using discrete components.

deformable mirror and is sampled by a beam splitter. The light sample is analyzed in a wavefront sensor that determines the error in each part of the beam. The required corrections are computed and applied to the deformable mirror whose surface forms the shape necessary to flatten the reflected wavefront. The result is to remove the optical error at the sampling point so that the light passing through the beam splitter may be focused to a sharp image. Nonlinear optical devices are also capable of performing some adaptive optics functions; these devices operate at high optical power levels. *See* ABERRATION (OPTICS); GEOMETRICAL OPTICS; NONLINEAR OPTICAL DEVICES.

The practical development of adaptive optics started in the late 1960s. Its main applications have been to compensate for the effects of atmospheric turbulence in ground-based astronomical telescopes and to improve the beam quality of high-power lasers. Adaptive optics is now used routinely at several astronomical observatories. [J.W.Ha.]

Adaptive signal processing Signal processing deals with the extraction of information from signals. The devices that perform this task can be physical hardware devices, specialized software codes, or combinations of both. Some notable applications, in areas ranging from biomedical engineering to wireless communications, include the suppression of interference arising from noisy measurement sensors, the elimination of distortions introduced when signals travel through transmission channels, and the recovery of signals embedded in a multitude of echoes created by multipath effects in mobile communications.

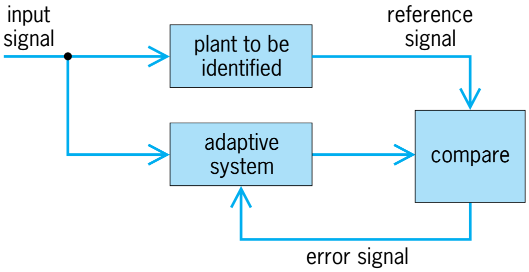
Statistically based systems. Any functional system is expected to meet certain performance specifications. The requirements, as well as the design methodology, vary according to the nature of the end application. One distinctive design methodology, which dominated much of the earlier work in the information sciences, especially in the 1950s and 1960s, is based on statistical considerations. This framework assumes the availability of information in advance about the statistical nature of the signals involved, and then proceeds to design systems that optimize some statistical criterion. The resulting optimal designs are, in general, complex to implement. Only in special, yet important cases have they led to successful breakthroughs culminating with the Wiener and Kalman filters. *See* ESTIMATION THEORY; OPTIMIZATION.

Moreover, in many situations a design that is motivated by statistical considerations may not be immediately feasible, because complete knowledge of the necessary statistical information may not be available. It may even happen that the statistical conditions vary with time. It therefore may be expected, in these scenarios, that the performance of any statistically based optimal design will degrade as the real physical application deviates from the modeling assumptions.

Adaptive systems. Adaptive systems are devices that adjust themselves to an ever-changing environment; the structure of an adaptive system changes in such a way that its performance improves through a continuing interaction with its surroundings. Its superior performance in nonstationary environments results from its ability to track slow variations in the statistics of the signals and to continually seek optimal designs.

Adaptive signal processing deals with the design of adaptive systems for signal-processing applications. Related issues arise in control design, where the objective is to alter the behavior of a system, and lead to the study of adaptive control strategies; the main issue is the stability of the system under feedback. *See* ADAPTIVE CONTROL.

Operation. The operation of an adaptive system can be illustrated with a classical example in system identification. The illustration shows a plant (or system) whose input-output behavior is unknown and may even be time variant. The objective is to design an adaptive system that provides a good approximation to the input-output map of the plant. For this purpose, the plant is excited by a known input signal, and the response is taken as a reference signal. Moreover, a structure is chosen for the adaptive system, say a finite-impulse response structure of adequate length, and it is excited by the same input signal as the plant. At each time instant the output of the finite-impulse response system is compared with the reference signal, and the resulting error signal is used to change the coefficients of the finite-impulse response configuration. This learning process is continued over time, and the output of the adaptive system is expected to provide better tracking of the plant output as time progresses, especially when the structure of the plant is time invariant or varies only slowly with time. [A.H.Sa.; B.Ha.; T.Ka.]



Adaptive system identification.

Addictive disorders Addictive disease disorders are characterized by the chronic use of a drug (such as heroin, cocaine, or amphetamines), alcohol, or similar substances. These disorders usually result in (1) the development of tolerance for the substance, with the need for increasing amounts to achieve the desired effect; (2) physical dependence, characterized by a sequence of well-defined signs and physiological symptoms, such as the withdrawal or abstinence syndrome on cessation of use of the substance; and (3) compulsive drug-seeking behavior, with chronic, regular, or intermittent use, despite possible harm to self or others. Since the early 1960s, research has been increasing in the biology of addictive diseases, and emphasis has shifted from only psychological, sociological, and epidemiological studies to investigations of the metabolic, neurobiological, and molecular bases of addiction.

The four major addictive diseases are alcoholism, narcotic (or opiate) addiction, cocaine and other stimulant addiction, and nicotine addiction. Drug addiction may also occur after chronic use of other types of agents such as barbiturates, benzodiazepines, and marijuana. *See* ALCOHOLISM; BARBITURATES; COCAINE; NARCOTIC; OPIATES.

Opiate receptors (cell structures that function as an intermediary between the opioid and the physiological response) here conclusively identified in mammals (including humans) in 1973. Since then, it has been determined that there are at least three different types of opioid receptors—mu receptors, delta receptors, and kappa receptors. The genes encoding each of these receptor types were cloned for the first time in 1992, beginning with the delta opioid receptor. Subsequent to the discovery of specific opioid receptors, endogenous ligands which bind to these receptors, the so-called endogenous opioids, were discovered. Opioids include substances that are produced endogenously (such as the enkephalins, endorphins, and dynorphins) and may be produced synthetically. Exogenous synthetic opioids are used extensively in the treatment of pain. *See* ENDORPHINS.

It is not known to what extent the endogenous opioids play a role in addictive diseases. It has been suggested that narcotic addiction may be a disorder characterized by (1) a relative or absolute deficiency of endogenous opioids; (2) an end organ or receptor failure to respond to normal or possibly increased levels of endogenous opioids; (3) genetic or acquired (for example, short-acting opiate or stimulant drug–induced) abnormalities in the feedback control of the synthesis, release, and processing, or degradation of one or more types of the endogenous opioids; or (4) genetic variations in the opioid receptors.

The possible role of endogenous opioids in alcoholism is also not clear. It has been shown that a specific opioid antagonist, naloxone, may reverse or ameliorate some of the signs and symptoms and physical abnormalities of the acute alcohol intoxication syndrome. However, this apparent beneficial effect of an opioid antagonist may not be related to the addictive disease per se, but may be due to the counteracting of the possible acute release of large amounts of endogenous opioids in response to excessive acute alcohol ingestion. Whether there are some common mechanisms with a genetic, metabolic, or purely behavioral basis underlying these two addictive diseases has not yet been defined.

There are three approaches to the management of opiate (primarily heroin) addiction: pharmacological treatment, drug-free treatment following detoxification, and incarceration. Statistical data over the last century reveal that after release from prison, completion of drug-free treatment, or discontinuation of chronic pharmacological treatment with methadone or other mu agonists, partial agonists, or antagonists, fewer than 30% of former long-term heroin addicts are able to stay drug-free. (Long-term addiction is defined as more than 1 year of daily use of several doses of heroin, with tolerance, physical dependence, and drug-seeking behavior.)

Since the 1960s, methadone maintenance treatment has been documented to be medically safe and the most effective available treatment for heroin addiction. Unlike heroin, which has a 3-min half-life in humans, and its major metabolite, morphine, which has a half-life of 4–6 h, methadone has a 24-h half-life. Therefore, when given orally daily, methadone prevents the signs and symptoms of narcotic abstinence and also prevents drug hunger, without causing any narcotic-induced euphoria during the 24 h between doses. Steady moderate to high doses of methadone can be used in the treatment of addiction over long periods of time without tolerance developing to these desired effects. Because of the high degree of cross-tolerance developed for other narcotics, a patient receiving methadone maintenance treatment does not experience any narcotic high or other effects after self-administration of a dose of short-acting narcotic such as heroin. Through this cross-tolerance mechanism, methadone blocks any illicit narcotic effect. 60–90% of heroin addicts who have entered into methadone maintenance treatment will stay in treatment voluntarily for 1 year or more. Illicit opiate abuse drops to less than 15% during such treatment when adequate doses of methadone (usually 60–150 mg per day) are administered. Cocaine or polydrug abuse or alcohol abuse may persist in 20–30% of patients even in excellent methadone programs, since methadone maintenance is specific for treatment of narcotic dependency. Chronic methadone treatment also brings about the normalization of the multiple physiological alterations caused by chronic heroin abuse. Methadone-maintained patients, who are not chronic abusers of other drugs or alcohol, are able to work, to attend school, and to take part in normal socialization, including restoration of family life. However, when maintenance treatment is discontinued, over 70% of all patients will return to opiate abuse within 2 years.

A second type of pharmacological treatment of narcotic addiction is chronic treatment with a specific narcotic antagonist, naltrexone. This drug also prevents any narcotic effect from illicitly administered heroin, but does so by way of direct opioid receptor blocking, with displacement of endogenous or exogenous opioids from receptor binding. Naltrexone treatment has limited acceptance by unselected opiate addicts; only 15–30% of former narcotic addicts entering treatment with this agent remain in treatment for 6 months or more. Therefore, although it may be a worthwhile treatment for some small defined special populations, it does not seem to be an effective treatment for the majority of unselected long-term heroin addicts.

Drug-free treatment involving either long-term institutionalization in a drug-free residence or, less frequently, attendance at an outpatient resource, has resulted in long-term success in approximately 10–30% of all unselected heroin addicts who enter treatment.

Alcoholism has been difficult to treat over a long-term period. There is no specific pharmacological replacement treatment for alcoholism. Disulfiram (Antabuse) is an agent which blocks the metabolism of acetaldehyde, the major metabolite of ethanol. When a person treated with Antabuse drinks alcohol, there is a rapid buildup of acetaldehyde and a severe physiological syndrome ensues, which frequently prevents or modifies further immediate drinking behavior.

The most widely used treatment of alcoholism is self-help groups, such as Alcoholics Anonymous (AA), where mutual support is available on a 24-h basis, along with group recognition of chronic problems with alcohol. However, only around 20–40% of severe chronic alcoholics are able to stay alcohol-free for more than 2 years even under such management. Early studies of the use of an opioid antagonist naltrexone or nalmefene for the treatment of chronic alcoholism have shown that about 50% of the subjects had reduced numbers and magnitudes of relapse events. Ethanol, unlike heroin and other narcotics, has many well-defined severes, specific toxic effects on several organs, including the liver, brain, and reproductive system, so even relatively short drug-free intervals will decrease exposure to this toxin. Therefore, it has been suggested that success in treatment of alcoholism be measured in part by increasing lengths of alcohol-free intervals, and not just by permanent restoration of the alcohol-free state.

Cocaine addiction may also involve disruption of the endogenous opioid system in addition to the well-known primary effect of cocaine in blocking reuptake of dopamine by the synaptic dopamine transporter protein. This effect results in the accumulation of dopamine in the synapse and similar actions at the serotonin and norepinephrine reuptake transporter. Demonstrated changes in the mu and kappa endogenous opioid system increase the complexity of the effect of cocaine and may contribute to its resultant reinforcing properties leading to addiction, as well as to the drug craving and relapse. This may explain in part the resultant difficulties in developing a pharmacotherapeutic approach for the treatment of cocaine addiction. [M.J.Kr.]

Addition One of the four fundamental operations of arithmetic and algebra. The term addition is applied to many kinds of objects other than numbers. For example, two vectors **x**, **y** are added to produce a third vector **z** obtained from them by the "parallelogram" law, and two sets *A*, *B* are added to form a third set *C* consisting of all the elements of *A* and of *B*. *See* CALCULUS OF VECTORS.

As an operation on pairs of real or complex numbers, addition is associative, Eq. (1), and commutative, Eq. (2); and multiplication is distributive over addition, Eq. (3). There are

$$a + (b + c) = (a + b) + c \tag{1}$$

$$a + b = b + a \tag{2}$$

$$a(b + c) = a \cdot b + a \cdot c \tag{3}$$

important mathematical structures in which an addition operation is defined that lacks one or more of these properties. *See* ALGEBRA; DIVISION; MULTIPLICATION; NUMBER THEORY; SUBTRACTION. [L.M.Bl.]

Adenohypophysis hormone Of the endocrine glands, the anterior pituitary, or adenohypophysis, occupies the prime place because, through the secretion of various hormones, it controls the functioning of certain other endocrine glands, namely, the adrenal cortex, the thyroid, and the gonads. In addition, hormones from the anterior pituitary influence the growth and metabolism of the organism through direct action on skeletal, muscular, and other tissues. The pituitary maintains control over the various target organs by a feedback mechanism which is sensitive to circulating levels of hormones from the target organs.

Pituitary hormones are also released in response to metabolic conditions which they help to control. One factor influencing the secretion of growth hormone, for example, is the level of blood glucose.

There are eight anterior pituitary hormones whose existence has been firmly established for some time. They include the two gonadotropic hormones, interstitial-cell stimulating hormone (ICSH, or luteinizing hormone, LH) and follicle-stimulating hormone (FSH); thyrotropic hormone (thyroid-stimulating hormone, TSH); lactogenic hormone (prolactin); growth hormone (GH, or somatotropin, STH); adrenocorticotropic hormone (ACTH, or adrenocorticotropin, or corticotropin); and the two melanocyte-stimulating hormones (α-MSH and β-MSH). In addition, two peptides have been isolated which are structurally related to ACTH and the MSHs. These peptides have been designated β-lipotropic hormone (β-LPH) and γ-lipotropic hormone (γ-LPH). The hormones of the adenohypophysis are composed of amino acids in peptide linkage and are therefore classed as either polypeptides or proteins, depending on their size. In addition, three of the hormones, TSH, ICSH, and FSH, contain carbohydrate and are therefore categorized as glycoproteins. *See* Amino acids; Hormone; Protein.

In the female, FSH initiates the development of ovarian follicles. ICSH, acting synergistically with FSH, is necessary for the final stages of follicular maturation and the production of estrogen. ICSH also stimulates the development of the corpus luteum. In the male, FSH stimulates spermatogenesis through its action on the germinal epithelium of the testis, and ICSH primarily activates the Leydig cells which produce androgen.

TSH stimulates the growth of the thyroid gland and the secretion of thyroid hormones.

Through a process which requires other hormones as well, lactogenic hormone stimulates the mammary gland to secrete milk. There is evidence that in some species of mammals lactogenic hormone also plays a role in maintaining the corpus luteum in the ovary. In contrast to all nonprimate species investigated, a distinct lactogenic hormone has never been isolated from the pituitaries of the monkey or the human. In these two species a hormone containing lactogenic activity can indeed be isolated from the pituitary, but it also has growth-promoting activity and in major respects corresponds to growth hormones isolated from nonprimate species. Thus, in nonprimates, a distinct growth hormone, having no lactogenic activity, can be isolated from the pituitary gland. In the primates, however, growth-promoting and lactogenic activities are present in the same molecule. In spite of its dual activities, the primate hormone is usually referred to simply as growth hormone, which promotes an increase in body size. It stimulates the growth of bones, muscles, and other tissues and enhances the effects of other pituitary hormones on their target organs. Although certain cellular effects of growth hormone are known, such as increasing incorporation of amino acids into muscle protein, the biochemical mechanisms whereby this hormone exerts its effects at the cellular level remain a mystery.

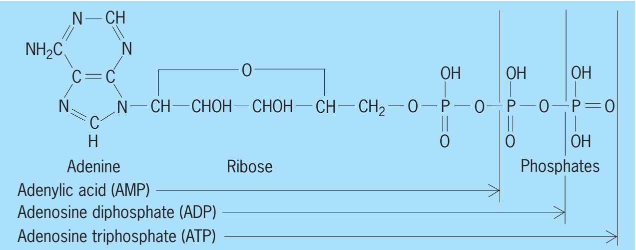
The hormone ACTH stimulates the growth of the adrenal cortex and the secretion of cortisol and other cortical hormones. An interesting aspect of the ACTH molecule is that it contains in part a sequence found in the melanocyte-stimulating hormones and lipotropic hormones (see below). In accordance with their chemical similarities, it is not surprising that all of these hormones exhibit both melanocyte-stimulating and lipolytic activities.

The melanocyte-stimulating hormones are also called intermedins, since they can be isolated from the intermediate lobe of the pituitary in those animals which have a distinct intermediate lobe. Melanocyte-stimulating activity refers to the ability of these hormones to cause dispersion of pigment granules in melanocytes, producing a darkening of the skin. Two types of MSHs have been isolated. α-MSH is the most potent melanocyte-stimulating hormone; β-MSH has about 50% of the activity of α-MSH, while ACTH and the LPHs have about 1%.

In 1965–1966, β-lipotropic hormone and γ-lipotropic hormone, were isolated from the pituitaries of sheep and chemically characterized. The term lipotropic refers to the lipolytic activity of these substances on adipose tissue. Subsequently, it was learned that they also possessed melanocyte-stimulating activity. Lipolytic activity refers to the ability of certain hormones to stimulate the breakdown of lipid in adipose tissue to free fatty acids and glycerol. As has been mentioned, ACTH and the MSHs are also lipolytic hormones, and are, in fact, of greater potency in this regard than the LPHs. *See* Animal growth; Lactation; Pituitary gland; Thyroid gland. [C.H.L.]

Adenosine diphosphate (ADP) A coenzyme and an important intermediate in cellular metabolism as the partially dephosphorylated form of adenosine triphosphate. The compound is 5′-adenylic acid with an additional phosphate group attached through a pyrophosphate bond. ADP is produced from adenosine triphosphate and reconverted to this compound in coupled reactions concerned with the energy metabolism of living systems. ADP is also produced from 5′-adenylic acid by the transfer of a phosphate group from adenosine triphosphate in a reaction that is catalyzed by an enzyme, myokinase. *See* Metabolism. [M.D.]

Adenosine triphosphate (ATP) A coenzyme and one of the most important compounds in the metabolism of all organisms, since it serves as a coupling agent between different enzymatic reactions. Adenosine triphosphate is adenosine diphosphate (ADP) with an additional phosphate group attached through a pyrophosphate linkage to the terminal phosphate group (see illustration). ATP is a powerful donor of phosphate groups to suitable acceptors because of the pyrophosphate nature of the bonds between its three phosphate radicals. For instance, in the phosphorylation of glucose, which is an essential reaction in carbohydrate metabolism, the enzyme hexokinase catalyzes the transfer of the terminal phosphate group.



Structure of adenylic acid and phosphate derivatives ADP and ATP.

ATP serves as the immediate source of energy for the mechanical work performed by muscle. In its presence, the muscle protein actomyosin contracts with the formation of adenosine diphosphate and inorganic phosphate. ATP is also involved in the activation of amino acids, a necessary step in the synthesis of protein. *See* Muscle.

In metabolism, ATP is generated from adenosine diphosphate and inorganic phosphate mainly as a consequence of energy-yielding oxidation-reduction reactions. In respiration, ATP is generated during the transport of electrons from the substrate to oxygen via the cytochrome system. In photosynthetic organisms, ATP is generated as a result of photochemical reactions. *See* Carbohydrate metabolism; Cytochrome.

By virtue of its energy-rich pyrophosphate bonds, ATP serves as a link between sources of energy available to a living system and the chemical and mechanical work which is associated with growth, reproduction, and maintenance of living substance. For this reason, it has been referred to as the storehouse of energy of living systems. Because ATP, ADP, and adenylic acid are constantly interconverted through participation in various metabolic processes, they act as coenzymes for the coupled reactions in which they function. *See* BIOCHEMISTRY; BIOLOGICAL OXIDATION; COENZYME; METABOLISM. [M.D.]

Adeno-SV40 hybrid virus A type of defective virus particle in which part of the genetic material of papovavirus SV40 is encased within an adenovirus protein coat (capsid). Adenovirus progeny possesses properties different from those of the original parent adenovirus. It produces tumors in newborn hamsters; it replicates in monkey cell cultures; and although it does not produce infectious SV40, it causes monkey cells in culture to produce a new cellular antigen known to be specifically induced by SV40—the SV40 tumor, or T, antigen. The new virus stock therefore behaves like a hybrid. It has proved to be a population of two distinct kinds of virus particles. One kind of particle is a true adenovirus. The other particle is the adeno-SV40 hybrid, which has an adenovirus coat, but whose genetic material appears to consist of defective adenovirus type 7 DNA, representing about 85% of the adenovirus genome, covalently linked to a portion (about 50%) of an SV40 genome.

In this virus population the particle carrying the SV40 genetic material has been termed PARA (particle aiding replication of adenovirus). The PARA is considered an unconditionally defective virus, since under no known conditions can it reproduce itself except in a cell coinfected with adenovirus. The adenovirus is considered conditionally defective, since it can reproduce independently in human cells but not in monkey cells. *See* ADENOVIRIDAE; ANIMAL VIRUS. [J.L.Me.]

Adenoviridae A family of viral agents associated with pharyngoconjunctival fever, acute respiratory disease, epidemic keratoconjunctivitis, and febrile pharyngitis in children. A number of types have been isolated from tonsils and adenoids removed from surgical patients. Although most of the illnesses caused by adenoviruses are respiratory, adenoviruses are frequently excreted in stools, and certain adenoviruses have been isolated from sewage. Distinct serotypes of mammalian and avian species are known. These genera contain 87 and 14 species, respectively. *See* ANIMAL VIRUS.

Infective virus particles, 70 nanometers in diameter, are icosahedrons with shells (capsids) composed of 252 subunits (capsomeres). No outer envelope is known. The genome is double-stranded deoxyribonucleic acid (DNA), with a molecular weight of $20–25 \times 10^6$. Three major soluble antigens are separable from the infectious particle by differential centrifugation. These antigens—a group-specifc antigen common to all adenovirus types, a type-specific antigen unique for each type, and a toxinlike material which also possesses group specificity—represent virus structural protein subunits that are produced in large excess of the amount utilized for synthesis of infectious virus.

The known types of adenoviruses of humans total at least 33, and previously unrecognized types continue to be isolated. The serotypes are antigenically distinct in neutralization tests, but they share a complement-fixing antigen, which is probably a smaller soluble portion of the virus.

The virus does not commonly produce acute disease in laboratory animals but is cytopathogenic, that is, destroys cells, in cultures of human tissue. Certain human adenovirus serotypes produce cancer when injected into newborn hamsters.

Base ratio determinations have revealed three distinct groups of adenoviruses: those with a low guanine plus cytosine (G + C) content (48–49%); those with an intermediate G + C content (50–53%); and those with a high G + C content (56–60%). The strongly oncogenic adenovirus types 12, 18, and 31 are the only members of the group with low G + C, and certain adenoviruses in the intermediate group (types 3, 7, 14, 16, and 21) are mildly oncogenic. The adenovirus mRNA observed in transformed and tumor cells has a G + C content of 50–52% in the DNA. This suggests that viral DNA regions containing 47–48% G + C are integrated into the tumor cells or that such regions are preferentially transcribed. However, the mRNA from tumor cells induced by one subgroup such as the highly oncogenic adenoviruses (types 12 and 18) do not hybridize with DNA from the other two subgroups. Apparently, different viralcoded information is involved in carcinogenesis by the three different groups of adenoviruses.

With simian adenovirus 7 (SA7), the intact genome, as well as the heavy and light halves of the viral DNA, is capable of inducing tumors when injected into newborn hamsters. Extensive studies have failed to demonstrate adenovirus DNA or viral-specific mRNA in human tumors.

Live virus vaccines against type 4 and type 7 have been developed and used extensively in military populations. When both are administered simultaneously, vaccine recipients respond with neutralizing antibodies against both virus types. *See* ADENO-SV40 HYBRID VIRUS; ANTIGEN; COMPLEMENT-FIXATION TEST; DEPENDOVIRUS; NEUTRALIZATION REACTION (IMMUNOLOGY); VIRUS CLASSIFICATION. [J.L.Me.; M.E.Re.]

Adhesive A material capable of fastening two other materials together by means of surface attachment. The terms glue, mucilage, mastic, and cement are synonymous with adhesive. In a generic sense, the word adhesive implies any material capable of fastening by surface attachment, and thus will include inorganic materials such as portland cement and solders. In a practical sense, however, adhesive implies the broad set of materials composed of organic compounds, mainly polymeric, which can be used to fasten two materials together. The materials being fastened together by the adhesive are the adherends, and an adhesive joint or adhesive bond is the resulting assembly. Adhesion is the physical attraction of the surface of one material for the surface of another.

The phenomenon of adhesion has been described by many theories. The most widely accepted and investigated is the wettability-adsorption theory. This theory states that for maximum adhesion the adhesive must come into intimate contact with the surface of the adherend. That is, the adhesive must completely wet the adherend. This wetting is considered to be maximized when the intermolecular forces are the same forces as are normally considered in intermolecular interactions such as the van der Waals, dipole-dipole, dipole-induced dipole, and electrostatic interactions. Of these, the van der Waals force is considered the most important. The formation of chemical bonds at the interface is not considered to be of primary importance for achieving maximum wetting, but in many cases it is considered important in achieving durable adhesive bonds. *See* ADSORPTION; CHEMICAL BONDING; INTERMOLECULAR FORCES.

The greatest growth in the development and use of organic compound-based adhesives came with the application of synthetically derived organic polymers. Broadly, these materials can be divided into two types: thermoplastics and thermosets. Thermoplastic adhesives become soft or liquid upon heating and are also soluble. Thermoset adhesives cure upon heating and then become solid and insoluble. Those adhesives which cure under ambient conditions by appropriate choice of chemistry are also considered thermosets. *See* POLYMER.

Pressure-sensitive adhesives are mostly thermoplastic in nature and exhibit an important property known as tack. That is, pressure-sensitive adhesives exhibit a measurable adhesive strength with only a mild applied pressure. Pressure-sensitive adhesives are derived from elastomeric materials, such as polybutadiene or polyisoprene.

Structural adhesives are, in general, thermosets and have the property of fastening adherends that are structural materials (such as metals and wood) for long periods of time even when the adhesive joint is under load. Phenolic-based structural adhesives were among the first structural adhesives to be developed and used. The most widely used structural adhesives are based upon epoxy resins. An important property for a structural adhesive is resistance to fracture (toughness). Thermoplastics, because they are not cured, can deform under load and exhibit resistance to fracture. As a class, thermosets are quite brittle, and thermoset adhesives are modified by elastomers to increase their resistance to fracture.

Hot-melt adhesives are used for the manufacture of corrugated paper, in packaging, in bookbinding, and in shoe manufacture. Pressure-sensitive adhesives are most widely used in the form of coatings on tapes, such as electrical tape and surgical tape. Structural adhesives are applied in the form of liquids, pastes, or 100% adhesive films. Epoxy liquids and pastes are very widely used adhesive materials, having application in many assembly operations ranging from general industrial to automotive to aerospace vehicle construction. Solid-film structural adhesives are used widely in aircraft construction. Acrylic adhesives are used in thread-locking operations and in small-assembly operations such as electronics manufacture which require rapid cure times. The largest-volume use of adhesives is in plywood and other timber products manufacture. Adhesives for wood bonding range from the natural products (such as blood or casein) to the very durable phenolic-based adhesives. *See* BOOK MANUFACTURE; MUCILAGE; PLYWOOD. [A.V.P.]

Adhesive bonding The process of using an adhesive to manufacture an assembly. The adhesive-bonded assembly is known as an adhesive joint, and the materials to which the adhesive adheres are known as the adherends.

Adhesive joints are designed by first knowing the loads that are to be supported by the joint. Adherends and adhesives are chosen according to the needs of the application, that is, the stiffness, toughness (fracture resistance), and elongation. Mechanical engineering principles are applied to ensure that the joint can support the necessary load. A properly designed adhesive joint will provide for adherend failure rather than adhesive failure unless the joint is designed to be reworked or reused. Usually, the design is subjected to a test protocol before going into production.

Adhesive joints are made by means of surface attachment; thus the condition of the adherend surface must be taken into account. This is particularly important when the adhesive joint is to be exposed to adverse environmental conditions such as temperature and humidity. In general, the purpose of a surface preparation is to remove weak boundary layers (such as oils and greases), increase the adherend surface energy, and provide a surface with enough mechanical roughness to "key" the adhesive into the surface of the adherend. In some cases, a primer is applied to the adherend before applying the adhesive.

For a proper adhesive joint, the adhesive must "wet" the adherend; that is, the adhesive must come into intimate contact with the adherend. As a guideline, the adhesive must have a liquid surface energy less than the critical wetting tension of the adherend. If the adherend's surface has been properly prepared or primed, this is usually achievable. Alternatively, the correct adhesive can be chosen such that this condition of intimate contact is achievable. *See* INTERFACE OF PHASES; SURFACE TENSION.

Joint assembly is an important consideration in adhesive bonding. In many cases, the adhesive has a "set time"; that is, the adhesive has little, or no strength until some solidification takes place. During the solidification process, the adherends must be kept in place.

Pressure-sensitive adhesives usually require no processing to solidify, as they are already viscoelastic solids; that is, they display both liquidlike and solidlike character. Adhesives such as rubber-based adhesives and contact bond adhesives require the evaporation of solvent or water to solidify. Other adhesives undergo a chemical reaction to solidify. For example, two-part epoxy adhesives must be properly mixed in order to effect the solidification or "cure" of the adhesive. Some adhesives require the application of heat to cure the adhesive. Other adhesives are cured by the action of light or some other actinic source of energy. Hot-melt adhesives are heated to and applied in the liquid state, and solidify upon cooling.

Adhesives are used in a wide range of applications, including electronics, automotive, aircraft, furniture construction, and plywood manufacture, to name some. Adhesives are also used in many noncritical applications such as paper binding, carton sealing (hot-melt adhesives), and envelope sealing. In medicine, adhesives are used as tissue sealants during surgeries and transdermal drug delivery systems. *See* ADHESIVE. [A.V.P.]

Adiabatic demagnetization The removal or diminution of a magnetic field applied to a magnetic substance when the latter has been thermally isolated from its surroundings. The process concerns paramagnetic substances almost exclusively, in which case a drop in temperature of the working substance is produced (magnetic cooling). *See* PARAMAGNETISM.

Nuclear magnetic moments are one or two thousand times smaller than their ionic (that is, electronic) counterparts, and the characteristic temperature of their mutual interaction lies in the microkelvin rather than millikelvin region. Successful experiments in nuclear adiabatic demagnetization date from the mid-1950s. *See* ABSOLUTE ZERO; CRYOGENICS; LOW-TEMPERATURE PHYSICS. [R.P.Hu.]

Adiabatic process A thermodynamic process in which the system undergoing the change exchanges no heat with its surroundings. An increase in entropy or degree of disorder occurs during an irreversible adiabatic process. However, reversible adiabatic processes are isentropic; that is, they take place with no change in entropy. In an adiabatic process, compression always results in warming, and expansion always results in cooling. *See* ENTROPY; ISENTROPIC PROCESS.

During an adiabatic process, temperature changes are due to internal system fluctuations. For example, the events inside an engine cylinder are nearly adiabatic because the wide fluctuations in temperature take place rapidly, compared to the speed with which the cylinder surfaces can conduct heat. Similarly, fluid flow through a nozzle may be so rapid that negligible exchange of heat between fluid and nozzle takes place. The compressions and rarefactions of a sound wave are rapid enough to be considered adiabatic. *See* NOZZLE; SOUND; THERMODYNAMIC PROCESSES. [P.E.Bl.]

Adipose tissue A type of connective tissue that is specialized for the storage of neutral fats (lipids). Adipose cells have names reflecting their gross physical appearance: white fat, which can be yellowish if the animal's diet is rich in carotenoids, and brown fat, containing vascularization and respiratory pigments.

White fat is the more common type of adipose cell. These cells are found in a wide variety of locations in the mammalian body, and their function varies from location to location. For example, they may act to store food reserves and to provide thermal and physical insulation. The number of white adipose cells and the amount of fat in a cell are regulated by various factors, including genetics, hormones, diet, innervation, and physical activity. Many animals, especially migratory and hibernating mammals, greatly increase their fat reserves in preparation for travel or for hibernation.

Brown adipose tissue is mainly found in subscapular, interscapular, and mediastinal areas. Brown adipose cells are associated with thermogenesis (heat production), mainly in hibernating and newborn mammals. *See* CONNECTIVE TISSUE; LIPID. [T.Ge.]

Admittance The ratio of the current to the voltage in an alternating-current circuit. In terms of complex current I and voltage V, the admittance of a circuit is given by Eq. (1), and is related to the impedance of the circuit Z by Eq. (2). Y is a complex number given by Eq. (3). G, the real part of the admittance,

$$Y = \frac{I}{V} \tag{1}$$

$$Y = \frac{1}{Z} \tag{2}$$

$$Y = G + jB \tag{3}$$

is the conductance of the circuit, and B, the imaginary part of the admittance, is the susceptance of the circuit. The units of admittance are called siemens or mhos (reciprocal ohms). *See* Conductance; Susceptance. [J.O.S.]

Adrenal gland A complex endocrine organ in proximity to the kidney. Adrenal gland tissue is present in all vertebrates. The adrenal consists of two functionally distinct tissues: steroidogenic cells and catecholamine-secreting cells. While "adrenal" refers to the gland's proximity to the kidney, significant variation exists among vertebrates in its anatomic location as well as the relationship of the two endocrine tissues which make up the gland. In mammals, steroidogenic cells are separated into distinct zones that together form a cortex. This cortical tissue surrounds the catecholamine-secreting cells, constituting the medulla. In most other vertebrates, this unique anatomic cortical-medullary relationship is not present. In species of amphibians and fish, adrenal cells are found intermingling with kidney tissue, and the steroidogenic cells are often termed interrenal tissue.

Development. The adrenal gland forms from two primordia: cells of mesodermal origin which give rise to the steroid-secreting cells, and neural cells of ectodermal origin which develop into the catecholamine-secreting tissue (also known as chromaffin tissue). In higher vertebrates, mesenchymal cells originating from the coelomic cavity near the genital ridge proliferate to form a cluster of cells destined to be the adrenal cortex. During the second month of human development, cells of the neural crest migrate to the region of the developing adrenal and begin to proliferate on its surface. The expanding cortical tissue encapsulates the neural cells forming the cortex and medulla. In mammals, three distinct zones form within the cortex: the outermost zona glomerulosa, the middle zona fasiculata, and the inner zona reticularis. The glomerulosa cells contain an enzyme, aldosterone synthase, which converts corticosterone to aldosterone, the principal steroid (mineralocorticoid) secreted from this zone. The inner zones (fasiculata and reticularis) primarily secrete glucocorticoids and large amounts of sex steroid precursors. In many lower vertebrates, the two tissues form from similar primordia but migrate and associate in different ways to the extent that in some cases the two tissues develop in isolation from each other.

Comparative anatomy. While the paired adrenals in mammals have a characteristic cortical-medullary arrangement with distinct zonation present in the cortex, such distinctions are lacking in nonmammalian species. In more primitive fishes, chromaffin cells form in isolation from steroidogenic tissue. A general trend is present, however, throughout vertebrates for a closer association of chromaffin and steroidogenic tissues. Zonation in steroidogenic tissue is largely confined to mammals, although suggestions of separate cell types have been postulated in birds and in some other species.

Comparative endocrinology. Hormones are secreted from the cells of both the medulla and the cortex.

Chromaffin cells. In all vertebrates, chromaffin cells secrete catecholamines into circulation. In most species, the major catecholamine secreted is epinephrine, although significant amounts of norepinephrine are released by many animals. Some dopamine is also secreted. No phylogenetic trend is obvious to explain or predict the ratio of epinephrine to norepinephrine secreted in a given species. A given species may release the two catecholamines in different ratios, depending on the nature of the stimulus. The great majority of the norepinephrine in circulation actually originates from that which is released from non-adrenal sympathetic nerve endings and leaks into the bloodstream. In addition to catecholamines, chromaffin cells secrete an array of other substances, including proteins such as chromogranin A and opioid peptides. *See also* Epinephrine.

Biologic effects of catecholamines are mediated through their binding to two receptor classes, α- and β-adrenergic receptors. Further examination of these receptors has revealed that subclasses of each type exist and likely account for the responses on different target tissues. In general, biologic responses to catecholamines include mobilization of glucose from liver and muscle, increased alertness, increased heart rate, and stimulation of metabolic rate.

Steroid hormones. In broad terms, most steroids secreted by adrenal steroidogenic cells are glucocorticoids, mineralocorticoids, or sex hormone precursors. However, these classes have been established largely on the basis of differential actions in mammals. The principal glucocorticoids are cortisol and corticosterone, while the main mineralocorticoid is aldosterone. This division of action holds for mammalian species and likely for reptiles and birds. In other vertebrates, such as fish and amphibians, steroids from the interrenal tissue do not show such specialized actions; instead, most show activities of both glucocorticoid and mineralocorticoid type. Mammals, birds, reptiles, and amphibians secrete cortisol, corticosterone, and aldosterone. The ratios of the two glucocorticoids vary across species; in general, corticosterone is the more important product in nonmammalian species. Even within mammals, a large variation exists across species, due to the relative ratio of cortisol to corticosterone from the adrenal cortex.

Effects of adrenal-derived steroids in lower vertebrates involve a diverse array of actions, including control of distribution and availability of metabolic fuels such as glucose, and regulation of sodium and extracellular fluid volume. In nonmammalian vertebrates, corticosterone, cortisol, and aldosterone possess mineralocorticoid effects. Other areas where adrenal steroids likely contribute to biologic processes include control of protein, fat, and carbohydrate balance; reproduction; and growth and development. *See* Steroid. [R.J.K.]

Adrenal gland disorders Malfunctions of the paired adrenal glands. The adrenal glands each consist of two morphologically and functionally distinct components, the cortex and medulla. These secrete different types of hormones: the cortex secretes steroids and the medulla secretes amines. The cortex is controlled by hormones from the anterior pituitary and the kidney; the medulla is directly controlled by the nervous system. Although the cortex and medulla are functionally separate, they both contribute to the mammalian body's response to outside stimuli, especially stress. *See* Pituitary gland; Steroid.

The adrenal glands can have congenital defects and can be damaged by infections and destructive tumors. Anencephaly, that is, gross underdevelopment of the brain in fetal life, leads to hypoplasia of the adrenal cortex. The cortex is also, although rarely, invaded by acute bacterial diseases, for example, septicemia due to the colon bacillus or meningococcus, which can result in failure of the adrenal cortex followed by shock and death (Waterhouse-Friderichsen syndrome). Chronic infection of the cortex by the tubercle bacillus or a fungal infection such as histoplasmosis can cause primary adrenal deficiency. Cancer may spread to the adrenal glands, and there are uncommon primary tumors of the adrenal that do not secrete hormones. The most important disorders of the adrenal cortex and medulla are those characterized by abnormal hormone secretion.

Adrenal cortex. There are a number of disorders of the adrenal cortex. Primary adrenal cortical insufficiency, or Addison's disease, is rare, but if it is not treated it always results in death. The disease is usually caused by autoimmune destruction of the adrenals, by tuberculosis, or less often by chronic fungal diseases. Symptoms include lassitude, muscular weakness, weight loss, prostration during minor illnesses, low blood pressure, and brown pigmentation of the skin. The water and electrolyte loss associated with this condition results from deficiency of the adrenal hormone, aldosterone. Maintenance therapy with small daily doses of hydrocortisone and synthetic, salt-retaining steroids permits a normal life. *See* ALDOSTERONE; TUBERCULOSIS.

Secondary adrenal cortical insufficiency sometimes accompanies pituitary failure due to tumors, vascular accidents, chronic infectious diseases, or granulomas. The clinical picture differs from Addison's disease: weak, listless, and intolerant of minor illness, individuals also are pale and usually show neurologic signs related to the pituitary lesion. Treatment consists of cortisol, thyroid hormone, and sex steroids. A more common form of secondary adrenal failure follows long-term administration of high doses of semisynthetic steroids for treatment of such diseases as rheumatoid arthritis, asthma, and acute lymphoblastic leukemia. *See* THYROID GLAND.

Manifestations of adrenal cortical hyperfunction, or hyperadrenocorticism, can result from excessive secretion of steroid hormones normally secreted by the adrenal cortex. The four classes of adrenal cortical hormones include mineralocorticoids, such as aldosterone, which regulate salt retention; glucocorticoids, such as cortisol, that affect carbohydrate and protein metabolism, muscle function, and blood pressure; androgens, such as dehydroepiandrosterone; and estrogens, such as estradiol. *See* ANDROGEN; ESTROGEN.

Excess secretion of aldosterone produces hyperaldosteronism. The classic primary form arises from a small unilateral tumor known as an adenoma of the adrenal cortex, from bilateral nodular overgrowth of the cortex, or sometimes from overfunction of the kidney's renin-angiotensin system which stimulates the cortex to secrete too much aldosterone (Bartter's syndrome). The affected individuals have high blood pressure, muscle weakness, and decreased levels of potassium in the blood. The tumors can be removed surgically. In cases where there is no tumor, the individual can be treated with diuretics that act by physiologically opposing the action of aldosterone on the kidney. Secondary hyperaldosteronism occurs in very severe hypertension and in advanced liver disease (cirrhosis), kidney disease (nephrotic syndrome), and heart failure when the body retains excess salt and water with swelling.

Excessive secretion of cortisol produces hypercortisolism, or Cushing's syndrome. Clinical manifestations include obesity of the trunk with thin arms and legs, round red face, thin skin, brittle bones, high blood pressure, diabetes mellitus, and, in women, virilism (masculinity). If not treated, Cushing's syndrome is fatal within five years because of complications of hypertension or infections. The most common cause of Cushing's syndrome is overactivity of the pituitary gland, often due to a small tumor that secretes excess adrenocorticotropic hormone. The disease is difficult to treat; methods include surgical removal of the pituitary tumor, x-ray or proton-beam treatment of the pituitary region, chemotherapy, or surgical removal of both adrenals. If the excess cortisol secretion is controlled, the individual can lead a normal life, although sometimes requiring hormone replacement. *See* CANCER (MEDICINE).

Adrenal medulla. There is no recognized hormone deficiency of the adrenal medulla in humans. Excess secretion of norepinephrine and epinephrine accompanies pheochromocytoma, a rare adrenal medullary tumor that may be single or multiple, benign or malignant. Sometimes the tumor occurs in multiple endocrine adenomatosis, type II (Sipple's syndrome), characterized clinically by pheochromocytoma, tumors of the parathyroid glands with high blood calcium, and carcinoma of the thyroid. Treatment is difficult, and consists of careful surgical removal of the tumor. Neuroblastoma (in children), ganglioneuroblastoma, and ganglioneuroma are malignant tumors of the adrenal medulla or sympathetic ganglia; they may secrete amines that have only a minor effect on blood pressure. The clinical importance of these tumors arises from their extreme malignancy, but some are known to regress spontaneously. *See* ENDOCRINE MECHANISMS; EPINEPHRINE. [N.P.C.]

Adsorption A process in which atoms or molecules move from a bulk phase (that is, solid, liquid, or gas) onto a solid or liquid surface. An example is purification by adsorption where impurities are filtered from liquids or gases by their adsorption onto the surface of a high-surface-area solid such as activated charcoal. Other examples include the segregation of surfactant molecules to the surface of a liquid, the bonding of reactant molecules to the solid surface of a heterogeneous catalyst, and the migration of ions to the surface of a charged electrode.

Adsorption is to be distinguished from absorption, a process in which atoms or molecules move into the bulk of a porous material, such as the absorption of water by a sponge. Sorption is a more general term that includes both adsorption and absorption. Desorption refers to the reverse of adsorption, and is a process in which molecules adsorbed on a surface are transferred back into a bulk phase. The term adsorption is most often used in the context of solid surfaces in contact with liquids and gases. Molecules that have been adsorbed onto solid surfaces are referred to generically as adsorbates, and the surface to which they are adsorbed as the substrate or adsorbent. *See* ABSORPTION.

At the molecular level, adsorption is due to attractive interactions between a surface and the species being adsorbed. The magnitude of these interactions covers approximately two orders of magnitude (8–800 kilojoules/mole), similar to the range of interactions found between atoms and molecules in bulk phases. Traditionally, adsorption is classified according to the magnitude of the adsorption forces. Weak interactions (<40 kJ/mol) analogous to those between molecules in liquids give rise to what is called physical adsorption or physisorption. Strong interactions (>40 kJ/mol) similar to those found between atoms within a molecule (for example, covalent bonds) give rise to chemical adsorption or chemisorption. In physisorption the adsorbed molecule remains intact, but in chemisorption the molecule can be broken into fragments on the surface, in which case the process is called dissociative chemisorption.

The extent of adsorption depends on physical parameters such as temperature, pressure, and concentration in the bulk phase, and the surface area of the adsorbent, as well as on chemical parameters such as the elemental nature of the adsorbate and the adsorbent. Low temperatures, high pressures, high surface areas, and highly reactive adsorbates or adsorbents generally favor adsorption.

Adsorption is directly applied in processes such as filtration and detergent action.

Adsorption also plays an important role in processes such as heterogeneous catalysis, electrochemistry, adhesion, lubrication, and molecular recognition. In heterogeneous catalysis, gas or solution-phase molecules adsorb onto the catalyst surface, and reactions in the adsorbed monolayer lead to products which are desorbed from the surface. In electrochemistry, molecules adsorbed to the surface of an electrode donate or accept electrons from the electrode as part of oxidation or reduction reactions. In adhesion and lubrication, the chemical and mechanical properties of adsorbed monolayers play a role in determining how solid surfaces behave when in contact with one another. In biological systems, the adsorption of atoms and molecules onto the surface of a cell membrane is the first step in molecular recognition. *See* ELECTROCHEMISTRY; MOLECULAR RECOGNITION. [B.E.Be.]

Adsorption operations Processes for separation of gases based on the adsorption effect. When a pure gas or a gas mixture is contacted with a solid surface, some of the gas molecules are concentrated at the surface due to gas-solid attractive forces, in a phenomenon known as adsorption. The gas is called the adsorbate and the solid is called the adsorbent.

Adsorption can be either physical or chemical. Physisorption resembles the condensation of gases to liquids, and it may be mono- or multilayered on the surface. Chemisorption is characterized by the formation of a chemical bond between the adsorbate and the adsorbent.

If one component of a gas mixture is strongly adsorbed relative to the others, a surface phase rich in the strongly adsorbed species is created. This effect forms the basis of separation of gas mixtures by gas adsorption operations. Gas adsorption has become a fast-growing unit operation for the chemical and petrochemical industries, and it is being applied to solve many different kinds of gas separation and purification problems of practical importance. *See* Adsorption; Unit operations.

Most separations and purifications of gas mixtures are done in packed columns (that is, columns filled with solid adsorbent particles). Desorption of adsorbates from a column is usually accomplished by heating the column with a hot, weakly adsorbed gas; lowering the column pressure; purging the column with a weakly adsorbed gas; or combinations of these methods.

Microporous adsorbents like zeolites, activated carbons, silica gels, and aluminas are commonly employed in industrial gas separations. These solids exhibit a wide spectrum of pore structures, surface polarity, and chemistry which makes them specifically selective for separation of many different gas mixtures. Separation is normally based on the equilibrium selectivity. However, zeolites and carbon molecular sieves can also separate gases based on molecular shape and size factors which influence the rate of adsorption. *See* Molecular sieve; Zeolite.

The most frequent industrial applications of gas adsorption have been the drying of gases, solvent vapor recovery, and removal of impurities or pollutants. The adsorbates in these cases are present in dilute quantities. These separations use a thermal-swing adsorption process whereby the adsorption is carried out at a near-ambient temperature followed by thermal regeneration using a portion of the cleaned gas or steam. The adsorbent is then cooled and reused.

Pressure-swing adsorption processes are used for separating bulk gas mixtures. The adsorption is carried out at an elevated pressure level to give a product stream enriched in the more weakly adsorbed component. After the column is saturated with the strongly adsorbed component, it is regenerated by depressurization and purging with a portion of the product gas. The cycle is repeated after raising the pressure to the adsorption level. Key examples of pressure-swing adsorption processes are the production of enriched oxygen and nitrogen from air; production of ultrapure hydrogen from various hydrogen-containing streams such as steam-methane reformer off-gas; and separation of normal from branched-chain paraffins. Both thermal-swing and pressure-swing adsorption processes use multiple adsorbent columns to maintain continuity, so that when one column is undergoing adsorption the others are in various stages of regeneration modes. The thermal-swing adsorption processes typi- cally use long cycle times (hours) in contrast to the rapid cycle times (minutes) for pressure-swing adsorption processes. [A.L.M.; S.Sir.]

Aerial photograph

A photograph of a portion of the Earth's surface taken from an aircraft or from a satellite. Most often, photographs are taken sequentially and overlap each other, to give complete coverage of the area of interest. Thus they may be viewed stereoscopically to give a three-dimensional view of the Earth's surface. Although the camera in the aircraft may be pointed obliquely to the side of the line of flight, the most common type of aerial photograph is taken with the camera pointed vertically downward beneath the plane.

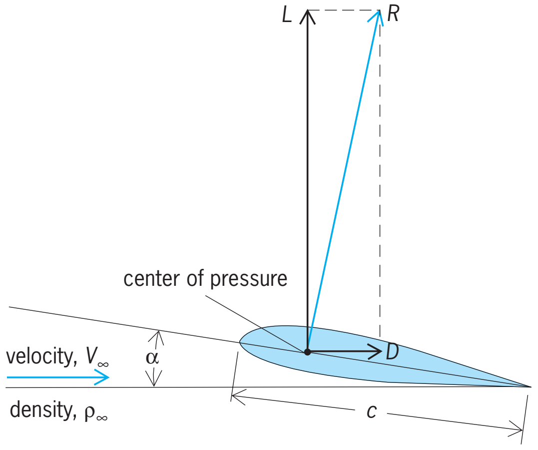
Aerial photographs have two main uses, the making of planimetric and topographic maps, and interpretation or data-gathering in a variety of specialized fields. All modern topographic (contour) maps are made from stereoscopic aerial photographs, usually black-and-white panchromatic vertical photographs. The science of making accurate measurements and maps from aerial photographs is called photogrammetry. The geometric discrepancy between the distribution of features seen on the photograph and their actual distribution on the Earth's surface depends on several variables, the most important of which is the relief of the surface. The error becomes greater as relief increases. Photogrammetry deals with these errors and allows highly accurate and complete map production. Topographic maps are made from one or more stereoscopic pairs of aerial photographs by means of optical-mechanical plotting machines or mathematical methods (analytical photogrammetry). *See* Cartography; Geophysical exploration; Topographic surveying and mapping.

The other major use of aerial photographs is photo interpretation, utilizing all types of film. Photo interpretation is the attempt to extract information about the Earth's surface (and sometimes, subsurface) from aerial photographs. The systematic study of aerial photographs, particularly when they are viewed stereoscopically, gives specialists the ability to gather rapidly, record, map, and interpret a great deal of information. In addition, an aerial photograph is a record at a moment in time; photographs taken at intervals give an excellent record of the change with time in surface features of the Earth. [L.H.L.]

Aerodynamic force

The force exerted on a body whenever there is a relative velocity between the body and the air. There are only two basic sources of aerodynamic force: the pressure distribution and the frictional shear stress distribution exerted by the airflow on the body surface. The pressure exerted by the air at a point on the surface acts perpendicular to the surface at that point; and the shear stress, which is due to the frictional action of the air rubbing against the surface, acts tangentially to the surface at that point. The distribution of pressure and shear stress represent a distributed load over the surface. The net aerodynamic force on the body is due to the net imbalance between these distributed loads as they are summed (integrated) over the entire surface. *See* Boundary-layer flow; Fluid flow; Wind stress.

For purposes of discussion, it is convenient to consider the aerodynamic force on an airfoil (see illustration). The net resultant aerodynamic force R acting through the center of pressure on the airfoil represents mechanically the same effect as that due to the actual pressure and shear stress loads distributed over the body surface. The velocity of the airflow V_∞ is called the free-stream velocity or the free-stream relative wind. By definition, the component of R perpendicular to the relative wind is the lift, L, and the component of R parallel to the relative wind is the drag D. The orientation of the body with respect to the direction of the free stream is given by the angle of attack, α. The magnitude



Resultant aerodynamic force (*R*), and its resolution into lift (*L*) and drag (*D*) components.

of the aerodynamic force R is governed by the density ρ_∞ and velocity of the free stream, the size of the body, and the angle of attack. *See* AIRFOIL.

An important measure of aerodynamic efficiency is the ratio of lift to drag, L/D. The higher the value of L/D, the more efficient is the lifting action of the body. The value of L/D reaches a maximum, denoted by $(L/D)_{\max}$, at a relatively low angle of attack. Beyond a certain angle the lift decreases with increasing α. In this region, the wing is said to be stalled. In the stall region the flow has separated from the top surface of the wing, creating a type of slowly recirculating dead-air region, which decreases the lift and substantially increases the drag. *See* FLIGHT CHARACTERISTICS. [J.D.A.]

Aerodynamic sound Sound that is generated by the unsteady motion of a gas and its interaction with surrounding surfaces. Aerodynamic sound or noise may be pleasant, such as the sound generated by a flute, or unpleasant, such as the noise of an aircraft on landing or takeoff, or the impulsive noise of a helicopter in descending or forward flight.

Sources of aerodynamic sound may be classified according to their multipole order. Sources associated with unsteady mass addition to the gas are called monopoles. These could be caused by the unsteady mass flux in a jet exhaust or the pulsation of a body. The sound power radiated by monopoles scales with the fourth power of a characteristic source velocity. Sources related to unsteady forces acting on the gas are called dipoles. The singing in telephone wires is related to the nearly periodic lift variations caused by vortex shedding from the wires. Such sources, called dipoles, generate a sound power that scales with the sixth power of the characteristic source velocity. *See* KARMAN VORTEX STREET.

A turbulent fluid undergoes local compression and extension as well as shearing. These events are nearly random on the smallest scales of turbulent motion but may have more organization at the largest scales. The earliest theories of aerodynamic noise, called acoustic analogies, related these unsteady stresses in the fluid to the noise that they would generate in a uniform ambient medium with a constant speed of sound. Such sources are called quadrupoles. The sound power that they radiate scales with the eighth power of the characteristic source velocity. *See* TURBULENT FLOW.

Subsequent extensions of these theories allowed for the motion of these sources relative to a listener. This may result in a Doppler shift in frequency and a convective amplification of the sound if the sources are moving toward the listener. In addition, if the sources are embedded in a sheared flow, such as the exhaust plume of a jet engine, the sound is refracted away from the jet downstream axis. As sound propagates away from the source region, it experiences attenuation due to spherical spreading and real-gas and relaxational effects. The latter effects are usually important only for high-amplitude sound or sound propagation over large distances. *See* ATMOSPHERIC ACOUSTICS; DOPPLER EFFECT; SOUND ABSORPTION. [P.J.M.]

Aerodynamic wave drag The force retarding an airplane, especially in supersonic flight, as a consequence of the formation of shock waves. Although the physical laws governing flight at speeds in excess of the speed of sound are the same as those for subsonic flight, the nature of the flow about an airplane and, as a consequence, the various aerodynamic forces and moments acting on the vehicle at these higher speeds differ substantially from those at subsonic speeds. Basically, these variations result from the fact that at supersonic speeds the airplane moves faster than the disturbances of the air produced by the passage of the airplane. These disturbances are propagated at roughly the speed of sound and, as a result, primarily influence only a region behind the vehicle.

The primary effect of the change in the nature of the flow at supersonic speeds is a marked increase in the drag, resulting from the formation of shock waves about the configuration. These strong disturbances, which may extend for many miles from the airplane, cause significant energy losses in the air, the energy being drawn from the airplane. At supersonic flight speeds these waves are swept back obliquely, the angle of obliqueness decreasing with speed. For the major parts of the shock waves from a well-designed airplane, the angle of obliqueness is equal to $\sin^{-1}(1/M)$, where M is the Mach number, the ratio of the flight velocity to the speed of sound. *See* SHOCK WAVE; SUPERSONIC FLIGHT.

The shock waves are associated with outward diversions of the airflow by the various elements of the airplane. This diversion is caused by the leading and trailing edges of the wing and control surfaces, the nose and aft end of the fuselage, and other parts of the vehicle. Major proportions of these effects also result from the wing incidence required to provide lift.

For a well-designed vehicle, wave drag is usually roughly equal to the sum of the basic skin friction and the induced drag due to lift. *See* AERODYNAMIC FORCE; AIRFOIL; TRANSONIC FLIGHT.

The wave drag at the zero lift condition is reduced primarily by decreasing the thickness-chord ratios for the wings and control surfaces and by increasing the length-diameter ratios for the fuselage and bodies. Also, the leading edge of the wing and the nose of the fuselage are made relatively sharp. With such changes, the severity of the diversions of the flow by these elements is reduced, with a resulting reduction of the strength of the associated shock waves. Also, the supersonic drag wave can be reduced by shaping the fuselage and arranging the components on the basis of the area rule. *See* WING; WING STRUCTURE.

The wave drag can also be reduced by sweeping the wing panels. Some wings intended for supersonic flight have large amounts of leading-edge sweep and little or no trailing-edge sweep. The shape changes required are now determined using very complex fluid-dynamic relationships and supercomputers. *See* COMPUTATIONAL FLUID DYNAMICS. [R.T.Wh.]

Aerodynamics The applied science that deals with the dynamics of airflow and the resulting interactions between this airflow and solid boundaries. The solid boundaries may be a body immersed in the airflow, or a duct of some shape through which the air is flowing. Although, strictly speaking, aerodynamics is concerned with the flow of air, in modern times the term has been liberally interpreted as dealing with the flow of gases in general.

Depending on its practical objectives, aerodynamics can be subdivided into external and internal aerodynamics. External aerodynamics is concerned with the forces and moments on, and heat transfer to, bodies moving through a fluid (usually air). Examples are the generation of lift, drag, and moments on airfoils, wings, fuselages, engine nacelles, and whole airplane configurations; wind forces on buildings; the lift and drag on automobiles; and the aerodynamic heating of high-speed aerospace vehicles such as the space shuttle. Internal aerodynamics involves the study of flows moving internally through ducts. Examples are the flow properties inside wind tunnels, jet engines, rocket engines, and pipes. In short, aerodynamics is concerned with the detailed physical properties of a flow field and also with the net effect of these properties in generating an aerodynamic force on a body immersed in the flow, as well as heat transfer to the body. *See* AERODYNAMIC FORCE; AEROTHERMODYNAMICS.

Aerodynamics can also be subdivided into various categories depending on the dominant physical aspects of a given flow. In low-density flow the characteristic size of the flow field, or a body immersed in the flow, is of the order of a molecular mean free path (the average distance that a molecule moves between collisions with neighboring molecules); while in continuum flow the characteristic size is much greater than the molecular mean free path. More than 99% of all practical aerodynamic flow problems fall within the continuum category. *See* RAREFIED GAS FLOW.

Continuum flow can be subdivided into viscous flow, which is dominated by the dissipative effects of viscosity (friction), thermal conduction, and mass diffusion; and inviscid flow, which is, by definition, a flow in which these dissipative effects are negligible. Both viscous and inviscid flows can be subdivided into incompressible flow, in which the density is constant, and compressible flow, in which the density is a variable. In low-speed gas flow, the density variation is small and can be ignored. In contrast, in a high-speed flow the density variation is keyed to temperature and pressure variations, which can be large, so the flow must be treated as compressible. *See* COMPRESSIBLE FLOW; FLUID FLOW; INCOMPRESSIBLE FLOW; VISCOSITY.

In turn, compressible flow is subdivided into four speed regimes: subsonic flow, transonic flow, supersonic flow, and hypersonic flow. These regimes are distinguished by the value of the Mach number, which is the ratio of the local flow velocity to the local speed of sound.

A flow is subsonic if the Mach number is less than 1 at every point. Subsonic flows are characterized by smooth streamlines with no discontinuity in slope. The flow over light, general-aviation airplanes is subsonic. *See* SUBSONIC FLIGHT.

A transonic flow is a mixed region of locally subsonic and supersonic flow. The flow far upstream of the airfoil can be subsonic, but as the flow moves around the airfoil surface it speeds up, and there can be pockets of locally supersonic flow over both the top and bottom surfaces of the airfoil. *See* TRANSONIC FLIGHT.

In a supersonic flow, the local Mach number is greater than 1 everywhere in the flow. Supersonic flows are frequently characterized by the presence of shock waves. Across shock waves, the flow properties and the directions of streamlines change discontinuously, in contrast to the smooth, continuous variations in subsonic flow. *See* SUPERSONIC FLIGHT.

Hypersonic flow is a regime of very high supersonic speeds. A conventional rule is that any flow with a Mach number equal to or greater than 5 is hypersonic. Examples include the space shuttle during ascent and reentry into the atmosphere, and the flight of the X-15 experimental vehicle. The kinetic energy of many hypersonic flows is so high that, in regions where the flow velocity decreases, kinetic energy is traded for internal energy of the gas, creating high temperatures. Aerodynamic heating is a particularly severe problem for bodies immersed in a hypersonic flow. *See* ATMOSPHERIC ENTRY; HYPERSONIC FLIGHT. [J.D.A.]

Aeroelasticity The branch of applied mechanics which deals with the interaction of aerodynamic, inertial, and structural forces. It is important in the design of airplanes, helicopters, missiles, suspension bridges, power lines, tall chimneys, and even stop signs. Variations on the term aeroelasticity have been coined to denote additional significant interactions. Aerothermoelasticity is concerned with effects of aerodynamic heating on aeroelastic behavior in high-speed flight. Aeroservoelasticity deals with the interaction of automatic controls and aeroelastic response and stability. In the field of hydroelasticity, a liquid rather than air generates the fluid forces.

The primary concerns of aeroelasticity include flying qualities (that is, stability and control), flutter, and structural loads arising from maneuvers and atmospheric turbulence. Methods of aeroelastic analysis differ according to the time dependence of the inertial and aerodynamic forces that are involved. For the analysis of flying qualities and maneuvering loads wherein the aerodynamic loads vary relatively slowly, quasi-static methods are applicable, although autopilot interaction could require more general methods. The remaining problems are dynamic, and methods of analysis differ according to whether the time dependence is arbitrary (that is, transient or random) or simply oscillatory in the steady state.

The redistribution of airloads caused by structural deformation will change the lifting effectiveness on the aerodynamic surfaces from that of a rigid vehicle. The simultaneous analysis of the equilibrium and compatibility among the external airloads, the internal structural and inertial loads, and the total flow disturbance, including the disturbance resulting from structural deformation, leads to a determination of the equilibrium aeroelastic state. If the airloads tend to increase the total flow disturbance, the lift effectiveness is increased; if the airloads decrease the total flow disturbance, the effectiveness decreases.

The airloads induced by means of a control-surface deflection also induce an aeroelastic loading of the entire system. Equilibrium is determined as in the analysis of load redistribution. Again, the effectiveness will differ from that of a rigid system, and may increase or decrease depending on the relationship between the net external loading and the deformation.

A self-excited vibration is possible if a disturbance to an aeroelastic system gives rise to unsteady aerodynamic loads such that the ensuing motion can be sustained. At the flutter speed a critical phasing between the motion and the loading permits extraction of an amount of energy from the airstream equal to that dissipated by internal damping during each cycle and thereby sustains a neutrally stable periodic motion. At lower speeds any disturbance will be damped, while at higher speeds, or at least in a range of higher speeds, disturbances will be amplified.

Transient meteorological conditions such as wind shears, vertical drafts, mountain waves, and clear air or storm turbulence impose significant dynamic loads on aircraft. So does buffeting during flight at high angles of attack or at transonic speeds. The response of the aircraft determines the stresses in the structure and the comfort of the occupants. Aeroelastic behavior makes a condition of dynamic overstress possible; in many instances, the amplified stresses can be substantially higher than those that would occur if the structure were much stiffer. *See* CLEAR-AIR TURBULENCE (CAT); LOADS; DYNAMIC; TRANSONIC FLIGHT. [W.P.R.]

Aeromonas A bacterial genus in the family Vibrionaceae comprising oxidase-positive, facultatively anaerobic, monotrichously flagellated gram-negative rods. The mesophilic species are *A. hydrophila, A. caviae*, and *A. sobria*; the psychrophilic one is *A. salmonicida*. Aeromonads are of aquatic origin and are found in surface and waste water but not in seawater. They infect chiefly cold-blooded animals such as fishes, reptiles, and amphibians and only occasionally warm-blooded animals and humans. Human wound infections may occur following contact with contaminated water. Septicemia has been observed mostly in patients with abnormally low white blood counts or liver disease. There is evidence of intestinal carriers. The three mesophilic species are also associated with diarrheal disease (enteritis and colitis) worldwide. *See* DIARRHEA.

A related lophotrichous genus, *Plesiomonas* (single species, *P. shigelloides*), is also known as an aquatic bacterium and is associated with diarrhea chiefly in subtropical and tropical areas. It is also found in many warm-blooded animals. Systemic disease in humans is rare. *See* MEDICAL BACTERIOLOGY. [A.W.C.V.G.]

Aeronautical engineering That branch of engineering concerned primarily with the special problems of flight and other modes of transportation involving a heavy reliance on aerodynamics or fluid mechanics. The main emphasis is on airplane and missile flight, but aeronautical engineers work in many related fields such as hydrofoils, which have many problems in common with aircraft wings, and with such devices as air-cushion vehicles, which make use of airflow around the base to lift the vehicle a few feet off the ground, whereupon it is propelled forward by use of propellers or gas turbines. *See* AERODYNAMICS; AIR-CUSHION VEHICLE; AIRPLANE; FLUID MECHANICS; HYDROFOIL CRAFT; MISSILE.

Aeronautical engineering expanded dramatically after 1940. Flight speeds increased from a few hundred miles per hour to satellite and space-vehicle velocities. The common means of propulsion changed from propellers to turboprops, turbojets, ramjets, and rockets. This change gave rise to new applications of basic science to the field and a higher reliance on theory and high-speed computers in design and testing, since it was often not feasible to proceed by experimental methods only. *See* JET PROPULSION; PROPULSION; ROCKET PROPULSION; SPACE TECHNOLOGY.

Aeronautical engineers frequently serve as system integrators of important parts of a design. For example, the control system of an aircraft involves, among other considerations, aerodynamic input from flow calculations and wind-tunnel tests; the structural design of the aircraft (since the flexibility and strength of the structure must be allowed for); the mechanical design of the control system itself; electrical components, such as servomechanisms; hydraulic components, such as hydraulic boosters; and interactions with other systems that affect the control of the aircraft, such as the propulsion system. The aeronautical engineer is responsible for ensuring that all of these factors operate smoothly together.

Aircraft and missile structural engineers have raised the technique of designing complex structures to a level never considered possible before the advent of high-speed computers. Structures can now be analyzed in great detail and the results incorporated directly into computer-aided design (CAD) programs. *See* COMPUTER-AIDED DESIGN AND MANUFACTURING. [J.R.Se.]

Aeronautical meteorology The branch of meteorology that deals with atmospheric effects on the operation of vehicles in the atmosphere, including winged aircraft, lighter-than-air devices such as dirigibles, rockets, missiles, and projectiles. The air which supports flight or is traversed on the way to outer space contains many potential hazards.

Poor visibility caused by fog, snow, dust, and rain is a major cause of aircraft accidents and the principal cause of flight cancellations or delays.

The weather conditions of ceiling and visibility required by regulations for crewed aircraft during landing or takeoff are determined by electronic and visual aids operated by the airport and installed in the aircraft. The accurate forecasting of terminal conditions is critical to flight economy, and to safety where sophisticated landing aids are not available. Improved prediction methods are under continuing investigation and development, and are based on mesoscale and microscale meteorological analyses, electronic computer calculations, radar observations of precipitation areas, and observations of fog trends. *See* MESOMETEOROLOGY; MICROMETEOROLOGY.

Atmospheric turbulence is principally represented in vertical currents and their departures from steady, horizontal airflow. When encountered by an aircraft, turbulence produces abrupt excursions in aircraft position, sometimes resulting in discomfort or injury to passengers, and sometimes even structural damage or failure. Major origins of turbulence are (1) mechanical, caused by irregular terrain below the flow of air; (2) thermal, associated with vertical currents produced by heating of air in contact with the Earth's surface; (3) thunderstorms and other convective clouds (Fig. 1); (4) mountain wave, a regime of disturbed airflow leeward of mountains or hills, often comprising both smooth and breaking waves formed when stable air is forced to ascend over the mountains; and (5) wind shear, usually variations of horizontal wind in the vertical direction, occurring along air-mass boundaries, temperature inversions (including the tropopause), and in and near the jet stream.

While encounters with strong turbulence anywhere in the atmosphere represent substantial inconvenience, encounters with rapid changes in wind speed and direction at low altitude can be catastrophic. Generally, wind shear is most dangerous when encountered below 1000 ft (300 m) above the ground, where it is identified as low-altitude wind shear. Intense convective microbursts, downdrafts usually associated with thunderstorms, have caused many aircraft accidents often resulting in a great loss of life. The downdraft emanating from convective clouds, when nearing the Earth's surface, spreads horizontally as outrushing rain-cooled air. When entering a microburst outflow, an aircraft first meets a headwind that produces increased performance by way of increased airspeed over the wings. Then within about 5 s, the aircraft encounters a downdraft and then a tailwind with decreased performance. A large proportion of microburst accidents, both after takeoff and on approach to landing, are caused by this performance decrease, which can result in rapid descent. *See* THUNDERSTORM.

Turbulence and low-altitude wind shear can readily be detected by a special type of weather radar, termed Doppler radar. By measuring the phase shift of radiation backscattered by hydrometeors and other targets in the atmosphere, both turbulence and wind shear can be clearly identified. It is anticipated that Doppler radars located at airports, combined with more thorough pilot training regarding the need to avoid microburst wind shear, will provide desired protection from this dangerous aviation weather phenomenon. *See* DOPPLER RADAR.

Since an aircraft's speed is given by a propulsive component plus the speed of the air current bearing the aircraft, there are aiding or retarding effects depending on wind direction in relation to the track flown. Wind direction and speed vary only moderately from day to day and from winter to summer in certain parts of the world, but fluctuations of the vector wind at middle and high latitudes in the troposphere and lower stratosphere can exceed 200 knots (100 mph). The role of the aeronautical meteorologist is to provide accurate forecasts of the wind and temperature field, in space and time, through the operational ranges of each aircraft involved. For civil jet-powered aircraft, the optimum flight plan must always represent a compromise among wind, temperature, and turbulence conditions. *See* UPPER-ATMOSPHERE DYNAMICS; WIND.

The jet stream is a meandering, shifting current of relatively swift wind flow which is embedded in the general westerly circulation at upper levels. Sometimes girdling the globe at middle and subtropical latitudes, where the strongest jets are found, this band of strong winds, generally 180–300 mi (300–500 km) in width, has great operational significance for aircraft flying at cruising levels of 4–9 mi (6–15 km). The jet stream challenges the forecaster and the flight planner to utilize tailwinds to the greatest extent possible on downwind flights and to avoid retarding headwinds as much as practicable on upwind flights. As with considerations of wind and temperature, altitude and horizontal coordinates are considered in flight planning for jet-stream conditions. Turbulence in the vicinity of the jet stream is also a forecasting problem. *See* JET STREAM.

An electrical discharge or lightning strike to or from an aircraft is experienced as a blinding flash and a muffled explosive sound. Atmospheric conditions favorable for lightning strikes follow a consistent pattern, characterized by solid clouds or enough clouds for the aircraft to be flying intermittently on instruments; active precipitation of an icy character; and ambient air temperature near or below 32°F (0°C). Saint Elmo's fire, radio static, and choppy air often precede the strike. However, the charge separation processes necessary for the production of strong electrical fields is destroyed by strong turbulence. Thus turbulence and lightning usually do not coexist in the same space. *See* ATMOSPHERIC ELECTRICITY; LIGHTNING.

Modern aircraft operation finds icing to be a major factor in the safe flight. Icing usually occurs when the air temperature is near or below freezing (32°F or 0°C) and the relative humidity is 80% or more. Clear ice is most likely to form when the air temperature is between 32 and −4°F (0 and −20°C) and the liquid water content of the air is high (large drops or many small drops). As these drops impinge on the skin of an aircraft, the surface temperature of which is 32°F (0°C) or less, the water freezes into a hard, high-density solid. When the liquid water content is small and when snow or ice pellets may also be present, the resulting rime ice formation is composed of drops and encapsulated air, producing an ice that is less dense and opaque in appearance. Accurate forecasts and accurate delineation of freezing conditions are essential for safe aircraft operations. [J.T.Le.; J.M.]

Aeronautics The science and art of flying through the air. This term now refers to all aspects of flight in the atmosphere, from design and manufacturing to operation and maintenance of aircraft and spacecraft, and extends to the economics and logistics of airline operation. *See* AIR TRANSPORTATION.

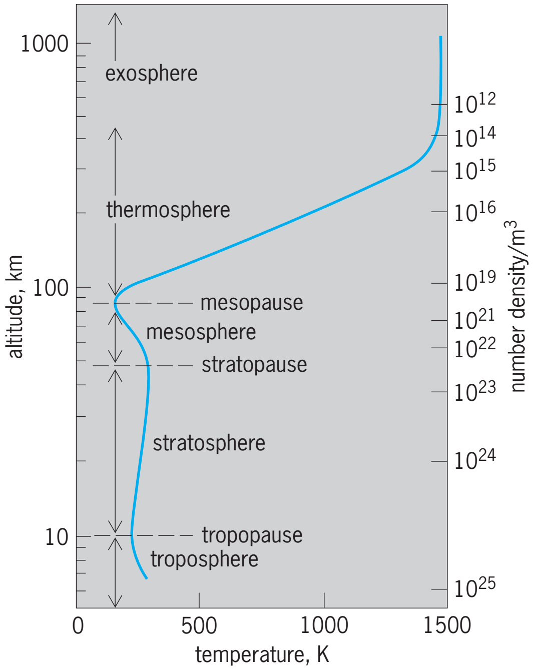
Contributors to the field of aeronautics come from many disciplines, including engineering, particularly aeronautical engineering, business administration, economics, computer technology, and such basic disciplines as physics, chemistry, and materials science. Pilot training is another traditional source of entry into the field. Specialties which are important for aeronautics include aerodynamics, airfoil theory, heat transfer, compressor and turbine analysis, jet propulsion, and structural design. *See* AERODYNAMICS; AERONAUTICAL ENGINEERING; AIRFOIL; ASTRONAUTICS; HEAT TRANSFER; JET PROPULSION; TURBINE PROPULSION. [J.R.Se.]

Aeronomy The study of the chemistry and physics of the regions above the tropopause or upper part of the atmosphere. The region of the atmosphere below the tropopause is the site of most of the weather phenomena that so directly affect all life on the planet; this region has primarily been the domain of meteorology.

The chemical and physical properties of the atmosphere and the changes that result from external and internal forces impact all altitudes and global distributions of atoms, molecules, ions, and electrons, both in composition and in density. Dynamical effects are seen in vertical and horizontal atmospheric motion, and energy is transferred through radiation, chemistry, conduction, convection, and wave propagation.

The atmosphere of the Earth is separated into regions defined by the variation of temperature with height. In the middle atmosphere, that region of the atmosphere between the tropopause and the mesopause (10–100 km or 6–60 mi), the temperature varies from 250 K (−9.7°F) at the tropopause to 300 K (80°F) at the stratopause and back down to 200 K (−100°F) at the mesopause (see illustration). These temperatures are average values, and they vary with season and heat and winds due to the effect of the Sun on the atmosphere. Over this same height interval the atmospheric density varies by over five orders of magnitude. Although there is a constant mean molecular weight over this region, that is, a constant relative abundance of the major atmospheric constituents of molecular oxygen and nitrogen, there are a number of minor constituents that have a profound influence on the biosphere and an increasing influence on the change in the atmosphere below the tropopause associated with the general topic of global change. These constituents, called the greenhouse gases (water vapor, ozone, carbon dioxide, methane, chlorine compounds, nitrogen oxides, chlorofluorocarbons, and others), are all within the middle atmosphere. *See* MESOSPHERE; STRATOSPHERE; TROPOSPHERE.

Understanding the aeronomy of the middle atmosphere requires the study of the physical motion of the atmosphere. The particular composition and chemistry at any given time, location, or altitude depends on how the various constituents are transported from one region to another. Thus, global circulation models for both horizontal and vertical motions are needed to completely specify the chemical state of the atmosphere. In understanding the dynamics of the middle atmosphere, internal gravity waves and acoustic gravity waves play significant roles at different altitudes, depending on whether the particle motion associated with the wave is purely transverse to the direction of propagation or has some longitudinal component. These waves originate primarily in meteorological events such as wind shears, turbulent storms, and weather fronts; and their magnitude can also depend on orographic features on the Earth's surface. *See* MIDDLE-ATMOSPHERE DYNAMICS.



Typical atmospheric temperature variation with altitude and constituent number density (number of atoms and molecules per cubic meter) at high solar activity. °F = (K × 1.8) − 459.67. 1 km = 0.6 mi.

The upper atmosphere is that region above the middle atmosphere that extends from roughly 100 km (60 mi) to the limit of the detectable atmosphere of the planet. This region is characterized by an increasing temperature until it reaches a constant exospheric temperature. There is a slow transition from the region of constant mean molecular weight associated with the middle atmosphere to that of almost pure atomic hydrogen at high altitudes of the exosphere. This is also the region of transition between transport dominated by collision and diffusion, and transport influenced by plasma convection in the magnetic field. The neutral density varies by over ten orders of magnitude from one end to the other and is dominated by molecular processes in the high-density region and an increasing importance of atomic, electron, and ion processes as the density decreases with altitude.

As the Sun sets on the atmosphere, dramatic changes due to the loss of the solar radiation occur. The excitation of the atmosphere declines, and chemical reactions between the constituents become more and more dominant as the night progresses. When observed with very sensitive instruments, the night sky appears to glow at various colors of light. Prominent green and red atomic emissions due to oxygen at 555.7 and 630 nm, respectively, and yellow sodium light at 589 nm appear, while molecular bands of the hydroxyl radical and molecular oxygen even further in the red collectively contribute most of the total intensity of the nightglow spectrum.

The aurora that appears in the southern and northern polar regions is the optical manifestation of the energy loss of energetic particles precipitating into the atmosphere. The region of highest probability of occurrence is called the auroral oval. At high altitudes, electrons and ions present in the magnetosphere are accelerated along magnetic field lines into the atmosphere at high polar latitudes. *See* AURORA; MAGNETOSPHERE. [G.J.R.]

Aerosol A suspension of small particles in a gas. The particles may be solid or liquid or a mixture of both. Aerosols are formed by the conversion of gases to particles, the disintegration of liquids or solids, or the resuspension of powdered material. Aerosol formation from a gas results in much finer particles than disintegration processes (except when condensation takes place directly on existing large particles). Dust, smoke, fume, haze, and mist are common terms for aerosols. Dust usually refers to solid particles produced by disintegration, while smoke and fume particles are generally smaller and formed from the gas phase. Mists are composed of liquid droplets. These special terms are helpful but are difficult to define exactly.

Aerosol particles range in size from molecular clusters on the order of 1 nanometer to 100 micrometers. The stable clusters formed by homogeneous nucleation and the smallest solid particles that compose agglomerates have a significant fraction of their molecules in the surface layer.

Aerosols are important in the atmospheric sciences and air pollution; inhalation therapy and industrial hygiene; manufacture of pigments, fillers, and metal powders; and fabrication of optical fibers. Atmospheric aerosols influence climate directly and indirectly. They directly affect radiation transfer on global and regional scales. Indirect effects result from their role as cloud condensation nuclei in changing droplet size distributions that affect the optical properties of clouds and precipitation. There is evidence that the stratospheric aerosol is significant in ozone destruction. *See* METEOROLOGICAL OPTICS; RADIATIVE TRANSFER.

The atmospheric aerosol consists of material emitted directly from sources (primary component) and material formed by gas-to-particle conversion in the atmosphere (secondary component). The secondary component is usually the result of chemical reactions which take place in either the gas or aerosol phases. Contributions to the atmospheric aerosol come from both natural and anthropogenic sources. The effects of the atmospheric aerosol are largely determined by the size and chemical composition of the individual particles and their morphology (shape or fractal character). For many applications, the aerosol can be characterized sufficiently by measuring the particle size distribution function and the average distribution of chemical components with respect to particle size. The chemical composition of the atmospheric aerosol can be used to resolve its sources, natural or anthropogenic, by a method based on chemical signatures. Particle-to-particle variations in chemical composition and particle structural characteristics can also be measured; they probably affect the biochemical behavior and nucleating properties of aerosols.

Aerosol optical properties depend on particle size distribution and refractive index, and the wavelength of the light. These are determining factors in atmospheric visibility and the radiation balance.

Effects of the atmospheric aerosol on human health have led to the establishment of ambient air-quality standards by the United States and other industrialized nations. Adverse health effects have stimulated many controlled studies of aerosol inhalation by humans and animals. There is much uncertainty concerning the chemical components of the atmospheric aerosol that produce adverse health effects detected in epidemiological studies. *See* AIR POLLUTION.

Aerosols containing pharmaceutical agents have long been used in the treatment of lung diseases such as asthma. Current efforts are directed toward systemic delivery of drugs, such as aerosolized insulin, which are transported across the alveolar walls into the blood.

Aerosol processes are used routinely in the manufacture of fine particles. Aerosol reaction engineering refers to the design of such processes, with the goal of relating product properties to the properties of the aerosol precursors and the process conditions. The most important large-scale commercial systems are flame reactors for production of pigments and powdered materials such as titania and fumed silica. Optical fibers are fabricated by an aerosol process in which a combustion-generated silica fume is deposited on the inside walls of a quartz tube a few centimeters in diameter, along with suitable dopant aerosols to control refractive index. Pyrolysis reactors are used in carbon black manufacture. Micrometer-size iron and nickel powders are produced industrially by the thermal decomposition of their carbonyls. Large pilot-scale aerosol reactors are operated using high-energy electron beams to irradiate flue gases from fossil fuel combustion. The goal is to convert sulfur oxides and nitrogen oxides to ammonium sulfate and nitrate that can be sold as a fertilizer.

Atmospheric aerosols and aerosols emitted from industrial sources are normally composed of mixtures of chemical compounds. Each chemical species is distributed with respect to particle size in a way that depends on its source and past history; hence, different substances tend to accumulate in different particle size ranges. This effect has been observed for emissions from pulverized coal combustion and municipal waste incinerators, and it undoubtedly occurs in emissions from other sources. Chemical segregation with respect to size has important implications for the effects of aerosols on public health and the environment, because particle transport and deposition depend strongly on particle size. [S.K.F.]

Aerospace medicine The special field of medicine that deals with humans in environments encountered beyond the surface of the Earth. It includes both aviation medicine and space medicine and is concerned with humans, their environment, and the vehicles in which they fly. Its objective is to ensure human health, safety, well-being, and effective performance through careful selection and training of flight personnel, protection from the unique flight environment and its physiological and psychological effects, and understanding of the flight vehicle and humans' interaction with it.

The environment encountered in air or space flight is very different from that on Earth. Consequently aerospace medicine must deal with the physics of the atmosphere and space and with the conditions and influences introduced by the flight vehicle. Aerospace medicine is therefore concerned with the physiological effects of changes in barometric pressure, atmospheric constituents, toxic substances, acceleration, weightlessness, noise, vibration, ionizing radiation, and thermal and other environmental stresses, as well as psychological stresses and their effects on behavior and performance.

The flight conditions of advanced supersonic aircraft introduce extreme variations in temperature, extensive and sudden changes in pressure, and rapid acceleration. Exposure to the low pressure at altitudes may release nitrogen gas normally held in the blood in solution and thus produce bends symptoms. As altitude increases, oxygen continues to constitute 21% of the atmosphere, but the decreased pressure of the upper atmosphere and consequently of the oxygen results in reduced oxygenation of the blood, affecting physical well-being and the ability to think and to reason. The physiological problems of acceleration are an integral part of aerospace medicine because humans are exposed to forces of acceleration almost constantly throughout flight that are different from the 1-*g* environment of Earth. When positive *g* (increased acceleration) forces are applied to the body, the blood is forced downward away from the head and heart, and blackout and unconsciousness may occur. Under negative *g* (decreased acceleration) conditions, the blood is forced upward so that the blood vessels of the head are engorged. This may result in redout, a condition in which the visual field reddens due to engorged eye blood vessels, and unconsciousness. *See* ACCELERATION.

All of the environmental hazards incumbent in flight in aircraft are present in space flight, but space also has unique hazards, of which weightlessness is paramount. The equilibrium of many biological systems is disrupted by extended exposure to weightlessness.

Neurovestibular effects associated with space motion sickness occur during the first few days in orbit. At the same time there is a shift in body fluids toward the head, and faces become puffy. This is followed by a loss of fluids and electrolytes. With decreased fluids, red blood cell mass slowly decreases for about 60 days into flight. Cardiovascular deconditioning also occurs within the first month. These systems in general appear to acclimate to the weightless environment in 4–6 weeks. Postflight symptoms include orthostatic intolerance associated with shifts in body fluid and resultant cardiopulmonary neuroreceptor reflex responses. Difficulties in postural equilibrium and occasionally motion sickness accompany neurovestibular readaptation. *See* WEIGHTLESSNESS.

The potential biological effects of galactic cosmic radiation include damage to bone marrow and lymphopoietic, intestinal, and gonadal tissues, as well as infertility, cancer induction, and heritable effects. Shielding and radioprotective chemicals afford some protection from space radiation. Total shielding is impossible, however, because of the excess weight it would impart to the spacecraft and the ability of heavy ions to penetrate even heavy shielding. Space medicine consequently has the responsibility to identify appropriate protective procedures, define exposure limits, and develop therapeutic measures. *See* RADIATION BIOLOGY; RADIATION INJURY (BIOLOGY).

Countermeasures used to prevent or control deleterious physiological responses to space flight include physical, psychological, pharmacological, and nutritional means. Specifically, these include exercise, especially of the lower extremities, by using unique bicycles and treadmills; a vacuum suit that applies negative pressure to the lower body to stress the cardiovascular system; salt water loading on the last day of flight to increase blood volume and prevent orthostatic intolerance; and nutritional supplements including calcium. Pharmacologic agents may be used to curb space sickness symptoms and to protect against radiation. [T.W.H.]

Aerospike engine The aerospike engine (Fig. 1*a*) is an advanced liquid-propellant rocket engine with unique operating characteristics and performance advantages over conventional rocket engines. It combines a contoured axisymmetric plug nozzle (Fig. 2), an annular torus-shaped combustion chamber, conventional turbopumps, a turbine exhaust system that injects the turbine drive gases into the base of the plug nozzle, and a simple combustion tap-off engine cycle. The aerospike is one-quarter the length of a conventional rocket engine, yet it delivers comparable performance (efficiency) at high altitude and superior performance at low altitude. The low-altitude performance advantage is primarily due to the fact that the plug nozzle compensates for altitude whereas the nozzle of a conventional rocket engine does not. While the plug nozzle and its benefits are not new to the field of air-breathing propulsion, the aerospike represents the first application of this type of nozzle to the field of rocket propulsion. Typical propellants are liquid hydrogen (fuel) and liquid oxygen (oxidizer).

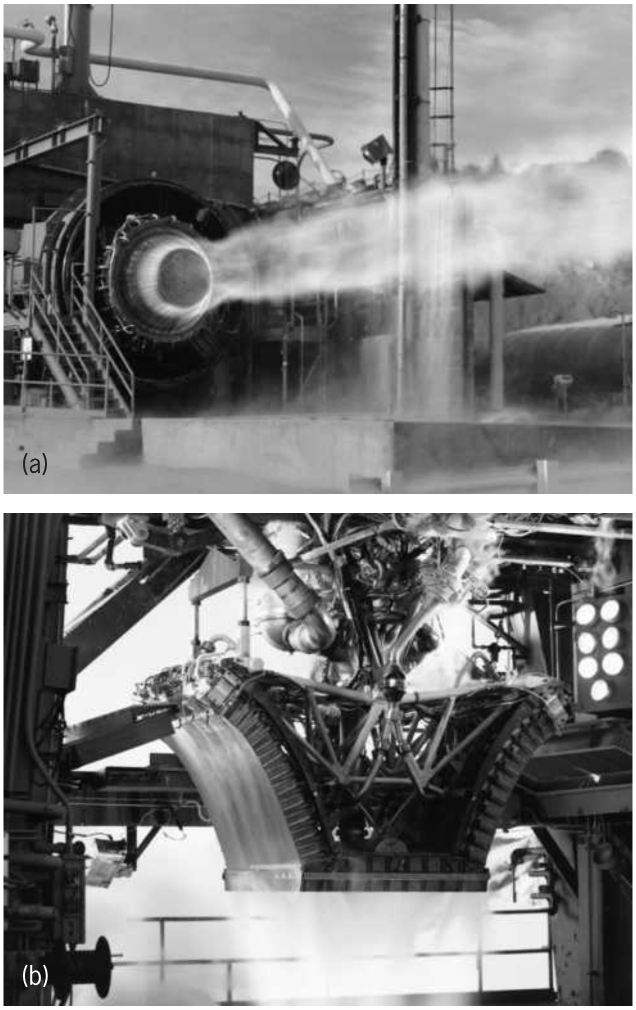


Fig. 1. Static firing tests of (*a*) aerospike engine with 250,000 pounds (1,112,000 newtons) of thrust, and (*b*) linear aerospike engine with 125,000 pounds (556,000 newtons) of thrust. Both engines use hydrogen/oxygen propellants. (*Boeing Company, Rocketdyne Division*)

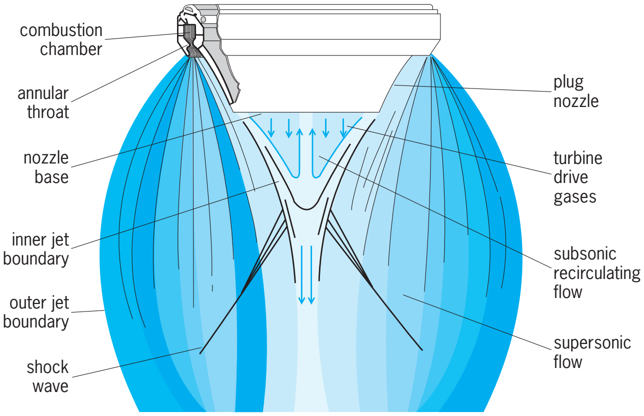

Fig. 2. Aerospike engine with plug nozzle, torus-shaped combustion chamber, and combustion gases expanding outside the nozzle. (*Boeing Company, Rocketdyne Division*)

Linear aerospike. A variation is the linear aerospike engine (Fig. 1*b*). This rocket engine concept offers the same performance advantages as the annular aerospike while offering some unique configurational advantages owing to its linear shape. The combustion chamber is made up of a series of modular chamber segments, and the gas generator engine cycle is used in place of the combustion tap-off cycle.

Advanced launch vehicles. Interest has been renewed in single-stage-to-orbit reusable launch vehicles. Numerous studies have shown that reduced launch costs will be best achieved through the development of a fully reusable single-stage-to-orbit vehicle.

Unlike multistage launch vehicles that depend upon one rocket propulsion system for boost and others for high-altitude operation, future single-stage-to-orbit vehicles will be dependent on a single rocket propulsion system from boost to orbit insertion. While each rocket engine of a multistage vehicle can be individually tailored to meet the requirements of its portion of the trajectory, rocket engines for single-stage-to-orbit vehicles must provide high performance over the entire flight trajectory. Thus, advanced rocket propulsion technologies that further increase the performance of liquid-propellant rocket engines will be required. The aerospike engine is one of these advanced propulsion concepts. *See* ROCKET PROPULSION; SPACECRAFT PROPULSION. [J.E.Be.]

Aerostatics The science of the equilibrium of gases and of solid bodies immersed in them when under the influence only of natural gravitational forces. Aerostatics is concerned with the balance between the weight of the gases and the weight of any object within them. Archimedes' law that an immersed body experiences a buoyancy force equal to the weight of the fluid displaced is the principal law of aerostatics, if the fluid is air, or of hydrostatics, if the fluid is water. Some phases of meteorology and the flight of balloons and dirigibles are based on aerostatics. In meteorology cloud and fog subsidence and simple pressure and temperature relations with altitude are predicted from aerostatic principles. *See* HYDROSTATICS. [J.R.Se.]

Aerothermodynamics Flow of gases in which heat exchanges produce a significant effect on the flow. Traditionally, aerodynamics treats the flow of gases, usually air, in which the thermodynamic state is not far different from standard atmospheric conditions at sea level. In such a case the pressure, temperature, and density are related by the simple equation of state for a perfect gas; and the rest of the gas's properties, such as specific heat, viscosity, and thermal conductivity, are assumed constant. Because fluid properties of a gas depend upon its temperature and composition, analysis of flow systems in which temperatures are high or in which the composition of the gas varies (as it does at high velocities) requires simultaneous examination of thermal and dynamic phenomena. For instance, at hypersonic flight speed the characteristic temperature in the shock layer of a blunted body or in the boundary layer of a slender body is proportional to the square of the Mach number. These are aerothermodynamic phenomena.

Two problems of particular importance require aerothermodynamic considerations: combustion and high-speed flight. Chemical reactions sustained by combustion flow systems produce high temperatures and variable gas composition. Because of oxidation (combustion) and in some cases dissociation and ionization processes, these systems are sometimes described as aerothermochemical. In high-speed flight the kinetic energy used by a vehicle to overcome drag forces is converted into compression work on the surrounding gas and thereby raises the gas temperature. Temperature of the gas may become high enough to cause dissociation (at Mach number ≥ 7) and ionization (at Mach number ≥ 12); thus the gas becomes chemically active and electrically conducting. *See* COMBUSTION; HYPERSONIC FLIGHT; JET PROPULSION; MACH NUMBER; ROCKET PROPULSION. [S.Y.C.]

Affective disorders A group of psychiatric conditions, also known as mood disorders, characterized by disturbances of affect, emotion, thinking, and behavior. Depression is the most common of these disorders, and about 10–20% of those affected also experience manic episodes. The affective disorders are not distinct diseases but are psychiatric syndromes that likely have multiple or complex etiologies.

Clinical syndromes. The most common form of affective disorder is a major depressive episode. The episode is defined by a pervasively depressed or low mood (which is experienced most of the day over a period of 2 weeks or longer) and at least four associated symptoms affecting sleep, appetite, hedonic capacity, interest, and behavior.

Major depressive episodes have several clinical forms. Melancholia is a severe episode characterized by anhedonia, marked anorexia with weight loss, early morning awakening, observable motor disturbances (extreme slowing, or retardation, or pacing and stereotypic agitated behaviors), and diurnal mood variation (mood is worse in the morning). *See* ANOREXIA NERVOSA.

Common among young patients, especially women, is a milder syndrome historically referred to as atypical depression. Atypical depression is characterized by intact mood reactivity (one's spirits can go up or down in response to day-to-day events) and reverse symptoms: oversleeping, overeating, or gaining weight. Significant anxiety symptoms, including phobias and panic attacks, also are common in atypical depression.

A more chronic, insidious form of depression known as dysthymia "smolders" at a subsyndromal level (that is, there are three or four daily symptoms) for at least 2 years. Dysthymia often begins early in life and, historically, has been intertwined with atypical and neurotic characteristics.

A manic episode is heralded by euphoric or irritable mood and at least four of the following: increased energy, activity, self-esteem, or speed of thought; decreased sleep; poor judgment; and risk-taking. About one-half of manic episodes are psychotic. The delusions of mania typically reflect grandiose or paranoid themes. Most people who have manic episodes also experience recurrent depressive episodes.

The term bipolar affective disorder has largely replaced the old term manic-depression, although both names convey the cyclical nature of this illness. The classical presentation (which includes full-blown manic episodes) is known as type 1 disorder. The diagnosis of bipolar type 2 disorder is used when there are recurrent depressive episodes and at least one hypomania. The diagnosis of cyclothymia is used when neither hypomanias nor depressions have reached syndromal levels.

Two variations of bipolar episodes are increasingly recognized. A mixed episode is diagnosed when the symptoms of mania and depression coexist. The term rapid cycling is used when there have been four or more episodes within a time frame of 1 year.

A number of affective disorders follow a seasonal pattern. A pattern of recurrent fall/winter depressions (also known as seasonal affective disorder) has generated considerable interest because it may be treated with bright white light, which artificially lengthens the photoperiod.

Literally all forms of affective disorder can be caused by general medical illnesses and medications that affect brain function (such as antihypertensives, hormonal therapies, steroids, and stimulant drugs). The diagnosis "mood disorder associated with a general medical condition" is applied to these conditions.

Pathophysiology. The affective disorders have diverse biopsychosocial underpinnings that result, at least in part, in extreme or distorted responses of several neurobehavioral systems. The neurobehavioral systems of greatest relevance regulate a person's drives and pursuits, responses to acute stress, and capacity to dampen or quiet pain or distress.

Although there is considerable evidence that affective disorders are heritable, vulnerability is unlikely to be caused by a single gene. It is likely that some combination of genes conveys greater risk and, like an amplifier, distorts the neural signals evoked by stress and distress. *See* BEHAVIOR GENETICS; HUMAN GENETICS.

Research permits several firm conclusions about brain neurochemistry in stress and depression. Acute stress mobilizes the release of three vital brain monoamines–serotonin, norepinephrine, and dopamine—as well as glucocorticoids such as cortisol. Sustained and unresolvable stress eventually depletes the neurotransmitters (cortisol levels remain high), inducing a behavioral state of learned helplessness. Severe depression, especially recurrent episodes of melancholia, affects the brain similarly.

Psychosocial and neurobiologic vulnerabilities, no doubt, intersect. For example, harsh early maltreatment, neglect, or other abuses can have lasting effects on both self-concept and brain responses to stress.

Epidemiology. The lifetime rates of affective disorders are increasing, with an earlier age of onset. The onset of major depression most often occurs in the late 20s to mid-30s; dysthymia and bipolar disorder typically begin about a decade earlier. However, no age group is immune to an affective disorder. Vulnerability is not related to social class or race, although the affluent are more likely to receive treatment.

Treatment. Most episodes of dysthymia and major depressive disorder respond to treatment with either psychotherapy or antidepressant medication, either singly or in combination. Many experts now recommend the newer forms of psychotherapy, including cognitive behavior therapy and interpersonal therapy, because they have been better studied than more traditional psychoanalytic therapies and because they have been found to be as effective as medications.

Nearly 30 antidepressant medications are available worldwide, with most falling into three classes: tricyclic antidepressants (TCAs), selective serotonin reuptake inhibitors (SSRIs), and monoamine oxidase reuptake inhibitors (MAOIs). Most classes of antidepressants enhance the efficiency of serotonin or norepinephrine neurotransmission. Antidepressants are not habit-forming and have no mood-elevating effects for nondepressed people. *See* PSYCHOPHARMACOLOGY; PSYCHOTHERAPY.

Acute manic episodes are usually treated with either lithium salts or divalproex sodium. Psychotic symptoms and severe agitation sometimes warrant the acute use of antipsychotic drugs. Although psychotherapy does not have a major role in the acute treatment of mania, it may help people come to terms with their illness, cope more effectively with stress, or curb minor depressive episodes.

When pharmacotherapies are not effective, the oldest proven treatment of the affective disorders, electroconvulsive therapy (ECT), still provides a powerful alternative. Today, ECT is a highly modified and carefully monitored treatment that has little in common with its depictions in the movies. Nevertheless, confusion and transient amnesia are still problems. *See* ELECTROCONVULSIVE THERAPY. [M.E.T.]

Aflatoxin Any of a group of secondary metabolites produced by the common molds *Aspergillus flavus* and *A. parasiticus* that cause a toxic response in vertebrates when introduced in low concentration by a natural route. The group constitutes a type of mycotoxin. The naturally occurring aflatoxins are identified in physicochemical assays as intensely blue (aflatoxins B$_1$ and B$_2$) or blue-green (aflatoxins G$_1$ and G$_2$) fluorescent compounds under long-wave ultraviolet light. The common structural feature of the four major aflatoxins is a dihydrodifurano or tetrahydrodifurano group fused to a substituted coumarin group (see illustration). The relative proportions of the four major aflatoxins synthesized by *Aspergillus* reflect the genetic constitution of the producing strain and the parameters associated with fungal growth. In addition, derivative aflatoxins are produced as metabolic or environmental products. *See* TOXIN.

Aflatoxins are formed through a polyketide pathway involving a series of enzymatically catalyzed reactions. In laboratory cultures, aflatoxins are biosynthesized after active growth has ceased, as is typical for secondary metabolites. By using blocked mutants and metabolic inhibitors, many of the intermediates have been identified as brightly colored anthraquinones.

Aflatoxins are potent molecules with many biological effects. They are toxigenic, carcinogenic, mutagenic, and teratogenic in various animal species. Aflatoxin B$_1$ is usually the most abundant naturally occurring member of the family, and most studies on the pharmacological activity of aflatoxin have been conducted with this congener. Aflatoxin B$_1$ is the most potent hepatocarcinogenic agent known, although the liver by no means is the only organ susceptible to aflatoxin carcinogenesis. Aflatoxin is listed as a probable human carcinogen by the International Agency for Research on Cancer. *See* LIVER DISORDERS; PLANT PATHOLOGY.

Aflatoxins are a major agricultural problem. Contamination can occur in the field, during harvest, or in storage and processing. Corn, rice, cottonseed, and peanuts are the major crops regularly displaying high levels of aflatoxin contamination. Since *A. flavus* and *A. parasiticus* are nearly ubiquitous in the natural environment, numerous other grain, legume, nut, and spice crops, as well as coffee and cocoa, have been reported to contain aflatoxins. Given the potential of aflatoxins as human carcinogens and their known activity as toxins in animal feeds, many international regulatory agencies monitor aflatoxin levels in susceptible crops. Prevention is the main line of defense against aflatoxins entering the food chain. Moisture, temperature, and composition of the substrate are the chief factors affecting fungal growth and toxin production. In the field, insect damage is often involved. Detoxification is a last line of defense. Several commercially feasible methods of ammoniation have been developed for reducing levels of aflatoxin contamination in animal feeds. *See* AGRONOMY; MYCOTOXIN. [J.W.Be.]

Africa A continent that straddles the Equator, extending between 37°N and 35°S. It is the second largest continent, exceeded by Eurasia. The area, shared by 55 countries, is 11,700,000 mi^2 (30,300,00 km^2), approximately 20% of the world's total land area. Despite its large area, it has a simple geological structure, a compact shape with a smooth outline, and a symmetrical distribution of climate and vegetation.

Africa has few inlets or natural harbors and a small number of offshore islands that are largely volcanic in origin. Madagascar is the largest island, with an area of 250,000 mi^2 (650,000 km^2).

Africa is primarily a high interior plateau bounded by steep escarpments. These features show evidence of the giant faults created during the drift of neighboring continents. The surface of the plateau ranges from 4000–5000 ft (1200–1500 m) in the south to about 1000 ft (300 m) in the Sahara. These differences in elevation are particularly apparent in the Great Escarpment region in southern Africa, where the land suddenly drops from 5000 ft (1500 m) to a narrow coastal belt. Although most of the continent is classified as plateau, not all of its surface is flat. Rather, most of its physiographic features have been differentially shaped by processes such as folding, faulting, volcanism, erosion, and deposition. *See* Escarpment; Fault and fault structures; Plateau.

The rift valley system is one of the most striking features of the African landscape. Sliding blocks have created wide valleys 20–50 mi (30–80 km) wide bounded by steep walls of variable depth and height. Within the eastern and western branches of the system, there is a large but shallow depression occupied by Lake Victoria. *See* Rift valley.

Several volcanic features are associated with the rift valley system. The most extensive of these are the great basalt highlands that bound either side of the rift system in Ethiopia. These mountains rise over 10,000 ft (3000 m), with the highest peak, Ras Dashan, reaching 15,158 ft (4500 m). There are also several volcanic cones, including the most renowned at Mount Elgon (14,175 ft; 4321 m); Mount Kenya (17,040 ft; 5194 m); and Mount Kilimanjaro, reaching its highest point at Mount Kibo (19,320 ft; 5889 m). Mounts Kenya and Kilimanjaro are permanently snowcapped. *See* Basalt.

Since the Equator transects the continent, the climatic conditions in the Northern Hemisphere are mirrored in the Southern Hemisphere. Nearly three-quarters of the continent lies within the tropics and therefore has high temperatures throughout the year. Frost is uncommon except in mountainous areas or some desert areas where nighttime temperatures occasionally drop below freezing. These desert areas also record some of the world's highest daytime temperatures, including an unconfirmed record of 136.4°F (58°C) at Azizia, Tripoli. *See* Equator.

Africa can be classified into broad regions based on the climatic conditions and their associated vegetation and soil types. The tropical rainforest climate starts at the Equator and extends toward western Africa. The region has rainfall up to 200 in. (500 cm) per year and continuously high temperatures averaging 79°F (26°C). The eastern equatorial region does not experience these conditions because of the highlands and the presence of strong seasonal winds that originate from southern Asia.

The areal extent of the African rainforest region (originally 18%) has dwindled to less than 7% as a result of high rates of deforestation. Despite these reductions, the region is still one of the most diverse ecological zones in the continent. *See* Rainforest.

Extensive savanna grasslands are found along the Sudanian zone of West Africa, within the Zambezian region and the Somalia-Masai plains. Large areas such as the Serengeti plains in the Somalia-Masai plains are home to a diverse range of wild animals.

The tropical steppe forms a transition zone between the humid areas and the deserts. This includes the area bordering the south of the Sahara that is known as the Sahel, the margins of the Kalahari basin, and the Karoo grasslands in the south.

The structural evolution of the continent has much to do with the drainage patterns. Originally, most of the rivers did not drain into the oceans, and many flowed into the large structural basins of the continent. However, as the continental drift occurred and coasts became more defined, the rivers were forced to change courses, and flow over the escarpments in order to reach the sea. Several outlets were formed, including deep canyons, waterfalls, cataracts, and rapids as the rivers carved out new drainage patterns across the landscape. Most of the rivers continue to flow through or receive some of their drainage from the basins, but about 48% of them now have a direct access into the surrounding oceans. The major rivers are the Nile, Congo (Zaire), Niger, and Zambezi. *See* River.

The tremendous diversity in wildlife continues to be one of the primary attractions of this continent. Africa is one of the few remaining places where one can view game fauna in a natural setting. There is a tremendous diversity in species, including birds, reptiles, and large mammals. Wildlife are concentrated in central and eastern Africa because of the different types of vegetation which provide a wide range of habitats.

Africa is not a densely populated continent. With an estimated population of 743,000,000, its average density is 64 per square mile (26 per square kilometer). However, some areas have large concentrations, including the Nile valley, the coastal areas of northern and western Africa, the highland and volcanic regions of eastern Africa, and parts of southern Africa. These are mostly areas of economic or political significance. [F.L.M.]

African horsesickness A highly fatal insect-borne viral disease of horses and mules, and a mild subclinical disease in donkeys and zebras. It normally occurs in sub-Saharan Africa but occasionally spreads to North Africa, the Iberian Peninsula, and Asia Minor.

The African horsesickness virus is an orbivirus (family Reoviridae) measuring 68–70 nanometers in diameter. The outer layer of the double-layered protein shell is ill defined and diffuse and is formed by two polypeptides. The highly structured core consists of five structural proteins arranged in icosa-hedral symmetry. The viral genome is composed of 10 double-stranded ribonucleic acid (RNA) segments (genes) ranging in size from 240,000 to 2,530,000 daltons. Nine distinct serotypes which can be distinguished by neutralization tests are known. The virus can be cultivated in various cell cultures, in the brains of newborn mice, and in embryonated hen eggs by intravascular inoculation. *See* Animal virus.

African horsesickness is a noncontagious disease that can readily be transmitted by the injection of infective blood or organ suspensions. In nature, the virus is biologically transmitted by midges of the genus *Culicoides*, such as *C. imicola*. The disease has a seasonal incidence in temperate regions (late summer to autumn), and its prevalence is influenced by climatic conditions favoring insect breeding (for example, warm, moist conditions in low-lying areas). Mechanical transmission by large biting flies is possible, but plays a much smaller role than biological transmission in the epidemiology of this disease.

There is no specific treatment for this disease. Infected animals should be given complete rest as the slightest exertion may result in death. Stabling of horses at night during the African horsesickness season reduces exposure to insect vectors and hence the risk of disease transmission. Prophylactic vaccination is the most practical and effective control measure. In epidemic situations outside Africa, the causal virus should be serotyped as soon as possible, allowing the use of a monovalent vaccine. However, in endemic regions it is imperative to use a polyvalent vaccine, which should render protection against all nine serotypes of African horsesickness virus. *See* Disease; Epidemic; Vaccination. [B.E.]

Afterburner A device in a turbojet aircraft engine, between turbine and nozzle, which improves thrust by the burning of additional fuel (see illustration). To develop additional

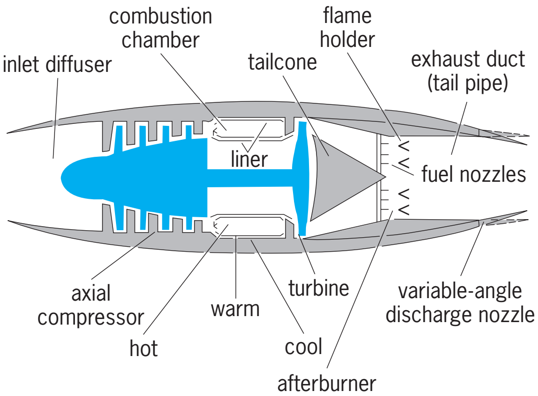

Diagram of turbojet engine showing afterburner.

thrust for takeoff and climb and for periods of dash of military aircraft, it is advantageous to augment the engine thrust. This is done by afterburning, also called reheating, tail-pipe burning, or postcombustion. The augmentation of thrust obtained by afterburning may be well over 40% of the normal thrust and at supersonic flight can exceed 100% of normal thrust. *See* TURBOJET. [B.P.]

Agar A major constituent of the cell walls of certain red algae, especially members of the families Gelidiaceae and Gracilariaceae. Extracted for its gelling properties, it is one of three algal polysaccharides of major economic importance, the others being alginate and carrageenan. Agar is composed of two similar fractions, agarose and agaropectin, in which the basic unit is galactose, linked alternately α-1,3-(D-galactose) and β-1,4-(α-L-galactose).

Agar is prepared by boiling the algae in water, after which the filtered solution is cooled, purified, and dried. It is an amorphous, translucent material that is packaged in granules, flakes, bricks, or sheets. One of its chief uses is as a gelling agent in media for culturing microorganisms. It is also used in making confections, as an emulsifier in cosmetics and food products, as a sizing agent, as an inert carrier of drugs in medicine, and as a laxative. *See* CULTURE; RHODOPHYCEAE. [P.C.Si; R.L.Moe.]

Agate A variety of chalcedonic quartz that is distinguished by the presence of color banding in curved or irregular patterns (see illustration). Most agate used for ornamental purposes is composed of two or more tones or intensities of brownish-red, often interlayered with white, but it is also commonly composed of various shades of gray and white. Since agate is relatively porous, it can be dyed permanently in red, green, blue, and a variety of other colors.

Section of polished agate showing the characteristic banding. (*Field Museum of Natural History, Chicago*)

The term agate is also used with prefixes to describe certain types of chalcedony in which banding is not evident. Moss agate is a milky or almost transparent chalcedony containing dark inclusions in a dendritic pattern. Iris agate exhibits an iridescent color effect. Fortification, or landscape, agate is translucent and contains inclusions that give it an appearance reminiscent of familiar natural scenes. Banded agate is distinguished from onyx by the fact that its banding is curved or irregular, in contrast to the straight, parallel layers of onyx. The properties of agate are those of chalcedony: refractive indices of 1.535 and 1.539, a hardness of $6^1/_2$ to 7, and a specific gravity of about 2.60. *See* CHALCEDONY; GEM; QUARTZ. [R.T.L.]

Agglutination reaction A reaction in which suspended particles are aggregated or clumped. It occurs upon the admixture of another type of particle, a change in the composition of the suspending fluid, or the addition of a soluble agent that acts as a bridge between two or more particles. The reaction is a secondary one in that the process resulting in agglutination occurs after the primary antigen-antibody linkage has taken place.

The particles undergoing agglutination may be either unicellular or microscopic multicellular organisms (such as bacteria and parasites), individual cells of multicellular organisms (such as erythrocytes and lymphocytes), or artificial particles (such as beads of plastic, glass, or polysaccharide). The immunological specificity of agglutination depends upon the uniqueness of the reaction between a marker substance on one type of particle and a receptor on either another type of particle or a specific antibody in solution. The marker can be a usual biological component of the surface of the particle or blood group substance on red cells. It can be an enzymatically or a chemically modified chemical group on the surface of biological particles. It can also be an adsorbed or a chemically attached substance. The attachment can be to biological particles or artificial ones. The receptor can be a biological component of the particle, an attached antibody, or antibody in solution. A reverse reaction is one in which the antibody is attached to a particle and the addition of the antigen causes the mixture to clump. Inhibition of agglutination can also be used to test for antigens, especially of low molecular weight, in a manner similar to that for agglutination itself. *See* ANTIGEN-ANTIBODY REACTION; IMMUNOASSAY. [A.B.]

Agglutinin A substance that will cause a clumping of particles such as bacteria or erythrocytes. Of major importance are the specific or immune agglutinins, which are antibodies that will agglutinate bacteria containing the corresponding antigens on their surfaces. Agglutinins are readily determined, and their presence is of diagnostic value to indicate present or past host contact with the microbial agent sufficient to result in antibody formation. *See* AGGLUTINATION REACTION; ANTIBODY.

Analogous reactions involve erythrocytes and their corresponding antibodies, the hemagglutinins. Hemagglutinins to a variety of erthyrocytes occur in many normal sera, and their amounts may be increased by immunization. The blood group isoagglutinins of humans and animals are important special cases which must be considered in all proposed blood transfusions lest transfusion reactions result. *See* BLOOD GROUPS. [H.P.T.]

Aggression Behavior that is intended to threaten or inflict physical injury on another person or organism; a broader definition may include such categories as verbal attack, discriminatory behavior, and economic exploitation. The inclusion of intention in defining aggression makes it difficult to apply the term unequivocally to animals in which there is no clear means of determining the presence or absence of intention. As a result, animal violence is usually equated with aggression. There are four main approaches to understanding the causes or origins of human aggression. First, the basis may be differences among people, due either to physiological difference or to early childhood experiences. Second, there are sociological approaches which seek the causes of aggression in social factors such as economic deprivation and social (including family) conflicts. Third, causes may be found in the power relations of society as whole, where aggression arises as a function of control of one group by another. Fourth, aggression may be viewed as an inevitable (genetic) part of human nature; this approach has a long history and has produced extensive arguments. Given the wide variation in aggressive behavior in different societies and the occasional absence of such behavior in some groups and some individuals, a general human genetic factor is unlikely. However, some genetic disposition to react with force when an individual is blocked from reaching a goal may provide an evolutionary basis for the widespread occurrence of violence and aggression. The existence of different kinds of aggression suggests that different evolutionary scenarios need to be invoked and that aggression is not due to a single evolutionary event; it is likely that aggression is multidetermined and rarely, if ever, due to a single factor. *See* BEHAVIOR GENETICS.

Aggression in humans ranges through fear-induced aggression, parental disciplinary aggression, maternal aggression, and sexual aggression. One clearly biologically adaptive type, defensive aggression, occurs when fight responses are mobilized in defense of an organism's vital interests, such as obtaining food or the protection of its young. The aim of defensive aggression is not destruction but the preservation of life. Thus, aggression can serve both destructive and constructive purposes. Among animals, the varieties of aggression include most of the human types as well as predatory aggression, territorial defense, and sexually related aggression in competition for a mate. [G.M.]

Aging Definitions of aging differ between biologists and behavioral scientists. Biologists regard aging as reflecting the sum of multiple and typical biological decrements occurring after sexual maturation; behavioral scientists view it as reflecting regular and expected changes occurring in genetically representative organisms advancing through the life cycle under normal environmental conditions. It is difficult to define normal aging, since many changes observed in older adults and previously perceived as concomitants of normal aging are now recognized as effects of disease in later life. The behavioral science view allows for incremental as well as decremental changes with aging. Senescence is not always equated with aging; it is viewed as the increasing vulnerability or decreasing capacity of an organism to maintain homeostasis as it progresses through its life span. Gerontology refers to the study of aging. Geriatrics refers to the clinical science that is concerned with health and illness in the elderly.

Inquiries into why organisms age involve both the purpose of aging and the process of aging. There are theories, but no conclusive evidence, in both areas. The most common explanations of the purpose of aging are based on theories that aging is adaptive for a species. Theories about the process of aging concern how people age. These biological theories address two sets of factors—intrinsic and extrinsic to the organism. Intrinsic factors are influences operating on the body from within, such as the impact of genetic programming. Extrinsic factors are influences on the body from the environment, such as the impact of cumulative stresses. Despite an abundance of theories to explain the process of aging, its mechanisms remain a mystery.

It is important to differentiate between life expectancy and life span. Life expectancy is the average number of years of life in a given species; it is significantly influenced by factors beyond aging alone, such as famine and disease. Life span is the maximum number of years of life possible for that species; it is more fundamentally linked to the process of aging itself. Over the centuries, life expectancy has increased (due to improved sanitation and health care practices); life span has not. Approximately 115 years appears to be the upper limit of life span in humans. *See* DEATH; HUMAN GENETICS. [G.D.C.]

Agnosia An impairment in the recognition of stimuli in a particular sensory modality. True agnosias are associative defects, where the perceived stimulus fails to arouse a meaningful state. An unequivocal diagnosis of agnosia requires that the recognition failure not be due to sensory-perceptual deficits, to generalized intellectual impairment, or to impaired naming (as in aphasia). Because one or more of these conditions frequently occur with agnosia, some clinical scientists have questioned whether pure recognition disturbances genuinely exist; but careful investigation of appropriate cases has affirmed agnosia as an independent entity which may occur in the visual, auditory, or somesthetic modalities. *See* APHASIA.

The patient with visual object agnosia, though quite able to identify objects presented auditorily or tactually, cannot name or give other evidence of recognizing visually presented objects. Because visual object agnosia is a rather rare disorder, knowledge of its underlying neuropathology is incomplete. Most reported cases have shown bilateral occipital lobe lesions, with the lesion extending deep into the white matter and often involving the corpus callosum. Prosopagnosia is the inability to recognize familiar faces. Persons well known to the individual before onset of the condition, including members of the immediate family, are not recognized. In many instances, individuals fail to recognize picture or mirror images of themselves. Isolated impairment of reading is frequently considered to be an exotic form of aphasia. Logically, however, it may be considered as a visual-verbal agnosia (also referred to as pure word blindness or alexia without agraphia). Individuals with this disorder show a marked reduction in their ability to read the printed word, though their writing and other language modalities remain essentially intact.

The term auditory agnosia is most often used to indicate failure to recognize nonverbal acoustic stimuli despite adequate hearing sensitivity and discrimination. In most well-documented cases of agnosia for sounds, the subjects have had bilateral temporal lobe lesions. Auditory-verbal agnosia (or pure word deafness) is a disturbance in comprehension of spoken language, in the presence of otherwise intact auditory functioning and essentially normal performance in other language modalities. The person's speech expression is remarkably intact in comparison with the gross impairment in understanding speech. Like its visual analog, visual-verbal agnosia, this is a disconnection syndrome. It is produced by damage to the left primary auditory cortex (or the tracts leading to it) coupled with a lesion to the corpus callosum. Phonagnosia is a disturbance in the recognition of familiar voices. The person has good comprehension of what is spoken, but the speaker cannot be identified. *See* BRAIN; HEARING (HUMAN); HEMISPHERIC LATERALITY; PSYCHOACOUSTICS; VISION. [G.J.C.]

Agonomycetes Mitosporic or anamorphic (asexual or imperfect) fungi (Deuteromycotina) that not only lack fruit bodies but also fail to produce conidia, the thallus consisting of septate hyphae. Somatic structures of propagation or survival, termed propagules, are varied and include chlamydospores and bulbils. Hyphae are modified to form sclerotia, pseudosclerotia, rhizomorphs, strands, and cords. About 40 genera (with +30 synonyms) containing 220 species are recognized. The Agonomycetes constitute an artificial group that does not consist of closely related genera and is recognized for its practicality rather than homogeneous taxonomic composition. They are circumscribed not only by what they lack, such as conidia, asci and ascospores, basidia and basidiospores, and zygospores, but also by the apparent superficial similarity between some of the members in, for example, hyphal, chlamydospore, and sclerotial form.

Agonomycetes are generally considered to be combative species which are persistent and long-lived, largely because of the resistant nature of their vegetative structures and their slow and intermittent reproduction or complete absence of reproduction. Whether they are capable of defending captive resources and have good enzymatic competence, which are other features of combative species, is largely unknown. However, they occupy diverse ecological niches, including aquatic habitats, soil, wood in various stages of decay, other decaying plant material, and dung. They also function as root and foliar pathogens, and many cause serious diseases in terms of host damage and economic loss, especially of roots, corms, and bulbs. Agonomycetes sometimes cause damage in commercial mushroom-growing environments, and *Papulaspora byssina* in particular is associated with the brown plaster mold problem in mushroom beds. *Armillaria*, a basidiomycete with a *Rhizomorpha* agonomycete state, is a severe parasite of a wide range of woody and herbaceous plants. *See* DEUTEROMYCOTINA; PLANT PATHOLOGY. [B.C.S.]

Agouti A large rodent that resembles the rabbit or hare in size and shape as well as in the elongated hindlegs, which make them well adapted for speed (see illustration). The agouti and the closely related smaller acouchi are inhabitants of clearings in

The agouti (*Dasyprocta aguti*), a rodent found In Mexico, South America, and the West Indies.

forested areas of the Amazon region. Some range into Central America and as far as the Guianas.

Thirteen species of agouti have been described, the most common being *Dasyprocta aguti*. Some authorities are of the opinion that all of these are varieties or subspecies of *D. aguti*. The acouchi is represented by two species, the green acouchi (*Myoprocta pratti*) and the red acouchi (*M. acouchy*). *See* RODENTIA. [C.B.C.]

Agricultural aircraft Aircraft designed, or adapted from a general utility airframe, for use in agriculture and forestry and for control of insect vectors of human, animal, and plant diseases. Agricultural aircraft have become an indispensable tool for high-productivity agriculture and have contributed to the worldwide crop production revolution. Aircraft use covers a wide range of agricultural crop and pest applications, including control of competing weeds and unwanted brush and trees, control of insect and disease pests, application of plant nutrients, and broadcast seeding of many crops. *See* FERTILIZER; PESTICIDE.

The principal advantages of either fixed- or rotary-wing aircraft for the treatment of crops lies with their ability to rapidly cover large crop acreages and to travel over rough terrain, irrigation structures, and wet fields. This timeliness factor is often considered critical to optimum pest control and effective crop protection. The primary disadvantage is their inability to direct the released material onto the target crop with the precision that can be accomplished with ground-based applications. Increasing limitations are being placed on aircraft use, especially when highly toxic crop chemicals are to be applied to small fields and where sensitive nontarget crops are grown nearby.

Application equipment is an integral part of agricultural aircraft. This includes hoppers to hold the material to be applied, pumps or spinning devices to move material from the hoppers to the spreading or spraying equipment, and spreading or spraying equipment for dry and wet materials, respectively. The aerodynamic wake or air dispersion produced by the action of the wing or helicopter rotor and the mass of air displaced by the aircraft in motion are utilized to aid in spreading either liquid or dry materials. The interaction of the wing or rotor length and the length of the spray boom, along with the strength of the wake and height of flight, controls the usable swath width laid down by the aircraft.

While larger, faster-flying (up to 140 mi/h or 225 km/h) aircraft can accomplish greater hourly productivity, other factors such as size and location of crop fields, distance to fields from suitable landing strips, and time lost in field turns also affect field productivity. Helicopters, which can turn quickly and can land and be serviced close to crop fields or even on landing docks on top of service trucks, can thus gain back some of the lowered productivity of these aircraft due to smaller load capacity and lower field speeds. However, it is the greater application precision and downblast from their rotary wing (at reduced forward speeds) that has generated the increased use of helicopters, in spite of their greater initial and operating costs. *See* AGRICULTURE; AIRPLANE; HELICOPTER. [N.B.A.]

Agricultural chemistry The science of chemical compositions and changes involved in the production, protection, and use of crops and livestock. As a basic science, it embraces, in addition to test-tube chemistry, all the life processes through which humans obtain food and fiber for themselves and feed for their animals. As an applied science or technology, it is directed toward control of those processes to increase yields, improve quality, and reduce costs. One important branch of it, chemurgy, is concerned chiefly with utilization of agricultural products as chemical raw materials.

The goals of agricultural chemistry are to expand understanding of the causes and effects of biochemical reactions related to plant and animal growth, to reveal opportunities for controlling those reactions, and to develop chemical products that will provide the desired assistance or control. Every scientific discipline that contributes to agricultural progress depends in some way on chemistry. Hence agricultural chemistry is not a distinct discipline, but a common thread that ties together genetics, physiology, microbiology, entomology, and numerous other sciences that impinge on agriculture.

Chemical materials developed to assist in the production of food, feed, and fiber include scores of herbicides, insecticides, fungicides, and other pesticides, plant growth regulators, fertilizers, and animal feed supplements. Chief among these groups from the commercial point of view are manufactured fertilizers, synthetic pesticides (including herbicides), and supplements for feeds. The latter include both nutritional supplements (for example, minerals) and medicinal compounds for the prevention or control of disease. *See* AGRICULTURAL SCIENCE (ANIMAL); AGRICULTURAL SCIENCE (PLANT); AGRICULTURE; FERTILIZER; HERBICIDE; PESTICIDE; SOIL. [R.N.H.]

Agricultural engineering A discipline concerned with solving the engineering problems of providing food and fiber for the people of the world. These problems include designing improved tools to work the soil and harvest the crops, as well as developing water supplies for agriculture and systems for irrigating and draining the land where necessary. Agricultural engineers design buildings in which to house animals or store grains. They also work on myriad problems of processing, packaging, transporting, and distributing the food and fiber products. Agricultural engineering combines the disciplines of mechanical, civil, electrical, and chemical engineering with a basic understanding of biological sciences and agricultural practices. Some agricultural engineers work directly with farmers. Most, however, work with the companies that manufacture and supply equipment, feeds, fertilizers, and pesticides. Others work for companies that provide services to farmers, such as developing irrigation and drainage systems or erecting buildings and facilities. Still others work with food-processing companies. *See* AGRICULTURAL BUILDINGS; AGRICULTURAL MACHINERY; AGRICULTURE. [R.E.Ga.]

Agricultural machinery Mechanized systems of food and fiber production used in agriculture. These systems extend from initial tillage of the soil through planting, cultural practices during the growing season, protection from pests, harvesting, conditioning, livestock feeding, and delivery for processing. The use of hydraulic power has made possible highly specialized mechanisms to perform intricate operations. Hydraulic power offers the advantages of being easily controlled and automated. Sophisticated technology is used to increase the precision needed in modern agriculture: lasers for laying out fields for surface irrigation systems; microprocessors for sensing and controlling intricate operations, such as controlling feed mixtures for dairy cows and grading fruits and vegetables; and electronic devices in the automation of many harvesters.

Primary and secondary tillage equipment, such as plows, disks, and harrows, are designed to prepare the seedbed and root zones for crop production. Multipurpose machines are used where a high degree of precision and specialization is needed.

The illustration shows a machine that may be used to simultaneously rototill the soil, form beds and irrigation furrows, incorporate a herbicide, and plant the seed in one trip across the field. Laser land-leveling machinery allows the farmer to prepare a field for surface irrigation by grading the field to an exact slope. *See* IRRIGATION (AGRICULTURE).

Agricultural planting equipment is commonly used for the planting of raw uncoated seed. For some crops, other types of planting equipment may be used to plant tubers, such as potatoes, and transplants, such as tomatoes. No-till planters have been developed for the planting of seed into undisturbed soil; no-till farming eliminates all primary and secondary tillage normally conducted between cropping years, and therefore the soil remains undisturbed.

Crop cultivation is accomplished primarily to rid the crop of competing weeds. Cultivation equipment is normally quite simple and is designed to cut, slice, bury, or rip out weeds.

Crop chemicals, such as fertilizers and pesticides, are routinely used in agricultural production. Liquid pesticides are commonly applied with high- or low-pressure sprayers mounted on tractors, trailers, trucks, and aircraft. Air-blast or orchard-type sprayers utilize a high-speed airstream to carry the liquid chemical to the surface being treated. Dry chemicals, such as fertilizers, are applied with either broadcast or band-type applicators. Broadcast applicators spread the chemical over the entire field surface at a prescribed rate, while band-type applicators apply the chemical at a prescribed rate in strips or bands across the field. *See* AGRICULTURAL AIRCRAFT; FERTILIZING.

Mechanized operations around farmsteads vary from very little on subsistence-type farms to nearly complete on larger commercial farms. These operations are for either crop conditioning or materials handling. The equipment is powered by electric motors if it is stationary, and by tractor hydraulics or power takeoff shafts if it is portable. Stationary equipment includes conveyors and grinders, and portable equipment includes feed wagons, mixers, and manure spreaders.

Self-propelled hay cubers compress hay into small cubes to make it easy to handle with conveyors. Practically all small grains are harvested by self-propelled combines that cut the crop and deliver the grain to a truck. Cotton harvesting is done by stripping the fiber-containing bolls from the plant or by rotating spindles that collect the fibers with a twisting action and release them in an airstream that carries them into a hopper.

The biggest demand for hand labor has been in the harvest of fruits and vegetables. Much research has been done on breeding of plants and on machine development to reduce hand labor, primarily during harvesting. Most successful attempts have utilized shaking of trees or vines to remove fruits. Most of these machines are nonselective, that is, all of the crop is harvested in one operation whether it is mature or not. Selection for color, maturity, and size is usually done by people on machines or at grading stations. Electronics are used for color maturity sorting on tomato harvesters. There are several selective harvesters in use, but on a very limited basis. *See* AGRICULTURAL SOIL AND CROP PRACTICES; AGRICULTURE; DAIRY MACHINERY. [J.W.Ru.; M.O'B.]

Multipurpose machine used for precision tillage, planting, bed shaping, and fertilizing in one pass, and for later bed shaping, cultivating, and fertilizing. (*Johnson Farm Machinery Co.*)

Agricultural meteorology A branch of meteorology that examines the effects and impacts of weather and climate on crops, rangeland, livestock, and various agricultural operations. The branch of agricultural meteorology dealing with atmospheric-biospheric processes occurring at small spatial scales and over relatively short time periods is known as micrometeorology, sometimes called crop micrometeorology for managed vegetative ecosystems and animal biometeorology for livestock operations. The branch that studies the processes and impacts of climatic factors over larger time and spatial scales is often referred to as agricultural climatology. *See* CLIMATOLOGY; MICROMETEOROLOGY.

Agricultural meteorology, or agrometeorology, addresses topics that often require an understanding of biological, physical, and social sciences. It studies processes that occur from the soil depths where the deepest plant roots grow to the atmospheric levels where seeds, spores, pollen, and insects may be found. Agricultural meteorologists characteristically interact with scientists from many disciplines.

Agricultural meteorologists collect and interpret weather and climate data needed to understand the interactions between vegetation and animals and their atmospheric environments. The climatic information developed by agricultural meteorologists is valuable in making proper decisions for managing resources consumed by agriculture, for optimizing agricultural production, and for adopting farming practices to minimize any adverse effects of agriculture on the environment. Such information is vital to ensure the economic and environmental sustainability of agriculture now and in the future. *See* WEATHER OBSERVATIONS.

Agricultural meteorologists also quantify, evaluate, and provide information on the impact and consequences of climate variability and change on agriculture. Increasingly, agricultural meteorologists assist policy makers in developing strategies to deal with climatic events such as floods, hail, or droughts and climatic changes such as global warming and climate variability.

Agricultural meteorologists are involved in many aspects of agriculture, ranging from the production of agronomic and horticultural crops, trees, and livestock to the final delivery of agricultural products to market. They study the energy and mass exchange processes of heat, carbon dioxide, water vapor, and trace gases such as methane, nitrous oxide, and ammonia, within the biosphere on spatial scales ranging from a leaf to a watershed and even to a continent. They study, for example, the photosynthesis, productivity, and water use of individual leaves, whole plants, and fields. They also examine climatic processes at time scales ranging from less than a second to more than a decade. [B.L.B.]

Agriculture The art and science of crop and livestock production. In its broadest sense, agriculture comprises the entire range of technologies associated with the production of useful products from plants and animals, including soil cultivation, crop and livestock management, and the activities of processing and marketing. The term agribusiness has been coined to include all the technologies that mesh in the total inputs and outputs of the farming sector. In this light, agriculture encompasses the whole range of economic activities involved in manufacturing and distributing the industrial inputs used in farming; the farm production of crops, animals, and animal products; the processing of these materials into finished products; and the provision of products at a time and place demanded by consumers.

Many different factors influence the kind of agriculture practiced in a particular area. Among these are climate, soil, water availability, topography, nearness to markets, transportation facilities, land costs, and general economic level. Climate, soil, water availability, and topography vary widely throughout the world. This variation brings about a wide range in agricultural production enterprises. Certain areas tend toward a specialized agriculture, whereas other areas engage in a more diversified agriculture. As new technology is introduced and adopted, environmental factors are less important in influencing agricultural production patterns. Continued growth in the world's population makes critical the continuing ability of agriculture to provide needed food and fiber.

The primary agricultural products consist of crop plants for human food and animal feed and livestock products. The crop plants can be divided into 10 categories: grain crops (wheat, for flour to make bread, many bakery products, and breakfast cereals; rice, for food; maize, for livestock feed, syrup, meal, and oil; sorghum grain, for livestock feed; and oats, barley, and rye, for food and livestock feed); food grain legumes (beans, peas, lima beans, and cowpeas, for food; and peanuts, for food and oil); oil seed crops (soybeans, for oil and high-protein meal; and linseed, for oil and high-protein meal); root and tuber crops (principally potatoes and sweet potatoes); sugar crops (sugarbeets and sugarcane); fiber crops (principally cotton, for fiber to make textiles and for seed to produce oil and high-protein meal); tree and small fruits; nut crops; vegetables; and forages (for support of livestock pastures and range grazing lands and for hay and silage crops). The forages are dominated by a wide range of grasses and legumes, suited to different conditions of soil and climate.

Livestock products include cattle, for beef, tallow, and hides; dairy cattle, for milk, butter, cheese, ice cream, and other products; sheep, for mutton (lamb) and wool; pigs, for pork and lard; poultry (chiefly chickens but also turkeys and ducks) for meat and eggs; and horses, primarily for recreation. *See* BEEF CATTLE PRODUCTION; DAIRY CATTLE PRODUCTION; POULTRY PRODUCTION; SHEEP; SWINE PRODUCTION. [J.J.]

Agroecosystem A model for the functionings of an agricultural system, with all inputs and outputs. An ecosystem may be as small as a set of microbial interactions that take place on the surface of roots, or as large as the globe. An agroecosystem may be at the level of the individual plant-soil-microorganism system, at the level of crops or herds of domesticated animals, at the level of farms or agricultural landscapes, or at the level of entire agricultural economies.

Characteristics. Agroecosystems differ from natural ecosystems in several fundamental ways. First, the energy that drives all autotrophic ecosystems, including agroecosystems, is either directly or indirectly derived from solar energy. However, the energy input to agroecosystems includes not only natural energy (sunlight) but also processed energy (fossil fuels) as well as human and animal labor. Second, biodiversity in agroecosystems is generally reduced by human management in order to channel as much energy and nutrient flow as possible into a few domesticated species. Finally, evolution is largely, but not entirely, through artificial selection where commercially desirable phenotypic traits are increased through breeding programs and genetic engineering. Agroecosystems are usually examined from a range of perspectives including energy flux, exchange of materials, nutrient budgets, and population and community dynamics.

Solar energy influences agroecosystem productivity directly by providing the energy for photosynthesis and indirectly through heat energy that influences respiration, rates of water loss, and the heat balance of plants and animals. *See* BIOLOGICAL PRODUCTIVITY; ECOLOGICAL ENERGETICS; PHOTOSYNTHESIS.

Nutrient uptake from soil by crop plants or weeds is primarily mediated by microbial processes. Some soil bacteria fix atmospheric nitrogen into forms that plants can assimilate. Other organisms influence soil structure and the exchange of nutrients, and still other microorganisms may excrete ammonia and other metabolic by-products that are useful plant nutrients. There are many complex ways that microorganisms influence nutrient cycling and uptake by plants. Some microorganisms are plant pathogens that reduce nutrient uptake in diseased plants. Larger organisms may influence nutrient uptake indirectly by modifying soil structure or directly by damaging plants. *See* SOIL MICROBIOLOGY.

Although agroecosystems may be greatly simplified compared to natural ecosystems, they can still foster a rich array of population and community processes such as herbivory, predation, parasitization, competition, and mutualism. Crop plants may compete among themselves or with weeds for sunlight, soil nutrients, or water. Cattle overstocked in a pasture may compete for forage and thereby change competitive interactions among pasture plants, resulting in selection for unpalatable or even toxic plants. Indeed, one important goal of farming is to find the optimal densities for crops and livestock. *See* HERBIVORY; POPULATION ECOLOGY; WEEDS.

Widespread use of synthetic chemical pesticides has bolstered farm production worldwide, primarily by reducing or eliminating herbivorous insect pests. Traditional broad-spectrum pesticides such as DDT, however, can have far-ranging impacts on agroecosystems. For instance, secondary pest outbreaks associated with the use of many traditional pesticides are not uncommon due to the elimination of natural enemies or resistance of pests to chemical control. Growers and pesticide developers in temperate regions have begun to focus on alternative means of control. Pesticide developers have begun producing selective pesticides, which are designed to target only pest species and to spare natural enemies, leaving the rest of the agroecosystem community intact. Many growers are now implementing integrated pest management programs that incorporate the new breed of biorational chemicals with cultural and other types of controls. *See* FOREST PEST CONTROL; PESTICIDE.

Genetic engineering. The last few decades have seen tremendous advances in molecular approaches to engineering desirable phenotypic traits in crop plants. Although artificially modifying crop plants is nothing new, the techniques used in genetic engineering allow developers to generate new varieties an order-of-magnitude faster than traditional plant breeding. In addition, genetic engineering differs from traditional breeding in that the transfer of traits is no longer limited to same-species organisms. Scientists are still assessing the effects that the widespread deployment of these traits may have on agroecosystems and natural ecosystems. There is some concern, for instance, that engineered traits may escape, via genes in pollen transferred by pollinators, and become established in weedy populations of plants in natural ecosystems, in some cases creating conservation management problems and new breeds of superweeds. As with pesticides, there is evidence that insects are already becoming resistant to some more widespread traits used in transgenic plants, such as the antiherbivore toxin produced by the bacterium *Bacillus thuringiensis*. *See* BIOTECHNOLOGY; GENETIC ENGINEERING. [C.R.Ca.; C.A.H.; J.E.Ba.]

Agronomy The science and study of crops and soils. Agronomy is the umbrella term for a number of technical research and teaching activities: crop physiology and management, soil science, plant breeding, and weed management frequently are included in agronomy; soil science may be treated separately; and vegetable and fruit crops generally are not included. Thus, agronomy refers to extensive field cultivation of plant species for human food, livestock and poultry feed, fibers, oils, and certain industrial products. *See* AGRICULTURE.

Agronomic studies include some basic research, but the specialists in this field concentrate on applying information from the more basic disciplines, among them botany, chemistry, genetics, mathematics, microbiology, and physiology. Agronomists also interact closely with specialists in other applied areas such as ecology, entomology, plant pathology, and weed science. The findings of these collaborative efforts are tested and recommended to farmers through agricultural extension agents or commercial channels to bring this knowledge into practice. This critical area is now focused on the efficiency of resource use, profitability of management practices, and minimization of the impact of farming on the immediate and the off-farm environment. *See* AGRICULTURAL SOIL AND CROP PRACTICES; AGROECOSYSTEM; SOIL CONSERVATION. [C.A.F.]

Aharonov-Bohm effect The predicted effect of an electromagnetic vector or scalar potential in electronic interference phenomena, in the absence of electric or magnetic fields on the electrons.

The fundamental equations of motion for a charged object are usually expressed in terms of the magnetic field $\vec{B}$ and the electric field $\vec{E}$. The force $\vec{F}$ on a charged particle can be conveniently written as in the equations below, where q is the particle's charge,

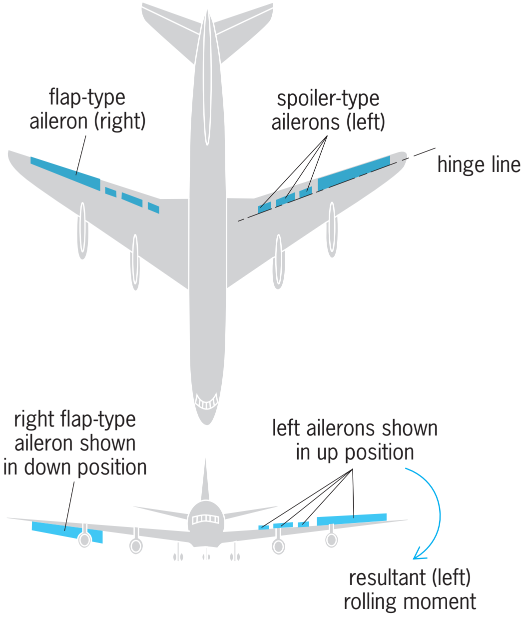
$$\vec{F} = q\vec{E} \qquad \vec{F} = q\vec{v} \times \vec{B}$$

$\vec{v}$ is its velocity, and the symbol × represents the vector product. Associated with $\vec{E}$ is a scalar potential V defined at any point as the work W necessary to move a charge from minus infinity to that point, $V = W/q$. Generally, only the difference in potentials between two points matters in classical physics, and this potential difference can be used in computing the electric field. Similarly, associated with $\vec{B}$ is a vector potential $\vec{A}$, a convenient mathematical aid for calculating the magnetic field. *See* CALCULUS OF VECTORS; ELECTRIC FIELD; MAGNETIC FIELD; POTENTIALS.

In quantum mechanics, however, the basic equations that describe the motion of all objects contain $\vec{A}$ and V directly, and they cannot be simply eliminated. Nonetheless, it was initially believed that these potentials had no independent significance. In 1959, Y. Aharonov and D. Bohm discovered that both the scalar and vector potentials should play a major role in quantum mechanics. They proposed two electron interference experiments in which some of the electron properties would be sensitive to changes of $\vec{A}$ or V, even when there were no electric or magnetic fields present on the charged particles. The absence of $\vec{E}$ and $\vec{B}$ means that classically there are no forces acting on the particles, but quantum-mechanically it is still possible to change the properties of the electron. These counterintuitive predictions are known as the Aharonov-Bohm effect.

Surprisingly, the Aharonov-Bohm effect plays an important role in understanding the properties of electrical circuits whose wires or transistors are smaller than a few micrometers. The electrical resistance in a wire loop oscillates periodically as the magnetic flux threading the loop is increased, with a period of h/e (where h is Planck's constant and e is the charge of the electron), the normal-metal flux quantum. In single wires, the electrical resistance fluctuates randomly as a function of magnetic flux. Both these observations, which were made possible by advances in the technology for fabricating small samples, reflect an Aharonov-Bohm effect. They have opened up a new field of condensed-matter physics because they are a signature that the electrical properties are dominated by quantum-mechanical behavior of the electrons, and that the rules of the classical physics are no longer operative. *See* QUANTUM MECHANICS. [R.A.Web.]

Aileron The hinged rear portion of an aircraft wing, moved differentially on each side of the aircraft to obtain lateral or roll control moments. The angular settings of the ailerons are controlled by the human or automatic pilot through the flight control system. Typical flap- and spoiler-type ailerons are shown in the illustration. *See* FLIGHT CONTROLS.



Flap- and spoiler-type ailerons on jet transport airplane.

The operating principles of ailerons are the same as for all trailing-edge hinged control devices. Deflection of an aileron changes the effective camber, or airfoil curvature relative to the wing chord, of the entire wing forward of the aileron. With the trailing edge deflected upward, reduced local flow velocities are produced on the upper wing surface, and increased local flow velocities are produced on the lower wing surface. By Bernoulli's law, this results in a reduction of lift over the portion of the wing forward of the aileron, and on the aileron itself. Conversely, trailing-edge down deflection of a flap-type aileron increases the lift in the same areas. Ailerons are located as close as possible to the wing tips, to maximize rolling moment by increasing the moment arm of the force due to the change in wing lift. In the case of flap-type ailerons, when the trailing edge is raised on one wing, say the left, the trailing edge of the aileron on the opposite or right wing is lowered by about the same amount. The decrease in lift on the left wing is accompanied by a lift increase on the right wing. While the net wing lift remains about the same, a rolling moment or torque about the aircraft's fore-and-aft axis develops in a left, or counterclockwise, direction as seen by the pilot.

Flap-type ailerons are replaced or supplemented by spoiler-type ailerons for a variety of reasons. Spoiler ailerons are usually installed forward of the landing flaps on commercial jet transports, in order to supplement aileron effectiveness during landing approaches, when the landing flaps are extended. Greatly reduced takeoff and landing speeds can be obtained by devoting the trailing edge of the entire wing to high-lift flaps. This is made possible by substituting spoilers for flap-type ailerons. [M.J.A.]

Air A predominantly mechanical mixture of a variety of individual gases enveloping the terrestrial globe to form the Earth's atmosphere. In this sense air is one of the three basic components, air, water, and land (atmosphere, hydrosphere, and lithosphere), that interblend to form the life zone at the face of the Earth. *See* ATMOSPHERE. [C.V.C.]

Air armament That category of weapons which are typically delivered on target by fixed or rotary-wing aircraft, with the exception of nuclear weapons. Specifically included are guns and ammunition, rockets, free-fall bombs, cluster weapons that consist of a dispenser and submunitions, air-to-air and air-to-surface guided weapons, mines, and antiradiation missiles. Nuclear weapons such as the air-launched cruise missile and nuclear bombs, which are delivered by aircraft, are considered strategic weapons, a specific class of air armament.

The most widely used aircraft guns outside the former Communist countries are the French DEFA and British Aden 30-mm guns, followed by the United States 20-mm M61 Vulcan. The most modern aircraft guns are the 27-mm Mauser developed for multirole use on the German, Italian, and British multirole combat aircraft (MRCA) Tornado, and the large 30-mm GAU-8 and

GAU-13 antiarmor guns which carry high-explosive incendiary (HEI) and armor-piercing incendiary (API) ammunition.

Free rockets, or unguided rockets, developed during World War II, are more accurate than bombs but less accurate than guns. Although rocket systems are often considered obsolete, virtually all major powers maintain one or more in their arsenal. *See* ROCKET.

Conventional bombs employing TNT or TNT-based mixtures have been made in many types and sizes. Armor-piercing bombs were designed for use against concrete fortifications and submarine pens. Demolition bombs have thin steel cases and maximum explosive loads. General-purpose bombs are a compromise between armor-piercing and demolition. Bombs have been made to deliver virtually anything against any type of target. Some examples are incendiary bombs to ignite wooden buildings; napalm or jellied gasoline for use against anything that can be damaged by flame; underwater bombs for use against hydroelectric dams; cluster bombs, which separate and disperse to saturate an area; and leaflet bombs to deliver propaganda.

An entirely new class of aircraft armament known as cluster weapons has evolved since the 1950s. It is partly an outgrowth of cluster bombs from World War II and partly a result of the realization that many targets, notably personnel and light vehicles, could be destroyed more efficiently with several small bombs than with one large bomb. The primary advantage of cluster weapons over unitaries is their large footprint or area covered, which compensates for delivery errors and target uncertainty errors incurred by unguided weapons.

Although not normally included as part of the field of aircraft armament, fire control is the term that covers the sighting, aiming, and computation which enables the pilot or aircrew to hit the target. Basically, it examines the conditions of the engagement and indicates when to release the armament in order to obtain hits.

Guided weapons is a generic term which applies to any of the previously described ballistic systems when they are deliberately perturbed from their ballistic path after launch in order to increase the probability of hitting a target. There are three fundamental problems in guided weapons: determining where the target is or will be, determining where the weapon is, and correcting the weapon's location to coincide with the target's location at the time of closest encounter. The first two problems are called guidance; the third, control. Control is usually accomplished by aerodynamic-control-surface deflection. *See* AUTOPILOT; FLIGHT CONTROLS.

There are five fundamental concepts of guidance, namely inertial guidance, command guidance, active guidance, semiactive guidance, and passive guidance, and many different implementations of each. In command guidance, the weapon system operator or on-board sensors observe the relative location of weapon and target and direct trajectory corrections. In an active guidance system, electromagnetic emissions, for example, radar, microwave, or laser, are transmitted from the weapon to the target, and the return energy reflections are measured to determine range and angle to the target. Semiactive guidance resembles active guidance except that the illumination of the target is provided by a designator not located on the weapon. Passive guidance uses the natural emissions radiating from targets to uniquely acquire a target and subsequently guide the weapon to the target. *See* LIDAR; RADAR.

The ultimate objective of a weapon system is to be completely autonomous. An example of an autonomous system is one combining inertial and passive or active terminal guidance, and the appropriate algorithms to acquire the target after launch without operator intervention. In this case, the weapon is launched into an area where targets are known to exist, and, upon reaching the area, the weapon searches and finds its own target, homes in on it, and destroys it. The trend toward weapons that can autonomously acquire targets allows weapons to be built that have a substantial standoff capability which increases the survivability of the launch platform, improves accuracy, increases proficiency, and reduces the logistical burden.

There are two classes of smart weapons. The first class consists of those guided weapons that possess some form of terminal guidance and home in on the target. Weapon systems in this class include laser-guided bombs. The second class of smart weapons includes those that autonomously acquire the target after launch, and are usually termed lock-on-after-launch, fire-and-forget, or brilliant weapons. [S.La.]

Air brake A friction type of energy-conversion mechanism used to retard, stop, or hold a vehicle or other moving element. The activating force is applied by a difference in air pressure. With an air brake, a slight effort by the operator can quickly apply full braking force. *See* FRICTION.

The air brake, operated by compressed air, is used in buses; heavy-duty trucks, tractors, and trailers; and off-road equipment. The air brake is required by law on locomotives and railroad cars. The wheel-brake mechanism is usually either a drum or a disk brake. The choice of an air brake instead of a mechanical, hydraulic, or electrical brake depends partly on the availability of an air supply and the method of brake control.

In a motor vehicle, the air-brake system consists of three subsystems: the air-supply, air-delivery, and parking/emergency systems. The air-supply system includes the compressor, reservoirs, governor, pressure gage, low-pressure indicator, and safety valve. The engine-driven compressor takes in air and compresses it for use by the brakes and other air-operated components. The compressor is controlled by a governor that maintains air compression within a preselected range. The compressed air is stored in reservoirs. The air-delivery system includes a foot-operated brake valve, one or more relay valves, the quick-release valve, and the brake chambers. The system delivers compressed air from the air reservoirs to the brake chambers, while controlling the pressure of the air. The amount of braking is thereby regulated. In the brake chambers, the air pressure is converted into a mechanical force to apply the brakes. As the pressure increases in each brake chamber, movement of the diaphragm pushrod forces the friction element against the rotating surface to provide braking. When the driver releases the brake valve, the quick-release valve and the relay valve release the compressed air from the brake chambers. The parking/emergency system includes a parking-brake control valve and spring brake chambers. These chambers contain a strong spring to mechanically apply the brakes (if the brakes are properly adjusted) when air pressure is not available. During normal vehicle operation, the spring is held compressed by system air pressure acting on a diaphragm. For emergency stopping, the air-brake system is split into a front brake system and a rear brake system. If air pressure is lost in the front brake system, the rear brake system will continue to operate. However, the supply air will be depleted after several brake applications. Loss of air pressure in the rear brake system makes the front brake system responsible for stopping the vehicle, until the supply air is depleted. [D.L.An.]

Air conditioning The control of certain environmental conditions including air temperature, air motion, moisture level, radiant heat energy level, dust, various pollutants, and microorganisms.

Comfort air conditioning refers to control of spaces to promote the comfort, health, or productivity of the inhabitants. Spaces in which air is conditioned for comfort include residences, offices, institutions, sports arenas, hotels, factory work areas, and motor vehicles. Process air-conditioning systems are designed to facilitate the functioning of a production, manufacturing, or operational activity.

A comfort air-conditioning system is designed to help maintain body temperature at its normal level without undue stress and to provide an atmosphere which is healthy to breathe. The heat-dissipating factors of temperature, humidity, air motion, and radiant heat flow must be considered simultaneously. Within limits, the same amount of comfort (or, more objectively, of heat-dissipating ability) is the result of a combination of these factors in an enclosure. Conditions for constant comfort are related to the operative temperature. The perception of comfort is related to one's metabolic heat production, the transfer of this heat to the environment, and the resulting physiological adjustments and body temperature.

Engineering of an air-conditioning system starts with selection of design conditions; air temperature and relative humidity are principal factors. Next, loads on the system are calculated. Finally, equipment is selected and sized to perform the indicated functions and to carry the estimated loads.

Each space is analyzed separately. A cooling load will exist when the sum of heat released within the space and transmitted to the space is greater than the loss of heat from the space. A heating load occurs when the heat generated within the space is less than the loss of heat from it. Similar considerations apply to moisture. *See* Air cooling.

The rate at which heat is conducted through the building envelope is a function of the temperature difference across the envelope and the thermal resistance of the envelope (R value). Overall R values depend on materials of construction and their thickness along the path of heat flow, and air spaces with or without reflectances and emittances, and are evaluated for walls and roofs exposed to outdoors, and basements or slab exposed to earth. In some cases, thermal insulations may be added to increase the R value of the envelope.

Solar heat loads are an especially important part of load calculation because they represent a large percentage of heat gain through walls, windows, and roofs, but are very difficult to estimate because solar irradiation is constantly changing. *See* Solar radiation.

Humidity as a load on an air-conditioning system is treated by the engineer in terms of its latent heat, that is, the heat required to condense or evaporate the moisture, approximately 1000 Btu/lb (2324 kilojoules/kg) of moisture. People at rest or at light work generate about 200 Btu/h (586 W). Steaming from kitchen activities and moisture generated as a product of combustion of gas flames, or from all drying processes, must be calculated. As with heat, moisture travels through the space envelope, and its rate of transfer is calculated as a function of the difference in vapor pressure across the space envelope and the permeance of the envelope construction. *See* Humidity control.

A complete air-conditioning system is capable of adding and removing heat and moisture and of filtering airborne substitutes, such as dust and odorants, from the space or spaces it serves. Systems that heat, humidify, and filter only, for control of comfort in winter, are called winter air-conditioning systems; those that cool, dehumidify, and filter only are called summer air-conditioning systems, provided they are fitted with proper controls to maintain design levels of temperature, relative humidity, and air purity. *See* Air filter.

Built-up or field-erected systems are composed of factory-built subassemblies interconnected by means such as piping, wiring, and ducting during final assembly on the building site. Their capacities range up to thousands of tons of refrigeration and millions of Btu per hour of heating. Most large buildings are so conditioned.

There are three principal types of central air-conditioning systems: all-air, all-water, and air-processed in a central air-handling apparatus. In one type of all-air system, called dual-duct, warm air and chilled air are supplied to a blending or mixing unit in each space. In a single-duct all-air system, air is supplied at a temperature for the space requiring the coldest air, then reheated by steam or electric or hot-water coils in each space. [R.L.K.; E.C.Sh.]

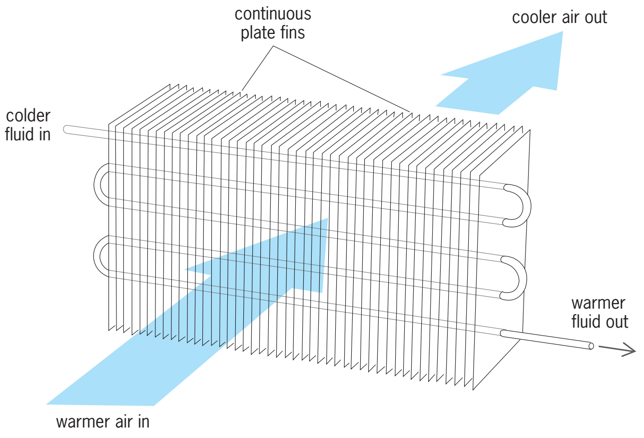
Air cooling Lowering of air temperature for comfort, process control, or food preservation. Air and water vapor occur together in the atmosphere. The mixture is commonly cooled by direct convective heat transfer of its internal energy (sensible heat) to a surface or medium at lower temperature. In the most compact arrangement, transfer is through a finned (extended surface) coil, metallic and thin, inside of which is circulating either chilled water, antifreeze solution, brine, or boiling refrigerant. The fluid acts as the heat receiver. Heat transfer can also be directly to a wetted surface, such as waterdroplets in an air washer or a wet pad in an evaporative cooler. *See* Air conditioning; Heat transfer.

For evaporative cooling, nonsaturated air is mixed with water. Some of the sensible heat transfers from the air to the evaporating water. The heat then returns to the airstream as latent heat of water vapor. The technique is employed for air cooling of machines where higher humidities can be tolerated; for cooling of industrial areas where high humidities are required, as in textile mills; and for comfort cooling in hot, dry climates, where partial saturation results in cool air at relatively low humidity. *See* Humidity.

In the evaporative cooler the air is constantly changed and the water is recirculated, except for that portion which has evaporated and which must be made up. Water temperature remains at the adiabatic saturation (wet-bulb) temperature. If water temperature is controlled, as by refrigeration, the leaving air temperature can be controlled within wide limits. Entering warm, moist air can be cooled below its dew point so that, although it leaves close to saturation, it leaves with less moisture per unit volume of air than when it entered. An apparatus to accomplish this is called an air washer. It is used in many industrial and comfort air-conditioning systems, and performs the added functions of cleansing the airstream of dust and of gases that dissolve in water, and in winter, through the addition of heat to the water, of warming and humidifying the air.

The most important form of air cooling is by finned coils, inside of which circulates a cold fluid or cold, boiling refrigerant (see illustration). The latter is called a direct-expansion (DX) coil. In most applications the finned surfaces become wet as condensation occurs simultaneously with sensible cooling. Usually, the required amount of dehumidification determines the temperature at which the surface is maintained and, where this results in air that is colder than required, the air is reheated to the proper temperature. Droplets of condensate are entrained in the airstream, removed by a suitable filter (eliminator), collected in a drain pan, and wasted.

Well water is available for air cooling in much of the world. Temperature of water from wells 30 to 60 ft (10 to 20 m) deep is approximately the average year-round air temperature in the locality of the well. For installations that operate only occasionally, such as some churches and meeting halls, water recirculated and cooled over ice offers an economical means for space cooling.



Typical extended-surface air-cooling coil.

Where electric power is readily available, the cooling function of the ice is performed by a mechanical refrigerator. [R.L.K.]

Air-cushion vehicle A transportation vehicle, also called a hovercraft, that rides slightly above the Earth's surface on a cushion of air. The air is continuously forced under the vehicle by a fan, generating the cushion that greatly reduces friction between the moving vehicle and the surface. The air is usually delivered through ducts and injected at the periphery of the vehicle in a downward and inward direction. The design of the vehicle's underside, combined with seals or skirts attached below the hull around the perimeter, restrains the air, creating the cushion. Because the vehicle is not in contact with the surface, it has six dimensions of motion. *See* Degree of freedom (mechanics); Ducted fan.

Generally, an air-cushion vehicle is an amphibious aerostatic craft capable of slight vertical lift regardless of forward speed. This type of air-cushion vehicle can operate equally well over ice, water, marsh, or relatively level land. A variation is the surface-effect ship (SES), which has rigid side hulls that ride in the water like a catamaran, containing the air cushion and reducing air loss. *See* Aerodynamic force; Aerostatics.

Commercial uses of air-cushion vehicles include transportation, supply, and pipeline and cable inspection and maintenance. In scheduled service, large air-cushion vehicles have been used to ferry cars and passengers across the English Channel (Fig. 1). Military missions of air-cushion vehicles, which can be lightly armed, include patrolling, and transporting troops and equipment from ship to shore and across the beach. Small air-cushion vehicles are available in single-seat, two-seat, and four-seat versions. Most are personal sport craft for recreational use on land or over calm water. Air-cushion vehicles of various sizes and maximum speeds are employed by government agencies in law enforcement, fire fighting, and disaster relief. *See* Naval surface ship.

Fig. 2. Wing-in-ground-effect craft used over water as a commuter vehicle. (*FlareCraft Corp.*)

Another type of vehicle relying on a cushion of air for support is the wing-in-ground-effect (WIG) craft, also called the wing-in-surface-effect (WISE) craft. Similar in design to an aircraft, the ground-effect craft is an aerodynamic vehicle that generally travels only over water and requires forward speed to provide lift. It is designed to take advantage of two characteristics of an airfoil moving through air while close to the surface: (1) Air pressure builds up under the wing, producing greater lift than if the wing were in conventional flight; and (2) the induced drag of the wing is less than in conventional flight because wingtip vortices are weaker and downwash angle decreases. The result is an increase in the ratio of lift to drag when a craft is flying in ground effect. *See* Aerodynamic force; Aerodynamics; Aircraft; Aircraft design; Airfoil; Airplane.

Several types and sizes of wing-in-ground-effect vehicles are available (Fig. 2). Some designs utilize composite construction and are comparable in performance with hydrofoils. *See* Hydrofoil craft. [D.L.An.]

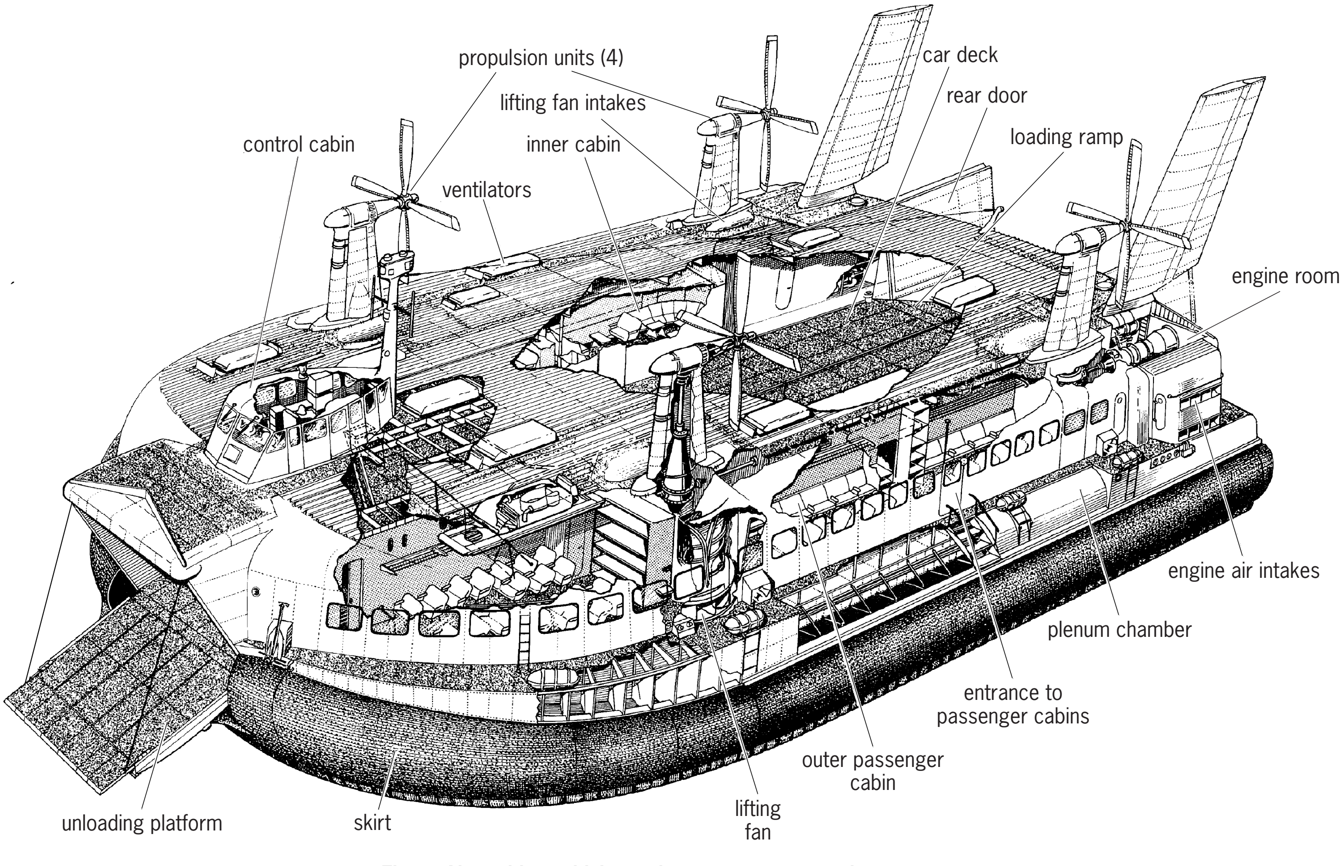


Fig. 1. Air-cushion vehicle used to transport cars and passengers across the English Channel. (*British Hovercraft Corp.*)

Air filter A component of most systems in which air is used for industrial processes, for ventilation, or for comfort air conditioning. The function of an air filter is to reduce the concentration of solid particles in the airstream to a level that can be tolerated by the process or space occupancy purpose. *See* VENTILATION.

Solid particles in the airstream range in size from 0.01 micrometer to objects that can be caught by ordinary fly screens, such as lint, feathers, and insects. The particles generally include soot, ash, soil, lint, and smoke, but may include almost any organic or inorganic material, even bacteria and mold spores. This wide variety of airborne contaminants, added to the diversity of systems in which air filters are used, makes it impossible to have one type that is best for all applications.

Three basic types of air filters are in common use: viscous impingement, dry, and electronic. The principles employed by these filters in removing airborne solids are viscous impingement, interception, impaction, diffusion, and electrostatic precipitation. Some filters utilize only one of these principles; others employ combinations. A fourth method, inertial separation, is finding increasing use as a result of the construction boom throughout most of the Middle East. [M.A.B.]

Air heater A component of a steam-generating unit that absorbs heat from the products of combustion after they have passed through the steam-generating and superheating sections. Heat recovered from the gas is recycled to the furnace by the combustion air and is absorbed in the steam-generating unit, with a resultant gain in overall thermal efficiency. Use of preheated combustion air also accelerates ignition and promotes rapid burning of the fuel. Air heaters often are used in conjunction with economizers, because the temperature of the inlet air is less than that of the feedwater to the economizer, and in this way it is possible to reduce further the temperature of flue gas before it is discharged to the stack. *See* BOILER ECONOMIZER. [G.W.K.]

Air mass In meteorology, an extensive body of the atmosphere which is relatively homogeneous horizontally. An air mass may be followed on the weather map as an entity in its day-to-day movement in the general circulation of the atmosphere. The expressions air mass analysis and frontal analysis are applied to the analysis of weather maps in terms of the prevailing air masses and of the zones of transition and interaction (fronts) which separate them.

The relative horizontal homogeneity of an air mass stands in contrast to sharper horizontal changes in a frontal zone. The horizontal extent of important air masses is reckoned in millions of square miles. In the vertical dimension an air mass extends at most to the top of the troposphere, and frequently is restricted to the lower half or less of the troposphere. *See* FRONT; METEOROLOGY; WEATHER MAP.

The occurrence of air masses as they appear on the daily weather maps depends upon the existence of air-mass source regions, areas of the Earth's surface which are sufficiently uniform that the overlying atmosphere acquires similar characteristics throughout the region. *See* ATMOSPHERIC GENERAL CIRCULATION.

The thermodynamic properties of air mass determine not only the general character of the weather in the extensive area that it covers, but also to some extent the severity of the weather activity in the frontal zone of interaction between air masses. Those properties which determine the primary weather characteristics of an air mass are defined by the vertical distribution of water vapor and heat (temperature). On the vertical distribution of water vapor depend the presence or absence of condensation forms and, if present, the elevation and thickness of fog or cloud layers. On the vertical distribution of temperature depend the relative warmth or coldness of the air mass and, more importantly, the vertical gradient of temperature, known as the lapse rate. The lapse rate determines the stability or instability of the air mass for thermal convection and consequently, the stratiform or convective cellular structure of the cloud forms and precipitation. The most unstable moist air mass is characterized by severe turbulence and heavy showers or thundershowers. In the most stable air mass there is observed an actual increase (inversion) of temperature with increase of height at low elevations. *See* TEMPERATURE INVERSION. [H.C.Wi.; E.Ke.]

Air navigation The process of planning and directing the progress of an aircraft between selected geographic points or over a selected route. The primary tasks involved are planning the flight, guiding it safely along the desired route, conforming with the rules of flight and with special procedures such as noise abatement, and maximizing fuel efficiency.

The simplest form of air navigation is pilotage, in which the pilot directs the aircraft by visual reference to objects on the ground. More complex methods rely upon navigational aids external to the aircraft or upon self-contained, independent systems. *See* PILOTAGE.

Dead reckoning is the process of estimating one's current position from measurements of the change in position since the last accurate position fix. In an aircraft, dead reckoning requires an airspeed indicator, outside-air-temperature gage, altimeter, clock, compass, and chart (map). The high accuracy and the increasing availability of real-time satellite based position fixes will eventually relegate dead reckoning to a backup role used primarily during outages of high quality satellite signals. *See* DEAD RECKONING.

Flight planning. Air navigation begins with a flight plan. For a flight in visual meteorological conditions (VMC), a simple plan may start with drawing a course line on a specially designed aeronautical chart between the point of departure and the destination. From the chart and the course line, the pilot, using a protractor, determines the true course (in degrees clockwise from true north), magnetic variation, and distance to be flown, usually in nautical miles. Following a preflight weather briefing, the pilot has the necessary facts to prepare a simple flight plan: wind direction and velocity, which were included in the briefing; true course, which was determined from the course line on the chart; and true airspeed, which is calculated by applying the corrections for temperature and altitude to the indicated airspeed. With the wind, true course, and true airspeed, the pilot can construct a wind triangle to determine the effect of the wind on speed and heading. With the planned groundspeed and the distance to be flown in miles, the pilot can compute the flight time and the fuel required. Extra fuel is added to assure an adequate reserve upon landing.

The process assumes greater complexity for a higher-performance aircraft, for a longer flight, or for a flight in adverse weather. The flight plan of a commercial jet is commonly prepared on a large specially programmed computer.

Air navigation is three-dimensional, and selection of a flight altitude is an important part of the planning process. Light, piston-engine aircraft are usually operated at altitudes of 10,000 ft (3000 m) or less, while jet aircraft commonly operate at much higher altitudes, where they may take advantage of the jet's increased fuel economy. During flight planning for large turboprop and jet aircraft, the time en route and the fuel used at various altitudes or over different routes are often compared to select the optimum altitude and route.

Altimetry. Aircraft altitude may be obtained from a barometric altimeter, a radio altimeter, or the Global Positioning System (GPS). A barometric altimeter translates the linear pressure changes experienced during climbs or descents into an indication of aircraft altitude. A radio altimeter (also known as a radar altimeter) shows actual altitude above the terrain immediately below the aircraft. The Global Positioning System is designed to provide accurate altitude information, unaffected by the errors found in barometric altimetry.

Navigation charts. All navigation requires special maps or charts such as topographic maps intended for pilotage or radio navigation charts intended to be used with ground radio aids. Aeronautical maps such as sectional charts show terrain contours

Electronic navigation systems

System	Frequency band
VOR*	108–118 MHz
DME*, TACAN	960–1215 MHz
ILS localizer*	108–112 MHz
ILS glideslope*	329–335 MHz
Doppler radar	10–20 GHz
Loran-C	90–110 kHz
MLS	5.0–5.25 GHz
GPS	1227, 1575 MHz
ADF/NDB*	190–1600 kHz
Weather radar	5, 9 GHz

*Internationally standardized systems.

and the elevation of significant terrain and other obstacles, such as mountain peaks, buildings, and television towers.

Operational air navigation. The operational phase of air navigation commences with the preflight cockpit check of clocks, radios, compasses, and other flight and navigation equipment.

After the flight is on course toward the first fix, the pilot's primary navigational task is to assure that the aircraft stays on course. If navigation is by pilotage, the pilot frequently checks the aircraft's position by reference to topographic features on the aeronautical chart being used, and the aircraft's heading is corrected as necessary to follow the course. Using dead reckoning, the pilot estimates the time that the aircraft is expected to be over the next fix, based on the speed thus far made good and the speed anticipated over the next segment.

The most common form of en route navigation over land masses in the western world uses a network of very high-frequency (VHF) omnidirectional radio range (VOR) stations. VOR transmitters are spaced at strategic intervals, averaging about 100 mi (160 km) between stations within the United States, but sometimes much farther apart. Designated routes between VOR stations are referred to as airways.

VOR transmitters emit a directional signal which can be received and interpreted by suitably equipped aircraft. The pilot can then determine the direction from the ground station to the aircraft, measured in degrees magnetic and referred to as a radial. Distance from the station is displayed when a distance-measuring equipment (DME) transmitter is colocated with the VOR. An airway is defined by a series of VOR stations along an airway route. Modern automatic pilots can follow the selected VOR radial automatically, leaving the human pilot to monitor the flight and make necessary adjustments as succeeding stations are selected along the route. *See* Autopilot; Distance-measuring equipment; VOR (VHF omnidirectional range).

A high-altitude jet starts descending miles from the landing airport. Unpressurized aircraft carrying passengers fly much lower, but their descent must be more gradual to minimize passenger discomfort in adjusting to the change in atmospheric pressure. Regardless of the aircraft type, the pilot estimates as accurately as possible the time and point to start descending. Every instrument approach for landing has its own chart, containing such things as the radio frequency and identification of the aids to be used, altitudes to be observed at various points during the approach, heading of the final approach course, minimum weather conditions required for the approach, missed approach instructions, and airport altitude.

The preferred aid for instrument landing use is ILS. It consists of two separate radio beams: one called the localizer is aligned very precisely with the runway centerline, and the other called the glideslope is projected upward at a slight angle from the landing touchdown point on the runway. By following the two beams very closely on the cockpit instruments, the pilot can line up with the runway and descend safely for landing, regardless of weather.

Additional navigation aids and systems. The navigation systems discussed thus far—VOR for en route use and ILS for terminal use—are sometimes augmented or replaced by other navigational equipment and systems. These systems are particularly useful for long-distance flights or when more conventional navigational aids are minimal or nonexistent. The table lists the principal frequency bands that are used by the electronic systems discussed, and indicates which systems are internationally standardized. [D.E.C.]

Air pollution The presence in the atmospheric environment of natural and artificial substances that affect human health or well-being, or the well-being of any other specific organism. Pragmatically, air pollution also applies to situations where contaminants impact structures and artifacts or esthetic sensibilities (such as visibility or smell). Most artificial impurities are injected into the atmosphere at or near the Earth's surface. The lower atmosphere (troposphere) cleanses itself of some of these pollutants in a few hours or days as the larger particles settle to the surface and soluble gases and particles encounter precipitation or are removed through contact with surface objects. Unfortunately, removal of some pollutants (for example, sulfates and nitrates) by precipitation and dry deposition results in acid deposition, which may cause serious environmental damage. Also, mixing of the pollutants into the upper atmosphere may dilute the concentrations near the Earth's surface, but can cause long-term changes in the chemistry of the upper atmosphere, including the ozone layer. *See* Atmosphere; Troposphere.

Types of sources. Sources may be characterized in a number of ways. First, a distinction may be made between natural and anthropogenic sources. Another frequent classification is in terms of stationary (power plants, incinerators, industrial operations, and space heating) and moving (motor vehicles, ships, aircraft, and rockets) sources. Another classification describes sources as point (a single stack), line (a line of stacks), or area (city).

Different types of pollution are conveniently specified in various ways: gaseous, such as carbon monoxide, or particulate, such as smoke, pesticides, and aerosol sprays; inorganic, such as hydrogen fluoride, or organic, such as mercaptans; oxidizing substances, such as ozone, or reducing substances, such as oxides of sulfur and oxide s of nitrogen; radioactive substances, such as iodine-131; inert substances, such as pollen or fly ash; or thermal pollution, such as the heat produced by nuclear power plants.

Air contaminants are produced in many ways and come from many sources; it is difficult to identify all the various producers. Also, for some pollutants such as carbon dioxide and methane, the natural emissions sometimes far exceed the anthropogenic emissions.

Both anthropogenic and natural emissions are variable from year to year, depending on fuel usage, industrial development, and climate. In some countries where pollution control regulations have been implemented, emissions have been significantly reduced. For example, in the United States sulfur dioxide emissions dropped by about 30% between 1970 and 1992, and carbon monoxide (CO) emissions were cut by over 30% in the same period. However, in some developing countries emissions continually rise as more cars are put on the road and more industrial facilities and power plants are constructed. In dry regions, natural emissions of nitrogen oxides (NO_x), carbon dioxide (CO_2), and hydrocarbons can be greatly increased during a season with high rainfall and above-average vegetation growth.

The anthropogenic component of most estimates of the methane budget is about two-thirds. Ruminant production and emissions from rice paddies are regarded as anthropogenic because they result from human agricultural activities. The perturbations to carbon dioxide since the industrial revolution are also principally the result of human activities. These emissions have not yet equilibrated with the rest of the carbon cycle and so have had a profound effect on atmospheric levels, even though emissions from fossil fuel combustion are dwarfed by natural emissions.

Effects. The major concern with air pollution relates to its effects on humans. Since most people spend most of their time indoors, there has been increased interest in air-pollution concentrations in homes, workplaces, and shopping areas. Much of the early information on health effects came from occupational health studies completed prior to the implementation of general air-quality standards.

Air pollution principally injures the respiratory system, and health effects can be studied through three approaches, clinical, epidemiological, and toxicological. Clinical studies use human subjects in controlled laboratory conditions, epidemiological studies assess human subjects (health records) in real-world conditions, and toxicological studies are conducted on animals or simple cellular systems. Of course, epidemiological studies are the most closely related to actual conditions, but they are the most difficult to interpret because of the lack of control and the subsequent problems with statistical analysis. Another difficulty arises because of differences in response among different people. For example, elderly asthmatics are likely to be more strongly affected by sulfur dioxide than the teenage members of a hiking club. *See* EPIDEMIOLOGY.

Damage to vegetation by air pollution is of many kinds. Sulfur dioxide may damage field crops such as alfalfa and trees such as pines, especially during the growing season (Fig. 1). Both hydrogen fluoride (HF) and nitrogen dioxide (NO_2) in high concentrations have been shown to be harmful to citrus trees and ornamental plants, which are of economic, importance in central Florida. Ozone and ethylene are other contaminants that cause damage to certain kinds of vegetation.

Air pollution can affect the dynamics of the atmosphere through changes in longwave and shortwave radiation processes. Particles can absorb or reflect incoming short-wave solar radiation, keeping it from the Earth's surface during the day. Greenhouse gases can absorb long-wave radiation emitted by the Earth's surface and atmosphere.

Carbon dioxide, methane, fluorocarbons, nitrous oxides, ozone, and water vapor are important greenhouse gases. These represent a class of gases that selectively absorb long-wave radiation. This effect warms the temperature of the Earth's atmosphere and surface higher than would be found in the absence of an atmosphere (the greenhouse effect). Because the amount of greenhouse gases in the atmosphere is rising, there is a possibility that the temperature of the atmosphere will gradually rise, possibly resulting in a general warming of the global climate over a time period of several generations. *See* GREENHOUSE EFFECT.

Researchers are also concerned with pollution of the stratosphere (10–50 km or 6–30 mi above the Earth's surface) by aircraft and by broad surface sources. The stratosphere is important, because it contains the ozone layer, which absorbs part of the Sun's short-wave radiation and keeps it from reaching the surface. If the ozone layer is significantly depleted, an increase in skin cancer in humans is expected. Each 1% loss of ozone is estimated to increase the skin cancer rate 3–6%. *See* STRATOSPHERE.

Visibility is reduced as concentrations of aerosols or particles increase. The particles do not just affect visibility by themselves but also act as condensation nuclei for cloud or haze formation. In each of the three serious air-pollution episodes discussed above, smog (smoke and fog) were present with greatly reduced visibility.

Chemistry. Air pollution can be divided into primary and secondary compounds, where primary pollutants are emitted directly from sources (for example, carbon monoxide, sulfur dioxide) and secondary pollutants are produced by chemical reactions between other pollutants and atmospheric gases and particles (for example, sulfates, ozone). Most of the chemical transformations are best described as oxidation processes. In many cases these secondary pollutants can have significant environmental effects, such as acid rain and smog.

Smog is the best-known example of secondary pollutants formed by photochemical processes, as a result of primary emissions of nitric oxide (NO) and reactive hydrocarbons from anthropogenic sources such as transportation and industry as well as natural sources. Energy from the Sun causes the formation of nitrogen dioxide, ozone (O_3), and peroxyacetalnitrate, which cause eye irritation and plant damage.

It has been shown that when emissions of sulfur dioxide and nitrogen oxide from tall power plant and other industrial stacks are carried over great distances and combined with emissions from other areas, acidic compounds can be formed by complex chemical reactions. In the absence of anthropogenic pollution sources, the average pH of rain is around 5.6 (slightly acidic). In the eastern United States, acid rain with a pH less than 5.0 has been measured and consists of about 65% dilute sulfuric acid, 30% dilute nitric acid, and 5% other acids. [S.R.H.; P.J.S.]

Air pollution, indoor The presence of gaseous and particulate contaminants in the indoor environment. Most pollution is due to human (anthropomorphic) sources. Natural sources do exist, including plants, animals, and other living organisms, and water sources that release various chemical aerosols. Contamination can occur from infiltration indoors of atmospheric pollutants generated outdoors, and thus the indoor environment is affected by meteorological conditions.

Natural sources are soils and water that release radon progeny, volatile organic compounds, fungi, and such. Chemical releases (emissions) originate from various types of appliances, combustion sources (including those in garages), building materials and water, and living organisms that release allergens (for example, dander from pets). Carbon dioxide (CO_2) is generated by combustion and living organisms. Other sources involve molds, microorganisms (such as bacteria and viruses), insects and arthropods, and pollen from outdoor and indoor plants. Human activity has been noted to increase air contamination from all of these sources. Some pollutants are individually generated such as tobacco smoke or are generated through use of consumer products. *See* PARTICULATES; RADON.

The generation and behavior of pollutants from sources in enclosed environments are also affected by most meteorological factors. Indoor environments are often sealed to the extent that the weather is cold or hot. Infiltration of pollutants is affected also by climate, temperature, humidity, barometric pressure, and wind speed and direction. The small particles and the gases that infiltrate most, that is, nitrogen oxide (NO_x) and volatile organic compounds, are affected by outdoor concentrations, tightness (being sealed, with little air exchange), operation of heating and cooling systems, convection currents, full growth (or lack thereof) of local trees and shrubs, and so forth. Indoor environments also possess individual characteristics of ventilation, dispersion, and deposition. Some gases, for example, sulfur dioxide (SO_2) and ozone (O_3), infiltrating the indoor environment are absorbed readily by materials and exist in high concentrations only when the outdoor concentrations are very high. Chemical-physical mass-balance models are used to estimate pollutant concentrations, as are statistical models. *See* AEROSOL; OZONE. [M.D.L.]

Air pressure The force per unit area that the air exerts on any surface in contact with it, arising from the collisions of the air molecules with the surface. It is equal and opposite to the pressure of the surface against the air, which for atmospheric air in normal motion approximately balances the weight of the atmosphere above, about 15 pounds per square inch (psi) at sea level. It is the same in all directions and is the force that balances the weight of the column of mercury in the Torricellian barometer, commonly used for its measurement. *See* BAROMETER.

The units of pressure traditionally used in meteorology are based on the bar, defined as equal to 1,000,000 dynes/cm^2. One bar equals 1000 millibars or 100 centibars.

In the meter-kilogram-second or International System of Units (SI), the unit of force, the pascal (Pa), is equal to 1 newton/m^2. One millibar equals 100 pascals. The normal pressure at sea level is 1013.25 millibars or 101.325 kilopascals.

Also widely used in practice are units based on the height of the mercury barometer under standard conditions, expressed commonly in millimeters or in inches. The standard atmosphere (760 mmHg) is also used as a unit, mainly in engineering, where large pressures are encountered. The following equivalents show the conversions between the commonly used units of pressure, where $(\text{mmHg})_n$ and $(\text{in. Hg})_n$ denote the millimeter and inch of mercury, respectively, under standard (normal) conditions, and where $(\text{kg})_n$ and $(\text{lb})_n$ denote the weight of a standard kilogram and pound mass, respectively, under standard gravity.

$$\begin{aligned}
1\ \text{kPa} &= 10\,\text{millibars} = 1000\,\text{N/m}^2 \\
&= 7.50062\,(\text{mmHg})_n \\
&= 0.295300\,(\text{in. Hg})_n \\
1\ \text{millibar} &= 100\,\text{Pa} = 1000\,\text{dynes/cm}^2 \\
&= 0.750062\ (\text{mmHg})_n \\
&= 0.0295300\ (\text{in. Hg})_n \\
1\ \text{atm} &= 101.325\ \text{kPa} = 1013.25\ \text{millibars} \\
&= 760\ (\text{mmHg})_n = 29.9213\ (\text{in. Hg})_n \\
&= 14.6959\ (\text{lb})_n/\text{in.}^2 \\
&= 1.03323\ (\text{kg})_n/\text{cm}^2 \\
1\,(\text{mmHg})_n &= 1\ \text{torr} = 0.03937008\,(\text{in. Hg})_n \\
&= 1.333224\ \text{millibars} \\
&= 133.3224\ \text{Pa} \\
1\ (\text{in. Hg})_n &= 33.8639\ \text{millibars} \\
&= 25.4\ (\text{mmHg})_n \\
&= 3.38639\ \text{kPa}
\end{aligned}$$

Because of the almost exact balancing of the weight of the overlying atmosphere by the air pressure, the latter decreases with height. A standard equation is used in practice to calculate the vertical distribution of pressure with height above sea level. The temperature distribution in a standard atmosphere, based on mean values in middle latitudes, has been defined by international agreement. The use of the standard atmosphere yields a definite relation between pressure and height. This relation is used in all altimeters which are basically barometers of the aneroid type. The difference between the height estimated from the pressure and the actual height is often considerable; but since the same standard relationship is used in all altimeters, the difference is the same for all altimeters at the same location, and so causes no difficulty in determining the relative position of aircraft. Mountains, however, have a fixed height, and accidents have been caused by the difference between the actual and standard atmosphere. *See* ALTIMETER.

In addition to the large variation with height, atmospheric pressure varies in the horizontal and with time. The variations of air pressure at sea level, estimated in the case of observations over land by correcting for the height of the ground surface, are routinely plotted on a map and analyzed, resulting in the familiar weather map representation with its isobars showing highs and lows. The movement of the main features of the sea-level pressure distribution, typically from west to east, produces characteristic fluctuations of the pressure at a fixed point, varying by a few percent within a few days. Smaller-scale variations of sea-level pressure, too small to appear on the ordinary weather map, are also present. These are associated with various forms of atmospheric motion, such as small-scale wave motion and turbulence. Relatively large variations are found in and near thunderstorms, the most intense being the low-pressure region in a tornado. The pressure drop within a tornado can be a large fraction of an atmosphere, and is the principal cause of the explosion of buildings over which a tornado passes. *See* WEATHER MAP.

It is a general rule that in middle latitudes at localities below 1000 m (3280 ft) in height above sea level, the air pressure on the continents tends to be slightly higher in winter than in spring, summer, and autumn; whereas at considerably greater heights on the continents and on the ocean surface, the reverse is true.

The practical importance of air pressure lies in its relation to the wind and weather. It is because of these relationships that pressure is a basic parameter in weather forecasting, as is evident from its appearance on the ordinary weather map.

The large-scale variations of pressure at sea level shown on a weather map are associated with characteristic patterns of vertical motion of the air, which in turn affect the weather. Descent of air in a high heats the air and dries it by adiabatic compression, giving clear skies, while the ascent of air in a low cools it and causes it to condense and produce cloudy and rainy weather. These processes at low levels, accompanied by others at higher levels, usually combine to justify the clear-cloudy-rainy marking on the household barometer. [R.J.D.; E.Ke.]

Air register A device attached to an air-distributing duct for the purpose of discharging air into the space to be heated or cooled. These openings are referred to as registers, diffusers, supply outlets, or grills (*see* illustration). By common acceptance, a register is an opening provided with means for discharging the air in a confined jet, whereas a diffuser is an outlet which discharges the air in a spreading jet. Both registers and diffusers may be placed at a number of locations in a room, including the floor, baseboard, low on the sidewall, window sill, high on the sidewall, or ceiling.

One of the more common diffusers, a round ceiling type. (*Titus Manufacturing Corp.*)

For heating, the preferred location is in the floor, at the baseboard, or at the low sidewall of the outside wall, preferably under a window. For cooling, the preferred location is high on the inside wall or the ceiling. For year-round air conditioning in homes, a compromise location is the floor, baseboard, or low sidewall at the exposed wall, especially if adequate air velocity in an upward direction is provided at the supply outlet. [S.Ko.]

Air separation Separation of atmospheric air into its primary constituents. Nitrogen, oxygen, and argon are the primary constituents of air. Small quantities of neon, helium, krypton, and xenon are present at constant concentrations and can be separated as products. Varying quantities of water, carbon dioxide, hydrocarbons, hydrogen, carbon monoxide, and trace environmental impurities (sulfur and nitrogen oxides, chlorine) are present depending upon location and climate. Typical quantities are shown in the table. These impurities are removed during air separation to maximize efficiency and avoid hazardous operation. *See* AIR; ARGON; HELIUM; KRYPTON; NEON; XENON.

Three different technologies are used for the separation of air: cryogenic distillation, ambient temperature adsorption, and membrane separations. The latter two have evolved to full commercial status. Membrane technology is economical for the production of nitrogen and oxygen-enriched air (up to about 40% oxygen) at small scale. Adsorption technology produces nitrogen

Composition of dry air

Component	Percent by volume	Component	Parts per million by volume
Nitrogen	78.084	Carbon dioxide	350–400
Oxygen	20.946	Neon	18.2
Argon	0.934	Helium	5.2
		Krypton	1.1
		Xenon	0.09
		Methane	1–15
		Acetylene	0–0.5
		Other hydrocarbons	0–5

and medium-purity oxygen (85–95% oxygen) at flow rates up to 100 tons/day. The cryogenic process can generate oxygen or nitrogen at flows of 2500 tons/day from a single plant and make the full range of products.

Air separation is a major industry. Nitrogen and oxygen rank second and third in the scale of production of commodity chemicals; and air is the primary source of argon, neon, krypton, and xenon. Oxygen is used for steel, chemicals manufacture, and waste processing. Important uses are in integrated gasification combined cycle production of electricity, waste water treatment, and oxygen-enriched combustion. Nitrogen provides inert atmospheres for fuel, steel, and chemical processing and for the production of semiconductors. [R.M.Th.]

Air temperature The temperature of the atmosphere represents the average kinetic energy of the molecular motion in a small region, defined in terms of a standard or calibrated thermometer in thermal equilibrium with the air. Many different types of thermometer are used for the measurement of air temperature, the most common depending on the expansion of mercury with temperature, the variation of electrical resistance with temperature, or the thermoelectric effect (thermocouple). *See* TEMPERATURE; THERMOMETER.

The temperature of a given small mass of air varies with time because of heat added or subtracted from it, and also because of work done during changes of volume.

The rate at which the temperature changes at a particular point, that is, as measured by a fixed thermometer, depends on the movement of air as well as physical processes such as absorption and emission of radiation, heat conduction, and changes of phase of water involving latent heat of condensation and freezing. The large changes of air temperature from day to day are mainly due to the horizontal movement of air, bringing relatively cold or warm air masses to a particular point, as the large-scale pressure-wind systems move across the weather map. *See* AIR MASS; AIR PRESSURE.

Temperatures near the surface are read at one or more fixed times daily, and the day's extremes are obtained from special maximum and minimum thermometers, or from the trace (thermogram) of a continuously recording instrument (thermograph). The average of these two extremes, technically the midrange, is considered in the United States to be the day's average temperature. The true daily mean, obtained from a thermogram, is closely approximated by the mean of 24 hourly readings, but may differ from the midrange by 1 or 2°F (0.6 or 1°C), on the average. In many countries temperatures are read daily at three or four fixed times, so that their weighted mean closely approximates the true daily mean.

Averages of daily maximum and minimum temperature for a single month for many years give mean daily maximum and minimum temperatures for that month. The average of these values is the mean monthly temperature, while their difference is the mean daily range for that month. Monthly means, averaged through the year, give the mean annual temperature; the mean annual range is the difference between the hottest and coldest mean monthly values. The hottest and coldest temperatures in a month are the monthly extremes; their averages over a period of years give the mean monthly maximum and minimum (used extensively in Canada), while the absolute extremes for the month (or year) are the hottest and coldest temperatures ever observed. The interdiurnal range or variability for a month is the average of the successive differences, regardless of sign, in daily temperatures.

Over the oceans the mean daily, interdiurnal, and annual ranges are slight, because water absorbs the insolation and distributes the heat through a thick layer. In tropical regions the interdiurnal and annual ranges over the land are small also, because the annual variation in insolation is relatively small. The daily range also is small in humid tropical regions, but may be large (up to 40°F or 22°C) in deserts. Interdiurnal and annual ranges increase generally with latitude, and also with distance from the ocean; the mean annual range defines continentality. The daily range depends on aridity, altitude, and noon Sun elevation. *See* ATMOSPHERE; INSOLATION; RADIATION. [R.J.D.]

Air-traffic control A service to promote the safe, orderly, and expeditious flow of air traffic. Safety is principally a matter of preventing collisions with other aircraft, obstructions, and the ground; assisting aircraft in avoiding hazardous weather; assuring that aircraft do not operate in airspace where operations are prohibited; and assisting aircraft in distress. Orderly and expeditious flow assures the efficiency of aircraft operations along the routes selected by the operator. It is provided through the equitable allocation of system resources to individual flights.

In the United States, air-traffic control (ATC) is the product of the National Airspace System (NAS), comprising airspace; air navigation facilities and equipment; airports and landing areas; aeronautical charts, information, and publications; rules, regulations, and procedures; technical information; and personnel.

Flight rules. Two principal categories of rules governing air traffic are visual flight rules (VFR) and instrument flight rules (IFR). Visual flight rules govern the procedures for conducting flight where the visibility, the ceiling, and the aircraft distance from clouds are equal to or greater than established minima. Ceiling is the height above the Earth's surface of the lowest layer of clouds or obscuring phenomenon that significantly restricts visibility. The minima for operation under visual flight rules vary by airspace. In controlled airspace, the ceiling must be at least 1000 ft (305 m) and the visibility must be at least 3 statute miles (4830 m). The aircraft must remain clear of clouds, at least 500 ft (150 m) below, 1000 ft (305 m) above, and 2000 ft (610 m) horizontally. Instrument flight rules go into effect when visibility, distance from clouds, and ceiling conditions are less than the minima specified for visual flight rules. To operate under these rules, the pilot must pass an instrument flight examination and have an adequately instrumented aircraft.

Aircraft operating under visual flight rules (VFR aircraft) maintain separation from other aircraft visually. IFR aircraft in controlled airspace operate in accordance with clearances and instructions provided by air-traffic controllers for the purpose of maintaining separation and expediting the flow of traffic. Flight crews operating under instrument flight rules are responsible for seeing and avoiding other aircraft, but the air-traffic control clearances they receive provide substantial added assurance of safe separation. Consequently, flight crews often will operate under instrument flight rules even though the weather satisfies visual meteorological conditions.

Flight plans. A flight plan is filed with the authority providing air-traffic control services [in the United States, the Federal Aviation Administration (FAA)] to convey information about the intended flight of the aircraft. All flight plans contain essentially the same information, that is, aircraft identification number, make and model, and color; planned true airspeed and cruising altitude; origin and destination airports; planned departure time and estimated time en route; planned route of flight, fuel, and number of people on board; pilot's name and address; navigation equipment on board; and the aircraft's radio call sign, if different from the aircraft identification number.

Generally, a flight plan is not required for a flight under visual flight rules. However, if a flight plan is filed and the aircraft is overdue at its destination, search and rescue procedures will be initiated. Hence the flight plan under visual flight rules provides a significant safety benefit. An IFR flight plan is required for operation in controlled airspace when instrument meteorological conditions prevail.

Airspace. The two principal categories of airspace are controlled and uncontrolled airspace. In controlled airspace some or all aircraft are required to operate in accordance with air-traffic control clearances in order to assure safety, to meet user needs for air-traffic control, or to accommodate high volumes of traffic. Air-traffic control services including air-to-ground communications and navigation aids are provided in controlled airspace. Uncontrolled airspace simply is airspace that has not been designated as controlled; air-traffic control services may not be available in such airspace.

Two specific examples of controlled airspace are class A (the positive control area or PCA) and class B (the terminal control area or TCA). The positive control area is, with a few exceptions, the airspace within the conterminous 48 states and Alaska extending from 18,000 to 60,000 ft (5490 to 18,290 m) above mean sea level. Terminal control areas are centered on primary airports and extend from the surface to specified altitudes. An air-traffic control clearance and prescribed equipment are required prior to operating within a terminal control area regardless of weather conditions.

Air-to-ground communications. Two-way air-to-ground voice communications between civil pilots and air-traffic controllers are conducted in the very high frequency (VHF) band. In addition, certain radio navigation aids can provide one-way communications from controllers to aircraft. These channels generally are used to broadcast weather and aeronautical information to pilots. *See* RADIO SPECTRUM ALLOCATIONS.

Air-to-ground data communications (that is, data link) increasingly are used to transfer information to and from the cockpit. Many of the communications errors associated with humans incorrectly reading, speaking, and hearing text are eliminated by communications protocols that detect errors in data transmissions, by electronically displaying the information received, and by storing the received information so that it can be reviewed. Data link also permits large quantities of data to be exchanged between ground-based and airborne computers. Civil aviation is exploiting three data-link media: some VHF voice channels, Mode S, and communications satellites.

Radio navigation aids. Radio navigation aids are used to determine the plan position of the aircraft (that is, the position in the horizontal plane) in coordinates referenced either to the navigation aid or to the Earth (that is, latitude and longitude). For most operations, the aircraft vertical position is determined by sensing atmospheric pressure on board and converting this pressure to altitude, based on a standard model of the atmosphere. For the landing phase of flight, precision landing aids provide horizontal and vertical position referenced to the runway. *See* ALTIMETER.

VOR is a principal system used for determining plan position, with approximately 1000 ground stations nationwide. The system provides the magnetic azimuth from the VOR station to the receiving aircraft accurate to $\pm 1^\circ$. Position determinations can be obtained from the intersection of radials from VORs with overlapping coverage volumes. With the addition of distance-measuring equipment at a VOR station, it is possible to obtain a position determination from a single station. *See* DISTANCE-MEASURING EQUIPMENT; RHO-THETA SYSTEM; VOR (VHF OMNIDIRECTIONAL RANGE).

Nondirectional radio beacon is an older technology, with few installations remaining. The system radiates a continuous signal from which direction-finding receivers can determine the azimuth to the ground station. *See* DIRECTION-FINDING EQUIPMENT.

Loran C is a pulsed system, with chains of ground stations each consisting of one master station and at least two secondary stations organized to transmit their signals in synchronism. Loran C coverage in the United States includes the conterminous 48 states and southern Alaska. *See* LORAN.

In order to conduct approaches and landings in low-visibility conditions, it is necessary that an electronic glideslope (or glidepath) be provided as a reference for controlling the descent of the aircraft. In addition, a stable guidance signal is required to align the aircraft with the runway centerline. The instrument landing system (ILS) has been the standard means for providing precision landing guidance to the runway, and is installed on approximately 1000 runways in the United States. The localizer antenna transmits the lateral (left and right) guidance signal over a 20° sector, 10° on both sides of the extended runway centerline. The glideslope antenna transmits the elevation guidance signal over a 1.4° sector, 0.7° on both sides of the glidepath, which is normally 3.0° above the horizontal. *See* INSTRUMENT LANDING SYSTEM (ILS).

A new standard system for providing precision approach guidance, the microwave landing system (MLS) has been designed to eliminate limitations of the instrument landing system. It utilizes scanning-beam technology to provide proportional landing guidance over 80° in azimuth (40° on both sides of the extended runway centerline) and 15° in elevation. The system can provide three-dimensional landing guidance within the scanned volume, thereby permitting curved approaches and approaches at higher glideslope angles than those available from the instrument landing system. *See* MICROWAVE LANDING SYSTEM (MLS).

The constellation of Global Positioning System (GPS) satellites provides a highly accurate worldwide position determination and time transfer capability. In the horizontal plane, the position determined by a GPS receiver is within 330 ft (100 m) of the true receiver position at least 95% of the time. The vertical position is accurate to within 459 ft (140 m) on the same 95% probability basis. In addition, the receiver provides Coordinated Universal Time (UTC) with an accuracy of 310 ns (95% probability). Coordinated Universal Time is an internationally accepted time standard that never differs from Greenwich Mean Time by more than 1 s. The principal advantages of GPS are its accuracy and worldwide coverage. *See* AIR NAVIGATION; ELECTRONIC NAVIGATION SYSTEMS; SATELLITE NAVIGATION SYSTEMS.

Surveillance systems. Air-traffic controllers use radar to monitor the positions of aircraft and to monitor areas of heavy precipitation. The radar information is used to develop clearances and instructions for separating aircraft operating under instrument flight rules, and to provide traffic advisories to IFR aircraft and to VFR aircraft receiving the traffic advisory service. Traffic advisories provide the ranges, bearings, and altitudes of aircraft in the pilot's immediate vicinity. The pilot is responsible for visually acquiring and avoiding any traffic that may be a collision threat. Two principal types of radar are used in civil air-traffic control: secondary, or beacon, radar and primary radar. *See* RADAR.

Secondary radar is an interrogate-respond system. The rotating directional antenna of the ground station transmits a pulse pair to the transponder in the aircraft. The pulse spacing encodes one of two messages, "transmit your altitude" (the Mode C interrogation) or "transmit your identity" (the Mode A interrogation). The aircraft transponder transmits an encoded pressure-altitude reply in response to the first interrogation and a four-digit identity code, assigned by air-traffic control and entered into the transponder by the pilot, in response to the second.

Primary radar operates by transmitting high-power, radio-frequency pulses from a rotating directional antenna. The energy is reflected from any aircraft in the directional beam and received by the antenna. The aircraft is displayed at the azimuth corresponding to the pointing direction of the antenna and the range corresponding to the round-trip time between pulse transmission and receipt of the reflected signal. Primary radar has the advantage that aircraft without air-traffic control transponders can be detected, and energy reflected from heavy precipitation indicates to the controller areas of potentially hazardous weather. However, extraneous returns (clutter) from surrounding buildings and terrain can reduce the effectiveness of primary radar in detecting aircraft. At most air-traffic control radar sites, the secondary radar antenna is mounted on the primary radar antenna, and they are turned by a common drive system.

The secondary radar system has been improved through the addition of Mode S, which employs more sophisticated signaling formats than Modes A and C. Each aircraft transponder is permanently assigned a unique address and interrogations therefore can be addressed to individual aircraft.

In the oceanic environment, the ground-based surveillance systems described above obviously cannot be used. Oceanic operations are now based on rigid procedures and high-frequency (HF) communications that sometimes are unreliable. With the advent of commercially available mobile satellite communication systems, the development of a technique called automatic dependent surveillance (ADS) has been undertaken to provide real-time position information from aircraft over the ocean. In the operation of this system, the position of the aircraft, as determined from on-board navigation sensors, is communicated to air-traffic control facilities when requested by satellite relay. This position information can be displayed to controllers as though it had been determined by a radar system.

Automation. The principal elements of the controller's workstation are the plan view display, a track ball or mouse, the data-entry keyboard, printed flight strips showing the flight plans of aircraft for which the controller is responsible, and interfaces with communications facilities linking the controller with aircraft and with other controllers and facilities. The plan view display shows two principal types of data, map data and radar data. Map data include the locations of airports and their runways, navigation aids, airways, obstructions, and the geographical limits of the facility's airspace. Radar data comprise the positions of aircraft, including their altitudes, ground speeds, and radio call signs, as well as areas of precipitation. The data-entry keyboard allows the controller to modify data stored in the automation system, including flight plans. Extensive automation (computer) equipment is used in maintaining the flight-plan databases and processing radar data. A number of automation aids have been developed to assist controllers in separating aircraft as well as in sequencing and metering aircraft into and out of busy terminal areas.

Flight management computer systems are installed in aircraft for the purpose of guiding the aircraft along its planned route of flight while minimizing operating costs by selecting optimum speeds and altitudes. Extensive databases are stored in the flight management computer system (FMCS), including the current flight plan, wind velocities and air temperatures along the planned route of flight, and the positions and operating frequencies of the radionavigation aids to be used. Interfaces with the FMCS for air-to-ground data communications permit changes to be made to the databases in flight and allow information to be extracted, such as automatic dependent surveillance position reports and estimated times of arrival at specific points along the planned route of flight. *See* AIRCRAFT INSTRUMENTATION.

Airborne collision avoidance systems are installed in aircraft to provide ground-independent protection from midair collisions, as a backup to the conventional air-traffic control system. Within the United States, the system is known as the Traffic Alert and Collision Avoidance System (TCAS). The TCAS equipment in the aircraft interrogates the secondary surveillance radar transponders in proximate aircraft and processes the replies to determine if any aircraft is on a collision course. Traffic advisories are displayed to the pilot to portray the range, bearing, and relative altitude of any aircraft that penetrates a protection volume around the TCAS-equipped aircraft. A resolution advisory will be displayed to tell the pilot how to maneuver to avoid a collision, if necessary.

Airways and procedures. Two fixed-route systems have been established for air navigation. From 1200 ft (360 m) above the surface up to but not including 18,000 ft (5490 m) above mean sea level, there are designated airways based on VORs and nondirectional beacons. The most prevalent are the so-called victor (V) airways defined by VORs. Jet (J) routes are defined from 18,000 to 45,000 ft (5490 to 13,710 m) above mean sea level, based solely on VORs.

There are three principal categories of procedures: departure procedures for leaving terminal areas, arrival procedures for entering terminal areas, and en route procedures. Departure procedures prescribe the process for route clearance delivery to an aircraft, for providing takeoff runway and taxi instructions, and for defining or placing limitations on the climb-out route of the aircraft. Generally, pilots of IFR aircraft call the clearance delivery controller for their route clearance prior to taxiing. The route in the clearance may differ from the filed route because of system restrictions such as excess traffic, facility outages, and weather.

En route procedures deal principally with reporting aircraft flight progress to air-traffic control (position reporting) when the aircraft is outside radar coverage or is operating in holding patterns.

Arrival procedures prescribe the process for making the transition from the en route structure to the terminal area, for approaching the landing runway, and for executing a missed approach when a landing cannot be accomplished. An instrument approach procedure is a series of predetermined maneuvers by reference to flight instruments for the orderly transfer of an aircraft from an initial approach fix to a landing or to a point from which a landing can be made visually. Several procedures, using different navigation and approach aids, may be established for an airport.

Facilities. Air-traffic control facilities include flight service stations, air-route traffic control centers (ARTCCs), and terminal facilities. Flight service stations provide preflight briefings for pilots, accept flight plans, broadcast aviation weather information, assist lost aircraft and aircraft in distress, and monitor the operation of radio navigation aids. Air-route traffic control centers monitor all IFR aircraft not under the control of military or terminal facilities. They assure separation of IFR aircraft by issuing clearances and instructions as necessary and issuing traffic advisories, provide weather advisories, accept amendments to flight plans from flight crews, and assist aircraft in distress. Flight plans submitted to flight service stations usually are transmitted to the parent air-route traffic control center, where they are processed and the route clearance is generated.

At terminal facilities, the ground controller position is responsible for all ground traffic not on active runways. The local controller has jurisdiction over the active runways and the airspace close to the airport. Controllers generally visually acquire and track aircraft and direct their movements by using radio or, when an aircraft has no operating radio, signal lights. In some locations, however, radar indicator equipment is installed in the tower to electronically display traffic that is being tracked by the local air-traffic control radar. *See* AIR TRANSPORTATION. [C.A.Mi.]

Air transportation

The movement of passengers and cargo by aircraft such as airplanes and helicopters. Air transportation has become the primary means of common-carrier traveling. Greatest efficiency and value are obtained when long distances are traveled, high-value payloads are moved, immediate needs must be met, or surface terrain prevents easy movement or significantly raises transport costs. Although the time and cost efficiencies obtained decrease as distance traveled is reduced, air transport is often worthwhile even for relatively short distances. Air transportation also provides a communication link, which is sometimes vital, between the different groups of people being served. [D.V.M.]

Airborne radar Radar equipment carried by commercial and military aircraft. These aircraft use airborne radar systems to assist in weather assessment and navigation. Military systems also provide other specialized capabilities such as targeting of hostile aircraft for air-to-air combat, detection and tracking of moving ground targets, targeting of ground targets for bombing missions, and very accurate terrain measurements for assisting in low-altitude flights. Airborne radars are also used to map and monitor the Earth's surface for environmental and topological study.

Airborne radars present unique design challenges, mainly in the severe nature of the ground echo received by the radar and in the installation constraints on the size of the radar. The peculiar clutter situation governs the nature of the signal processing, and the installation limitations influence the antenna design and the radio frequency to be used (the two being strongly related) as well as the packaging of the rest of the radar. Similar considerations influence the design of space-based radars as well.

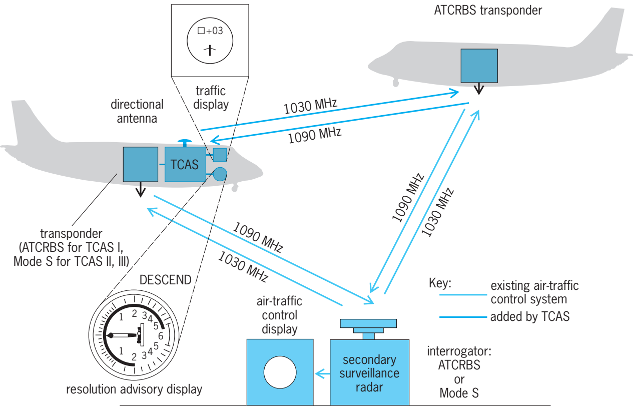
A particularly valuable use of airborne radar is weather assessment. Radars generally operating in the C or X bands (around 6 GHz or around 10 GHz, respectively) permit both penetration of heavy precipitation, required for determining the extent of thunderstorms, and sufficient reflection from less intense precipitation. *See* Meteorological radar; Radar meteorology.

Another basic and valuable airborne radar function is altimetry. The aircraft's altitude can be continuously measured, using (generally) C-band frequencies (around 6 GHz), low-power transmission, and a downward-oriented antenna beam. Sometimes, information from additional beams (looking somewhat forward, for example) is combined with measurements of the Doppler shift of the ground echo received to further aid in navigation. Another type of radar used in navigation is the radar beacon, in which a ground-based receiver detects an interrogation pulse from the aircraft and sends back a so-called reply on a different frequency, to which the receiver on the aircraft is tuned. *See* Air-traffic control; Altimeter; Doppler effect; Surveillance radar.

Airborne radars are used effectively to provide high-resolution mapping of Earth's (or other planetary) surface, with a technique called synthetic aperture radar (SAR). The processing uses the fact that surface objects produce a Doppler shift (due to the aircraft's flight) unique to their position as the aircraft passes by; this Doppler history is indicative of the scatterer's lateral, or cross-range, position at the particular range determined by the usual echo timing. With very stable radars and well-measured flight characteristics (and other focusing methods), picture cells (pixels) of 1 ft × 1 ft (0.3 m × 0.3 m) can be formed in the processed images from radars tens or hundreds of miles away. The resolution is somewhat like that possible had the flight path itself been used as a huge antenna, the synthetic aperture. [R.T.H.]

Aircraft Any vehicle which carries one or more persons and which navigates through the air. The two main classifications of aircraft are lighter-than-air and heavier-than-air. The term lighter-than-air is applied to all aircraft which sustain their weight by displacing an equal weight of air, for example, blimps and dirigibles. Heavier-than-air craft are supported by giving the surrounding air a momentum in the downward direction equal to the weight of the aircraft. *See* Airplane; Convertiplane; Helicopter. [R.G.Bo.]

Aircraft collision avoidance system Electronic equipment in an aircraft that gives the pilot relative position information concerning nearby aircraft; some versions also display resolution advisories of maneuvers to avoid a collision. The system operates independently of ground-based air-traffic control equipment, but makes use of transponders carried by most aircraft to reply to air-traffic control surveillance.



Relation of the Traffic Alert and Collision Avoidance System (TCAS) to the existing air-traffic control system. TCAS interrogations elicit replies from transponders of nearby aircraft, enabling TCAS to show the pilot their relative position on a traffic display, and when appropriate, to issue a resolution advisory. Here, TCAS instructs the pilot to descend to avoid a threat aircraft 300 ft above.

To achieve surveillance of aircraft carrying Air-Traffic Control Radar Beacon System (ATCRBS) transponders (see illustration), TCAS transmits interrogations once per second using 0.8-microsecond pulses at 1030 MHz, in a format similar to those of the ground radars. The transponders reply with a block of 0.45-μs pulses at 1090 MHz, their sequence announcing the aircraft's barometric altitude quantized to the nearest 100 ft (30.5 m). TCAS measures the round-trip time from its interrogation to the received reply to determine the slant range, and decodes the altitude information contained in the reply sequence.

The collision avoidance logic must distinguish a genuine collision threat from routine safe passages. The relative range rate is derived from successive range reports. Likewise, an altitude rate is estimated from the other aircraft's altitude, and also for the system's aircraft. An estimate of the time of closest approach (τ) can be calculated from the equation below.

$$\tau = \frac{-\text{range}}{\text{range rate}}$$

Each nearby aircraft is evaluated once per second, and is deemed a threat if the range is already small or if τ is small, and if the relative altitude is predicted to be small. When a threat is declared, the effects of potential climb and descent maneuvers are estimated. The maneuver sense that gives the greater separation is chosen, except that a vertical crossing is not selected if the noncrossing sense gives adequate separation. An advisory is selected (such as limit climb; do not climb; descend) that is predicted to prevent a collision while minimizing the displacement from the aircraft's flight path.

An important part of TCAS is its traffic display, enabling crews to locate nearby traffic even when weather hinders visual sighting. At present, the format in use depicts nearby aircraft in plan view, centered about the TCAS aircraft (see illustration). [A.D.Z.]

Aircraft compass system An instrument that indicates the bearing, or angle of the direction in which an aircraft is pointing in the horizontal plane. A compass may indicate magnetic heading or bearing, bearing referenced to a radio signal source, or bearing with respect to an inertially maintained line of position.

In modern commercial jet transport or military fighter aircraft, the primary sensor of the aircraft compass system is the inertial reference system (IRS). This system provides a gyroscopically derived reference to an inertial reference axis by sensing the linear and angular accelerations of the aircraft and continuously integrating these values to provide angular and linear velocities. The inertial reference system derives its position and attitude in an inertial frame referenced to true north. This approach represents an increase in precision over the original compass systems, which developed their lines of position referenced to magnetic north. *See* GYROSCOPE; INERTIAL GUIDANCE SYSTEM.

The magnetic and true bearings of the aircraft are presented on computer-generated cathode-ray tubes or flat-panel displays. These displays present aircraft heading in the form of a compass rose on both the primary flight display and the navigation display.

The magnetic compass remains a simple, inexpensive, and reliable instrument for indicating the aircraft bearing. Limitations in the accuracy of this compass are due to the accelerations and vibrations of the aircraft, the local induced magnetic field of the aircraft, and lack of knowledge of local magnetic variation (the difference between true north and magnetic north). The magnetic compass is a secondary sensor of bearing on jet transports and most military aircraft, although it remains the primary instrument for many small, general aviation aircraft. This compass is typically a stand-alone instrument consisting of a card indicating the bearing installed in a liquid-filled case. The liquid serves to dampen rapid aircraft movements or oscillations. *See* MAGNETIC COMPASS.

In some aircraft, the magnetic compass has been coupled with a gyroscopic element to provide the gyroslaved, or gyrosynchronized, magnetic compass. The gyrosynchronized compass uses a directional gyro to determine the local horizon and to sense accelerations and thus correct for gravity effects on the compass output. *See* AIRCRAFT INSTRUMENTATION. [R.W.Sc.]

Aircraft design The process of designing an aircraft, generally divided into three distinct phases: conceptual design, preliminary design, and detail design. Each phase has its own unique characteristics and influence on the final product. These phases all involve aerodynamic, propulsion, and structural design, and the design of aircraft systems.

Design phases. Conceptual design activities are characterized by the definition and comparative evaluation of numerous alternative design concepts potentially satisfying an initial statement of design requirements. The conceptual design phase is iterative in nature. Design concepts are evaluated, compared to the requirements, revised, reevaluated, and so on until convergence to one or more satisfactory concepts is achieved. During this process, inconsistencies in the requirements are often exposed, so that the products of conceptual design frequently include a set of revised requirements.

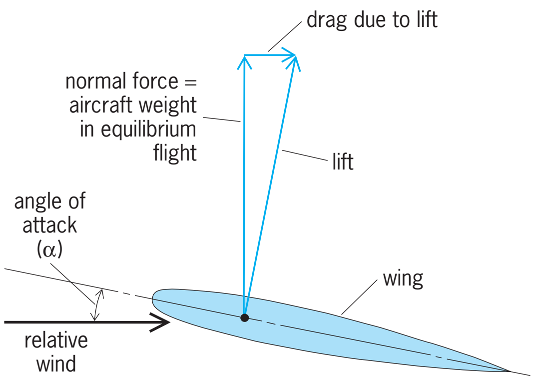
During preliminary design, one or more promising concepts from the conceptual design phase are subjected to more rigorous analysis and evaluation in order to define and validate the design that best meets the requirements. Extensive experimental efforts, including wind-tunnel testing and evaluation of any unique materials or structural concepts, are conducted during preliminary design. The end product of preliminary design is a complete aircraft design description including all systems and subsystems. *See* WIND TUNNEL.

During detail design the selected aircraft design is translated into the detailed engineering data required to support tooling and manufacturing activities.

Requirements. The requirements used to guide the design of a new aircraft are established either by an emerging need or by the possibilities offered by some new technical concept or invention. Requirements can be divided into two general classes: technical requirements (speed, range, payload, and so forth) and economic requirements (costs, maintenance characteristics, and so forth).

Aerodynamic design. Initial aerodynamic design centers on defining the external geometry and general aerodynamic configuration of the new aircraft.

The aerodynamic forces that determine aircraft performance capabilities are drag and lift. The basic, low-speed drag level of the aircraft is conventionally expressed as a term at zero lift composed of friction and pressure drag forces plus a term associated with the generation of lift, the drag due to lift or the induced drag. Since wings generally operate at a positive angle to the relative wind (angle of attack) in order to generate the necessary life forces, the wing lift vector is tilted aft, resulting in a component of the lift vector in the drag direction (see illustration). *See* AERODYNAMIC FORCE; AIRFOIL; WING.



Wing lift and drag due to lift.

Aircraft that fly near or above the speed of sound must be designed to minimize aerodynamic compressibility effects, evidenced by the formation of shock waves and significant changes in all aerodynamic forces and moments. Compressibility effects are mediated by the use of thin airfoils, wing and tail surface sweepback angles, and detailed attention to the lengthwise variation of the cross-sectional area of the configuration. *See* COMPRESSIBLE FLOW; SHOCK WAVE.

The size and location of vertical and horizontal tail surfaces are the primary parameters that determine aircraft stability and control characteristics. Developments in digital computing and flight-control technologies have made the concept of artificial stability practical. *See* STABILITY AUGMENTATION.

Propulsion design. Propulsion design comprises the selection of an engine from among the available models and the design of the engine's installation on or in the aircraft.

Selection of the best propulsion concept involves choosing from among a wide variety of types ranging from reciprocating engine-propeller power plants through turboprops, turbojets, turbofans, and ducted and unducted fan engine developments. The selection process involves aircraft performance analyses comparing flight performance with the various candidate engines installed. In the cases where the new aircraft design is being based on a propulsion system which is still in development, the selection process is more complicated. *See* AIRCRAFT ENGINE; TURBOFAN; TURBOPROP.

Once an engine has been selected, the propulsion engineering tasks are to design the air inlet for the engine, and to assure the satisfactory physical and aerodynamic integration of the inlet, engine, and exhaust nozzle or the engine nacelles with the rest of the airframe. The major parameters to be chosen include the throat area, the diffuser length and shape, and the relative bluntness of the inlet lips.

Structural design. Structural design begins when the first complete, integrated aerodynamic and propulsion concept is formulated. The process starts with preliminary estimates of design airloads and inertial loads (loads due to the mass of the aircraft being accelerated during maneuvers).

During conceptual design, the structural design effort centers on a first-order structural arrangement which defines major structural components and establishes the most direct load paths through the structure that are possible within the constraints of the aerodynamic configuration. An initial determination of structural and material concepts to be used is made at this time, for example, deciding whether the wing should be constructed from built-up sheet metal details, or by using machined skins with integral stiffeners, or from fiber-reinforced composite materials.

During preliminary design, the structural design effort expands into consideration of dynamic loads, airframe life, and structural integrity. Dynamic loading conditions arise from many sources: landing impact, flight through turbulence, taxiing over rough runways, and so forth. *See* LOADS,; DYNAMIC.

Airframe life requirements are usually stated in terms of desired total flight hours or total flight cycles. To the structural designer this translates into requirements for airframe fatigue life. Fatigue life measures the ability of a structure to withstand repeated loadings without failure. Design for high fatigue life involves selection of materials and the design of structural components that minimize concentrated stresses.

Structural integrity design activities impose requirements for damage tolerance, the ability of the structure to continue to support design loads after specified component failures. Fail-safe design approaches are similar to design for fatigue resistance: avoidance of stress concentrations and spreading loads out over multiple supporting structural members. *See* STRUCTURAL DESIGN.

Aircraft systems design. Aircraft systems include all of those systems and subsystems required for the aircraft to operate. Mission systems are those additional systems and subsystems peculiar to the role of military combat aircraft. The major systems are power systems, flight-control systems, navigation and communication systems, crew systems, the landing-gear system, and fuel systems.

Design of these major subsystems must begin relatively early in the conceptual design phase, because they represent large dimensional and volume requirements which can influence overall aircraft size and shape or because they interact directly with the aerodynamic concept (as in the case of flight-control systems) or propulsion selection (as in the case of power systems).

During preliminary design, the aircraft system definition is completed to include additional subsystems. The installation of the many aircraft system components and the routing of tubing and wiring through the aircraft are complex tasks which are often aided by the construction of partial or complete aircraft mock-ups. These are full scale models of the aircraft, made of inexpensive materials, which aid in locating structural and system components. *See* AIRPLANE. [P.L.M.]

Aircraft engine

A component of an aircraft that develops either shaft horsepower or thrust and incorporates design features most advantageous for aircraft propulsion. An engine developing shaft horsepower requires an additional means to convert this power to useful thrust for aircraft, such as a propeller, a fan, or a helicopter rotor. It is common practice in this case to designate the unit developing shaft horsepower as the aircraft engine, and the combination of engine and propeller, for example, as an aircraft power plant. In case thrust is developed directly as in a turbojet engine, the terms engine and power plant are used interchangeably.

Air-breathing types of aircraft engines use oxygen from the atmosphere to combine chemically with fuel carried in the vehicle, providing the energy for propulsion, in contrast to rocket types in which both the fuel and oxidizer are carried in the aircraft. *See* INTERNAL COMBUSTION ENGINE; JET PROPULSION; RECIPROCATING AIRCRAFT ENGINE; ROCKET PROPULSION; TURBINE PROPULSION. [R.Ha.]

Aircraft fuel

The source of energy required for the propulsion of airborne vehicles. Aircraft fuel is burned with ambient air and is thereby distinct from rocket propellants, which carry both fuel and oxidant. An important criterion for aircraft fuel is that its energy density, or heat of combustion per unit of weight, be high. This allows reasonable expenditures of fuel during takeoff, efficient performance in flight, and long range of flight duration.

There are two general types of aircraft fuels in conventional use: gasolines for reciprocating (piston) engines, and kerosene-like fuels (called jet fuels) for turbine engines. Because of anticipated limitations in the supply of these crude-oil derived fuels, alternative fuels are being considered for future aircraft.

Piston engine fuels, or aviation gasolines, are special blends of gasoline stocks and additives that produce a high-performance fuel that is graded by its antiknock quality. The gasoline blending stocks are virgin (uncracked) naphtha, alkylate, and catalytically cracked gasoline. In general, the chemical composition of aviation gasoline can be approximated as $C_xH_{1.9x}$ where the number of carbon atoms x is between 4 and approximately 10. Tetraethyllead (Tel) is a common additive used in concentrations of up to 4 ml/gal (1.057 ml/liter) of fuel to increase the antiknock quality of the fuel. *See* GASOLINE; NAPHTHA.

Turbine engine fuels are distillate hydrocarbon fuels, like kerosenes, used to operate turbojet, turbofan, and turboshaft engines. While all piston engine fuels have the same volatility but differ in combustion characteristics, jet fuels differ primarily in volatility; differences in their combustion qualities are minor. Turbine fuel contains aromatic hydrocarbons; limits are placed on this content owing to concerns about smoke and coke formation. An increasingly important requirement is to provide a fuel that is stable at relatively high temperatures.

Many forecasts of world crude production indicate a peak or plateau in the oil production rate before 2010; hence, the availability of crude-based fuels for aircraft is not certain. Alternative fuels made from coal, oil shale, or solar or nuclear energy plus a suitable raw material are being considered. [J.B.P.]

Aircraft icing

Aircraft icing encompasses a range of conditions during which frozen precipitation forms on an aircraft. It is usually separated into two broad classifications, ground icing and in-flight icing. Icing can compromise flight safety by affecting the performance, stability, and control of the aircraft, and as a result the ability of the pilot to maintain the desired flight path.

Ice accretion. Ground icing occurs when the aircraft is on the ground, and becomes significant when it affects the aircraft's ability to take off. This form of icing occurs when ice, snow, or freezing rain collects on the upper surfaces of the aircraft or when frost forms on the aircraft.

In-flight icing forms when an aircraft flies through a cloud of supercooled precipitation. Water droplets approach the aircraft, approximately following the air streamlines. Near the surface of the aircraft, large changes in velocity exist. The droplets, because of their inertia, cannot change velocity rapidly enough to follow the air around the aircraft, and strike or impinge on the aircraft surface. Ice forms on the leading or forward-facing edges of the wings, tail, antennas, windshield, radome, engine inlet, and so forth. *See* CLOUD PHYSICS.

Aerodynamics. Probably the most dangerous way that ice acts on an aircraft is through its effect on the aerodynamics, which results in degraded performance and control. Small amounts of ice or frost add roughness to the airplane surfaces. The roughness increases the friction of the air over the surface; this is called skin friction.

Large accretions can drastically alter the shape of the wing. Then, in addition to skin friction, flow separation results in a further reduction in aerodynamic performance of the aircraft.

Aircraft control can be seriously affected by ice accretion. Ice accretion on the tail can lead to reduced elevator effectiveness, reducing the longitudinal control (nose up and down) of the aircraft. In some situations, the tail can stall or lose lift prematurely, resulting in the aircraft pitching nose down. Similarly, ice on the wing ahead of the aileron can result in roll upset. Both tail stall and roll upset are thought to be the cause of recent aircraft icing accidents. *See* AERODYNAMICS; FLIGHT CONTROLS.

Ice protection. All large aircraft and many light aircraft are equipped with in-flight ice protection systems to reduce the effect of ice. Ice protection systems are classified as de-ice or anti-ice systems. De-ice systems allow some ice to accrete, and then they periodically remove the ice. Anti-ice systems prevent ice from forming either by heating the surface above 0°C (32°F) or through the use of freezing-point depressants. [M.B.B.]

Aircraft instrumentation A coordinated group of instruments that provide the flight crew with information about the aircraft and its subsystems. These instruments provide flight data, navigation, power plant performance, and aircraft auxiliary equipment operating information to the flight crew, air-traffic controllers, and maintenance personnel. While not considered as instrumentation, communication equipment is, however, directly concerned with the instrumentation and overall indirect control of the aircraft.

Situation information on the operating environment, such as weather reports and traffic advisories, has become a necessity for effective flight planning and decision making. The prolific growth and multiplicity of instruments in the modern cockpit and the growing need for knowledge about the aircraft's situation are leading to the introduction of computers and advanced electronic displays as a means for the pilot to better organize and assimilate this body of information.

Instrumentation complexity and accuracy are dictated by the aircraft's performance capabilities and the conditions under which it is intended to operate. Light aircraft may carry only a minimum set of instruments; an airspeed indicator, an altimeter, an engine tachometer and oil pressure gage, a fuel quantity indicator, and a magnetic compass. These instruments allow operation by a pilotage technique. *See* AIRSPEED INDICATOR; ALTIMETER; PILOTAGE.

Operation under low visibility and under Instrument Flight Rules (IFR) requires this same information in a more precise form and also requires attitude and navigation data. An attitude-director indicator (ADI) presents an artificial horizon, bank angle, and turn coordination data for attitude control without external visual reference. The attitude-director indicator may contain a vertical gyro within the indicator, or a gyro may be remotely located as a part of a flight director or navigational system. Flying through a large speed range at a variety of altitudes is simplified if the indicated airspeed is corrected to true airspeed for navigation purposes and the Mach number (M) is also shown on the ADI for flight control and performance purposes. Rate-of-climb is provided by an instantaneous vertical-speed indicator (IVSI). Heading data are provided by a directional gyro or data derived from an inertial reference system. *See* GYROSCOPE; INERTIAL GUIDANCE SYSTEM.

Navigation aids include: very-high-frequency omnidirectional radio ranges (VOR) that transmit azimuth information for navigation at specified Earth locations; distance-measuring equipment (DME) that indicates the distance to radio aids on or near airports or to VORs; automatic direction finders (ADF) that give the bearing of other radio stations (generally low-frequency); low-range radio altimeters (LRRA) which by radar determine the height of the aircraft above the terrain at low altitudes; and instrument landing systems (ILS) that show vertical and lateral deviation from a radio-generated glide-path signal for landing at appropriately equipped runways. Some inertial navigation systems include special-purpose computers that provide precise Earth latitude and longitude, ground speed, course, and heading. *See* AIR-TRAFFIC CONTROL; AUTOPILOT; DIRECTION-FINDING EQUIPMENT; DISTANCE-MEASURING EQUIPMENT; ELECTRONIC NAVIGATION SYSTEMS.

Engines require specific instruments to indicate limits and efficiency of operation. For reciprocating engines, instruments may display intake and exhaust manifold pressures, cylinder head and oil temperature, oil pressure, and engine speed. For jet engines, instruments display engine pressure ratio (EPR), exhaust gas temperature (EGT), engine rotor speed, oil temperature and pressure, and fuel flow. Vibration monitors on both types of engines indicate unbalance and potential trouble.

Depending on the complexity of the aircraft and the facilities that are provided, there is also an assortment of instruments and controls for the auxiliary systems.

Electronic technology developments include: ring laser gyros, strap-down inertial reference systems, microprocessor digital computers, color cathode-ray tubes (CRT), liquid crystal displays (LCD), light-emitting diodes (LED), and digital data buses. Application of this technology allows a new era of system integration and situation information on the aircraft flight deck and instrument panels. Commercial jet transports will use digital electronics to improve safety, performance, economics, and passenger service. The concept of an integrated flight management system (FMS) includes automatic flight control, electronic flight instrument displays, communications, navigation, guidance, performance management, and crew alerting to satisfy the requirements of the current and future air-traffic and energy-intensive environment.

Effective flight management is closely tied to providing accurate and timely information to the pilot. The nature of the pilot's various tasks determines the general types of data which must be available. The key is to provide these data in a form best suited for use. If the pilot is not required to accomplish extensive mental processing before information can be used, then more information can be presented and less effort, fewer errors, and lower training requirements can be expected. Computer-generated displays offer significant advances in this direction.

The electronic horizontal-situation indicator (EHSI) provides an integrated multicolor map display of the airplane's position, plus a color weather radar (WXR) display. The scale for the radar and map can be selected by the pilots. [B.C.H.]

Aircraft propulsion Flying machines obtain their propulsion by the rearward acceleration of matter. This is an application of Newton's third law: For every action there is an equal and opposite reaction.

In propeller-driven aircraft, the propulsive medium is the ambient air which is accelerated to the rear by the action of the propeller. The acceleration of the air that passes through the engine provides only a secondary contribution to the thrust.

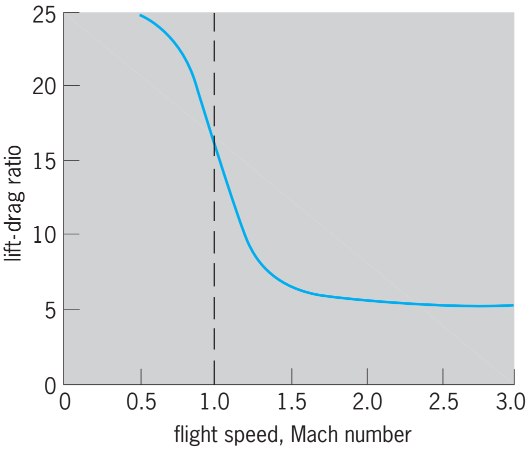
In the case of turbojet and ramjet engines, the ambient air is again the propulsive medium, but the thrust is obtained by the acceleration of the air as it passes through the engine. After being compressed and heated in the engine, this air is ejected rearward from the engine at a greater velocity than it had when it entered. *See* JET PROPULSION.

Rockets carry their own propulsive medium. The propellants are burned at high pressure in a combustion chamber and are ejected rearward to produce thrust. *See* ROCKET PROPULSION.

In every case, the thrust provided is equal to the mass of propulsive medium per second multiplied by the increase in its velocity produced by the propulsive device. This is substantially Newton's second law. *See* FLUID FLOW.

The airplane lift-drag ratio L/D is a primary factor that determines the thrust required from the propulsion system to fly a given airplane. To sustain flight, the airplane lift must be equal to airplane gross weight, and the engine thrust must be equal to the airplane drag. The higher the lift-drag ratio, the more efficient is the airplane. A sharp reduction in L/D occurs with increase in flight Mach number in the vicinity of a Mach number of unity, and this is reflected in a sharp increase in the thrust required for flight. Flight Mach number is the ratio of the airplane speed to the speed of sound in the ambient atmosphere. At standard sea-level conditions, the speed of sound is 773 mi/h (346 m/s).

The competition among nations and among commercial airlines has created a continuing demand for increased flight speed. The reduction in aircraft L/D that accompanies an increase in speed (see illustration) requires an increase in engine thrust for an airplane of a given gross weight. For a given engine specific

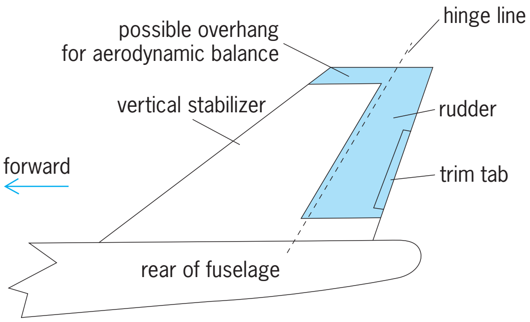


Lift-drag ratios of aircraft. Curve represents envelope of a variety of designs of various wing sweep angles. (*Taken from 27th Wright Brothers Lecture by G. S. Schairer, J. Aircraft, vol. 1, no. 2, 1964*)

weight, an increase in required engine thrust results in an increase in engine weight and hence a reduction in fuel load and payload that an airplane of a given gross weight can carry. If the engine weight becomes so large that no fuel can be carried by the airplane, the airplane has zero flight range regardless of the efficiency of the engine. At some speed before this point is reached, it becomes advantageous to shift to an engine type that has a lower specific engine weight even at the cost of an increased specific fuel consumption.

At low subsonic flight speeds, the piston-type reciprocating engine, because of its low specific fuel consumption, provides the best airplane performance in terms of payload and flight range. As flight speed increases, specific weight of reciprocating engines increases because of falling propeller efficiency. This effect, coupled with reduction in L/D which accompanies increase in flight speed, results in the weight of reciprocating engines becoming excessive at a flight speed of about 400 mi/h (180 m/s). At about this speed it is advantageous to shift to the lighter-weight turboprops even if the efficiency of the latter is poorer. At about 550 mi/h (245 m/s) it is advantageous to shift from the turboprop to the lighter but less efficient turbojet. Intermediate between the turboprop and turbojet in the spectrum of flight speeds is the turbofan. *See* RECIPROCATING AIRCRAFT ENGINE; TURBOFAN; TURBOJET; TURBOPROP. [B.Pi.]

Aircraft rudder The hinged rear portion of an airplane's vertical tail. The vertical tail is composed of the vertical stabilizer and the rudder. The vertical stabilizer is mounted to the fuselage and is fixed relative to it. The rudder is hinged to the rear of the vertical stabilizer (see illustration) and moves to the left or right in response to control inputs from the rudder pedals or from an automatic stability and control system.



Vertical tail of an airplane, showing location of the rudder.

The rudder provides an aerodynamic moment about the aircraft's center of gravity for the purpose of yaw control. When the rudder turns clockwise, for example, as viewed from above, its trailing edge moves to the left, effectively adding camber to the vertical tail. The result is that an aerodynamic side force is produced on the vertical tail to the right. This force, in turn, produces a counterclockwise yawing moment about the airplane's center of gravity, resulting in a turn to the left. *See* AIRFOIL.

An additional, small, movable surface, known as a trim tab, may be hinged to the rudder. When deflected to a fixed position, the tab causes the rudder to deflect to, and hold, a desired angle. [B.W.McC.]

Aircraft testing Subjecting a complete aircraft or its components (such as wings, engines, or electronics systems) to simulated or actual flight conditions in order to measure and record physical phenomena that indicate operating characteristics. Testing is essential to the design, development, and acceptance of any new aircraft.

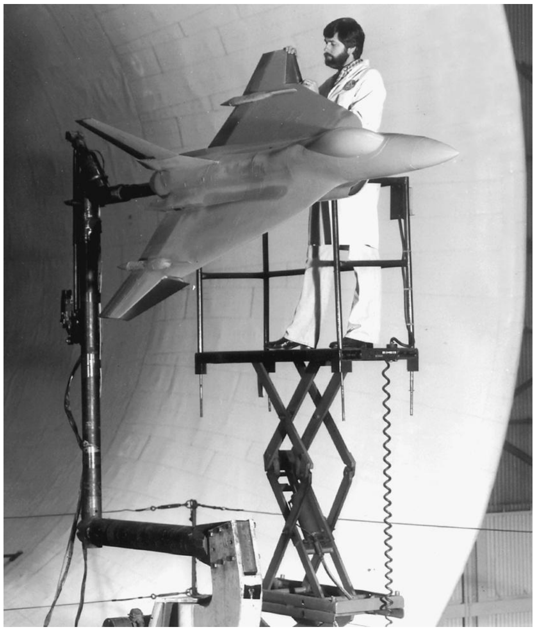
Aircraft and their components are tested to verify design theories, obtain empirical data where adequate theories do not exist, develop maximum flight performance, demonstrate flight safety, and prove compliance with performance requirements. Testing programs originate in laboratories with the evaluation of new design theory; progress through extensive tests of components, subsystems, and subsystem assemblies in controlled environments; and culminate with aircraft tests in actual operational conditions.

Laboratory testing. Instrument testing, in controlled conditions of environment and performance, is used extensively during the design performance assessment of new aircraft to avoid the costly and sometimes dangerous risks of actual flight.

A wind tunnel is basically an enclosed passage through which air is forced to flow around a model of a structure to be tested, such as an aircraft. Wind tunnels vary greatly in size and complexity, but all of them contain five major elements: an air-drive system, a controlled stream of air, a model, a test section, and measurement instruments. The drive system is usually a motor and one or more large fans that push air through the tunnel at carefully controlled speeds to simulate various flight conditions. A scale model of an actual or designed aircraft is supported inside the test section (see illustration), where instruments, balances, and sensors directly measure the aerodynamic characteristics of the model and its stream of airflow. Wind tunnel tests measure and evaluate airfoil (wing) and aircraft lift and drag characteristics with various configurations, stability and control parameters, air load distribution, shock wave interactions, stall characteristics, airflow separation patterns, control surface characteristics, and aeroelastic effects. *See* AIRFOIL.

Aircraft components are integrated into subsystems, system elements, and complete operational systems to help resolve interface problems. Integration tests establish functional and operational capability and evaluate complete system compatibility, operation, maintenance, safety, reliability, and best possible performance.

Rocket-propelled sled tests evaluate crew ejection escape systems for high-performance aircraft. A fuselage section, mounted on a sled, is propelled by rockets along fixed tracks. When a desired speed is reached, the ejection mechanism is automatically triggered, firing rockets that propel crew seats (containing instrumented mannequins) clear of the fuselage, and activating parachutes to limit the free-flight trajectory of the mannequins and allow safe descent to the ground. Water-propelled sled tests study landing gear systems and runway surface materials. Other dynamic ground tests include acceleration and arresting tests of aircraft fuel system venting, transfer, and delivery, which are evaluated while the system is subjected to flightlike forces and attitudes.



Scale model of fighter aircraft being mounted inside test section of large wind tunnel. (*NASA*)

Proof load tests of actual aircraft are usually done on one or more of the first airframes built. An airframe, mounted in a laboratory, is fitted with thousands of strain gages, the outputs of which are recorded on an automatic data-recording system. Simulated air and inertia loads are applied to airframe components, which are loaded simultaneously, in specified increments, to simulate loads encountered during takeoff, maneuvering flight, and landing. Loadings are increased to design limit and then to ultimate failure to locate possible points of excessive yield. Component parts and system subassemblies are also tested with various loadings while operating under expected extremes of temperature, humidity, and vibration to determine service life. *See* AIRFRAME. [M.Pa.]

Flight simulation. Aircraft flight and systems characteristics are represented with varying degrees of realism for research, design, or training simulation purposes. The representation is usually in the form of analytic expressions programmed on a digital computer. Flight simulation may be performed with or without a human pilot in the loop. The pilot imposes additional constraints on the simulator such as requiring a means of control in a manner consistent with the means provided in the aircraft being simulated. Flight simulation requires representation of the environment to an extent consistent with the purposes of the simulation, and it further requires that all events in the simulator occur in real time. Real time is a term which is used to indicate that all time relationships in the simulator are preserved with respect to what they would be in the airplane in flight. *See* REAL-TIME SYSTEMS.

Simulators range in size and complexity from actual aircraft, outfitted with special flight decks that can be reconfigured to test different systems, to desk-top simulators that can test individual or integrated components. [F.Ca.]

Simulators may be classified by their use in research, design, or training. Research simulators are usually employed to determine patterns of human behavior under various workloads or in response to different flight instrument display configurations or different aircraft dynamic characteristics. Design simulators are used to conduct tradeoff studies to evaluate different design approaches in the aircraft. The most pervasive use of flight simulators is for training operators of the aircraft and its systems and maintenance personnel. The simulator is in many cases a better training device than the aircraft. This is true because of the safety, versatility, and speed with which critical maneuvers may be performed. [M.Pa.]

Flight testing. Flight testing can be considered the final step in the proving of a flight vehicle or system as capable of meeting its design objectives. This definition applies whether the concept is a complete vehicle, a vehicle subsystem, or a research concept. Flight testing can be categorized as research, development, and operational evaluation. These categories apply both to aircraft and to spacecraft and missiles.

The purpose of research testing is to validate or investigate a new concept or method with the goal of increasing the researchers' knowledge. Many times, the vehicle used is a one- or two-of-a-kind article designed specifically for the concept being investigated.

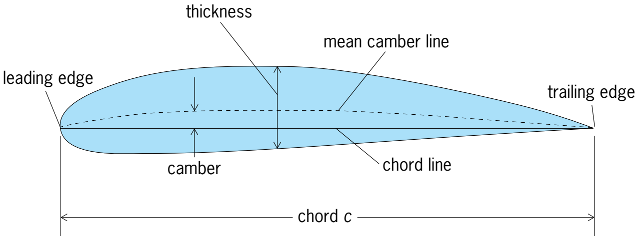
A new vehicle or subsystem enters development testing after it has been designed and the basic concepts proven in research flight testing. During this phase of testing, problems with the design are uncovered and solutions are developed for incorporation in the production aircraft.

Operational testing involves customer participation to evaluate the capability of the fully equipped vehicle to meet its intended mission objectives. Testing is performed to determine system reliability, define maintenance requirements, and evaluate special support equipment. Military vehicles are also tested to determine weapon delivery techniques and effectiveness, including target acquisition capabilities, ability to perform in all weather conditions, operational behavior in battlefield conditions, and, in the case of naval aircraft, carrier suitability. Commercial aircraft are tested for blind landing-approach systems, passenger services, baggage and cargo loading, noise levels, and safety provisions. Crew training simulators, handbooks, and procedures are also tested in this phase to demonstrate the ability to maintain and operate the aircraft effectively. [M.Wa.; D.W.D.]

Airfoil

Airfoil The cross section of a body that is placed in an airstream in order to produce a useful aerodynamic force in the most efficient manner possible. The cross sections of wings, propeller blades, windmill blades, compressor and turbine blades in a jet engine, and hydrofoils on a high-speed ship are examples of airfoils. *See* COMPRESSOR; PROPELLER (AIRCRAFT); TURBINE PROPULSION; WIND POWER; WING.

The mean camber line of an airfoil (see illustration) is the locus of points halfway between the upper and lower surfaces as measured perpendicular to the mean camber line itself. The most forward and rearward points of the mean camber line are the leading and trailing edges, respectively. The straight line connecting the leading and trailing edges is the chord line of the airfoil, and the distance from the leading to the trailing edge measured along the chord line is simply designated the chord of the airfoil, represented by c. The thickness of the airfoil is the distance from the upper to the lower surface, measured perpendicular to the chord line, and varies with distance along the chord. The maximum thickness, and where it occurs along the chord, is an important design feature of the airfoil. The camber is the maximum distance between the mean camber line and the chord line, measured perpendicular to the chord line. Both the maximum thickness and the camber are usually expressed in terms



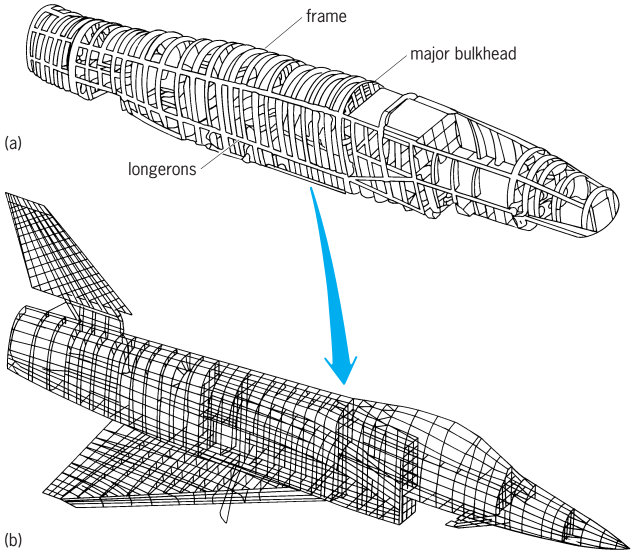
Airfoil nomenclature. The shape shown is an NACA 4415 airfoil.

of a percentage of the chord length; for example, a 12% thick airfoil has a maximum thickness equal to 0.12*c*.

The airfoil may be imagined as part of a wing which projects into and out of the page, stretching to plus and minus infinity. Such a wing, with an infinite span perpendicular to the page, is called an infinite wing. The aerodynamic force on the airfoil, by definition, is the force exerted on a unit span of the infinite wing. For this reason, airfoil data are frequently identified as infinite wing data.

The flow of air (or any fluid) over the airfoil results in an aerodynamic force (per unit span) on the airfoil, denoted by R. The relative wind is the magnitude and direction of the free-stream velocity far ahead of the airfoil. The angle between the chord line and relative wind is defined as the angle of attack of the airfoil, denoted by α. By definition, the component of R perpendicular to the relative wind is the lift, L; similarly, the component of R parallel to the relative wind is the drag, D.

The airfoil may be visualized as being supported by an axis perpendicular to the airfoil, and taken through any point on the airfoil. The airfoil has a tendency to twist about this axis; that is, there is an aerodynamic moment exerted on the airfoil. By definition, the moment is positive or negative if it tends to increase or decrease respectively the angle of attack (that is, if it tends to pitch the airfoil up or down, respectively). [J.D.A.]



X-31 aircraft. (*a*) Fuselage structural load paths. (*b*) Finite element model. (*Rockwell International*)

Airframe The structural backbone of an aircraft that balances the internal and external loads acting upon the craft. These loads consist of internal mass inertia forces (equipment, payload, stores, fuel, and so forth), flight forces (propulsion thrust, lift, drag, maneuver, wind gusts, and so forth), and ground forces (taxi, landing, and so forth).

The strength capability of the airframe must be predictable to ensure that these applied loads can be withstood with an adequate margin of safety throughout the life of the airplane. In addition to strength, the airframe requires structural stiffness to prevent excessive deformation under load and to provide a satisfactory natural frequency of the structure (the number of times per second the structure will vibrate when a load is suddenly imposed or changed). The aerodynamic loads on the airframe can oscillate in magnitude under some circumstances, and if these oscillations are near the same rate as the natural frequency of the structure, runaway deflections (called flutter) and failure can occur. Consequently, adequate structural stiffness is needed to provide a natural frequency far above the danger range. *See* AEROELASTICITY.

The overall airframe structure is made up of a number of separate components, each of which performs discrete individual functions. The fuselage provides the accommodations of crew, passengers, cargo, fuel, and environmental control systems. The empennage consists of the vertical and horizontal stabilizers, which are used, respectively, for turning and pitching flight control. The wing passing through the air provides lift to the aircraft. Its related control devices, leading-edge slats and trailing-edge flaps, are used to increase this lift at slow airspeeds, such as during landing and takeoff, to prevent stalling and loss of lift. The ailerons increase lift on one side of the wing and reduce lift on the other in order to roll the airplane about its fore-and-aft axis. *See* AILERON; ELEVON; FUSELAGE; WING; WING STRUCTURE.

Performance requirements (range, payload, speed, altitude, landing and takeoff distance, and so forth) dictate that the airframe be designed and constructed so as to minimize its weight. All the airframe material must be arranged and sized so that it is utilized as near its capacity as possible, and so that the paths between applied loads and their reactions are as direct and as short as possible. The accomplishment of these goals, however, is compromised by constraints such as maintenance of the aerodynamic shape, the location of equipment, minimum sizes or thicknesses that are practical to manufacture, and structural stability, among others.

To maintain structural efficiency (minimum weight), the material that forms the aerodynamic envelope of the airplane is also utilized as a primary load-carrying member of the airframe. For example, the thin sheets that are commonly used for outer fuselage skins are very efficient in carrying in-plane loads like tension and shear when they are stabilized (prevented from moving or deflecting out of the way when loads are applied). This structural support is provided by circumferential frames and longitudinal primary members called longerons. The compression loads are also carried in the longerons and the thin skins when they are additionally stabilized by multiple secondary longitudinal stiffeners that are normally located between the frames. Illustration *a* shows a typical fuselage primary load path structure indicating the frames and longerons. This skeleton will be covered by thin skins.

Various analytical techniques may be used to determine the internal stress levels for each of the airframe components. The most common analytical methods use the technique of reducing these highly complex structural arrangements into a group of well-defined simple structures known as finite elements. This simplification allows the load distribution to be solved by a series of algebraic equations.

The finite element model used for the determination of the internal load distribution must support various structural objectives that include the analysis of strength, stiffness, and damage tolerance characteristics of the aircraft. In order to accomplish these objectives the finite element model must represent the vehicle configuration in sufficient detail to define adequately the basic characteristics of the local structural load paths and provide for application of all external loading parameters. Illustration *b* shows the complete finite element model of an airframe. The many varied loading parameters include airloads, structural weight, engine thrust, landing gear reactions, fuel tanks, cargo, and passengers. Environmental factors such as cabin pressure and structural heating must also be considered. [L.M.La.; D.S.Kl.]

Airglow Visible, infrared, and ultraviolet emissions from the atoms and molecules in the atmosphere above 30 km (20 mi), generally in layers, and mostly between 70 and 300 km (45 and 200 mi). The airglow, together with the ionosphere, is found in the uppermost parts of the atmosphere that absorb the incoming energetic radiations from the Sun. While the airglow consists of spectral features similar to those of the aurora, it is mostly uniform over the sky; and it is caused by the absorption of solar ultraviolet and x-radiations, rather than energetic particles. *See* AURORA.

The daytime airglow (dayglow) is caused mainly by fluorescence processes as molecules and atoms are photodissociated and photoionized. The photoelectrons that are produced in the ionization processes are a further source of airglow in their collisions with other atoms and molecules. *See* FLUORESCENCE.

Twilight offers an opportunity to observe resonant scattering of sunlight on layers such as those of the alkali atoms sodium, lithium, and potassium. As the Earth's shadow scans through the layers, the changes of intensity allow their heights (near 90 km or 55 mi) to be measured. *See* ALKALI EMISSIONS.

The nighttime airglow (nightglow) is predominantly due to recombination emissions. The ionospheric plasma recombines near the bottom of the F region (150–200 km or 90–120 mi) where the densities and thus collision frequencies are higher, producing bright atomic oxygen (O) spectral lines in the red (at 630 and 636 nanometers) and a weaker green (558-nm) line. [B.A.T.]

Airplane A heavier-than-air vehicle designed to use the pressures created by its motion through the air to lift and transport useful loads. To achieve practical, controllable flight, an airplane must consist of a source of thrust for propulsion, a geometric arrangement to produce lift, and a control system capable of maneuvering the vehicle within prescribed limits. Further, to be satisfactory, the vehicle should display stable characteristics, so that if it is disturbed from an equilibrium condition, forces and moments are created which return it to its original condition without necessitating corrective action on the part of the pilot. Efficient design will minimize the aerodynamic drag, thereby reducing the propulsive thrust required for a given flight condition, and will maximize the lifting capability per pound of airframe and engine weight, thereby increasing the useful, or transportable, load. *See* AIRCRAFT PROPULSION; AIRFRAME; FLIGHT CONTROLS. [D.C.H.]

Airport engineering A terminal facility used for aircraft takeoff and landing, and including facilities for handling passengers and cargo and for servicing aircraft. Facilities at airports are generally described as either airside, which commences at the secured boundary between terminal and apron and extends to the runway and to facilities beyond, such as navigational or remote air-traffic-control emplacements; or landside, which includes the terminal, cargo-processing, and land-vehicle approach facilities.

Airport design provides for convenient passenger access, efficient aircraft operations, and conveyance of cargo and support materials. Airports provide facilities for changing transportation modes, such as people transferring from cars and buses to aircraft, cargo transferring from shipping containers to trucks, or regional aircraft supplying passengers and cargo for intercontinental aircraft. In the United States, engineers utilize standards from the Federal Aviation Administration (FAA), aircraft performance characteristics, cost benefit analysis, and established building codes to prepare detailed layouts of the essential airport elements: airport site boundaries, runway layout, terminal-building configuration, support-building locations, roadway and rail access, and supporting utility layouts. Airport engineers constantly evaluate new mechanical and computer technologies that might increase throughput of baggage, cargo, and passengers.

Site selection. Site selection factors vary somewhat according to whether (1) an entirely new airport is being constructed or (2) an existing facility is being expanded. Few metropolitan areas have large areas of relatively undeveloped acreage within reasonable proximity to the population center to permit development of new airports. For those airports requiring major additional airfield capacity, however, and hence an entirely new site, the following factors must be evaluated for each alternate site: proximity to existing highways and major utilities; demolition requirements; contamination of air, land, and water; air-traffic constraints such as nearby smaller airport facilities; nearby mountains; numbers of households affected by relocation and noise; political jurisdiction; potential lost mineral or agricultural production; and costs associated with all these factors. Some governments have elected to create sites for new airports using ocean fills. The exact configuration of the artifical island sites is critical due to the high foundation costs, both for the airport proper and for the required connecting roadway and rail bridges.

Airfield configuration. Since the runways and taxiways constitute the largest portion of the airport's land mass, their layout, based on long-term forecasts of numbers of aircraft landings and departures, is generally one of the first steps in the airport design. A paved runway surface 12,000 ft (3660 m) long and 150 ft (45 m) wide is suitable for most applications. Runway length requirements change according to the type of aircraft, temperature, altitude, and humidity encountered. A parallel taxiway is generally constructed 600 ft (180 m) from the runway (measured centerline to centerline). It is connected by shorter high-speed taxiways to allow arriving aircraft to leave the runway surface quickly in order to clear another aircraft arrival as quickly as possible. This combination is generally referred to as a runway-taxiway complex.

Ideally, airports can exclusively utilize parallel runway complexes so that incoming and departing aircraft can also be parallel for safe, simultaneous operations. Under these conditions, runway thresholds would be slightly staggered to avoid wake turbulence interference between incoming aircraft. Staggered thresholds might also be used to minimize crossing of active runways by taxiing aircraft. Each crossing is a potential aircraft delay and a safety hazard.

When airports have sufficiently high-velocity crosswinds or tailwinds from more than one direction, crosswind runways must also be provided. These crosswind runways are located at some angle to the primary runway as dictated by a wind rose analysis. *See* WIND ROSE.

Runways are paved with concrete, asphalt, concrete-treated base, or some combination of layers of these materials. Runways for larger aircraft require thicker, more expensive pavement sections. Engineers design these pavements for long design lives. The expected life of a concrete runway can be increased from 20 to 40 years, based on enhanced mix designs and sections. *See* CONCRETE; PAVEMENT.

A system of vehicle service roads must be provided around the perimeter of the airfield both for access to the runways and for security patrols of the perimeter fencing. Airfield security fencing with a series of access gates is monitored with patrols and, increasingly, a remote camera surveillance system.

Terminal configuration. The terminal is generally the airport building that houses ticketing, baggage claim, and transfer to ground transportation. The concourse is generally the combination of facilities for boarding aircraft, sorting baggage according to flight, and unloading cargo carried in commercial aircraft. Airport terminal and concourse configurations generally fall into three categories: (1) terminal contiguous with concourse satellite extensions (known as piers or fingers) used for boarding aircraft; (2) unit terminals, which serve as transfer points both from ground transportation modes into the building and from the building into the aircraft; (3) and detached terminal and concourses, sometimes referred to as a landside and airside terminals, connected by a people-mover train system, an underground walkway or a surface transport vehicle.

Support buildings. The primary types of support buildings required by the airlines for their airport operations are flight kitchens to prepare meals for passengers, hangars to service aircraft, and ground support equipment buildings to service ground support vehicles such as tugs, baggage carts, and service trucks. The high number of trips for support vehicles to travel from these buildings to load or service aircraft requires that the buildings be located in reasonable proximity to the aircraft gates. However, the buildings should be sufficiently far to allow the concourses to be expanded without requiring demolition of these support facilities.

An airport requires fire equipment to provide extremely fast primary and secondary response to each and every runway. Locating the aircraft rescue and fire-fighting stations requires careful positioning with respect to the taxiway system. Other types of support buildings include storage buildings, employee facilities, administrative offices, vehicle maintenance buildings for snow removal and airport vehicles, roadway revenue plaza offices, and training facilities.

Fuel and deicing facilities. Economies of scale and safety considerations generally encourage the implementation of large, centralized common systems for aircraft fuel. The large storage tanks required to ensure adequate reserves of fuel are located in remote areas of the airport, generally in aboveground facilities. Underground distribution piping then transports the fuel to hydrant pits or truck fueling stations close to aircraft operations. This system, like most utilities, is designed with backup capacity by looping piping around each service area. If a break occurs in a section of pipe, valves are automatically closed and the supply direction is reversed. Fuel tanks require extensive analysis of structural, mechanical, and electrical design. These tanks are widely spaced to avoid the transmission of fire and to allow room for a surface detention area to store burning fuel. [G.S.E.]

Airport noise The unwanted sound from airport operations, primarily from aircraft of all types. It affects neighbors both adjacent to and farther from the airport.

Source noise control of jets has progressed with time. The first jet aircraft, called stage 1, had no noise control on their engines. Federal law now prohibits use of stage 1 in the United States. Simple muffling was added to the jet engines in the 1970s to give stage 2 aircraft. At the same time, improvements were made to the engine design, resulting in about 10 decibels of noise reduction for a given aircraft type. This type of engine powers the stage 3 aircraft. As of January 1, 2000, all large turbojet aircraft operating in the United States were stage 3, by federal mandate. In anticipation of the stage 3 mandate, owners of stage 2 aircraft could sometimes use an engine retrofit, called a hushkit, to meet the stage 3 noise criteria, prolonging the useful life of the aircraft. Additional improvements, starting in 1992, have continued to reduce aircraft noise emissions. In June 2001, the International Civil Organization (ICAO) adopted the next quieter level, called Chapter 4 of their regulations (Annex 16). It effectively eliminates hushkitted older aircraft from operating in countries which adopt these rules. *See* AIRCRAFT ENGINE PERFORMANCE; JET PROPULSION; MUFFLER; TURBOJET.

Airports can reduce the noise from backing up, repositioning, or taxiing by having the aircraft towed to or from the gate. The source noise during flight can be reduced by using lower thrust settings when planes fly over noise-sensitive areas. The most common path noise control is by use of barriers or berms. For effective noise reduction (at least 5 dB), the top of the barrier must intercept the line-of-sight between the aircraft engine and the observer.

Airport noise is measured with noise monitors, consisting of microphones and meters. Most large airports have a distributed network of permanent noise monitors which record observed noise levels and accumulate the data for future transfer to the airport's computer. Small airports are most likely to have only portable measuring equipment or to use consultants. *See* ACOUSTIC NOISE; NOISE MEASUREMENT. [N.S.T.]

Airport surface detection equipment A ground mapping system that uses analog radar equipment to provide surveillance of aircraft and other surface vehicles on an airport surface. It is used by air-traffic controllers in airport control towers to monitor and control the movement of aircraft and vehicles. A situation display of the targets includes a map identifying the runways and taxiways and a visual map of the airport features, created through the contrast on the radar display resulting from the absence of returns from smooth concrete surfaces and the ground-clutter returns from grassy areas. An important safety function of the airport surface detection equipment (ASDE) is to determine whether or not a runway is clear for the next departure or arrival operation. This runway clearance determination is aided by the ASDE's capability to display an image of the aircraft in which the target's extremities (nose, tails, and wing tips), especially for large aircraft, are evident to the eye. *See* AIRPORT.

The ASDE antenna revolves at 60 revolutions per minute, providing a rapid update of target movements. It is located on a high vantage point, typically on top of the tower cab or on a special remote tower, that provides line-of-sight coverage of the desired areas. Modern ASDEs utilize digital processing and an interrogation technique called frequency agility, which permits the transmission of up to 16 different Ku-band frequencies within a cycle. These techniques optimize target detection in the presence of ground and rain clutter and the rejection of false targets. In the digital processing, different thresholds for rejecting clutter are used on specified areas of the airport surface, such as on paved surfaces versus grassy areas. These systems are designed to detect all aircraft and vehicles having a radar cross section of 30 ft^2 (3 m^2) or greater, and will resolve two closely spaced targets when separated by 40 ft (12 m) in range or 80 ft (24 m) in azimuth at a range of 12,000 ft (3650 m). The basic coverage is the entire airport surface out to 24,000 ft (7300 m) in range and 200 ft (60 m) in altitude. Areas where coverage is not desired are ignored for detection and blanked out on the situation display.

The digital processing in modern ASDEs also provides the basis for automation functions that process target data to provide controllers with improved information. Principal automation features include target tracking, the application of runway safety logic functions to the tracks, and automatic alerting of the controller to dangerous situations determined by the logic. The design requirements for advanced surface surveillance systems include providing data that allows determination of target identity and target intent from flight-plan information or from data-link messages between the control tower and aircraft. *See* AIR-TRAFFIC CONTROL; ELECTRONIC NAVIGATION SYSTEMS; MOVING-TARGET INDICATION; RADAR. [R.A.Ba.]

Airship A propelled and steered aerial vehicle, dependent on the displacement of air by a lighter gas for lift. An airship, or dirigible balloon, is composed primarily of a streamlined hull, usually a prolate ellipsoid which contains one or more gas cells, fixed and movable tail surfaces for control, a car or cabin for the crew or passengers, and a propulsion system.

Two fundamentally different designs have been successfully used for past airships, the nonrigid and the rigid. A third type, the semirigid, is essentially a variant of the nonrigid type, differing by the addition of rigid keel.

A typical nonrigid airship, or blimp, consists of a flexible envelope, usually fabric, filled with lifting gas that is slightly pressurized. Internal air compartments (ballonets) expand and contract to maintain the pressure in the envelope as atmospheric pressure and temperature vary. Ballonet volume is controlled by ducting air from the prop wash or by electric blowers. The weights of the car structure, propulsion system, and other concentrated loads are supported by catenary systems attached to the envelope.

The nonrigid airships are historically significant for two reasons. First, a nonrigid airship was the first aircraft of any type to achieve controllable flight, in the 1850s. Second, nonrigid airships were the last type to be used on an extensive operational basis; the U.S. Navy decommissioned the last of its non-rigid airship fleet in the early 1960s.

The structure of a rigid airship (see illustration) was usually an aluminum ring-and-girder frame. An outer covering was at-

***Akron*, rigid airship of the U.S. Navy.**

tached to the frame to provide a suitable aerodynamic surface. Several gas cells were arrayed longitudinally within the frame. These cells were free to expand and contract, thereby allowing for pressure and temperature variations. Thus, despite their nearly identical outward appearance, rigid and nonrigid airships were significantly different in their construction and operation.

Many modern airship vehicle concepts have been proposed. The fully buoyant conventional concepts are modern versions of the classical, fully buoyant, rigid, and nonrigid airship concepts. Fully buoyant means all the lift is provided by displacement. These airships would make extensive use of modern aircraft structural materials, propulsion systems, control systems, and electronics.

Other concepts include partially buoyant, or hybrid, designs in which the buoyant lift is substantially augmented by aerodynamic or propulsive lift. Thus, these vehicles are partly heavier than air and partly lighter than air. Some hybrids are short-takeoff and landing (STOL) vehicles, and others have vertical-takeoff and landing (VTOL) capability. An important advantage of the hybrids is that they promise to alleviate the costly ground-handling requirement of past airship designs. *See* SHORT TAKEOFF AND LANDING (STOL); VERTICAL TAKEOFF AND LANDING (VTOL).

Airships are once again being seriously considered for many civil and military applications. An airship's natural attributes compared with other vehicles draw attention to short-range transportation and to missions requiring high loiter time, that is, patrol and surveillance applications. *See* BALLOON. [M.D.A.]

Airspeed indicator A device that computes and displays speed of an aircraft relative to the air mass in which the aircraft is flying. The commonest type is the indicated airspeed meter, which measures differential pressure between the total ram pressure from the Pitot system and the total static pressure; it then converts this difference into units of speed (mi/h or knots) under standard conditions. Although the indicated values are incorrect above zero altitude, the relationship to the aircraft handling remains essentially unchanged, thus providing a measure of the flyability of the aircraft.

True airspeed indicators are similar but include a more complex mechanism that also senses both the absolute pressure and temperature, and compensates for the change of density of the air mass, thus obtaining true airspeed. This indication is of value in computing course information.

For those aircraft that reach higher speeds (transonic and supersonic), the ratio of the actual speed to the local speed of sound is used. Devices that compute this value are known as Machmeters. *See* MACH NUMBER; PITOT TUBE. [J.W.A.]

Aistopoda An order of extremely elongate, limbless fossil amphibians in the subclass Lepospondyli from Permo-Carboniferous rocks of North America and the British Isles. The order includes three families: Lethiscidae (*Lethiscus*), Ophiderpetontidae (*Coloraderpeton, Ophiderpeton*), and Phlegethontiidae (*Aornerpeton, Phlegethontia, Sillerpeton*).

The skulls of aistopods are fenestrated and exhibit a reduced number of bony elements. The vertebral centra are holospondylous (single-pieced), hourglass-shaped, and fused to their neural arches. Vertebrae can exceed 200 in number and frequently bear foramina for passage of spinal nerves. Ribs typically bear a unique process, which gives them a K-shape in some species.

Most aistopods were presumably aquatic, although rib specializations, and the more gracile proportions of phlegethontiids, suggest a rather snakelike, terrestrial habit. *See* AMPHIBIA; LEPOSPONDYLI. [C.F.W.]

Albedo A term referring to the reflecting properties of surfaces. White surfaces have albedos close to 1; black surfaces have albedos close to 0.

Several types of albedos are in common use. The Bond albedo (A_B) determines the energy balance of a planet or satellite and is defined as the fraction of the total incident solar energy that the planet or satellite reflects to space. The "normal albedo" of a surface, more properly called the normal reflectance (r_n), is a measure of the relative brightness of the surface when viewed and illuminated vertically. Such measurements are referred to as a perfectly white Lambert surface—a surface which absorbs no light and scatters the incident energy isotropically—usually approximated by magnesium oxide (MgO), magnesium carbonate ($MgCO_3$), or some other bright material. *See* PHOTOMETRY; PLANET.

Bond albedos for solar system objects range from 0.9 for Saturn's icy satellite Enceladus and Neptune's Triton to values as low as 0.01–0.02 for dark objects such as the satellites of Mars. Cloud-shrouded Venus has the highest Bond albedo of any planet (0.76). The value for Earth is 0.35. The Bond albedo is defined over all wavelengths, and its value therefore depends on the spectrum of the incident radiation.

Normal reflectances of some common materials are listed in the table. The normal reflectances of many materials are strongly dependent on wavelength, a fact that is commonly used in planetary science to infer the composition of surfaces remotely. While the Bond albedo cannot exceed unity, the normal reflectance of a surface can if the material is more backscattering at opposition than the reference surface. [J.V.]

Normal reflectances of materials*

Material	Albedo
Lampblack	0.02
Charcoal	0.04
Carbonaceous meteorites	0.05
Volcanic cinders	0.06
Basalt	0.10
Iron meteorites	0.18
Chondritic meteorites	0.29
Granite	0.35
Olivine	0.40
Quartz	0.54
Pumice	0.57
Snow	0.70
Sulfur	0.85
Magnesium oxide	1.00

* Powders; for wavelengths near 0.5 micrometer.

Albite A sodium-rich plagioclase feldspar mineral whose composition extends over the range $Ab_{100}An_0$ to $Ab_{90}An_{10}$, where Ab (= albite) is $NaAlSi_3O_8$ and An (= anorthite) is $CaAl_2Si_2O_8$. Albite occurs in crustal igneous rocks as a major component of pegmatites and granites, in association with quartz, mica (usually muscovite), and potassium feldspar (orthoclase or microcline). Sodium and potassium feldspars usually occur as distinct mineral grains, sizes varying from millimeter to meter scale. They are frequently intergrown; if the intergrowth is visually observable in a hand specimen, the composite material is known as macroperthite; if visible only in a microscope, microperthite; and if submicroscopic in scale, cryptoperthite. In metamorphic rocks albite is found in granitic gneisses, and it may be the principal component of arkose, a feldspar-dominant, sedimentary rock. Cleavelandite, a platy variety, is sometimes found in lithium-rich pegmatites. *See* Arkose; Feldspar; Gneiss; Igneous rocks; Pegmatite; Perthite. [P.H.R.]

Albumin A type of globular protein that is characterized by its solubility in water and in 50% saturated aqueous ammonium sulfate. Albumins are present in mammalian tissues, bacteria, molds, and plants, and in some foods. Serum albumin, which contains 584 amino acid residues, is the most abundant protein in human serum, and it performs two very important physiological functions. It is responsible for about 80% of the total osmotic regulation in blood, and it transports fatty acids from adipose tissue to muscle. When excessive amounts of albumin are found in the urine upon clinical examination, some form of kidney disease is usually indicated. Another important albumin, ovalbumin, is found in egg white. This protein is about two-thirds the size of serum albumin, and it contains sugar residues in addition to amino acid residues (that is, it is a glycoprotein). *See* Protein. [J.M.M.]

Alcohol A member of a class of organic compounds composed of carbon, hydrogen, and oxygen. They can be considered as hydroxyl derivatives of hydrocarbons produced by the replacement of one or more hydrogens by one or more hydroxyl (S—OH) groups.

Classification. Alcohols may be mono-, di-, tri-, or polyhydric, depending upon the number of hydroxyl groups they possess. They are classified as primary (RCH_2OH), secondary (R_2CHOH), or tertiary (R_3COH), depending on the number of hydrogen atoms attached to the carbon atom bearing the hydroxyl group. Alcohols can also be characterized by the molecular configuration of the hydrocarbon portion (aliphatic, cyclic, heterocyclic, or unsaturated). There are two systems in use for alcohol nomenclature, the common naming system and the IUPAC (International Union of Pure and Applied Chemistry) naming system. The common name is sometimes associated with the natural source of the alcohol or with the hydrocarbon portion (for example, methyl alcohol, ethyl alcohol). The IUPAC method is a systematic procedure with agreed-upon rules. The name of the alcohol is derived from the parent hydrocarbon which corresponds to the longest carbon chain in the alcohol. The final “e” in the hydrocarbon name is dropped and replaced with “ol”; and a number before the name indicates the position of the hydroxyl. Examples of these two systems are given in the table.

Oxidation of primary alcohols produces aldehydes (RCHO) and carboxylic acids (RCO_2H); oxidation of secondary alcohols yields ketones (RCOR′). Dehydration of alcohols produces alkenes and ethers (ROR). Reaction of alcohols with carboxylic acids results in the formation of esters (ROCOR′), a reaction of great industrial importance. The hydroxyl group of an alcohol is readily replaced by halogens or pseudohalogens. *See* Aldehyde; Alkene; Carboxylic acid; Ester; Ether; Ketone.

Uses. Industrially, the monohydric aliphatic alcohols are classified according to their uses as the lower alcohols (1–5 carbon atoms), the plasticizer-range alcohols (6–11 carbon atoms), and the detergent-range alcohols (12 or more carbon atoms). The lower alcohols are employed as solvents, extractants, and antifreezes. Esters of the lower alcohols are employed extensively as solvents for lacquers, paints, varnishes, inks, and adhesives. The plasticizer-range alcohols find their primary use in the form of esters as plasticizers and also as lubricants in high-speed applications such as jet engines. The detergent-range alcohols are used in the form of sulfate and ethoxysulfate esters in detergents and surfactants.

Alcohols and their formulas

Name		
Common	IUPAC	Formula
Methyl alcohol	Methanol	CH_3OH
Ethyl alcohol	Ethanol	CH_3CH_2OH
n-Propyl alcohol	1-Propanol	$CH_3CH_2CH_2OH$
Isopropyl alcohol	2-Propanol	$(CH_3)_2CHO$
n-Butyl alcohol	1-Butanol	$CH_3(CH_2)_2CH_2OH$
sec-Butyl alcohol	2-Butanol	$CH_3CH_2CHOHCH_3$
tert-Butyl alcohol	2-Methyl-2-propanol	$(CH_3)_3COH$
Isobutyl alcohol	2-Methyl-1-propanol	$(CH_3)_2CHCH_2OH$
n-Amyl alcohol	1-Pentanol	$CH_3(CH_2)_3CH_2OH$
n-Hexyl alcohol	1-Hexanol	$CH_3(CH_2)_4CH_2OH$
Allyl alcohol	2-Propen-1-ol	$CH_2{=}CHCH_2OH$
Crotyl alcohol	2-Buten-1-ol	$CH_3CH{=}CHCH_2OH$
Ethylene glycol	1,2-Ethanediol	$HOCH_2CH_2OH$
Propylene glycol	1,2-Propanediol	$CH_3CHOHCH_2OH$
Trimethylene glycol	1,3-Propanediol	$HOCH_2CH_3CH_2OH$
Glycerol	1,2,3-Propanetriol	$CH_2OHCHOHCH_2OH$

Alcohols are derived either from natural-product processing, such as the fermentation of carbohydrates and the reductive cleavage of natural fats and oils, or by chemical synthesis based on the hydrocarbons derived from petroleum or the synthesis gas from coal.

The fermentation of sugars and starches (carbohydrates) to produce alcoholic beverages has been employed at least since history has been recorded. The industrial fermentation process is the biological transformation of a carbohydrate by a highly specialized strain of yeast to produce the desired product, such as ethanol, or 1-butanol and acetone. Fermentation is no longer the major source of 1-butanol, but still accounts for all potable ethanol and a large proportion of the ethanol used industrially worldwide. As sources of hydrocarbons based on petroleum continue to be depleted, fermentation processes based on renewable raw materials are likely to become more important. *See* Distilled spirits; Fermentation. [P.E.F.]

Alcohol fuel Any alcohol burned as a fuel. If available, any alcohol may be used as a fuel, but ethanol and methanol are the only ones which are sufficiently inexpensive. Alcohols are useful fuels, even though the oxygen atom in any alcohol molecule reduces its heating value, because the molecular structure increases the combustion efficiency. *See* Combustion; Gasoline.

Ethanol burns well in engines designed for gasoline and has a high octane rating. However, because of the high cost of the raw materials required, or of their conversion, it costs much more than gasoline. Gasohol is produced by dissolving 5–15% absolute (water-free) alcohol in gasoline. The 5% water fraction in 95% alcohol causes phase separation because of its insolubility, making 95% alcohol unsuitable for use in gasohol. *See* Ethyl alcohol; Octane number.

Carbon in any material can be converted to methanol. Natural gas has been favored as a raw material, and its energy may be delivered at a much lower cost if the gas is converted to methanol than if it is piped directly or if the gas is converted to liquefied natural gas, shipped, and stored at its cryogenic temperature. *See* Liquefied natural gas (LNG); Natural gas.

Methanol is the most versatile and cheapest liquid fuel that can be made. It is also less flammable than gasoline; accidental fires are extinguished with water instead of being spread as flaming films. When it combusts, it yields neither particulates (soot) nor sulfur oxides, and yields lower quantities of nitrogen oxides than any other fuel. When produced from natural gas or solid fuel, methanol can always be regasified to give substitute natural gas (SNG) with only a small loss of energy. Even when expensive chemical-grade methanol is used in automobiles with relatively insignificant changes, the mileage costs are less for these vehicles than when they use gasoline as a fuel. *See* METHANOL. [D.F.O.]

Alcoholism The continuous or excessive use of alcohol (ethanol) with associated pathologic results. Alcoholism is characterized by constant or periodic intoxication, although the pattern of consumption varies markedly. Individuals admitted for the first time to an alcoholism treatment center typically have been consuming approximately 3–4 oz (80–100 g) of pure alcohol per day, corresponding to about seven to nine drinks or bottles of beer or glasses of wine. Studies have shown that problem drinking in these populations starts at about 2 oz/day (60 g/day), that is, four to five drinks per day, and that these are consumed in rapid succession, leading to intoxication on three or more days per week. Individuals who consume these levels of alcohol have also a greater than average risk of developing alcoholic liver cirrhosis. However, the levels should not be taken as absolute, since they can vary greatly in different individuals, according to body weight and other factors.

The symptoms and consequences associated with severe alcohol consumption also vary greatly; that is, in some individuals only a few may be present. These may consist of the development of physical dependence manifested as a state of physical discomfort or hyperexcitability (tremors or shakes) that are reduced by continued consumption; the development of tolerance to the effects of alcohol, which leads individuals to increase their consumption; accidents while intoxicated; blackouts, characterized by loss of memory of events while intoxicated; work problems, including dismissal; loss of friends and family association; marital problems, including divorce; financial losses, including bankruptcy or continual unemployment. Medical problems can include gastric ulcers, pancreatitis, liver disease, and brain atrophy. The last is often associated with cognitive deficiencies, as shown by the inability to comprehend relatively simple instructions or to memorize a series of numbers. *See* COGNITION.

Almost without exception, individuals seeking an early treatment for their alcohol problems have very good probabilities of recovery. The lesser the number of presenting problems described above, the better the chances of favorable outcome, and so an early identification of problem drinking by family, friends, employers, or physicians becomes very important. The types of intervention vary greatly, progressing from self-monitoring techniques to intensive outpatient and inpatient programs to Alcoholics Anonymous groups.

The exact mechanisms of the pharmacological actions of alcohol are not known. Alcohol can act as a stimulant at lower doses and as a depressant at higher doses. Even at very low doses alcohol can impair the sensitivity to odors and taste. Also, low doses are known to alter motor coordination and time and space perception, important aspects of car driving. Some effects are already seen at levels of 0.05%. Pain sensitivity is diminished with moderate doses. In some individuals, alcohol is known to diminish feelings of self-criticism and to inhibit fear and anxiety, effects which are probably related to an alcohol-induced sociability. These effects act, no doubt, as psychological reinforcers for the use of alcoholic beverages.

It is generally accepted that alcohol affects the nerve cell by preventing the production and propagation of electric impulses along a network consisting of axons and synapses. A major finding in the mid-1980s was that some of the neurologic effects of alcohol can be quickly reversed by new experimental drugs. Studies have shown that alcohol enhances the actions of an inhibitory brain neurotransmitter referred to as gamma-aminobutyric acid (GABA). Benzodiazepines, such as diazepam, are anxiety-reducing and sedative drugs which also enhance the effects of GABA. These effects can be reduced by experimental antagonist molecules, which interact in the brain in the same regions where GABA is found. *See* SYNAPTIC TRANSMISSION.

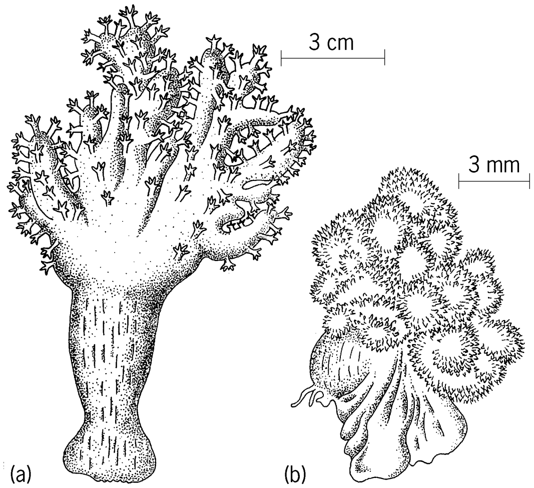
The liver is responsible for about 80% of the metabolism of alcohol. In the liver, alcohol is first oxidized to acetaldehyde and then to acetate, which is metabolized in many tissues, including the brain, heart, and muscles. A 150-lb (68-kg) person metabolizes approximately 0.4 oz (10 g) of pure alcohol per hour (about 1 oz of a distilled beverage per hour) or, if alcohol is continuously present in the bloodstream, about 8–10 oz (190–240 g) of pure alcohol per day, equivalent to 1300–1600 calories per day. Since alcoholic beverages contain negligible levels of essential nutrients, these calories are called "empty calories." Many alcoholics show malnutrition due to the fact that an important part of their caloric intake is alcohol. Alcohol also impairs the absorption and the metabolism of some essential nutrients. In the presence of alcohol, about 80% of oxygen consumed by the liver is devoted to the metabolism of alcohol; as a consequence, other substances such as fats, normally oxidized by the liver, are not metabolized, leading to fat accumulation in the liver. *See* LIVER; MALNUTRITION.

Alcoholic liver disease is characterized by two conditions: failure of the liver to detoxify noxious substances and to produce essential products; and increased resistance to blood flow through the liver. Alcoholic liver disease and liver cirrhosis rank among the 10 leading causes of mortality in the United States and Canada. *See* CIRRHOSIS.

There is abundant evidence that tendency to alcoholism can be of familial origin, due to environmental, cultural, and genetic factors. A Swedish study demonstrated that identical twins are twice as likely to have a common alcoholic problem as fraternal twins. In an American-Danish study, it was shown that children of alcoholic parents are more likely to develop alcoholism (18%) than children of nonalcoholic parents (4%) when both groups of children were adopted by nonrelatives within 6 weeks of birth. *See* BEHAVIOR GENETICS; BEHAVIORAL TOXICOLOGY. [Y.I.]

Pharmacotherapy for alcohol rehabilitation has been gaining wider acceptance. Specific pharmacotherapies which have received the most research attention utilize naltrexone and disulfiram. Other promising pharmacological interventions are acamprosate and buspirone. Naltrexone is an opiate receptor antagonist which blocks the effects of endogenous opioids in the brain. Research from animal studies suggests that alcohol activates endogenous opioid systems and, thereby, may contribute to the pleasurable effects produced by alcohol consumption. Consequently, naltrexone might reduce the reinforcing effects of alcohol consumed by people and decrease their incentive to drink. Disulfiram is a drug which causes an inhibition of the enzyme aldehyde dehydrogenase, leading to an increase in acetaldehyde blood levels. This rise will produce nausea, vomiting, tachycardia, difficulty in breathing, and changes in blood pressure leading to hypotension. Acamprosate may function to reduce alcohol-induced euphoria related to the effects of excitatory neurotransmitters such as *N*-methyl-D-aspartate and have some blocking effects on opiate receptors. Buspirone, a nonbenzodiazepine antianxiety agent, may decrease anxiety symptoms associated with a protracted alcohol withdrawal syndrome, thus reducing alcohol relapse potential. Both of these medications require further investigation to determine their effectiveness as a pharmacotherapeutic agent in the treatment of alcoholism. [S.Mar.]

Alcyonacea An order of the subclass Alcyonaria. Alcyonacea, the soft corals (see illustration), are littoral anthozoans, which form massive or dendriform colonies with yellowish, brown, or olive colors. Most attach to some solid substratum; however, some remain free in sandy or muddy places. The only skeletal structures are small, elongated, spindle-shaped or rodlike, warty sclerites which are scattered over the mesoglea. The colony is supple and leathery. The polyp body is embedded in the coenenchyme, from which retractile anthocodia protrude in



Alcyonaceans. (*a*) *Alcyonium palmatum* (*after Y. De/age*). (*b*) *Dendronephthya sp.* (*after H. Utinomli*).

Alcyonium. In *Xenia* and *Heteroxenia*, anthocodia are nonretractile. The polyp base is protected by many sclerites and is termed a calyx. *See* ALCYONARIA; COELENTERATA. [K.At.]

Alcyonaria A subclass of the Anthozoa. These coelenterates are colonial; most are sedentary and littoral, and some live at great depths. The ordinary polyp, the autozooid, has eight motile, contractile, hollow, pinnately branched tentacles. Eight complete mesenteries are present, of which the dorsal or asulcal pair is the most developed and bears the largest, heavily ciliated ectodermal filaments. The remaining mesenteries bear endodermal filaments having many glandular cells. Longitudinal retractor muscles are strongly developed on their ventral or sulcal surfaces. The stomodeum or pharynx, with a single siphonoglyph in its sulcal edge, is lined by a ciliated glandular epithelium. The gastrovascular cavity of each polyp is interconnected by complex canal systems or solenia. These permeate the colonial spiculiferous mesoglea or coenenchyme. The skeleton is formed by a deposition of horny material secreted by ectoderm cells, or by ectodermal scleroblasts which secrete calcareous spicules or sclerites of various shapes. The musculatures are not particularly well developed.

The oral end of the polyp is termed the anthocodium. The basal portion, or anthostele, is embedded in coenenchyme containing numerous ameboid cells and scleroblasts.

The Alcyonaria are characterized by a strongly developed siphonoglyph, which serves to circulate water in a colony. Alcyonaria are either dioecious or monoecious. The gonads ripen in the endodermal mesenteric filaments. The daughter polyp buds asexually from the solenial system or from a parent's body wall. Pennatulacea and some other forms are dimorphic. The siphonozooid is smaller than the autozooid. It lacks tentacles or the tentacles are rudimentary and usually sterile. *See* ANTHOZOA; COELENTERATA. [K.At.]

Aldebaran A cool red giant star, prominently located in the constellation Taurus. With its red color, it appropriately represents the eye of the Bull. At a distance of 20 parsecs (65 light-years), Aldebaran, or α Tauri, is among the nearest (and brightest) giant stars to the Sun. The star is an example of a K-type giant, a very common type of evolved star that derives its energy from the thermonuclear burning of helium in a core surrounded by a thin, hydrogen-burning shell. Its spectral type of K5III corresponds to an effective temperature of 6700°F (4000 K) and a radius of about 40 times the Sun. It is nearly 150 times more luminous than the Sun and, as is typical for K giants, its brightness varies by a modest amount. Aldebaran is accompanied in a long-period binary-star system by a cool dwarf companion star some 100,000 times fainter than the giant. *See* BINARY STAR; GIANT STAR; STAR; TAURUS. [H.A.McA.]

Aldehyde One of a class of organic chemical compounds represented by the general formula RCHO. Formaldehyde, the simplest aldehyde, has the formula HCHO, where R is hydrogen. For all other aldehydes, R is a hydrocarbon radical which may be substituted with other groups such as halogen or hydroxyl (see table). Because of their high chemical reactivity, aldehydes are important intermediates for the manufacture of resins, plasticizers, solvents, dyes, and pharmaceuticals.

Aldehydes and their formulas

Compound	Formula
Formaldehyde	HCHO
Acetaldehyde	CH_3CHO
Acetaldol	$CH_3CHOHCH_2CHO$
Propionaldehyde	C_2H_5CHO
n-Butyraldhyde	$CH_3(CH_2)_2CHO$
Isobutyraldehyde	$(CH_3)_2CHCHO$
Acrolein	$CH_2{=}CHCHO$
Crotonaldehyde	$CH_3CH{=}CHCHO$
Chloral	CCl_3CHO
Chloral hydrate	$CCl_3CH(OH)_2$
Benzaldehyde	Cinnamaldehyde	
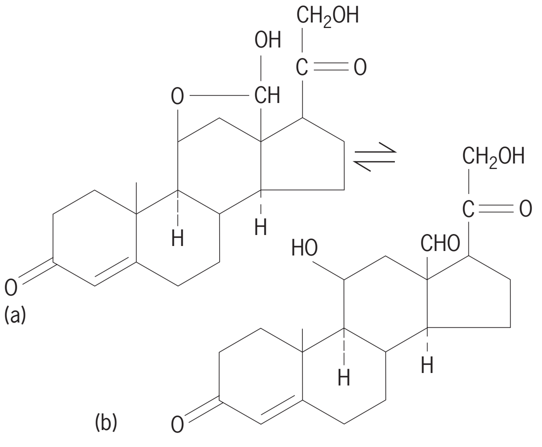
At room temperature formaldehyde is a colorless gas. The other low-molecular-weight aldehydes are colorless liquids having characteristic, somewhat acrid odors. The unsaturated aldehydes acrolein and crotonaldehyde are powerful lacrimators. The important reactions of aldehydes include oxidation, reduction, aldol condensation, Cannizzaro reaction, and reactions with compounds containing nitrogen.

Because of the importance of aldehydes as chemical intermediates, many industrial and laboratory syntheses have been developed. The more important of these methods include catalytic dehydrogenation of primary alcohols, oxidation of primary alcohols, oxidation of olefins, and hydroformylation of olefins. *See* FORMALDEHYDE. [P.E.F.]

Alder A deciduous tree, *Alnus rubra*, which grows from Alaska to northern California and eastern Idaho. It is recognized by its stalked buds, simple leaves, and dry, conelike, ellipsoid fruit. With the big-leaf maple it shares the role of principal hardwood tree in the Pacific Northwest, where most of the commercially important trees are conifers. The wood is used in furniture. *See* FAGALES. [A.H.G./K.P.D.]

Aldosterone The steroid hormone found in the biologically active amorphous fraction that remains after separation of the various crystalline steroid substances, such as cortisol and corticosterone, from adrenal extracts. In solution, aldosterone



Structures for two forms of aldosterone in an equilibrium mixture, (*a*) aldo and (*b*) lactol.

exists as an equilibrium mixture of aldo and lactol forms (see illustration).

The chief function of aldosterone is the regulation of electrolyte metabolism, that is, promotion of sodium retention and enhancement of potassium excretion. Aldosterone is the most potent of the hormones which are concerned in this type of metabolism. *See* ADRENAL GLAND; HORMONE; STEROID. [C.H.L.]

Alfalfa The world's most valuable forage legume, *Medicago sativa*, known also as lucerne. It is grown for hay, pasture, and silage. Valued highly as livestock feed, alfalfa hay cut at a late bud or early bloom stage (and cured properly) contains 17–24% protein and is a good source of certain vitamins and minerals. *See* ROSALES.

Alfalfa is a herbaceous perennial legume characterized by a deep taproot, which shows a varying degree of branching. Erect or semierect stems, bearing an abundance of leaves, grow to a height of 2–3 ft (0.6–0.9 m). The number of stems arising from a single woody crown may vary from just a few to 50 or more. New stems develop when older ones are mature or have been cut or grazed. Flowers are borne on axillary racemes which vary greatly in size and number of flowers. Flower color is predominantly purple, or bluish-purple, but white, cream, yellow, green, lavender, and reddish-purple occur. The fruit is a legume, or pod, usually spirally coiled in *M. sativa*, but crescent-shaped or straight in *M. falcata*. Seeds are small and the color varies from yellow to brown.

Reproduction in alfalfa is mainly by cross-fertilization. Pollination is effected largely by bees. Seed production is favored by bright sunny days, cool nights, an abundance of bees, and dry weather for harvesting.

Alfalfa is widely adapted to temperate and subtropical climates and soils. It is grown from 40°S in Argentina and New Zealand to 60°N in Canada, Sweden, and Russia. It is not well adapted to humid tropical conditions.

Deep fertile loams are best and good drainage is essential. The water requirement for sustained high yields is great, and moisture deficiency often is a serious limiting factor in areas dependent on natural rainfall.

More than 80 improved cultivars of alfalfa are recognized as eligible for seed certification in the United States. These trace to three basic stocks: *M. sativa*, purple-flowered, narrow-crowned, and erect; *M. falcata*, yellow-flowered, somewhat prostrate, with deep-set crown and branching roots; and an intermediate form, often called variegated, derived from crossing *M. sativa* and *M. falcata*. [C.H.H.]

Alfvén waves Propagating oscillations in electrically conducting fluids or gases in which a magnetic field is present. Magnetohydrodynamics deals with the effects of magnetic fields on fluids and gases which are efficient conductors of electricity. Molten metals are generally good conductors of electricity, and they exhibit magnetohydrodynamic phenomena. Gases can be efficient conductors of electricity if they become ionized. Ionization can occur at high temperatures or through the ionizing effects of high-energy (usually ultraviolet) photons. A gas which consists of free electrons and ions is called a plasma. Most gases in space are plasmas, and magnetohydrodynamic phenomena are expected to play a fundamental role in the behavior of matter in the cosmos. *See* PLASMA (PHYSICS).

Waves are a particularly important aspect of magnetohydrodynamics. They transport energy and momentum from place to place and may, therefore, play essential roles in the heating and acceleration of cosmical and laboratory plasmas. A wave is a propagating oscillation. If waves are present, a given parcel of the fluid undergoes oscillations about an equilibrium position. The parcel oscillates because there are restoring forces which tend to return it to its equilibrium position. In an ordinary gas, the only restoring force comes from the thermal pressure of the gas. This leads to one wave mode: the sound wave. If a magnetic field is present, there are two additional restoring forces: the tension associated with magnetic field lines, and the pressure associated with the energy density of the magnetic field. These two restoring forces lead to two additional wave modes. Thus there are three magnetohydrodynamic wave modes. However, each restoring force does not necessarily have a unique wave mode associated with it. Put another way, each wave mode can involve more than one restoring force. Thus the usual sound wave, which involves only the thermal pressure, does not appear as a mode in magnetohydrodynamics. The three modes have different propagation speeds, and are named fast mode (F), slow mode (S), and intermediate mode (I). The intermediate mode is sometimes called the Alfvén wave, but some scientists refer to all three magnetohydrodynamic modes as Alfvén waves. The intermediate mode is also called the shear wave. Some scientists give the name magnetosonic mode to the fast mode.

Basic equations. The magnetohydrodynamic wave modes are analyzed by using the magnetohydrodynamic equations for the motion of a conducting fluid in a magnetic field, combined with Maxwell's equations and Ohm's law. *See* MAXWELL'S EQUATIONS.

It is possible to combine Ohm's law with Faraday's law of induction. The resultant equation is called the magnetohydrodynamic induction equation, which is the mathematical statement of the "frozen-in" theorem. This theorem states that magnetic field lines can be thought of as being frozen into the fluid, with the proviso that the fluid is always allowed to slip freely along the field lines. It is the coupling between the fluid and the magnetic field which makes magnetohydrodynamic waves possible. The oscillating magnetic field lines cause oscillations of the fluid parcels, while the fluid provides a mass loading on the magnetic field lines. This mass loading has the effect of slowing down the waves, so that they propagate at speeds much less than the speed of light (which is the propagation speed of waves in a vacuum). *See* ELECTROMAGNETIC RADIATION; LIGHT.

Unfortunately, the basic equations are too difficult to be of much use because some of them are nonlinear; that is, they contain products of the quantities for which a solution is sought. Nonlinear magnetohydrodynamics is still only in its infancy, and only a few specialized solutions are known. In order to get solvable equations, scientists accept the limitation of dealing with small-amplitude waves and linearize the equations, so that products of the unknowns are removed. Fortunately, much can still be learned from this procedure; the resulting equations have solutions which are harmonic in time and space. *See* HARMONIC MOTION.

The motions are pure shears. There is no compression of the plasma. The tension in the magnetic field lines is the only restoring force involved in the propagation of the wave. This mode is therefore closely analogous to the propagation of waves on a string.

Because these waves channel energy along magnetic fields, they may be responsible for the observed fact that cosmical plasmas are strongly heated in the presence of magnetic fields.

The fast mode is difficult to analyze. However, many cosmical and laboratory plasmas satisfy the strong-magnetic-field case where the fast mode is more easily understood.

Fast waves are compressive, and the magnetic field strength fluctuates as well. Thus fast waves are governed by the two restoring forces associated with the tension and pressure in the magnetic field.

The fast mode can propagate energy across the magnetic field.

Like the fast mode, the slow mode is difficult to study in general, and the discussion will again be confined to strong magnetic fields. The slow mode in a strong field is equivalent to sound waves which are guided along the strong magnetic field lines. The strong magnetic field lines can be thought of as a set of rigid pipes which allow free fluid motion along the pipes, but which restrict motion in the other two directions. The motions on the individual pipes are not coupled together, and thus the slow mode is analogous to the sound waves on a set of independent organ pipes. The slow mode channels energy along the magnetic field. Because the sound speed is small, by assumption, the slow mode transmits energy less effectively than the fast or intermediate modes.

Only small-amplitude waves have been considered. Real waves have finite amplitude, and nonlinear effects can sometimes be important. One such effect is the tendency of waves to steepen, ultimately forming magnetohydrodynamic shock waves and magnetohydrodynamic discontinuities. There is an abundance of magnetohydrodynamic discontinuities in the solar wind. *See* Shock wave; Solar wind.

It is also possible that waves can degenerate into turbulence. There are indications that this too happens in the solar wind. *See* Turbulent flow.

Only waves in a spatially uniform background have been considered. While the analysis of magnetohydrodynamic waves in a nonuniform background is complicated, it is possible to consider an extreme limit, in which the background is uniform except at certain surfaces where it changes discontinuously. Surfaces can support magnetohydrodynamic waves, which are in some respects similar to waves on the surface of a lake. These waves may play important roles in heating cosmical and laboratory plasmas. *See* Magnetohydrodynamics. [J.V.H.]

Algae An informal assemblage of predominantly aquatic organisms that carry out oxygen-evolving photosynthesis but lack specialized water-conducting and food-conducting tissues. They may be either prokaryotic (lacking an organized nucleus) and therefore members of the kingdom Monera, or eukaryotic (with an organized nucleus) and therefore members of the kingdom Plantae, constituting with fungi the subkingdom Thallobionta. They differ from the next most advanced group of plants, Bryophyta, by their lack of multicellular sex organs sheathed with sterile cells and by their failure to retain an embryo within the female organ. Many colorless organisms are referable to the algae on the basis of their similarity to photosynthetic forms with respect to structure, life history, cell wall composition, and storage products. The study of algae is called algology (from the Latin *alga*, meaning sea wrack) or phycology (from the Greek *phykos*, seaweed). *See* Bryophyta; Plant kingdom; Thallobionta.

General form and structure. Algae range from unicells 1–2 micrometers in diameter to huge thalli [for example, kelps often 100 ft (30 m) long] with functionally and structurally distinctive tissues and organs. Unicells may be solitary or colonial, attached or free-living, with or without a protective cover, and motile or nonmotile. Colonies may be irregular or with a distinctive pattern, the latter type being flagellate or nonmotile. Multicellular algae form packets, branched or unbranched filaments, sheets one or two cells thick, or complex thalli, some with organs resembling roots, stems, and leaves (as in the brown algal orders Fucales and Laminariales). Coenocytic algae, in which the protoplast is not divided into cells, range from microscopic spheres to thalli 33 ft (10 m) long with a complex structure of intertwined siphons (as in the green algal order Bryopsidales).

Classification. Sixteen major phyletic lines (classes) are distinguished on the basis of differences in pigmentation, storage products, cell wall composition, flagellation of motile cells, and structure of such organelles as the nucleus, chloroplast, pyrenoid, and eyespot. These classes are interrelated to varying degrees, the interrelationships being expressed by the arrangement of classes into divisions (the next-higher category). Among phycologists there is far greater agreement on the number of major phyletic lines than on their arrangement into divisions.

Superkingdom Prokaryotae
Kingdom Monera
Division Cyanophycota (= Cyanophyta, Cyanochloronta)
Class Cyanophyceae, blue-green algae
Division Prochlorophycota (= Prochlorophyta)
Class Prochlorophyceae
Superkingdom Eukaryotae
Kingdom Plantae
Subkingdom Thallobionta
Division Rhodophycota (= Rhodophyta, Rhodophycophyta)
Class Rhodophyceae, red algae
Division Chromophycota (= Chromophyta)
Class: Chrysophyceae, golden or golden-brown algae
Prymnesiophyceae (= Haptophyceae)
Xanthophyceae (= Tribophyceae), yellow-green algae
Eustigmatophyceae
Bacillariophyceae, diatoms
Dinophyceae, dinoflagellates
Phaeophyceae, brown algae
Raphidophyceae, chloromonads
Cryptophyceae, cryptomonads
Division Euglenophycota (= Euglenophyta, Euglenophycophyta)
Class Euglenophyceae
Division Chlorophycota (= Chlorophyta, Chlorophycophyta)
Class: Chlorophyceae, green algae
Charophyceae, charophytes
Prasinophyceae

Placing more taxonomic importance on motility than on photosynthesis, zoologists traditionally have considered flagellate unicellular and colonial algae as protozoa, assigning each phyletic line the rank of order. *See* Bacillariophyceae; Chrysophyceae; Cryptophyceae; Cyanophyceae; Dinophyceae; Euglenophyceae; Eukaryotae; Eustigmatophyceae; Phaeophyceae; Prasinophyceae; Prochlorophyceae; Prokaryotae; Protozoa; Prymnesiophyceae; Raphidophyceae; Rhodophyceae; Thallobionta; Xanthophyceae.

Although some unicellular algae are naked or sheathed by mucilage or scales, most are invested with a covering (wall, pellicle, or lorica) of diverse composition and construction. These coverings consist of at least one layer of polysaccharide (cellulose, alginate, agar, carrageenan, mannan, or xylan), protein, or peptidoglycan that may be impregnated or encrusted with calcium carbonate, iron, manganese, or silica. They are often perforated and externally ornamented. Diatoms have a complex wall composed almost entirely of silica. In multicellular and coenocytic algae, most reproductive cells are naked, but vegetative cells have walls whose composition varies from class to class. *See* CELL WALLS (PLANT).

Characteristics. Prokaryotic algae lack membrane-bounded organelles. Eukaryotic algae have an intracellular architecture comparable to that of higher plants but more varied. Among cell structures unique to algae are contractile vacuoles in some freshwater unicells, gas vacuoles in some planktonic blue-green algae, ejectile organelles in dinoflagellates and cryptophytes, and eyespots in motile unicells and reproductive cells of many classes. Chromosome numbers vary from $n = 2$ in some red and green algae to $n \geq 300$ in some dinoflagellates. The dinoflagellate nucleus is in some respects intermediate between the chromatin region of prokaryotes and the nucleus of eukaryotes and is termed mesokaryotic. Some algal cells characteristically are multinucleate, while others are uninucleate. Chloroplasts, which always originate by division of preexisting chloroplasts, have the form of plates, ribbons, disks, networks, spirals, or stars and may be positioned centrally or along the cell wall. Photosynthetic membranes (thylakoids) are arranged in distinctive patterns and contain pigments diagnostic of individual classes. *See* CELL (BIOLOGY); CELL PLASTIDS; CHROMOSOME; PHOTOSYNTHESIS; PLANT CELL.

In all classes of algae except Prochlorophyceae, there are cells that are capable of movement. The slow, gliding movement of certain blue-green algae, diatoms, and reproductive cells of red algae presumably results from extracellular secretion of mucilage. Ameboid movement, involving pseudopodia, is found in certain Chrysophyceae and Xanthophyceae. An undulatory or peristaltic movement occurs in some Euglenophyceae. The fastest movement is produced by flagella, which are borne by unicellular algae and reproductive cells of multicellular algae representing all classes except Cyanophyceae, Prochlorophyceae, and Rhodophyceae.

Internal movement also occurs in algae in the form of cytoplasmic streaming and light-induced orientation of chloroplasts. *See* CELL MOTILITY; CILIA AND FLAGELLA.

Sexual reproduction is unknown in prokaryotic algae and in three classes of eukaryotic unicells (Eustigmatophyceae, Cryptophyceae, and Euglenophyceae), in which the production of new individuals is by binary fission. In sexual reproduction, which is found in all remaining classes, the members of a copulating pair of gametes may be morphologically indistinguishable (isogamous), morphologically distinguishable but with both gametes motile (anisogamous), or differentiated into a motile sperm and a relatively large nonmotile egg (oogamous). Gametes may be formed in undifferentiated cells or in special organs (gametangia), male (antheridia) and female (oogonia). Sexual reproduction may be replaced or supplemented by asexual reproduction, in which special cells (spores) capable of developing directly into a new alga are formed in undifferentiated cells or in distinctive organs (sporangia). *See* REPRODUCTION (PLANT).

Most algae are autotrophic, obtaining energy and carbon through photosynthesis. All photosynthetic algae liberate oxygen and use chlorophyll *a* as the primary photosynthetic pigment. Secondary (accessory) photosynthetic pigments, which capture light energy and transfer it to chlorophyll *a*, include chlorophyll *b* (Prochlorophyceae, Euglenophyceae, Chlorophycota), chlorophyll *c* (Chromophycota), fucoxanthin among other xanthophylls (Chromophycota), and phycobiliproteins (Cyanophyceae, Rhodophyceae, Cryptophyceae). Other carotenoids, especially β-carotene, protect the photosynthetic pigments from oxidative bleaching. Except for different complements of accessory pigments (resulting in different action spectra), photosynthesis in algae is identical to that in higher plants. Carbon is predominantly fixed through the C_3 pathway. *See* CAROTENOID; CHLOROPHYLL.

The source of carbon for most photosynthetic algae is carbon dioxide (CO_2), but some can use bicarbonate. Many photosynthetic algae are also able to use organic substances (such as hexose sugars and fatty acids) and thus can grow in the dark or in the absence of CO_2. Colorless algae obtain both energy and carbon from a wide variety of organic compounds in a process called oxidative assimilation.

Numerous substances are liberated into water by living algae, often with marked ecological effects. These extracellular products include simple sugars and sugar alcohols, wall polysaccharides, glycolic acid, phenolic substances, and aromatic compounds. Some secreted substances inhibit the growth of other algae and even that of the secreting alga. Some are toxic to fishes and terrestrial animals that drink the water.

Occurrence. Algae are predominantly aquatic, inhabiting fresh, brackish, and marine waters without respect to size or degree of permanence of the habitat. They may be planktonic (free-floating or motile) or benthic (attached). Benthic marine algae are commonly called seaweeds. Substrates include rocks (outcrops, boulders, cobbles, pebbles), plants (including other algae), animals, boat bottoms, piers, debris, and less frequently sand and mud. Some species occur on a wide variety of living organisms, suggesting that the hosts are providing only space. Many species, however, have a restricted range of hosts and have been shown to be (or are suspected of being) at least partially parasitic. All reef-building corals contain dinoflagellates, without which their calcification ability is greatly reduced. Different phases in a life history may have different substrate preferences. Many fresh-water algae have become adapted to a nonaquatic habitat, living on moist soil, masonry and wooden structures, and trees. A few parasitize higher plants (expecially in the tropics), producing diseases in such crops as tea, coffee, and citrus. Thermophilic algae (again, chiefly blue-greens) live in hot springs at temperatures up to 163°F (73°C), forming a calcareous deposit known as tufa. One of the most remarkable adaptations of certain algae (blue-greens and greens) is their coevolution with fungi to form a compound organism, the lichen. *See* LICHENS; PHYTOPLANKTON; TUFA.

Geographic distribution. Fresh-water algae, which are distributed by spores or fragments borne by the wind or by birds, tend to be widespread if not cosmopolitan, their distribution being limited by the availability of suitable habitats. Certain species, however, are characteristic of one or another general climatic zone, such as cold-temperate regions or the tropics. Marine algae, which are spread chiefly by water-borne propagules or reproductive cells, often have distinctive geographic patterns. Many taxonomic groups are widely distributed, but others are characteristic of particular climatic zones or geographic areas. *See* PLANT GEOGRAPHY.

Economic importance. Numerous red, brown, and green seaweeds as well as a few species of fresh-water algae are consumed by the peoples of eastern Asia, Indonesia, Polynesia, and the North Atlantic. Large brown seaweeds may be chopped and added to poultry and livestock feed or applied whole as fertilizer for crop plants. The purified cell-wall polysaccharides of brown and red algae (alginate, agar, carrageenan) are used as gelling, suspending, and emulsifying agents in numerous industries. Some seaweeds have specific medicinal properties, such as effectiveness against worms. Petroleum is generally believed to result from bacterial degradation of organic matter derived primarily from planktonic algae.

Planktonic algae, as the primary producers in oceans and lakes, support the entire aquatic trophic pyramid and thus are the basis of the fisheries industry. Concomitantly, their production of oxygen counteracts its uptake in animal respiration. The ability of certain planktonic algae to assimilate organic nutrients makes them important in the treatment of sewage. *See* FOOD WEB.

On the negative side, algae can be a nuisance by imparting tastes and odors to drinking water, clogging filters, and making swimming pools, lakes, and beaches unattractive. Sudden growths (blooms) of planktonic algae can produce toxins of varying potency. In small bodies of fresh water, the toxin (usually from blue-green algae) can kill fishes and livestock that drink the water. In the ocean, toxins produced by dinoflagellate blooms (red tides) can kill fishes and render shellfish poisonous to humans.

Fossil algae. At least half of the classes of algae are represented in the fossil record, usually abundantly, in the form of siliceous, calcareous, or organic remains, impressions, or indications. Blue-green algae were among the first inhabitants of the Earth, appearing in rocks at least as old as 2.3 billion years. Their predominance in shallow Precambrian seas is indicated by the extensive development of stromatolites.

All three classes of seaweeds (reds, browns, and greens) were well established by the close of the Precambrian, 600 million years ago (mya). By far the greatest number of fossil taxa belong to classes whose members are wholly or in large part planktonic. Siliceous frustules of diatoms and endoskeletons of silicoflagellates, calcareous scales of coccolithophorids, and highly resistant organic cysts of dinoflagellates contribute slowly but steadily to sediments blanketing ocean floors, as they have for tens of millions of years. Cores obtained in the Deep Sea Drilling Project have revealed an astounding chronology of the appearance, rise, decline, and extinction of a succession of species and genera. From this chronology, much can be deduced about the climate, hydrography, and ecology of particular geological periods. *See* PALEOBOTANY; STROMATOLITE. [P.C.Si.; R.L.Moe.]

Algebra

The branch of mathematics dealing with the solution of equations. These equations involve unknowns, or variables, along with fixed numbers from a specified system. The origins of algebra were based on the need to develop equations that modeled real-world problems. From this came a very extensive theory based on the need to find the values that can be successfully used in the equations.

Number systems. Classical algebra is conducted in one of several number systems. The most basic is the natural numbers, consisting of the counting numbers: 1, 2, 3, 4, ... The natural numbers along with their negatives and 0 form the set of integers: ..., −2, −1, 0, 1, 2, ... Any number which can be expressed as a quotient a/b of two integers a and b is called a rational number. If the decimal expansion of a number either is repeating or terminates in a string of zeros, it is always possible to find integers a and b such that the quotient a/b gives the original number. Numbers where the decimal expansion cannot be written as a quotient of integers are the so-called irrational numbers. Early mathematicians did not recognize the existence of such numbers until geometric considerations showed that they must exist as the lengths of sides of right triangles.

The sets of rational numbers and irrational numbers have no elements in common, and together they make up the real-number system. It is within the system of real numbers that algebraic tasks are most often performed. However, there is a still larger set of numbers, known as the complex numbers, which serve much more completely in solving equations. The complex numbers consist of numbers of the form $a + bi$, where i is a symbol representing -1. The symbol i is commonly called the imaginary root of -1, and the numbers of the form bi are known as the set of imaginary numbers. In a complex number $a + bi$, the real number a is called the real part while the real number b is the imaginary part.

Real numbers are often represented on a number line (Fig. 1*a*). The complex numbers can be represented on a two-dimensional plane (Fig. 1*b*), by plotting the real part on the horizontal axis and the imaginary part on the vertical axis.

Operations. Within any number system there is a set of operations which can be performed on some or all of the members of the system. Operations take a pair of numbers in the system and produce a single new number from this pair. The most standard operations are addition (+), multiplication (·), subtraction (−), and division (÷). A set is closed under an operation if the application of the operation to any pair of numbers in the set results in another number in the same set. For example, the set of natural numbers is closed under + but not under − (since, for example, $1 - 2 = -1$ is not a natural number). The rational numbers, the real numbers, and the complex numbers are closed under all four of the basic operations (except in the case where division by 0 may occur). *See* ARITHMETIC.

Other operations arise from the four basic ones. Exponentiation is derived from the process of repeatedly multiplying a number by itself. If n is a positive integer, the symbol a^n indicates that the number a is multiplied by itself n times. If $n > 0$ is an integer, then a^{-n} refers to the quotient $1/a^n$. Fractional exponents can also be considered by defining $a^{1/n}$ to be the number b such that $b^n = a$. This notion is further extended by letting $a^{m/n} = (a^{1/n})^m$. For real numbers, some fractional exponents may not exist. For example, $(-1)^{1/2}$ is not a real number. The complex numbers, however, are closed with respect to exponentiation.

Algebraic expressions. In algebra, symbols are frequently used to designate unknown values. For example, letters such as x and y can stand for any one of a set of numbers satisfying certain conditions. These symbols are combined with numbers and the basic operations to form algebraic expressions such as (1).

$$3x^2 + 5y^3x - 6 \qquad \frac{(x^5 - 1)^{3xy}}{y^2 + 2^x} \tag{1}$$

The symbols are usually called variables, while the numbers (or constants) multiplied by them are the coefficients of the expression. The coefficients are all assumed to come from a designated number system. Algebraic expressions take on specific values when each of the variables involved is assigned a numerical value.

Algebraic equations. A statement is a relationship between several algebraic expressions. This relationship can be equality (=) or an inequality (< or >), but in any case it puts restrictions on the values of the variables. For example, each of expressions (2) represents a relationship between the variables x and y, while Eq. (3) relates the three variables, x, y, and z.

$$x^2 + 3xy = y - 3 \qquad 2xy > y^5 - 1 \tag{2}$$

$$4z - 2xy = 5 + yz^2 \tag{3}$$

If, when specific values from an appropriate number system are substituted for the variables in an equation, the resulting statement is true, then these numbers are said to be a solution to the equation. The solutions of a particular equation are dependent on the number system in use. For instance, the

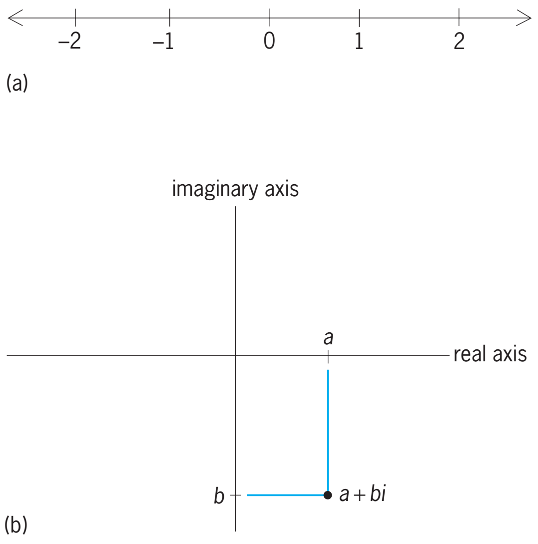


Fig. 1. Representations of number systems. (*a*) Of real numbers on a number line. (*b*) Of complex numbers on a two-dimensional plane.

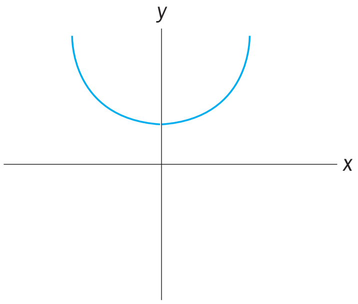

Fig. 2. Graph of the function $f(x) = x^2 + 3$.

equation $x^4 = 2$ has no solutions in the set of rational numbers, two solutions ($x = 2^{1/4}$ and $x = -2^{1/4}$) in the real numbers, and four solutions in the complex field.

Functions. Some of the most fundamental algebraic equations are those involving two variables. When one of these variables, say y, can be expressed in terms of the other variable, say x, in such a way that each value of x produces exactly one value of y, then the relationship described by the equation is known as a function. More general relationships which may or may not produce unique values of y from each value of x are called relations. In a function such as has been described, the variable x is called the independent variable while the resulting variable y is called the dependent variable. The possible values that can be used by the independent variable make up the domain of the function (or, more generally, the relation). The resulting values of the dependent variable compose the range of the function. It is most common and quite practical to write a variable y which is dependent on a variable x in the form $y = f(x)$.

Graphs. Relations, and more specifically functions, are frequently represented effectively with graphs. If an equation involves the variables x and y, then a two-dimensional coordinate system can be used to depict the values that correspond in the equation. All of the ordered pairs (x, y) given by the equation combine to give a complete graphic representation of the relationship described by the equation (Fig. 2).

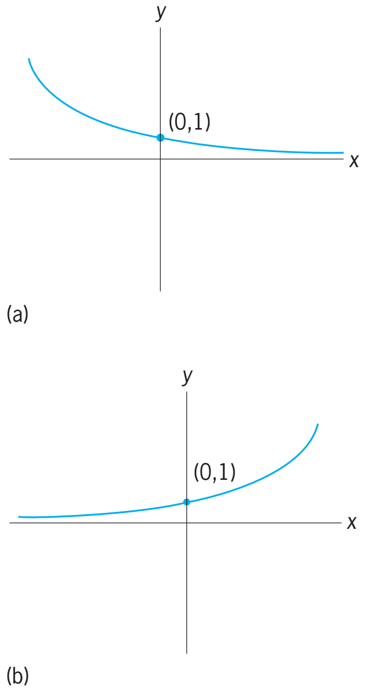

Fig. 3. Graphs of exponential functions. (*a*) Decreasing graph of $y = (\frac{1}{2})^x$. (*b*) Increasing graph of $y = 2^x$.

Polynomials. There are many special functions which are commonly used to describe real situations. One of the most basic is the polynomial, which is a function of the form (4). Each

$$f(x) = a_0 + a_1x + a_2x^2 + \cdots + a_nx^n \tag{4}$$

coefficient $a_0, a_1, \ldots a_n$ is a real number, and the exponents of the variables are nonnegative integers. The largest exponent of x is called the degree of the polynomial. When graphed, a polynomial of degree n will reverse directions no more than $n - 1$ times.

Even in the real numbers, a polynomial often may be factored into other polynomials of lesser degree. This allows for analysis of the polynomial by consideration of the simpler factors.

Rational functions. Functions which are of the form $f(x) = g(x)/h(x)$, where $g(x)$ and $h(x)$ are polynomials, are called rational functions. They frequently appear in instances where comparisons of two polynomials are necessary.

Exponential functions. In general, an exponential function is one which has the form $f(x) = b^x$ for some constant b in the number system. The graphs of these functions take on one of two basic types. The graph is decreasing if $0 < b < 1$ (Fig. 3*a*), and it is increasing if $b > 1$ (Fig. 3*b*).

Exponential functions are of special importance in describing a situation where the rate of growth is proportional to the amount present. Among the situations that can be described by exponential functions are those involving the calculation of interest, radioactive decay, and population growth.

Logarithmic functions. Another function that plays an especially important role in algebra is the logarithm. The logarithm function is defined in terms of exponentials by reversing the roles of the x and y variables, as in Eqs. (5).

$$y = \log_b x \leftrightarrow x = b^y \tag{5}$$

[W.B.P.]

Algebraic geometry

The study of zero sets of polynomial equations. Examples are the parabola $y - x^2 = 0$, thought of as sitting in the (x, y)-plane, and the locus of all points (t, t^2, t^3, t^4), which is defined by Eqs. (1), in the coordinate space with

$$y^2 = xz \qquad yx = wz \qquad wy = x^2 \tag{1}$$

coordinates w, x, y, z. Another interesting example is an elliptic curve, typically defined by an equation like Eq. (2), where A and

$$y^2 = x(x - A)(x - B) \tag{2}$$

B are constants. Objects such as these are called affine algebraic sets. They exist in affine n-space, denoted A^n, which is defined to be the coordinate space with coordinates $x_1, \ldots, x_n$. The coordinate ring $k[V]$ of an affine algebraic set V is the set of functions on V obtained by restriction from polynomial functions on the ambient affine space. These functions can be added, subtracted, and multiplied (that is, they form a ring). For example, the coordinate ring of the parabola has in it functions y and x satisfying $y = x^2$. This relation can be used to eliminate all references to y, so that the coordinate ring of the parabola is identified with the ring of polynomials in x. *See* ANALYTIC GEOMETRY; RING THEORY.

The possibility of studying a question geometrically via the zero loci of polynomials or algebraically via the algebra of the coordinate ring gives the subject much of its power and flavor. This has led to an amazing growth in applications to other disciplines. For example, the integers $\ldots, -2, -1, 0, 1, 2, \ldots$ form a ring that is algebraically similar to the coordinate ring of the affine line, and algebrogeometric methods have come to play a central role in number theory. In studying the path space of strings and the partition function, modern physicists have made the moduli space of curves a central object of research. Finally, a number of differential equations in engineering and physics can best be studied algebrogeometrically, although their solutions are not algebraic functions. *See* DIFFERENTIAL EQUATION; NUMBER THEORY. [S.J.B.]

Alginate A major constituent (10–47% dry weight) of the cell walls of brown algae. Extracted for its suspending, emulsifying, and gelling properties, it is one of three algal polysaccharides of major economic importance, the others being agar and carrageenan. The chief sources of alginate are members of the family Fucaceae (rockweeds) and the order Laminariales (kelps), harvested from naturally occurring stands on North Atlantic and North Pacific shores.

Because of its colloidal properties, alginate finds numerous industrial applications, especially in the food, textile, paper, printing, paint, cosmetics, and pharmaceutical industries. About half of the consumption is in the making of ice cream and other dairy products, in which alginate prevents the formation of coarse ice crystals and provides a smooth texture. As an additive to paint, it keeps the pigment in suspension and minimizes brush marks. An alginate gel is used in making dental impressions. *See* AGAR; CARRAGEENAN; ICE CREAM; MILK; PHAEOPHYCEAE. [P.C.Si; R.L.Moe.]

Algorithm A well-defined procedure to solve a problem. The study of algorithms is a fundamental area of computer science. In writing a computer program to solve a problem, a programmer expresses in a computer language an algorithm that solves the problem, thereby turning the algorithm into a computer program. *See* COMPUTER PROGRAMMING.

Operation. An algorithm generally takes some input, carries out a number of effective steps in a finite amount of time, and produces some output. An effective step is an operation so basic that it is possible, at least in principle, to carry it out using pen and paper. In computer science theory, a step is considered effective if it is feasible on a Turing machine or any of its equivalents. A Turing machine is a mathematical model of a computer used in an area of study known as computability, which deals with such questions as what tasks can be algorithmically carried out and what cannot. *See* AUTOMATA THEORY; RECURSIVE FUNCTION.

Many computer programs deal with a substantial amount of data. In such applications, it is important to organize data in appropriate structures to make it easier or faster to process the data. In computer programming, the development of an algorithm and the choice of appropriate data structures are closely intertwined, and a decision regarding one often depends on knowledge of the other. Thus, the study of data structures in computer science usually goes hand in hand with the study of related algorithms. Commonly used elementary data structures include records, arrays, linked lists, stacks, queues, trees, and graphs.

Applications. Many algorithms are useful in a broad spectrum of computer applications. These elementary algorithms are widely studied and considered an essential component of computer science. They include algorithms for sorting, searching, text processing, solving graph problems, solving basic geometric problems, displaying graphics, and performing common mathematical calculations.

Sorting arranges data objects in a specific order, for example, in numerically ascending or descending orders. Internal sorting arranges data stored internally in the memory of a computer. Simple algorithms for sorting by selection, by exchange, or by insertion are easy to understand and straightforward to code. However, when the number of objects to be sorted is large, the simple algorithms are usually too slow, and a more sophisticated algorithm, such as heap sort or quick sort, can be used to attain acceptable performance. External sorting arranges stored data records.

Searching looks for a desired data object in a collection of data objects. Elementary searching algorithms include linear search and binary search. Linear search examines a sequence of data objects one by one. Binary search adopts a more sophisticated strategy and is faster than linear search when searching a large array. A collection of data objects that are to be frequently searched can also be stored as a tree. If such a tree is appropriately structured, searching the tree will be quite efficient.

A text string is a sequence of characters. Efficient algorithms for manipulating text strings, such as algorithms to organize text data into lines and paragraphs and to search for occurrences of a given pattern in a document, are essential in a word processing system. A source program in a high-level programming language is a text string, and text processing is a necessary task of a compiler. A compiler needs to use efficient algorithms for lexical analysis (grouping individual characters into meaningful words or symbols) and parsing (recognizing the syntactical structure of a source program). *See* SOFTWARE ENGINEERING; WORD PROCESSING.

A graph is useful for modeling a group of interconnected objects, such as a set of locations connected by routes for transportation. Graph algorithms are useful for solving those problems that deal with objects and their connections—for example, determining whether all of the locations are connected, visiting all of the locations that can be reached from a given location, or finding the shortest path from one location to another.

Mathematical algorithms are of wide application in science and engineering. Basic algorithms for mathematical computation include those for generating random numbers, performing operations on matrices, solving simultaneous equations, and numerical integration. Modern programming languages usually provide predefined functions for many common computations, such as random number generation, logarithm, exponentiation, and trigonometric functions.

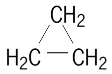
In many applications, a computer program needs to adapt to changes in its environment and continue to perform well. An approach to make a computer program adaptive is to use a self-organizing data structure, such as one that is reorganized regularly so that those components most likely to be accessed are placed where they can be most efficiently accessed. A self-modifying algorithm that adapts itself is also conceivable. For developing adaptive computer programs, biological evolution has been a source of ideas and has inspired evolutionary computation methods such as genetic algorithms. *See* GENETIC ALGORITHMS.

Certain applications require a tremendous amount of computation to be performed in a timely fashion. An approach to save time is to develop a parallel algorithm that solves a given problem by using a number of processors simultaneously. The basic idea is to divide the given problem into subproblems and use each processor to solve a subproblem. The processors usually need to communicate among themselves so that they may cooperate. The processors may share memory, through which they can communicate, or they may be connected by communication links into some type of network such as a hypercube. *See* CONCURRENT PROCESSING; MULTIPROCESSING; SUPERCOMPUTER. [S.C.Hs.]

Alicyclic hydrocarbon An organic compound that contains one or more closed rings of carbon atoms. The term alicyclic specifically excludes carbocyclic compounds with an array of π-electrons characteristic of aromatic rings. Compounds with one to five alicyclic rings of great variety and complexity are found in many natural products such as steroids and terpenes. By far the majority of these have six-membered rings. *See* AROMATIC HYDROCARBON; STEROID; TERPENE.

Structures and nomenclature. The bonding in cyclic hydrocarbons is much the same as that in open-chain alkanes and alkenes. An important difference, however, is the fact that the atoms in a ring are part of a closed loop. Complete freedom of rotation about a carbon-carbon bond (C—C) is not possible; the ring has faces or sides, like those of a plate.

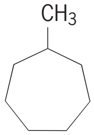
Simple monocyclic hydrocarbons are usually represented as bond line structures; for example, cyclopropane (**1***a*) is usually represented as structure (**1***b*) and methylcycloheptane as structure (**2**). These hydrocarbons are named by adding the prefix cyclo to the stem of the alkane corresponding to the number of atoms in the ring. When two or more substituents are attached to the ring, the relative positions and orientation must be specified: *cis* on the same side and *trans* on the other, as in *cis*-1,2-dimethylcyclopentane (**3**) and *trans*-1,3-dimethylcyclopentane (**4**).



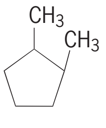
(**1***a*)

≡

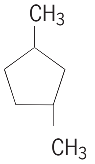
(**1***b*)



(**2**)

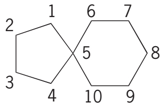


(**3**)

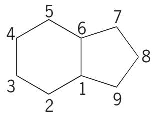


(**4**)

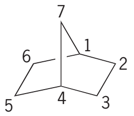
In bicyclic compounds the rings can be joined in three ways: spirocyclic, fused, and bridged, as illustrated in the structures for spiro[4.5]decane (**5**), bicyclo[4.3.0]nonane (**6**), and bicyclo[2.2.1]heptane (**7**). In each case the name indicates the total number of carbon atoms, and the number of atoms in each bridge. Atoms are numbered as shown.



(**5**)

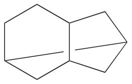


(**6**)

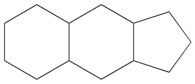


(**7**)

Any of these bicyclic systems can be transformed to a tricyclic array by introduction of another bond between nonadjacent carbons, as in structure (**8**), or an additional ring, as in structure (**9**).

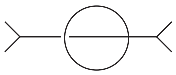


(**8**)

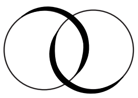


(**9**)

Cyclic structure gives rise to the possibility of compounds made up of molecular subunits that are linked mechanically rather than chemically. In rotaxanes (**10**), bulky groups are introduced at the ends of a long chain that is threaded through a large ring ($>C_{30}$). Cyclization of the ends leads to a catenane (**11**). Several examples of compounds with these structures have been prepared.



(**10**)



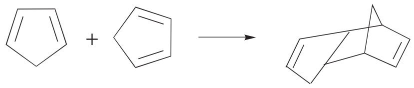
(**11**)

The boiling points, melting points, and densities of cycloalkanes are all higher than those of their open-chain counterparts, reflecting the more compact structures and greater association in both liquid and solid. Geometrical constraints in the smaller rings have significant effects on reactions of cycloalkanes and derivatives. Because of ring strain, ring-opening reactions of cyclopropane, such as isomerization to propene, take place under conditions that do not affect alkanes or larger-ring cycloalkanes.

Comparison of reaction rates of compounds with different ring size or cis-trans configuration has provided important insights about reaction mechanism and conformational analysis.

Ring-forming reactions. A number of useful methods have been devised that lead to alicyclic rings. These reactions are of three types: C-C bond formation between atoms in an open-chain precursor, cycloaddition or cyclooligomerization, and expansion or contraction of a more readily available ring. In cycloaddition, two molecules react with formation of two bonds; in cyclooligomerization, three or more molecules combine to form three or more bonds.

Two alicyclic compounds are manufactured in large volume; both are products of the petroleum industry. Cyclopentadiene (**12**) is formed from various alkylcyclopentanes in naphtha fractions during the refining process. It is a highly reactive diene and spontaneously dimerizes in a 4 + 2 cycloaddition [see reaction below]; it is used as a copolymer in several resins.



(**12**)

Cyclohexane is produced in large quantity by hydrogenation of benzene. The principal use of cyclohexane is conversion by oxidation in air to a mixture of cyclohexanol and the ketone, which is then oxidized further to adipic acid for the manufacture of nylon. *See* ORGANIC SYNTHESIS. [J.A.Mo.]

Alismatales A small order of flowering plants, division Magnoliophyta (Angiospermae), which gives its name to the subclass Alismatidae of the class Liliopsida (monocotyledons). It consists of three families (Alismataceae, Butomaceae, and Limnocharitaceae) and less than a hundred species. They are aquatic and semiaquatic herbs with a well-developed, biseriate perianth that is usually differentiated into three sepals and three petals, and with a gynoecium of several or many, more or less separate carpels. Each flower is usually subtended by a bract. *Butomus umbellatus* (flowering rush) and species of *Sagittaria* (arrowhead, family Alismataceae) of this order are sometimes cultivated as ornamentals. *See* LILIOPSIDA; MAGNOLIOPHYTA.

The Alismatales and some related orders have often been treated as a single order Helobiae or Helobiales, embracing most of what is here treated as the subclass Alismatidae. *See* ALISMATIDAE; PLANT KINGDOM. [A.Cr.]

Alismatidae A relatively primitive subclass of the class Liliopsida (monocotyledons) of the division Magnoliophyta (Angiospermae), the flowering plants, consisting of 4 orders, 16 families, and less than 500 species. Typically they are aquatic or semiaquatic, with apocarpous flowers and nonendospermous seeds. They have trinucleate pollen, and the stomates usually have two subsidiary cells. The orders Alismatales, Hydrocharitales, and Najadales are closely related among themselves and have often been treated as a single order, Helobiae or Helobiales. The Triuridales differ from the other orders in being terrestrial and mycotrophic, without chlorophyll, and in having abundant endosperm in the seeds. *See* ALISMATALES; HYDROCHARITALES; TRIURIDALES; MAGNOLIOPHYTA; NAJADALES; PLANT KINGDOM. [A.Cr.; T.M.Ba.]

Alkali Any compound having highly basic properties, strong acrid taste, and ability to neutralize acids. Aqueous solutions of alkalies are high in hydroxyl ions, have a pH above 7, and turn litmus paper from red to blue. Caustic alkalies include sodium hydroxide (caustic soda), the sixth-largest-volume chemical produced in the United States, and potassium hydroxide. They are extremely destructive to human tissue; external burns should be washed with large amounts of water. The milder alkalies are the carbonates of the alkali metals; these include the industrially important sodium carbonate (soda ash) and potassium carbonate (potash), as well as the carbonates of lithium, rubidium, and cesium, and the volatile ammonium hydroxide. Sodium bicarbonate is a still milder alkaline material. *See* ACID AND BASE; PH.

About 50% of the caustic soda produced goes into making many chemical products, about 16% into pulp and paper, 6.5% each into aluminum, petroleum, and textiles (including rayon), with smaller percentages into soap and synthetic detergents, and cellophane. For soda ash, about 50% goes to react mainly with sand in making glass, 25% to making miscellaneous chemicals, 6.5% each to alkaline cleaners and pulp and paper, and a few percent to water treatment and other uses. *See* ALKALI METALS; ELECTROCHEMICAL PROCESS; GLASS; HYDROXIDE; PAPER; SOAP. [D.F.O.]

Alkali emissions Light emissions in the upper atmosphere from elemental lithium, potassium, and especially sodium. These alkali metals are present in the upper atmosphere at altitudes from about 50 to 62 mi (80 to 100 km) and are very efficient in resonant scattering of sunlight. The vertical column contents (number of atoms per square meter) of the alkali atoms are easily deduced from their respective emission intensities. First detected with ground-based spectrographs, the emissions were observed mainly at twilight since they tend to be overwhelmed by intense scattered sunlight present in the daytime. A chemiluminescent process gives rise to so-called nightglow emissions at the same wavelengths. The development of lidars (laser radars) that are tuned to the resonance lines have enabled accurate resolution of the concentrations of these elements versus altitude for any time of the day. *See* AERONOMY; AIRGLOW; CHEMILUMINESCENCE.

There is little doubt that the origin of these metals is meteoritic ablation. Rocket-borne mass spectrometers have found that meteoritic ions are prevalent above the peaks of neutral atoms with a composition similar to that found in carbonaceous chondrites, a common form of meteorites. The ratio of the concentrations of ions to neutral atoms rises rapidly with altitude above 55 mi (90 km). *See* METEORITE.

Sodium (Na) is the most abundant alkali metal in meteorites. The sodium D-lines, a doublet at 589 and 589.6 nanometers, were first detected in the nightglow in the late 1920s and at twilight a decade later. The nominal peak concentration of sodium is 3×10^9 atoms m^{-3} near 55 mi (90 km) where the total gas concentration of the atmosphere is 7×10^{19} atoms (or molecules) m^{-3}.

Potassium (K) is 15 times less abundant than sodium in meteorites. The ratio of the potassium and sodium column contents in the mesosphere ranges from 1/10 to 1/100. The potassium doublet at 767 and 770 nm is estimated to have a nightglow intensity near the night sky background, 50 times smaller than the typical intensity of the sodium nightglow. The potassium nightglow has never been detected.

Lithium (Li) is 35 times less abundant in meteorites than potassium, and 500 times less abundant than sodium. Nevertheless, the lithium emission at 671 nm has been observed at twilight by spectrometers and at night by lidars. The lithium nightglow emission is undetectable. [W.Sw.]

Alkali metals The elements of group I in the periodic table (lithium, sodium, potassium, rubidium, cesium, francium). Of the alkali metals, lithium differs most from the rest of the group, and tends to resemble the alkaline-earth metals (group II of the periodic table) in many ways. In this respect lithium behaves as do many other elements that are the first members of groups in the periodic table; these tend to resemble the elements in the group to the right rather than those in the same group. Francium, the heaviest of the alkali-metal elements, has no stable isotopes and exists only in radioactive form.

In general, the alkali metals are soft, low-melting, reactive metals. This reactivity accounts for the fact that they are never found uncombined in nature but are always in chemical combination with other elements. This reactivity also accounts for the fact that they have no utility as structural metals (with the possible exception of lithium in alloys) and that they are used as chemical reactants in industry rather than as metals in the usual sense. The reactivity in the alkali-metal series increases in general with increase in atomic weight from lithium to cesium. *See* CESIUM; ELECTROCHEMICAL SERIES; FRANCIUM; LITHIUM; PERIODIC TABLE; SODIUM. [M.Si.]

Alkaline-earth metals Usually calcium, strontium, and barium, the heaviest members of group II of the periodic table (excepting radium). Other members of the group are beryllium, magnesium, and radium, sometimes included among the alkaline-earth metals. Beryllium resembles aluminum more than any other element, and magnesium behaves more like zinc and cadmium. The gap between beryllium and magnesium and the remainder of the elements of group II makes it desirable to discuss these elements separately. Radium is often treated separately because of its radioactivity.

The alkaline earths form a closely related group of highly metallic elements in which there is a regular gradation of properties. The metals, none of which occurs free in nature, are all harder than potassium or sodium, softer than magnesium or beryllium, and about as hard as lead. The metals are somewhat brittle, but are malleable, extrudable, and machinable. They conduct electricity well; the specific conductivity of calcium is 45% of that of silver. The oxidation potentials of the triad are as great as those of the alkali metals.

The elements and their compounds find important industrial uses in low-melting alloys, deoxidizers, and drying agents and as cheap sources of alkalinity. *See* BARIUM; BERYLLIUM; CALCIUM; MAGNESIUM; PERIODIC TABLE; RADIUM; STRONTIUM. [R.F.R.]

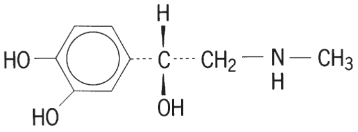
Alkaloid A cyclic organic compound that contains nitrogen in a negative oxidation state and is of limited distribution among living organisms. Over 10,000 alkaloids of many different structural types are known; and no other class of natural products possesses such an enormous variety of structures. Therefore, alkaloids are difficult to differentiate from other types of organic nitrogen-containing compounds.

Simple low-molecular-weight derivatives of ammonia, as well as polyamines and acyclic amides, are not considered alkaloids because they lack a cyclic structure in some part of the molecule. Amines, amine oxides, amides, and quaternary ammonium salts are included in the alkaloid group because their nitrogen is in a negative oxidation state (the oxidation state designates the positive or negative character of atoms in a molecule). Nitro and nitroso compounds are excluded as alkaloids. The almost-ubiquitous nitrogenous compounds, such as amino acids, amino sugars, peptides, proteins, nucleic acids, nucleotides, prophyrins, and vitamins, are not alkaloids. However, compounds that are exceptions to the classical-type definition (that is, a compound containing nitrogen, usually a cyclic amine, and occurring as a secondary metabolite), such as neutral alkaloids (colchicine, piperine), the β-phenyl-ethylanines, and the purine bases (caffeine, theophylline, theobromine), are accepted as alkaloids.

Alkaloids often occur as salts of plant acids such as malic, meconic, and quinic acids. Some plant alkaloids are combined with sugars, for example, solanine in potato (*Solanum tuberosum*) and tomatine in tomato (*Lycopersicum esculentum*). Others occur as amides, for example, piperine from black pepper (*Piper nigrum*), or as esters, for example, cocaine from coca leaves (*Erythroxylum coca*). Still other alkaloids occur as quaternary salts or tertiary amine oxides.

While most alkaloids have been isolated from plants, a large number have been isolated from animal sources. They occur in mammals, anurans (frogs, toads), salamanders, arthropods (ants, millipedes, ladybugs, beetles, butterflies), marine organisms, mosses, fungi, and certain bacteria.

Many alkaloids exhibit marked pharmacological activity, and some find important uses in medicine. Atropine, the optically inactive form of hyoscyamine, is used widely in medicine as an antidote to cholinesterase inhibitors such as physostigmine and insecticides of the organophosphate type; it is also used in drying cough secretions. Morphine and codeine are narcotic analgesics, and codeine is also an antitussive agent, less toxic and less habit-forming than morphine. Colchicine, from the corms and seeds of the autumn crocus, is used as a gout suppressant. Caffeine, which occurs in coffee, tea, cocoa, and cola, is a central nervous system stimulant; it is used as a cardiac and respiratory stimulant and as an antidote to barbiturate and morphine poisoning. Emetine, the key alkaloid of ipecac root (*Cephaelis ipecacuanha*), is used in the treatment of amebic dysentery and other protozoal infections. Epinephrine or adrenaline (see structure), produced in most animal species by the adrenal medulla, is used as a bronchodilator and cardiac stimulant and to counter allergic reactions, anesthesia, and cardiac arrest. *See* Epinephrine. [S.W.Pe.]



Alkane A compound with the general formula C_nH_{2n+2}. Alkanes are open-chain (aliphatic or noncyclic) hydrocarbons with no multiple bonds or functional groups. They consist of tetrahedral carbon atoms, up to 10^5 carbons or more in length. The C-C σ bonds are formed from sp^3 orbitals, and there is free rotation around the bond axis.

Alkanes provide the parent names for all other aliphatic compounds in systematic nomenclature. Alkanes are designated by the ending -ane appended to a stem denoting the chain length. The straight-chain isomer is designated by the prefix C (normal); other isomers are named by specifying the size of the branch and its location (see table). The number of isomers increases enormously in larger molecules; thus there are 75 isomers of $C_{10}H_{22}$ and over 4 billion for $C_{30}H_{62}$.

Alkanes with four or fewer carbons are gases at atmospheric pressure. Higher C alkanes are liquids or, above about 20 carbons, solids known as paraffin wax. Alkanes have densities lower than that of water and have very low water solubility; other properties depend on the degree of branching. The heat of formation (ΔH_f°) is a measure of the energy content of a compound relative to the component elements in standard states. For example, comparison of heat of formation values for three alkane isomers with the molecular formula C_5H_{12} indicates that the relative energy content of the three pentane isomers decreases with increased branching, that is, the branched isomer is thermodynamically most stable. *See* Paraffin.

Nomenclature and properties of alkanes

Name	Structure	Boiling point, °C (°F)	Heat of formation (ΔH_f°), kJ
Methane	CH_4	−162 (−260)	−74.5
Ethane	CH_3CH_3	−89 (−128)	−83.45
Propane	$CH_3CH_2CH_3$	−42 (−44)	−104.6
Butane	$CH_3(CH_2)_2CH_3$	−0.5 (33)	−125.7
2-Methylpropane (isobutane)	$(CH_3)_2CHCH_3$	−11.7 (10.9)	−134.2
Pentane	$CH_3(CH_2)_3CH_3$	36.1 (97.0)	−146.87
2-Methylbutane (isopentane)	$(CH_3)_2CHCH_2CH_3$	29.9 (85.8)	−153.7
2,2-Dimethyl propane (neopentane)	$(CH_3)_4C$	9.4 (49)	−167.9
Hexane	$CH_3(CH_2)_4CH_3$	68.7 (156)	−167.0

Alkanes are the major components of natural gas and petroleum, which are the only significant sources. Much smaller amounts of alkanes have been produced from coal at various times and locations, either indirectly by the Fischer-Tropsch process or by direct liquefaction. *See* Fischer-Tropsch process; Natural gas; Petroleum.

Individual lower alkanes can be separated from the more volatile distillate fractions of petroleum, but beyond the C_7–C_8 range the alkanes obtained are mixtures of many isomers. Compounds of a specific structure can be prepared in a laboratory scale by chemical synthesis. Various C-C bond-forming steps such as coupling or condensation are carried out to build up the desired carbon skeleton. The final step is usually removal of a functional group by some type of reduction.

Much of the chemistry of alkanes begins at the petroleum refinery, where several reactions are carried out to adjust the hydrocarbon composition of crude oil to that needed for a constantly changing set of applications. Major reactions are (1) isomerization of straight-chain alkanes to branched compounds; (2) cracking to produce smaller molecules; (3) alkylation, for example, combination of propylene and butane to give 2,3-dimethylpentane; and (4) cyclodehydrogenation (platforming), in which aromatizations occur. An important objective in some of these processes is to increase the yield of highly branched alkanes in the C_6–C_8 range needed for gasoline. *See* Alkylation (petroleum); Aromatization; Cracking; Gasoline.

By far the most important end use of alkanes is combustion as fuel to provide heat and electric or motive power. In most cases, complete oxidation is not achieved, and varying amounts of incompletely oxidized fragments, carbon monoxide, and elemental carbon are produced.

Controlled partial oxidation is possible if all the C-H bonds in an alkane are equivalent or if one C-H bond is significantly weaker than all the others. An example of the latter situation is isobutane, which is converted to the hydroperoxide on industrial scale for the manufacture of *t*-butyl alcohol. *See* Autoxidation; Combustion.

Alkanes have been referred to as paraffin hydrocarbons to indicate their low affinity or reactivity. They contain no unshared electron pairs or accessible empty bonding orbitals, and they are unaffected by many reagents that attack π-bonds or other functional groups. One type of reaction that does occur is substitution by a radical chain process. Examples are chlorination and vapor-phase nitration, involving the odd-electron species $Cl\cdot$ and $NO_2\cdot$, respectively. Neither reaction is selective; when two or more types of C-H bonds are present in the alkane, mixtures of products are usually obtained. Thus propane gives rise to 1- and 2-chloropropanes as well as dichloro compounds. Nitration of propane leads to a mixture of 1- and 2-nitropropane, and also nitromethane and nitroethane by C-C bond cleavage. *See* Halogenated hydrocarbon; Halogenation; Nitration. [J.A.Mo.]

Alkene One of the class of acyclic hydrocarbons containing one or more carbon-to-carbon double bonds. Alkenes (also called olefins) and alkynes (also called acetylenes) together constitute the family of organic compounds called unsaturated hydrocarbons, since they contain less than the number of hydrogens found in the corresponding saturated compound, alkane. When the double bond is present in a nonaromatic ring (alicyclic hydrocarbon), the compound is termed a cycloalkene. Hydrocarbons containing more than one double bond are termed dienes, trienes, and so forth, or collectively, polyenes. *See* Alicyclic hydrocarbon; Alkane; Alkyne.

In naming alkenes by the system of the International Union of Pure and Applied Chemistry (IUPAC), the longest chain containing the double bond is identified. The presence of the double bond is indicated by changing the "-ane" ending of the alkane having the same number of carbon atoms to "-ene," and the position of the double bond is indicated by a prefixed number.

Alkenes and dienes (common name given in parentheses)

Name	Formula
Ethene (ethylene)	$CH_2{=}CH_2$
Propene (propylene)	$CH_2{=}CHCH_3$
1-Butene	$CH_2{=}CHCH_2CH_3$
2-Butene	$CH_3CH{=}CHCH_3$
2-Methylpropene (isobutylene)	$CH_2{=}\overset{\overset{CH_3}{\mid}}{C}CH_3$
1,3-Butadiene	$CH_2{=}CHCH{=}CH_2$
2-Methyl-1,3-butadiene (isoprene)	$CH_2{=}\overset{\overset{CH_3}{\mid}}{C}CH{=}CH_2$

Examples are given in the table, with common or nonsystematic names which are still frequently used given in parentheses.

The lower alkenes and dienes which have up to five carbon atoms are gases at room temperature and pressure. Higher alkenes are colorless liquids or solids. Like other hydrocarbons, alkenes are insoluble in water. Liquid alkenes have specific gravities well below 1.0. Alkenes may undergo polymerization, cyclization, and addition reactions. A major share of structural and elastic polymers are based on homopolymers or copolymers of alkenes and dienes. Alkenes and dienes cyclize readily under various conditions.

Addition reactions of alkenes are among the most important in the entire field of organic chemistry. Industrially, high-octane gasoline is made by the acid-catalyzed alkylation of the three- and four-carbon alkenes. A variety of alkylated aromatics are made by the alkylation of benzene with olefins.

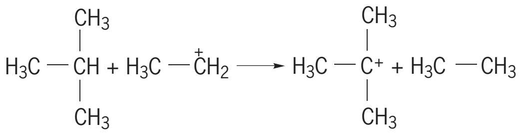
The commercially important alkenes are produced on a large scale in the petroleum industry by thermal or catalytic cracking processes. In the laboratory, most methods for the preparation of alkenes involve some type of elimination reaction, in which atoms or groups on adjacent carbon atoms are removed with concomitant formation of the carbon-carbon double bond. *See* ALKYLATION (PETROLEUM); CRACKING; HALOGENATION; HYDROGENATION. [P.E.F.]

Alkylation (petroleum) In the petroleum industry, a chemical process in which an alkene (ethylene, propylene, and so forth) and a hydrocarbon, usually 2-methylpropane, are combined to produce a higher-molecular-weight and higher-carbon-number product. The product has a higher octane rating and is used to improve the quality of gasoline-range fuels. The process was originally developed during World War II to produce high-octane aviation gasoline. Its current main application is in the production of unleaded automotive gasoline. *See* ALKENE; GASOLINE.

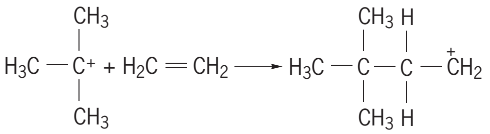
The alkylation reaction is initiated by the addition of a proton (H^+) to the olefin [reaction (1)]. The protonated olefin

$$H_2C{=}CH_2 + H^+ \longrightarrow H_3C{-}CH_2^+ \qquad (1)$$

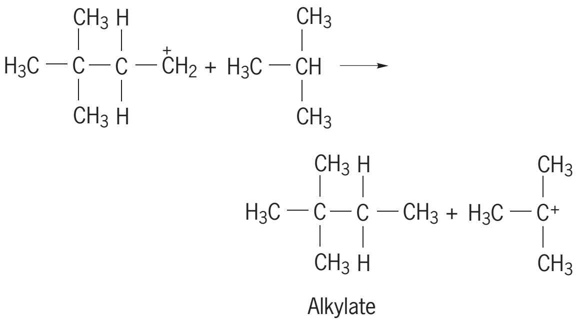
(carbonium ion) then reacts with the isobutane by abstraction of a proton from the isobutane to produce the *t*-butyl carbonium ion [reaction (2)]. Reaction of this tertiary carbonium ion with the olefin proceeds by combination of the two species [reaction (3)] to produce a more complex six-carbon carbonium ion which yields a stabilized product by abstraction of a proton from another molecule of isobutane [reaction (4)].



$$H_3C{-}\underset{CH_3}{\underset{\mid}{\overset{\overset{CH_3}{\mid}}{CH}}} + H_3C{-}\overset{+}{C}H_2 \longrightarrow H_3C{-}\underset{CH_3}{\underset{\mid}{\overset{\overset{CH_3}{\mid}}{C^+}}} + H_3C{-}CH_3 \qquad (2)$$



$$H_3C{-}\underset{CH_3}{\underset{\mid}{\overset{\overset{CH_3}{\mid}}{C^+}}} + H_2C{=}CH_2 \longrightarrow H_3C{-}\underset{CH_3}{\underset{\mid}{\overset{\overset{CH_3}{\mid}}{C}}}{-}\underset{H}{\underset{\mid}{\overset{\overset{H}{\mid}}{C}}}{-}\overset{+}{C}H_2 \qquad (3)$$



$$H_3C{-}\underset{CH_3}{\underset{\mid}{\overset{\overset{CH_3}{\mid}}{C}}}{-}\underset{H}{\underset{\mid}{\overset{\overset{H}{\mid}}{C}}}{-}\overset{+}{C}H_2 + H_3C{-}\underset{CH_3}{\underset{\mid}{\overset{\overset{CH_3}{\mid}}{CH}}} \longrightarrow \underbrace{H_3C{-}\underset{CH_3}{\underset{\mid}{\overset{\overset{CH_3}{\mid}}{C}}}{-}\underset{H}{\underset{\mid}{\overset{\overset{H}{\mid}}{C}}}{-}CH_3}_{\text{Alkylate}} + H_3C{-}\underset{CH_3}{\underset{\mid}{\overset{\overset{CH_3}{\mid}}{C^+}}} \qquad (4)$$

The reaction progresses to more product by reaction of the *t*-butyl and carbonium ion, as already shown in reaction (3). *See* REACTIVE INTERMEDIATES. [J.G.S.]

Alkyne One of a group of organic compounds containing a carbon-to-carbon triple-bond linkage (—C≡C—). They are termed acetylenes or alkynes. While exhibiting many of the characteristics of alkenes as regards unsaturation, the acetylenes have many unique properties. Since the bonding in alkyne molecules is linear, R—C≡C—R, cis-trans isomerism is not possible. In the simplest alkyne, acetylene (HC≡CH), or in monosubstituted acetylenes, the hydrogen attached to triply bonded carbon is acidic to such a degree that it is replaceable with metals such as sodium. Structural formulas of several alkynes are as follows:

$CH{\equiv}CH$ — Ethyne or acetylene

$CH{\equiv}CH_2{-}CH_2{-}CH_3$ — 1-Butyne

$CH{\equiv}C{-}CH_3$ — Propyne

$CH_3{-}C{\equiv}C{-}CH_3$ — 2-Butyne

General methods for the preparation of alkynes depend on dehydrohalogenation of α,β-dihaloparaffins, conversion of aldehydes or ketones to dihaloparaffins with subsequent dehydrohalogenation, and alkylation of metallic acetylides with alkyl halides in liquid ammonia. Grignard reagents of 1-alkynes behave similarly.

The reactions of triply bonded carbon compounds are in general similar to those of compounds containing ethylenic bonds. Addition reactions proceed in two stages to form first a vinyl compound or substituted ethylene, and second the substituted paraffin. In the presence of catalytic quantities of alkoxides, acetylene adds to alcohols and phenols to give vinyl ethers. Reactions of this type, in which addition takes place by replacement of hydrogen with a vinyl group, are termed vinylation. Another form of addition reaction known as ethynylation involves the addition of acetylene to unsaturated compounds. A general reaction of alkynes involves the addition of carbon monoxide and water, or other compounds having an active hydrogen, in the presence of nickel carbonyl.

Polymerization of alkynes may yield acyclic, aromatic, or alicyclic derivatives. In the presence of cuprous chloride, acetylene dimerizes to vinyl acetylene, which adds hydrogen chloride to give chloroprene (2-chloro-1,3-butadiene). Polymerization of chloroprene in the presence of free radical initiators gives the commercially important synthetic rubber, neoprene. Thermal polymerization of acetylene yields benzene as the major product and also a wide variety of polynuclear aromatic compounds. Of great theoretical and practical importance is the polymerization of acetylene to the cyclic tetramer, cyclooctatetraene. *See* ACETYLENE; ALKENE. [C.A.Co./P.E.F.]

Allantois A fluid-filled sac- or sausagelike, extraembryonic membrane lying between the outer chorion and the inner amnion and yolk sac of the embryos of reptiles, birds, and mammals. It is composed of an inner layer of endoderm cells, continuous with the endoderm of the embryonic gut, or digestive tract, and an outer layer of mesoderm, continuous with the splanchnic mesoderm of the embryo. It arises as an outpouching of the ventral floor of the hindgut and dilates into a large allantoic sac which spreads throughout the extraembryonic coelom. The allantois remains connected to the hindgut by a narrower allantoic stalk which runs through the umbilical cord. *See* AMNION; CHORION; GERM LAYERS.

The allantois eventually fuses with the overlying chorion to form the compound chorioallantois, which lies just below the shell membranes in reptiles and birds. The chorioallantois is supplied with an extensive network of blood vessels and serves as an important respiratory and excretory organ for gaseous interchange. The allantoic cavity also serves as a reservoir for kidney wastes in some mammals, in reptiles, and in birds. In the latter two groups the allantois assists in the absorption of albumin. In some mammals, including humans, the allantois is vestigial and may regress, yet the homologous blood vessels persist as the important umbilical arteries and veins connecting the embryo with the placenta. *See* FETAL MEMBRANE; PLACENTATION. [N.T.S.]

Allele Any of a number of alternative forms of a gene. Allele is a contraction of allelomorph, a term used to designate one of the alternative forms of a unit showing mendelian segregation. New alleles arise from existing ones by mutation. The diversity of alleles produced in this way is the basis for hereditary variation and evolution. The different alleles of a given gene determine the degree to which the specific hereditary characteristic controlled by that gene is manifested. The particular allele which causes that characteristic to be expressed in a normal fashion is often referred to as the wild-type allele. Mutations of the wild-type allele result in mutant alleles, whose functioning in the development of the organism is generally impaired relative to that of the wild-type allele. *See* DEOXYRIBONUCLEIC ACID (DNA); GENE; GENE ACTION; GENETIC CODE; MENDELISM; MUTATION.

An allele occupies a fixed position or locus in the chromosome. In the body cells of most higher organisms, including humans, there are two chromosomes of each kind and hence two alleles of each kind of gene, except for the sex chromosomes. Such organisms and their somatic cells are said to carry a diploid complement of alleles. A diploid individual is homozygous if the same allele is present twice, or heterozygous if two different alleles are present. Let A and a represent a pair of alleles of a given gene; then A/A and a/a are the genetic constitutions or genotypes of the two possible homozygotes, while A/a is the genotype of the heterozygote. Usually the appearance or phenotype of the A/a individuals resembles that of the A/A type; A is then said to be the dominant allele and a the recessive allele. In the case of the sex chromosomes, one sex (usually the male in most higher animals, with the exception of birds) has only one X chromosome, and the Y lacks almost all of the genes in X. The male thus carries only one dose of X-linked genes and is said to be hemizygous for alleles carried on his X chromosome. As a result, if a male inherits a recessive mutant allele such as color blindness on his X chromosome, he expresses color blindness because he lacks the wild-type allele on his Y chromosome. *See* CHROMOSOME; SEX-LINKED INHERITANCE.

In a population of diploid individuals, it is possible to have more than two alleles of a given gene. The aggregate of such alleles is called a multiple allelic series. Since genes are linear sequences of hundreds or even thousands of nucleotide base pairs, the potential number of alleles of a given gene which can arise by base substitution alone is enormous. [E.B.L.]

Allelopathy The biochemical interactions among all types of plants, including microorganisms. The term is usually interpreted as the detrimental influence of one plant upon another but is used more and more, as intended originally, to encompass both detrimental and beneficial interactions. At least two forms of allelopathy are distinguished: (1) the production and release of an allelochemical by one species inhibiting the growth of only other adjacent species, which may confer competitive advantage for the allelopathic species; and (2) autoallelopathy, in which both the species producing the allelochemical and unrelated species are indiscriminately affected. The term allelopathy, frequently restricted to interactions among higher plants, is now applied to interactions among plants from all divisions, including algae. Even interactions between plants and herbivorous insects or nematodes in which plant substances attract, repel, deter, or retard the growth of attacking insects or nematodes are considered to be allelopathic. Interactions between soil microorganisms and plants are important in allelopathy. Fungi and bacteria may produce and release inhibitors or promoters. Some bacteria enhance plant growth through fixing nitrogen, others through providing phosphorus. The activity of nitrogen-fixing bacteria may be affected by allelochemicals, and this effect in turn may influence ecological patterns. The rhizosphere must be considered the main site for allelopathic interactions. *See* NITROGEN FIXATION; RHIZOSPHERE.

Allelopathy is clearly distinguished from competition: In allelopathy a chemical is introduced by the plant into the environment, whereas in competition the plant removes or reduces such environmental components as minerals, water, space, gas exchange, and light. In the field, both allelopathy and competition usually act simultaneously. [M.Ru.]

Allergy Altered reactivity in humans and animals to allergens (substances foreign to the body that cause allergy) induced by exposure through injection, inhalation, ingestion, or skin contact. The most common clinical manifestations of allergy are hay fever, asthma, hives, atopic (endogenous) eczema, and eczematous skin lesions caused by direct contact with allergens such as poison ivy or certain chemicals.

A large variety of substances may cause allergies: pollens, animal proteins, molds, foods, insect venoms, foreign serum proteins, industrial chemicals, and drugs. Most natural allergens are proteins or polysaccharides of moderate molecular size (molecular weights of 10,000 to 200,000). Chemicals or drugs of lower molecular weight (haptens) have first to bind to the body's own proteins (carriers) in order to become fully effective allergens.

For the development of the hypersensitivity state underlying clinical allergies, repeated contact with the allergen is required. Duration of the sensitization period is usually dependent upon the sensitizing strength of the allergen and the intensity of exposure. Some allergens (for example, saliva, urine, and hair proteins of domestic animals) are more sensitizing than others. In most instances, repeated contact with minute amounts of allergen is required; several annual seasonal exposures to grass pollens or ragweed pollen usually occur before an overt manifestation of hay fever. On the other hand, allergy to cow milk proteins in infants can develop within a few weeks. When previous contacts with allergens have not been apparent (for example, antibiotics in food), an allergy may become clinically manifest even upon the first conscious encounter with the offending substance.

Besides the intrinsic sensitizing properties of allergens, individual predisposition of the allergic person to become sensitized also plays an important role. Clinical manifestations, such as hay fever, allergic asthma, and atopic (endogenous) dermatitis, occur more frequently in some families. In other clinical forms of allergy, genetic predisposition, though possibly present as well, is not as evident.

Exposure to sensitizing allergens may induce several types of immune response, and the diversity of immunological mechanisms involved is responsible for the various clinical forms of allergic reactions which are encountered in practice. Three principal types of immune responses are encountered: the production of IgE antibodies, IgG or IgM antibodies, and sensitized lymphocytes. *See* ANTIBODY; IMMUNOGLOBULIN.

Diagnosis of allergic diseases encompasses several facets. Since many clinical manifestations of allergy are mimicked by nonallergic mechanisms, it is usually necessary to use additional diagnostic procedures to ascertain whether the person has developed an immune response toward the incriminated allergen. Such procedures primarily consist of skin tests, in which a small amount of allergen is applied on or injected into the skin. If the individual is sensitized, a local immediate reaction ensues, taking the form of a wheal (for IgE-mediated reactions), or swelling and redness occurs after several hours (for delayed hypersensitivity reactions). The blood may also be analyzed for IgE and IgG antibodies by serological assays, and sensitized lymphocytes are investigated by culturing them with the allergen.

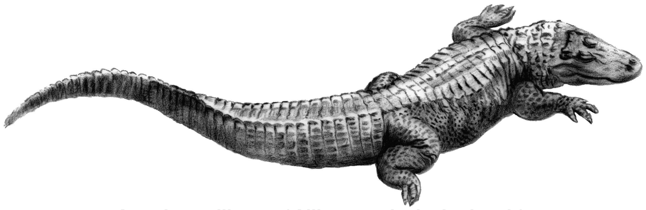
Since the discovery of the responsible allergens markedly influences therapy and facilitates prediction of the allergy's outcome, it is important to achieve as precise a diagnosis as possible. Most tests indicate whether the individual is sensitized to a given allergen, but not whether the allergen is in fact still causing the disease. Since in most cases the hypersensitive state persists for many years, it may well happen that sensitization is detected for an allergen to which the individual is no longer exposed and which therefore no longer causes symptoms. In such cases, exposition tests, consisting of close observation of the individual after deliberate exposure to the putative allergen, may yield useful information.

The most efficient treatment, following identification of the offending allergen, remains elimination of allergen from the person's environment and avoidance of further exposure. This form of treatment is essential for allergies caused by most household and workplace allergens. *See* ANTIGEN; HYPERSENSITIVITY. [A.L.deW.]

Alligator Large aquatic reptile of the family Alligatoridae. Common usage generally restricts the name to the two living species of the genus *Alligator*. The American alligator (*A. mississippiensis*) ranges throughout the southeastern United States from coastal North Carolina (southeastern Virginia in historical times) to the Rio Grande in Texas, and north into southeastern Oklahoma and southern Arkansas (see illustration).

The second species is the Chinese alligator (*A. sinensis*), restricted to the region of the Yangtze River valley in China, where it inhabits burrows in the floodplains and riverbanks. It is also an endangered species and is now protected in China.

The American alligator is by far the larger of the two species, reaching a length in excess of 15 ft (4.5 m). The average length of *A. sinensis* is 4–5 ft (1.2–1.5 m). *See* REPTILIA. [H.W.C.]



American alligator (*Alligator mississippiensis*).

Alloeocoela An order of the Turbellaria, mainly marine but with some fresh-water and terrestrial species. They possess a well-defined gut, with a simple, variable (modified dolioform) or plicate pharynx and a diverticulated intestine. The nervous system has three or four pairs of longitudinal nerves, with connecting commissures. The ovary is paired. The testes are follicular, and a well-defined penis papilla is present. There is a pair of protonephridia, often with two or three main branches to each and with a number of nephridiopores. Anterior ciliated pits or grooves are common; eyes and statocysts are less so, but present in some.

Alloeocoels are generally 0.04–0.40 in. (1–10 mm) in length and cylindrical in shape, but sometimes plump or elongate. They are generally grayish white to brown, but may be more brightly colored due to gut contents or yellow to orange lipid reserves. They occur in the littoral zone among algae, on sandy or muddy bottoms, and occasionally in clear rock pools. *See* TURBELLARIA. [J.B.J.]

Allometry The study of changes in the characteristics of organisms with body size. Characteristics such as body parts or timing of reproductive events do not necessarily change in direct proportion to body size, and the ways in which they change relative to body size can often provide insights into organisms' construction and behavior. Large organisms are often not merely magnified small ones.

Many characteristics, ranging from brain size and heart rate to life span and population density, change consistently with body size. These relationships normally fit a simple power function given by Eq. (1), where y is the variable under study, m is

$$y = km^b \tag{1}$$

body mass, k is the allometric constant, and b is the allometric exponent. The use of logarithms makes the equation easier to visualize—the exponent becomes the slope of a straight line when the logarithm of the variable (y) is plotted against the logarithm of body mass (m) [Eq. (2)].

$$\log(y) = \log(k) + b\log(m) \tag{2}$$

Unless the allometric exponent (b) equals 1, the ratio of y/m varies with m. The terms isometry, positive allometry, and negative allometry are sometimes used for $b = 1$, $b > 1$, and $b < 1$, respectively. If the variable of interest is the mass of an organ, under isometry the organ mass is a fixed proportion of body mass; under positive allometry the larger organisms have disproportionately large organs; and under negative allometry the larger organisms have disproportionately small organs. *See* LOGARITHM.

Allometry is perhaps most powerful when known allometric relations are coupled with theory to produce new hypotheses that can be tested. For example, mammal species with large bodies grow more slowly, mature later, have fewer but larger young after longer gestation periods, and live longer than do small species; these traits remain correlated with each other among deviations from the allometric lines. Allometric models predict not only the allometric exponents but also the correlations among the deviations. The models even provide a framework for asking questions vital to understanding scaling, such as what factors affect the evolution of body size itself. *See* BIOPHYSICS. [A.Pu.; P.H.Ha.]

Allosteric enzyme Any one of the special bacterial enzymes involved in regulatory functions. End-product inhibition is a bacterial control mechanism whereby the end product of a biosynthetic pathway can react with the first enzyme of the pathway and prevent its activity. This end-product inhibition is a device through which a cell conserves its economy by shutting off the synthesis of building blocks when too many are present.

A model to explain the action of allosteric enzymes suggests that the enzyme molecule is a complex consisting of identical subunits, each of which has a site for binding the substrate and another for binding the regulatory substance. These subunits interact in such a way that two conformational forms may develop. One form is in a relaxed condition (*R* state) and has affinity for the substrate and activator; the other form is in a constrained or taut condition (*T* state) and has affinity for the inhibitor. The forms exist in a state of equilibrium, but this balance can be readily tipped by binding one of the reactants. The substrate and activator are bound by the relaxed form; when this happens, the balance is tipped in favor of that state. Conversely, the inhibitor will throw the balance toward the constrained state. The balance is thus tipped one way or the other, depending on the relative concentrations of substrate and inhibitor. Since the two states require subunit interaction for their maintenance, it can be seen why dissociation of the subunits leads to a simple monomeric enzyme which no longer exhibits allosteric effects. The model also shows how the binding sites may interact in either a cooperative or antagonistic manner. *See* ENZYME. [J.S.G.]

Allotheria One of the four subclasses of Mammalia, containing a single order, the Multituberculata. The Allotheria first appeared in the Late Jurassic and survived well into the Cenozoic, a period of at least 100,000,000 years. Fossils are known from North America, Europe, and Asia.

The diagnostic features of the subclass are in the dentition. There is a pair of enlarged incisors above and below; reduced lateral incisors may persist in the upper jaw. Canines are absent, leaving a diastema between incisors and cheek teeth. Premolars are variable and often reduced. The lower molars have five or more cusps in two parallel longitudinal rows, and the upper molars have two or three parallel rows of cusps; hence the molars are multituberculate. *See* DENTITION; MAMMALIA; MULTITUBERCULATA. [D.D.D./F.S.S.]

Allowance An intentional difference in sizes of two mating parts. With running or sliding fits, allowance is a clearance, usually for a film of oil. In this sense, allowance is the space "allowed" for motion between parts.

With force or shrink fits allowance is an interference of metal; that is, a portion of metal in one part tends to occupy the same space as the adjacent portion of metal in the mating part. In this sense, allowance is the interference "allowed" to produce pressure between parts. *See* FORCE FIT; LOCATION FIT; PRESS FIT; RUNNING FIT; SHRINK FIT; TOLERANCE. [P.H.B.]

Alloy A metal product containing two or more elements (1) as a solid solution, (2) as an intermetallic compound, or (3) as a mixture of metallic phases. Alloys are frequently described on the basis of their technical applications. They may also be categorized and described on the basis of compositional groups. For example, *See* BERYLLIUM ALLOYS; IRON ALLOYS.

Except for native copper and gold, the first metals of technological importance were alloys. Bronze, an alloy of copper and tin, is appreciably harder than copper. This quality made bronze so important an alloy that it left a permanent imprint on the civilization of several millennia ago now known as the Bronze Age. Today the tens of thousands of alloys involve almost every metallic element of the periodic table.

Alloys are used because they have specific properties or production characteristics that are more attractive than those of the pure, elemental metals. For example, some alloys possess high strength; others have low melting points; others are refractory with high melting temperatures; some are especially resistant to corrosion; and others have desirable magnetic, thermal, or electrical properties. These characteristics arise from both the internal and the electronic structure of the alloy. An alloy is usually harder than a pure metal and may have a much lower conductivity.

Bearing alloys are used for metals that encounter sliding contact under pressure with another surface; the steel of a rotating shaft is a common example. Most bearing alloys contain particles of a hard intermetallic compound that resist wear. These particles, however, are embedded in a matrix of softer material which adjusts to the hard particles so that the shaft is uniformly loaded over the total surface. The most familiar bearing alloy is babbitt. Bearings made by powder metallurgy techniques are widely used because they permit the combination of materials which are incompatible as liquids, for example, bronze and graphite, and also permit controlled porosity within the bearings so that they can be saturated with oil before being used, the so-called oilless bearings. *See* ANTIFRICTION BEARING; WEAR.

Certain alloys resist corrosion because they are noble metals. Among these alloys are the precious-metal alloys. Other alloys resist corrosion because a protective film develops on the metal surface. This passive film is an oxide which separates the metal from the corrosive environment. Stainless steels and aluminum alloys exemplify metals with this type of protection. The bronzes, alloys of copper and tin, also may be considered to be corrosion-resisting. *See* CORROSION; STAINLESS STEEL.

Dental alloys contain precious metals. Amalgams are predominantly silver-mercury alloys, but they may contain minor amounts of tin, copper, and zinc for hardening purposes. Liquid mercury is added to a powder of a precursor alloy of the other metals. After being compacted, the mercury diffuses into the silver-base metal to give a completely solid alloy. Gold-base dental alloys are preferred over pure gold because gold is relatively soft. The most common dental gold alloy contains gold, silver, and copper. For higher strengths and hardnesses, palladium and platinum are added, and the copper and silver are increased so that the gold content drops. Vitallium and other corrosion-resistant alloys are used for bridgework and special applications. *See* SILVER ALLOYS.

Die-casting alloys have melting temperatures low enough so that in the liquid form they can be injected under pressure into steel dies. Such castings are used for automotive parts and for office and household appliances which have moderately complex shapes. Most die castings are made from zinc-base or aluminum-base alloys. Magnesium-base alloys also find some application when weight reduction is paramount. Low-melting alloys of lead and tin are not common because they lack the necessary strength for the above applications. *See* METAL CASTING.

In certain alloy systems a liquid of a fixed composition freezes to form a mixture of two basically different solids or phases. An alloy that undergoes this type of solidification process is called a eutectic alloy. A homogeneous liquid of this composition on slow cooling freezes to form a mixture of particles of nearly pure copper embedded in a matrix (background) of nearly pure silver.

The advantageous mechanical properties inherent in composite materials have been known for many years. Attention is being given to eutectic alloys as they are basically natural composite materials. *See* EUTECTICS; METAL MATRIX COMPOSITE.

Fusible alloys generally have melting temperatures below that of tin (449°F or 232°C), and in some cases as low as 122°F (50°C). Using eutectic compositions of metals such as lead, cadmium, bismuth, tin, antimony, and indium achieves these low melting temperatures. These alloys are used for many purposes, for example, in fusible elements in automatic sprinklers, forming and stretching dies, filler for thin-walled tubing that is being bent, and anchoring dies, punches, and parts being machined.

High-temperature alloys have high strengths at high temperatures. In addition to having strength, these alloys must resist oxidation by fuel-air mixtures and by steam vapor. At temperatures up to about 1380°F (750°C), the austenitic stainless steels serve well. An additional 180°F (100°C) may be realized if the steels also contain 3% molybdenum. Both nickel-base and cobalt-base alloys, commonly categorized as superalloys, may serve useful functions up to 2000°F (1100°C). Nichrome, a nickel-base alloy containing chromium and iron, is a fairly simple superalloy. More sophisticated alloys invariably contain five, six, or more components; for example, an alloy called René-41 contains Cr, Al, Ti, Co, Mo, Fe, C, B, and Ni. Other alloys are equally complex. A group of materials called cermets, which are mixtures of metals and compounds such as oxides and carbides, have high strength at high temperatures, and although their ductility is low, they have been found to be usable. One of the better-known cermets consists of a mixture of titanium carbide and nickel, the nickel acting as a binder or cement for the carbide. *See* CERMET.

Metals are bonded by three principal procedures: welding, brazing, and soldering. Welded joints melt the contact region of the adjacent metal; thus the filler material is chosen to approximate the composition of the parts being joined. Brazing and soldering alloys are chosen to provide filler metal with an appreciably lower melting point than that of the joined parts. Typically, brazing alloys melt above 750°F (400°C), whereas solders melt at lower temperatures. *See* BRAZING; SOLDERING.

Aluminum and magnesium, with densities of 2.7 and 1.75 g/cm^3, respectively, are the bases for most of the light-metal alloys. Titanium (4.5 g/cm^3) may also be regarded as a light-metal alloy if comparisons are made with metals such as steel and copper. Aluminum and magnesium must be hardened to receive extensive application. Age-hardening processes are used for this purpose. *See* ALUMINUM; MAGNESIUM.

Low-expansion alloys include Invar, the dimensions of which do not vary over the atmospheric temperature range, and Kovar, which is widely used because its expansion is low enough to match that of glass. *See* THERMAL EXPANSION.

Soft and hard magnetic materials involve two distinct categories of alloys. The former consists of materials used for magnetic cores of transformers and motors, and must be magnetized and demagnetized easily. For alternating-current applications, silicon-ferrite is commonly used. This is an alloy of iron containing as much as 5% silicon. Permalloy and some comparable cobalt-base alloys are used in the communications industry. Ceramic ferrites, although not strictly alloys, are widely used in high-frequency applications because of their low electrical conductivity and negligible induced-energy losses in the magnetic field. Permanent or hard magnets may be made from steels which are mechanically hardened, either by deformation or by quenching. The Alnicos are also widely used for magnets. Since these alloys cannot be forged, they must be produced in the form of castings. The newest hard magnets are being produced from alloys of cobalt and the rare-earth type of metals. *See* MAGNETIC MATERIALS.

In addition to their use in coins and jewelry, precious metals such as silver, gold, and the heavier platinum metals are used extensively in electrical devices in which contact resistances must remain low, in catalytic applications to aid chemical reactions, and in temperature-measuring devices such as resistance thermometers and thermocouples. The unit of alloy impurity is commonly expressed in karats, where each karat is a $^1/_{24}$ part. The most common precious-metal alloy is sterling silver (92.5% Ag, with the remainder being unspecified, but usually copper). The copper is very beneficial in that it makes the alloy harder and stronger than pure silver.

Metallic implants demand extreme corrosion resistance because body fluids contain nearly 1% NaCl, along with minor amounts of other salts, with which the metal will be in contact for indefinitely long periods of time. Type 316 stainless steels resist pitting corrosion but are subject to crevice corrosion. Vitallium and other cobalt-base alloys have orthopedic applications. Titanium alloys gained wide usage in Europe during the early 1970s for pacemakers and for retaining devices in artificial heart valves. While excellent for corrosion resistance, this alloy is subject to mechanical wear; therefore, it is not satisfactory in hip-joint prostheses and applications with similar frictional contacts. *See* PROSTHESIS.

Shape memory alloys have a very interesting and desirable property. In a typical case, a metallic object of a given shape is cooled from a given temperature T_1 to a lower temperature T_2 where it is deformed so as to change its shape. Upon reheating from T_2 to T_1 the shape change accomplished at T_2 is recovered so that the object returns to its original configuration. This thermoelastic property of the shape memory alloys is associated with the fact that they undergo a martensitic phase transformation (that is, a reversible change in crystal structure that does not involve diffusion) when they are cooled or heated between T_1 and T_2. Shape memory alloys are capable of being employed in a number of useful applications. One example is for thermostats; another is for couplings on hydraulic lines or electrical circuits.

Superconducting alloys, with zero resistivity, are of great interest in the design of certain fusion reactors which require very large magnetic fields to contain the plasma in a closed system. The advantage of the use of a material with a resistivity approaching zero is obvious. However, two significant problems are involved in the use of superconducting alloys in large electromagnetics: the critical temperature, and the fact that above a certain critical current density the superconducting materials tend to become normal conductors with a finite resistance. Serious materials problems still have to be solved before these materials can be used successfully. *See* SUPERCONDUCTIVITY.

Thermocouple alloys include Chromel and Alumel. These two alloys together form the widely used Chromel-Alumel thermocouple, which can measure temperatures up to 2200°F (1204°C). Another common thermocouple alloy, constantan, is used to form iron-constantan and copper-constantan couples, employed at lower temperatures. *See* STEEL; THERMOCOUPLE.

[L.H.V.V./R.E.R.H.]

As discussed here, prosthetic alloys are alloys used in internal prostheses, that is, surgical implants such as artificial hips and knees. External prostheses are devices that are worn by patients outside the body; alloy selection criteria are different from those for internal prostheses. Alloy selection criteria for surgical implants can be stringent primarily because of biomechanical and chemical aspects of the service environment. The most widely used prosthetic alloys therefore include high-strength, corrosion-resistant ferrous, cobalt-based, or titanium-based alloys: for example, cold-worked stainless steel; cast Vitallium; a wrought alloy of cobalt, nickel, chromium, molybdenum, and titanium; titanium alloyed with aluminium and vanadium; and commercial-purity titanium. *See* PROSTHESIS. [J.Br.]

An alloy of niobium and titanium (NbTi) has a great number of applications in superconductivity; it becomes superconducting at 9.5 K (critical superconducting temperature, T_c). This alloy is preferred because of its ductility and its ability to carry large amounts of current at high magnetic fields, represented by $J_c(H)$ [where J_c is the critical current and H is a given magnetic field], and still retain its superconducting properties. Novel high-temperature superconducting materials may have revolutionary impact on superconductivity and its applications. These materials are ceramic, copper oxide-based materials that contain at least four and as many as six elements. Typical examples are yttrium-barium-copper-oxygen (T_c 93 K); bismuth-strontium-calcium-copper-oxygen (T_c 110 K); and thallium-barium-calcium-copper-oxygen (T_c 125 K). These materials become superconducting at such high temperatures that refrigeration is simpler, more dependable, and less expensive. *See* CERAMICS; SUPERCONDUCTIVITY. [D.Gu.]

Alloy structures Metals in actual commercial use are almost exclusively alloys, and not pure metals, since it is possible for the designer to realize an extensive variety of physical properties in the product by varying the metallic composition of the alloy. As a case in point, commercially pure or cast iron is very brittle because of the small amount of carbon impurity always present, while the steels are much more ductile, with greater strength and better corrosion properties. In general, the highly purified single crystal of a metal is very soft and malleable, with high electrical conductivity, while the alloy is usually harder and may have a much lower conductivity. The conductivity will vary with the degree of order of the alloy, and the hardness will vary with the particular heat treatment used. For commercial applications of alloys and other information *see* ALLOY.

The basic knowledge of structural properties of alloys is still in large part empirical, and indeed, it will probably never be possible to derive formulas which will predict which metals to mix in a certain proportion and with a certain heat treatment to yield a specified property or set of properties. However, a set of rules exists which describes the qualitative behavior of certain groups of alloys. These rules are statements concerning the relative sizes of constituent atoms for alloy formation, and concerning what kinds of phases to expect in terms of the valence of the constituent atoms. The rules were discovered in a strictly empirical way, and for the most part, the present theoretical understanding of alloys consists of rudimentary theories which describe how the rules arise from the basic principles of physics. [R.M.T.]

Size factor. The empirical rules for alloy formation state that, for substitutional alloys, the size of the constituents must be approximately the same, whereas one of the constituents of an interstitial alloy must be small compared to the other. Simply stated, the size factor recognizes the importance of choosing two metals which can fit together in a lattice structure. In order to define the concept of size, one must refer to the general ideas of the band theory of solids. According to this theory, the valence electrons of the metal atoms are detached from the immediate vicinity of the atom and contribute to the conduction band. In the conduction band the electrons have many of the characteristics of free particles similar to the atoms of a gas. The conduction electrons are spread over the metal, filling the interstices between the remaining ion cores of the metal atoms. The electrons of the inner shells remain tightly bound to the individual ions, however. *See* FREE-ELECTRON THEORY OF METALS; VALENCE.

Interstitial alloys. Examples of interstitial alloys are some of the alloys of the transition elements and, most familiarly, those of iron. The iron lattice is face-centered cubic at medium temperatures. If the face-centered lattice is considered to be made up of hard spheres of radius a_0, the largest atom which can be fitted into an interstitial position (the cube center) has a radius $0.59a_0$. There are only four neutral atoms which have smaller radii than this value for the transition-metal group. They are hydrogen, carbon, nitrogen, and boron. Carbon is actually an exception to the rule for iron, as it has a radius of $0.63a_0$ for the iron lattice. Actually, these four elements are not metals in their normal state, even though they do form metallic alloys with the transition metals. *See* CRYSTAL DEFECTS; CRYSTAL STRUCTURE; CRYSTALLOGRAPHY.

Substitutional alloys. In the substitutional primary solutions the solute atom takes the place of one of the solvent atoms. In this case the size of the solvent and solute must be nearly the same. It is possible to calculate in a crude way the maximum permissible difference in size. The size difference is reflected in a lattice distortion, which is a contribution to the internal energy of the system.

The substitutional alloys are the commonest type of alloy structure and have received the most study. Cu-Au is a good example of the substitutional alloy. The atomic sizes are very close, and the electronic structures of Cu and Au are very similar. As a result, this system forms a single primary solid solution system from one end of the composition diagram to the other. The only complexities are due to ordering phenomena, which will be discussed later.

Valence factor. In addition to the effects of the size of the ions on the formation of alloys, the electronic structure of the atoms involved also plays a role. It is the electronic configuration of the atoms which determines why mixtures of some elements form metallic alloys, whereas some form insulating compounds. Qualitatively, it is found that alloys are formed from the atoms of the middle of the electrochemical series of the elements. The reason is that there is always a tendency for the ions of the metallic state to polarize with respect to their neighbors and form an ionic solid instead of the metallic one. If the tendency is strong, no metallic alloy state can be formed; hence, only elements from the middle of the series, where there is little change in the ionization potential from one atom to another, can form successful alloys. *See* ELECTROCHEMICAL SERIES.

Stoichiometry. Closely related to the polarization effect is the reason why the alloys are nonstoichiometric (that is, why they form mixtures which do not consist of small-number ratios of one element to the other) and form homogeneous phases over wide ranges of composition. For example, copper and gold mix homogeneously for any composition. This result is in striking contrast to the behavior of the ionic compounds such as sodium chloride, NaCl. *See* STOICHIOMETRY.

In NaCl an excess Na ion is bound in the crystal with an energy less by about 1 eV than a normal ion, and this energy discrepancy is large enough so that, when the crystal becomes far from stoichiometric, the homogeneous compound is no longer formed. The excess constituent forms a separate phase, either as Na metal crystals embedded in the matrix or as bubbles of Cl_2. The energy discrepancy in the case of NaCl is primarily due to the excess of charge of one sign or the other when the wrong ion is on a lattice site. Since the lattice is completely ionized, the excess charge due to the excess ion amounts to the complete ionic charge. *See* IONIC CRYSTALS.

Screening length. A further effect is the screening of the polarization around the gold atom by the conduction electrons themselves. In this case, when the region around the gold is polarized, a voltage difference is also generated. Hence, the electrons of the metal tend to rush into the affected region to even out the discrepancy. However, it is not possible to redress the balance completely, and a region of the order of the size of the gold atomic volume itself remains polarized. The size of this region is indicated by the screening length of the electrons of the metal, which are here listed for several metals in units of lattice spacing a_0: Cu, 1.1; Al, 1.4; Tl, 1.0; Fe, 3.2; and Ni, 4.8.

Structure and electron density. It appears that in numerous cases there is a tendency for a particular type of crystal structure to correspond to a particular electron density in the conduction band. Thus, when zinc is alloyed to copper, near the 50% composition there is a phase change from the face-centered-cubic (fcc) lattice of copper to a body-centered-cubic (bcc) lattice. If it is assumed that all the valence electrons of all the atoms are contributed to the conduction band, there will be an average of 1.5 electrons per atom of the alloy in this band, since the valence of copper is 1 and the valence of zinc is 2. For the alloys Cu_3Al and Cu_5Sn, the crystal structure is also bcc for the same average free electron concentration.

H. Jones has used the free-electron theory of metals modified by perturbation theory to derive an expression for the difference in energy of the electrons of the fcc and bcc crystals. His result is that as the Brillouin zone is filled, at first the energy is very nearly equal for the two crystals. The energy of the fcc crystal then drops below that of the bcc crystal at an electron concentration of about 1 electron per atom; but at a concentration close to 1.5, the situation reverses and the bcc crystal becomes more stable. Similar discussions have been given for the hexagonal lattices; these show that certain distortions of the symmetry of the perfect hexagonal lattice which occur are due to electronic effects related to filling the Brillouin zone. *See* BRILLOUIN ZONE.

However, in spite of the seeming success of the theory in confirming the electron compound concept in terms of the interaction of the electrons with the boundaries of the Brillouin zone, the Jones treatment must be considered a very limited theory. First of all, Jones assumed, when he adopted the free-electron picture, that the role of the ions in the alloy is a minor one. On the other hand, when a zinc atom is placed in a copper lattice, it is necessary that the vicinity of the zinc atom be highly polarized, according to the discussion of the preceding section. In a 50% alloy of Cu-Zn, the atomic volume of a zinc ion will have only 1.5 electrons to cancel the charge of a double ionized core. Thus, the lattice cell of the zinc atom has a net charge of $+^1/_2$. Hence, the valence electrons from zinc atoms cannot be freely contributed to the free-electron cloud of the crystal. There must be a considerable clumping of this charge around the various different ions of the alloy in such a way that the excess charge of the ions is screened. In addition, there is some evidence from the experiments on nuclear magnetic resonance in dilute alloys that the electron density in the conduction band does not change as the divalent ion is added, in direct contradiction to the simple free-electron picture.

Order-disorder in alloys. In the preceding discussion on the formation of alloys, it was tacitly assumed that the atoms of the two constituents were randomly distributed on the lattice of the alloy. In very dilute primary solutions the random distribution holds because the free energy of the system in the completely random state is lower than that of a more symmetric state. To be more specific, in a dilute solution of metal B in metal A, if there is no gain of internal energy by ordering B (placing the atoms of B in a regular arrangement on the lattice sides of A), the free energy, $U - TS$, is a minimum when B is completely randomized.

On the other hand, if an appreciable percentage of the lattice sites are occupied by B and if there is a difference in the interatomic forces between A-B nearest-neighbor atom pairs and those between A-A or B-B pairs, the situation is different. The internal energy of the alloy is then given by Eq. (1), where N_{AB}

$$U = N_{\mathrm{AB}}E_{\mathrm{AB}} + N_{\mathrm{AA}}E_{\mathrm{AA}} + N_{\mathrm{BB}}E_{\mathrm{BB}} \qquad (1)$$

is the number of A-B nearest-neighbor pairs in the alloy, E_{AB} is the energy of interaction between an A-B pair, and so on. It is assumed that the alloy atoms interact appreciably only when they are nearest neighbors. If the interaction between A-B pairs is greater than that between B-B or A-A pairs, then the state of lowest energy is that in which the number of like pairs is minimized. This state is also a completely ordered state of the crystal.

For any given temperature the equilibrium state of the crystal is that for which the free energy is minimized, and a balance is struck between the contradictory tendencies of the U and TS terms of the free energy. At low temperatures the U term can be expected to predominate, and ordering will usually occur, while at higher temperatures the entropy term will predominate, and a transition to a disordered state is usual.

Long- and short-range order. The ordering of a crystal is described in terms of two different order parameters. One is called local or short-range order, and the other is called long-range order. For the initial discussion of the long- and short-range order parameters, a 50% A-B alloy will be considered. It will also be supposed that the lattice structure is bcc and that the unlike pair interaction is the stronger one. The advantage of the bcc lattice for the discussion is that, in this lattice, all the neighbors of any given atom can be made unlike atoms.

In the completely ordered state every atom of the crystal is surrounded by unlike nearest neighbors, and the crystal becomes disordered when some of the A atoms exchange with B atoms. The long-range order parameter Σ is a measure of the number of such interchanges and expresses the number of sites occupied by the wrong atom, as in Eq. (2). Here n_a is the number of A sites

$$\Sigma = \frac{2n_a}{N} - 1 \qquad (2)$$

occupied by A atoms, and N is the total number of A lattice sites. The quantity Σ varies from -1 to $+1$, and the state of complete disorder corresponds to $\Sigma = 0$.

The short-range order expresses the fact that the neighbors surrounding any given A atom will have a tendency to be all B atoms. If this tendency is averaged over the lattice, the short-range order σ is defined in Eq. (3). Here σ is the local-order

$$\sigma = 2(q - {}^1/_2) \qquad (3)$$

parameter, and q is the number of A-B pairs in the crystal divided by the total number of atom pairs in the crystal. The parameter σ has the range -1 to $+1$, with complete disorder at $\sigma = 0$.

Variation with temperature. A good qualitative notion of the behavior of the order of a crystal is obtained by observing the variation of the order parameter of a crystal as a function of temperature. The long-range order decreases from a state of complete order at absolute zero temperature. At a critical transition temperature which depends on the strength of the A-B bonds relative to the A-A bonds, the long-range order drops to zero. The local order also starts at absolute zero with a maximum value, but decreases more slowly than the long-range order does and remains finite for all temperatures.

The discussion up till now has been based on the model of a 50% alloy in a simple lattice. The theory for a material in which the composition is allowed to vary over the entire composition diagram is exceedingly complicated. The complication is due to the difficulty of specifying the types of order configurations which are possible, and computing their entropy. However, the general results are still comparable with the simple case. Long- and short-range order parameters can still be defined, with a transition temperature at the point where the long-range order disappears. The short-range order again persists to a considerable degree even above the transition temperature.

Transition temperature. The existence of the transition temperature amounts to a change of phase, because there is an attendant singularity in the specific-heat curve of the material. The phase change may be of the first or second order, depending on the type of singularity present in the long-range order at the transition temperature. A general rule seems to be that for lattices in which the completely ordered state has only neighbors of A-B bonds, the transition is second order. The bcc lattice is such a case, as has already been explained. However, in close-packed lattices such as the fcc lattice, it is not possible for all the bonds of a 50% alloy to be of the sort A-B, and in such cases, it is found experimentally that the transition is first order.

Detection of order. The presence of order in a crystal and the transition from the ordered to the disordered state are detected by a variety of techniques. The resistance of the alloy at low temperatures varies with the order of the crystal because the electron waves of the crystal are sensitive to irregularities in the crystal, so that as disorder increases, the resistivity increases also. X-ray and neutron scattering of the lattice are also functions of the degree of order for the same reason. The specific heat of the crystal varies with the order, since as the crystal loses its order, energy must be supplied to the lattice to form the A-A and B-B bonds which have higher energy. At the transition temperature the specific heat rises to a sharp peak, which is easily detected. *See* NEUTRON DIFFRACTION; X-RAY DIFFRACTION.

Superlattices. The x-ray and neutron scattering of a completely ordered crystal have an interesting peculiarity. In the Bragg scattering processes new lines appear, called superlattice lines. The name is derived from the fact that the lines correspond to the appearance of a secondary crystalline structure in the lattice. Their explanation is clear in the light of the discussion of the ordered lattice. For a 50% A-B lattice in the bcc form, the

A atoms form the corners of the cube, while the B atoms are at the center positions. The crystal is then composed of two interpenetrating simple cubic crystals, and is called a superlattice. The x-ray lines for two simple cubic structures appear instead of those for a bcc crystal. [R.M.T.]

Allspice The dried, unripe fruits of a small, tropical, evergreen tree, *Pimenta officinalis*, of the myrtle family (Myrtaceae). This species is a native of the West Indies and parts of Central and South America. The spice, alone or in mixtures, is much used in sausages, pickles, sauces, and soups. The extracted oil is used for flavoring and in perfumery. Allspice is so named because its flavor resembles that of a combination of cloves, cinnamon, and nutmeg. *See* MYRTALES; SPICE AND FLAVORING. [P.D.St.E.L.C.]

Almanac A book that contains astronomical or meteorological data arranged according to days, weeks, and months of a given year and may also include diverse information of a nonastronomical character. This article is restricted to astronomical and navigational almanacs.

The Astronomical Almanac contains ephemerides, which are tabulations, at regular time intervals, of the orbital positions and rotational orientation of the Sun, Moon, planets, satellites, and some minor planets. It also contains mean places of stars, quasars, pulsars, galaxies, and radio sources, and the times for astronomical phenomena such as eclipses, conjunctions, occultations, sunrise, sunset, twilight, moonrise, and moonset. This volume contains the fundamental astronomical data needed by astronomers, geodesists, navigators, surveyors, and space scientists. The theory and methods on which *The Astronomical Almanac* is based are provided in the *Explanatory Supplement to the Astronomical Almanac. See* ASTRONOMICAL COORDINATE SYSTEMS; EPHEMERIS.

While *The Astronomical Almanac* is basically designed for the determination of positions of astronomical objects as observed from the Earth, *The Nautical Almanac* and *The Air Almanac* are designed to determine the navigator's position from the tabulated position of the celestial object. *The Nautical Almanac* contains hourly values of the Greenwich hour angle and declination of the Sun, Moon, Venus, Mars, Jupiter, and Saturn and the sidereal hour angle and declination of 57 stars for every third day. Monthly apparent positions are tabulated for an additional 173 navigational stars. The positions are tabulated to an angular accuracy of 0.1 minute of arc, which is equivalent to 0.1 nautical mile (0.2 km). Since tabular quantities must be combined to derive the navigational fix, this tabular accuracy is sufficient to produce a computed position with an error no greater than 0.3 to 0.4 nmi (0.6 to 0.7 km). *The Air Almanac* gives the positions of the Sun, first point of Aries, three planets, and the Moon at 10-min intervals. As necessary, information is adjusted so that the tabulated data at any given time can be used during the interval to the next entry, without interpolation, to an accuracy sufficient for practical air navigation. While designed for air navigators, *The Air Almanac* is used by mariners who accept the reduced accuracy in exchange for its greater convenience compared with *The Nautical Almanac.*

The latest source of high-precision astronomical data is the *Multi-Year Interactive Computer Almanac (MICA),* which provides data on compact disks. Thus, in addition to being able to compute the almanac data as published, the user is able to compute data for a particular location and time. [P.K.S.]

Almond A small deciduous tree, *Prunus amygdalus* (also known as *P. dulcis* or *Amygdalus communis*), closely related to the peach and other stone fruits and grown widely for its edible seeds. Almonds are of two general types: the bitter type is a source of prussic acid and flavoring extracts, and the sweet type has various food uses. Almond kernels contain approximately 50% fat or oil, 20% protein, 20% carbohydrate, and a variety of minerals and vitamins. *See* ROSALES.

In the United States, commercial production is limited to California. Spain is the second leading producer, but the amount produced is about one-half that of the United States. Italy has historically been a leading producer, primarily from the Bari and Sicily areas, but production has declined sharply.

Almonds are used in a variety of products. Some are roasted whole and salted to be used as snacks. Others are blanched (the skin is removed) by steam and subjected to slicing, dicing, or halving. These may be roasted, and go into products such as candy bars, bakery products, ice cream, and almond paste, among many other uses. [D.E.K.]

Alpaca A member of the camel family, Camelidae, which belongs to the mammalian order Artiodactyla, the even-toed ungulates. The alpaca (*Lama pacos*) is found at elevations above 12,000 ft (3600 m) along the shores of Lake Titicaca on the boundaries of Peru and Bolivia.

The alpaca's neck and head are elongate, and the upper lip has a deep cleft. The long, slender legs terminate in two toes; the feet are digitigrade, that is, the animals walk on the toes and not on the entire foot or the tip of the digits. The long, fine repellent hair, or wool, ranges in color from black to white and is highly prized for manufacturing cloth, particularly the white wool. Like many breeds of domesticated animals, the alpaca has been bred to produce pure strains for the wool. Although the alpaca is raised chiefly for its wool, its flesh is edible and palatable. *See* ARTIODACTYLA; CAMEL; LLAMA; MAMMALIA; NATURAL FIBER. [C.B.C.]

Alpha Centauri The third brightest star in the sky, apparent magnitude -0.3, and the brightest in the southern constellation Centaurus. It is the closest star to the Sun at a distance of 1.35 parsecs (2.59×10^{13} mi or 4.16×10^{13} km), and its light takes more than 4 years to reach the Earth. *See* CENTAURUS.

Alpha Centauri is in reality a triple system, the two main components orbiting each other with period of nearly 80 years. The orbit is eccentric, and their mean separation is approximately 23 astronomical units. α Cen A and B, as they are also known, are main-sequence stars of spectral types G2 and K1, respectively, and the brightest of the two is very similar to the Sun in mass, luminosity, and effective temperature. *See* ASTRONOMICAL UNIT; BINARY STAR; SPECTRAL TYPE.

The third component of this system, known as Proxima Centauri, is a faint reddish star of 11th magnitude, approximately 2.2° away in the sky. Proxima is actually slightly closer to the Sun, which makes it the Earth's nearest neighbor in space. The linear separation from α Cen A and B is estimated to be about 13,000 astronomical units. Although the probability of such a close association in space and in projected motion occurring by chance among field stars is very small, measurements of the velocity of Proxima relative to the close binary cannot yet determine whether it is gravitationally bound. *See* STAR. [D.W.L.]

Alpha fetoprotein A glycoprotein that is normally present in significant amounts only in the serum of the fetus. It is produced in the yolk sac, the liver, and other tissues of the gastrointestinal tract. Its role is unknown, but alpha fetoprotein may function as a carrier (or modulator of the concentration) of a small ligand, as an immunosuppressive, as a modulator of intracellular transport of unsaturated fatty acids, as a factor in estrogen transport, or as a means of binding retinoic acid. Peak concentration of alpha fetoprotein in human fetal serum occurs at 13 weeks of gestation, and at that time it also reaches maximum levels in the amniotic fluid. Concentration of alpha fetoprotein in maternal serum peaks at approximately week 30–32 of gestation, reflecting the effect of both the production rate in the fetus, which is already declining at that age, and the mass of the growing fetal liver.

Substantially increased levels of alpha fetoprotein were first observed in association with certain tumors, especially of the liver. Subsequently, increased concentrations were noted in the amniotic fluid and maternal serum of pregnant women carrying a fetus affected by an open-neural-tube defect. Thus, screening of maternal serum is now routine.

While the majority of pregnant women having a high concentration of serum alpha fetoprotein experience normal pregnancies, others manifest various problems, including multiple fetuses and placental abnormalities, or defects. Further, about one out of three pregnancies in which alpha fetoprotein is increased has an adverse outcome, including fetal growth retardation, low birth weight, and increased perinatal mortality. In pregnancies where the fetus is affected by trisomy 21 (Down syndrome), there is lower concentration of alpha fetoprotein than usual. *See* DOWN SYNDROME. [A.B.]

Alpha particles Helium nuclei, which are abundant throughout the universe both as radioactive-decay products and as key participants in stellar fusion reactions. Alpha particles can also be generated in the laboratory, either by ionizing helium or from nuclear reactions. They expend their energy rapidly as they pass through matter, primarily by taking part in ionization processes, and consequently have short penetration ranges. Numerous technological applications of alpha particles can be found in fields as diverse as medicine, space exploration, and geology. Alpha particles are also major factors in the health concerns associated with nuclear waste and other radiation hazards.

The helium nucleus, or alpha particle (α), with mass 4.00150 atomic mass units (u) and charge +2, is a strongly bound cluster of two protons (p) and two neutrons (n). Its stability is evident from mass-energy conservation in the hypothetical fusion reaction $2p + 2n \rightarrow \alpha$. The product mass (= 4.00150 u) is less than the reactant mass ($= 2 \times 1.00728$ u $+ 2 \times 1.00866$ u) by 0.03038 u. By using Einstein's relation $E = mc^2$ (where c is the speed of light), this decrease in mass m (the alpha-particle binding energy) is equivalent to 28.3 MeV of energy E. The enormous magnitude of this energy is reflected in the fact that the fusion transformation of hydrogen into helium is the main process responsible for the Sun's energy. *See* CONSERVATION OF ENERGY; ENERGY; HELIUM; NUCLEAR BINDING ENERGY; PROTON-PROTON CHAIN; STELLAR EVOLUTION.

Alpha radioactivity. Coulombic repulsion between the protons within a nucleus leads to increasingly larger ratios of neutron number N to proton number Z for stable nuclei, as the mass numbers increase. Neutron-deficient nuclei can improve their N/Z ratios by means of alpha decay. The decay occurs because the parent nucleus has a total mass greater than the sum of the masses of the daughter nucleus and the alpha particle. The energy converted from mass energy to kinetic energy, called the Q value, is shared between the daughter nucleus and the alpha particle in accordance with the conservation of momentum. Thus, each radioactive alpha-emitting nuclide emits the alpha with a characteristic kinetic energy, which is one fingerprint in identification of the emitter. *See* NUCLEAR REACTION; RADIOACTIVITY.

There are three major natural series, or chains, through which isotopes of heavy elements decay by successions of alpha decays. Within these series, and with all reaction-produced alpha emitters as well, each isotope decays with a characteristic half-life and emits alpha particles of particular energies and intensities. The presence of these radioactive nuclides in nature depends upon either a continuous production mechanism, for example the interaction of cosmic rays with the atmosphere, or extremely long half-lives of heavy radioactive nuclides produced in past cataclysmic astrophysical events, which accounts for uranium and thorium ores in the Earth. The relative abundances of uranium-238, uranium-235, and their stable final decay products in ores of heavy elements can be used to calculate the age of the ore, and presumably the age of the Earth. *See* GEOCHRONOMETRY.

In addition to the study of alpha-particle emitters that appear in nature, alpha decay has provided a useful tool to study artificial nuclei, which do not exist in nature due to their short half-lives. Alpha decay is a very important decay mode for nuclei far from stability with a ratio of protons to neutrons that is too large to be stable, especially for nuclei with atomic mass greater than 150 u. Because of the ease of detecting and interpreting decay alpha particles, their observation has aided tremendously in studying these nuclei far from stability, extending the study of nuclei to the very edge of nuclear existence. Nuclear structure information for more than 400 nuclides has been obtained in this way. In addition, fine structure peaks appear in the alpha-particle spectra for many of these nuclides; each such fine structure peak gives similar information about an excited state in the daughter nucleus.

Interactions with matter. By virtue of their kinetic energy, double positive charge, and large mass, alpha particles follow fairly straight paths in matter, interacting strongly with atomic electrons as they slow down and stop. These electrons may be excited to higher energy states in their host atoms, or they may be ejected, forming ion pairs in which the initial host atom becomes positively charged and the electron leaves. The more energetic ejected electrons, known as delta electrons, cause considerable secondary ionization, which accounts for 60–80% of the total ionization. A cascade of processes occurs along the alpha particle's track, leading to tens of thousands of disruptive events per alpha particle. *See* RADIATION DAMAGE TO MATERIALS.

The amount of energy expended by an alpha particle to form a single ion pair in passing through a medium is nearly independent of the alpha particle's energy, but it depends strongly on the absorbing medium. While it takes about 35 eV in air and 43 eV in helium to form an ion pair, an energy of only 2.9 eV is required in germanium and 3.6 eV in silicon. The energies expended in gases are roughly correlated to their ionization potentials. For germanium, silicon, and other semiconductors, the lower ion pair energy is, effectively, the amount required to raise an electron to the conduction band. *See* IONIZATION POTENTIAL; SEMICONDUCTOR.

The distance (or range) that an alpha particle travels before it stops depends both on the energy of the particle and on the absorbing medium. The passage of alpha particles through silicon is a particularly important example. The semiconductor industry now produces chips so small that alpha particles from contaminants in the packaging materials can disrupt the memory-array areas of the chips, a serious problem which has been researched in considerable detail. *See* INTEGRATED CIRCUITS; RADIATION HARDENING.

In biological systems, the ionization and excitation produced by alpha particles can damage or kill cells. By rupturing chemical bonds and forming highly reactive free radicals, alpha particles can be far more destructive than other forms of radiation which interact less strongly with matter. *See* CHARGED PARTICLE BEAMS; RADIATION CHEMISTRY; RADIATION INJURY (BIOLOGY).

Applications. In the promising medical field of charged-particle radiotherapy, alpha particles are useful in the treatment of inaccessible tumors and vascular disorders. The ionizing power of alpha particles is concentrated near the ends of their paths. Thus they can deliver destructive energy to a tumor while doing little damage to nearby healthy tissue. With proper acceleration, positioning, and dosage, the energy can be delivered so precisely that alpha-particle radiotherapy is uniquely suited for treating highly localized tumors near sensitive normal tissue (for example, the spinal cord). *See* RADIOLOGY.

The element-specific energies of backscattered (Rutherford-scattered) alpha particles are used in remote probes to analyze the mineral composition of geological formations. In particular, alpha particles scattered by light elements transfer more energy than those scattered by heavy elements. In another alpha-particle device, the energy from ^{238}Pu alpha decay is reliably harnessed in batteries based on the Brayton cycle, and used to power scientific equipment left on the Moon. Large power systems of this type are contemplated for use in space stations. *See* ION-SOLID INTERACTIONS; NUCLEAR BATTERY. [C.Bin.]

Alpine vegetation Plant growth forms characteristic of upper reaches of forests on mountain slopes. In such an environment, trees undergo gradual changes that, though subtle at first, may become dramatic beyond the dense forest as the zone of transition leads into the nonforested zone of the alpine tundra. In varying degrees, depending on the particular mountain setting, the forest is transformed from a closed-canopy forest to one of deformed and dwarfed trees interspersed with alpine tundra species. This zone of transition is referred to as the forest-alpine tundra ecotone. The trees within the ecotone are stunted, often shrublike, and do not have the symmetrical shape of most trees within the forest interior. *See* PLANT GEOGRAPHY.

The forest-alpine tundra ecotone is a mosaic of both tree and alpine tundra species; and it extends from timberline (the upper limit of the closed-canopy forest of symmetrically shaped, usually evergreen trees) to treeline (the uppermost limit of tree species) and the exposed alpine tundra. With elevational increases, tree deformation is magnified, tree height is reduced, and the total area occupied by trees becomes smaller as the alpine shrub, grass, and herbaceous perennials become more dominant.

The environment in which these tenacious individuals survive is harsh and involves a complex interaction of many factors, with the major controlling factor often being climate. The climate is characterized by a short growing season, low air temperatures, frozen soils, drought, high levels of ultraviolet radiation, irregular accumulation of snow, and strong winds. The interaction of all these factors produces varying levels of stress within the trees. *See* WIND.

The ultimate cause of the tree deformations and of the eventual complete cessation of tree growth lies in the inability of the tissues of the shoots and the needles to mature and prepare for the harsh environmental conditions. As the length of the growing season decreases with elevation, new needles often do not mature; they have thinner cuticles (the waxlike covering on the needles that protects against desiccation and wind abrasion), and they are less acclimated against low air temperatures. Factors that particularly affect the length of the growing season include air and soil temperatures, and the depth and distribution of snow. *See* AIR TEMPERATURE. [K.J.H.]

Alternating current Electric current that reverses direction periodically, usually many times per second. Electrical energy is ordinarily generated by a public or a private utility organization and provided to a customer, whether industrial or domestic, as alternating current.

One complete period, with current flow first in one direction and then in the other, is called a cycle, and 60 cycles per second (60 hertz) is the customary frequency of alternation in the United States and in all of North America. In Europe and in many other parts of the world, 50 Hz is the standard frequency. On aircraft a higher frequency, often 400 Hz, is used to make possible lighter electrical machines.

When the term alternating current is used as an adjective, it is commonly abbreviated to ac, as in ac motor. Similarly, direct current as an adjective is abbreviated dc.

The voltage of an alternating current can be changed by a transformer. This simple, inexpensive, static device permits generation of electric power at moderate voltage, efficient transmission for many miles at high voltage, and distribution and consumption at a conveniently low voltage. With direct (unidirectional) current it is not possible to use a transformer to change voltage. On a few power lines, electric energy is transmitted for great distances as direct current, but the electric energy is generated as alternating current, transformed to a high voltage, then rectified to direct current and transmitted, then changed back to alternating current by an inverter, to be transformed down to a lower voltage for distribution and use.

In addition to permitting efficient transmission of energy, alternating current provides advantages in the design of generators and motors, and for some purposes gives better operating characteristics. Certain devices involving chokes and transformers could be operated only with difficulty, if at all, on direct current. Also, the operation of large switches (called circuit breakers) is facilitated because the instantaneous value of alternating current automatically becomes zero twice in each cycle and an opening circuit breaker need not interrupt the current but only prevent current from starting again after its instant of zero value.

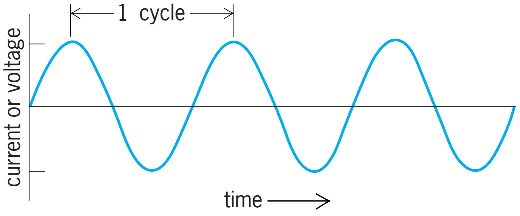


Fig. 1. Diagram of sinusoidal alternating current.

Alternating current is shown diagrammatically in Fig. 1. In this diagram it is assumed that the current is alternating sinusoidally; that is, the current i is described by the equation below, where

$$i = I_m \sin 2\pi f t$$

I_m is the maximum instantaneous current, f is the frequency in cycles per second (hertz), and t is the time in seconds. *See* SINE WAVE.

A sinusoidal form of current, or voltage, is usually approximated on practical power systems because the sinusoidal form results in less expensive construction and greater efficiency of operation of electric generators, transformers, motors, and other machines.

A useful measure of alternating current is found in the ability of the current to do work, and the amount of current is correspondingly defined as the square root of the average of the square of instantaneous current, the average being taken over an integer number of cycles. This value is known as the root-mean-square (rms) or effective current. It is measured in amperes. It is a useful measure for current of any frequency. The rms value of direct current is identical with its dc value. The rms value of sinusoidally alternating current is $I_m/\sqrt{2}$ (see Fig. 1 and the equation). Other useful quantities are the phase difference φ between voltage and current and the power factor. *See* PHASE (PERIODIC PHENOMENA); POWER FACTOR.

The phase angle and power factor of voltage and current in a circuit that supplies a load are determined by the load. Thus a load of pure resistance, such as an electric heater, has unity power factor. An inductive load, such as an induction motor, has a power factor less than 1 and the current lags behind the applied voltage. A capacitive load, such as a bank of capacitors, also has a power factor less than 1, but the current leads the voltage, and the phase angle φ is a negative angle.

Three-phase systems are commonly used for generation, transmission, and distribution of electric power. A customer may be supplied with three-phase power, particularly if a large amount of power is used or the use of three-phase loads is desired. Small domestic customers are usually supplied with single-phase power. A three-phase system is essentially the same as three ordinary single-phase systems, with the three voltages of

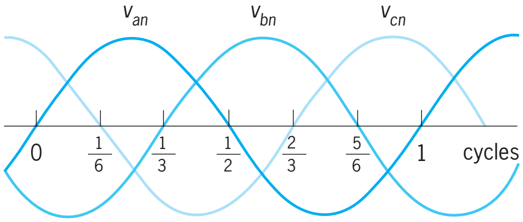

Fig. 2. Voltages of a balanced three-phase system.

the three single-phase systems out of phase with each other by one-third of a cycle (120 degrees), as shown in Fig. 2. The three-phase system is balanced if the maximum voltage in each of the three phases is equal, and if the three phase angles are equal, $^1/_3$ cycle each as shown. It is only necessary to have three wires for a three-phase system (*a*, *b*, and *c* of Fig. 3) plus a fourth wire *n* to serve as a common return or neutral conductor. On some systems the earth is used as the common or neutral conductor.

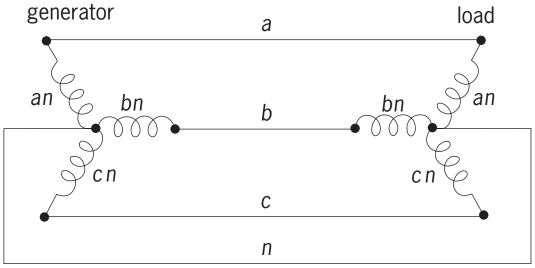

Fig. 3. Connections of a simple three-phase system.

Each phase of a three-phase system carries current and conveys power and energy. If the three loads on the three phases of the three-phase system are equal and the voltages are balanced, then the currents are balanced also. The sum of the three currents is then zero at every instant. This means that current in the common conductor (*n* of Fig. 3) is always zero, and that the conductor could theoretically be omitted entirely. In practice, the three currents are not usually exactly balanced, and either of two situations obtains. Either the common neutral wire *n* is used, in which case it carries little current (and may be of high resistance compared to the other three line wires), or else the common neutral wire *n* is not used, only three line wires being installed, and the three phase currents are thereby forced to add to zero even though this requirement results in some imbalance of phase voltages at the load.

The total instantaneous power from generator to load is constant (does not vary with time) in a balanced, sinusoidal, three-phase system. This results in smoother operation and less vibration of motors and other ac devices. In addition, three-phase motors and generators are more economical than single-phase machines.

AC circuits are also used to convey information. An information circuit, such as telephone, radio, or control, employs varying voltage, current, waveform, frequency, and phase. Efficiency is often low, the chief requirement being to convey accurate information even though little of the transmitted power reaches the receiving end. For further consideration of the transmission of information *See* RADIO; TELEPHONE; WAVEFORM.

An ideal power circuit should provide the customer with electric energy always available at unchanging voltage of constant waveform and frequency, the amount of current being determined by the customer's load. High efficiency is greatly desired. *See* CAPACITANCE; CIRCUIT (ELECTRICITY); ELECTRIC CURRENT; ELECTRIC FILTER; ELECTRICAL IMPEDANCE; ELECTRICAL RESISTANCE; INDUCTANCE; JOULE'S LAW; OHM'S LAW; RESONANCE (ALTERNATING-CURRENT CIRCUITS). [H.H.Sk.]

Alternating-current generator A machine that converts mechanical power into alternating-current electric power. Almost all electric power is produced by alternating-current (ac) generators that are driven by rotating prime movers. Most of the prime movers are steam turbines whose thermal energy comes from steam generators that use either fossil or nuclear fuel. Combustion turbines are often used for the smaller units and in cases where gas or oil is the available fuel. Where water power is available from dams, hydroelectric ac generators are powered by hydraulic turbines. Small sites may also use diesel or gasoline engines to drive the generator, but these units are usually used only for standby generation or to provide electric power in remote areas. *See* DIESEL ENGINE; GAS TURBINE; HYDRAULIC TURBINE; HYDROELECTRIC GENERATOR; INTERNAL COMBUSTION ENGINE; STEAM ELECTRIC GENERATOR; STEAM TURBINE.

Alternating-current generators are used instead of direct-current (dc) generators because ac power can easily be stepped up in voltage, by using transformers, for more efficient transmission of power over long distances and in larger amounts. Similar transformers step the voltage down again at the utilization site to levels that are safer and more convenient for general use. *See* DIRECT-CURRENT GENERATOR; ELECTRIC POWER SYSTEMS; TRANSFORMER.

Most ac generators are synchronous machines, that is, the rotor is driven at a speed that is exactly related to the rated frequency of the ac network. Generators of this type have a stationary armature with three windings that are displaced at regular intervals around the machine to produce three-phase voltages. These machines also have a field winding that is attached to the rotor. This winding provides magnetic flux that crosses the air gap and links the stator coils to produce a voltage according to Faraday's law. The field winding is supplied with direct current, usually through slip rings. *See* ARMATURE; SLIP RINGS; WINDINGS IN ELECTRIC MACHINERY.

Induction generators, based on the principle of the induction motor, have been used in a few remote applications where maintenance of the excitation system is a problem. These units are essentially like induction motors, but are driven by a prime mover at speeds slightly above synchronous speed, forcing the unit to generate power due to the reverse slip. The units draw reactive power from the system and are not as efficient as synchronous generators. *See* INDUCTION MOTOR.

High-frequency single-phase generators have been built as induction alternators, usually with twice as many stator poles (teeth) as rotor poles, and with a constant air-gap flux supplied from a homopolar field coil in the center of the machine, pushing flux into the stator at one end and out at the other. Their effectiveness is lower than that of the synchronous machine because the flux is a pulsating unidirectional field, rather than an alternating field. *See* ALTERNATING CURRENT; ELECTRIC ROTATING MACHINERY; GENERATOR. [L.A.K.; P.M.A.]

Alternating-current motor An electrical machine that converts alternating-current (ac) electric energy to mechanical energy. Alternating-current motors are widely used because of the general availability of ac electric power and because they can be readily built with a variety of characteristics and in a large range of sizes, from a few watts to many thousands of kilowatts. They can be broadly classified into three groups—induction motors, synchronous motors, and ac series motors:

- Induction motors
  - Single-phase
    - Split-phase
      - Capacitor-start
      - Capacitor-run
  - Polyphase
- Synchronous motors
  - Single-phase
    - Permanent-magnet (PM)
    - Reluctance
    - Hysteresis
  - Polyphase
    - Wound-field
    - Permanent-magnet (PM)
    - Reluctance
- AC series or universal motors (single-phase)

See ALTERNATING CURRENT; DIRECT-CURRENT MOTOR.

The most common type of ac motor, both in total number and in total power, is the induction motor. In larger sizes these machines employ a polyphase stator winding, which creates a rotating magnetic field when supplied with polyphase ac power. The speed of rotation depends upon the frequency of the supply and the number of magnetic poles created by the winding; thus, only a discrete number of speeds are possible with a fixed frequency supply.

Currents are induced in the closed coils of the rotor for any rotor speed different from the speed of the rotating field. The difference in speed is called the slip speed, and efficient energy conversion occurs only when the slip speed is small. These machines are, therefore, nearly constant-speed machines when operated from a constant-frequency supply. They are, however, routinely started from zero speed and accelerated through the inefficient high-slip-speed region to reach operating speed. *See* INDUCTION MOTOR; SLIP (ELECTRICITY).

In contrast to an induction motor, the rotor of a synchronous motor runs exactly at the rotating field speed and there are no induced rotor currents. Torque is produced by the interaction of the rotating field with a direct-current (dc) field created by injected dc rotor current or permanent magnets, or with a rotor magnetic structure that has an easy direction for magnetization (in the reluctance motor). Since for any frequency of excitation there is only one speed for synchronous torque, synchronous machines have no starting torque unless the frequency is variable. When the motor is used in fixed-frequency applications, an induction-machine winding is also placed on the rotor to allow starting as an induction motor and running as a synchronous motor. *See* SYNCHRONOUS MOTOR.

A dc motor with the armature and field windings in series will run on ac since both magnetic fields reverse when the current reverses. Since these machines run on ac or dc, they are commonly called universal motors. The speed can be controlled by varying the voltage, and these machines are therefore widely used in small sizes for domestic appliances that require speed control or higher speeds than can be attained with 60-Hz induction motors. *See* ELECTRIC ROTATING MACHINERY; MOTOR; UNIVERSAL MOTOR; WINDINGS IN ELECTRIC MACHINERY. [D.W.N.]

Alternative fuel vehicle Conventional fuels such as gasoline and diesel are gradually being replaced by alternative fuels such as gaseous fuels (natural gas and propane), alcohol (methanol and ethanol), and hydrogen. Conventional fuels can also be modified to a reformulated gasoline to help reduce toxic emissions. Technological advances in the automotive industry (such as in fuel cells and hybrid-powered vehicles) are helping to increase the demand for alternative fuels.

Vehicle emissions from natural gas and propane are expected to be lower and less harmful to the environment than those of conventional gasoline. Because natural gas and propane are less complex hydrocarbons, the levels of volatile organic compounds and ozone emissions should be reduced. Both of these fuels are introduced to the engine as a gas under most operating conditions and require minimal fuel enrichment during warm-up. Leaner burning fuels, they also achieve lower carbon dioxide and carbon monoxide levels than gasoline. However, because they burn at higher temperatures, emissions of nitrogen oxide are higher. An important property of gaseous fuels is their degree of resistance to engine knock. Because of their higher-octane value relative to gasoline, there is less of a tendency for these fuels to knock in spark-ignition engines. To achieve the optimal performance and maximum environmental benefits of natural gas and propane, technological advancements must continue to reduce the costs of dedicated vehicles to be competitive with conventional vehicles, and the necessary fueling infrastructure must be ensured.

The most significant advantage of alcohol fuels over gasoline is their potential to reduce ozone concentrations and to lower levels of carbon monoxide. Another important advantage is their very low emissions of particulates in diesel engine applications. In comparison with hydrocarbon-based fuels, the exhaust emissions from vehicles burning low-level alcohol blends (such as gasohol containing 10% alcohol by volume) contain negligible amounts of aromatics and reduced levels of hydrocarbons and carbon monoxide but higher nitrogen oxide content.

Exposure to aldehydes, in particular formaldehyde which is considered carcinogenic, is an important air-pollution concern. The aldehyde fraction of unburned fuel, particularly for methanol, is appreciably greater than for hydrocarbon-based fuels; therefore, catalytic converters are required on methanol vehicles to reduce the level of formaldehyde to those associated with gasoline. *See* ALCOHOL FUEL.

Hydrogen-powered vehicles can use internal combustion engines or fuel cells. They can also be hybrid vehicles of various combinations. When hydrogen is used as a gaseous fuel in an internal combustion engine, its very low energy density compared to liquid fuels is a major drawback requiring greater storage space for the vehicle to travel a similar distance to gasoline. Although hybrid vehicles can be more efficient than conventional vehicles and result in lower emissions, the greatest potential to alleviate air-pollution problems is thought to be in the use of hydrogen-powered fuel cell vehicles. Though currently very expensive, fuel cells are more efficient than conventional internal combustion engines. They can operate with a variety of fuels, but the fuel of choice is gaseous hydrogen since it optimizes fuel cell performance and does not require on-board modification. *See* FUEL CELL; HYDROGEN.

Conventional gasoline is a complex mixture of many different chemical compounds. The U.S. Clean Air Act Amendments (CAAA) have served to increase interest in using regulated changes to motor fuel characteristics as a means of achieving environmental goals. The reformulated gasoline (RFG) program was designed to resolve ground-level ozone problems in urban areas. Under this program, compared to conventional gasoline, the amount of heavy hydrocarbons is limited in reformulated gasoline, and the fuel must include oxygenates and contain fewer olefins, aromatics, and volatile organic compounds. [M.He.]

Altimeter Any device which measures the height of an aircraft. The two chief types are the pressure altimeter, which measures the aircraft's distance above sea level, and the radar altimeter, which measures distance above the ground.

Pressure altimeter. A pressure altimeter precisely measures the pressure of the air at the level an aircraft is flying and converts the pressure measurement to an indication of height above sea level according to a standard pressure-altitude relationship. In essence, a pressure altimeter is a highly refined aneroid barometer since it utilizes an evacuated capsule whose movement or force is directly related to the pressure on the outside of the capsule. Various methods are used to sense the capsule function and cause a display to respond such that the pilot sees the altitude level much as one looks at a watch.

Because altitude measured in this manner is also subject to changes in local barometric pressure, altimeters are provided with a barosetting that allows the pilot to compensate for these weather changes, the sea-level air pressure to which the altimeter is adjusted appearing in a window of the dial. Flights below 18,000 ft (5486 m) must constantly contact the nearest traffic center to keep the altimeters so updated. Flights above 18,000 ft and over international waters utilize a constant altimeter setting of 29.92 in. Hg, or 1013.2 millibars (101.32 kilopascals), so that all high-flying aircraft have the same reference and will be interrelated, providing an extra margin of safety. *See* AIR NAVIGATION. [J.W.A.]

Radar altimeter. A radar altimeter is a low-power radar that measures the distance of an aircraft (or other aerospace vehicle) above the ground. Radar altimeters are often used in aircraft during bad-weather landings. They are an essential part of many blind-landing and automatic navigation systems and are used over mountains to indicate terrain clearance. Special types are used in surveying for quick determination of profiles. Radar altimeters are used in bombs, missiles, and shells as proximity fuses to cause detonation or to initiate other functions at set altitudes. Radar altimeters have been used on various spacecraft, starting with *Skylab* in 1973, to measure the shape of the geoid and heights of waves and tides over the oceans. Other spacecraft altimeters provide topographic information on other planets, particularly Venus. *See* AUTOMATIC LANDING SYSTEM; GROUND PROXIMITY WARNING SYSTEM.

Like other radar devices, the altimeter measures distance by determining the time required for a radio wave to travel to and from a target, in this case the Earth's surface. If the Earth were a perfectly flat horizontal plane or smooth sphere, the signal would come only from the closest point, and would be a true measure of altitude. Actually, the Earth is not smooth, and energy is scattered back to the radar from all parts of the surface illuminated by the transmitter. For the radar to measure distance to the ground accurately, it must distinguish between the energy from points near the vertical and that from more distant points.

Most radio altimeters use either pulse or frequency modulation, the former being more popular for high altitudes, and the latter for low altitudes. In a typical pulse altimeter the radio-frequency carrier is modulated with short pulses (under 0.25 microsecond). The short pulse permits measurements, even at low altitudes, of the time delay between the leading edge of the transmitted pulse and that of the pulse returned from the ground. Early pulse altimeters displayed the received signal on a cathode-ray tube with circular sweep, allowing the pilot to determine the leading-edge position of the echo signal. Modern pulse altimeters use a tracking gate system. One gate is kept close to the leading edge by a servo system that adjusts the position of the gate to the optimum delay point. A simple single-gate system can be used, but most pulse altimeters use two or three gates to achieve better distance measurement in the presence of noise and fading. *See* PULSE MODULATOR.

In a frequency-modulated (FM) altimeter, the frequency of a continuous carrier is swept in some manner, usually to give a triangular frequency-time curve. The difference in frequency between that received from the ground (but transmitted earlier) and that being transmitted is a measure of the time delay. *See* FREQUENCY MODULATION. [R.K.Mo.]

Altitudinal vegetation zones Intergrading regions on mountain slopes characterized by specific plant life forms or species composition, and determined by complex environmental gradients. Along an altitudinal transect of a mountain, there are sequential changes in the physiognomy (growth form) of the plants and in the species composition of the communities. *See* LIFE ZONES.

Such life zones are associated with temperature gradients present along mountain slopes. Research on patterns of altitudinal zonation has centered on the response of species and groups of species to a complex of environmental gradients. Measurements of a species along a gradient, for example, the number of individuals, biomass, or ground coverage, generally form a bell-shaped curve. Peak response of a species occurs under optimum conditions and falls off at both ends of the gradient. The unique response of each species is determined by its physiological, reproductive, growth, and genetic characteristics. Zones of vegetation along mountain slopes are formed by intergrading combinations of species that differ in their tolerance to environmental conditions. Zones are usually indistinct entities rather than discrete groupings of species. However, under some conditions of localized disjunctions, very steep sections of gradients, or competitive exclusion, discontinuities in the vegetation can create discrete communities. Vegetation zones are often defined by the distributions of species having the dominant growth form, most frequently trees.

Altitudinal vegetation zonation, therefore, is an expression of the response of individual species to environmental conditions. Plants along an altitudinal transect are exposed, not to a single environmental gradient, but to a complex of gradients, the most important of which are solar radiation, temperature, and precipitation. Although these major environmental gradients exist in most mountain ranges of the world, the gradients along a single altitudinal transect are not always smooth because of topographic and climatic variability.

The solar energy received by mountain surfaces increases with altitude, associated with decreases in air density and the amount of dust and water vapor. An overcast sky is more efficient at reducing short-wave energy reaching low elevations and can increase the difference in energy input to 160%. However, more frequent clouds over high elevations relative to sunnier lower slopes commonly reduces this difference. Vegetation patterns are also strongly influenced by the decline in air temperature with increasing altitude, called the adiabatic lapse rate. Lapse rates are generally between 1.8°F to 3.6°F per 1000 ft (1°C to 2°C per 300 m), but vary with the amount of moisture present; wet air has a lower lapse rate. Thus, plants occurring at higher elevations generally experience cooler temperatures and shorter growing periods than low-elevation plants. Variation in the temperature gradient can be caused by differences in slope, aspect, radiation input, clouds, and air drainage patterns. The precipitation gradient in most mountains is the reverse of the temperature gradient: precipitation increases with altitude. *See* AIR TEMPERATURE; PRECIPITATION (METEOROLOGY).

General changes in vegetation with increases in altitude include reduction in plant size, slower growth rates, lower production, communities composed of fewer species, and less interspecific competition. However, many regional exceptions to these trends exist.

Characteristics of vegetation zones also vary with latitude. Mountains at higher latitudes have predominantly seasonal climates, with major temperature and radiation extremes between summer and winter. Equatorial and tropical mountains have a strong diurnal pattern of temperature and radiation input with little seasonal variation. The upper altitudinal limit of trees, and the maximum elevation of plant growth generally, decreases with distance from the Equator, with the exception of a depression near the Equator. [J.S.C.]

Alum A colorless to white crystalline substance which occurs naturally as the mineral kalunite and is a constituent of the mineral alunite. Alum is produced as aluminum sulfate by treating bauxite with sulfuric acid to yield alum cake or by treating the bauxite with caustic soda to yield papermaker's alum. Other industrial alums are potash alum, ammonium alum, sodium alum, and chrome alum (potassium chromium sulfate). Major uses of alum are as an astringent, styptic, and emetic. For water purification alum is dissolved. It then crystallizes out into positively charged crystals that attract negatively charged organic impurities to form an aggregate sufficiently heavy to settle out. Alum is also used in sizing paper, dyeing fabrics, and tanning leather. With sodium bicarbonate it is used in baking powder and in some fire extinguishers. *See* ALUMINUM; COLLOID. [F.H.R.]

Aluminum A metallic chemical element, symbol Al, atomic number 13, atomic weight 26.98154, in group 13 of the periodic system. Pure aluminum is soft and lacks strength, but it can be alloyed with other elements to increase strength and impart a number of useful properties. Alloys of aluminum are light, strong, and readily formable by many metalworking processes; they can be easily joined, cast, or machined, and accept a wide variety of finishes. Because of its many desirable physical, chemical, and metallurgical properties, aluminum has become the most widely used nonferrous metal. *See* PERIODIC TABLE.

Aluminum is the most abundant metallic element on the Earth and Moon but is never found free in nature. The element is widely distributed in plants, and nearly all rocks, particularly igneous rocks, contain aluminum in the form of aluminum silicate minerals. When these minerals go into solution, depending upon the chemical conditions, aluminum can be precipitated out of the solution as clay minerals or aluminum hydroxides, or both. Under such conditions bauxites are formed. Bauxites serve as principal raw materials for aluminum production. *See* Bauxite; Clay minerals; Igneous rocks; Weathering processes.

Aluminum is a silvery metal having a density of 1.56 oz/in.^{3} at 68°F (2.70 g/cm^3 at 20°C). Naturally occurring aluminum consists of a single isotope, $^{27}_{13}\mathrm{Al}$. Aluminum crystallizes in the face-centered cubic structure with edge of the unit lattice cube of 4.0495 angstroms (0.40495 nanometer). Aluminum is known for its high electrical and thermal conductivities and its high reflectivity.

The electronic configuration of the element is $1s^2 2s^2 2p^6 3s^2 3p^1$. Aluminum exhibits a valence of +3 in all compounds, with the exception of a few high-temperature monovalent and divalent gaseous species.

Aluminum is stable in air and resistant to corrosion by seawater and many aqueous solutions and other chemical agents. This is due to protection of the metal by a tough, impervious film of oxide. At a purity greater than 99.95%, aluminum resists attack by most acids but dissolves in aqua regia. Its oxide film dissolves in alkaline solutions, and corrosion is rapid. *See* Corrosion.

Aluminum is amphoteric and can react with mineral acids to form soluble salts and to evolve hydrogen.

Molten aluminum can react explosively with water. The molten metal should not be allowed to contact damp tools or containers.

At high temperatures aluminum reduces many compounds containing oxygen, particularly metal oxides. These reactions are used in the manufacture of certain metals and alloys.

Applications in building and construction represent the largest single market of the aluminum industry. Millions of homes use aluminum doors, siding, windows, screening, and down-spouts and gutters. Aluminum is also a major industrial building product. Transportation is the second largest market. Many commercial and military aircraft have become virtually all-aluminum. In automobiles, aluminum is apparent in interior and exterior trim, grilles, wheels, air conditioners, automatic transmissions, and some radiators, engine blocks, and body panels. Aluminum is also found in rapid-transit car bodies, rail cars, forged truck wheels, cargo containers, and in highway signs, divider rails, and lighting standards. In aerospace, aluminum is found in aircraft engines, frames, skins, landing gear, and interiors, often making up 80% of a plane's weight. The food packaging industry is a fast-growing market.

In electrical applications, aluminum wire and cable are major products. Aluminum appears in the home as cooking utensils, cooking foil, hardware, tools, portable appliances, air conditioners, freezers, and refrigerators, and in sporting equipment such as skis, ball bats, and tennis rackets.

There are hundreds of chemical uses of aluminum and aluminum compounds. Aluminum powder is used in paints, rocket fuels, and explosives, and as a chemical reductant. *See* Aluminum alloys. [A.S.Ru.]

Aluminum alloys Substances formed by the addition of one or more elements, usually metals, to aluminum. The principal alloying elements in aluminum-base alloys are magnesium, silicon, copper, zinc, and manganese. In wrought products, which constitute the greatest use of aluminum, the alloys are identified by four-digit numbers of the form NXXX, where the value of N denotes the alloy type and the principal alloying element(s) as follows: 1 (Al; at least 99% aluminum by weight), 2 (Cu), 3 (Mn), 4 (Si), 5 (Mg), 6 (Mg + Si), 7 (Zn), 8 (other). *See* Aluminum.

Iron and silicon are commonly present as impurities in aluminum alloys, although the amounts may be controlled to achieve specific mechanical or physical properties. Minor amounts of other elements, such as Cr, Zr, V, Pb, and Bi, are added to specific alloys for special purposes. Titanium additions are frequently employed to produce a refined cast structure.

Aluminum-base alloys are generally prepared by making the alloying additions to molten aluminum, forming a liquid solution. As the alloy freezes, phase separation occurs to satisfy phase equilibria requirements and the decrease in solubility as the temperature is lowered. The resultant solidified structure consists of grains of aluminum-rich solid solution and crystals of intermetallic compounds. *See* Eutectics.

A decrease in solubility with falling temperature also provides the basis for heat treatment of solid aluminum alloys. In this operation, the alloy is held for some time at a high temperature to promote dissolution of soluble phases and homogenization of the alloy by diffusion processes. The limiting temperature is the melting point of the lowest melting phase present. The time required depends both on temperature and on the distances over which diffusion must occur to achieve the desired degree of homogenization. The solution heat treatment is followed by a quenching operation in which the article is rapidly cooled, for example, by plunging it into cold or hot water or by the use of an air blast.

Casting alloys are significant users of secondary metal (recovered from scrap for reuse). Thus, casting alloys usually contain minor amounts of a variety of elements; these do no harm as long as they are kept within certain limits. The use of secondary metal is also of increasing importance in wrought alloy manufacturing as producers take steps to reduce the energy required in producing fabricated aluminum products. *See* Alloy. [A.S.Ru.]

Since aluminum comprises 70–80% of the weight of an airframe, metallurgists have been pursuing aluminum alloy development programs directed toward producing materials which would be characterized by stronger, stiffer, and lighter-weight properties. In addition, the titanium alloys of aircraft gas turbines are prime targets for replacement by lighter-weight alloys. Researchers have improved aluminum alloys by adding lithium and by blending aluminum alloy powders and silicon carbide fibers to form a composite. *See* Composite material. [T.H.S.]

Alunite A mineral of composition $KAl_3(SO_4)^2(OH)_6$. Alunite occurs in white to gray rhombohedral crystals or in fine-grained, compact masses. Alunite is produced by sulfurous vapors on acid volcanic rocks and also by sulfated meteoric waters affecting aluminous rocks. Alunite is used as a source of potash or for making alum. Alum has been manufactured from the well-known alunite deposits at Tolfa, near Civita Vecchia, Italy, since the mid-15th century. In the United States alunite is widespread in the West. *See* Alum. [E.C.T.C.]

Alzheimer's disease A disease of the nervous system characterized by a progressive dementia that leads to profound impairment in cognition and behavior. Dementia occurs in a number of brain diseases where the impairment in cognitive abilities represents a decline from prior levels of function and interferes with the ability to perform routine daily activities (for example, balancing a checkbook or remembering appointments). Alzheimer's disease is the most common form of dementia, affecting 5% of individuals over age 65. The onset of the dementia typically occurs in middle to late life, and the prevalence of the illness increases with advancing age to include 25–35% of individuals over age 85. *See* Aging.

Memory loss, including difficulty in remembering recent events and learning new information, is typically the earliest clinical feature of Alzheimer's disease. As the illness progresses, memory of remote events and overlearned information (for example, date and place of birth) declines together with other cognitive abilities. In the later stages of Alzheimer's disease, there is increasing loss of cognitive function to the point where the individual is bedridden and requires full-time assistance with basic living skills (for example, eating and bathing). Behavioral disturbances that can accompany Alzheimer's disease include agitation, aggression, depressive mood, sleep disorder, and anxiety. *See* Memory.

The major neuropathological features of Alzheimer's disease include the presence of senile plaques, neurofibrillary tangles, and neuronal cell loss. Although the regional distribution of brain pathology varies among individuals, the areas commonly affected include the association cortical and limbic regions.

Deficits in cholinergic, serotonergic, noradrenergic, and peptidergic (for example, somatostatin) neurotransmitters have been demonstrated. Dysfunction of the cholinergic neurotransmitter system has been specifically implicated in the early occurrence of memory impairment in Alzheimer's disease, and it has been a target in the development of potential therapeutic agents. *See* ACETYLCHOLINE; NEUROBIOLOGY; NORADRENERGIC SYSTEM.

A definite diagnosis of Alzheimer's disease is made only by direct examination of brain tissue obtained at autopsy or by biopsy to determine the presence of senile plaques and neurofibrillary tangles. A clinical evaluation, however, can provide a correct diagnosis in more than 80% of cases. The clinical diagnosis of Alzheimer's disease requires a thorough evaluation to exclude all other medical, neurological, and psychiatric causes of the observed decline in memory and other cognitive abilities.

Although the cause of Alzheimer's disease is unknown, a number of factors that increase the risk of developing this form of dementia have been identified. Age is the most prominent risk factor, with the prevalence of the illness increasing twofold for each decade of life after age 60. Research in molecular genetics has shown that Alzheimer's disease is etiologically heterogeneous. Gene mutations on several different chromosomes are associated with familial inherited forms of Alzheimer's disease.

A major strategy for the treatment of Alzheimer's disease has focused on the relation between memory impairment and dysfunction of the acetylcholine neurotransmitter system. Other treatment strategies to delay or diminish the progression of Alzheimer's disease are being explored. Behavioral and pharmacological interventions are also available to treat the specific behavioral disturbances that can occur in Alzheimer's disease. [G.Al.]

Amalgam An alloy of mercury. Practically all metals will form alloys or amalgams with mercury, with the notable exception of iron. Amalgams are used as dental materials, in the concentration of gold and silver from their ores, and as electrodes in various industrial and laboratory electrolytic processes. Amalgams used in dental work require the following composition: silver, 65% minimum; copper, 6% maximum; zinc, 2% maximum; and tin, 25% minimum. These amalgams are prepared by the dentist as needed, and harden within 3–5 min, but may be shaped by carving for 15 min or so. *See* ALLOY; GOLD; SILVER. [E.E.W.]

Amaranth An annual plant (seldom perennial) of the genus *Amaranthus* (family Amaranthaceae), distributed worldwide in warm and humid regions. Amaranths are botanically distinguished by their small chaffy flowers, arranged in dense, green or red, monoecious or dioecious inflorescences, with zero to five perianth segments and two or three styles and stigmata, and by their dry membranous, indehiscent, one-seeded fruit. *See* FLOWER; FRUIT.

Physiological, genetic, and nutritional studies have revealed their potential economic value. Of particular interest are high rate of productivity as a rapidly growing summer crop, the large amounts of protein in both seed and leaf with high lysine, the overall high nutritional value, and the water use efficiency for the C_4 photosynthetic pathway. Amaranths are important in the culture, diet, and agricultural economy of the people of Mexico, Central and South America, Africa, and northern India. Genetic, ethnobotanical, and agronomic research has been undertaken to develop amaranths as an important food plant in modern agriculture. [S.K.J.]

Amateur radio Two-way radio communications by individuals as a leisure-time activity. Amateur, or ham, radio is defined by international treaty as a "service of self-training, intercommunications, and technical investigation carried on by amateurs; that is, by duly authorized persons interested in radio technique solely with a personal aim and without pecuniary interest." *See* RADIO.

The government allows amateur operators many privileges because the hobby is partially based on service to the general public, and hams can be relied on to assist during emergencies. Groups of amateur operators meet annually to practice handling emergency communications in the field and to compete against other groups nationwide in performing certain emergency-related tasks. Amateur operators may set up warning and relief networks during the hurricane and tornado seasons, and handle communication when phone lines are damaged by disasters.

In addition to public service activities, amateurs enjoy many recreational activities, including DXing (where the objective is to contact amateurs in as many foreign countries as possible), contesting (where the amateurs compete for the maximum number of contacts in a given time span), and foxhunting (where the objective is to use radio skills to locate a hidden transmitter).

Since high-frequency (HF) signals (below 30 MHz) are reflected from the Kennelly-Heaviside ionosphere layers, amateurs are commonly able to carry out international communication. Very high frequencies (VHF; 30–300 MHz) and ultrahigh frequencies (UHF; 300–3000 MHz) have been subject to exploration by amateurs at the leading edge of communications technology. Amateurs bounce signals off the Moon or ionized meteor trails, and communicate through amateur operator-built earth satellites called OSCAR (orbiting satellites carrying amateur radio). [S.Man.]

Amber Most commonly, a generic name for all fossil resins, although it has been restricted by some to refer only to succinite, the mineralogical species of fossil resin making up most of the Baltic Coast deposits. Resins generally are complex mixtures of mono-, sesqui-, di-, and triterpenoids; however, some resins contain aromatic phenols. Among the plants, primarily trees, that produce copious amounts of resin that may fossilize to become amber, two-thirds are tropical or subtropical.

Although ambers occur throughout the world in deposits from Carboniferous to Pleistocene in age, they have been reported most commonly from Cretaceous and Tertiary strata and often are associated with coal or lignites. Amber may contain beautifully preserved insects, spiders, flowers, leaves, and even small animals. The most extensively studied deposits are those from the Baltic Coast, Alaska, Canada, Burma, Dominican Republic, and Mexico.

When amber is used for jewelry, it usually is transparent yellow, reddish-brown, or "amber" color. Translucent or semitranslucent amber is used for pipe stems, decorating small boxes, and a variety of ornamental purposes. The specific gravity varies from 1.05 to 1.10, and hardness from 1 to 3 on Mohs scale.

At one time, chemical studies of amber were mineralogically oriented because the purpose was to describe and classify amber as a semiprecious gem. However, phytochemical studies comparing fossil and present-day resins are providing information regarding the botanical origins of ambers.

The predominantly tropical or subtropical occurrence of amber-producing plants through geologic time has led to evolutionary studies of the natural purpose of resins and their possible defensive role for trees against injury and disease inflicted by the high diversity of insects and fungi in tropical environments. *See* GEM; MINERALOGY; RESIN. [J.H.L.]

Ambergris A fatty substance formed in the intestinal tract of the sperm whale (*Physeter catodon*). Ambergris contains acids, alkaloids, and a fatty substance, its main constituent, called ambrein. Although fresh ambergris is soft and black and has an offensive odor, it hardens into pleasantly fragrant gray or yellow masses when exposed to the air, sun, and sea. Being lighter than water, it is found in lumps floating on tropical seas or cast up on the shores. It is also gathered directly from the abdomens of dead or captured whales. Collecting grounds for ambergris are principally on the shores of China, Japan, Africa, the Americas, tropical islands, and the Bahamas.

Ambergris is valued in the manufacture of perfumes. The ambergris is ground and used in the form of a tincture, dissolved in a dilute solution of alcohol, which when added to perfume acts as a fixative, increasing the duration of the fragrance while adding its own sweet, earthy scent. [S.P.P.]

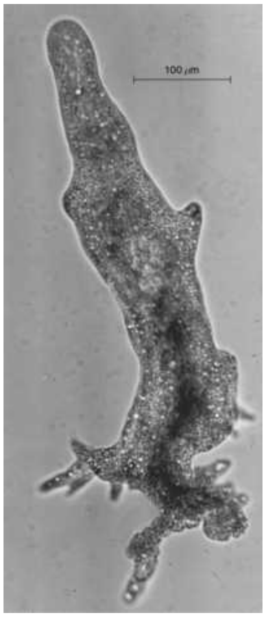
Amblygonite A lithium aluminum phosphate mineral of basic formula $LiAl(PO_4F)$. The structure of amblygonite consists of phosphate (PO_4) groups of tetrahedra and AlO_6 groups of octahedra. Each PO_4 tetrahedron is connected to an AlO_6 octahedron. Amblygonite crystallizes in the triclinic system. Its color is commonly white or gray with tints of blue, green, and yellow. Amblygonite is transparent to translucent and has a vitreous to pearly luster.

The best-known occurrences of amblygonite are in Montebras, France; the Black Hills of South Dakota; the White Picacho District in Arizona; pegmatite districts in Maine; the Tanco pegmatite in Manitoba, Canada; and Portland, Connecticut. While amblygonite has been mined as an ore of lithium, it is not a major ore. *See* Phosphate minerals. [C.K.S.]

Amblypygi An order of arachnids, the tailless whip scorpions, comprising about 80 species of flattened, crablike forms from the tropical and warm temperate regions of the world. The somber red or brownish species vary considerably in size, from 0.16–1.80 in. (4 to 45 mm), the largest being *Acanthophyrnus coronatus* of California and Mexico. The pedipalps are long raptorial organs set with many sharp spines that grasp and crush insect prey. The first pair of legs is modified into very long, lashlike whips which are used as sensory feelers. No tail is present on the abdomen. The amblypygids are harmless, nocturnal types that live under stones, in rock fissures and caves, and frequently in houses. No venom or repellent glands are present. *See* Arachnida. [W.J.Ger.]

Ameba Any protozoon moving by means of protoplasmic flow. In their entirety, the ameboid protozoa include naked amebas, those enclosed within a shell or test, as well as more highly developed representatives such as the heliozoians, radiolarians, and foraminiferans. Ameboid movement is accomplished by pseudopods—cellular extensions which channel the flow of protoplasm. Pseudopods take varied forms and help distinguish among the different groups. A lobe-shaped extension or lobopod is perhaps the simplest type of pseudopod. The shapelessness and plasticity of these locomotory organelles impart an asymmetric, continually changing aspect to the organism. Other, more developed, representatives have pseudopodial extensions containing fibrous supporting elements (axopods) or forming an extensive network of anastomosing channels (reticulopods). Though involved in locomotion, these organelles are also functional in phagocytosis—the trapping and ingesting of food organisms (usually bacteria, algae, or other protozoa) or detritus. *See* Foraminiferida; Heliozoia; Phagocytosis; Radiolaria.

Amebas range from small soil organisms, such as *Acanthamoeba* (20 micrometers), to the large fresh-water forms *Amoeba proteus* (600 μm; see illustration) and *Pelomyxa* (1 mm, or more). Some types, such as *Amoeba,* are uninucleate; others are multinucleate. Reproduction is by mitosis with nuclear division preceding cytoplasmic division to produce two daughters. Multinucleate forms have more unusual patterns of division, since nuclear division is not immediately or necessarily followed by cytoplasmic division. Transformation of the actively feeding ameba into a dormant cyst occurs in many species, particularly those found in soil or as symbionts. The resting stages allow survival over periods of desiccation, food scarcity, or transmission between hosts. *See* Reproduction (animal).



Phase-contrast photomicrograph of *Amoeba proteus*, a large fresh-water ameba. The organism is seen moving by means of a single lobose pseudopod.

Amebas are found in a variety of habitats, including freshwater and marine environments, soil, and as symbionts and parasites in body cavities and tissues of vertebrates and invertebrates. Because of their manner of locomotion, amebas typically occur on surfaces, such as the bottom of a pond, on submerged vegetation, or floating debris. In soil, they are a significant component of the microfauna, feeding extensively on bacteria and small fungi. Amebas in marine habitats may be found as planktonic forms adapted for floating at the surface (having oil droplets to increase bouyancy and projections to increase surface area), where they feed upon bacteria, algae, and other protozoa. Several species of amebas may be found in the human intestinal tract as harmless commensals (for example, *Entamoeba coli*) or as important parasites responsible for amebic dysentery (*E. histolytica*). [F.L.Sc.]

Americium A chemical element, symbol Am, atomic number 95. The isotope ^{241}Am is an alpha emitter with a half-life of 433 years. Other isotopes of americium range in mass from 232 to 247, but only the isotopes of mass 241 and 243 are important. The isotope ^{241}Am is routinely separated from "old" plutonium and sold for a variety of industrial uses, such as 59-keV gamma sources and as a component in neutron sources. The longer-lived ^{243}Am (half-life 7400 years) is a precursor in ^{244}Cm production.

In its most prominent aqueous oxidation state, 3+, americium closely resembles the tripositive rare earths. The formal analogy to the rare earths is also marked in anhydrous compounds of both tripositive and tetrapositive americium. Americium is different in that it is possible to oxidize Am^{3+} to both the 5+ and 6+ states.

Americium metal has a vapor pressure markedly higher than that of its neighboring elements and can be purified by distillation. The metal is nonmagnetic and superconducting at 0.79 K. Under high pressure the metal has been compressed to 80% of its room-temperature volume and displays the α-uranium structure. *See* Actinide elements; Berkelium; Curium; Nuclear reaction; Periodic table; Transuranium elements. [R.A.Pe.]

Amethyst The transparent purple to violet variety of the mineral quartz. Amethyst is rare in the deep colors that characterize fine quality. It is usually colored unevenly and is often heated slightly in an effort to distribute the color more evenly. Heating at higher temperatures usually changes it to yellow or brown (rarely green), and further heating removes all color. The principal sources are Brazil, Arizona, Uruguay, and Russia. *See* GEM; QUARTZ. [R.T.L.]

Amide A derivative of a carboxylic acid with general formula $RCONH_2$, where R is hydrogen or an alkyl or aryl radical. Amides are divided into subclasses, depending on the number of substituents on nitrogen. The simple, or primary, amides are considered to be derivatives formed by replacement of the carboxylic hydroxyl group by the amino group, NH_2. They are named by dropping the "-ic acid" or "-oic acid" from the name of the parent carboxylic acid and replacing it with the suffix "amide." In the secondary and tertiary amides, one or both hydrogens are replaced by other groups. The presence of such groups is designated by the prefix capital *N* (for nitrogen).

Except for formamide, all simple amides are relatively low-melting solids, stable, and weakly acidic. They are strongly associated through hydrogen bonding, and hence soluble in hydroxylic solvents, such as water and alcohol. Because of ease of formation and sharp melting points, amides are frequently used for the identification of organic acids and, conversely, for the identification of amines.

Commercial preparation of amides involves thermal dehydration of ammonium salts of carboxylic acids. Thus, slow pyrolysis of ammonium acetate forms water and acetamide. *N*,*N*-dimethylacetamide may be similarly prepared from dimethylammonium acetate.

Amides are important chemical intermediates since they can be hydrolyzed to acids, dehydrated to nitriles, and degraded to amines containing one less carbon atom by the Hofmann reaction. In pharmacology, acetophenetidin is a popular analgesic. However, the most important commercial application of amides is in the preparation of polyamide resins, also called nylons. *See* ACID ANHYDRIDE; POLYAMIDE RESINS. [P.E.F.]

Amiiformes An order of Actinopterygian fishes, also known as the Halecomorphi. The characters include abbreviate heterocercal tail, in some almost symmetrical; usually fusiform body; median fin rays arranged one per pterygiophore; scales with a ganoine surface but typically thin; no spiracle; vascularized swim bladder with a duct; reduced maxilla which is free from the preopercle posteriorly; an orbit which is bordered below and behind by a series of enlarged bones; and, in Recent species, an enlarged gular plate and elongate dorsal fin.

The order, which appeared first in the Triassic, includes six families, of which only the Amiidae survived into the Cenozoic. The single Recent species, *Amia calva*, inhabits sluggish fresh waters of eastern North America. *See* ACTINOPTERYGII; OSTEICHTHYES. [R.M.B.]

Amine A member of a group of organic compounds which can be considered as derived from ammonia by replacement of one or more hydrogens by organic radicals. Generally amines are bases of widely varying strengths, but a few which are actually acidic are known.

Amines constitute one of the most important classes of organic compounds. The lone pair of electrons on the amine nitrogen enables amines to participate in a large variety of reactions as a base or a nucleophile. Amines play prominent roles in biochemical systems; they are widely distributed in nature in the form of amino acids, alkaloids, and vitamins. Many complex amines have pronounced physiological activity, for example, epinephrine (adrenalin), thiamin or vitamin B_1, and Novocaine. The odor of decaying fish is due to simple amines produced by bacterial action. Amines are used to manufacture many medicinal chemicals, such as sulfa drugs and anesthetics. The important synthetic fiber nylon is an amine derivative.

Amines are classified according to the number of hydrogens of ammonia which are replaced by radicals. Replacement of one hydrogen results in a primary amine (RNH_2), replacement of two hydrogens results in a secondary amine (R_2NH), and replacement of all three hydrogens results in a tertiary amine (R_3N). The substituent groups (R) may be alkyl, aryl, or aralkyl. Another group of amines are those in which the nitrogen forms part of a ring (heterocyclic amines). Examples of such compounds are nicotine, which is obtained commercially from tobacco for use as an insecticide, and serotonin, which plays a key role as a chemical mediator in the central nervous system.

Many aromatic and heterocyclic amines are known by trivial names, and derivatives are named as substitution products of the parent amine. Thus, $C_6H_5NH_2$, is aniline and $C_6H_5NHC_2H_5$ is *N*-ethylaniline.

According to the Brønsted-Lowry theory of acids and bases, amines are basic because they accept protons from acids. Stable salts suitable for the identification of amines are in general formed only with strong acids, such as hydrochloric, sulfuric, oxalic, chloroplatinic, or picric.

Commercial preparation of aliphatic amines can be accomplished by direct alkylation of ammonia or by catalytic alkylation of amines with alcohols at elevated temperatures. Reduction of various nitrogen functions carrying the nitrogen in a higher state of oxidation also leads to amines. Such functions are nitro, oximino, nitroso, and cyano. For the preparation of pure primary amines, Gabriel's synthesis and Hofmann's hypohalite reaction are preferred methods. The Bucherer reaction is satisfactory for the preparation of polynuclear primary aromatic amines. *See* AMINO ACIDS. [P.E.F.]

Amino acid dating Determination of the relative or absolute age of materials or objects by measurement of the degree of racemization of the amino acids present. With the exception of glycine, the amino acids found in proteins can exist in two isomeric forms called D- and L-enantiomers. Although the enantiomers of an amino acid rotate plane-polarized light in equal but opposite directions (the D form rotates it to the right and the L form to the left), their other chemical and physical properties are identical. It was discovered by L. Pasteur around 1850 that only L-amino acids are generally found in living organisms, but scientists still have not formulated a convincing reason to explain why life is based on only L-amino acids. *See* AMINO ACIDS.

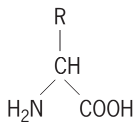
Under conditions of chemical equilibrium, equal amounts of both enantiomers are present ($D/L = 1.0$); this is called a racemic mixture. Living organisms maintain a state of disequilibrium through a system of enzymes that selectively utilize only the L-enantiomers. Once a protein has been synthesized and isolated from active metabolic processes, the L-amino acids are subject to a racemization reaction that converts them into a racemic mixture. Since racemization is a chemical process, the extent of racemization is dependent not only on the time that has elapsed since the L-amino acids were synthesized but also on the exposure temperature: the higher the temperature, the faster the rate of racemization. The rate of racemization is also different for most of the various amino acids. *See* RACEMIZATION.

A variety of analytical procedures can be used to separate amino acid enantiomers; gas chromatography and high-performance liquid chromatography are the most widely used. Since these techniques have sensitivities in the parts per billion range, only a few hundred milligrams of sample material are normally required. Samples are first hydrolyzed in hydrochloric acid to break down the proteins into free amino acids, which are then isolated by cation-exchange chromatography. *See* CHROMATOGRAPHY.

Since the late 1960s, the geochemical and biological significance of amino acid racemization has been extensively investigated. Geochemical uses of amino acid racemization include the dating of fossils or, in the case of known age specimens, the determination of their temperature history. Fossil types such as bones, teeth, and shells have been studied, and racemization has been found to be particularly useful for dating specimens that were difficult to date by other methods. Racemization has also been observed in the metabolically inert tissues of living mammals. Racemization can be studied in certain organisms and used to assess the biological age of a variety of mammalian species; in addition, it may be important in determining the biological lifetime of certain proteins. Fossils have been found to contain both D- and L-amino acids, and the extent of racemization generally increases with geologic age. *See* Archeological chemistry; Geochronometry; Radiocarbon dating; Rock age determination. [J.L.Ba.]

Amino acids Organic compounds possessing one or more basic amino groups and one or more acidic carboxyl groups. Of the more than 80 amino acids which have been found in living organisms, about 20 serve as the building blocks for the proteins.

All the amino acids of proteins, and most of the others which occur naturally, are α-amino acids, meaning that an amino group ($—NH_2$) and a carboxyl group (—COOH) are attached to the same carbon atom. This carbon (the α carbon, being adjacent to the carboxyl group) also carries a hydrogen atom; its fourth valence is satisfied by any of a wide variety of substitutent groups, represented by the letter R in the structural formula below.



In the simplest amino acid, glycine, R is a hydrogen atom. In all other amino acids, R is an organic radical; for example, in alanine it is a methyl group ($—CH_3$), while in glutamic acid it is an aliphatic chain terminating in a second carboxyl group ($—CH_2—CH—COOH$). Chemically, the amino acids can be considered as falling roughly into nine categories based on the nature of R (see table).

Occurrence. Amino acids occur in living tissues principally in the conjugated form. Most conjugated amino acids are peptides, in which the amino group of one amino acid is linked to the carboxyl group of another. Amino acids are capable of linking together to form chains of various lengths, called polypeptides. Proteins are polypeptides ranging in size from about 50 to many thousand amino acid residues. Although most of the conjugated amino acids in nature are proteins, numerous smaller conjugates occur naturally, many with important biological activity. The line between large peptides and small proteins is difficult to draw, with insulin (molecular weight = 7000; 50 amino acids) usually being considered a small protein and adrenocorticotropic hormone (molecular weight = 5000; 39 amino acids) being considered a large peptide.

Free amino acids are found in living cells, as well as the body fluids of higher animals, in amounts which vary according to the tissue and to the amino acid. The amino acids which play key roles in the incorporation and transfer of ammonia, such as glutamic acid, aspartic acid, and their amides, are often present in relatively high amounts, but the concentrations of the other amino acids of proteins are extremely low, ranging from a fraction of a milligram to several milligrams per 100 g wet weight of tissue. The presence of free amino acids in only trace amounts points to the existence of extraordinarily efficient regulation mechanisms. Each amino acid is ordinarily synthesized at precisely the rate needed for protein synthesis.

General properties. The amino acids are characterized physically by the following: (1) the pK_1, or the dissociation constant of the various titratable groups; (2) the isoelectric point, or pH at which a dipolar ion does not migrate in an electric field; (3) the optical rotation, or the rotation imparted to a beam of plane-polarized light (frequently the D line of the sodium spectrum) passing through 1 decimeter of a solution of 100 grams in 100 milliliters; and (4) solubility. *See* Ionic equilibrium; Isoelectric point; Optical activity.

Since all of the amino acids except glycine possess a center of asymmetry at the α carbon atom, they can exist in either of two optically active, mirror-image forms, or enantiomorphs. All of the common amino acids of proteins appear to have the same configuration about the α carbon; this configuration is symbolized by the prefix L-. The opposite, generally unnatural, form is given the prefix D-. Some amino acids, such as isoleucine, threonine, and hydroxyproline, have a second center of asymmetry and can exist in four stereoisomeric forms. *See* Stereochemistry.

At ordinary temperatures, the amino acids are white crystalline solids; when heated to high temperatures, they decompose rather than melt. They are stable in aqueous solution, and with few exceptions can be heated as high as 120°C (248°F) for short periods without decomposition, even in acid or alkaline solution. Thus, the hydrolysis of proteins can be carried out under such conditions with the complete recovery of most of the constituent free amino acids.

Biosynthesis. Since amino acids, as precursors of proteins, are essential to all organisms, all cells must be able to synthesize those they cannot obtain from their environment. The selective advantage of being able rapidly to shift from endogenous to exogenous sources of these compounds has led to the evolution of very complex and precise methods of adjusting the rate of synthesis to the available level of the compound. An immediately effective control is that of feedback inhibition. The biosynthesis of amino acids usually requires at least three enzymatic steps. In most cases so far examined, the amino acid end product of the biosynthetic pathway inhibits the first enzyme to catalyze a reaction specific to the biosynthesis of that amino acid. This inhibition is extremely specific; the enzymes involved have special sites for binding the inhibitor. This inhibition functions to shut off the pathway in the presence of transient high levels of the product, thus saving both carbon and energy for other biosynthetic reactions. When the level of the product decreases, the pathway begins to function once more.

The metabolic pathways by which amino acids are synthesized generally are found to be the same in all living cells investigated, whether microbial or animal. Biosynthetic mechanisms thus appear to have developed soon after the origin of life and to have remained unchanged through the divergent evolution of modern organisms.

Biosynthetic pathway diagrams reveal only one quantitatively important reaction by which organic nitrogen enters the amino groups of amino acids: the reductive amination of α-ketoglutaric acid to glutamic acid by the enzyme glutamic acid dehydrogenase. All other amino acids are formed either by transamination

Amino acids of proteins, grouped according to the nature of R

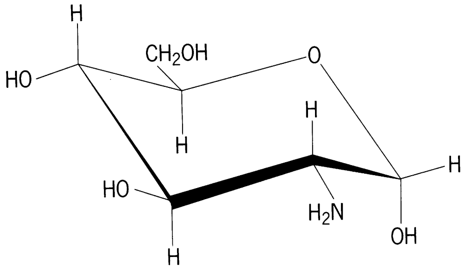
Amino acids	R
Glycine	Hydrogen
Alanine, valine, leucine, isoleucine	Unsubstituted aliphatic chain
Serine, threonine	Aliphatic chain bearing a hydroxyl group
Aspartic acid, glutamic acid	Aliphatic chain terminating in an acidic carboxyl group
Asparagine, glutamine	Aliphatic chain terminating in an amide group
Arginine, lysine	Aliphatic chain terminating in a basic amino group
Cysteine, cystine, methionine	Sulfur-containing aliphatic chain
Phenylalanine, tyrosine	Terminates in an aromatic ring
Tryptophan, proline, histidine	Terminates in a heterocyclic ring

*See articles on the individual amino acids listed in the table.

(transfer of an amino group, ultimately from glutamic acid) or by a modification of an existing amino acid. An example of the former is the formation of valine by transfer of the amino group from glutamic acid to α-ketoisovaleric acid; an example of the latter is the reduction and cyclization of glutamic acid to form proline.

Importance in nutrition. The nutritional requirement for the amino acids of protein can vary from zero, in the case of an organism which synthesizes them all, to the complete list, in the case of an organism in which all the biosynthetic pathways are blocked. There are 8 or 10 amino acids required by certain mammals; most plants synthesize all of their amino acids, while microorganisms vary from types which synthesize all, to others (such as certain lactic acid bacteria) which require as many as 18 different amino acids. *See* NUTRITION; PROTEIN METABOLISM. [E.A.Ad.; P.T.M.; R.G.M.]

Amino sugar A sugar in which one or more nonglycosidic hydroxyl groups is replaced by an amino or substituted amino group. The most abundant example is D-glucosamine (2-amino-2-deoxy-D-glucose) [see illustration].

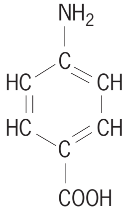


Structural formula of D-glucosamine (α-pyranose ring form).

A linear polymer of *N*-acetyl-D-glucosamine is widely distributed as chitin, the exoskeletal material of arthropods. The glycoproteins of higher animals, which are components of the proteoglycans of cartilage and skin, consist of polysaccharides that are generally sulfated and have *N*-acetylated glucosamine or galactosamine alternating with a uronic acid.

Amino sugars are important constituents of glycoproteins and oligosaccharides involved in biological recognition. Amino sugars of the greatest structural diversity are found in microorganisms as constituents of cell walls, in antigenic carbohydrates produced at the cell surface, and as antibiotic substances secreted from the cell. Streptomycin is the first demonstrated example of numerous amino-sugar-containing antibiotics produced notably by Actinomycetes (bacteria). *See* CHITIN; GLYCOPROTEIN; OLIGOSACCHARIDE; POLYSACCHARIDE. [D.Ho.]

para-Aminobenzoic acid A compound also known as PABA, often considered to be a water-soluble vitamin. *p*-Aminobenzoic acid, with the structure below, is widely



distributed in foods and has been isolated from liver, yeast, and other sources rich in vitamin B. *p*-Aminobenzoic acid is a part of the folic acid milecule, and its presence in a folic acid-deficient diet results in increased intestinal synthesis of the folic acid. *p*-Aminobenzoic acid antagonizes the bacteriostatic action of sulfonamides. It is an effective antirickettsial agent and has been used to treat typhus, scrub typhus, and Rocky Mountain spotted fever. *See* FOLIC ACID. [S.N.G.]

Ammeter An instrument for the measurement of electric current. The unit of current, the ampere, is the base unit on which rests the International System (SI) definitions of all the electrical units. The operating principle of an ammeter depends on the nature of the current to be measured and the accuracy required. Currents may be broadly classified as direct current (dc), low-frequency alternating current (ac), or radio frequency. At frequencies above about 10 MHz, where the wavelength of the signal becomes comparable with the dimensions of the measuring instrument, current measurements become inaccurate and finally meaningless, since the value obtained depends on the position where the measurement is made. In these circumstances, power measurements are usually used. *See* CURRENT MEASUREMENT.

The measurement of current in terms of the voltage that appears across a resistive shunt through which the current passes has become the most common basis for ammeters, primarily because of the very wide range of current measurement that it makes possible, and more recently through its compatibility with digital techniques. *See* ELECTRICAL UNITS AND STANDARDS; MULTIMETER; VOLTMETER.

The moving-coil, permanent-magnet (d'Arsonval) ammeter remains important for direct-current measurement. Generally they are of modest accuracy, no better than 1%. Digital instruments have taken over all measurements of greater precision because of the greater ease of reading their indications where high resolution is required.

Moving-iron instruments are widely used as ammeters for low-frequency ac applications.

High-frequency currents are measured by the heating effect of the current passing through a physically small resistance element. In modern instruments the temperature of the center of the wire is sensed by a thermocouple, the output of which is used to drive a moving-coil indicator. *See* THERMOCOUPLE. [R.B.D.K.]

Ammine One of a group of complex compounds formed by the coordination of ammonia molecules with metal ions and, in a few instances, such as calcium, strontium, and barium, with metal atoms. Although ammines are formally analogous to many salt hydrates, the general characteristics of the group of ammines differ considerably from those of the hydrates. For example, hydrated Co(III) salts are strong oxidizing agents whereas Co(II) ammines are strong reducing agents. The ammines of principal interest are those of the transition metals and of the zinc family, but even here there is wide variation in stability or rate of decomposition. Ammines are prepared by treating aqueous solutions of the metal salt with ammonia or, in some instances, by the action of dry gaseous or liquid ammonia on the anhydrous salt. *See* AMMONIA; COORDINATION CHEMISTRY. [H.H.S.]

Ammonia The most familiar compound composed of the elements nitrogen and hydrogen, NH_3. It is formed as a result of the decomposition of most nitrogenous organic material, and its presence is indicated by its pungent and irritating odor.

Ammonia has a wide range of industrial and agricultural applications. Examples of its use are the production of nitric acid and ammonium salts, particularly the sulfate, nitrate, carbonate, and chloride, and the synthesis of hundreds of organic compounds including many drugs, plastics, and dyes. Its dilute aqueous solution finds use as a household cleansing agent. Anhydrous ammonia and ammonium salts are used as fertilizers, and anhydrous ammonia also serves as a refrigerant, because of its high heat of vaporization and relative ease of liquefaction. *See* FERTILIZER.

The physical properties of ammonia are analogous to those of water and hydrogen fluoride in that the physical constants are abnormal with respect to those of the binary hydrogen compounds of the other members of the respective periodic families. These abnormalities may be related to the association of molecules through intermolecular hydrogen bonding. Ammonia is highly mobile in the liquid state and has a high thermal coefficient of expansion.

Most of the chemical reactions of ammonia may be classified under three chief groups: (1) addition reactions, commonly called ammonation; (2) substitution reactions, commonly called ammonolysis; and (3) oxidation-reduction reactions.

Ammonation reactions include those in which ammonia molecules add to other molecules or ions. Most familiar of the ammonation reactions is the reaction with water to form ammonium hydroxide. The strong tendency of water and ammonia to combine is evidenced by the very high solubility of ammonia in water. Ammonia reacts readily with strong acids to form ammonium salts. Ammonium salts of weak acids in the solid state dissociate readily into ammonia and the free acid. Ammonation occurs with a variety of molecules capable of acting as electron acceptors (Lewis acids), such as sulfur trioxide, sulfur dioxide, silicon tetrafluoride, and boron trifluoride. Included among ammonation reactions is the formation of complexes (called ammines) with many metal ions, particularly transition metal ions. Ammonolytic reactions include reactions of ammonia in which an amide group ($\text{—}NH_2$), an imide group ($=NH$), or a nitride group ($\equiv N$) replaces one or more atoms or groups in the reacting molecule.

Oxidation-reduction reactions may be subdivided into those which involve a change in the oxidation state of the nitrogen atom and those in which elemental hydrogen is liberated. An example of the first group is the catalytic oxidation of ammonia in air to form nitric oxide. In the absence of a catalyst, ammonia burns in oxygen to yield nitrogen. Another example is the reduction with ammonia of hot metal oxides such as cupric oxide.

The physical and chemical properties of liquid ammonia make it appropriate for use as a solvent in certain types of chemical reactions. The solvent properties of liquid ammonia are, in many ways, qualitatively intermediate between those of water and of ethyl alcohol. This is particularly true with respect to dielectric constant; therefore, ammonia is generally superior to ethyl alcohol as a solvent for ionic substances but is inferior to water in this respect. On the other hand, ammonia is generally a better solvent for covalent substances than is water.

The Haber-Bosch synthesis is the major source of industrial ammonia. In a typical process, water gas (CO, H_2, CO_2) mixed with nitrogen is passed through a scrubber cooler to remove dust and undecomposed material. The CO_2 and CO are removed by a CO_2 purifier and ammoniacal cuprous solution, respectively. The remaining H_2 and N_2 gases are passed over a catalyst at high pressures (up to 1000 atm or 100 megapascals) and high temperatures (approx. 1300°F or 700°C). Other industrial sources of ammonia include its formation as a byproduct of the destructive distillation of coal, and its synthesis through the cyanamide process. In the laboratory, ammonia is usually formed by its displacement from ammonium salts (either dry or in solution) by strong bases. Another source is the hydrolysis of metal nitrides. *See* AMIDE; NITROGEN. [H.H.S.]

Ammonium salt A product of a reaction between ammonia, NH_3, and various acids. The general reaction for formation is $NH_3 + HX \rightarrow NH_2X$. Examples of ammonium salts are ammonium chloride, NH_4Cl, ammonium nitrate, NH_4NO_3, ammonium sulfate, $(NH_4)_2SO_4$, and ammonium carbonate, $(NH_4)_2CO_3$. These compounds are addition products of ammonia and the acid. For this reason, their formulas are sometimes written as $[H(NH_3)]X$.

All ammonium salts decompose into ammonia and the acid when heated. Their stability, however, varies according to the nature of the acid. Salts of weak acids decompose at lower temperatures than do salts of strong acids.

Ammonium chloride is made by absorbing ammonia in hydrochloric acid. This salt, sometimes called sal ammoniac, is used in galvanizing iron, in textile dyeing, and in manufacturing dry cell batteries.

Ammonium nitrate is prepared from ammonia and nitric acid. It is used as a source of nitrous oxide, N_2O, or laughing gas, and in the manufacture of explosives. A mixture of ammonium nitrate and trinitrotoluene is known as amatol.

Ammonium sulfate, obtained from ammonia and sulfuric acid, is prepared commercially by passing ammonia and carbon dioxide, CO_2, into a suspension of finely ground calcium sulfate, $CaSO_4$. Large quantities are also produced as a byproduct of coke ovens and coal-gas works. The chief use of ammonium sulfate is as a fertilizer.

Ammonium carbonate may be prepared by bringing ammonia and carbon dioxide together in aqueous solution. It is also obtained by heating a mixture of ammonium sulfate and a fine suspension of calcium carbonate. *See* AMMONIA; FERTILIZER; HYDROLYSIS. [F.J.J.]

Amnesia A significant but relatively selective inability to remember. Amnesia can be characterized along two dimensions with respect to its onset: an inability to remember events that occurred after the onset of amnesia is referred to as anterograde amnesia, and a deficit in remembering events that occurred prior to the onset of amnesia is referred to as retrograde amnesia. Amnesia can be due to a variety of causes and can be classified according to whether the cause is primarily neurological or psychological in origin. Neurological amnesias are the result of brain dysfunction and can be transient or permanent. They are usually characterized by a severe anterograde amnesia and a relatively less severe retrograde amnesia. Transient amnesias are temporary memory disturbances and can range in duration from hours to months, depending on the cause and severity. They can be caused by epilepsy, head injury, and electroconvulsive therapy (most frequently used for the treatment of depression). In cases of transient global amnesia, an extensive amnesia that is usually sudden in onset and resolves within a day, the cause is still not known, although many believe that it is vascular in origin.

Permanent amnesia usually occurs following brain damage to either the diencephalons or the medial temporal lobe. Amnesia resulting from impairment to the medial temporal lobe can occur following anoxia, cerebrovascular accidents, head injury, and viral infections to the brain. The primary structures involved in the processing of memory within the medial temporal lobe are the hippocampus and the amygdala. One of the most common causes of diencephalic amnesia is Wernicke-Korsakoff syndrome, a disorder caused by a thiamine deficiency, usually related to chronic alcoholism.

Memory impairment that is not associated with brain damage is referred to as functional amnesia. Functional amnesia can be classified according to whether the amnesia is nonpathological or pathological. Nonpathological functional amnesia is a normal memory loss for events occurring during infancy and early childhood, sleep, hypnosis, and anesthesia. Pathological functional amnesia is an abnormal memory loss found in cases of functional retrograde amnesia and multiple personality. In contrast to neurological amnesia, pathological functional amnesia is usually associated with more severe retrograde than anterograde amnesia. *See* BRAIN; MEMORY. [R.S.Le.]

Amnion A thin, cellular, extraembryonic membrane forming a closed sac surrounding the embryo in all reptiles, birds, and mammals. It is present only in these forms; the collective term amniotes is applied to these animals. The amnion contains a serous fluid in which the embryo is immersed. *See* AMNIOTA.

Typically, the amnion wall is a tough, transparent, nerve-free, and nonvascular membrane consisting of two layers of cells: an inner, single-cell-thick layer of ectodermal epithelium and an outer covering of mesodermal, connective, and specialized smooth muscular tissue. Early after the formation of the amnion, waves of contraction of the muscles pass over the amniotic sac and produce a characteristic rocking of the embryo. *See* GERM LAYERS.

The major function of the amnion and its fluid is to protect the delicate embryo. Thus, developmental stages of terrestrial animals are provided with the same type of cushioning against mechanical shock as is provided by the water environment of aquatic forms. *See* FETAL MEMBRANE. [N.T.S.]

Amniota A collective term for the classes Reptilia (reptiles), Aves (birds), and Mammalia (mammals) of the subphylum Vertebrata. The remaining vertebrates, including the several classes of fishes and the amphibians, are grouped together as the Anamnia. Members of the Amniota are characterized by having a series of specialized protective extraembryonic membranes during development. Three of the membranes—amnion, chorion or serosa, and allantois—occur only in this group, but a fourth, the yolk sac, is sometimes present and is found in many anamniotes. The presence of the extraembryonic membranes makes it possible for the embryonic development of the amniotes to take place out of the water. In the most primitive forms the early stages of development take place inside a shell-covered egg that is deposited on land. This pattern is typical of most reptiles, all birds, and some mammals. In these animals the amnion and chorion form fluid-filled sacs which protect the embryo from desiccation and shock. The allantois usually acts as a storage place for digestive and nitrogenous wastes and, in conjunction with the chorion, as a respiratory structure. In viviparous reptiles and mammals the chorion and allantois generally fuse and become more or less intimately associated with the uterine lining of the mother. Nutritive, excretory and respiratory exchanges take place across the chorioallantoic membrane between the allantoic circulation of the embryo and the uterine circulatory vessels of the mother. *See* ALLANTOIS; AMNION; ANAMNIA; CHORION; VERTEBRATA; YOLK SAC. [J.M.S.]

Amoebida An order of Lobosia without protective coverings (tests). These protozoa range in size from about 4 micrometers to 0.08–0.12 in. (2–3 mm). Pellicles may be thin, as in *Amoeba proteus*, or thicker and less flexible, as in *Thecamoeba verrucosa*. Pellicular folds may develop during locomotion, particularly in species with thick pellicles. Both flagellate and ameboid stages occur in certain soil amebas.

The term ameboid movement is rather loose because locomotion of Amoebida varies somewhat from genus to genus. In some cases movement involves protoplasmic flow of the body as a whole, without typical pseudopodia. In *A. proteus* there may be several ridged indeterminate pseudopodia, into one of which the organism appears to flow in locomotion. In other species determinate pseudopodia never become large enough to direct locomotion. In some cases the form of the pseudopodia may vary in a single species. Certain amebas commonly have a relatively inert posterior mass, the uroid, which may or may not be partially constricted, is sometimes covered with projections, and often contains food vacuoles. Locomotion involving protoplasmic flow depends upon sol-gel reversibility. *See* CELL MOTILITY.

Amebas, normally phagotrophic, usually contain food vacuoles. Certain species contain crystals of apparently differing chemical nature. Other inclusions are globules of different sizes, mitochondria, and stored food reserves. In addition, bacteria or algae may occur in the cytoplasm, changing the color to a gray or green. Nuclei range in number from one to several hundred, as in *Chaos carolinensis*. The giant amebas are visible without a microscope.

Those species found in the digestive tract of invertebrates and vertebrates include relatively harmless species and a few pathogens, such as *Entamoeba histolytica* of humans and *E. invadens* of reptiles. *Entamoeba histolytica* causes amebiasis. In primary cases the amebas are localized in the colon. Cases range from mild amebiasis to acute amebic dysentery.

Entamoeba coli, a similar ameba, does not invade human tissues. Also limited to the lumen of the colon are *Endolimax nana, Iodamoeba bütschlii*, and *Dientamoeba fragilis*. These four are relatively harmless although sometimes associated with digestive disturbances. Uncooked vegetables from soil fertilized with human feces are a potential source of infection. Standard methods of water purification seem reasonably protective, but it is difficult to control spread of cysts by food handlers. *See* LOBOSIA; PROTOZOA; SARCODINA; SARCOMASTIGOPHORA. [R.P.H.]

Amorphous solid A rigid material whose structure lacks crystalline periodicity; that is, the pattern of its constituent atoms or molecules does not repeat periodically in three dimensions. In the present terminology amorphous and noncrystalline are synonymous. A solid is distinguished from its other amorphous counterparts (liquids and gases) by its viscosity: a material is considered solid (rigid) if its shear viscosity exceeds $10^{14.6}$ poise ($10^{13.6}$ Pa · s). *See* CRYSTAL; VISCOSITY.

Oxide glasses, generally the silicates, are the most familiar amorphous solids. However, as a state of matter, amorphous solids are much more widespread than just the oxide glasses. There are both organic (for example, polyethylene and some hard candies) and inorganic (for example, the silicates) amorphous solids. Glasses can be prepared which span a broad range of physical properties. Dielectrics (for example, SiO_2) have very low electrical conductivity and are optically transparent, hard, and brittle. Semiconductors (for example, As_2SeTe_2) have intermediate electrical conductivities and are optically opaque and brittle. Metallic glasses have high electrical and thermal conductivities, have metallic luster, and are ductile and strong. *See* METALLIC GLASSES.

The obvious uses for amorphous solids are as window glass, container glass, and the glassy polymers (plastics). Less widely recognized but nevertheless established technological uses include the dielectrics and protective coatings used in integrated circuits, and the active element in photocopying by xerography, which depends for its action upon photoconduction in an amorphous semiconductor. In optical communications a highly transparent dielectric glass in the form of a fiber is used as the transmission medium.

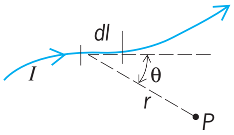
It is the changes in short-range order (on the scale of a localized electron), rather than the loss of long-range order alone, that have a profound effect on the properties of amorphous semiconductors. For example, the difference in resistivity between the crystalline and amorphous states for dielectrics and metals is always less than an order of magnitude and is generally less than a factor of 3. For semiconductors, however, resistivity changes of 10 orders of magnitude between the crystalline and amorphous states are not uncommon, and accompanying changes in optical properties can also be large.

One class of amorphous semiconductors is the glassy chalcogenides, which contain one (or more) of the chalcogens sulfur, selenium, or tellurium as major constituents. These materials have application in switching and memory devices. Another group is the tetrahedrally bonded amorphous solids, such as amorphous silicon and germanium. These materials cannot be formed by quenching from the melt (that is, as glasses) but must be prepared by one of the deposition techniques mentioned above.

When amorphous silicon (or germanium) is prepared by evaporation, not all bonding requirements are satisfied, so a large number of dangling bonds are introduced into the material. These dangling bonds create states deep in the gap which limit the transport properties. The number of dangling bonds can be reduced by a thermal anneal below the crystallization temperature, but the number cannot be reduced sufficiently to permit doping. *See* SEMICONDUCTOR. [B.G.B.]

Ampère's law A law of electromagnetism which expresses the contribution of a current element of length *dl* to the magnetic induction (flux density) *B* at a point near the current. Ampère's law, sometimes called Laplace's law, was derived by A. M. Ampère after a series of experiments during 1820–1825.

Whenever an electric charge is in motion, there is a magnetic field associated with that motion. The flow of charges through a conductor sets up a magnetic field in the surrounding region. Any current may be considered to be broken up into infinitesimal elements of length *dl*, and each such element contributes to the magnetic induction at every point in the neighborhood. The contribution *dB* of the element is found to depend upon the current *I*, the length *dl* of the element, the distance *r* of the point *P* from the current element, and the angle θ between the current element and the line joining the element of the point *P* (see illustration). Ampère's law expresses the manner of the dependence by Eq. (1). The field near a current may be calculated by finding



Graphic representation of Ampère's law.

$$dB = k\frac{I\ dl\ \sin\theta}{r^2} \tag{1}$$

the vector sum of the contributions of all the various elements that make up the current.

The proportionality factor *k* depends upon the units used in Eq. (1) and upon the properties of the medium surrounding the current. In the SI system, the factor *k* is assigned a value of 10^{-7} weber/ampere-meters when the current is in empty space. As in other equations associated with electric and magnetic fields, for example Coulomb's law, it is convenient to replace *k* by a new factor μ_0 related to *k* as in Eq. (2). This substitution removes

$$\mu_0 = 4\pi k \tag{2}$$

the factor 4π from many derived equations in which it would otherwise appear. With this substitution Ampère's law becomes Eq. (3). The factor μ_0 is called the permeability of empty space.

$$dB = \frac{\mu_0}{4\pi}\frac{I\ dl\ \sin\theta}{r^2} \tag{3}$$

The direction of *dB* at each point may be described in terms of a right-hand rule. If the current element is grasped by the right hand with the thumb pointing in the direction of the current, the fingers encircle the current in the direction of the magnetic induction. [K.V.M.]

Amphetamine A stimulating drug that affects the brain and the body in a variety of ways, also known by the trade name Benzedrine. Chemically, amphetamine is a racemic mixture of the L and D isomers of α-methyl-β-phenethylamine. The L isomer has more pronounced effects on the body, while the D isomer (commonly referred to as Dexedrine) has a greater effect on the brain. On the whole, the pharmacological effects of amphetamine are to produce an increase in blood pressure, a relaxation of bronchial smooth muscle, a constriction of the blood vessels supplying the skin and mucous membranes, and a variety of alterations in behavior. The mechanisms by which amphetamine produces its effects are not precisely defined. The effects on the body seem to be mediated predominantly through an increase in the activity of the neurons in the sympathetic nervous system via the transmitter norepinephrine. Amphetamine has the ability to release norepinephrine from nerve terminals. The consequence of release is that amphetamine has a spectrum of activity similar to the normal physiological effects of norepinephrine on the peripheral nervous system. Similarly, the major effects of amphetamine on the brain have been related to its ability to release norepinephrine in the hypothalamus, the reticular activating system, and the cerebral cortex. *See* Central nervous system; Sympathetic nervous system.

The ability of amphetamine to contract blood vessels in the mucous membranes and to relax smooth muscles in the lung make it an efficacious nasal decongestant. Its ability to cause hyperventilation has resulted in its use as an analeptic. The arousing and insomnia-producing effects have been exploited to treat narcolepsy, a disease characterized by an inability to stay awake. Furthermore, the ability of amphetamine to cause a loss of appetite has promoted its use in diet programs as an anorexic. The enhanced sense of well-being and mild euphoria that are seen after taking amphetamine have led to its use in certain forms of psychiatric depression. One important use of amphetamine is in the treatment of hyperkinetic children, although the paradox of how a stimulant can reduce hyperkinetic behavior is not understood.

Just as the therapeutic uses of amphetamine are a consequence of its pharmacology, so are its side effects. The typical side effects on the body include dry mouth, heart rhythm alterations (palpitations and arrhythmias), hypertension, stomach cramps, and decreased urinary frequency. The central nervous system side effects include dizziness, dysphoria, headache, tremor, restlessness, insomnia, decreased appetite, increased aggressiveness, anxiety, and paranoid panic states. Extreme overdosage can result in convulsions, cerebral hemorrhaging, coma, and death.

The stimulant and euphorogenic side effects of amphetamine have made this drug subject to widespread abuse. The patterns of this abuse, however, vary greatly. The diversity of people taking amphetamine without proper medical supervision makes it difficult to characterize a typical user. More serious abuse occurs in some individuals who take the drug over long periods. As with other drugs of abuse, tolerance will occur after repeated dosing. Chronic use of large amounts of amphetamine can have severe effects on personality. It has been shown that large doses of amphetamine can induce a behavioral state in humans that is nearly indistinguishable from paranoid schizophrenia, but can be reversed upon cessation of the drug. The question of whether or not physical dependence occurs with amphetamine is unresolved. *See* Addictive disorders; Narcotic. [R.E.C.]

Amphibia One of the four classes composing the superclass Tetrapoda of the subphylum Vertebrata, the other classes being Reptilia, Aves, and Mammalia. The living amphibians number approximately 2460 species, and are classified in three orders: the Anura or Salientia (frogs and toads, slightly less than 2000 species); Urodela or Caudata (salamanders, 300 species); and Apoda or Gymnophiona (caecilians, about 160 species). The orders in the subclasses Labyrinthodontia and Lepospondyli existed in the geologic past and are now extinct. A classification scheme for the Amphibia follows:

- Class Amphibia
  - Subclass Labyrinthodontia
    - Order: Ichthyostegalia
      - Temnospondyli
      - Anthracosauria
  - Subclass Lepospondyli
    - Order: Nectridea
      - Aistopoda
      - Microsauria
      - Lysorophia
  - Subclass Lissamphibia
    - Order: Anura
      - Urodela
      - Apoda

A typical amphibian is characterized by a moist, glandular skin, the possession of gills at some point in its life history, four limbs, and an egg lacking the embryonic membrane called the amnion. *See* Amnion; Anamnia.

The closest relatives of the amphibians are the fishes, from which they evolved, and the reptiles, to which they gave rise. Present-day amphibians, however, are highly specialized animals, rather different from the primitive forms that probably first arose from crossopterygian fishes and far removed from those that gave rise to the earliest reptiles.

In general, modern amphibians as adults differ from fishes in lacking scales, breathing by means of the skin and lungs instead of gills, and having limbs in place of fins. There are many exceptions to these generalizations, however. Reptiles usually have a dry, scaly skin that is relatively impervious to water loss and very different from the amphibians with their moist skin that permits much evaporation. Young (larval) amphibians have gills, but there is no comparable gill-breathing, larval stage in the life history of a reptile. A most important difference between the two groups is the absence of the amnion in the Amphibia, and its presence in the Reptilia. Lacking this membrane, amphibian eggs must be laid in water or in very moist places. The amnion of the reptile egg makes it more able to resist desiccation, and the eggs can be laid in relatively dry places. The ability to resist water loss through the skin and the development of a land egg are perhaps the differences between reptiles and amphibians that are of the greatest evolutionary significance. *See* Reptilia.

The all-important factor in amphibian life is water. Most species must return to the water to breed, and all must have access to water (even if only in the form of rain or dew) or die of dehydration in a short time. An important consequence of this basic fact of physiology is that vast arid and semiarid areas of the Earth are inhabited by a relatively few specialized amphibians. The majority of amphibian species are found in moist, tropical regions.

Amphibians are among the so-called cold-blooded animals; that is, the temperature of the body of an amphibian is not regulated internally to a high level as is that of mammals and birds, but fluctuates with that of the environment. An animal such as an amphibian that burns none of its food energy in keeping warm is able to get along on much less food than a bird or mammal of similar size. This advantage is offset by the inability of amphibians to be active under cold conditions that do not inhibit a warm-blooded animal. Thus the far northern and southern parts of the world which support large populations of birds and mammals are almost devoid of amphibian life. The amphibians mark a significant point in the evolution of the vertebrates, the transition from aquatic to terrestrial life. As animals neither divorced from the water nor fully at home on land, they suffer from their intermediate mode of life. Reptiles, and later mammals, came to dominate the land, and fishes the waters, leaving the amphibians of today as a relatively unimportant but nevertheless highly interesting group of vertebrates. *See* Tetrapoda; Thermoregulation. [R.G.Z.]

The fossil record of the three groups of living amphibians is extensive, and the earliest member of each has been found in Mesozoic rocks. However, no intermediary forms linking the three groups together have been found in the Mesozoic, and it is necessary to look in the Paleozoic, some 100 million years earlier, for the common ancestor of modern amphibians, with the earliest known amphibians having been found in the Upper Devonian rocks of Greenland.

It is clear that modern amphibians have a very long history extending back almost to the time of the origin and radiation of land vertebrates 340 million years ago. Their unique sensory biology and specialized glands must have evolved at that time and remained unchanged to the present day. [T.R.Sm.]

Amphibole A group of common ferromagnesian silicate minerals that occur as major or minor constituents in a wide variety of rocks. The crystal structure of the amphiboles is very flexible and, as a result, the amphiboles show a larger range of chemical composition than any other group of minerals. The structural and chemical complexity of the amphiboles reveals considerable information on the geological processes that have affected the rocks in which they occur. *See* Mineral.

A general formula for amphiboles may be written as $A_{0-1}B_2C_5T_8O_{22}W_2$, where

$A = \mathrm{Na, K, Ca}$

$B = \mathrm{Ca, Na, Mn^{2+}, Fe^{2+}, Li, Mg}$

$C = \mathrm{Mg, Fe^{2+}, Al, Fe^{3+}, Ti^{4+}, Mn, Li}$

$T = \mathrm{Si, Al, Ti^{4+}}$

$O = \mathrm{oxygen}$

$W = \mathrm{OH, F, O^{2-}, Cl}$

and the chemical species are written in order of their importance. Amphiboles are divided into four main groups, according to the type of chemical species in the B group:

$B = (\mathrm{Fe^{2+}, Mg, Mn^{2+}, Li})_2$	Iron-magnesium-manganese amphiboles
$B = \mathrm{Ca_2}$	Calcic amphiboles
$B = \mathrm{NaCa}$	Sodic-calcic amphiboles
$B = \mathrm{Na_2}$	Sodic amphiboles

Amphiboles can have orthorhombic and monoclinic symmetries; these can be distinguished either by x-ray crystallography or by the optical properties of the mineral in polarized light. *See* X-ray crystallography.

Monoclinic amphiboles are by far the most common. The characteristic feature of the amphibole structure is the chain of corner-sharing tetrahedrally coordinated groups. Inspection of the structure down the y axis shows that the amphibole structure consists of sheets of tetrahedra interleaved with octahedrally coordinated C-group cations. In the monoclinic structure, the tetrahedral layers all stack in the x direction with the same sense of displacement (along the z direction) relative to the underlying layer, and hence the x axis is inclined to the z axis, producing a monoclinic structure. In the orthorhombic structure, the displacement of the tetrahedral layers reverses every third layer, and hence the x axis is orthogonal to the z axis, producing an orthorhombic structure. *See* Crystal; Crystal structure; Crystallography.

Amphiboles do not show the complete range of possible compositions suggested by the general chemical formula and common idealized compositions described above. In particular, there is not a continuous range of chemical composition between the four main amphibole groups: the iron-magnesium-manganese amphiboles, the calcic amphiboles, the sodic-calcic amphiboles, and the alkali amphiboles. This lack of so-called solid solution is a result of the structure not being able to accommodate two types of cations (positively charged atoms) of very different size (or charge) at the same set of sites in the structure of a single crystal.

The degree to which two amphiboles are immiscible often varies as a function of temperature and pressure; at high temperatures or pressures, miscibility is usually enhanced. The immiscible region, which is known as a miscibility gap, is narrow at high temperature but widens at lower temperature. When the amphibole composition is within the miscibility gap, a single amphibole is no longer stable. It is here that the process of exsolution (or unmixing) occurs. Coexisting amphiboles and exsolution textures are very informative about temperatures of crystallization and cooling history, particularly in metamorphic rocks. *See* Phase equilibrium; Solid solution.

Amphiboles are common minerals in many types of igneous rocks, and the composition of the amphibole reflects the silica content of the rock. Calcic amphiboles, particularly pargasite, are characteristic of ultramafic and metabasaltic rocks and are usually quite rich in magnesium. Titanium-rich hornblendes and kaersutites occur in intermediate rocks and are often strongly oxidized—an unusual feature in amphiboles from any other environment. Acidic rocks, particularly granites, contain a wide range of amphiboles, from hastingsite to riebeckite and arfvedsonite; these are often iron-rich and can contain significant amounts of more unusual elements such as Li, Zn, and Mn. Amphiboles usually weather very easily and hence are not important in sedimentary rocks, although they can be significant components of soil. Iron-rich alkali amphiboles can form at essentially ambient conditions in the sedimentary environment, but this occurrence is rare. Amphiboles are common and important rock-forming minerals in many types of metamorphic rocks. They are particularly abundant in rocks of basaltic composition at most grades of metamorphism.

Amphiboles are economically important as commercial asbestos minerals and as semiprecious gem materials. World asbestos production is dominated by the serpentine-group mineral chrysotile; but the amphibole minerals anthophyllite, cummingtonite-grunerite (amosite), actinolite, and riebeckite (crocidolite) are also important, particularly in Australia and South Africa. Some amphiboles with attractive physical properties are marketed as semiprecious gem material. Most important is nephrite, a dense compact form of fibrous actinolite that is a principal variety of jade. Fibrous riebeckite is marketed as one of the less common varieties of tiger's eye. Iridescent gedrite and gem-quality pargasite are used as semiprecious gems in contemporary jewelry. *See* Gem; Jade; Mineralogy. [F.C.Ha.]

Amphibolite A class of metamorphic rocks with one of the amphibole minerals as the dominant constituent. Most of the amphibolites are dark green to black crystalline rocks that occur as extensive layers widely distributed in mountain belts and deeply eroded shield areas of the continental crust. Amphibolite is the main country rock that has been intruded by the large granite masses found in most mountain ranges, with small and large masses of amphibolite present also as inclusions in granites.

Amphibolites are the products of regional metamorphism and crustal deformation of older materials of appropriate composition. The features of the original rock are obliterated; thus it is difficult and sometimes impossible to determine the premetamorphic rock. Apparent differences in the formation of the bulk composition are used to classify amphibolites as ortho or para. Compositional relations between the minor elements titanium, chromium, and nickel have been used to distinguish the ortho from para amphibolites in some occurrences. *See* Metamorphic rocks. [G.W.DeV.]

Amphidiscosa An order of the subclass Amphidiscophora in the class Hexactinellida. These sponges are distinguished from the order Hemidiscosa in that the birotulates are amphidiscs. Examples of this order are *Pheronema*, *Monorhaphis*, and *Hyahnema*. The record of fossil Amphidiscosa is poor, but goes back to the Carboniferous *Uralonema*. *See* Hemidiscosa. [W.D.H.]

Amphilinidea An order of tapeworms of the subclass Cestodaria. They have a protrusible proboscis and frontal glands at the anterior end. No holdfast organ is evident. All members of the order inhabit the coelom of sturgeon and other fish. The only life history which is completely known is that of *Amphilina*. The 10-hooked embryos leave the parental uterus through a pore, and if upon escaping into the water they are eaten by an amphipod crustacean, they undergo further development to the procercoid larva. When the parasitized amphipod is eaten by a sturgeon, the larval worm enters its coelom and develops to sexual maturity. *See* Cestodaria. [C.P.R.]

Amphionidacea An order of the Eucarida comprising a single species, *Amphionides reynaudii*. Because of the similarity of its early larval stages to those found among the caridean shrimps, for more than a century it was classified as an aberrant member of the Caridea. However, the fact that the pleuron of the second abdominal somite never overlaps that of the first in any stage immediately distinguishes this species from all true Caridea. *Amphionides reynaudii* has worldwide distribution, primarily in equatorial regions. Adult females have been collected at depths between 21,000 and 111,000 ft (700 and 3700 m), while most larvae occur in depths of only 90–300 ft (30–100 m). *See* Eucarida. [P.A.McL.]

Amphipoda An order of crustaceans in the subclass Malacostraca, which lack a carapace, bear unstalked eyes, and respire by thoracic branchiae, or gills. The abdomen usually bears three pairs of biramous swimmerets (pleopods), three pairs of rather rigid uropods, and a telson which may be lobed or entire. The body is usually flattened laterally, and the pereiopods (walking legs) are elongated so that walking is difficult. The maxillipeds lack epipodites. The sexes are separate, but reproductive and copulatory organs are very simple. The eggs are extruded by the female into a ventral brood pouch composed of setose lamellae attached to the medial bases of the legs. The young hatch as miniature adults, growing usually to a length of 0.12–0.48 in. (3–12 mm), and in exceptional cases to 5.6 in. (140 mm). *See* Isopoda.

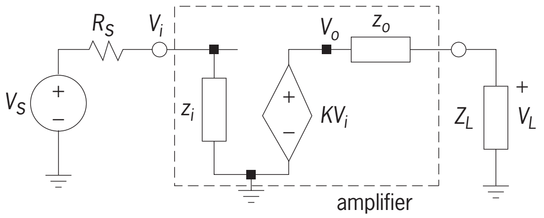
Four suborders are known, the Gammaridea, Hyperiidea, Caprellidea, and Ingolfiellidea. Amphipods are very abundant in the oceans, being represented by 3200 species. More than 600 other species occur in streams, lakes, and subterranean waters and in terrestrial leaf molds and mosses. Many are excellent swimmers. Nonpelagic species of the suborders Gammaridea and Caprellidea live on aquatic bottoms, plants, and epifaunal growths. Predation by amphipods is occasional. Their mouthparts are well adapted for chewing: they either eat aquatic plants, debris, and detritus or swallow mud containing food particles.

Marine species are important food for various stages of many commercial fishes. Hyperiids are the principal food of seals at certain seasons, and also of balaenoid whales at times. One gammaridean genus, *Chelura*, is a minor wood borer, associated with the isopod *Limnoria*.

A few fossil species are known in Tertiary amber deposits. *See* Amber; Caprellidea; Gammaridea; Hyperiidea; Malacostraca. [J.L.B.]

Amplifier A device capable of increasing the magnitude of a physical quantity. This article discusses a couple of basic electronic amplifiers whose operation depends on transistors. Some amplifiers are magnetic, while others may take the form of rotating electrical machinery. Forms of nonelectrical amplifiers are hydraulic actuators and levers which are amplifiers of mechanical forces. *See* Direct-current motor; Hydraulic actuator; Lever.

The operation of an amplifier can be explained with a model (see illustration). A controlled voltage source of gain K generates



Amplifier model with source, load, and input and output impedances.

an output voltage $V_o = KV_i$ from an input voltage V_i. This input voltage is obtained from a source voltage V_S with source resistance R_S via voltage division with the amplifier's input impedance z_i. The load voltage V_L across the load impedance Z_L is obtained from V_o by voltage division with the amplifier's output impedance z_o. The input voltage and load voltage are given by Eqs. (1), where k_i and k_o, respectively, express the effects of the amplifier loading the source and of the load impedance loading the amplifier. The impedances z_i and z_o mostly consist of a resistor in parallel with a capacitor; often they may be assumed to be purely resistive: $z_i = r_i$ and $z_o = r_o$. From Eq. (1), the amplifier's operation is given by Eq. (2). Thus, the amplification is decreased

$$\begin{aligned} V_i &= \frac{z_i}{z_i + R_S} V_S = k_i V_S \\ V_L &= \frac{Z_L}{Z_L + z_o} V_o = k_o V_o \end{aligned} \qquad (1)$$

$$V_L = k_i K k_o V_S = \frac{z_i}{z_i + R_S} K \frac{Z_L}{Z_L + z_o} V_S \qquad (2)$$

from the ideal value K by the two load factors k_i and k_o. The reduction in gain is avoided if the two factors equal unity, that is, if $z_i = \infty$ and $z_o = 0$. Thus, in addition to the required gain K, a good amplifier has a very large input impedance z_i and a very small output impedance z_o. *See* Gain.

The operational amplifier (op amp) is a commonly used general-purpose amplifier. It is implemented as an integrated circuit on a semiconductor chip, and functions as a voltage amplifier whose essential characteristics at low frequencies are very high voltage amplification, very high input resistance, and very low output resistance. *See* Integrated circuits.

The transconductance amplifier has become widely used. In contrast to operational amplifiers, which convert an input voltage to an output voltage, transconductors are voltage-to-current converters described by the transconductance parameter g_m, which satisfies Eq. (3). Thus, the output current I_{out} is proportional to the input voltage V_{in}.

$$I_{\text{out}} = g_m V_{\text{in}} \qquad (3)$$

As do operational amplifiers, ideal transconductors have an infinite input resistance, but they also have an infinite output resistance so that the output is an ideal current source. One of the attractive properties of transconductance amplifiers is their wide bandwidth. Very simple transconductance circuits can be designed which maintain their nominal g_m values over bandwidths of several hundred megahertz, whereas operational amplifiers often have high gain only over a frequency range of less than 100 Hz, after which the gain falls off rapidly. Consequently, in high-frequency communications applications, circuits built with transconductance amplifiers generally give much better performance than those with operational amplifiers.

Typically, amplifiers increase the power or signal levels from low-power sources, such as microphones, strain gages, magnetic disks, or antennas. After the small signals have been amplified, the amplifier's output stage must deliver the amplified signal efficiently, with minimal loss, and with no distortion to a load, such as a loudspeaker. [R.Sc.]

Amplitude (wave motion) The maximum magnitude (value without regard to sign) of the disturbance of a wave. The term "disturbance" refers to that property of a wave which perturbs or alters its surroundings. It may mean, for example, the displacement of mechanical waves, the pressure variations of a sound wave, or the electric or magnetic field of light waves. Sometimes in older texts the word amplitude is used for the disturbance itself; in that case, amplitude as meant there is called peak amplitude. This is no longer common usage.

If the medium which a wave disturbs dissipates the wave by some nonlinear behavior or other means, then the amplitude will, in general, depend upon position. *See* Displacement (mechanics); Light; Sound; Wave motion. [S.A.Wi.]

Amplitude modulation The process or result of the process whereby the amplitude of a carrier wave is changed in accordance with a modulating wave. This broad definition includes applications using sinusoidal carriers, pulse carriers, or any other form of carrier, the amplitude factor of which changes in accordance with the modulating wave in any unique manner. *See* Modulation.

Practical examples of amplitude modulation (AM) include AM radio broadcasting, single-sideband transmission systems, vestigial-sideband systems, frequency-division multiplexing, time-division multiplexing, phase-discrimination multiplexing, and reduced-carrier systems. *See* Multiplexing; Single sideband.

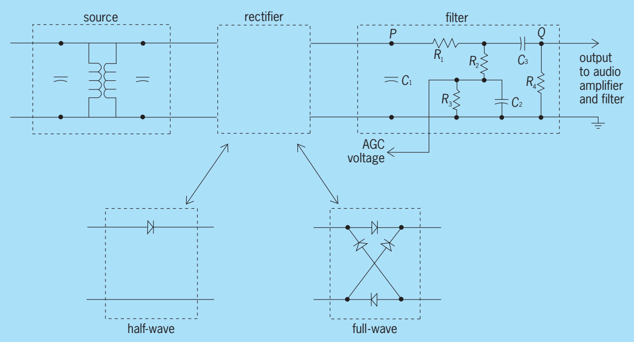
Amplitude modulation is also defined in a more restrictive sense to mean modulation in which the amplitude factor of a sine-wave carrier is linearly proportional to the modulating wave. AM radio broadcasting is a familiar example. At the radio transmitter the modulating wave is the audio-frequency program signal to be communicated; the modulated wave that is broadcast is a radio-frequency, amplitude-modulated sinusoid. *See* Amplitude-modulation radio.

In AM the modulated wave is composed of the transmitted carrier, which conveys no information, plus the upper and lower sidebands, which (assuming the carrier frequency exceeds twice the top audio frequency) convey identical and therefore mutually redundant information. J. R. Carson in 1915 was the first to recognize that, under these conditions and assuming adequate knowledge of the carrier, either sideband alone would uniquely define the message. This eventually led to the development of single-sideband (SSB) and vestigial-sideband (VSB) modulation. Apart from a scale factor, the spectrum of the upper sideband and lower sideband is the spectrum of the modulating wave displaced, respectively, without and with inversion by an amount equal to the carrier frequency. *See* Amplitude-modulation detector; Amplitude modulator; Frequency modulation. [H.S.Bl.]

Amplitude-modulation detector A device for recovering information from an amplitude-modulated (AM) electrical signal. Such a signal is received, usually at radio frequency, with information impressed in one of several forms. The carrier signal may be modulated by the information signal as double-sideband (DSB) suppressed-carrier (DSSC or DSBSC), double-sideband transmitted-carrier (DSTC or DSBTC), single-sideband suppressed-carrier (SSBSC or SSB), vestigial sideband (VSB), or quadrature-amplitude modulated (QAM).

The field of amplitude-modulation detector requirements splits by application, complexity, and cost into the two categories of synchronous and asynchronous detection. Analog implementation of nonlinear asynchronous detection, which is typically carried out with a diode circuit, is favored for consumer applications, AM-broadcast radio receivers, minimum-cost products, and less critical performance requirements. Synchronous detectors, in which the received signal is multiplied by a replica of the carrier signal, are implemented directly according to their mathematics and block diagrams, and the same general detector satisfies the detection requirements of all SSB, DSB, and VSB signals. Although synchronous detectors may operate in the analog domain by using integrated circuits, more commonly digital circuits are used because of cost, performance, reliability, and power advantages.

In synchronous detection there are two conceptual approaches: to reverse the modulation process (which is rather difficult), or to remodulate the signal from the passband (at or near the transmitter's carrier frequency) to the baseband (centered at dc or zero frequency). The remodulation approach is routine. Unfortunately, a nearly exact replica of the transmitter's



Diode detector circuit. ***P*** **= input point of filter;** ***Q*** **= output point of filter.**

carrier signal is needed at the receiver in order to synchronously demodulate a transmitted signal. Synchronous means that the carrier-signal reference in the receiver has the same frequency and phase as the carrier signal in the transmitter. There are three means available to obtain a carrier-signal reference. First, the carrier signal may actually be available via a second channel. There are no difficulties with this method because a perfect replica is in hand. Second, the carrier signal may be transmitted with the modulated signal. It then must be recovered by a circuit known as a phase-lock loop with potential phase and frequency errors. Third, the carrier signal may be synthesized by a local oscillator at the receiver, with great potential for errors. Unless otherwise stated, it will be assumed that a perfect replica of the carrier signal is available. *See* OSCILLATOR; PHASE-LOCKED LOOPS.

Asynchronous detection applies to DSTC signals whose modulation index is less than 1, and is quite simple. First the received signal is full-wave rectified, then the result is low-pass filtered to eliminate the carrier frequency and its products, and finally the average value is removed (by dc blocking, that is, ac coupling). This result is identical to that which is obtained by synchronous detection with a reference that has been amplitude distorted to a square wave. The cheaper but less efficient half-wave rectifier can also be used, in which case the demodulation process is called envelope detection.

A diode detector circuit in a radio receiver has three stages (see illustration). The first stage is the signal source, which consists of a pair of tuned circuits that represent the last intermediate-frequency (i.f.) transformer which couples the signal energy out of the i.f.-amplifier stage into the detector. The second stage is a diode rectifier, which may be either full wave or half wave. Finally, the signal is passed through the third stage, a filter, to smooth high-frequency noise artifacts and remove the average value. *See* DIODE; INTERMEDIATE-FREQUENCY AMPLIFIER; RADIO RECEIVER; RECTIFIER.

The waveform shaping at the input point of the filter (see illustration) is determined by a capacitor C_1 in parallel with an equivalent resistance of R_1, the latter in series with a parallel combination of resistors, R_2 and R_4. The filter also has a capacitor C_3 between R_2 and R_4, and a parallel combination of a resistor R_3 and a capacitor C_2 in series with R_2. The reactances of both capacitors C_2 and C_3 are quite small at the information frequency, so the capacitors can be viewed as short circuits. Meanwhile, the C_3-R_4 combination serves as a dc-blocking circuit to eliminate the constant or dc component at the output point of the filter. In order to bias the output point properly for the next amplifier stage, R_4 is replaced by a biasing resistor network in a real filter; R_4 is the single-resistor equivalent. *See* ELECTRICAL IMPEDANCE.

The strength of the signal arriving at the detector is proportional to the mean value of the signal at the input point of the filter and is sensed as the automatic-gain-control (AGC) voltage. Changes in this voltage level are used to adjust the amplification before the detector so that the signal strength at the detector input can remain relatively constant, although the signal strength at the receiver's antenna may fluctuate. Since capacitor C_2 shunts all signal energy and any surviving carrier energy to ground, the AGC voltage is roughly the average value at the input point of the filter scaled by $R_3/(R_1 + R_2 + R_3)$ because R_1 is much smaller than R_4.

Additional filtering can be provided as necessary to reduce the noise to an acceptable level. This amplified and filtered signal is finally delivered to an output device, such as a loudspeaker. The ragged waveform of the filter output contrasts with the smooth waveform of the information signal. The raggedness vanishes as the ratio of the i.f. frequency to the information frequency increases. While a synthetic example with a low ratio can be used to clearly show the effects within the demodulator, the amplitude of this raggedness noise decreases in almost direct proportion to the increase in the frequency ratios. The raggedness of the output signal from the filter after half-wave rectification is much greater than that of the full-wave-rectifier case.

The actual worst-case ratio for standard-broadcast amplitude-modulation radio is 46.5:1. In this case the raggedness on the filtered outputs is reduced to a fuzz that can be seen in graphs of the waveforms but is well outside the frequency range of audio circuits, loudspeakers, and human hearing. *See* AMPLITUDE MODULATOR; MODULATION; WAVEFORM. [S.A.Wh.]

Amplitude-modulation radio Radio communication employing amplitude modulation of a radio-frequency carrier wave as the means of conveying the desired intelligence. In amplitude modulation the amplitude of the carrier wave is made to vary corresponding to the fluctuations of a sound wave, television image, or other information to be conveyed. *See* AMPLITUDE MODULATION; RADIO.

Amplitude modulation (AM), the oldest and simplest form of modulation, is widely used for radio services. The most familiar of these is broadcasting; others include radiotelephony and radiotelegraphy, television picture transmission, and navigational aids.

European and Asian countries use low frequencies in the range 150–255 kilohertz (kHz) for some broadcast services. An advantage of these frequencies is stable and relatively low-attenuation wave propagation. When not limited by atmospheric noise, large areas may be served by one station. In the United States these frequencies are reserved for navigational systems and so are not available for broadcasting.

The frequencies in the range from 535 to 1605 kHz are reserved all over the world for AM (standard) broadcasting. In the Western Hemisphere this band is divided into channels at 10-kHz intervals, certain channels being designated as clear, regional, and local, according to the licensed coverage and class of service. European medium-frequency (mf) broadcasting channels are assigned at 9-kHz intervals.

Small bands of high frequencies between 3000 and 5000 kHz are used in tropical areas of high atmospheric noise for regional broadcasting. This takes advantage of the lower atmospheric noise at these frequencies and permits service under conditions where medium frequencies have only severely limited coverage.

The first radiotelephony was by means of amplitude modulation, and its use has continued with increasing importance. Radiotelephony refers to two-way voice communication. Amplitude modulation and a modified form called single-sideband are used almost exclusively for radiotelephony on frequencies below 30 megahertz. Above 30 MHz, frequency or phase modulation is used almost exclusively, a notable exception being 118–132 MHz, where amplitude modulation is used for all two-way vhf radiotelephony in aviation operations.

The least expensive method known for communicating by telephony over distances longer than a few tens of miles is by using the high frequencies of 3–30 MHz. Furthermore, since radio is the only way to communicate with ships and aircraft, hf AM radiotelephony has remained essential to these operations, except for short distances that can be covered from land stations using the very high frequencies.

Single-sideband (SSB) hf telephony is a modified form of amplitude modulation in which only one of the modulation sidebands is transmitted. In some systems the carrier is transmitted at a low level to act as a pilot frequency for the regeneration of a replacement carrier at the receiver. Since 1933 most transoceanic and intercontinental telephony has been by single-sideband reduced-carrier radio transmission on frequencies between 4000 and 27,000 kHz. In time, SSB will gradually displace AM radiotelephony to reduce serious interference due to overcrowding of the radio spectrum.

Amplitude-modulated radio has a dominant role in guidance and position location, especially in aviation, which is almost wholly under radio guidance.

Amplitude modulation is used everywhere for the broadcasting of the picture (video) portion of television. In England, France, and a few other places amplitude modulation is also used for the sound channel associated with the television picture, but frequency modulation is more commonly used for sound.

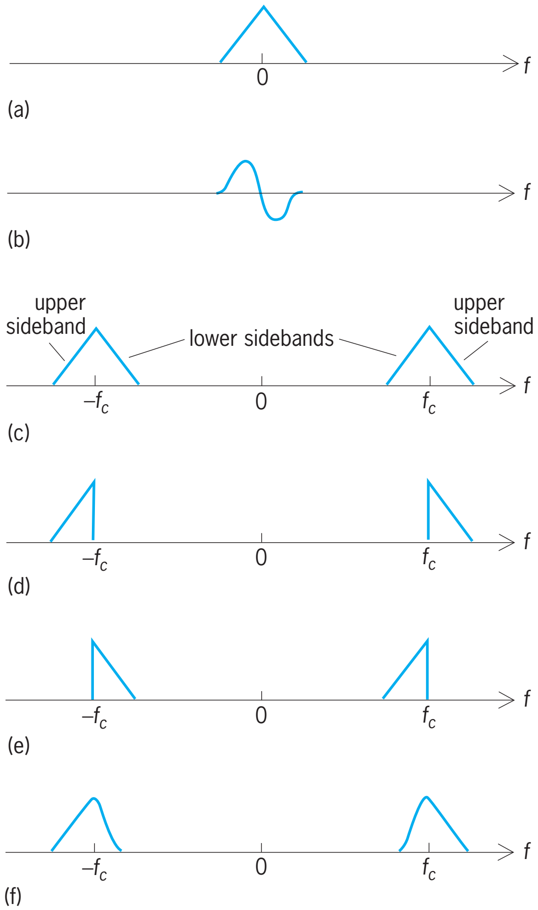
Countries of the Western Hemisphere, Japan, Philippines, Thailand, and Iran broadcast television video in an emission band of 4.25 MHz; the English video bandwidth is 3 MHz; the French system, 10 MHz. The rest of continental Europe (except the Soviet Union) use a bandwidth of 5.25 MHz. The carrier frequencies employed are between 40 and 216 MHz, and 470 to 890 MHz. A channel allocation includes the spectrum needed for both sound and picture. Japan and Australia also use 88–108 MHz for television broadcasting. [E.A.L.]

A number of systems for stereophonic AM radio broadcasting exist that allow stations to transmit two channels of information in the same spectrum space where only one could exist previously. The result is similar to that of stereophonic FM, audio cassette, and other binaural entertainment media. To transmit in AM stereo, a broadcast station employs a device known as an exciter to adapt its existing transmitter. The exciter has left- and right-channel audio inputs as well as summed audio- and radio-frequency outputs. Stereophonic audio program material is connected to the audio inputs, while the outputs attach to the AM transmitter. Stereophonic AM broadcasting methods all have their roots in a system known as quadrature multiplexing. This system allows the transmission of two channels of information on a single carrier frequency, but true quadrature transmissions are inherently incompatible with the majority of radios available to consumers. The differences between various systems employed to transmit stereophonic AM broadcasts all relate to the methods used to overcome this incompatibility. *See* Amplitude modulation; Radio; Stereophonic radio transmission. [S.Sa.]

Amplitude modulator A device for moving the frequency of an information signal, which is generally at baseband (such as an audio or instrumentation signal), to a higher frequency, by varying the amplitude of a mediating (carrier) signal. The motivation to modulate may be to shift the signal of interest from a frequency band (for example, the baseband, corresponding to zero frequency or dc) where electrical disturbances exist to another frequency band where the information signal will be subject to less electrical interference; to isolate the signal from shifts in the dc value, due to bias shifts with temperature or time of the characteristics of amplifiers, or other electronic circuits; or to prepare the information signal for transmission.

Familiar applications of amplitude modulators are standard-broadcast or amplitude-modulation (AM) radio; data modems (modem = modulator + demodulator); and remote sensing, where the information signal detected by a remote sensor is modulated by the remote signal-conditioning circuitry for transmission to an electrically quiet data-processing location. *See* Amplitude-modulation radio; Modem; Remote sensing.

The primary divisions among amplitude modulators are double sideband (DSB); single sideband (SSB); vestigial sideband (VSB); and quadrature amplitude (QAM), where two DSB signals share the same frequency and time slots simultaneously. Each of these schemes can be additionally tagged as suppressed carrier (SC) or transmitted carrier (TC).



Baseband spectra and spectra of outputs from suppressed-carrier modulators. Amplitudes and phases are shown as functions of frequency *f*. (*a*) Baseband amplitude spectrum. (*b*) Baseband phase spectrum. (*c*) Amplitude spectrum of output from double-sideband (DSB) modulator. (*d*) Amplitude spectrum of output from upper single-sideband (SSB) modulator. (*e*) Amplitude spectrum of output from lower single-sideband (SSB) modulator. (*f*) Amplitude spectrum of output from vestigial-sideband (VSB) modulator.

To amplitude-modulate an information signal is (in its simplest form) to multiply it by a second signal, known as the carrier signal (because it then carries the information). A real (as opposed to complex) information signal at baseband, or one whose spectrum is centered about zero frequency, has an amplitude spectrum which is symmetric (an even function; illus. *a*) and a phase spectrum which is asymmetric (an odd function; illus. *b*) in frequency about zero. Because of this symmetry, the information in the upper or positive sideband (positive frequencies) replicates the information in the lower or negative sideband (negative frequencies). Balanced modulation or linear multiplication (that is, four-quadrant multiplication where each of the two inputs is free to take on positive or negative values without disturbing the validity of the product) of this information signal by a sinusoidal carrier of single frequency, f_c, moves the information signal from baseband and replicates it about the carrier frequencies f_c and $-f_c$ (illus. *c*).

Linear multiplication (described above) produces double-sideband suppressed-carrier (DSSC or DSBSC) modulation of the carrier by the information. One of the redundant sidebands of information may be eliminated by filtering (which can be difficult and costly to do adequately) or by phase cancellation (which is usually a much more reasonable process) to produce the more efficient single-sideband suppressed-carrier (SSBSC or SSB) modulation (illus. *d, e*). The process of only partially removing the redundant sideband (usually by deliberately imperfect filtering) and leaving only a vestige of it is called vestigial-sideband (VSB) modulation (illus. *f*). *See* ELECTRIC FILTER.

Receivers demand a carrier-signal reference to properly demodulate (detect) the transmitted signal. This reference may be provided in one of three ways: it may be transmitted with the modulated signal, for example, in double-sideband transmitted-carrier (DSTC or DSBTC) modulation, which is the method used for standard-broadcast AM radio; transmitted on a separate channel (often the case for instrumentation systems); or generated at the receiver.

DSSC modulation, no matter how it is disguised, is just ordinary (linear) multiplication, or a reasonable approximation to that multiplication. Furthermore, a DSTC signal can be modeled as a DSSC signal with the carrier added. Any amplitude modulator is therefore simply some sort of embodiment of a linear multiplier with or without a means to add the carrier.

High-level DSTC modulation is usually done by varying the power-supply voltage to the final high-power amplifier in the radio-frequency transmitter by summing the information signal with the dc output voltage of the power supply. Low-level DSTC modulation is carried out by integrated circuits that approximate the multiplications, followed by a linear amplifier. *See* AMPLIFIER.

Because of the falling costs and improving performance of digital devices, signals are now generally represented by digital data, that is, signal values which are sampled in time and encoded as numbers to represent their sampled values. Digital signal-processing (DSP) functions are carried out by some sequence of addition (or subtraction), multiplication, and delays. Efficient mechanization of each of these functions has been the subject of considerable effort. Digitally, waveform generation and linear multiplication are highly optimized processes. Advances in integrated-circuit fabrication techniques have so lowered the cost of digital circuits for modulation that the overwhelming majority of amplitude modulators in use are now digital. Custom application-specific integrated circuits (ASICs), general-purpose programmable DSP devices, and customizable arrays such as programmable logic arrays (PLAs) and field-programmable arrays (FPAs) are all in widespread use as amplitude modulators and demodulators. Digital modems as data transmission equipment dominate the production of amplitude modulators. *See* INTEGRATED CIRCUITS; AMPLITUDE MODULATION; MODULATION; MODULATOR. [S.A.Wh.]

Amylase An enzyme which breaks down (hydrolyzes) starch, the reserve carbohydrate in plants, and glycogen, the reserve carbohydrate in animals, into reducing fermentable sugars, mainly maltose, and reducing nonfermentable or slowly fermentable dextrins. Amylases are classified as saccharifying (β-amylase) and as dextrinizing (α-amylases). The α- and β-amylases are specific for the α- and β-glucosidic bonds which connect the monosaccharide units into large aggregates, the polysaccharides. The α-amylases are found in all types of organs and tissues, whereas β-amylase is found almost exclusively in higher plants. *See* CARBOHYDRATE; ENZYME; GLYCOGEN; MALTOSE.

In animals the highest concentrations of amylase are found in the saliva and in the pancreas. Salivary amylase is also known as ptyalin and is found in humans, the ape, pig, guinea pig, squirrel, mouse, and rat.

In plants, starch is broken down during the germination of seeds (rich in starch) by associated plant enzymes into sugars. These constitute the chief energy source in the early development of the plant. β-Amylase occurs abundantly in seeds and cereals such as malt. It also is found in yeasts, molds, and bacteria. [D.N.La.]

Amyloidosis A disorder characterized by the accumulation of an unusual extracellular fibrous protein (amyloid) in the connective tissue of the body. The deposition of amyloid may be widespread, involving major organs and leading to serious clinical consequences, or it may be very limited with little effect on health.

Amyloidosis has been classified clinically as: (1) primary amyloidosis, with no evidence for preexisting or coexisting disease; (2) amyloidosis associated with multiple myeloma; (3) secondary amyloidosis, associated with chronic infections (such as osteomyelitis, tuberculosis, leprosy), chronic inflammatory disease (such as rheumatoid arthritis, ankylosing spondylitis, regional enteritis), or neoplasms (such as medullary carcinoma of the thyroid); (4) heredofamilial amyloidosis, associated with familial Mediterranean fever and a variety of heritable neuropathic, renal, cardiovascular, and other syndromes; (5) local amyloidosis, with local, often tumorlike, deposits in isolated organs without evidence of systemic involvement; (6) amyloidosis associated with aging. There is no specific treatment for amyloidosis, but supportive treatment is very useful. [A.S.Co.]

Anaerobic infection An infection caused by anaerobic bacteria (organisms that are intolerant of oxygen). Most such infections are mixed, involving more than one anaerobe and often aerobic or facultative bacteria as well. Anaerobes are prevalent throughout the body as indigenous flora, and virtually all anaerobic infections arise endogenously, the principal exception being *Clostridium difficile* colitis. Factors predisposing to anaerobic infection include those disrupting mucosal or other surfaces (trauma, surgery, and malignancy or other disease), those lowering redox potential (impaired blood supply, tissue necrosis, and growth of nonanaerobic bacteria), drugs inactive against anaerobes (such as aminoglycosides), and virulence factors produced by the anaerobes (toxins, capsules, and collagenase, hyaluronidase, and other enzymes). Anaerobic gram-negative bacilli (*Bacteroides, Prevotella, Porphyromonas, Fusobacterium*) and anaerobic gram-positive cocci (*Peptostreptococcus*) are the most common anaerobic pathogens. *Clostridium* (spore formers) may cause serious infection. The prime pathogen among gram-positive nonsporulating anaerobic bacilli is *Actinomyces*. Of the infections commonly involving anaerobes, the oral and dental pleuropulmonary, intraabdominal, obstetric-gynecologic, and skin and soft tissue infections are most important in terms of frequency of occurrence. To document anaerobic infection properly, specimens for culture must be obtained so as to exclude normal flora and must be transported under anaerobic conditions. Therapy includes surgery and antimicrobial agents. *See* ANTIBIOTIC; GANGRENE; GAS; INFECTION. [S.M.F.]

Analcime A mineral with a framework structure in which all the aluminosilicate tetrahedral vertices are linked, thus allying it to the feldspars, feldspathoids, and zeolites. Its formula is $Na(H_2O)[AlSi_2O_6]$; in this sense it is a tectosilicate.

The analcime structure type includes several other mineral species. These include high-temperature leucite, pollucite, and wairakite. Crystals are most frequently trapezohedra, and rarely the mineral is massive granular. Hardness is 5–5$^1/_2$ on Mohs scale; specific gravity is 2.27.

Analcime most frequently occurs as a low-temperature mineral in vesicular cavities in basalts, where it is associated with zeolites (particularly natrolite), datolite, prehnite, and calcite. Small grains are frequent constituents of sedimentary rocks and muds in oceanic basins associated with volcanic sources. *See* FELDSPAR; FELDSPATHOID; LEUCITE ROCK; ZEOLITE. [P.B.M.]

Analgesic Any of a group of drugs of diverse chemical structure and physiological effects which are commonly used for the relief of pain. To qualify as an analgesic a drug must selectively reduce or abolish pain without causing impairment of consciousness, mental confusion, incoordination or paralysis, or other derangements of the nervous system.

The oldest and best-known of the class of narcotic alkaloid analgesics are opium, a drug obtained by extracting the juice of the poppy seed, and its most active alkaloid, morphine. Morphine and related drugs reduce or block the activation of pain neurons in the gray matter of the spinal cord, and at receptor sites in the brainstem and thalamus. In addition to their use as analgesic drugs, opiates have other biological effects such as sedation, pupillary constriction, suppression of cough reflex, respiratory depression, reduction of intestinal motility, impairment of segmental flexor reflexes, and decrease in body temperature. This functional diversity is attributed to the activation of other inhibitory systems of neurons. While morphine is the most powerful medical analgesic substance, there are many other naturally occurring alkaloids derived from opium. The best known of these is codeine. Common to all opiates is the attribute that if they are taken for weeks or months the recipient will need larger doses to obtain the same analgesic and sedative effects. This response is called tolerance. If the drug is stopped, disagreeable withdrawal or abstinence effects are experienced within hours to days. There is severe pain, sweating, salivation, hyperventilation, restlessness, and confusion. These abstinence symptoms, which are marks of habituation, pressure the addicted person to take extreme measures to obtain the narcotic in order to avoid the symptoms. *See* ADDICTIVE DISORDERS; ALKALOID; ENDORPHINS; MORPHINE ALKALOIDS; NARCOTIC; OPIATES; SEDATIVE.

Because of the strong addictive properties of morphine and related compounds, chemists have synthesized other drugs of similar chemical structure, in the hope of securing analgesia without addiction. This effort has been only partially successful. Methadone, a drug that has been given to addicts as a substitute for morphine, is an effective analgesic when taken orally and is less addictive than morphine. Meperidine (Demerol) is a strong synthetic analgesic but definitely addictive. Other synthetic analgesics are oxycodone (Percodan), levorphanol (levodromoran), propoxyphene (Darvon), and pentazocine (Talwin). The last two of this series cause little or no addiction but, unfortunately, are not strong analgesics. Another synthetic drug, Naloxone, blocks the analgesic effect of all opiate agonists and precipitates withdrawal symptoms in addicted individuals.

Another class of analgesic drugs, which are nonnarcotic (nonaddictive), are the salicylates, the most familiar being acetylsalicylic acid (aspirin), and salicylatelike drugs such as phenylbutazone (Butazolidine), indomethacin (Indocin), acetaminophen, and phenacetin. These drugs are most effective in relieving skeletal pain due to inflammation (such as arthritis). Their analgesic properties, which are not nearly as strong as those of morphine and the synthetic opioids, are due to their action on both the peripheral and central nervous system. These drugs also have many other effects, such as reducing fever (antipyrexia) and preventing platelet agglutination. They are the most commonly used of all analgesic medications and are often combined with caffeine or a barbiturate sedative under a variety of trade names and sold for the relief of headache, backache, and so forth. *See* ASPIRIN; EICOSANOIDS; NERVOUS SYSTEM (VERTEBRATE); PAIN. [R.D.A.]

Analog computer A computer or computational device in which the problem variables are represented as continuous, varying physical quantities. An analog computer implements a model of the system being studied. The physical form of the analog may be functionally similar to that of the system, but more often the analogy is based solely upon the mathematical equivalence of the interdependence of the computer variables and the variables in the physical system. *See* SIMULATION.

Types. An analog computer is classified either in accordance with its use (general- or specific-purpose) or based on its construction (hydraulic, mechanical, or electronic). General-purpose implies programmability and adaptability to different applications or the ability to solve many kinds of problems. Most electronic analog computers were general-purpose systems, either real-time analog computers in which the results were obtained without any significant time-scale changes, or high-speed repetitive operation computers.

Since the 1970s, digital computer programs have been developed which essentially duplicate the functionality of the analog computer. Modern simulation languages, such as ACSL, GASP, GPSS, SLAM, and Simscript, have replaced electronic analog computers. They provide nearly the same highly interactive and parallel solution capabilities of electronic analog computers, but without the technical shortcomings of electronics: accuracy inherently limited to 0.01%, effective bandwidths of 1 MHz, and cumbersome and time-consuming programming. Simulation languages also avoid the large purchase investments and the continual maintenance dependencies of complex electronic systems.

Another type of analog computer is the digital multiprocessor analog system, in which the relatively slow speeds of sequential digital increment calculations have been radically boosted through parallel processing. In this type of analog computer it is possible to retain the programming convenience and data storage of the digital computer while approximating the speed, interaction potential, and parallel computations of the traditional electronic analogs.

The digital multiprocessor analog computer typically utilizes several specially designed high-speed processors for the numerical integration functions, the data (or variable) memory distributions, the arithmetic functions, and the decision (logic and control) functions. All variables remain as fixed or floating-point digital data, accessible at all times for computational and operational needs.

Description. The typical modern general-purpose analog computer consists of a console containing a collection of operational amplifiers; computing elements, such as summing networks, integrator networks, attenuators, multipliers, and function generators; logic and interface units; control circuits; power supplies; a patch bay; and various meters and display devices. The patch bay is arranged to bring input and output terminals of all programmable devices to one location, where they can be conveniently interconnected by various patch cords and plugs to meet the requirements of a given problem. Prewired problem boards can be exchanged at the patch bay in a few seconds and new coefficients set up typically in less than a half hour. Extensive automatic electronic patching systems have been developed to permit fast setup, as well as remote and time-shared operation.

The analog computer basically represents an instrumentation of calculus, in that it is designed to solve ordinary differential equations. This capability lends itself to the implementation of simulated models of dynamic systems. The computer operates by generating voltages that behave like the physical or mathematical variables in the system under study. Each variable is represented as a continuously varying (or steady) voltage signal at the output of a programmed computational unit. Specific to the analog computer is the fact that individual circuits are used for each feature or equation being represented, so that all variables are generated simultaneously. Thus the analog computer is a parallel computer in which the configuration of the computational units allows direct interactions of the computed variables at all times during the solution of a problem.

Programming. To solve a problem using an analog computer, the problem solver goes through a procedure of general analysis, data preparation, analog circuit development, and patchboard programming. Test runs of subprograms may also be made to examine partial-system dynamic responses before eventually running the full program to derive specific and final answers. The problem-solving procedure typically involves eight major steps, as follows:

1. The problem under study is described with a set of mathematical equations or, when that is not possible, the system configuration and the interrelations of component influences are defined in block-diagram form, with each block described in terms of black-box input-output relationships.
2. Where necessary, the description of the system (equations or system block diagram) is rearranged in a form that may better suit the capabilities of the computer, that is, avoiding duplications or excessive numbers of computational units, or avoiding algebraic (nonintegrational) loops.
3. The assembled information is used to sketch out an analog circuit diagram which shows in detail how the computer could be programmed to handle the problem and achieve the objectives of the study.
4. System variables and parameters are then scaled to fall within the operational ranges of the computer. This may require revisions of the analog circuit diagram and choice of computational units.
5. The finalized circuit arrangement is patched on the computer problem board.
6. Numerical values are set up on the attenuators, the initial conditions of the entire system model established, and test values checked.
7. The computer is run to solve the equations or simulate the black boxes so that the resultant values or system responses can be obtained. This gives the initial answers and the “feel” for the system.
8. Multiple runs are made to check the responses for specific sets of parameters and to explore the influences of problem (system) changes, as well as the behavior which results when the system configuration is driven with different forcing functions.

Hybrid computers. The accuracy of the calculations on a digital computer can often be increased through double precision techniques and more precise algorithms, but at the expense of extended solution time, due to the computer’s serial nature of operation. Also, the more computational steps there are to be done, the longer the digital computer will take to do them. On the other hand, the basic solution speed is very rapid on the analog computer because of its parallel nature, but increasing problem complexity demands larger computer size. Thus, for the analog computer the time remains the same regardless of the complexity of the problem, but the size of the computer required grows with the problem.

Interaction between the user and the computer during the course of any calculation, with the ability to vary parameters during computer runs, is a highly desirable and insight-generating part of computer usage. This hands-on interaction with the computed responses is simple to achieve with analog computers. For digital computers, interaction usually takes place through a computer keyboard terminal, between runs, or in an on-line stop-go mode. An often-utilized system combines the speed and interaction possibilities of an analog computer with the accuracy and programming flexibility of a digital computer. This combination is specifically designed into the hybrid computer.

In a modern analog-hybrid console, the mode switches in the integrators are interfaced with the digital computer to permit fast iterations of dynamic runs under digital computer control. Data flow in many ways and formats between the analog computer with its fast, parallel circuits and the digital computer with its sequential, logic-controlled programs. Special high-speed analog-to-digital and digital-to-analog converters translate between the continuous signal representations of variables in the analog domain and the numerical representations of the digital computer. Control and logic signals are more directly compatible and require only level and timing compatibility. *See* ANALOG-TO-DIGITAL CONVERTER; BOOLEAN ALGEBRA; DIGITAL-TO-ANALOG CONVERTER.

The programming of hybrid models is a more complex challenge than described above, requiring the user to consider the parallel action of the analog computer interlaced with the step-by-step computations progression in the digital computer. For example, in simulating the mission of a space vehicle, the capsule control dynamics will typically be handled on the analog computer in continuous form, but interfaced with the digital computer, where the navigational trajectory is calculated. *See* COMPUTER. [P.A.H.]

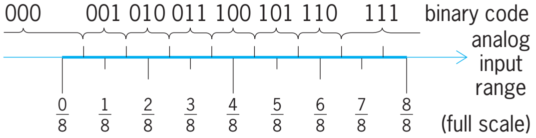
Analog states States in neighboring nuclear isobars that have the same total angular momentum, parity, and isotopic spin. They also have nearly identical nuclear structure wave functions except for the transformation of one or more neutrons into an equivalent number of protons, which occupy the same single-particle states as the neutrons. Analog states (or isobaric analog states, IAS) have been observed throughout the periodic table, indicating that isotopic spin is a good quantum number. *See* ANGULAR MOMENTUM; I-SPIN; NUCLEAR STRUCTURE; PARITY (QUANTUM MECHANICS).

Since the nucleon-nucleon interaction has been found to be approximately charge-independent, it is possible to consider protons and neutrons as representing different charge states of a single particle, that is, a nucleon. Thus, a level (commonly referred to as a parent state) in a nucleus with Z protons and N neutrons can be expected to have an analog in the neighboring isobar with $Z + 1$ protons and $N - 1$ neutrons (and the same total number of nucleons, $A = Z + N$), where the protons and neutrons occupy the same orbits as those in the parent state. The energy difference between the parent and analog states predominantly arises from the increased contribution from the electrostatic Coulomb interaction to the total energy arising from the extra proton in the analog state. From this amount must be subtracted the neutron-proton mass difference of 0.782 MeV (energies are given on the atomic mass scale). The agreement between such calculated energies of analog states and their measured values is in general fairly precise but not exact. The reason is that small additional factors influence the level energies, such as electromagnetic effects, a small charge-dependent nuclear interaction, isospin mixing, and nuclear structure effects.

The study of analog states provides important information used to test nuclear theories. For example, the double charge-exchange reactions (π^+, π^-) [where π^+ and π^- represent a pion with positive and negative charge, respectively] have been used to identify double isobaric analog states, that is, analogs in isobars removed by 2 charge units. Such data have been useful for testing various formulas for predicting the relative masses of isobaric multiplets. Single and double charge-exchange reactions utilizing incident pions have also been used to investigate giant resonances built upon analog states. The single-particle structure of parent states can be studied by observing the particle decay of the analog state when the decay resides in the nuclear continuum. Measurements of the widths of analog states provide information pertaining to their fragmentation, for example, their mixing with states of the same spin and parity but with total isospin lower by one unit. [D.J.Ho.]

Analog-to-digital converter A device for converting the information contained in the value or magnitude of some characteristic of an input signal, compared to a standard or reference, to information in the form of discrete states of a signal, usually with numerical values assigned to the various combinations of discrete states of the signal.

Analog-to-digital (A/D) converters are used to transform analog information, such as audio signals or measurements of physical variables (for example, temperature, force, or shaft rotation) into a form suitable for digital handling, which might involve any of these operations: (1) processing by a computer or by logic circuits, including arithmetical operations, comparison, sorting, ordering, and code conversion, (2) storage until ready for



A three-bit binary representation of a range of input signals.

further handling, (3) display in numerical or graphical form, and (4) transmission.

If a wide-range analog signal can be converted, with adequate frequency, to an appropriate number of two-level digits,or bits, the digital representation of the signal can be transmitted through a noisy medium without relative degradation of the fine structure of the original signal. *See* COMPUTER GRAPHICS; DATA COMMUNICATIONS; DIGITAL COMPUTER.

Conversion involves quantizing and encoding. Quantizing means partitioning the analog signal range into a number of discrete quanta and determining to which quantum the input signal belongs. Encoding means assigning a unique digital code to each quantum and determining the code that corresponds to the input signal. The most common system is binary, in which there are $2n$ quanta (where n is some whole number), numbered consecutively; the code is a set of n physical two-valued levels or bits (1 or 0) corresponding to the binary number associated with the signal quantum.

The illustration shows a typical three-bit binary representation of a range of input signals, partitioned into eight quanta. For example, a signal in the vicinity of 3/8; full scale (between 5/16 and 7/16) will be coded 011 (binary 3). *See* NUMBER SYSTEMS.

[D.H.S.]

Analysis of variance Total variation in experimental data is partitioned into components assignable to specific sources by the analysis of variance. This statistical technique is applicable to data for which (1) effects of sources are additive, (2) uncontrolled or unexplained experimental variations (which are grouped as experimental errors) are independent of other sources of variation, (3) variance of experimental errors is homogeneous, and (4) experimental errors follow a normal distribution. When data depart from these assumptions, one must exercise extreme care in interpreting the results of an analysis of variance. Statistical tests indicate the contribution of the components to the observed variation. *See* STATISTICS. [R.L.Bri.]

Analytic geometry A branch of mathematics in which algebra is applied to the study of geometry; the subject is also called cartesian geometry. The basis for an algebraic treatment of geometry is provided by the existence of a one-to-one correspondence between the elements, "points" of a directed line g, and the elements, "numbers," that form the set of all real numbers. Such a correspondence establishes a coordinate system on g, and the number corresponding to a point of g is called its coordinate. The point O of g with coordinate zero is the origin of the coordinate system. A coordinate system on g is cartesian provided that for each point P of g, its coordinate is the directed distance $\overline{OP}$. Then all points of g on one side of O have positive coordinates (forming the positive half of g) and all points on the other side have negative coordinates. The point with coordinate 1 is called the unit point. Since the relation $\overline{OP} + \overline{PQ} = \overline{OQ}$ is clearly valid for each two points P, Q of directed line g, then $\overline{PQ} = \overline{OQ} - \overline{OP} = q - p$, where p and q are the coordinates of P and Q, respectively.

Choose any two intersecting lines g_1, g_2 of the plane, with cartesian coordinate systems selected on each so that the intersection point has coordinate O in each system. To each point P of the plane an ordered pair of numbers (x,y) is attached as coordinates, where x is the coordinate of the point of intersection of g_l with the line through P parallel to g_2 and y is the coordinate of the point of intersection of g_2 with the line through P parallel to g_1. The lines g, and g_2 are called the x axis and y axis, respectively. It is usually convenient to take the same scale on each axis; that is, the segments joining the unit points on the two axes to the origin are congruent. The notation $P(x,y)$ denotes a point P with coordinates (x,y). If ω denotes the angle made by the positive halves of the two axes, and d the distance between points $P_1(x_1,y_1)$- and $P_2(x_2,y_2)$, application of the law of cosines yields

$$d = [(x_1 - x_2)^2 + (y_1 - y_2)^2 + 2(x_1 - x_2)(y_1 - y_2)\cos\omega]^{1/2}$$

Since $\cos 90^\circ = 0$, this important formula is simplified by taking the axes mutually perpendicular. Though it is occasionally useful to employ oblique axes ($\omega \neq 90^\circ$), the simplifications resulting from a rectangular cartesian coordinate system make it the usual choice. Such a cartesian coordinate system is assumed in what follows. Thus, the distance d between P_1 (x_1,y_1) and $P_2(x_2,y_2)$ is given by $[(x_1 - x_2)^2 + (y_l - y_2)^2]^{1/2}$.

The correspondence between the geometric entity "point" and the arithmetic entity "pair of real numbers," upon which plane analytic geometry is based, results in associating with each geometric locus one or more equations that are satisfied by the coordinates of all those (and only those) points forming the locus (equations of the locus), and in associating with each system of equations in the variables x, y the figure (graph of the equations) whose points are determined by the pairs of numbers satisfying the equations. Thus the algebraic method of studying geometry is balanced by a geometric interpretation of algebra. A central problem in analytic geometry is that of finding equations of certain important figures among curves and surfaces. *See* CURVE FITTING.

By use of the formula for the distance of two points and the definition of a circle, an equation for a circle with center $C(x_0,y_0)$ and radius r ($r \geq 0$) is found to be $(x - x_0)^2 + (y + y_0)^2 = r^2$.

Much of plane analytic geometry deals with a class of curves which (from the way in which they were first studied) are known as conic sections or conics. A conic is the locus of a point P that moves so that its distance from a fixed point F (the focus) is in a constant positive ratio ϵ (the eccentricity) to its distance from a fixed line (the directrix) which is not through F. Let $(c,0)$ be the coordinates of F, $c > 0$, and take the y axis as the directrix. Then $P(x,y)$ satisfies the equation $[(x - c)^2 + y^2]^{1/2} = \epsilon x$; that is, $(1 - \epsilon^2)x^2 + y^2 - 2cx + c^2 = 0$, and it is easily seen that each point whose coordinates satisfy this equation is on the conic. Hence each conic is represented by a second-degree equation in the cartesian coordinates (x,y). A conic is called a parabola, ellipse, or hyperbola accordingly as $\epsilon = 1$, $\epsilon < 1$, $\epsilon > 1$, respectively. *See* CONIC SECTION.

Let cartesian coordinate systems be established on each of three pairwise mutually perpendicular lines of 3-space that intersect in O, the common origin of the systems. Suppose equal scales and call the lines the x axis, y axis, and z axis. To each point P of space an ordered triple (x,y,z) of real numbers is attached as rectangular cartesian coordinates, where x is the coordinate of the foot of the perpendicular from P to the x axis, and y and z are similarly defined. Thus every point of space has unique coordinates, and each ordered triple of real numbers is the coordinates of a point of space. If d denotes the distance between two points $P_1(x_1,y_1,z_1)$ and $P_2(x_2,y_2,z_2)$, then

$$d = [(x_1 - x_2)^2 + (y_1 - y_2)^2 + (z_1 - z_2)^2]^{1/2}$$

It follows from the definition of a sphere and the formula for distance between two points that

$$(x - a)^2 + (y - b)^2 + (z - c)^2 = r^2$$

is an equation for the sphere with center (a,b,c) and radius r, and by completing the squares of the x, y, and z terms in the equation

$$x^2 + y^2 + z^2 + 2Dx + 2Ey + 2Fz + G = 0$$

it is seen that the locus of such an equation is a sphere with positive or zero radius, or there is no (real) locus.

Any equation in just two of the three coordinates is an equation of a cylinder whose elements are parallel to the axis of the missing variable. Thus the locus in 3-space of $x^2 + y^2 = r^2$ is a (right) circular cylinder whose elements are parallel to the z axis and which intersects the xy plane in the circle $x^2 + y^2 = r^2$, $z = 0$.

Any equation $f(x,y,z)$ 0, with $f(x,y,z)$ homogeneous in x, y, z (for example, $4xy - xz + yz = 0$, $x^3 - xy^2 + z^3 = 0$) has a cone with vertex O as locus.

A surface of revolution is obtained by rotating a plane curve C about a line g of its plane. If $f(x,y) = 0$, $z = 0$ are equations of C, and g is the x axis, the resulting surface of revolution has equation $f(x, \sqrt{y^2 + z^2}) = 0$. Thus the surface generated by revolving the circle $x_2 + (y - b)^2 = a^2$, $z = 0$, about the x axis (the torus or anchor ring, if $b > a$) has the equation

$$x^2 + (\sqrt{y^2 + z^2} - b)^2 = a^2$$

A quadric surface is the locus of points whose coordinates satisfy an equation of the form

$$Ax^2 + By^2 + Cz^2 + Dxy + Exz + Fyz + Gx + Hy + Jz + K = 0$$

where at least one coefficient of a second-degree term is not zero. Some surfaces obtained by rotating conics about a line belong to this class, for example, spheres, prolate and oblate spheroids (given by rotating an ellipse about its major and minor axes, respectively), hyperboloids and paraboloids resulting from rotations of hyperbolas and parabolas about their axes of symmetry, and right circular cones and cylinders. Cylinders with conics for directrix curves are also members. [L.M.Bl.]

Analytic hierarchy A framework for solving a problem. The analytic hierarchy process is a systematic procedure for representing the elements of any problem. It organizes the basic rationality by breaking down a problem into its smaller constituents and then calls for only simple pairwise comparison judgments, to develop priorities in each level.

The analytic hierarchy process provides a comprehensive framework to cope with intuitive, rational, and irrational factors in making judgments at the same time. It is a method of integrating perceptions and purposes into an overall synthesis. The analytic hierarchy process does not require that judgments be consistent or even transitive. The degree of consistency (or inconsistency) of the judgment is revealed at the end of the analytic hierarchy process.

Scale of relative Importance

Intensity of relative importance	Explanation
1 (equal importance)	Two activities contribute equally to the objective
3 (slight importance of one over another)	Experience and judgment slightly favor one activity over another
5 (essential or strong importance)	Experience and judgment strongly favor one activity over another
7 (demonstrated importance)	An activity is strongly favored and its dominance is demonstrated in practice
9 (absolute importance)	The evidence favoring one activity over another is of the highest possible order of affirmation
2, 4, 6, 8 (intermediate values between the two adjacent judgments)	When compromise is needed
Reciprocals of above nonzero numbers (if an activity has one of the above numbers assigned to it when compared with second activity, the second activity has the reciprocal value when compared to the first)	

People making comparisons use their feelings and judgment. Both vary in intensity. To distinguish among different intensities, the scale of absolute numbers in the table is useful.

The analytic hierarchy process can be decomposed into the following steps. Particular steps may be emphasized more in some situations than in others. Also as noted, interaction is generally useful for stimulation and for representing different points of view.

1. Define the problem and determine what knowledge is sought.
2. Structure the hierarchy from the top (the objectives from a broad perspective) through the intermediate levels (criteria on which subsequent levels depend) to the lowest level (which usually is a list of the alternatives).
3. Construct a set of pairwise comparison matrices for each of the lower levels, one matrix for each element in the level immediately above. An element in the higher level is said to be a governing element for those in the lower level since it contributes to it or affects it. In a complete simple hierarchy, every element in the lower level affects every element in the upper level. The elements in the lower level are then compared to each other, based on their effect on the governing element above. This yields a square matrix of judgments. The pairwise comparisons are done in terms of which element dominates the other. These judgments are then expressed as integers according to the judgment values in the table. If element A dominates element B, then the whole number integer is entered in row A, column B, and the reciprocal (fraction) is entered in row B, column A.
4. There are $n(n - 1)/2$ judgments required to develop the set of matrices in step 3, where n is the number of elements in the lower level.
5. Having collected all the pairwise comparison data and entered the reciprocals together with n unit entries down the main diagonal, the eigenvalue problem $Aw = \lambda_{\max} w$ is solved and consistency is tested, using the departure of $\lambda_{\max}$ from n (see below).
6. Steps 3, 4, and 5 are performed for all levels and clusters in the hierarchy.
7. Hierarchal composition is now used to weigh the eigenvectors by the weights of the criteria, and the sum is taken over all weighted eigenvector entries corresponding to those in the lower level of the hierarchy.
8. The consistency ratio of the entire hierarchy is found by multiplying each consistency index by the priority of the corresponding criterion and adding them together. The result is then divided by the same type of expression, using the random consistency index corresponding to the dimensions of each matrix weighted by the priorities as before. The consistency ratio should be about 10% or less to be acceptable. If not, the quality of the judgments should be improved, perhaps by revising the manner in which questions are asked in making the pairwise comparisons. If this should fail to improve consistency, it is likely that the problem should be more accurately structured; that is, similar elements should be grouped under more meaningful criteria. A return to step 2 would be required, although only the problematic parts of the hierarchy may need revision. *See* DECISION THEORY; SYSTEMS ENGINEERING. [T.L.S.]

Analytical chemistry The science of chemical characterization and measurement. Qualitative analysis is concerned with the description of chemical composition in terms of elements, compounds, or structural units, whereas quantitative analysis is concerned with the measurement of amount.

Analytical chemistry, once limited to the determination of chemical composition in terms of the relative amounts of elements or compounds in a sample, has been expanded to involve the spatial distribution of elements or compounds in a sample, the distinction between different crystalline forms of a given element or compound, the distinction between different chemical forms (such as the oxidation state of an element), the distinction between a component on the surface or in the interior of a particle, and the detection of single atoms on a surface. To permit these more detailed questions to be answered, as well as to improve the speed, accuracy, sensitivity, and selectivity of traditional analysis, a large variety of physical measurements are used. These methods are based on spectroscopic, electrochemical, chromatographic, chemical, and nuclear principles.

Modern analysis has also placed significant demands on sampling techniques. It has become necessary, for example, to handle very small liquid samples [in the nanoliter (10^{-9} liter) range or less] as part of the analysis of complex mixtures such as biological fluids and to simultaneously determine many different components. The sample may be a solid that must be converted through vaporization into a form suitable for analysis.

Spectroscopy includes the measurement of emission, absorption, reflection, and scattering phenomena resulting from interaction of a sample with gamma rays and x-rays at the high-energy end of the spectrum and with the less energetic ultraviolet, visible, infrared, and microwave radiation. *See* SPECTROSCOPY.

Lower-energy forms of excitation such as ultraviolet, visible, or infrared radiation are used in molecular spectroscopy. Ultraviolet radiation and visible radiation, which are reflective of the electronic structure of molecules, are used extensively for quantitative analysis. The radiation absorbed by the sample is measured. It is also possible to measure the radiation emitted (fluorescence). The absorption of infrared radiation is controlled by the properties of bonds between atoms, and it is accordingly most widely used for structure identification and determination. It is not widely used for quantitative analysis except for gases such as carbon monoxide (CO) and hydrocarbons. X-rays are used through emission of characteristic radiation, absorption, or diffraction. In the last case, characteristic diffraction patterns reveal information about specific structural entities, such as a particular crystalline form. Extended x-ray absorption fine structure (EXAFS) is based on the use of x-rays from a synchrotron source to reveal structural details such as interatomic distances. *See* INFRARED SPECTROSCOPY; X-RAY FLUORESCENCE ANALYSIS.

Though not strictly a spectroscopic technique, mass spectrometry is an important and increasingly applied method of analysis, especially for organic and biological samples. Among the applications are the analysis of more than 70 elements (spark-source mass spectrometry), surface analysis (secondary ion mass spectrometry and ion-probe mass spectrometry), and the determination of the structure of organic molecules and of proteins and peptides (high-resolution mass spectrometry). *See* MASS SPECTROMETRY.

Nuclear magnetic resonance measures the magnetic environment around individual atoms and provides one of the most important means for deducing the structure of a molecule. Atoms possessing nuclear spin are probed by monitoring the interaction between their nuclear spin and an applied external magnetic field. For large molecules these interactions are complex, and a variety of nuclear excitation techniques have been developed that permit establishment of the connectivity between the various atoms in a molecule. Since the technique is nondestructive, it can be used to monitor living systems. *See* NUCLEAR MAGNETIC RESONANCE (NMR).

Several forms of spectroscopy are especially useful for surface analysis. The scanning electron microscope (SEM) involves a finely collimated electron beam that sweeps across the surface to produce an image. At the same time the surface atoms are excited to emit characteristic x-rays, thus making it possible to obtain an image of the surface along with its spatially resolved elemental composition. The resolution of this technique (electron microprobe) is in the micrometer (10^{-4} cm) range. Images with a resolution of angstroms (10^{-8} cm) have been obtained by using the techniques of atomic force microscopy (AFM) and scanning tunneling microscopy (STM), which correspond to the dimensions of individual atoms. A significant advantage of the latter two techniques is that a high vacuum is not required, so samples can be analyzed at atmospheric pressure. *See* ELECTRON-PROBE MICROANALYSIS; ELECTRON SPECTROSCOPY.

Potentiometry is the most widely applied electrochemical technique, since it includes a variety of ion-selective electrodes, the most important of which is the glass electrode used to measure pH. Other important ion-selective electrodes measure ions of sodium, potassium, calcium, sulfide, chloride, and fluoride. When the electrodes are used in conjunction with gas-permeable membranes, gases such as ammonia, carbon dioxide, and hydrogen sulfide can be measured. *See* ELECTROCHEMISTRY; PH. [H.A.L.; G.S.W.]

Separation techniques include the various forms of chromatography and electrophoresis. They are based on the separation of a mixture of species in a sample due to differential migration. Two forces act in opposition: a stationary phase acts to retard a migrating species, while the mobile phase tends to promote migration. The mobile phase may be liquid (liquid chromatography) or gaseous (gas chromatography), while the stationary phase may be a solid or a solid covered with a thin film of liquid. The stationary phase is typically packed in a column through which the mobile phase is pumped. High-performance liquid chromatography (HPLC) has become especially important for the separation of complex mixtures of nonvolatile materials. Separations may often be accomplished in a matter of several minutes. The stationary phase can preferentially interact with the migrating species according to charge, size, hydrophobicity, or in some cases because of the special affinity which a species has for the stationary phase (affinity chromatography). The stationary phase can also be a thin layer of solid support deposited on a plate (thin-layer chromatography). *See* CHROMATOGRAPHY.

Alternatively, the driving force for separation will be the migration of charged species in an electric field (electrophoresis). The stationary phase may be a gel on a plate or in a tube, or a solution maintained in a capillary through which the analytes move. The important techniques in this area are capillary electrophoresis, isotachophoresis, and isoelectric focusing. *See* ELECTROPHORESIS.

Thermal methods are based on the heating of a sample over a range of temperatures. This approach may result in absorption of heat by the sample or in evolution of heat due to physical or chemical changes. Thermogravimetry involves the measurement of mass; differential thermal analysis involves a detection of chemical or physical processes through a measurement of the difference in temperature between a sample and a stable reference material; differential thermal calorimetry evaluates the heat evolved in such processes. A variety of calorimetric techniques are used to measure the extent of reactions that are otherwise difficult to evaluate. *See* CALORIMETRY. [G.S.W.]

Anamnia Those vertebrate animals, sometimes called Anamniota, which lack an amnion in development. The amnion is a protective embryonic envelope that encloses the embryo and its surrounding liquid, the amniotic fluid, during fetal life. An amnion is present in mammals, birds, and reptiles (collectively called the Amniota), but is absent in fishes and amphibians. *See* AMNION; AMNIOTA; AMPHIBIA; PISCES (ZOOLOGY). [R.M.B.]

Anaphylaxis A generalized or localized tissue reaction occurring within minutes of an antigen-antibody reaction. Similar reactions elicited by nonimmunologic mechanisms are termed anaphylactoid reactions. In humans, the clinical manifestations of anaphylaxis include reactions of the skin with itching, erythema, and urticaria; the upper respiratory tract with edema of the larynx; the lower respiratory tract with dyspnea, wheezing, and cough; the gastrointestinal tract with abdominal cramps, nausea, vomiting, and diarrhea; and the cardiovascular system with hypotension and shock. Individuals undergoing anaphylactic reactions may develop any one, a combination, or all of the signs and symptoms. Anaphylaxis may be fatal within minutes, or may occur days or weeks after the reaction, if the organs sustained considerable damage during the hypotensive phase.

Anaphylaxis in humans is most often the result of the interaction of specific IgE antibody fixed to mast cells and antigen. Two molecules of IgE are bridged by the antigen, which may be a complex protein or chemical (hapten) bound to protein. The antigen-antibody interaction leads to increased cell-membrane permeability, with influx of calcium and release of either preformed or newly formed pharmacologic mediators from the granules. Preformed mediators include histamine and eosinophilic or neutrophilic chemotactic factors. Newly formed molecules include leukotrienes or slow-reacting substance of anaphylaxis and prostaglandins. The mediator action induces bronchoconstriction, vasodilation, cellular infiltration, and increased mucus production.

Another mechanism for induction of anaphylaxis in humans occurs when antigen binds to preformed IgG antibody and complement components interact with the antigen-antibody complex. The early components of the complement system bind to the antibody molecule, leading to activation of other complement components. During the activation, components known as anaphylatoxins (C3a and C5a) are released which may directly cause bronchoconstriction with respiratory impairment, and vasodilation with hypotension or shock. *See* COMPLEMENT; EICOSANOIDS.

Anaphylaxis due to IgE mechanisms has been associated with foreign proteins such as horse antitoxins, insulin, adrenocorticotropic hormone (ACTH), protamine, and chymopapain injected into herniated discs; drugs such as penicillin and its derivatives; foods such as shellfish, nuts, and eggs; and venom of stinging insects. Anaphylaxis mediated by IgG is seen in blood-transfusion reactions and following the use of cryoprecipitate, plasma, or immunoglobulin therapy.

After the identification of the inciting agent for the anaphylactic reaction, prevention is the best mode of therapy. Immunotherapy with insect venom and desensitization with certain drugs are effective prophylactic measures. Individuals with recurrent episodes of anaphylaxis, when the etiological cause is unknown and preventive measures are impractical, should be provided with epinephrine in a form that can be self-administered whenever symptoms occur. *See* EPINEPHRINE.

The treatment of anaphylaxis is aimed at reducing the effect of the chemical mediators on the end organs and preventing further mediator release. The drug of choice for this is epinephrine given subcutaneously in repeated doses. Additionally, a clear airway and appropriate oxygenation must be maintained; hypotension should be treated, as should any cardiac arrhythmia. *See* ANTIGEN-ANTIBODY REACTION; HYPERSENSITIVITY; SHOCK SYNDROME. [S.B.Se.; J.N.F.]

Anaplasmosis A disease of ruminants caused by a specialized group of gram-negative bacteria of the order Rickettsiales, family Anaplasmataceae, genus *Anaplasma*. *Anaplasma* is an obligate intracellular parasite infecting erythrocytes of cattle, sheep, goats, and wild ruminants in most of the tropical and subtropical world. The most important species is *A. marginale*, which causes anemia and sometimes death in cattle. Anaplasmosis is one of the most important diseases of cattle and results in significant economic losses. *See* RICKETTSIOSES.

Transmission of *Anaplasma* occurs biologically by species of hard ticks. Rickettsiae are ingested with a blood meal and undergo complex development beginning in the tick gut. *Anaplasma* is transmitted from the salivary glands while ticks feed. Mechanical transmission occurs when the mouthparts of biting flies become contaminated while feeding on infected cattle and then quickly move to uninfected animals. Contaminated needles and instruments for dehorning, castration, and tagging may also transmit the organism throughout a herd.

The average prepatent period is 21 days postinfection, but animals may not exhibit clinical disease for as long as 60 days after infection. In acute anaplasmosis, cattle exhibit depression, loss of appetite, increased temperature, labored breathing, dehydration, jaundice, and a decrease in milk production. Death may result from severe anemia, and abortions may occur. Recovered animals gradually regain condition but remain chronically infected and are subject to periodic relapses.

The clinical manifestations of anaplasmosis can be halted or prevented if tetracycline antibiotics are administered early. The drug inhibits rickettsial protein synthesis but does not kill the organism. Tetracyclines may also be added to feeds to prevent clinical symptoms. Controlling fly and tick populations by chemical spraying or dipping may be used to reduce the spread of disease. Vaccination with killed *A. marginale* from erythrocytes provides protection against the acute disease but does not prevent infection. Boosters must be given annually. The less virulent species, *A. centrale*, is used as a live vaccine in some countries and provides some protection against *A. marginale*, but it can revert to a virulent form. *See* ANTIBIOTIC; VACCINATION.

Once cattle are infected with *Anaplasma*, they remain persistently infected and may serve as reservoirs of infection for other cattle or tick vectors. During this time the parasitemia fluctuates and at times may be undetectable. The spread of anaplasmosis may occur when these carrier cattle are moved to nonendemic areas. Ticks have been shown to transmit new infections after feeding on animals with undetectable parasitemias. Carrier animals may also have relapse infections, producing new herd infections.

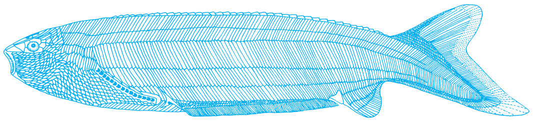
Cattle which recover from clinical anaplasmosis are protected from subsequent exposure to the same geographic strain of *Anaplasma*. Calves have a natural immunity to clinical disease if exposed within their first year. Protection is attributed to a complex combination of antibody and cell-mediated responses. *See* ANTIBIOTIC; IMMUNITY. [E.F.B.]

Anapsida A subclass of reptiles characterized by a roofed temporal region in which there are no temporal fenestrations. Chelonia (turtles), with living representatives, and the extinct Cotylosauria are the two major subdivisions of this subclass. The Mesosauria, an extinct group of aquatic reptiles from the early Permian, have been included, but the assignment is far from certain.

Among the cotylosaurs are found the most primitive known reptiles, which date from the Early Pennsylvanian. These forms and their immediate descendants flourished in the Permian and Triassic periods of the late Paleozoic and early Mesozoic eras, respectively. Turtles first appear as fossils in Triassic rocks and are well represented in the fossil record from that time to the present. Throughout their history anapsids have, for the most part, inhabited areas close to water, with some exceptions among the turtles, and many of them have been semiaquatic in habitat and adaptations. *See* MESOSAURIA. [E.C.O.]

Anaspida An extinct order of fresh- or brackish-water Agnatha, known from the Upper Silurian of Europe and Canada and from the Upper Devonian of Canada. The Middle Silurian Scottish *Jamoytius* is thought by some to be an anaspid.

Members of this group are small, not exceeding 10 in. (25 cm) in length, and typically have a slender, fusiform body covered with small scales and a rounded, jawless, terminal or sub-terminal mouth (see illustration). Long paired fins are present, at least in some genera, and the tail is unusual in having the muscular lobe turned downward. They were probably active, nectonic swimmers, adapted for feeding on minute particles.



Pharyngolepsis oblongus of the Anaspida, reconstruction. (*After A. Ritchie*)

A relationship to Osteostraci and Petromyzonida is indicated by the single dorsal nostril lying in front of the pineal eye and between the large paired eyes and by the paired rows of circular gill openings; all three orders are grouped in the superorder Hyperoartii. Anaspida are possibly ancestral to living lampreys. *See* OSTEOSTRACI; PETROMYZONTIDA. [R.H.De.]

Anatomy, regional The detailed study of the anatomy of a part or region of the body of an animal, most commonly applied to regional human anatomy. This is in contrast, but supplementary, to study of organ systems where all the structures pertaining to the system are studied in their continuity.

There are many methods of dividing the body into regions for study, and one such means of classification is shown in the illustration. This system includes only externally visible areas; other systems would include special internal regions as well.

The head, trunk, and extremities are the principal regions. Subdivision of these can be carried out, as illustrated, so that many distinct areas or especially vital regions are indicated. There is no end to the dividing and subdividing a specialist may do to make the task eventually less difficult. [T.S.P.]

Andalusite A nesosilicate mineral, composition Al_2SiO_5, crystallizing in the orthorhombic system. It occurs commonly in large, nearly square prismatic crystals. There is poor prismatic cleavage; the luster is vitreous and the color red, reddish-brown, olive-green, or bluish. Transparent crystals may show strong dichroism, appearing red in one direction and green in another in transmitted light. The specific gravity is 3.1–3.2; hardness is 7.5 on Mohs scale, but may be less on the surface because of alteration. *See* SILICATE MINERALS.

Andalusite was first described in Andalusia, Spain, and was named after this locality. It is found abundantly in the White Mountains near Laws, California, where for many years it was mined for manufacture of spark plugs and other highly refractive porcelain. Chiastolite, in crystals largely altered to mica, is found in Lancaster and Sterling, Massachusetts. Water-worn pebbles of gem quality are found at Minas Gerais, Brazil. [C.S.Hu.]

Andesine A plagioclase feldspar with composition $Ab_{70}An_{30}$ to $Ab_{50}An_{50}$ ($Ab = NaAlSi_3O_8$; $An = CaAl_2Si_2O_8$). Andesine occurs primarily in igneous rocks, often in a glassy matrix as small, chemically zoned, lathlike crystals known as microlites. The rock types may be called andesinites (if dominantly feldspar), andesites, andesitic basalts (or olivine-bearing andesites, as in Hawaiian lava flows), or pyroxene-, hornblende- or biotite-andesites (all are volcanic). *See* ANDESITE; FELDSPAR; IGNEOUS ROCKS.

The symmetry of andesine is triclinic, hardness on the Mohs scale 6, specific gravity 2.69, melting point $\sim 1210°C$ ($2210°F$). If quenched at very high temperatures, andesine has an albitelike structure, with aluminum (Al) and silicon (Si) essentially disordered in the structural framework of the crystals. But, in the course of cooling, most natural andesines develop an Al-Si ordered structure called e-plagioclases. *See* ALBITE; CRYSTAL STRUCTURE.

Calcic andesines and labradorites ($Ab_{55}An_{45}$-$Ab_{40}An_{60}$) may exsolve into two distinctly intergrown lamellar phases whose regularity of stacking produces beautiful interference colors like those in the feathers of a peacock. Polished specimens of this material are called spectrolite in the gem trade, and at some localities (notably eastern Finland) crystals up to 10 in. (25 cm) are mined by hand. Smaller crystals are made into cabochons for jewelry. They may be abundant enough in the host rock to be valued as a decorative stone. *See* GEM; LABRADORITE. [P.H.R.]

Andesite A typical volcanic rock erupted from a volcano associated with convergent plate boundaries. The process of subduction, which defines convergent plate boundaries, pushes oceanic lithosphere beneath either oceanic lithosphere or continental lithosphere. Andesites are the principal rocks forming the volcanoes of the "ring of fire," the arcuate chains of volcanoes which rim the Pacific Ocean basin. The Marianas and Izu-Bonin islands, the islands of Japan, the Aleutian Islands, the Cascades Range of the northwest United States, the Andes mountain chain of South America, and the Taupo Volcanic Zone of New Zealand are andesitic. *See* LITHOSPHERE; PLATE TECTONICS; VOLCANO.

Andesites are mostly dark-colored vesicular volcanic rocks which are typically porphyritic (containing larger crystals set in a fine groundmass). Phenocrysts (the larger crystals) comprise plagioclase; calcium-rich, calcium-poor pyroxene; and iron-titanium oxides set in a fine-grained, frequently glassy, groundmass. Some andesites contain phenocrysts of olivine, and some contain amphibole and biotite; these latter rocks generally contain more potassium. The porphyritic nature of andesites is derived from a complicated history of magmatic crystallization and evolution as the melts rise toward the surface from deep in the Earth. Phenocryst minerals commonly are strongly zoned and show evidence for disequilibrium during growth, consistent with an origin involving crystal fractionation and mixing processes. Andesites are readily classified in terms of their silicon dioxide (SiO_2) content, between 53 and 63 wt %, and potassium oxide (K_2O) content at a given SiO_2 content. They can also be readily discriminated on a total alkali versus SiO_2 diagram. Most andesite volcanoes erupt lavas and tephras (volcanic ash) which range in composition from basaltic andesite to dacite. Eruptions are often explosive, reflecting the relatively high water and gas content of the magmas. Pyroclastic flows are a particular feature of andesite-type volcanism and are among the most dangerous of volcanic hazards. *See* BASALT; LAVA; PYROCLASTIC ROCKS. [J.Ga.]

Andreaeopsida A class of the plant division Bryophyta, containing plants commonly called granite mosses. The class consists of one order and two families, the Andreaeobryaceae and the Andreaeaceae. The large tapered foot and short, massive seta of the Andreaeobryaceae show possible linkage to the Bryopsida, but the differences seem more fundamental and more significant than the similarities. The small, brittle plants grow as perennials on rocks in montane regions in dark red, red-brown, or blackish tufts. The stems are erect, simple or forked, and grow from a single apical cell with three cutting faces; they consist of a homogeneous tissue of thick-walled cells. The rhizoids are multicellular and filamentous or platelike. The leaves are spirally arranged, of various shapes and with or without a midrib. The leaf cells are thick-walled and often papillose. Paraphyses are present in both male and female inflorescences. *See* ANTHOCEROTOPSIDA; BRYOPHYTA; BRYOPSIDA; HEPATICOPSIDA; SPHAGNOPSIDA. [H.C.]

Androgen One of a class of steroid hormones. Androgens play a major role in the development and maintenance of masculine secondary sexual characters, for example, the seminal vesicle and prostate gland of the male mammal, and the comb, wattles, and spur of the male fowl. They also influence certain other secondary sexual characters, such as hair growth pattern and voice quality in humans. In the fowl, they affect the pattern and seasonal coloration of its feathers, as well as crowing. In addition, androgens affect nitrogen metabolism (anabolic). Androgens are produced in the testis, ovary, adrenal, and most likely, in the placenta. A small portion of the androgen is from corticoids, or adrenal cortex steroids, and from other C_{21} steroids, such as progesterone. *See* HORMONE; OVARY; PROGESTERONE; STEROID; TESTIS. [R.I.D.]

Andromeda Galaxy The spiral galaxy of type Sb nearest to the Milky Way system. This galaxy is a member of a small cluster of galaxies known as the Local Group. This group contains also the Milky Way system, the Triangulum Nebula (M33), the Large and Small Magellanic Clouds, NGC 6822, and several faint dwarf elliptical galaxies.

The Andromeda Galaxy M31 or NGC 224 is particularly important because it is close enough for its stellar and other content to be studied in great detail. The approximate distance to M31 is known from the apparent luminosities of the cepheid variable stars. The period-luminosity relation for cepheids, combined with the apparent brightness of these stars, gives a distance of about 2,500,000 light-years. All studies show that M31 is typical of other regular spiral galaxies of the Sb class. *See* CEPHEIDS; MILKY WAY GALAXY. [A.Sa.]

Anechoic chamber A room whose boundaries absorb effectively all the waves incident on them, thereby providing free-field conditions. A free field is a field whose boundaries exert negligible effect on the incident waves. In practice, it is a field in which the effects of the boundaries are negligible over the frequency range of interest. Acoustic chambers and radio-frequency and microwave chambers are examples.

Acoustic chambers. An acoustic anechoic chamber is a room in which essentially an acoustic free field exists. It is sometimes referred to as a free-field or dead room.

Free-field conditions can be approximated when the absorption by the boundaries of the room approaches 100%. To reduce sound reflected by the boundaries to a minimum, the absorption coefficient must be very high and the surface areas of the boundaries should be large.

The sound absorptive material usually installed in such rooms consists of glass fibers held together with a suitable binder. In order to achieve large surface area, a wall construction is used that includes wedges of sound absorptive material, the base of which is usually between 8 × 8 in. (20 × 20 cm) and 8 × 24 in. (20 × 60 cm), and the length of which is usually 3 to 5 ft (0.9 to 1.5 m). These wedges resemble stalagmites and stalactites and absorb about 99% of incident sound energy over most of the audio-frequency ranges. A horizontal net of thin steel cables just above floor wedges permits walking in the room. *See* REFLECTION OF SOUND; SOUND ABSORPTION. [C.M.H.]

Radio-frequency and microwave chambers. The radio-frequency or microwave anechoic chamber is a shielded (screened) enclosure in which internal reflections of electromagnetic waves are reduced to an absolute minimum, thus providing a zone that is free from radio noise, broadcast transmissions, and other extraneous signals, and that simulates free-space conditions. Its main use is to provide a controlled and well-defined environment for the testing of electronic equipment.

Shielded or screened enclosures may vary in size from small metallic boxes that are intended for the protection of circuit elements to large rooms capable of housing vehicles or aircraft. The purpose of such enclosures is to isolate sources of electromagnetic energy from electronic, radio, or other sensitive equipment which might suffer degradation of performance as a result of interaction with transmitters, radio-frequency heating equipment, and so forth. The provision of a radio-frequency quiet zone is an essential feature of many applications in electromagnetic tests and investigations, for example, the determination of antenna characteristics and the measurement of low-level emissions during electromagnetic compatibility assessments. *See* ELECTRICAL SHIELDING; ELECTROMAGNETIC COMPATIBILITY; MICROWAVE FREE-FIELD STANDARDS.

The attempt to reproduce free-space or open-field conditions within a shielded enclosure has led to the development of resistive material to line the enclosure walls to absorb rather than reflect the radio-frequency energy and hence create an anechoic chamber. Such material must have good basic dielectric properties, with a relative permittivity near unity to minimize reflection at the interface, and to incorporate increasing resistive loss through the material. In practice, foam plastics are ideal for the purpose, and these can be readily loaded with carbon, ferrite, or other conducting particles on a graded or layer basis to provide the increasing loss. *See* ABSORPTION OF ELECTROMAGNETIC RADIATION; CAVITY RESONATOR; DIELECTRIC MATERIALS; ELECTROMAGNETIC RADIATION; PERMITTIVITY; RECIPROCITY PRINCIPLE; REFLECTION OF ELECTROMAGNETIC RADIATION. [G.A.J.]

Anemia A reduction in the total quantity of hemoglobin or of red blood cells (erythrocytes) in the circulation. Because it generally is impractical to measure the total quantity, measures of concentration are used instead. Hemoglobin is contained in red blood cells, which are suspended in plasma, the liquid component of blood. Therefore, concentration is affected not only by quantities of hemoglobin and red blood cells but also by plasma volume. Thus, the apparent anemia found in many women in the third trimester of pregnancy is not really anemia at all: the red cell mass is actually increased, but the plasma volume is expanded even more. In other words, hemodilution is present. Conversely, in dehydration and other circumstances of hemoconcentration, the plasma volume is reduced, thereby tending to mask anemia. *See* BLOOD; HEMOGLOBIN.

The three measures of concentration most often employed are the hemoglobin, the red blood cell count, and the volume of packed red cells. In a group of healthy individuals, the values for hemoglobin, red cell count, and hematocrit approximate a "normal" distribution. Values that are less than 2.5 standard deviations below the mean are indicative of anemia if other clinical factors do not indicate a condition of hemodilution. The mean values are greater for adult males than for adult females, and greater for adults than children. (Lower atmospheric oxygen tension at higher altitudes results in higher mean values for hemoglobin, red cells, and hematocrit in healthy individuals living under these conditions; hence, anemia would be defined at a higher value). In the state of health, the rate of production of new red blood cells (erythropoiesis) equals the rate of removal of senescent red blood cells. Anemia occurs if the rate of erythropoiesis is reduced below normal. It also occurs if hemorrhage or destruction (hemolysis) of red blood cells within the body increases the rate of loss of erythrocytes and the rate of erythropoiesis does not increase enough to compensate.

Mechanisms. Red blood cell production may be affected by several different mechanisms. Erythropoietin, a growth factor produced by healthy kidneys, stimulates the bone marrow to produce more erythroblasts and accelerates their maturation. The proliferative response of the bone marrow to anemia may be defective or absent if the production of erythropoietin is diminished or absent, as occurs in chronic renal disease and some endocrine disorders. Ineffective erythropoiesis also results when, in the intact, stimulated bone marrow, red blood cell precursors either fail to mature, or die in the bone marrow prior to their delivery to the circulation as erythrocytes.

Aplastic anemia occurs when the bone marrow stem cells that give rise to precursors of erythroblasts are markedly diminished in number or respond inadequately to erythropoietin. This condition occurs when the bone marrow is adversely affected by certain chemicals or autoantibodies; is injured by irradiation; atrophies, or is replaced by fat; is replaced by fibrous (scar) tissue; or is infiltrated by cancer cells.

Defective synthesis of deoxyribonucleic acid (DNA) and abnormal nuclear maturation result from malabsorption of vitamin B_{12} (as in pernicious anemia) or dietary deficiency of folic acid or its malabsorption (sprue). These anemias are generally characterized by large red blood cells (macrocytes) and a specific morphological abnormality of the nuclear chromatin of erythroblasts which characterizes them as megaloblasts, and the condition as megaloblastic anemia.

Defective synthesis of hemoglobin impairs cytoplasmic maturation. The majority of cases are due to deficiency of body stores of iron and to abnormal release of iron from reticuloendothelial stores. The former occurs in iron-deficiency anemia, and the latter in the anemia of chronic inflammatory diseases.

Acute blood loss reduces the total blood volume and produces symptoms of weakness, dizziness, thirst, faintness, and shock, in that order, according to increasing magnitude of blood loss. The anemia which results is not detectable by measures of concentration until hemodilution occurs over subsequent days, or more rapidly if replacement fluids are given intravenously. The proliferative response of the healthy marrow will correct the anemia in 2–6 weeks, depending upon the size of the deficit and provided there are sufficient body stores of iron, folic acid, and vitamin B_{12}, required for hemoglobin synthesis. Chronic blood loss results in iron-deficiency anemia.

Hemolysis, the accelerated destruction of red blood cells, also induces a proliferative response from the marrow. However, it differs from hemorrhage because red blood cells are lost without plasma, and it thus diminishes the measures of concentration at the outset.

Diagnosis and treatment. Pallor, weakness, and fatigue are common to all anemias. They may not be noticed until anemia is advanced, if it is of gradual onset and there has been time for cardiovascular and biochemical adaptation. Faint jaundice in the sclerae is a feature of hemolytic anemia, whereas in anemia due to lack of vitamin B_{12}, glossitis and neuropathy may be noted.

Macrocytic anemias are often found to be megaloblastic and due to deficiency of vitamin B_{12} or folic acid. Administration of one of those vitamins will only cure individuals in whom its specific deficiency is established. Microcytic-hypochromic anemias are most often due to iron deficiency. The administration of iron will resolve iron-deficiency anemia. Prednisone and other adrenal corticosteroids are helpful in hemolytic anemias associated with autoantibodies.

Hereditary disorders are generally not amenable to therapy, except for those hemolytic diseases which may benefit after splenectomy. In all other cases, the treatment of the anemia is achieved by treating the underlying disease, such as hypothyroidism, rheumatoid arthritis, or leukemia. Blood transfusions are reserved for acute blood loss when symptoms of hypovolemia and shock are present, or in chronic anemia if there are signs of inadequate cardiovascular or pulmonary compensation and an underlying cause cannot be found or treated. *See* CLINICAL PATHOLOGY; HEMATOLOGIC DISORDERS. [A.H.]

Anemometer An instrument to measure the speed or velocity of gases either in a contained flow, such as airflow in a duct, or in unconfined flows, such as atmospheric wind. To determine the velocity, an anemometer detects change in some physical property of the fluid or the effect of the fluid on a mechanical device inserted into the flow.

An anemometer can measure the total velocity magnitude, the velocity magnitude in a plane, or the velocity component in a particular direction. The cup anemometer, for example, measures the velocity in a plane perpendicular to the axis of its rotation cups. If the cup anemometer is mounted with the shaft perpendicular to the horizontal, it will measure only the component of the wind that is parallel to the ground. Other anemometers, such as the pitot-static tube, are used with the tip aligned with the total velocity vector. Before using an anemometer, it is important to determine how it should be positioned and what component of the total velocity its measurement represents. *See* FLOW MEASUREMENT.

An anemometer usually measures gas flows that are turbulent. The cup anemometer, pitot-static tube, and thermal anemometer are mostly used to measure the mean velocity, while the hot-wire, laser Doppler, and sonic anemometers are usually used when turbulence characteristics are being measured. (The term "thermal anemometer" is often used to mean any anemometer that uses a relationship between heat transfer and velocity to determine velocity.) [D.E.St.]

Anesthesia Loss of sensation with or without loss of consciousness. There are several ways of producing anesthesia, with the choice dependent on the type of surgery and the medical condition and preference of the patient.

During general anesthesia a state of complete insensitivity or unconsciousness is produced when anesthetic gases are inhaled; adjuvant drugs are often given intravenously. Although the mechanism of general anesthesia is unknown, the anesthetics act on the upper reticular formation of neurons in the thalamus and midbrain (neuronal structures necessary for activating the cerebral cortex and maintaining an active, attentive state).

Analgesia, without loss of consciousness, results from injecting a solution of local anesthetic drug either into the cerebrospinal fluid surrounding the spinal cord (spinal anesthesia) or into the epidural space surrounding the cerebrospinal fluid (epidural anesthesia). The local anesthetic acts by blocking the conduction of nerve impulses. Narcotic opioids are injected postoperatively into either the epidural space or cerebrospinal fluid for pain relief.

Analgesia can be localized to a small area, for example, the forearm, by injecting a local anesthetic solution around nerves supplying the area (the bracheal plexus in the upper arm and chest supplies the forearm). Large peripheral nerves may also be blocked individually by using this method.

Acupuncture is an ancient procedure, once used only in China but now practiced in the United States and elsewhere. It involves inserting needles into specific points around the body, as determined from historical charts, and manipulation of the needles; sometimes electric current is applied. Weak analgesia results through alteration of pain perception. Although sometimes helpful for chronic pain, acupuncture generally has not been found satisfactory for surgical anesthesia. *See* CENTRAL NERVOUS SYSTEM; PAIN. [F.K.O.]

Aneurysm A localized, abnormal arterial dilation usually caused by a weakening of the vessel wall. Aneurysms are commonly found in the abdominal aorta, intracranial arteries, and thoracic aorta; however, they may also involve the femoral, popliteal, splenic, carotid, or renal arteries. Aneurysms vary in size from less than 1 in. (2.5 cm) to more than 4 in. (10 cm). They are usually classified as true or false: true aneurysms involve all layers of the artery (inner endothelium or intima, middle muscular layer or media, and outer connective tissue or adventitia); false aneurysms do not involve all layers. With the exception of intracranial aneurysms, atherosclerotic vessel disease is generally the cause of aneurysms; other causes include syphilis, trauma, cystic medial necrosis, bacterial infections, and arteritis.

The major clinical sign of all aneurysms (except intracranial) is a large pulsatile mass; other manifestations depend on the location of the aneurysm. The major complication of an aneurysm is rupture, the possibility of which is directly related to its size. Intracranial aneurysms, often called berry aneurysms, are congenital weaknesses in the intracranial arteries. These aneurysms are saclike outpocketings of the vessel and vary in size from 0.2 in. (0.4 cm) to greater than 0.6 in. (1.5 cm). The major manifestations are usually related to bleeding and can vary from a severe headache, to neurologic impairment, to death.

The best method of diagnosis is ultrasound or a computer x-ray analysis (computed tomography scan). The recommended treatment for all aneurysms is surgery. *See* ARTERIOSCLEROSIS; CARDIOVASCULAR SYSTEM; CIRCULATION DISORDERS; HEMORRHAGE; HYPERTENSION; MEDICAL IMAGING. [D.L.Ak.; M.D.K.]

Angle modulation Modulation in which the instantaneous angle varies in proportion to the modulating waveform.

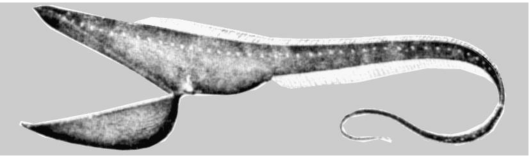
When used in an analog manner, it is referred to as either frequency modulation (FM) or phase modulation (PM), depending upon whether the instantaneous frequency or instantaneous phase varies with the modulation. When used in a digital modulation format, it is referred to as either frequency-shift keying (FSK) or phase-shift keying (PSK). Both FSK and PSK can be used with either a binary or an *M*-ary alphabet, where *M* is an integer greater than 2. Indeed, the most common forms of PSK correspond to an input alphabet size of either two or four; while for FSK alphabets of two, four, or eight, symbols are typically employed. *See* FREQUENCY MODULATION; MODULATION; PHASE MODULATION. [L.B.M.]

Anglesite A mineral with the chemical composition $PbSO_4$. Anglesite occurs in white or gray, orthorhombic, tabular or prismatic crystals or compact masses. It is a common secondary mineral, usually formed by the oxidation of galena. Fracture is conchoidal and luster is adamantine. Hardness is 2.5–3 on Mohs scale and specific gravity is 6.38. The mineral does not occur in large enough quantity to be mined as an ore of lead, and is therefore of no particular commercial value. Fine exceptional crystals of anglesite have been found throughout the world. [E.C.T.C.]

Anguilliformes A large order of actinopterygian fishes containing the true eels. This group, also known as the Apodes, now includes the former order Saccopharyngiformes or Lyomeri (gulpers or gulper eels). The Anguilliformes have a ribbonlike, larval stage in development. The chief characters of the Aguilliformes include a pectoral girdle which, when present, is free from the head and suspended from the vertebral column; no symplectic, mesocoracoid, and posttemporal bones; pectoral fin present or absent; absence of a pelvic fin and girdle in recent forms; no fin spines; elongate body with numerous vertebrae; scales present or absent; paired orbitosphenoids; and restricted gill apertures.

The typical eels (suborder Anguilloidei) have a swim bladder with a duct, a small opercle, and 6–22 branchiostegals, and the premaxilla, mesethmoid, and lateral ethmoids are fused into a tooth-bearing ethmopremaxillary block that separates the maxillae. Eels, which date from the Upper Cretaceous, are classified in about 20 Recent families and 110 genera, and there are several hundred species. *See* EEL.

The gulpers (suborder Saccopharyngoidei) have degenerative adaptations, including loss of swim bladder, opercle, branchiostegal rays, caudal fin, scales, and ribs. The tremendous mouth is greatly modified (see illustration), the eyes are tiny and placed far forward, the pharynx is enormously distensible, and the tail is slender and tapering. These are rare oceanic fishes, classified in three families, three genera, and nine species. Their fossil history is unknown. *See* ACTINOPTERYGII; OSTEICHTHYES; TELEOSTEI. [R.M.B.]



Gulper eel (*Eupharynx bairdi*). (*After G. B. Goode and T. H. Bean, Oceanic Ichthyology, U.S. Nat. Mus. Spec. Bull. no. 2, 1896*)

Angular correlations An experimental technique that involves measuring the manner in which the likelihood of occurrence (or intensity or cross section) of a particular decay or collision process depends on the directions of two or more radiations associated with the process. Traditionally, these radiations are emissions from the decay or collision process. However, a variant on this technique in which the angular correlations are between an incident and emitted beam of radiation has been widely used; this variant is known as angular distributions.

The fundamental reason for performing such measurements, rather than just scrutinizing a single radiation in a particular direction or measuring the total intensity for a process, is that the angular correlation or angular distribution measurement provides much more information on both the decay or collision process and on the structure and properties of the emitter of the radiation. The technique is used to study a variety of decay and collision processes in atomic and molecular physics, condensed-matter (solid-state) and surface physics, and nuclear and particle physics.

The principal use of this technique in nuclear physics has been to determine the angular momentum, or spin, and parity of excited nuclear states which are radioactive, that is, decay spontaneously, by measuring in coincidence the radiation in specific directions from two successive transitions in the radioactive cascade. The measurements are generally of coincidences between gamma rays, but coincidences between gamma rays and electrons (beta particles) are also used. The form of the angular correlation, the measured intensity as a function of the angle between the two radiations, gives the information about the intermediate excited state in the cascade. *See* NUCLEAR SPECTRA; RADIOACTIVITY.

In atomic and molecular collisions as well as in nuclear and particle collisions, this technique is employed as a means of completely specifying the dynamics of the collision, with the added proviso that the energies of the emitted radiations are also to be measured. Wide use has been made of angular correlations in the impact ionization of atoms by electrons where the directions of both the scattered electron and the ejected electron are measured. *See* ATOMIC STRUCTURE AND SPECTRA; SCATTERING EXPERIMENTS (ATOMS AND MOLECULES). [S.T.M.]

Angular momentum In classical physics, the moment of linear momentum about an axis. A point particle with mass m and velocity $\mathbf{v}$ has linear momentum $\mathbf{p} = m\mathbf{v}$. Let $\mathbf{r}$ be an instantaneous position vector that locates the particle from an origin on a specified axis. The angular momentum $\mathbf{L}$ can be written as the vector cross-product in Eq. (1).

$$\mathbf{L} = \mathbf{r} \times \mathbf{p} \tag{1}$$

See CALCULUS OF VECTORS; MOMENTUM.

The time rate of change of the angular momentum is equal to the torque $\mathbf{N}$. A rigid body satisfies two independent equations of motion (the dynamical equations) given by Eqs. (2) and (3),

$$\frac{d}{dt}\mathbf{p} = \mathbf{F} \tag{2}$$

$$\frac{d}{dt}\mathbf{L} = \mathbf{N} \tag{3}$$

where d/dt denotes the rate of change, the derivative with respect to time t. Only Eq. (2) is required for a point particle. Equation (2) indicates that a rigid body acts as a point particle located at its center of mass. The motion of the center of mass depends upon the net force $\mathbf{F}$, which is the vector sum of all applied forces. Equation (3) gives the angular motion about the center of mass. The case of statics occurs when the net force and net torque both vanish. *See* KINETICS (CLASSICAL MECHANICS); STATICS; TORQUE.

A symmetry is a transformation that leaves a physical system unchanged. A physical quantity is called invariant under a transformation if it remains the same after being transformed. For example, the solutions to Eqs. (2) and (3) are invariant under change of the coordinate origin or orientation of the $\mathbf{i}$, $\mathbf{j}$, and $\mathbf{k}$ axes. The freedom to choose any orientation of coordinate axes is called rotational invariance, because one choice of axes can be rotated into another. In physics, the rotational invariance follows from the isotropy and homogeneity of space that has been experimentally established to high accuracy.

The study of symmetry shows that one of the deepest relations in physics is that between dynamics and conservation. A physical quantity is conserved if it is constant in time, although it may vary in space. Noether's theorem states that if a physical system is invariant under a continuous symmetry, a conservation law exists, provided that the observable in question decreases rapidly enough at infinity. Thus, when the force is zero everywhere (the system is invariant under translation in space), the linear momentum is conserved. If the torque is zero everywhere (the system is invariant under rotation), the angular momentum is conserved. If the system is invariant under translations in time, the total energy is conserved. *See* CONSERVATION LAWS (PHYSICS); CONSERVATION OF ENERGY; CONSERVATION OF MOMENTUM.

Quantum mechanics has a richer and more complicated structure than classical physics. Because of this, the relationship between symmetry and conservation is even more useful. *See* NONRELATIVISTIC QUANTUM THEORY. [B.DeF.]

Anharmonic oscillator A generalized version of harmonic oscillator in which the relationship between force and displacement is nonlinear. The harmonic oscillator is a highly idealized system that oscillates with a single frequency, irrespective of the amount of pumping or energy injected into the system. Consequently, the harmonic oscillator's fundamental frequency of vibration is independent of the amplitude of the vibrations. Applications of the harmonic oscillator model abound in various fields, but perhaps the most commonly studied system is the Hooke's law mass-spring system. In the Hooke's law system the restoring force exerted on the mass is proportional to the displacement of the mass from its equilibrium position. This linear relationship between force and displacement mandates that the oscillation frequency of the mass will be independent of the amplitude of the displacement. *See* HARMONIC MOTION; HARMONIC OSCILLATOR; HOOKE'S LAW.

In a mechanical anharmonic oscillator, the relationship between force and displacement is not linear but depends upon the amplitude of the displacement. The nonlinearity arises from the fact that the spring is not capable of exerting a restoring force that is proportional to its displacement because of, for example, stretching in the material comprising the spring. As a result of the nonlinearity, the vibration frequency can change, depending upon the system's displacement. These changes in the vibration frequency result in energy being coupled from the fundamental vibration frequency to other frequencies through a process known as parametric coupling. *See* VIBRATION.

There are many systems throughout the physical world that can be modeled as anharmonic oscillators in addition to the nonlinear mass-spring system. For example, an atom, which consists of a positively charged nucleus surrounded by a negatively charged electronic cloud, experiences a displacement between the center of mass of the nucleus and the electronic cloud when an electric field is present. The amount of that displacement, called the electric dipole moment, is related linearly to the applied field for small fields, but as the magnitude of the field is increased, the field-dipole moment relationship becomes nonlinear, just as in the mechanical system. *See* DIPOLE MOMENT.

Further examples of anharmonic oscillators include the large-angle pendulum, which exhibits chaotic behavior as a result of its anharmonicity; nonequilibrium semiconductors that possess a large hot carrier population, which exhibit nonlinear behaviors of various types related to the effective mass of the carriers; and ionospheric plasmas, which also exhibit nonlinear behavior based on the anharmonicity of the plasma. In fact, virtually all oscillators become anharmonic when their pump amplitude increases beyond some threshold, and as a result it is necessary to use nonlinear equations of motion to describe their behavior. *See* CHAOS; PENDULUM; SEMICONDUCTOR. [D.R.A.]

Anhydrite A mineral with the chemical composition $CaSO_4$. Anhydrite occurs commonly in white and grayish granular masses, rarely in large, orthorhombic crystals. Fracture is uneven and luster is pearly to vitreous. Hardness is 3–3.5 on Mohs scale and specific gravity is 2.98. Anhydrite is an important rock-forming mineral and occurs in association with gypsum, limestone, dolomite, and salt beds. Under natural conditions, anhydrite hydrates slowly, but readily, to gypsum. It is not used as widely as gypsum. Anhydrite is of worldwide distribution. Large deposits occur in the Carlsbad district, Eddy County, New Mexico, and in salt-dome areas in Texas and Louisiana. *See* GYPSUM; SALINE EVAPORITE. [E.C.T.C.]

Animal Any living organism which possesses certain characteristics that distinguish it from plants. There is no single criterion that can be used to distinguish all animals from all plants. Animals usually lack chlorophyll and the ability to manufacture foods from raw materials available in the soil, water, and atmosphere. Animal cells are usually delimited by a flexible plasma or cell membrane rather than a cell wall. Animals generally are limited in their growth and most have the ability to move in their environment at some stage in their life history, whereas plants are usually not restricted in their growth and the majority are stationary.

The presence or lack of chlorophyll in an organism does not determine its affinity to the plant or animal kingdom. Among the protozoa, the class Phytamastigophora includes animals, such as the euglenids, which have chromatophores containing chlorophyll. These organisms are considered to be animals by zoologists and plants by phycologists. Higher parasitic plants and the large plant group Fungi also lack chlorophyll. Another borderline group is the slime molds: the Mycetozoa of zoologists and the Myxomycophyta of the botanists; these organisms exhibit both plant and animal characteristics during their life history. Movement is not a characteristic restricted to the animal kingdom; many of the thallophytes such as *Oscillatoria*, numerous bacteria, and colonial chlorophytes are motile.

Classifying organisms as plants or animals is difficult. Today biologists recognize up to five kingdoms. Most place the one-celled animals and plants, sometimes along with algae and certain other groups, into the Protista. Other kingdoms are the Monera for the bacteria and blue-green algae, and the Fungi for the slime molds and true fungi. These schemes for recognizing additional kingdoms have the practical advantage of eliminating the difficulties of delimiting and describing the kingdoms of multicellular animals and plants. *See* ANIMAL KINGDOM; PLANT; PLANT KINGDOM. [W.J.B.]

Animal communication A discipline within the field of animal behavior that focuses upon the reception and use of signals. Animal communication could well include all of animal behavior, since a liberal definition of the term signal could include all stimuli perceived by an animal. However, most research in animal communication deals only with those cases in which a signal, defined as a structured stimulus generated by one member of a species, is subsequently used by and influences the behavior of another member of the same species in a predictable way (intraspecific communication). In this context, communication occurs in virtually all animal species.

The field of animal communication includes an analysis of the physical characteristics of those signals believed to be responsible in any given case of information transfer. A large part of this interest is due to technological improvements in signal detection, coupled with analysis of the signals obtained with such devices.

Information transmission between two individuals can pass in four channels: acoustic, visual, chemical, and electrical. An individual animal may require information from two or more channels simultaneously before responding appropriately to reception of a signal. Furthermore, a stimulus may evoke a response under one circumstance but be ignored in a different context.

Acoustic signals have characteristics that make them particularly suitable for communication, and virtually all animal groups have some forms which communicate by means of sound. Sound can travel relatively long distances in air or water, and obstacles between the source and the recipient interfere little with an animal's ability to locate the source. Sounds are essentially instantaneous and can be altered in important ways. Both amplitude and frequency modulation can be found in sounds emitted by animals; in some species sound signals have discrete patterns due to frequency and timing of utterances. Since a wide variety of sound signals are possible, each species can have a unique set of signals in its repertoire. *See* PHONORECEPTION.

Sound signals are produced and received primarily during sexual attraction, including mating and competition. They may also be important in adult–young interactions, in the coordination of movements of a group, in alarm and distress calls, and in intraspecific signaling during foraging behavior. *See* REPRODUCTIVE BEHAVIOR.

Visual signaling between animals can be an obvious component of communication. Besides the normal range of human vision (visible light), visual signals include additional frequencies in the infrared and ultraviolet ranges. The quality of light that is often considered is color, but other characteristics are important in visual communication. Alterations of brightness, pattern, and timing also provide versatility in signal composition. The visual channel suffers from the important limitation that all visual signals must be line of sight. Information transfer is therefore largely restricted to the daytime (except for animals such as fireflies) and to rather close-range situations.

Intraspecific visual signaling appears to occur primarily during mate attraction. The color dimorphism of birds, the patterns of butterfly wings, the posturing of some fish, and firefly flashing are examples. Some parent–young interactions involve visual signaling. A young bird in the nest may open its mouth when it sees the underside of its parent's beak. Other examples are the synchronized behavior observed in schooling fish and flocking birds.

Chemical signals, like visual and sound signals, can travel long distances, but with an important distinction. Distant transmission of chemical signals requires a movement of air or water. Therefore, an animal cannot perceive an odor from a distance; it can only perceive molecules brought to it by a current of air or water. Animals do not hunt for an odor source by moving other than upwind or upcurrent in water because chemical signals do not travel in still air or water since diffusion is far too slow.

The fact that chemical signals comprise molecules means that, unlike acoustical or visual signals, chemical signals have a time lag. Chemical signals have to be of an appropriate concentration if they are to be effective. A chemical normally considered to be an attractant can serve as a repellent if it is too strong. Chemical signals may persist for a while, and time must pass before the concentration drops below the threshold level for reception by a searching animal. Since molecules of different sizes and shapes have varying degrees of persistence in the environment, the chemical channel is often involved in territorial marking, odor trail formation, and mate attraction. This channel is particularly suitable where acoustical or visual signals might betray the location of a signaler to a potential predator.

The array of molecular structure is essentially limitless, permitting a species-specific nature for chemical signals. Unfortunately, that specificity can make interception and analysis of chemical signals a difficult matter for research.

Pheromones are chemical signals that are produced by an animal and are exuded to influence the behavior of other members of the same species. If pheromones are incorporated into a recipient's body (by ingestion or absorption), they may chemically alter the behavior of such an individual for a considerable period of time. *See* CHEMICAL ECOLOGY; CHEMORECEPTION; PHEROMONE.

Some electric fish and electric eels live in murky water and have electric generating organs that are really modified muscle bundles. Communication by electric signaling is rapid; signals can travel throughout the medium (even murky water), and rather complex signals can be generated, permitting species-specific communication during sexual attraction. However, the electrical mode is apparently restricted to those species that have electric generating organs. *See* ELECTRIC ORGAN (BIOLOGY).

Animal communication is one of the most difficult areas of study in science for several reasons. First, experiments must be designed and executed in such a manner that extraneous cues (artifacts) are eliminated as potential causes of the observed results. Second, once supportive evidence has been obtained, each hypothesis must be tested. In animal communication studies, adequate tests often rely upon direct evidence—that is, evidence obtained by artificially generating the signal presumed responsible for a given behavioral act, providing that signal to a receptive animal, and actually evoking a specific behavioral act in a predictable manner. *See* ETHOLOGY; PSYCHOLINGUISTICS.

[A.M.We.]

Animal evolution The theory that modern animals are the modified descendants of animals that formerly existed and that these earlier forms descended from still earlier and different organisms.

Animals are multicellular organisms that feed by ingestion of other organisms or their products, being unable to derive energy through photosynthesis or chemosynthesis. Animals are currently classed into about 30 to 35 phyla, each of which has evolved a distinctive body plan or architecture.

All phyla began as invertebrates, but lineages of the phylum Chordata developed the internal skeletal armature, with spinal column, which was exploited in numerous fish groups and which eventually gave rise to terrestrial vertebrates. The number of phyla is uncertain partly because most of the branching patterns and the ancestral body plans from which putative phyla have arisen are not yet known. For example, arthropods (including crustaceans and insects) may have all diversified from a common ancestor that was a primitive arthropod, in which case they may be grouped into a single phylum; or several arthropod groups may have evolved independently from nonarthropod ancestors, in which case each such group must be considered a separate phylum. So far as known, all animal phyla began in the sea. *See* ANIMAL; ANIMAL KINGDOM.

Some features of the cells of primitive animals resemble those of the single-celled Protozoa, especially the flagellates, which have long been believed to be animal ancestors. Molecular phylogenies have supported this idea and also suggest that the phylum Coelenterata arose separately from all other phyla that have been studied by this technique. Thus animals may have evolved at least twice from organisms that are not themselves animals, and represent a grade of evolution and not a single branch (clade) of the tree of life. Sponges have also been suspected of an independent origin, and it is possible that some of the extinct fossil phyla arose independently or branched from sponges or cnidarians. *See* COELENTERATA; PORIFERA; PROTOZOA.

The earliest undoubted animal fossils (the Ediacaran fauna) are soft-bodied, and first appear in marine sediments nearly 650 million years (m.y.) old. This fauna lasted about 50 m.y. and consisted chiefly of cnidarians or cnidarian-grade forms, though it contains a few enigmatic fossils that may represent groups that gave rise to more advanced phyla. Then, nearly 570 m.y. ago, just before and during earliest Cambrian time, a diversification of body architecture began that produced most of the living phyla as well as many extinct groups. The body plans of some of these groups involved mineralized skeletons which, as these are more easily preserved than soft tissues, created for the first time an extensive fossil record. The soft-bodied groups were markedly diversified, though their record is so spotty that their history cannot be traced in detail. A single, exceptionally preserved soft-bodied fauna from the Burgess Shale of British Columbia that is about 530 m.y. old contains not only living soft-bodied worm phyla, but extinct groups that cannot be placed in living phyla and do not seem to be ancestral to them. *See* CAMBRIAN; FOSSIL.

Following the early phase of rampant diversification and of some concurrent extinction of phyla and their major branches, the subsequent history of the durably skeletonized groups can be followed in a general way in the marine fossil record. The composition of the fauna changed continually, but three major associations can be seen: one dominated by the arthropodlike trilobites during the early Paleozoic, one dominated by articulate brachiopods and crinoids (Echinodermata) in the remaining Paleozoic, and one dominated by gastropod (snail) and bivalve (clam) mollusks during the Mesozoic and Cenozoic. The mass extinction at the close of the Paleozoic that caused the contractions in so many groups may have extirpated over 90% of marine species and led to a reorganization of marine community structure and composition into a modern mode. Resistance to this and other extinctions seems to have been a major factor in the rise of successive groups to dominance. Annelids, arthropods, and mollusks are the more important invertebrate groups that made the transition to land. The outstanding feature of terrestrial fauna is the importance of the insects, which appeared in the late Paleozoic and later radiated to produce the several million living species, surpassing all other life forms combined in this respect. *See* ANNELIDA; ARTHROPODA; CENOZOIC; INSECTA; MESOZOIC; MOLLUSCA; PALEOZOIC. [J.W.V.]

The phylum Chordata consists largely of animals with a backbone, the Vertebrata, including humans. The group, however, includes some primitive nonvertebrates, the protochordates: lancelets, tunicates, acorn worms, pterobranchs, and possibly the extinct graptolites and conodonts. The interrelationships of these forms are not well understood. With the exception of the colonial graptolites, they are soft-bodied and have only a very limited fossil record. They suggest possible links to the Echinodermata in developmental, biochemical, and morphological features. In addition, some early Paleozoic fossils, the carpoids, have been classified alternatively as chordates and as echinoderms, again suggesting a link. In spite of these various leads, the origin of the chordates remains basically unclear. *See* VERTEBRATA.

Chordates are characterized by a hollow, dorsal, axial nerve chord, a ventral heart, a system of slits in the larynx that serves variously the functions of feeding and respiration, a postanal swimming tail, and a notochord that is an elongate supporting structure lying immediately below the nerve chord. The protochordates were segmented, although sessile forms such as the tunicates show this only in the swimming, larval phase.

The first vertebrates were fishlike animals in which the pharyngeal slits formed a series of pouches that functioned as respiratory gills. An anterior specialized mouth permitted ingestion of food items large in comparison with those of the filter-feeding protochordates. Vertebrates are first known from bone fragments found in rocks of Cambrian age, but more complete remains have come from the Middle Ordovician. Innovations, related to greater musculoskeletal activity, included the origin of a supporting skeleton of cartilage and bone, a larger brain, and three pairs of cranial sense organs (nose, eyes, and ears). At first the osseous skeleton served as protective scales in the skin, as a supplement to the notochord, and as a casing around the brain. In later vertebrates the adult notochord is largely or wholly replaced by bone, which encloses the nerve chord to form a true backbone. All vertebrates have a heart which pumps blood through capillaries, where exchanges of gases with the external media take place. The blood contains hemoglobin in special cells which carry oxygen and carbon dioxide. In most fishes the blood passes from the heart to the gills and thence to the brain and other parts of the body. In most tetrapods, and in some fishes, blood passes to the lungs, is returned to the heart after oxygenation, and is then pumped to the various parts of the body.

The jawless fish, known as Agnatha, had a sucking-rasping mouth apparatus rather than true jaws. They enjoyed great success from the Late Cambrian until the end of the Devonian. Most were heavily armored, although a few naked forms are known. They were weak swimmers and lived mostly on the bottom. The modern parasitic lampreys and deep-sea scavenging hagfish are the only surviving descendants of these early fish radiations. *See* DEVONIAN.

In the Middle to Late Silurian arose a new type of vertebrate, the Gnathostomata, characterized by true jaws and teeth. They constitute the great majority of fishes and all tetrapod vertebrates. The jaws are modified elements of the front parts of the gill apparatus, and the teeth are modified bony scales from the skin of the mouth. With the development of jaws, a whole new set of ecological opportunities was open to the vertebrates. Along with this, new swimming patterns appeared, made possible by the origin of paired fins, forerunners of which occur in some agnathans. *See* GNATHOSTOMATA; SILURIAN.

Four groups of fishes quickly diversified. Of these, the Placodermi and Acanthodii are extinct. The Placodermi were heavily armored fishes, the dominant marine carnivores of the Silurian and Devonian. The Acanthodii were filter-feeders mostly of small size. They are possibly related to the dominant groups of modern fishes, the largely cartilaginous Chondrichthyes (including sharks, rays, and chimaeras) and the Osteichthyes (the higher bony fishes). These also arose in the Late Silurian but diversified later. *See* ACANTHODII; CHONDRICHTHYES; OSTEICHTHYES; PLACODERMI.

The first land vertebrates, the Amphibia, appeared in the Late Devonian and were derived from an early group of osteichthyans called lobe-finned fishes, of which two kinds survive today, the Dipnoi or lungfishes, and the crossopterygian coelacanth *Latimeria*. They were lung-breathing fishes that lived in shallow marine waters and in swamps and marshes. The first amphibians fed and reproduced in or near the water. True land vertebrates, Reptilia, with a modified (amniote) egg that could survive on land, probably arose in the Mississippian. *See* AMNIOTA; AMPHIBIA; CROSSOPTERYGII; DIPNOI; MISSISSIPPIAN.

By the Middle Pennsylvanian a massive radiation of reptiles was in process. The most prominent reptiles belong in the Diapsida: dinosaurs, lizards and snakes, and pterosaurs (flying reptiles). The birds, Aves, which diverged from the dinosaur radiation in the Late Triassic or Early Jurassic, are considered to be feathered dinosaurs, and thus members of the Diapsida, whereas older authorities prefer to treat them as a separate case. In addition, there were several Mesozoic radiations of marine reptiles such as ichthyosaurs and plesiosaurs. Turtles (Chelonia) first appeared in the Triassic and have been highly successful ever since. *See* AVES; DINOSAUR; JURASSIC; PENNSYLVANIAN; REPTILIA.

The line leading to mammals can be traced to primitive Pennsylvanian reptiles, Synapsida, which diversified and spread worldwide during the Permian and Triassic. The first true mammals, based on characteristics of jaw, tooth, and ear structure, arose in the Late Triassic. Derived mammals, marsupials (Metatheria) and placentals (Eutheria), are known from the Late Cretaceous, but mammalian radiations began only in the early Cenozoic. By the end of the Eocene, all the major lines of modern mammals had become established. Molecular analyses (blood proteins, deoxyribonucleic acid, ribonucleic acid) of living mammals show that the most primitive group of placentals is the edentates (sloths, armadillos, and anteaters). An early large radiation included the rodents, primates (including monkeys, apes, and humans), and bats, possibly all closely related to the insectivores and carnivores. The newest radiations of mammals are of elephants and sea cows, while the whales are related to the artiodactyls (cattle, camels). *See* CENOZOIC; CRETACEOUS; EOCENE; MAMMALIA; PERMIAN; SYNAPSIDA; TRIASSIC. [K.S.Th.]

Animal growth The increase in mass or dimensions of an organism with time. It is one of the basic characteristics of living things and represents the visible result of a complex and interrelated series of metabolic and developmental events. One of the unique features of biological growth is that the organism changes in size and shape, and to some extent in chemical composition, although it still retains its integrity and its individuality. This is true because growth fundamentally involves synthesis by the organism of more materials like itself.

Growth occurs by two main processes: increase in the number of cells and increase in the size of cells. Living cells, removed from the body and placed in an appropriate culture medium, display growth in its most uncomplicated form. They grow by synthesizing new protoplasm, dividing into smaller cells, and then repeating the process over and over as long as essential nutrients are supplied and accumulation of deleterious waste products is prevented.

In the intact animal, growth begins at, or soon after, the initiation of development. It involves cell division and synthesis of new protoplasm from raw material, either contained in the egg or derived from the environment. However, the process is much more complex than the growth of cells in tissue culture. Except in early embryonic development, growth is normally never dissociated from such processes as differentiation (diversification of cell structure and function) and morphogenesis (change in the form and pattern of the embryo). In later development, growth by cell enlargement is the predominant process. *See* ANIMAL MORPHOGENESIS; CELL DIVISION; DIFFERENTIATION; EMBRYOLOGY; MITOSIS; TISSUE CULTURE.

The vast majority of animals, including most protozoa, require already elaborated organic molecules in order to synthesize new living material during growth. For animals in general, the chemical requirements for growth are (1) water, (2) inorganic substances, (3) organic substances, especially certain amino acids, and fatty acids, and (4) accessory factors or vitamins. *See* AXENIC CULTURE.

Water is important to all living cells as the solvent and vehicle through which essential substances enter and metabolic waste products leave. The cells composing the growing embryo are no exception. The embryos of animals that develop in an aquatic medium, both fresh-water and marine, take up considerable amounts of water as the nonliving, stored components of the egg (yolk) become hydrolyzed and synthesized into the living and nonliving components of the embryo. *See* ABSORPTION (BIOLOGY).

Inorganic substances are needed in large quantities for the formation of skeletal and other supporting structures. In both invertebrates and vertebrates, silicon, calcium, magnesium, carbon as carbonate, and phosphorus as phosphate are extremely important. Salts of sodium, potassium, calcium, and magnesium are essential components of body fluids. They contribute to the osmotic properties of the body fluids and provide a milieu in which cells, tissues, and organs can function properly. Some trace elements, found in protoplasm in only minute amounts, are essential for growth. Many are probably involved in the formation and action of enzymes and enzyme cofactors. *See* ENZYME; OSMOREGULATORY MECHANISMS.

The organic compounds used by animals as raw materials for growth are carbohydrates, proteins, and fats, or their breakdown products. Carbohydrate apparently is not essential; laboratory animals can grow in the complete absence of carbohydrate. Fat, as such, is probably also nonessential, although some animals need certain unsaturated fatty acids to sustain growth. However, carbohydrates and fats are major sources of energy during the process of growth. *See* CARBOHYDRATE; LIPID.

Proteins represent the chief organic constituent of living tissues and are the most important raw material for growth. During growth, the proteins stored in the egg or provided as food from outside are digested into their constituent amino acids. These are then resynthesized into the substance of the living cells. The proteins synthesized by the organism have specific characteristics which depend upon the kinds and numbers of amino acids they contain; therefore not all proteins are equally capable of supporting growth. Proteins that fail to induce growth are deficient in one or more essential amino acids (amino acids needed by the organism but which it cannot synthesize). *See* AMINO ACIDS; NUTRITION; PROTEIN.

In addition to the materials used to synthesize the bulk of the protoplasmic system, animal organisms also require certain accessory substances in order to grow. Some of these are now known as vitamins. *See* VITAMIN.

The growth of vertebrates is influenced by a specific growth hormone produced by the anterior lobe of the pituitary gland. Secretions from the thyroid gland, the adrenal cortex, and, in some instances, the gonads also affect growth, but perhaps less directly. Growth in various arthropods is controlled by hormone action. Molting, an essential prelude to growth in insects and crustaceans, is under hormonal control. *See* ENDOCRINE SYSTEM (INVERTEBRATE); ENDOCRINE SYSTEM (VERTEBRATE).

Growth determines not only the size of the animal but also its shape and form. As long as an animal grows at the same rate along all its dimensions, it will not change in bodily proportions. However, when the growth rate in certain directions is different from that along others, or when one or more parts of the growing organism develop more rapidly or more slowly than others, progressive changes in form result. Such relative growth is known as allometric growth, heterogony, or heterauxesis.

The form changes produced by alterations in body proportion are well illustrated in human development. At the second month of fetal life, the head and neck account for almost one-half the total volume of the fetus; at birth the relative size of the head is only 32% of the body; at maturity it is 10%. Conversely, at the same three stages, the legs comprise, respectively, 2%, 16%, and 29% of the total body volume. During this developmental span the relative size of the trunk remains constant at approximately 50% of body volume. Obviously, the growth of the head during prenatal development after the second fetal month is relatively smaller and that of the legs relatively larger than growth of the body as a whole.

There are many factors involved in the regulation of growth, some intrinsic, some environmental. One important factor is the histological differentiation of the cells of the organism; as differentiation proceeds, the rate of growth declines. Heredity is important in determining the limit and the rate of growth. Tall parents give rise to tall children, and the offspring of toy terriers and mastiffs grow to characteristic size. Hormonal influences also affect growth, as do such environmental factors as nutritive level, temperature, and degree of crowding. In most organisms, growth ceases at maturity, but in some, growth continues throughout life. Complete cessation of growth when the adult stage has been reached occurs mainly in terrestrial animals. [E.J.Bo.]

Animal kingdom One of five kingdoms of organisms: Animalia, Plantae, Fungi, Protista, and Monera. Animals are eukaryotic multicellular organisms that take food into their bodies and that develop from blastula embryos. Animal species are organized into phyla that are defined according to comparative patterns of development, body structures, behavior, biochemical pathways, modes of nutrition, and ancestry. *See* ANIMAL SYSTEMATICS.

Traditionally, animals have been grouped into invertebrates (without backbones) and vertebrates (with backbones). Vertebrates include mammals, amphibians, reptiles, birds, and fish. Members of all other animal phyla, more than 98% of all animal species, are invertebrates. Although invertebrates lack backbones, they achieve physical support by structures ranging from delicate glass spicules, to tough rings and rods, to hydrostatic pressure. The phylum Arthropoda alone comprises more than 1 million known species. If tropical species were better described, the arthropods might include as many as 10 million living species. *See* AMPHIBIA; AVES; CHONDRICHTHYES; CHORDATA; MAMMALIA; OSTEICHTHYES; REPTILIA. [K.V.S.]

Animal morphogenesis The development of form and pattern in animals. Animals have complex shapes and structural patterns which are faithfully reproduced during the embryonic development of each generation. Morphogenesis takes place by the generation of progressively more complex structures from a single cell: the fertilized egg, or zygote. The zygote divides repeatedly to form a multicellular embryo, within which groups of cells undergo structural and functional specialization (differentiation) in the precise spatial patterns that are recognized as tissues and organs.

Cell differentiation involves the differential expression of genes in the nuclear deoxyribonucleic acid (DNA) which code for the production of proteins specifying the structure and function of each cell type. During cleavage, nuclei divide equivalently so that all cells of the embryo receive the total complement of genes contained in the DNA of the zygote nucleus. However, cells in different regions of the embryo contain cytoplasm which differs in composition. The cytoplasmic composition of a cell controls which genes will be expressed in each region of the embryo, resulting in a patterned differentiation. Initially, different cell types arise because cells come to occupy unique positions; some cells are on the inside and others on the outside of the group of cells produced by the early divisions of the zygote. Interactions between subpopulations of cell types thus produced further alter regional cytoplasmic compositions, resulting in new patterns of gene expression. By means of many such interactions, all of the 200 or so different cell types of an animal body gradually emerge in the proper spatial patterns. *See* CELL DIFFERENTIATION; DEOXYRIBONUCLEIC ACID (DNA); GENE ACTION.

The structural patterns of animals and their parts exhibit polarity; that is, they display structural differences along one or more axes. In many animals, the overall polarities of the embryo are established during oogenesis and the period between fertilization and the first cleavage. For example, as the amphibian egg grows in the ovary, its posterior half becomes laden with yolk, and a dark pigment is deposited in the cortical cytoplasm of its anterior half. The line between the poles of these two halves defines the anterior-posterior axis of the future embryo. *See* FERTILIZATION; OOGENESIS; OVUM.

The dorsal-ventral axis develops perpendicular to the anterior-posterior axis, and is established by a reorganization of the zygote cytoplasm initiated by the events of fertilization. This axis can form in any of the planes which contain the anterior-posterior axis. The plane in which it actually forms is determined by the meridian at which the sperm enters the egg. Cytoplasmic reorganization occurs after fertilization. A tongue of yolky cytoplasm is formed on the elevated side as the heavy yolk flows down under the influence of gravity, and a new gray crescent appears on this side, its dorsal midline coinciding with the plane in which the anterior-posterior axis was tilted. The dorsal-ventral axis established by sperm entry becomes determined shortly before the first cleavage.

Two major cell types are formed during cleavage of the amphibian egg: large, yolky endoderm cells, and smaller, pigmented ectoderm cells, including the cells formed from the gray crescent region.

At the mid-blastula state, when the embryo consists of several thousand cells, an inductive interaction takes place between the endoderm cells and the gray crescent cells, causing the latter to become mesoderm cells. During gastrulation, these three cell types are rearranged to form three concentric layers, with ectoderm on the outside, endoderm on the inside, and mesoderm in between. The ectoderm develops into the skin epidermis and nervous system, endoderm into the organs of the alimentary tract, and mesoderm into muscles, skeleton, heart, kidneys, and connective tissue. *See* BLASTULATION; GASTRULATION; GERM LAYERS.

Prior to gastrulation, the prospective organ regions of the ectoderm and endoderm are not yet determined. Mesodermal organ regions, however, are highly self-organizing under these conditions. Ectodermal and endodermal organ regions become determined during and after gastrulation by the inductive action of the mesoderm. For example, dorsal mesoderm normally invaginates and stretches out along the dorsal midline where it differentiates as notochord and trunk muscles. The ectoderm overlying the dorsal mesoderm differentiates as the central nervous system. *See* FATE MAPS (EMBRYOLOGY).

Once induced, organ regions can themselves induce additional organs from undetermined tissue. For example, the retina and iris of the eye develop from a vesicle growing out of the forebrain. This vesicle induces a lens from the overlying head ectoderm, and the lens then induces the cornea from head ectoderm to complete the eye. By means of such cascades of inductive interactions, all the organs of the body are blocked out. *See* EMBRYONIC INDUCTION.

Once determined, an organ region constitutes a developmental system, called a morphogenetic field, which specifies the detailed pattern of cell differentiation within the organ. Cells differentiate in patterns dictated by their relative positions within the field. It is generally accepted that graded molecular signals, or cues, are the basis of this positional information. It is proposed that the source of the signals is a set of boundary cells which define the limits of the field. All the cells of a field thus derive their positional information from a common set of boundary cells.

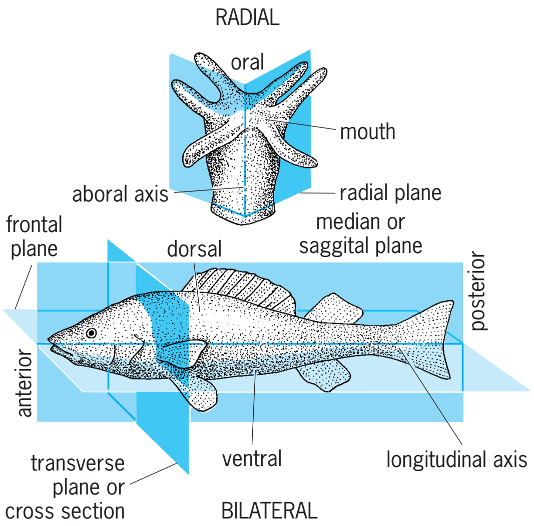
Most fields become inactive after the pattern they specify begins to differentiate; the ability to form normal organs after removal or interchange of cells is then lost. However, in some animals, the fields of certain organs can be reactivated by loss of a part, even in the adult. The missing part is then redeveloped in a process called regeneration. *See* REGENERATION (BIOLOGY).

Different kinds of cells secrete molecules of protein and protein complexed with carbohydrate which constitute specific types and patterns of extracellular matrix. The matrix stabilizes tissue and organ structure, guides migrating cells to their proper locations, and is a medium through which cell interactions take place. Cell interactions take place at cell surfaces, the molecular composition of which is distinct from one cell type to another, allowing them to recognize one another. These differences are reflected in varying degrees of adhesivity between different kinds of cells, and between cells and different kinds of extracellular matrix. Differential adhesivity is the property upon which cell migration, clustering, and rearrangement is based, and is thus important in creating the conditions for cell-cell and cell-matrix interactions. *See* CELLULAR ADHESION.

Another important mechanism for the development of complex patterns and shapes is the differential growth of organs and their parts. Differential growth is evident as soon as embryonic organ regions begin to develop. During the early part of their development, the growth rates of organs are controlled by intrinsic factors. At later stages of development, including postnatal life, organ growth is largely under the control of hormones secreted by cells of the endocrine glands.

Programmed cell death (apoptosis) is an important feature in the shaping of such structures as the head, limbs, hands, and feet of some animals. A striking example is foot development in ducks and chickens. Ducks have webbed toes while chickens do not. This difference results because as the chicken leg bud grows and forms the toes, the cells between the developing digits die. Various grafting and culturing experiments have indicated that it is a cell's relative position in the limb bud which establishes its fate to die at some later time in development. *See* ANIMAL GROWTH; DEVELOPMENTAL BIOLOGY; MOLECULAR BIOLOGY. [D.L.S.]

Animal symmetry Animal symmetry relates the organization of parts in animal bodies to the geometrical design that each type suggests. Spherical symmetry is exhibited by some protozoa, such as the Heliozoia and Radiolaria. The body is spherical with its parts concentrically around, or radiating from, a central point. Radial symmetry is exemplified by the echinoderms and most coelenterates. The body is structurally a



Types of symmetry and the axes, planes, and regions in animal bodies. (*After T. I. Storer et al., eds., General Zoology, 6th ed., McGraw-Hill, 1979*)

cylinder, tall or short, having a central axis named the longitudinal, anteroposterior, or oral-aboral axis (see illustration). Any plane through this axis divides the animal into like halves. Often several planes, from the axis outward, can divide the body into a number of like portions, or antimeres, five in most echinoderms. Ctenophores and many sea anemones and corals possess biradial symmetry, basically radial but with some parts arranged on one plane through the central axis. Most animals have bilateral, or two-sided, symmetry, in which a median or sagittal plane divides the body into equivalent right and left halves, each a mirror image of the other. [T.I.S.]

Animal systematics

The comparative analysis of living and fossil species, including their discovery, description, evolutionary relationships to other species, and patterns of geographic distribution.

Systematics can be divided into four major fields. Taxonomy, often equated with systematics, is the discipline concerned with the discovery, description, and classification of organism groups, termed taxa (singular, taxon). Classification is the clustering of species into a hierarchical arrangement according to some criterion, usually an understanding of their relationships to other species. Phylogenetic analysis, an increasingly important aspect of systematics, is the discovery of the historical, evolutionary relationships among species; this pattern of relationships is termed a phylogeny. The fourth component of systematics is biogeography, the study of species' geographic distributions. Historical biogeography examines how species' distributions have changed over time in relationship to the history of landforms, ocean basins, and climate, as well as how those changes have contributed to the evolution of biotas (groups of species living together in communities and ecosystems).

Systematic data and interpretations underlie progress in all of biology. An understanding of relationships, in particular, is fundamental for interpreting comparative data across different kinds of organisms, whether those data be morphological, physiological, or biochemical. [J.Cr.]

Animal virus

A small infectious agent that is unable to replicate outside a living animal cell. Unlike other intracellular obligatory parasites (for example, chlamydiae and rickettsiae), they contain only one kind of nucleic acid, either deoxyribonucleic acid (DNA) or ribonucleic acid (RNA). They do not replicate by binary fission. Instead, they divert the host cell's metabolism into synthesizing viral building blocks, which then self-assemble into new virus particles that are released into the environment. During the process of this synthesis, viruses utilize cellular metabolic energy, many cellular enzymes, and organelles which they themselves are unable to produce. Animal viruses are not susceptible to the action of antibiotics. The extracellular virus particle is called a virion, while the name virus is reserved for various phases of the intracellular development. *See* RIBONUCLEIC ACID (RNA).

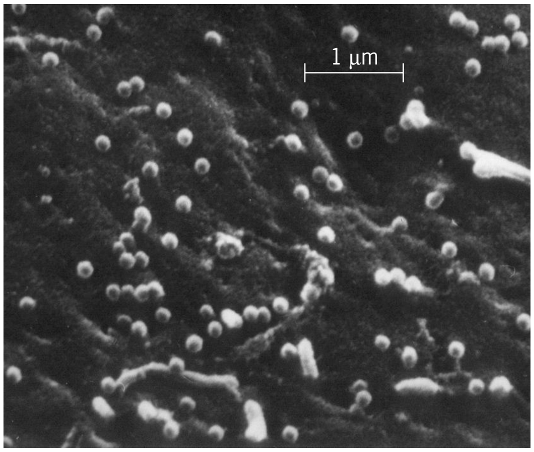
Morphology. Virions are small, 20–300 nanometers in diameter, and pass through filters which retain most bacteria. However, large virions (for example, vaccinia, which is 300 nm in diameter) exceed in size some of the smaller bacteria. The major structural components of the virion are proteins and nucleic acid, but some virions also possess a lipid-containing membranous envelope. The protein molecules are arranged in a symmetrical shell, the capsid, around the DNA or RNA. The shell and the nucleic acid constitute the nucleocapsid.

In electron micrographs of low resolution, virions appear to possess two basic shapes: spherical and cylindrical. High-resolution electron microscopy and x-ray diffraction studies of crystallized virions reveal that the "spherical" viruses are in fact polyhedral in their morphology, while the "cylindrical" virions display helical symmetry. The polyhedron most commonly encountered in virion structures is the icosahedron, in which the protein molecules are arranged on the surface of 20 equilateral triangles. Based on these morphological features, viruses are classified as helical or icosahedral. Certain groups of viruses do not exhibit any discernible features of symmetry and are classified as complex virions. Further distinction is made between virions containing RNA or DNA as their genomes and between those with naked or enveloped nucleocapsids.

Viral nucleic acid. The outer protein shell of the virion furnishes protection to the most important component, the viral genome, shielding it from destructive enzymes (ribonucleases or deoxyribonucleases). The viral genome carries information which specifies all viral structural and functional components required for the initiation and establishment of the infectious cycle and for the generation of new virions. This information may be contained in a double-stranded or single-stranded (parvoviruses) DNA, or double-stranded (reoviruses) or single-stranded RNA. The viral DNA may be linear or circular, and the viral RNA may be a single long chain or a number of shorter chains (fragmented genomes), each of which contains different genetic information. Furthermore, some RNA viruses have the genetic information expressed as a complementary nucleotide sequence. These are classified as negative-strand RNA viruses. Finally, the RNA tumor viruses have an intracellular DNA phase, during which the genetic information contained in the virion RNA is transcribed into a DNA and integrated into the host cell's genome. The discovery of this process came as a surprise, since it was believed that the flow of genetic information was unidirectional from DNA to RNA to protein and could not take place in the opposite direction. The transcription of RNA to DNA was termed reverse transcription, and the RNA tumor viruses are sometimes referred to as retroviruses. *See* GENETIC CODE.

When introduced into a susceptible cell by either chemical or mechanical means, the naked viral nucleic acid is in most cases itself infectious. Two exceptions are the negative-strand RNA viruses and the RNA tumor viruses. In these cases the RNA has to be first transcribed and reverse-transcribed, respectively, into the proper form of genetic information before the infectious process can take place. This task is carried out by means of an enzyme which is contained in the protein shell of the virion nucleocapsid. The whole nucleocapsid is therefore required for infectivity.

Viral infection is composed of several steps: adsorption, penetration, uncoating and eclipse, and maturation and release. Adsorption takes place on specific receptors in the membrane of an animal cell. The presence or absence of these receptors determines the tissue or species susceptibility to infection by a virus.



Scanning electron micrograph of the surface of a mouse cell infected with murine leukemia virus. A large number of virus particles are shown in the process of budding. (*Courtesy of R. MacLeod*)

Enveloped viruses exhibit surface spikes which are involved in adsorption; however, most animal viruses do not possess obvious attachment structures. Penetration takes place through invagination and ingestion of the virion by the cell membrane (phagocytosis or viropexis). Penetration is followed by uncoating of the nucleic acid, or in some cases by uncoating of the nucleocapsid. At this stage, the identity of the virion has disappeared, and viral infectivity cannot be recovered from disrupted cells. *See* PHAGOCYTOSIS.

The absence of infectious particles in cell extracts is characteristic of the eclipse period. During the eclipse the biochemical processes of the cell are manipulated to synthesize viral proteins and nucleic acids. The eclipse period in infections with DNA viruses starts with the transcription of the genetic information in the nucleus of the cell (except poxviruses), processing into mRNAs, and their translation into proteins (in the cytoplasm). This process is divided into early and late transcription. The early proteins are virus-encoded functional proteins which will participate in the synthesis of viral DNA and of intermediate and late viral proteins, as well as in the shutoff of various cellular functions which might be detrimental to viral synthesis. The major late products are the structural proteins of the nucleocapsid. Almost as soon as these proteins are synthesized, they assemble with newly synthesized DNA molecules into virion nucleocapsids.

The events of the eclipse period in infections with RNA viruses are similar, except that they take place in the cytoplasm (influenza virus excepted), and a division into early and late transcription cannot be made. In the case of positive-strand RNA viruses, the viral RNA is itself the mRNA. In infections with negative-strand RNA viruses, the virion RNA in the nucleocapsid is first transcribed into positive mRNAs. Intracellular nucleocapsids are present throughout the entire infectious cycle, and the eclipse period cannot be defined in the classical sense. RNA tumor viruses reverse-transcribe their RNA into DNA, which enters the cell nucleus and becomes integrated into the cellular DNA. All viral mRNAs and genomic RNAs are generated by transcription of the integrated DNA.

The event characteristic of the maturation step is virion assembly and release. In many cases the protein shell is assembled first (procapsid) and the nucleic acid is inserted into it. During this insertion, processing of some shell proteins by cleavage takes place and is accompanied by a modification of the structure to accommodate the nucleic acid. Unenveloped viruses which mature in the cytoplasm (for example, poliovirus) often exit the cell rapidly by a reverse-phagocytosis process, even before the breakdown of the cell. In some cases, however, a large number of virus particles may accumulate inside the cell in crystalline arrays called inclusion bodies. Viruses that mature in the nucleus are usually released slowly, and the damage to the cell is extensive. Enveloped viruses exit the cell by a process of budding. Viral envelope proteins (glycoproteins) become inserted at various sites into the cell membrane, where they also interact with matrix proteins and with nucleocapsids. The cellular membrane then curves around the complex and forms a bud which detaches from the rest of the cell (see illustration).

Effect of viral infections. Two extreme types of effects are identified with viral infections: lytic infections, which cause cell death by a variety of mechanisms with cell lysis as the most common outcome, and persistent infections, accompanied either by no apparent change in the host cell or by some interference with normal growth control, as in transformation of normal to cancer cells. In animals, extensive destruction of tissue may accompany an infection by a lytic virus. *See* LYTIC INFECTION.

As a defense to certain conditions of infection, animal cells generate a group of substances called interferons which, by a complex mechanism, inhibit replication of viruses. They are specific to the cell species from which they were derived but not to the virus which elicited their generation. (Mouse interferon will protect mouse but not human cells from any viral infection.)

Pathology. Virus infections spread in several ways: through aerosols and dust, by direct contact with carriers or their excretions, and by bites or stings of animal and insect vectors. At the point of entry, infected cells undergo viremia. From there, the virus becomes disseminated by secretions. It is carried through the lymphatic system and bloodstream to other target organs, where secondary viremias occur (except in localized infections like warts). In most cases viral infections are of short duration and great severity. However, persistent infections are not uncommon (herpes, adeno, various paramyxoviruses like measles).

The afflicted organism mounts a variety of defenses, the most important of which is the immune response. Circulating antibodies against viral proteins are generated. Those interacting with virion surface proteins neutralize the infectious potential of the virus. Although the antibodies are specific against the virus which has elicited them, they will cross-react with closely related virus strains. The specificity of neutralizing antibodies obtained from experimentally injected animals is utilized for diagnostic purposes or in quantitative assays. In addition to the circulating antibodies, cell-mediated immune responses also take place. The most important of these is the production of cytotoxic thymus-derived lymphocytes, found in the lymph nodes, spleen, and blood. They destroy all cells which harbor in their membrane viral glycoproteins. The cell-mediated immunity has been demonstrated to be more important to the process of recovery than circulating antibodies. In spite of their beneficial role, immune responses often seriously contribute to the pathology of the disease. Circulating antigen-antibody complexes can lodge in organs and cause inflammation; cell-mediated responses have been known to produce severe shock syndromes in patients with a history of previous exposures to the virus. *See* ANTIBODY; AUTOIMMUNITY; IMMUNITY.

Control. Viruses are resistant to the antibiotics commonly used against bacterial infections. The use of chemotherapeutic agents with antiviral activity is plagued by their toxicity to the animal host. However, the application of vaccines has been successful in the control of several viruses. The vaccines elicit immune responses and provide sometimes life-long protection. Two types of vaccines have been applied: inactivated virus and live attentuated virus. Various inactivation procedures are available. An attentuated laboratory strain of smallpox has been applied so successfully that the disease is considered to be eradicated. A small probability of back mutations of the attenuated virus to a virulent strain makes applications of live vaccines somewhat riskier. On the other hand, protection is longer-lasting and, by virtue of spread to nonvaccinated individuals, more beneficial to the population group (herd effect). *See* CHEMOTHERAPY; POLIOMYELITIS; VACCINATION; VIRUS CHEMOPROPHYLAXIS.

In order to achieve full protection, it is important that the vaccine contain all the distinct antigenic types of the virus.

Development of monoclonal antibodies led to a better characterization of these types in naturally occurring viruses. This information will undoubtedly lead to better vaccines. Moreover, monoclonal antibodies have aided investigations into the molecular structure of viral antigenic groups and brightened future prospects for synthetic vaccines. *See* MONOCLONAL ANTIBODIES; VIRUS; VIRUS CLASSIFICATION. [M.E.Re.]

Anise One of the earlist aromatics mentioned in literature. The plant, *Pimpinella anisum* (Umbelliferae), is an annual herb about 2 ft (0.6 m) tall and a native of the Mediterranean region. It is cultivated extensively in Europe, Asia Minor, India, and parts of South America. The small fruits are used for flavoring cakes, curries, pastry, and candy. The distilled oil is used in medicine, soaps, perfumery, and cosmetics. *See* APIALES; SPICE AND FLAVORING. [P.D.St./E.L.C.]

Anisomyaria An order containing seven superfamilies of marine and brackish bivalves with byssal attachment at some time in their geological history (the Ostreacea are exceptional, with the lower valve attached by byssal cement at settlement, and with no record of ancestral attachment by byssal threads). The Anisomyaria possess some primitive features and some secondarily simple features: the hinge is edentulous or with inconspicuous teeth (except *Spondylus*); there are no siphons; minimal points of fusion occur between the left and right mantle lobes; the Mytilacea, Pteriacea, Pectinacea, and Anomiacea have filibranch ctenidia. Specialized features include simultaneous hermaphroditism in some Pectinacea, sex reversal and incubation of larvae in some Ostreacea, and protandrous hermaphroditism in others. Few features are common to all Anisomyaria, and the systematic status is debatable. Studies suggest addition of the isomyarian Arcacea and Limopsacea, and placing in an order Pteriomorpha, subclass Lamellibranchia, class Bivalvia. *See* BIVALVIA; MOLLUSCA. [R.D.P.]

Ankerite The carbonate mineral $Ca(Fe,Mg)(CO_3)_2$, also commonly containing some manganese. The mineral has hexagonal (rhombohedral) symmetry and has the cation-ordered structure of dolomite. The name is applied only to those species in which at least 20% of the magnesium positions are occupied by iron or manganese; species containing less iron are termed ferroan dolomites. The pure compound, $CaFe(CO_3)_2$, has never been found in nature and has never been synthesized as an ordered compound. *See* DOLOMITE.

Ankerite is commonly white to light brown, its specific gravity is about 3, and its hardness is about 4 on Mohs scale. *See* CARBONATE MINERALS. [A.M.G.]

Annelida The phylum comprising the multisegmented, invertebrate wormlike animals, of which the most numerous are the marine bristle worms and the most familiar the terrestrial earthworms. The Annelida (meaning little annuli or rings) include the Polychaeta (meaning many setae); the earthworms and fresh-water worms, or Oligochaeta (meaning few setae); the marine and fresh-water leeches or Hirudinea; and two other marine classes having affinities with the Polychaeta: the Archiannelida (meaning primitive annelids), small heteromorphic marine worms, and the Myzostomaria (meaning sucker mouths), parasites of crinoid echinoderms. These five groups share few common characters and little resemblance except that most have a wormlike body. Typically they are bilaterally symmetrical, lack a skeleton, and have a short to long linear body divided into rings or segments, which are separated from one another by transverse walls or septa. The mouth is an anteroventral or anterior vent at the forward end of the alimentary tract, and the anus posterodorsal or posterior at the hind end of the gut. *See* ARCHIANNELIDA; HIRUDINEA; MYZOSTOMARIA; OLIGOCHAETA; POLYCHAETA.

The linear series of segments, or metameres, from anterior to posterior ends constitute the annelid body. These segments may be similar throughout, resulting in an annulated cylinder, as in earthworms and *Lumbrineris*. More frequently the successive segments are dissimilar, resulting in regions modified for particular functions. Each segment may be simple (uniannular) corresponding to a metamere, or it may be divided (multiannulate). The total number of segments varies from five to several hundred. Segments may have lateral fleshy outgrowths called parapodia (meaning side feet), armed with special secreted bristles or rods, called setae and acicula; they provide protection and aid in locomotion. Setae are lacking in Hirudinea and some polychaetes. The body is covered by a thin to thick epithelium which is never shed.

Annelids have sense organs of many kinds. Most conspicuous are those on the anterior and on parapodia. Eyes which function as photoreceptors may be variously developed. Feelers or tactoreceptors are frequently on the prostomium (a lobe of skin projecting from the first body segment) as antennae; on anterior segments as long filiform or thick fleshy tentacles; and on parapodia as cirri, papillae, scales, or tactile hairs. Cilia in bands or clusters or in grooves occur in specific patterns. The most conspicuous receptors are the large nuchal organs of amphinomid polychaetes, fleshy, folded, paired organs surrounding the cephalic structures.

Setae detect changes in the environment through their basal attachments. Shallow-water species often have short, strong, resistant setae, whereas abyssal species have long, slender, simple setae. Each organ is unique and well adapted to its role in the development, growth, protection, and reproduction of the species involved.

Chromatophores are cell clusters which change their shape and size to conform to the shadows of the animal's background, responding to changes in light intensities, and therefore are generally protective. They are well developed in translucent pelagic larvae which exist at the surface of the sea; they screen damaging intensities of light from delicate tissues. Oligochaetes and hirudineans, which generally lack eyes or special light receptors, are sensitive to light changes through the surface epithelium. *See* CHROMATOPHORE.

The alimentary tract of annelids is a straight or sinuous tube, consisting of mouth, pharynx, esophagus, stomach, gut, and pygidium or anus. The mouth may be a simple anterior (oligochaetes) or anteroventral (many polychaetes) pore provided with highly complex organs or accessory parts. Accessory organs include the grooved palpi of many polychaetes, which direct food to the mouth or also select and propel nutrients along ciliated tracts. The building organs and cementing glands of some tubicolous annelids are associated with the mouth; they select inert particles for shape and size and attach them in specific patterns to a basic secreted mucoid membrane, resulting in tubes which are highly characteristic.

The mouth is followed by the buccal cavity which may be modified as a phoboscis or saclike eversible pouch. The buccal cavity may be followed by a short to long muscularized eversible proboscis which captures and breaks up or compresses food particles. Its inner walls may be fortified by papillae or hard gnaths or jaws. A short esophagus leads to the muscular stomach or digestive region. Lateral ceca or pouches may be present, along esophageal and stomach portions, to increase the amount of surface for secretion and digestion, especially in short-bodied worms. Peristaltic (clasping and compressing) movements are rhythmic and result in the food bolus being digested, and wastes separated and pushed into the gut. In nonselective-feeding annelids the gut may be distended with great amounts of inert materials; in selective feeders there are few remains but those of living animals. The proctodaeum, or region preceding the anus, expels the wastes as fecal pellets of characteristic form.

The nervous system consists of a dorsal, bilaterally symmetrical, ganglionic mass or brain within or behind the preoral region. The brain is connected to the ventral cord through the circumesophageal connectives which extend about the oral cavity. The ventral cord may be single or paired, nearly smooth or nodular, or ganglionated according to the segmental pattern of the body. The brain sends out lateral branches to the eyes, palpi, antennae, or other structures; the ventral cord has lateral branches to all fleshy parts which receive stimuli. A giant axon is an enlarged part of the ventral cord, present in many long, muscular, or actively moving oligochaetes and polychaetes. It permits rapid transfer of stimuli and muscular response, resulting in abrupt response.

The circulatory system consists of dorsal and ventral longitudinal, median vessels located above and below the alimentary tract. Lateral branches extend to all parts of the body. Pulsating or propelling contractile portions, sometimes called hearts, are in the anterior dorsal vessel or also at intervals in the ventral vessels. In oligochaetes these are segmental vessels of varying number connecting the dorsal and ventral vessels and surrounding some portion of the alimentary tract. The contained blood may be red, through the presence of a hemoglobinlike substance, or green, through the presence of chlorocruorin. These colors when diluted are yellow or colorless, as in many small annelids. *See* Respiratory pigments (invertebrate).

Some annelids lack a closed circulatory system so that blood and coelomic fluids mix freely, resulting in a hemocoel; it may be partial or complete. Many annelids have a special organ called a cardiac or heart body surrounding the pulsating vessel and sometimes visible as a thick brown or red body of spongy tissue; its function is to dispose of circulatory wastes. The circulatory and coelomic fluids aid in maintaining turgidity of the annelid body, and with musculature control they act as a kind of skeleton.

Special organs for excretion are called nephridia. In their simplest form they are protonephridia, consisting of a strand of cells connecting the coelom to the body wall, usually a pair to a segment. More complex organs, or metanephridia, have a ciliated nephrostome or funnel opening into the coelom and continued to the surface as a complex organ. They function to transport wastes and at sexual maturity may serve to release gonadial products. Complex nephridia are present in all oligochaetes and many polychaetes.

The muscular system consists of an outer circular and an inner longitudinal system of muscles, each varying in extent and density according to species. In addition, an oblique series, between outer and inner layers, is well developed in annelids performing complex lateral movements. Long, very active burrowers or crawlers have an extensive musculature, whereas short, sluggish forms may have diminished musculature development. Movements are achieved mainly by coordinated muscular contractions and expansions of the laterally projecting parapodia or setae, resulting in an undulating or meandering movement. Swimming species may move from side to side or by successive forward darts and stops. Some annelids with reduced parapodia and a long proboscis use the latter in progression by extension and withdrawal of the eversible part of the alimentary tract.

The ability to replace lost parts is highly developed in annelids. Most frequent is the replacement of tail, parapodia, and setae. The anterior end may be replaced provided the break is postpharyngeal. The torn end is first covered over with scar tissue, then differentiated into epithelial cells and all other tissues characteristic of the whole animal.

Depending on the species, reproduction may be sexual, asexual, or both. Sexual reproduction may be dioecious, in which male and female are similar, rarely dissimilar. Individuals may be hermaphroditic, both male and female, but with cross fertilization. Some annelids are protandric hermaphrodites, in which the sexual stages alternate. *See* Protandry. [O.H.]

Fossil annelids, or segmented worms, are mostly soft-bodied, yet sufficiently common to indicate that this large and varied group of invertebrates has been abundant for more than 500 million years. The bulk of the annelidan fossil record is represented by the polychaetes. The earliest definite occurrences are from the Lower Cambrian of Greenland (Sirius Passet fauna).

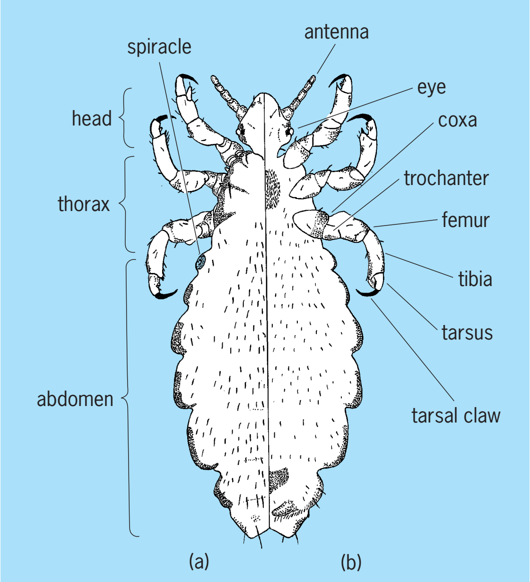
The fossil record of oligochaetes is poor, in part because their predominantly terrestrial and fresh-water habitats have a relatively poor rock record. Nevertheless, the reproductive cocoons characteristic of the clitellates (oligochaetes and leeches) have been recognized as far back as the Triassic and may be more common as fossils than is generally realized. *See* Fossil. [S.C.M.]

Anomopoda An order of fresh-water branchiopod crustaceans, formerly included in the Cladocera. Exceptionally these organisms may be as much as 6 mm (0.24 in.) in length, but often are less than 1 mm (0.04 in.). So-called water fleas of the genus *Daphnia* are the most familiar anomopods. Daphnia and its close relatives swim freely in open water; however, many anomopods are benthic, predominantly crawling species. Worldwide in distribution, anomopods are among the most abundant and successful of all fresh-water invertebrates. *See* Branchiopoda. [G.Fr.]

Anopla A class of the phylum Rhynchocoela which is divided into the orders Palaeonemertini and Heteronemertini. The simple tubular proboscis lacks stylets and resembles the body wall in structure. The mouth is posterior to the brain. The nervous system lies either immediately below the epidermis or among the musculature of the body wall. The vascular system is well developed. Anoplan rhynchocoelans are common on rocky shores, living beneath stones or interstitially in shell debris or coarser sands. *See* Enopla; Heteronemertini; Palaeonemertini; Rhynchocoela. [J.B.J.]

Anoplura A small group of insects usually considered to constitute an order. They are commonly known as the sucking lice. All are parasites living in the covering hair of mammals. About 250 species are now known, and these comprise probably about half of the species in the world, but the group is known in detail to few persons.

These lice are distinguishable from the Mallophaga by their mouthparts and manner of feeding. The mouthparts consist of three very slender stylets which form a tube. When at rest, they are retracted in a pocket which lies just behind the mouth. The antennae are usually five-segmented, rarely three-segmented. The thoracic segments are always very closely fused and lack wings. The claw is one-segmented, and on at least one pair of legs this claw is enlarged and can be folded into a process from the tibia to grasp a hair of the host. In some species two and in others all of the legs are thus modified. The ovipositor



The louse *Pediculus humanus*, female, shown in (*a*) dorsal and (*b*) ventral views.

is very much reduced. It consists of but little more than two flaps which are able to close around a hair. Eyes are commonly lacking, and in those species in which they do occur, they are reduced to a pair of simple lenses or two light-receptive spots. All the species are quite small; the largest scarcely exceeds 0.2 in. (5 mm) in length and the smallest does not attain 0.04 in. (1 mm).

Feeding is accomplished by thrusting forth the tube formed by the stylets, piercing the skin of the host, and sucking blood by a pump in the throat of the insect. This habit of sucking blood gives the Anoplura a special importance. They take up any disease-producing organisms in the host's blood and may transfer these organisms to another individual. Thus, they transfer the organisms which cause epidemic typhus, relapsing fever, and trench fever. The transfer of a louse, from one host to another, can occur only when the hosts are in close bodily contact, as in the nest or at the time of mating. In the case of humans, the lice may become detached and enter the clothing or the bedding. In times of social disturbance, such as war or when people are crowded together as formerly occurred on ships, or in jails or slums, the opportunities for an exchange of these parasites are enormously increased. The close restriction of each species of lice to its special host is sufficient to account for the fact that diseases are not transferred from one species of mammal to another.

There are two species of lice which occur as common ectoparasites upon humans. One of them is *Pediculus humanus*, the head and body louse which transmits the diseases mentioned above (see illustration). The other species is *Phthirius pubis*, known as the crab louse. It transmits no known disease. The lice of the Old World monkeys are referred to another genus, *Pedicinus*. *See* INSECTA; MALLOPHAGA. [G.F.F./D.M.DeL.]

Anorexia nervosa A psychiatric disorder in which a dramatic reduction in caloric intake consequent to excessive dieting leads to significant bodily, physiological, biochemical, emotional, psychological, and behavioral disturbances. Anorexia nervosa is typically an illness of adolescent females: 90% of all cases begin in girls who are between 12 and 20 years of age. Nevertheless, this disorder can also occur in males, in prepubertal girls, and in women well into their third decade. Moreover, if the illness becomes chronic, it can persist into mid-life and beyond. Anorexia nervosa literally means "nervous loss of appetite" but appears to have little to do with such. Rather, there is usually a conscious decision made by a teen-age girl, most commonly around the ages of 14 or 18 years, to embark upon a diet. The amount of weight lost can vary considerably. The usual criterion for making a diagnosis of anorexia nervosa is a weight change of at least 25% from premorbid weight (to at least 15% below ideal weight in persons who were overweight at the onset). But this figure should be viewed as only a rule of thumb. In addition to these core disturbances, there is an array of associated symptoms and practices that characterize most persons with anorexia nervosa. Amenorrhea (absence of menstruation); increased physical activity; insomnia; use of emetics, cathartics, and diuretics; difficulty in recognizing satiation; and obsessional thinking and depression. The course and prognosis of anorexia nervosa is highly variable. While a high recovery rate, perhaps above 67%, is found in those persons whose illness begins acutely in their early teens and who quickly receive treatment, the outlook is considerably bleaker in those persons who develop the disorder later, who do not receive early treatment, and who develop bulimia.

Perhaps as many as 40–50% of anorectic patients whose illness persists for more than 1–2 years will develop the additional eating disturbance known as bulimia. Literally meaning "ox-hunger," bulimia refers to binge eating or compulsive overeating wherein thousands of calories are consumed in a relatively brief period of time (for example, 2 h). The binge characteristically involves carbohydrates and will usually culminate in self-induced vomiting. The precise nature of the relationship of bulimia to anorexia nervosa remains unclear. Not all anorectics become bulimic and not all bulimics were anorectic. But dieting is common as a precursor to bulimia, and high premorbid weight and chronicity of weight loss seem to predispose the anorectic to developing bulimia.

Although there is a broad range of symptoms, personality styles, precipitants, and outcomes that characterize anorexia nervosa, there is no simple explanation of its origins. In one widely accepted conception, the illness is viewed as a desperate struggle by the vulnerable female adolescent to establish a sense of identity separate from that of her domineering, overbearing, controlling, and intrusive mother. There is considerable emphasis on viewing the family system as the matrix in which the illness develops and for which the illness must have significance. Anorexia is viewed as both a response to the lack of "living space" that the adolescent experiences and as a defense against the threats to the stability of the family system that the girl's normal development implies. Development of anorexia is thus a function of both individual and family. It should be noted, however, that these formulations suffer from a common problem. They are based on assessments of anorectic patients—and their families—after the illness has become established. Thus, these theories cannot very well differentiate among predisposing, precipitating, and sustaining factors.

There are numerous physical, physiological, and biochemical changes that reflect primarily, although not solely, the ravages of starvation. In addition to the general bodily emaciation they manifest, anorectic individuals show brittle nails, thinning hair, cold extremities, a slow pulse, a small heart, and a hypometabolic state. In anorectic women who also binge and vomit, tooth decay and enlargement of the salivary glands are common. A mild-to-moderate anemia and a diminished white blood cell count develop with progressive malnutrition. Diabetes insipidus can also occur in advanced cases. In addition, abnormalities in glucose tolerance and blood electrolytes have been observed. Particularly in women who vomit, the blood potassium level can be significantly low. *See* MALNUTRITION.

Because of the prominence of amenorrhea in its symptomatology, there has been a long-standing interest in the endocrinology of anorexia nervosa. A number of reliable hormonal abnormalities have been documented. Most prominent among these are diminished hypothalamic-pituitary-gonadal axis function and elevated hypothalamic-pituitary-adrenal axis function. Reversal of these endocrine aberrations usually occurs with clinical improvement, although considerable time may be required for full normalization. *See* ENDOCRINE MECHANISMS.

As with virtually all psychiatric conditions for which the etiology is unknown and where no single empirically effective treatment exists, the therapeutic approaches to anorexia nervosa are diverse and reflect the different disciplines, training biases, and experiences of their proponents. Individual, insight-oriented psychotherapy directed toward increasing confidence in identifying and accepting bodily feelings, and understanding the sources of one's low self-esteem and poor sense of self, has generally been the essence of treatment for nonhospitalized individuals, particularly before chronicity has set in. Individual psychotherapy still remains a critical part of any approach to treatment, but the recovery rate can be increased, perhaps beyond 80%, by the inclusion of regular family therapy as part of the treatment approach. In the hospital, the first priority of treatment is directed toward correcting the biological abnormalities created by the extreme dieting (and, when present, the vomiting). If the individual appears unable or unwilling to resume adequate caloric intake, despite firm but supportive nursing and concomitant individual and family psychotherapy, more extreme measures may have to be instituted, including behavior modification or intravenous hyperalimentation. There is some evidence that, particularly in anorectics who are also characterized by depression and bulimia, antidepressant or possibly anticonvulsant medication may be helpful in damping down the binging and thereby gradually normalizing eating behavior in general. *See* PSYCHOPHARMACOLOGY; PSYCHOTHERAPY. [J.L.Ka.]

Anorthite The calcium-rich plagioclase feldspar with composition Ab_0An_{100} to $Ab_{10}An_{90}$ ($Ab = NaAlSi_2O_8$; $An = CaAl_2Si_2O_8$), occurring in olivine-rich igneous rocks and rare volcanic ejecta (for example, at Mount Vesuvius, Italy, and Miyakejima, Japan). Hardness is 6 on Mohs scale, specific gravity 2.76, melting point 1550°C (2822°F). The crystal structure of Ab_0An_{100} consists of an infinite three-dimensional array of corner-sharing $[AlO_4]$ and $[SiO_4]$ tetrahedra, alternately linked together in a framework of $[Al_2Si_2O_8]_\infty^{2-}$ composition in which charge-balancing calcium (Ca^{2+}) cations occupy four distinct, irregular cavities. Natural anorthite has no commercial uses, but the synthetic material $[CaO \cdot Al_2O_3 \cdot 2SiO_2$ (known as CAS_2)] is important in the ceramic industry and in certain composite materials with high-temperature applications. *See* Feldspar. [P.H.R.]

Anorthoclase The name usually given to alkali feldspars which have a chemical composition ranging from $Or_{40}Ab_{60}$ to $Or_{10}Ab_{90}$ ± up to approximately 20 mole % An (Or, Ab, An = $KAlSi_3O_8$, $NaAlSi_3O_8$, $CaAl_2Si_2O_8$) and which deviate in one way or another from monoclinic symmetry tending toward triclinic symmetry. When found in nature, they usually do not consist of a single phase but are composed of two or more kinds of K- and Na-rich domains mostly of submicroscopic size. In addition, they are frequently polysynthetically twinned after either or both of the albite and pericline laws. It appears that they originally grew as the monoclinic monalbite phase, inverting and unmixing in the course of cooling during geological times. They are typically found in lavas or high-temperature rocks. *See* Feldspar; Igneous rocks. [F.H.L.]

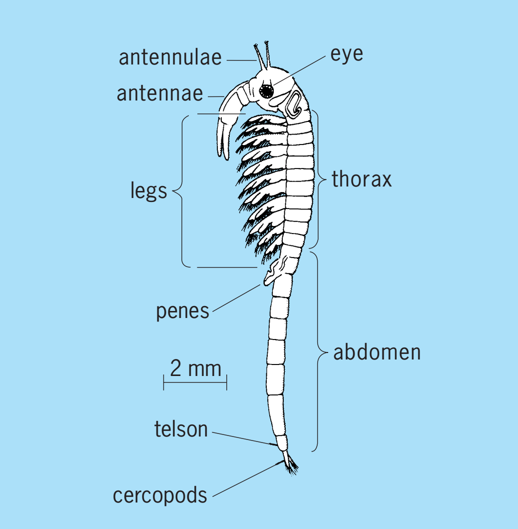
Anorthosite A rock composed of 90 vol % or more of plagioclase feldspar. Strictly, the rock is composed entirely of crystals discernible with the eye, but some finely crystalline examples from the Moon have been called anorthosite or anorthositic breccia. Scientists have been fascinated with anorthosites because they are spectacular rocks (dark varieties are quarried and polished for ornamental use); valuable deposits of iron and titanium ore are associated with anorthosites; and the massif anorthosites appear to have been produced during a unique episode of ancient Earth history (about $1\text{–}2 \times 10^9$ years ago).

Pure anorthosite has less than 10% of dark minerals—generally some combination of pyroxene, olivine, and oxides of iron and titanium; amphibole and biotite are rare, as are the light minerals apatite, zircon, scapolite, and calcite. Rocks with less than 90% but more than 78% of plagioclase are modified anorthosites (such as gabbroic anorthosite), and rocks with 78–65% of plagioclase are anorthositic (such as anorthositic gabbro). *See* Gabbro.

The structure, texture, and mineralogy vary with type of occurrence. One type of occurrence is as layers (up to several meters thick) interstratified with layers rich in pyroxene or olivine. The second type of occurrence is the massifs type and can have an area up to 11,600 mi^2 (30,000 km^2). Commonly, the massifs are domical in shape and weakly layered. Possibly there is a third group of anorthosite occurrences: extremely ancient bodies of layered rock in which the layers of anorthosite contain calcium-rich plagioclase and the adjacent layers are rich in chromite and amphibole in addition to pyroxene. There are only a few examples of these apparently igneous complexes, in Greenland, southern Africa, and India. However, they appear to be terrestrial counterparts of lunar anorthosites.

By comparison with terrestrial occurrences, most lunar anorthosites are very fine grained, although one rock has crystals up to a centimeter long. Much of the fine grain size results from comminution by meteorite impact, and some of it probably results from rapid crystallization of impact melts. *See* Andesine; Igneous rocks; Labradorite; Metamorphism; Moon. [A.T.A.]

Anostraca An order of branchiopod crustaceans, known as fairy shrimps and, in some cases, brine shrimps. These organisms range up to about 4 in. (100 mm) in length, but usually are much smaller. The trunk consists of 19 to 27 segments, of which usually the first 11, sometimes the first 17 or 19, bear limbs, plus a telson bearing flattened furcal rami (see illustration). The trunk limbs are foliaceous, and all are of the same basic type but differ a little among themselves; each limb is differentiated into a series of endites and is usually filtratory. By beating in metachronal rhythm they propel the animal forward and draw food particles toward it. Anostracans usually swim with their ventral surface uppermost.



***Branchinecta paludosa*, male, small specimen, lateral aspect.**

Most anostracans subsist on minute particles that they sieve from the water with their trunk limbs and pass forward to the mouthparts. Reproduction is usually bisexual, but some brine shrimps are parthenogenetic. Fairy shrimps frequent fresh water, usually temporary pools, in all regions of the world, but are also found in predator-free waters in Arctic and Antarctic regions. *See* Branchiopoda. [G.Fr.]

Anoxic zones Oxygen-depleted regions in marine environments. The dynamic steady state between oxygen supply and consumption determines the oxygen concentration. In regions where the rate of consumption equals the rate of supply, seawater becomes devoid of oxygen and thus anoxic. In the open ocean, the only large regions which approach anoxic conditions are between 165 and 3300 ft (50 and 1000 m) deep in the equatorial Pacific and between 330 and 3300 ft (100 and 1000 m) in the northern Arabian Sea and the Bay of Bengal in the Indian Ocean. The Pacific region consists of vast tongues extending from Central America and Peru nearly to the middle of the ocean in some places. In parts of this zone, oxygen concentrations become very low, 15 μmol/liter (atmospheric saturation is 200–300 μmol/liter). Pore waters of marine sediments are sometimes anoxic a short distance below the sediment-water interface. The degree of oxygen consumption in sediment pore waters depends upon the amount of organic matter reaching the sediments and the rate of bioturbation (mixing of the surface sediment by benthic animals). In shallow regions (continental shelf and slope), pore waters are anoxic immediately below the sediment-water interface; in relatively rapid sedimentation-rate areas of the deep sea, the pore waters are usually anoxic within a few centimeters of the interface; and in pore waters of slowly accumulating deep-sea sediments, oxygen may never become totally depleted. *See* MARINE SEDIMENTS.

Restricted basins (areas where water becomes temporarily trapped) are often either permanently or intermittently anoxic. Classic examples are the Black Sea, the Carioca Trench off the coast of Venezuela, and fiords which occupy the Norwegian and British Columbia coasts. Lakes which receive a large amount of nutrient inflow (either from natural or human-produced sources) are often anoxic during the period of summer stratification. *See* BLACK SEA; FIORD.

The chemistry of many elements dissolved in seawater (particularly the trace elements) is vastly changed by the presence or absence of oxygen. Since large areas of the ocean water mass are in contact with oxygen-depleted pore waters, the potential exists for anoxic conditions to have a marked effect on the chemistry of the sea. *See* SEAWATER; SEAWATER FERTILITY. [S.R.E.]

Anseriformes An order of birds comprising two families, the screamers (Anhimidae) of South America and the worldwide waterfowl (Anatidae). They are closely related to the Galliformes, with the screamers being a rather intermediate group. The giant, flightless diatrymids of the early Tertiary are specialized offshoots of the Anseriformes. *See* GALLIFORMES; GASTORNITHIFORMES.

The order Anseriformes is divided into the suborder Anhimae, containing the single family Anhimidae (screamers; 3 species), and the suborder Anseres, including only the family Anatidae (ducks, geese, and swans; 147 species). The waterfowl (Anatidae) are further subdivided into seven subfamilies, namely the primitive Anseranatinae (magpie goose of Australia), Dendrocygninae (tropical tree ducks), Anserinae (swans and geese), Tadorninae (shelducks of the Old World and South America), Anatinae (true ducks), Merginae (mainly Northern Hemisphere sea ducks and mergansers), and Oxyurinae (stiff-tailed ducks).

The South American screamers are turkey-sized, fowllike aquatic birds with a short, heavy, chickenlike beak. The legs are of medium length and heavy, with four toes having only a basal web. They fly slowly but soar well. Screamers live in marshes, walk on mats of floating vegetation, and sometimes swim. They feed on vegetable matter, are gregarious, and nest in solitary pairs.

The waterfowl vary in size from pygmy geese to large swans. They occur worldwide in fresh and marine (coastal) waters. All species have strong legs and feet with webbed toes and a flattened bill with comblike lamellae or teeth. The plumage is waterproof and varies from pure white to multihued to all black; females usually have a brown, cryptic plumage. The tongue is large and fleshy and serves in filter-feeding. Waterfowl feed on both plants and animals, obtained by filtering (many true ducks), grazing (swans and geese), and diving (sea ducks, mergansers, stiff-tailed ducks, and some true ducks). Diving ducks feed on mollusks and water plants, mergansers on fish. All species swim well, and most are strong fliers. Most species are gregarious except at breeding. Waterfowl are monogamous with a strong pair bond (some mate for life) and elaborate courtship.

The waterfowl are of immense economic importance. The mallard (*Anas platyrhynchos*; the common domesticated duck), muscovy duck (*Cairina moschata*), gray-lag goose (*Anser anser*; the common domesticated goose), and swan goose (*Anser cygnoid*) have been domesticated since ancient times for their flesh, eggs, and feathers. *See* AVES. [W.J.B.]

Ant All ants are classified in a single family, Formicidae; this reflects their limited structural variation. They are thought to have evolved from a wasplike ectoparasite of soil insects. Australia contains many primitive species, including the bulldog ants, which are large and fierce and live in small colonies (subfamily Myrmicinae). A common tropical group (Ponerinae) has evolved specialists in group raiding for soil insects, especially preying upon the ubiquitous termites. Also tropical is a set of predacious species (Dorylinae) whose colonies can contain a million workers, but only one queen; as well as hunting in groups, the whole colony roams nomadically through the forests. Other subfamilies are no longer exclusively predacious: in the Formicinae, which include the most conspicuous temperate region ants, plant-sucking bugs are used as a source of honeydew which, though mainly sugary, contains some soluble proteins. Wood ants (*Formica species*) pile dead vegetation into huge mound nests inside which they can retain their body heat. From the nests they establish permanent trackways to aphid-bearing trees, on which they also capture many insect larvae, including those injurious to forest trees. Each tree is part of a large territory which is defended against neighboring colonies. Yellow ants (*Lasius flavus*) culture aphids of many sorts on roots belowground and apparently use their carcasses as meat; in Europe they build soil mounds in old hillside grassland. In the tropics the leaf-nesting ants (*Oecophylla* species), which use larval silk to bind leaves together into a nest, culture plant-bugs in trees as well as prey upon a variety of insects; they can be used to protect fruit bushes from harmful insects.

In subfamily Myrmicinae, though there are many simple, mundane species with mixed diets, some specialists have almost given up predation. Thus grain collectors store and eat seeds; any seeds that germinate are put out and, mixed with rubbish, may start new plants nearer home (surely agriculture in its infancy). Then there are the leaf-cutting ants (tribe Attini) of Central America that collect vegetation and feed it to a species of fungus whose special bodies they then eat. These ants secrete a battery of chemicals for stopping the growth of weed species. Ants of another subfamily (Pseudomyrmicinae) have close mutualistic relations with plants: the plants supply special hollow galls, stems, or swollen thorns and offer nourishing tissues inside; the ants live and feed in these cavities and in exchange protect the plant from phytophagous insects and other enemies.

All female ants are social insects (the males exist only briefly to provide sperm) that live in dense clusters in nests made to protect against weather and enemies and to provide a work surface on which to rear their young. There are two types of female: small, wingless ones (called workers) that construct and defend the nest as well as collect and prepare food for the almost helpless larvae; and large, winged ones (called queens) that fly off to copulate, disperse, and start new nests, and which, after breaking off their wings, not only lay most of the eggs (usually all the female eggs and often the male ones too) but stimulate and organize worker activity. Workers usually have ovaries but no sperm sac, and the few eggs each lays are unfertilized; though haploid, they can produce males by parthenogenesis, for sex is determined by a haplo-diploid mechanism as in most insects of this order (Hymenoptera). *See* HYMENOPTERA; SOCIAL INSECTS. [M.V.B.]

Antarctic Circle An imaginary line that delimits the northern boundary of Antarctica. It is a distinctive parallel of latitude at approximately 66°30' south. Thus it is located about 4590 mi (7345 km) south of the Equator and about 1630 mi (2620 km) north of the south geographic pole.

All of Earth's surface south of the Antarctic Circle experiences one or more days when the Sun remains above the horizon for at least 24 h. The Sun is at its most southerly position on or about December 21 (slightly variable from year to year). This date is known as the summer solstice in the Southern Hemisphere and as the winter solstice in the Northern Hemisphere. At this time, because Earth is tilted on its axis, the circle of illumination reaches 23.50° to the far side of the South Pole and stops short 23.50° to the near side of the North Pole.

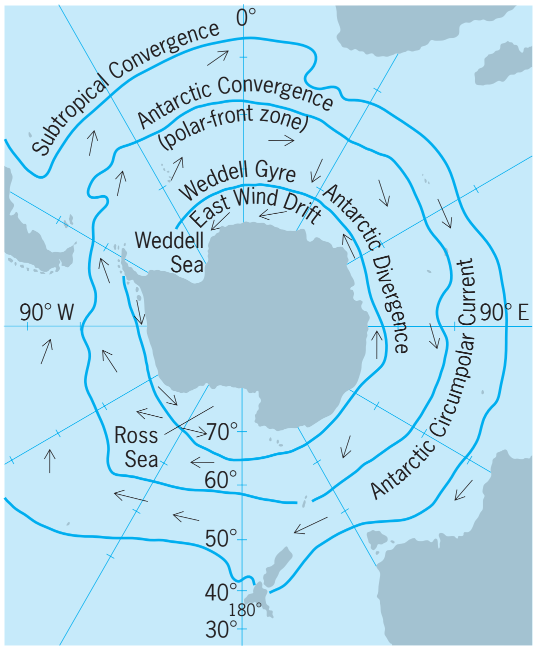
The longest period of continuous sunshine at the Antarctic Circle is 24 h, and the highest altitude of the noon Sun is 47° above the horizon at the time of the summer solstice. The long days preceding and following the solstice allow a season of about 5 months of almost continuous daylight.

Six months after the summer solstice, the winter solstice (Southern Hemisphere terminology) occurs on or about June 21 (slightly variable from year to year). On this date the Sun remains below the horizon for 24 h everywhere south of the Antarctic Circle; thus the circle of illumination reaches 23.50° to the far side of the North Pole and stops short 23.50° to the near side of the South Pole. *See* Arctic Ocean. [T.L.M.]

Antarctic Ocean The Antarctic Ocean, sometimes called the Southern Ocean, is the watery belt surrounding Antarctica. It includes the great polar embayments of the Weddell Sea and Ross Sea, and the deep circumpolar belt of ocean between 50 and 60°S and the southern fringes of the warmer oceans to the north. Its northern boundary is often taken as 30°S (see illustration). The Antarctic is a cold ocean, covered by sea ice during the winter from Antarctica's coast northward to approximately 60°S.

The remoteness of the Antarctic Ocean severely hampers the ability to observe its full character. The sparse data collected and the more recent addition of data obtained from satellite-borne sensors have led to an appreciation of the unique role that this ocean plays in the Earth's ocean and climate. Between 50 and 60°S there is the greatest of all ocean currents, the Antarctic Circumpolar Current sweeping seawater from west to east, blending waters of the Pacific, Atlantic, and Indian oceans. Observed within this current is the sinking of cool (approximately 4°C; 39.2°F), low-salinity waters to depths of near 1 km (0.6 mi), which then spreads along the base of the warm upper ocean waters or thermocline of more hospitable ocean environments. The cold polar atmosphere spreading northward from Antarctica removes great amount of heat from the ocean, heat which is carried to the sea surface from ocean depths, brought into the Antarctic Ocean from warmer parts of the ocean. At some sites along the margins of Antarctica, there is rapid descent of cold (near the freezing point of seawater, −1.9°C; 28.6°F) dense water, within thin convective plumes. This water reaches the sea floor, where it spreads northward, chilling the lower 2 km (1.2 mi) of the global ocean, even well north of the Equator.

The major flow is the Antarctic Circumpolar Current, or West Wind Drift (see illus). Along the Antarctic coast is the westward-flowing East Wind Drift. The strongest currents are in the vicinity of the polar front zone and restricted passages such as the Drake Passage, and over deep breaks in the meridionally oriented submarine ridge systems.



Direction of the surface circulation and major surface boundaries of the Antarctic Ocean.

The extreme cold of the polar regions causes an extensive ice field to form over the southern regions of the Antarctic Ocean. The extent of the ice is seasonal in that during the October-to-March period the area decreases, and it increases during the remaining months. The seasonal difference in the volume of sea ice is estimated as 2.3×10^{19} grams (8.1×10^{17} oz). Satellite photographs reveal that the sea ice field is not uniform, but has many large polynyas (areas of water). The sea ice plays an important role in the heat balance since it reflects much more solar radiation (and therefore heat) into space than would be the case for a water surface. The polynyas would therefore be of special interest in radiation and heat-balance studies. In addition to the ice formed at sea, the ice calving at the coast of Antarctica introduces icebergs into the ocean at a rate of approximately 1×10^{18} g/year (3.5×10^{12} oz/year). *See* Heat balance, terrestrial atmospheric; Iceberg; Sea ice.

Glacial (fresh-water) ice and the ocean meet along the shores of Antarctica. This occurs not only at the northern face of the ice sheet but also at hundreds of meters depth along the bases of floating ice shelves. Ocean-glacial ice interaction is believed to be a major factor in controlling Antarctica's glacial ice mass balance and stability. [A.L.G.]

Antarctica The coldest, windiest, and driest continent, overlying the South Pole. The lowest temperature ever measured on Earth was recorded at the Russian Antarctic station of Vostok at −89.2°C (−128.5°F) in July 1983. Katabatic (cold, gravitational) winds with velocities up to 50 km/h (30 mi/h) sweep down to the coast and occasionally turn into blizzards with 150 km/h (nearly 100 mi/h) wind velocities. Antarctica's interior is a cold desert with only a few centimeters of water-equivalent precipitation, while the coastal areas average 30 cm (12 in.).

Antarctica's area is about 14 million square kilometers (5.4 million square miles), which is larger than the contiguous 48 United States and Mexico together. It is the third smallest continent, after Australia and Europe. About 98% of it is buried under a thick ice sheet, which in places is 4 km (13,000 ft) thick, making it the highest continent, with an average elevation of over 2 km (6500 ft).

Although most of Antarctica is covered by ice, some mountains rise more than 3 km (almost 10,000 ft) above the ice sheet. The largest of these ranges is the Transantarctic Mountains separating east from west Antarctica, and the highest peak in Antarctica is Mount Vinson, 5140 m (16,850 ft), in the Ellsworth Mountains. Other mountain ranges, such as the Gamburtsev Mountains in East Antarctica, are completely buried, but isolated peaks called nunataks frequently thrust through the ice around the coast.

The Antarctic ice sheet is the largest remnant of previous ice age glaciations. It has probably been in place for the last 20 million years and perhaps up to 50 million years. It is the largest reservoir of fresh water on Earth, with a volume of about 25 million cubic kilometers (6 million cubic miles). Glaciers flow out from this ice sheet and feed into floating ice shelves along 30% of the Antarctic coastline. The two biggest ice shelves are the Ross and Filchner-Ronne. These shelves may calve off numerous large tabular icebergs, with thicknesses of several hundred meters, towering as high as 70–80 m (250 ft) above the sea surface. *See* Glaciology.

Year-round life on land in Antarctica is sparse and primitive. North of the Antarctic Peninsula a complete cover of vegetation, including moss carpets and only two species of native vascular plants, may occur in some places. For the rest of Antarctica, only lichen, patches of algae in melting snow, and occasional microorganisms occur. In summer, however, numerous migrating birds nest and breed in rocks and cliffs on the continental margins, to disappear north again at the beginning of winter. South of the Antarctic Convergence, 43 species of flying birds breed annually. They include petrels, skuas, and terns, cormorants, and gulls. Several species of land birds occur on the subantarctic islands. The largest and best-known of the Antarctic petrels are the albatrosses, which breed in tussock grass on islands north of the pack ice. With a wing span of 3 m (10 ft), they roam freely over the westerly wind belt of the Southern Ocean. *See* PROCELLARIIFORMES. [G.We.]

Antares α Scorpii, a cool supergiant star of spectral type M1Ib, whose red color stands out in the midsummer sky. With an effective temperature of approximately 6000°F (3600 K), Antares resembles Betelgeuse, the brightest of the red supergiants, and would fill the solar system beyond the orbit of Mars if it replaced the Sun. Antares is only about 100 parsecs (325 light-years) from the Sun, and its angular diameter of about 0.045 arc-second has been measured by interferometric and lunar occultation methods. Red supergiants of this type originate as stars with mass at least 20 times that of the Sun. Such stars quickly evolve through successive stages of thermonuclear fusion. Eventually, the supergiant star implodes in a type II supernova explosion. This fate is likely for Antares in less than a million years. Prior to this dramatic event, Antares will have shed up to 50% of its mass through a stellar wind of material blown away from the star into the surrounding interstellar medium. *See* BETELGEUSE; SCORPIUS; SPECTRAL TYPE; STELLAR EVOLUTION; SUPERGIANT STAR; SUPERNOVA.

Antares is a member of an association of young and primarily hot stars, and is gravitationally bound in a binary star system with a hot blue star of spectral type B3V. The two stars orbit each other with a period of about 900 years, from which their masses can be determined to be about 15 and 7 times that of the Sun for the red and blue components respectively. The interaction of the strong wind of matter from the supergiant with the radiation from the less massive, hot companion produces an unusual nebulosity surrounding the hot star. *See* BINARY STAR; NEBULA; STAR. [H.A.McA.]

Anteater A name associated with several animals in five different orders of the three major groups of living mammals (see table). They are so named because they are insectivorous, having a diet of ants and termites. The animal most frequently associated with this name is the ground-living *Myrmecophaga tridactyla*, the giant anteater, a member of the family Myrmecophagidae in the order Edentata (see illustration). This family has three other species, *Tamandua longicaudata, T. tetradactyla*, and *Cyclopes didactylus*, all of which are arboreal.

All four species are restricted to the tropical regions of South and Central America. *Myrmecophaga tridactyla* prefers the grasslands and more open forested areas. The animal is about 6 ft (1.8 m) long including the tail length, which measures about 2 ft (0.6 m). It is toothless, and the head extends into a long, tubular snout with a small mouth opening. The tongue is long, protrusible, and covered with a viscous mucous material which entraps the insects. The front feet have greatly enlarged claws used for tearing into ant and termite mounds and as defensive weapons. The body is covered with long hair, and in *Cyclopes* the tail is prehensile. Usually a single young is produced by the female, which she may carry on her back until it is quite large. *See* AARDVARK; EDENTATA; MARSUPIALIA; MONOTREMATA; PHOLIDOTA; TUBULIDENTATA. [C.B.C.]

The giant anteater (*Myrmecophaga tridactyla*).

Classification and scientific name of some animals commonly referred to as anteaters

Mammalian order	Scientific name	Common name
Monotremata	*Tachyglossus setosus*	Spiny anteater or Tasmanian echidna
	T. aculeatus	Australian echidna
	Zaglossus bruijini	Bruijn's echidna
	Z. bartoni	Barton's echidna
	Z. bubuensis	Bubu echidna
Marsupialia	*Myrmecobius fasciatus*	Marsupial anteater or banded anteater
	M. rufus	Rusty numbat
Pholidota	*Manis gigantea*	Scaly anteater or giant pangolin
	M. temmincki	Cape pangolin
	M. tricuspis	Tree pangolin
	M. longicaudata	Long-tailed tree pangolin
	M. pentadactyla	Chinese pangolin
	M. crassicaudata	Indian pangolin
	M. javanica	Malayan pangolin
Edentata	*Myrmecophaga tridactyla*	Giant anteater
	Tamandua longicaudata	Long-tailed anteater
	T. tetradactyla	Tamandua
	Cyclopes didactylus	Dwarf anteater
Tubulidentata	*Orycteropus afer*	Aardvark or Cape anteater

Antelope The name given to a group of hollow-horned, hoofed ruminants of the order Artiodactyla which are strictly confined to various areas of Africa and Asia. They are assigned to the subfamily Antilopinae in the family Bovidae and include 91 species in 31 genera.

In general, the third and fourth toes are well developed, while the second and fifth toes are reduced or absent. The males and usually the females have a pair of unbranched horns, which differ considerably in appearance among the various species of antelopes. These animals vary in size from the royal antelope (*Neotragus pygmaeus*), which is about 10–12 in. (25–30 cm) high at the shoulder, to the giant eland (*Taurotragus derbianus*), which measures about 6 ft (1.8 m) at the shoulder and weighs about 1 ton (0.9 metric ton). *See* ARTIODACTYLA; MAMMALIA. [C.B.C.]

Antenna (electromagnetism) The device that couples the transmitter or receiver network of a radio system to space. Radio waves are used to transmit signals from a source through space. The information is received at a destination which in some cases, such as radar, can be located at the transmitting source. Thus, antennas are used for both transmission and reception. *See* RADAR.

To be highly efficient, an antenna must have dimensions that are comparable with the wavelength of the radiation of interest. At long wavelengths such as the part of the spectrum used in broadcasting (a frequency of 1 MHz corresponds to a free-space wavelength λ of 300 m), the requirement on size poses severe structural problems, and it is consequently necessary to use structures that are portions of a wavelength in size (such as 0.1 λ or 0.25 λ). Such antennas can be described as being little more than quasielectrostatic probes protruding from the Earth's surface.

In order to control the spread of the energy, it is possible to combine antennas into arrays. As the wavelength gets shorter, it is possible to increase the size of the antenna relative to the wavelength; proportionately larger arrays are also possible, and techniques that are familiar in acoustics and optics can be employed (Fig. 1). For example, horns can be constructed with apertures that are large compared with the wavelength. The horn can be designed to make a gradual transition from the transmission line, usually in this case a single-conductor waveguide, to free space. The result is broadband impedance characteristics as well as directivity in the distribution of energy in space. Another technique is to use an elemental antenna such as a horn or dipole together with a reflector or lens. The elemental antenna is essentially a point source, and the elementary design problem is the optical one of taking the rays from a point source and converting them into a beam of parallel rays. Thus a radio searchlight is constructed by using a paraboloidal reflector or a lens. A very large scale structure of this basic form used as a receiving antenna (together with suitably designed receivers) serves as a radio telescope. Antennas used for communicating with space vehicles or satellites are generally large (compared to wavelength) structures as well. *See* Radio telescope; Space communications; Transmission lines; Waveguide.

A small electric or magnetic dipole radiates no energy along its axis, the contour of constant energy being a toroid. The most basic requirements of an antenna usually involve this contour in space, called the radiation pattern. The purpose of a transmitting antenna is to direct power into a specified region, whereas the purpose of a receiving antenna is to accept signals from a specified direction. In the case of a vehicle, such as an automobile with a car radio, the receiving antenna needs a nondirectional pattern so that it can accept signals from variously located stations, and from any one station, as the automobile moves. The antenna of a broadcast station may be directional; for example, a station in a coastal city would have an antenna that concentrated most of the power over the populated land. The antenna for transmission to or from a communication satellite should have a narrow radiation pattern directed toward the satellite for efficient operation, preferably radiating essentially zero power in other directions to avoid interference. *See* Directivity; Radio broadcasting.

The plane of the electric field of the radiated electromagnetic wave depends on the direction in which the current flows on the antenna. The electric field is in a plane orthogonal to the axis of a magnetic dipole. This dependence of the plane of the radiated electromagnetic wave on the orientation and type of antenna is termed polarization. A receiving antenna requires the same polarization as the wave that it is to intercept. By combining fields from electric and magnetic dipoles that have a common center, the radiated field can be elliptically polarized; by control of the contribution from each dipole, any ellipticity from plane polarization to circular polarization can be produced. *See* Polarization of waves.

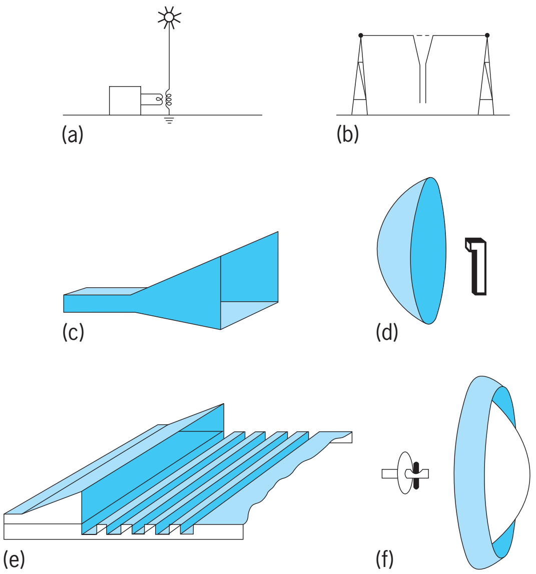


Fig. 1. Various types of antennas. (*a*) Top-loaded vertical mast; (*b*) center-fed horizontal antenna; (*c*) horn radiator; (*d*) paraboloidal reflector with a horn feed; (*e*) corrugated-surface wave system for end-fire radiation; (*f*) zoned dielectric lens with a dipole-disk feed. *(After D. J. Angelakos and T. E. Everhart, Microwave Communications, Krieger, 1983)*

The input impedance of an antenna is the ratio of the voltage to current at the terminals connecting the transmission line and transmitter or receiver to the antenna. The impedance can be real for an antenna tuned at one frequency but generally would have a reactive part at another frequency.

An array of antennas is an arrangement of several individual antennas so spaced and phased that their individual contributions add in the preferred direction and cancel in other directions. One practical objective is to increase the signal-to-noise ratio in the desired direction. Another objective may be to protect the service area of other radio stations, such as broadcast stations. *See* Signal-to-noise ratio.

The simplest array consists of two antennas. It makes possible a wide variety of radiation patterns, from nearly uniform radiation in azimuth to a concentration of most of the energy into one hemisphere, or from energy in two or more equal lobes to radiation into symmetrical but unequal lobes.

For further control over the radiation pattern a preferred arrangement is the broadside box array. In this array, antennas are placed in a line perpendicular to the bidirectional beam. Individual antenna currents are identical in magnitude and phase. The array can be made unidirectional by placing an identical array 90° to the rear and holding its phase at 90°. The directivity of such a box array increases with the length or aperture of the array.

Further use of array concepts has enabled improvements in communications. By introducing a network for each antenna element, it is possible to receive a signal from a source direction and to return a signal in the direction of the source. The returned signal can be modulated or amplified or have its frequency changed. Such an array is called a retrodirective array. Basically, the array seeks out the incoming signal and returns one of useful characteristics, such as that which is needed for the communication between a moving vehicle and a stationary or slowly moving source.

The bandwidth of an antenna may be limited by pattern shape, polarization characteristics, and impedance performance. Bandwidth is critically dependent on the value of Q; hence the larger the amount of stored reactive energy relative to radiated resistive energy, the less will be the bandwidth. *See* Q (electricity).

Antennas whose mechanical dimensions are short compared to their operating wavelengths are usually characterized by low radiation resistance and large reactance. This combination results in a high Q and consequently a narrow bandwidth. Current distribution on a short conductor is sinusoidal with zero current at the free end, but because the conductor is so short electrically, typically less than 30° of a sine wave, current distribution will be essentially linear. By end loading to give a constant current distribution, the radiation resistance is increased four times, thus greatly improving the efficiency but not noticeably altering the pattern.

Long-wire antennas, or traveling-wave antennas, are usually one or more wavelengths long and are untuned or nonresonant.

There are two principal approaches to constructing frequency-independent antennas. The first is to shape the antenna so that it can be specified entirely by angles; hence when dimensions are expressed in wavelengths, they are the same at every frequency. Planar and conical equiangular spiral antennas adhere to this principle (Fig. 2*a*). The second approach depends upon complementary shapes. According to this principle, which is used in constructing log-periodic antennas, before the structure shape changes very much, when measured in wavelengths, the

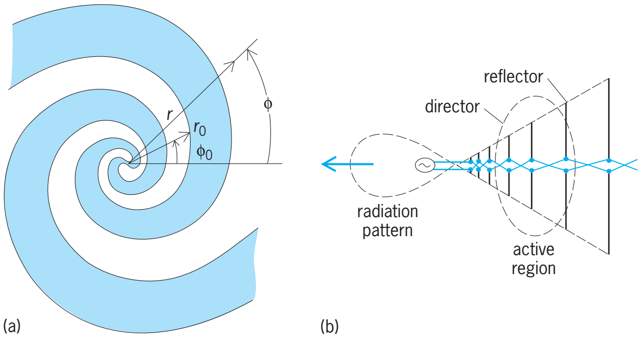

Fig. 2. Frequency-independent antennas. (*a*) Equiangular spiral (*after D. J. Angelakos and T. E. Everhart, Microwave Communications, Krieger, 1983*). (*b*) Log-periodic structure.

structure repeats itself (Fig. 2*b*). By combining periodicity and angle concepts, antenna structures of very large bandwidths become feasible.

When they are to be used at short wavelengths, antennas can be built as horns, mirrors, or lenses. Such antennas use conductors and dielectrics as surfaces or solids. *See* MICROWAVE OPTICS.

By using reflectors it is possible to achieve high gain, modify patterns, and eliminate backward radiation. A low-gain dipole, a slot, or a horn, called the primary aperture, radiates toward a larger reflector called the secondary aperture. The large reflector further shapes the radiated wave to produce the desired pattern.

A beam can be formed in a limited space by a two-reflector system. The commonest two-reflector antenna, the Cassegrain system, consists of a large paraboloidal reflector. It is illuminated by a hyperbolic reflector, which in turn is illuminated by the primary feed (Fig. 3).

A series of antennas are useful in situations which require a low profile. Slot antennas constitute a large portion of this group. In essence, replacing a wire (metal) by a slot (space), which is a complement of the wire, yields radiation characteristics that are basically the same as those of the wire antenna except that the electric and magnetic fields are interchanged.

Because flush-mounted antennas present a low profile and consequently low wind resistance, slot-type antennas have had considerable use in aircraft, space-launching rockets, missiles, and satellites. They have good radiation properties and are capable of being energized so as to take advantage of all the properties of arrays, such as scanning, being adaptive, and being retrodirective. These characteristics are obtained without physical motion of the antenna structures. Huge slot antenna arrays are commonly found on superstructures of aircraft carriers and other naval ships, and slot antennas are designed as integral parts of the structure of aircraft, such as the tail or wing.

The patch antenna consists of a thin metallic film which is attached to a dielectric substrate mounted on a metallic base. Depending on its use, the patch can be of different shapes and can be driven in various fashions. Driven at one end, the radiated electric field at this end has a polarization that is in phase with the radiated electric field at the farther end of the patch antenna.

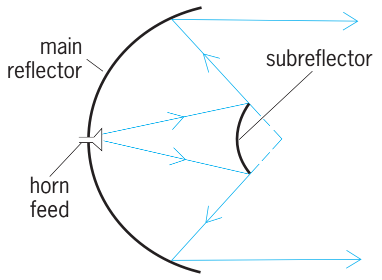

Fig. 3. Cassegrain system.

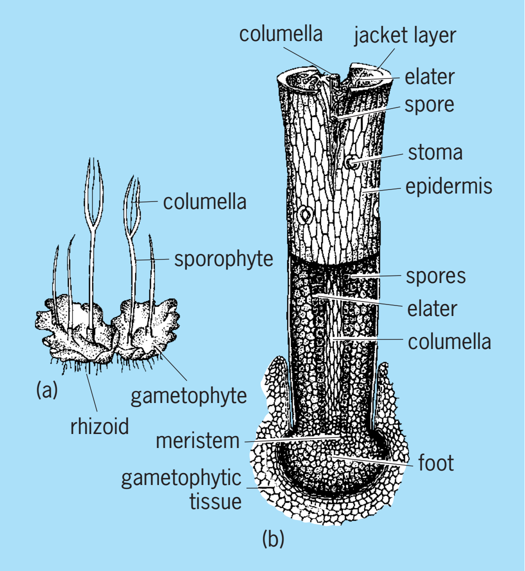
Planar antennas are designed as integral parts of monolithic microwave integrated circuits (MMICs). Coupling can be effected through the use of planar (flush-mounted) antennas fabricated directly on the microelectronics chips (integrated circuits). This arrangement eliminates the need for coaxial lines, which at these microwave frequencies exhibit considerable losses. As is the case with other planar antennas, it is possible to design circuitry so as to obtain many, if not all, the properties of arrays mentioned above. The elements of these arrays can take on the form of slot antennas or patch antennas (of course with suitable modification for use on the MMICs). *See* MICROWAVE. [D.J.A.]

Anthocerotopsida A small class of the plant division Bryophyta, made up of plants commonly called hornworts. There is a single order with six genera.

Gametophyte structure. The gametophytes are flat thalli, often forming rosettes of uniform thickness (see illustration) or, in *Dendroceros*, with a thickened midrib and crisped unistratose wings. Ventral scales are absent. Rhizoids are unicellular, with thin, smooth walls. The thallus of undifferentiated tissue is sometimes provided with cavities containing mucilage (and often occupied by *Nostoc* colonies) and ventral pores leading to them. The cells are thin-walled and lack oil bodies; at least those at the surface have one, two, or more large chloroplasts with a central pyrenoid. Slime papillae (or mucilage hairs) are lacking. The stalked antheridia develop from internal cells and occur singly or in groups in cavities beneath the upper surface of the thallus and become exposed by the rupture of overlying tissue. The archegonia, also endogenous, are embedded in the dorsal tissue of the thallus. Paraphyses are lacking. The sporophyte is surrounded at the base by a tubular involucre (or completely surrounded in *Notothylas*). A calyptra is lacking.

Sporophyte structure. The sporophyte consists of a massive foot and an erect, long-cylindric, green capsule (see illustration), though in *Notothylas* the capsule is horizontal and spindle-shaped. The capsule, indeterminate in growth owing to a basal meristem, dehisces from the apex into two valves which are usually twisted when dry. The wall consists of several cell layers in a more or less solid tissue having one, two, or more chloroplasts per



Hornwort *Anthoceros*. (*a*) Thalloid gametophyte with long hornlike sporophytes. (*b*) Elongated sporophyte with basal foot in gametophytic tissue. (*After H. J. Fuller and O. Tippo, College Botany, rev. ed., Holt, 1954*)

cell. Stomata with two guard cells are usually present. The spore sac, derived from the amphithecium, surrounds and overarches the slender columella (lacking in *Notothylas*). Spore maturation proceeds from the apex downward. The tetrahedral spores are mingled with pseudelaters of one to several cells, with or without spiral bands. A protonema is lacking. The haploid chromosome number is 5 or 6. *See* Reproduction (plant).

The elongate capsule dehiscing by two valves and its indeterminate growth from a basal meristematic tissue are unique, as are the large chloroplasts with a central pyrenoid and the endogenous origin of sex organs. (The chloroplasts are sometimes single in the gametophyte and paired in the sporophyte.) The spore mother cells undergo meiosis directly, but the elater mother cells usually undergo several mitotic divisions before differentiation as pseudelaters of an unreduced chromosome number. As a result, the pseudelaters may be more numerous than the spores. (In the Hepaticopsida, by contrast, the spore mother cells undergo meiosis directly or undergo several mitotic divisions before meiosis, whereas the elater mother cells mature directly into diploid elaters.) *See* Andreaeopsida; Bryophyta; Bryopsida; Hepaticopsida; Sphagnopsida. [H.Cr.]

Anthophyllite A magnesium-rich orthorhombic amphibole with perfect {210} cleavage and a color which varies from white to various shades of green and brown. It is a comparatively rare metamorphic mineral which occurs as slender prismatic needles, in fibrous masses, and sometimes in asbestiform masses. Anthophyllite may occur together with calcite, magnesite, dolomite, quartz, tremolite, talc, or enstatite in metacarbonate rocks; with plagioclase, quartz, orthopyroxene, garnet, staurolite, chlorite, or spinel in cordierite-anthophyllite rocks; and with quartz and hematite in metamorphosed iron formations, and with talc, olivine, chlorite, or spinel in metamorphosed ultrabasic rocks. Anthophyllite is distinguished from other amphiboles by optical examination or by x-ray diffraction, and from other minerals by its two cleavage directions at approximately 126° and 54°.

Anthophyllite has the general formula

$$(\mathrm{Mg, Fe^{2+}})_{7-x}\mathrm{Al}_x(\mathrm{Al}_x\mathrm{Si}_{8-x})\mathrm{O}_{22}(\mathrm{OH, F, Cl})_2$$

with $x<1.0$. For aluminum-poor varieties, up to about 40% of the Mg may be replaced by Fe^{2+}; higher iron contents result in the formation of the monoclinic amphibole cummingtonite. Increasing the aluminum content in anthophyllite beyond $x = 1.0$ results in the formation of the orthohombic amphibole gedrite; aluminous anthrophyllite can accommodate more Fe^{2+} than Al-poor varieties. *See* Amphibole; Cummingtonite. [J.V.C.]

Anthozoa A class of the phylum Coelenterata. These organisms are marine, solitary or colonial, and exclusively polypoid coelenterates with no traces of a medusoid stage. Most anthozoans live attached to some firm object of the shore or on the sea bottom; some embed in the soft sediment. Anthozoans have a cylindrical body with an oral disk, mouth, stomodeum, hollow tentacles, endodermal gonad, and cellular mesoglea. The gastrovascular cavity is partitioned longitudinally into radial compartments by endodermal mesenteries or septa whose free edges, particularly, thicken and differentiate into mesenteric or septal filaments. The nervous system is a diffuse network of scattered nerve cells over the ectoderm and the endoderm. No localized sense organs are present.

Both sexual and asexual reproduction occurs. The germ cells are derived from the endoderm, and fertilization occurs either in the female gastrovascular cavity or in the sea. The zygote develops into either a ciliated swimming larva, the planula, or a young polyp.

The class Anthozoa includes the soft, horny, stony, and black corals, the sea pens, and sea anemones. The horny corals include the sea fans, sea whips, and sea feathers. The Anthozoa may be classified as listed here. Separate articles appear on each group.

Class Anthozoa
  Subclass Alcyonaria (Octocorallia)
    Order: Stolonifera
      Telestacea
      Coenothecalia
      Alcyonacea
      Gorgonacea
      Pennatulacea
  Subclass Zoantharia (Hexacorallia)
    Order: Actiniaria
      Scleractinia (Madreporaria)
      Zoanthidea
      Antipatharia
      Ceriantharia
      Rugosa
      Tabulata

All anthozoans are marine and most are sedentary, except the free-swimming larval stages, while actinians, cerianthids, and pennatulans are somewhat movable. They are widely distributed over the world, extending from the Arctic to the Antarctic; however, they predominate in the tropic and subtropic areas of the Indo-Pacific Ocean. Actinians also inhabit colder water areas from which deep-sea species of gorgonians, pennatulans, and scleractinians have been collected.

Anthozoans seldom tolerate desiccation or heavy sedimentation. They are so sensitive to reduced salinity that they usually do not live near coastal areas where there is river drainage. Tropical corals are able to endure high temperatures and are adversely affected by low temperatures. Therefore, coral reefs are commonly located in tropic and subtropic regions. *See* Coelenterata; Hydrozoa; Scyphozoa. [K.At.]

Anthracosauria An order of Carboniferous and Permian labyrinthodont amphibians much less common than their temnospondyl relatives but important as including the ancestors of reptiles. In contrast with temnospondyls, the pleurocentra are retained and developed in the vertebral column, the tabular bones of the skull roof are in contact with the parietals, and the cheek is primitively but loosely attached to the skull roof. *See* Amphibia; Labyrinthodontia; Temnospondyli. [A.S.R.]

Anthrax An acute infectious zoonotic disease caused by the bacterium *Bacillus anthracis* and primarily associated with herbivorous mammals. Carnivorous mammals, birds, reptiles, amphibians, fish, and insects are generally resistant to anthrax infection. However, carnivorous and omnivorous mammals often succumb after ingestion of infected meat containing the anthrax toxins, which can cause swelling in the throat and suffocation. Humans primarily present with cutaneous lesions, appearing as black scabs or eschars, after contact with infected animals, carcasses, or animal products. *See* Zoonoses.

Anthrax is responsible for the deaths of thousands of domesticated and wild herbivorous animals annually. Parts of Africa, Asia, southern Europe, and North and South America are subject to repeated outbreaks. In the Western Hemisphere, anthrax is well controlled in livestock.

Bacillus anthracis is a gram-positive, rod-shaped, endospore-forming bacterium, approximately 1.0–1.2 micrometers in diameter and 3–8 μm long. The spores resist drying, cold, heat, and disinfectants, and can remain viable for many years in soil, water, and animal hides and products. *Bacillus anthracis* possesses three virulence factors: lethal toxin, edema toxin, and a poly-D-glutamic acid capsule. Lethal toxin is composed of two proteins, lethal factor and protective antigen. The protective antigen is produced by the anthrax bacillus at a molecular weight of 83 kDa, but must be cleaved by either serum or target cell surface proteases to 63 kDa before it complexes with lethal factor to form lethal toxin. The edema toxin is composed of edema factor and protective antigen, and it is believed to complex in a manner similar to that seen for lethal toxin. Protective antigen plays a central role in that it is required for transport of lethal factor and edema factor into host target cells. The macrophage appears to be the primary host target cell for lethal toxin, whereas the neutrophil appears to be the target cell for edema toxin in addition to other cells involved in edema formation. The third virulence factor is the capsule, which inhibits phagocytosis through its negatively charged poly-D-glutamic acid composition. All three toxin components are encoded by a plasmid, pXO1, whereas the enzymes required for capsule synthesis are encoded for by the pXO2 plasmid. Strains lacking either or both plasmids are avirulent, such as the veterinary vaccine Sterne strain, which lacks the pXO2 plasmid. *See* EDEMA.

Anthrax consists of two clinical forms, cutaneous and septicemic. The cutaneous form begins as a blisterlike lesion that eventually becomes an intensely dark, relatively painless, edematous lesion forming a black eschar. The lesions rapidly become sterile after antibiotic therapy and take several weeks to resolve, even with treatment. The cutaneous form is reported only in humans, rabbits, swine, and horses.

The septicemic form arises from various initial sites of infection, including cutaneous, oropharyngeal, gastrointestinal, or inhalational exposures. The course of septicemic disease depends on the exposure route and the susceptibility of the animal host. The vast majority of systemic anthrax cases in herbivorus animals occur from trauma to mucosal linings of the mouth and upper alimentary canal caused by ingested fibrous foods. Inhalation anthrax is believed to be initiated by phagocytosis of spores within the lungs by alveolar macrophages. Spore-laden macrophages pass through lymphatic channels to the sinuses of regional lymph nodes or migrate to the spleen, where the spores germinate within the macrophages, multiply, and overwhelm and escape the macrophages to invade the efferent lymphatics. For other portals of entry, mesenteric lymph nodes become involved. The bacilli move to the spleen, where they induce pronounced splenomegaly (enlargement of the spleen), and finally enter the bloodstream, where they induce secondary sites of infection, massive bacillemia, toxemia, and sudden death. Failure of the blood to clot, hemorrhages of skin, hemorrhagic meningitis, and reduced rigor mortis are frequently found in anthrax-infected carcasses. Exposure of contaminated body fluids to the lower atmospheric levels of carbon dioxide results in sporulation of the bacilli. Therefore, opening of infected carcasses should be avoided.

Besides its central role for binding the lethal and edema toxins to target cells, protective antigen plays an important role in the host's protective immune response against anthrax, hence the term protective antigen. Vaccines lacking protective antigen are not protective. For United States and United Kingdom human anthrax vaccines, protective antigen bound to aluminum salts is the principal immunogen. However, veterinary vaccines are composed of viable spores of *B. anthracis* Sterne strain, a nonencapsulated toxigenic variant. Full protection against anthrax with the veterinary vaccine is afforded by primary and annual booster vaccinations. *See* INFECTIOUS DISEASE. [J.W.Ez.]

Anthropology The observation, measurement, and explanation of human variability in time and space. This includes both biological variability and the study of cultural, or learned, behavior among contemporary human societies. These studies are closely allied with the fields of archeology and linguistics. Studies range from rigorously scientific approaches, such as research into the physiology, demography, and ecology of hunter-gatherers, to more humanistic research on topics such as symbolism and ritual behavior. *See* ARCHEOLOGY; PHYSICAL ANTHROPOLOGY.

Anthropology lacks a unified theory comparable to neo-Darwinian evolution in the biological sciences and is characterized, instead, by a wide variety of subfields that analyze and integrate studies of human behavior in different ways. Social-cultural anthropology examines the various ways in which learned techniques, values, and beliefs are transmitted from one generation to the next and acted upon in different situations. Most studies stress the historical development and internal structure and workings of particular cultural traditions, and anthropologists have amassed detailed bodies of documentation on different human societies. Significant, too, within social-cultural anthropology are cross-cultural studies that seek to identify essential structural or behavioral properties of human society. Modern scholars have sought to identify universal patterns of symbolic behavior and belief, and there are other social-cultural anthropologists actively testing these kinds of propositions in particular cases.

Increasingly, social-cultural anthropologists have applied their training and skills to issues of contemporary importance such as economic development in third world countries, public policies affecting ethnic minorities, and changes arising from contact between different societies (especially Western and non-Western ones). Sometimes referred to as applied anthropology, such studies are often made in situations where conflicting social values or expectations may arise.

Cultural linguistics is closely allied with both the goals and methods of social-cultural anthropology, especially with respect to the way in which linguists strive for a reliable understanding of how each different language works according to its own sound system (phonology) and grammatical structure. *See* PSYCHOLINGUISTICS.

There has been a developing tendency in anthropology toward integration of different subfields. For example, ethnoscience is a subject in which anthropologists apply approaches derived from linguistics to understand the grammatical structure and manipulation of cognitive perceptions by people in different societies of such things as color, weather, and biotic environment. Another growing subfield is ethnoarcheology, in which observations of material behavior (especially discard) in contemporary societies are used to interpret the archeological remains of prehistoric cultures. Modern anthropology is characterized by its breadth and diversity of approaches to the study of variability in human behavior. [R.A.G.]

Anthropometry The systematic quantitative representation of the human body. Anthropometric techniques are used to measure the absolute and relative variability in size and shape of the human body. Depending on the objective, anthropometric instrumentation may include weighing scale, anthropometer, skinfold calipers, body volume tanks, and bioelectrical impedance analyzers. Similarly, radiographic instruments and x-ray scanners such as dual-energy-ray absorption meters and ultrasound densitometers are used for quantifying cortical bone density, bone mass, subcutaneous fat density, and lean body mass.

Anthropometry follows a rigorous set of guidelines that include standardization of the measurement techniques, uniform landmarks, and establishing conditions of the measurements. Various references have been developed that can be used as base lines for expressing absolute and relative deviation from the average. Techniques of data analysis include the expression of individual values in the form of Z scores (the individual value minus the reference mean for the age and sex, divided by the corresponding standard deviation). This approach permits the investigator to express the measurements in terms of Z score units from the mean. Another approach involves expressing individual values in the form of percentiles placement. For this purpose, the investigator needs to compare the individual value to the percentile ranges given in the anthropometric standard. Thus, an individual measurement may be expressed as being either close to the 50th percentile or above or below the 95th or 5th percentile.

In biological anthropology and human paleontology, anthropometry is the technique of choice for quantifying variability and relationship of fossils and extant populations. Anthropometric measurements of the head, face, and long bones are also used in analyzing fossil taxa (using measurements from radiographs). Anthropometry is the most universally applicable, inexpensive, and noninvasive method available to assess nutritional history throughout life. It has been used to assess and predict the health of societies. For example, since fat is the main form of energy storage, and body muscle is composed largely of protein, anthropometric measurements of body composition provide indirect estimates of energy and protein reserves of the body. Reserves can be depleted during chronic malnutrition, resulting in muscle wasting, while during overnutrition reserves can grow, resulting in obesity.

Anthropometry is also essential to the field of forensics, specifically forensics anthropology, which is concerned with the relationship between medicine and the law. Forensic anthropologists make extensive use of anthropometry in human identification, whether for isolated cadavers, commingled remains, victims of mass disasters, or genocide victims.

Anthropometric measurements of the head and face are extensively employed in orthodontic diagnosis, in treatment planning, and following orthodontic treatment. Measurements made from cephalometric radiographs also serve in the identification of syndromes. Extensions of cephalometry (measurement of the living human head) in three dimensions (cartesian anthropometry) are used in sculpting head forms for use in the reconstructive surgery of accident victims.

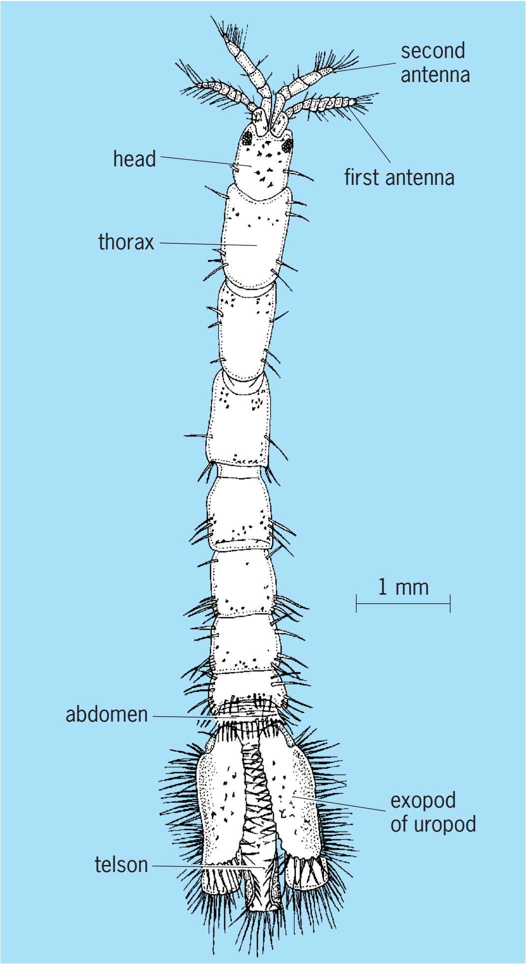
A relatively new use of anthropometry is for the design of clothing, equipment, and interiors. For example, through anthropometric techniques to establish human dimensions, gas masks, oxygen masks, dust masks, and respirators as well as military helmets have been designed. *See* Animal growth; Anthropology; Biometrics; Physical anthropology. [A.R.F.]

Anthroposcopy The observation of the human body (in contrast to anthropometry, the measurement of the human body). Inspection or observation of physical characteristics is the basic method of anthroposcopy, and in some instances the observations are made relative to a set of reference values or standards. Hence, the method has a high degree of subjectivity, although there is a trend toward more objective assessment of some characteristics.

Skin color; hair color, form, and distribution; and eye color are the more common physical characteristics assessed by anthroposcopy. Colorimetric charts or scales are the reference for comparison, with most emphasis on skin pigmentation. Problems with such scales relate to intermediate shades or gradations. The use of photometric devices that identify spectral wavelengths has provided more objective assessment of skin, hair, and eye color.

The assessment of physique is central to anthroposcopic studies. Physique refers to body build or form, that is, the total configuration of the body. The most widely used classification is the assessment of an individual's somatotype, which is based on the varying contributions of three components: endomorphy (laterality, fatness), mesomorphy (musculoskeletal dominance), and ectomorphy (linearity). The somatotype is a three-number rating, each referring to the contribution of endomorphy, mesomorphy, and ectomorphy, respectively, to an individual's somatotype. An individual's physique is defined by all three ratings so that specific component ratings may lose some of their meaning when analyzed separately. Studies of the development of pubic and axillary hair in both sexes, and facial hair in boys, breast development in girls, and genital development in boys rely on anthroposcopy. Ratings are made from standardized photographs or by visual inspection at clinical examination. Anthroposcopic ratings have been utilized successfully in the evaluation of relationships between physique and physical performance, in documenting physique changes during maturation, growth, and adulthood, and in estimating morphological distances among neighboring populations. *See* Anthropology; Anthropometry. [R.M.Ma.]

Anthuridea A suborder of the Isopods. These crustaceans are characterized by slender, elongate, subcylindrical bodies, and by the fact that the outer branch of the paired tail appendage (uropod) arches over the base of the terminal abdominal segment, the telson (see illustration). The uropods of anthurideans attach laterally to the abdomen and together with the telson form a caudal fan.



Paranthura infundibulata.

Marked sexual dimorphism is shown in the first pair of antennae which, in males of many species in both sections, develop brushlike whorls of setae on the flagellum. Female anthurideans carry the developing young beneath the thorax in a brood pouch, formed by overlapping plates originating from the bases of several pairs of legs. *See* Sexual dimorphism.

Anthurideans are mostly marine, but some live in brackish or freshwater habitats. Some are facultative ectoparasites of fishes. *See* Isopoda. [M.A.M.]

Antibiotic The original definition of an antibiotic was a chemical substance that is produced by a microorganism and, in dilute solutions, can inhibit the growth of, and even destroy, other microorganisms. This definition has been expanded to include similar inhibitory substances that are produced by plants, marine organisms, and total- or semisynthetic procedures. Since the discovery of penicillin by A. Fleming in 1928, thousands of antibiotics have been isolated and identified; some have been found to be of value in the treatment of infectious disease. They differ markedly in physicochemical and pharmacological properties, antimicrobial spectra, and mechanisms of action.

Production. Penicillin is produced by strains of the fungus *Penicillium notatum* and *P. chrysogenum*. Most of the other antibiotics in clinical use are produced by actinomycetes, particularly streptomycetes (natural antibiotics). Other antibiotics are produced by chemical synthesis (synthetic antibiotics). Based on structure, the major antibiotic classes are the β-lactams (penicillins and cephalosporins), aminoglycosides, macrolides, tetracyclines, quinolones, rifamycins, polyenes, azoles, glycopeptides, and polypeptides.

The key step in the production of natural antibiotics is a fermentation process. Strains of microorganisms, selected by elaborate screening procedures from randomly isolated pure cultures, are inoculated into sterile nutrient medium in large vats and incubated for varying periods of time. Different strains of a single microbial species may differ greatly in the amounts of antibiotics they produce. Strain selection is thus the most powerful tool in effecting major improvements in antibiotic yield. In addition, variations in culturing conditions often markedly affect the amount of antibiotic that is produced by a given strain. Chemical modifications of antibiotics produced by fermentation processes have led to semisynthetic ones with improved antimicrobial activity or pharmacological properties. *See* BACTERIAL PHYSIOLOGY AND METABOLISM; FERMENTATION.

Antimicrobial activity. All microorganisms can cause infectious diseases in animals and humans, though the majority of infections are caused by bacteria. Most antibiotics are active against bacteria. Although for the proper treatment of serious infections cultures and antibiotic sensitivities are required, antibiotic therapy is often empiric, with etiology being inferred from the clinical features of a disease.

Bacteria are divided into the gram positive and the gram negative; each group comprises a wide variety of different species. Staphylococci, pneumococci, and streptococci are the more common gram-positive organisms, while enterobacteria, *Pseudomonas*, and *Hemophilus* are the most common gram negative. Certain antibiotics are effective only against gram-positive bacteria. Others are effective against both gram-positive and gram-negative bacteria and are referred to as broad-spectrum antibiotics. *See* BACTERIA; MEDICAL BACTERIOLOGY.

Pathogenic fungi may be divided on the basis of their pathogenicity into true pathogens and opportunistic pathogens. The opportunistic occur mainly in debilitated and immunocompromised patients. Clinically useful antibiotics include amphotericin B, nystatin, griseofulvin and the azole antifungals. *See* FUNGI; MEDICAL MYCOLOGY; OPPORTUNISTIC INFECTIONS.

With some viruses that cause mild infections, such as the common-cold viruses (rhinoviruses), treatment is symptomatic. With others, such as the polio, smallpox (now eradicated), and hepatitis B viruses, the only way to prevent disease is by vaccination. With still other viruses, antibiotics, mostly synthetic, are the appropriate treatment. Clinically useful antibiotics are ribavirin, acyclovir, and zidovudine, which are active against, respectively, respiratory, herpes, and human immunodeficiency viruses. *See* ANIMAL VIRUS; VACCINATION.

Protozoa may be divided, on the basis of the site of infection, into intestinal, urogenital, blood, and tissue. Protozoan diseases such as malaria, trypanosomiasis, and amebiasis are particularly common in the tropics, in populations living under poor housing and sanitary conditions. In the developed countries, *P. carinii* is the most important opportunistic pathogen, being associated almost exclusively with acquired immune deficiency syndrome (AIDS). Antibiotics active against protozoa include metronidazole, trimethoprim-sulfamethoxazole, and quinine. *See* ACQUIRED IMMUNE DEFICIENCY SYNDROME (AIDS); MEDICAL PARASITOLOGY; PROTOZOA.

Antitumor activity. The observation of the antitumor activity of actinomycin sparked an intensive search for antitumor antibiotics in plants and microorganisms. Among the antibiotics used clinically against certain forms of cancer are daunorubicin, doxorubicin, mitomycin C, and bleomycin. *See* CANCER (MEDICINE).

Mechanism of action. Antibiotics active against bacteria are bacteriostatic or bacteriocidal; that is, they either inhibit growth of susceptible organisms or destroy them. On the basis of their mechanism of action, antibiotics are classified as (1) those that affect bacterial cell-wall biosynthesis, causing loss of viability and often cell lysis (penicillins and cephalosporins, bacitracin, cycloserine, vancomycin); (2) those that act directly on the cell membrane, affecting its barrier function and leading to leakage of intracellular components (polymyxin); (3) those that interfere with protein biosynthesis (chloramphenicol, tetracyclines, erythromycin, spectinomycin, streptomycin, gentamycin); (4) those that affect nucleic acid biosynthesis (rifampicin, novobiocin, quinolones); and (5) those that block specific steps in intermediary metabolism (sulfonamides, trimethoprim). *See* ENZYME; SULFONAMIDE.

Antibiotics active against fungi are fungistatic or fungicidal. Their mechanisms of action include (1) interaction with the cell membrane, leading to leakage of cytoplasmic components (amphotericin, nystatin); (2) interference with the synthesis of membrane components (ketoconazole, fluconazole); (3) interference with nucleic acid synthesis (5-fluorocytosine); and (4) interference with microtubule assembly (griseofulvin). *See* FUNGISTAT AND FUNGICIDE.

For an antibiotic to be effective, it must first reach the target site of action on or in the microbial cell. It must also reach the body site at which the infective microorganism resides in sufficient concentration, and remain there long enough to exert its effect. The concentration in the body must remain below that which is toxic to the human cells. The effectiveness of an antibiotic also depends on the severity of the infection and the immune system of the body, being significantly reduced when the immune system is impaired. Complete killing or lysis of the microorganism may be required to achieve a successful outcome. *See* IMMUNITY.

Antibiotics may be given by injection, orally, or topically. When given orally, they must be absorbed into the body and transported by the blood and extracellular fluids to the site of the infecting organisms. When they are administered topically, such absorption is rarely possible, and the antibiotics then exert their effect only against those organisms present at the site of application.

Microbial resistance. The therapeutic value of every antibiotic class is gradually eroded by the microbial resistance that invariably follows broad clinical use.

Some bacteria are naturally resistant to certain antibiotics (inherent resistance). Clinical resistance is commonly due to the emergence of resistant organisms following antibiotic treatment (acquired resistance). This emergence, in turn, is due to selection of resistant mutants of the infective species (endogenous resistance) or, usually, to transfer of resistance genes from other, naturally resistant species (exogenous resistance). A major challenge in antimicrobial chemotherapy is the horizontal spread of resistance genes and resistant strains, mostly in the hospital but also in the community. The consequences are increased patient morbidity and mortality, reduced drug options, and more expensive and toxic antibiotics.

Rapid detection of resistance and pathogen identification are critical for the rational use of antibiotics and implementation of infection control measures. In the absence of such information, treament is empiric, usually involving broad-spectrum agents, which exacerbates resistance development. Inadequate infection control measures encourage dissemination of resistant strains.

Importance. It is estimated that the average duration of many infectious diseases and the severity of certain others have decreased significantly since the introduction of antibiotic therapy. The dramatic drop in mortality rates for such dreaded diseases as meningitis, tuberculosis, and septicemia offers striking evidence of the effectiveness of these agents. Bacterial pneumonia, bacterial endocarditis, typhoid fever, and certain sexually transmitted diseases are also amenable to treatment with antibiotics. So are infections that often follow viral or neoplastic diseases, even though the original illness may not respond to antibiotic therapy. *See* Epidemiology.

Antibiotics in small amounts are widely used as feed supplements to stimulate growth of livestock and poultry. They probably act by inhibiting organisms responsible for low-grade infections and by reducing intestinal epithelial inflammation. Many experts believe that this use of antibiotics contributes to the emergence of antibiotic-resistant bacteria that could eventually pose a public health problem.

In cattle, sheep, and swine, antibiotics are effective against economically important diseases. The use of antibiotics in dogs and cats closely resembles their use in human medical practice. In fish farms, antibiotics are usually added to the food or applied to the fish by bathing. The incidence of infections in fish, and animals in general, may be reduced by the use of disease-resistant stock, better hygiene, and better diet. *See* Aquaculture.

Although effective against many microorganisms causing disease in plants, antibiotics are not widely used to control crop and plant diseases. Some of the limiting factors are instability of the antibiotic under field conditions, the possibility of harmful residues, and expense. Nevertheless, antibiotic control of some crop pathogens is being practiced, as is true of the rice blast in Japan, for example. *See* Plant pathology. [N.H.G.]

Antibody A protein found principally in blood serum and characterized by a specific reactivity with the corresponding antigen. Antibodies are important in resistance against disease, in allergy, and in blood transfusions, and can be utilized in laboratory tests for the detection of antigens or the estimation of immune status.

Antibodies are normally absent at birth unless derived passively from the mother through the placenta or colostrum. In time, certain antibodies appear in response to environmental antigens. Antibodies are also induced by artificial immunization with vaccines or following natural infections. The resulting antibody level declines over a period of months, but rapidly increases following renewed contact with specific antigen, even after a lapse of years. This is known as an anamnestic or booster response. *See* Allergy; Blood groups; Hypersensitivity; Isoantigen; Vaccination.

Antibody reactivity results in precipitation of soluble antigens, agglutination of particulate antigens, increased phagocytosis of bacteria, neutralization of toxins, and dissolution of bacterial or other cells specifically sensitive to their action; the antibodies so revealed are termed precipitins, agglutinins, opsonins, antitoxins, and lysins. One antibody may give many such reactions, depending on conditions, so these classifications are not unique or exclusive.

Three principal groups (IgG, IgM, IgA) and two minor groups (IgD, IgE) of antibodies are recognized. These all form part of the wider classification of immunoglobulins. Antibody diversity is generated by amino acid substitutions that result in unique antigen-binding structures. *See* Cellular immunology; Immunoglobulin.

The development of the technology for producing monoclonal antibodies, which can bind to specific sites on target antigens, revolutionized the uses of antibodies in biology and medicine. Unfortunately, almost all monoclonal antibodies originate in mice, and the murine immunoglobulin serves as an antigen, frequently acting immunogenic in human recipients. *See* Antigen; Monoclonal antibodies. [M.J.Po.]

Anticline A fold in layered rocks in which the strata are inclined down and away from the axes. The simplest anticlines (see illustration) are symmetrical, but in more highly deformed regions they may be asymmetrical, overturned, or recumbent. Most anticlines are elongate with axes that plunge toward the extremities of the fold, but some have no distinct trend; the latter are called domes. Generally, the stratigraphically older rocks are found toward the center of curvature of an anticline, but in more complex structures these simple relations need not hold. Under such circumstances, it is sometimes convenient to recognize two types of anticlines. Stratigraphic anticlines are those folds, regardless of their observed forms, that are inferred from stratigraphic information to have been anticlines originally. Structural anticlines are those that have forms of anticlines, regardless of their original form. *See* Syncline. [P.H.O.]

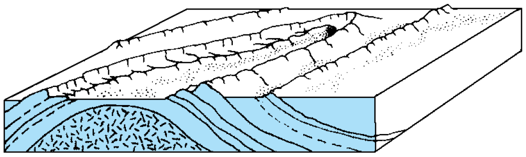


Diagram relating anticlinal structure to topography.

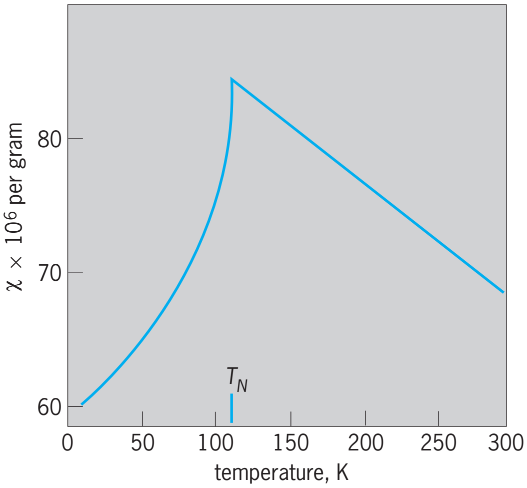
Antiferromagnetism A property possessed by some metals, alloys, and salts of transition elements in which the atomic magnetic moments, at sufficiently low temperatures, form an ordered array which alternates or spirals so as to give no net total moment in zero applied magnetic field. The most direct way of detecting such arrangements is by means of neutron diffraction. *See* Neutron diffraction.

The transition temperature below which the spontaneous antiparallel magnetic ordering takes place is called the Néel temperature. A plot of the magnetic susceptibility of a typical antiferromagnetic powder sample versus temperature is shown in the illustration. Below the Néel point, which is characterized by the sharp kink in the susceptibility, the spontaneous ordering opposes the normal tendency of the magnetic moments to align parallel to the applied field. Above the Néel point, the substance is paramagnetic, and the susceptibility χ obeys the Curie-Weisslaw, as in Eq. (1), with a negative paramagnetic Curie temperature $-\theta$. The Néel temperature is similar to the Curie temperature in ferromagnetism. *See* Curie-Weiss law.

$$\chi = C/(T + \theta) \qquad (1)$$

The cooperative transition that characterizes antiferromagnetism is thought to result from an interaction energy U of the form given in Eq. (2), where $\mathbf{S}_i$ and $\mathbf{S}_j$ are the spin angular momentum vectors associated with the magnetic moments of neighbor atoms i and j, and J_{ij} is an interaction constant. If all

$$U = -2\Sigma J_{ij}\boldsymbol{S}\cdot\boldsymbol{S}_j \qquad (2)$$



Magnetic susceptibility of powdered manganese oxide. (*After H. Bizette, C. F. Squire, and B. Tsai, 1938*)

J_{ij} are positive, the lowest energy is achieved with all $\mathbf{S}_i$ and $\mathbf{S}_j$ parallel, that is, coupled ferromagnetically. Negative J_{ij} between nearest-neighbor pairs (i,j) may lead to simple antiparallel arrays; if the distant neighbors also have sizable negative J_{ij}, a spiral array may have lowest total energy. The interaction constant in Eq. (2) probably arises from superexchange coupling. This is an effective coupling between magnetic spins which is indirectly routed via nonmagnetic atoms in salts and probably via conduction electrons in metals. *See* Ferromagnetism; Helimagnetism.

The magnetic moments are known to have preferred direction. Anisotropic effects come from magnetic dipole forces and also from spin-orbit coupling combined with superexchange. Some nearly antiparallel arrays such as Fe_2O_3 show a slight bending (called canting) and exhibit weak ferromagnetism. The anisotropy affects the susceptibility of powder samples and is of extreme importance in antiferromagnetic resonance. *See* Magnetic resonance. [E.A.; F.Ke.]

Antifreeze (biology) Glycoprotein or protein molecules synthesized by polar and north temperate fishes to enable them to survive in freezing seawater. Similar antifreezes are found in some insects, but relatively little is known about their structure and function.

In a marine fish, the amount of salt and other small molecules in the blood depresses its freezing point to about 30°F (−0.8°C). In the winter, the polar oceans and the nearshore water of north temperate oceans are at the freezing point of seawater 28.6°F (−1.9°C). In the absence of ice, many fishes survive by supercooling, a thermodynamic state of equilibrium in which a solution (the body fluids of the fish in this case) can be in liquid state, in the absence of ice nuclei, at a temperature lower than the equilibrium freezing point. However, polar waters are often laden with ice that can enter the fish by ingestion of seawater. Propagation of ice in the body fluids or tissues of the fish always leads to freezing damage and death. To avoid freezing, many fishes have evolved biological antifreezes that further lower the freezing point of their body fluids to 28°F (−2.2°C), which is 0.6°F (0.3°C) below the freezing point of seawater. *See* Cryptobiosis. [A.L.DeV.]

Antifreeze mixture A chemical substance that, when added to a liquid such as water, reduces the freezing point of the mixture. Antifreezes are used in a wide variety of applications, the most common being automotive cooling systems. Antifreeze liquids are also used in refrigeration systems (as a secondary coolant), heating and air-conditioning systems, ice skating rinks, and solar energy units, and as deicing agents for runways and aircraft. *See* Engine cooling; Refrigeration.

Properties of a desirable antifreeze include the ability to depress the freezing point of the liquid (typically water), good solubility, high boiling point (to provide boil-over protection), chemical compatibility with materials of construction, good heat transfer properties, appropriate viscosity, and low cost.

Chemicals that have been used as antifreezes include glycols, glycerol, brines (such as calcium chloride), and alcohols. Ethylene glycol is the most common antifreeze used in automotive cooling systems because of the outstanding freezing-point depression effect, boil-over protection, heat transfer characteristics, high flash point, and low vapor pressure. Propylene glycol, diethylene glycol, and methanol have also been used to a limited extent. Commercial automotive antifreezes contain corrosion inhibitors to protect the various types of metals in the cooling system. *See* Ethylene glycol; Inhibitor (chemistry).

Glycol antifreeze solutions are often used in aircraft deicing. These contain additional components for corrosion protection and wetting. Aircraft anti-icing fluids also contain a polymeric thickening agent to increase the fluid viscosity, which allows the fluid to adhere to the aircraft surface and provide protection against freezing for a limited period of time. [K.F.G.]

Antifriction bearing A machine element that permits free motion between moving and fixed parts. Antifrictional bearings are essential to mechanized equipment; they hold or guide moving machine parts and minimize friction and wear.

In its simplest form, a bearing consists of a cylindrical shaft, called a journal, and a mating hole, serving as the bearing proper. Ancient bearings were made of such materials as wood, stone, leather, or bone, and later of metal. It soon became apparent for this type of bearing that a lubricant would reduce both friction and wear and prolong the useful life of the bearing. Petroleum oils and greases are generally used for lubricants, sometimes containing soap and solid lubricants such as graphite or molybdenum disulfide, talc, and similar substances.

Materials. The greatest single advance in the development of improved bearing materials took place in 1839, when I. Babbitt obtained a United States patent for a bearing metal with a special alloy. This alloy, largely tin, contained small amounts of antimony, copper, and lead. This and similar materials have made excellent bearings. They have a silvery appearance and are generally described as white metals or as Babbitt metals.

Wooden bearings are still used for limited applications in light-duty machinery and are frequently made of hard maple which has been impregnated with a neutral oil. Wooden bearings made of lignum vitae, the hardest and densest of all woods, are still used.

Some of the most successful heavy-duty bearing metals are now made of several distinct compositions combined in one bearing. This approach is based on the widely accepted theory of friction, which is that the best possible bearing material would be one which is fairly hard and resistant but which has an overlay of a soft metal that is easily deformed. Figure 1 shows bearings in which graphite, carbon, plastic, and rubber have been incorporated into a number of designs illustrating some of the material combinations that are presently available.

Rubber has proved to be a surprisingly good bearing material, especially under circumstances in which abrasives may be present in the lubricant. The rubber used is a tough resilient compound similar in texture to that in an automobile tire. Cast iron is one of the oldest bearing materials. It is still used where the duty is relatively light.

Porous metal bearings are frequently used when plain metal bearings are impractical because of lack of space or inaccessibility for lubrication. These bearings have voids of 16–36% of the volume of the bearing. These voids are filled with a lubricant by a vacuum technique. During operation they supply a limited amount of lubricant to the sliding surface between the journal and the bearing. In general, these bearings are satisfactory for light loads and moderate speeds.

Lubricants. The method of supplying the lubricant and the quantity of lubricant which is fed to the bearing by the supplying

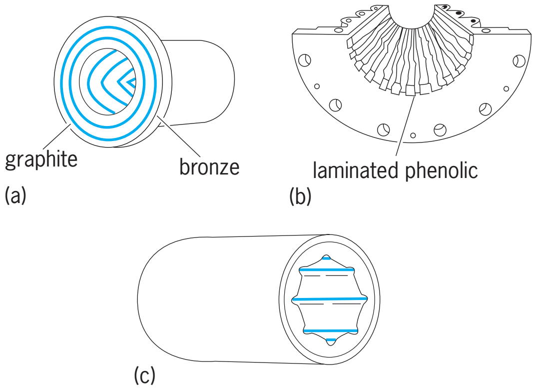


Fig. 1. Bearings with (*a*) graphite; (*b*) wood, plastic, and nylon (*after J. J. O'Connor, ed., Power's Handbook on Bearings and Lubrication, McGraw-Hill, 1951*); (*c*) rubber.

device will often be the greatest factor in establishing performance characteristics of the bearing. For example, if no lubricant is present, the journal and bearing will rub against each other in the dry state. Both friction and wear will be relatively high. The coefficient of friction of a steel shaft rubbing in a bronze bearing, for example, may be about 0.3 for the dry state. If lubricant is present even in small quantities, the surfaces hydrodynamic pressure in film become contaminated by this material whether it be an oil or a fat, and depending upon its chemical composition the coefficient of friction may be reduced to about 0.1. Now if an abundance of lubricant is fed to the bearing so that there is an excess flowing out of the bearing, it is possible to develop a self-generating pressure film in the clearance space as indicated in Fig. 2. These pressures can be sufficient to sustain a considerable load and to keep the rubbing surfaces of the bearing separated.

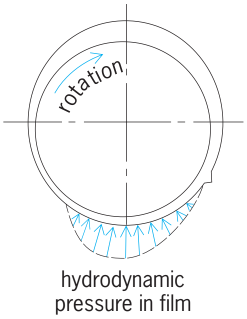

Fig. 2. Hydrodynamic fluid-film pressures in a journal bearing. (*After W. Stanlar, ed., Plant Engineering Handbook, 2d ed., McGraw-Hill, 1959*)

The types of oiling devices that usually result in insufficient feed to generate a complete fluid film are, for example, oil cans, drop-feed oilers, waste-packed bearings, and wick and felt feeders. Oiling schemes that provide an abundance of lubrication are oil rings, bath lubrication, and forced-feed circulating supply systems. The coefficient of friction for a bearing with a complete fluid film may be as low as 0.001.

Fluid-film hydrodynamic bearings. If the bearing surfaces can be kept separated, the lubricant no longer needs an oiliness agent. As a consequence, many extreme applications are presently found in which fluid-film bearings operate with lubricants consisting of water, highly corrosive acids, molten metals, gasoline, steam, liquid refrigerants, mercury, gases, and so on. The self-generation of pressure in such a bearing takes place no matter what lubricant is used, but the maximum pressure that is generated depends upon the viscosity of the lubricant. Thus, for example, the maximum load-carrying capacity of a gas-lubricated bearing is much lower than that of a liquid-lubricated bearing. The ratio of capacities is in direct proportion to the viscosity. Gas is the only presently known lubricant that can be used for operation at extreme temperatures. Because the viscosity of gas is so low, the friction generated in the bearing is correspondingly of a very low order. Thus gaslubricated machines can be operated at extremely high speeds because there is no serious problem in keeping the bearings cool.

The self-generating pressure principle is applied equally as well to thrust bearings as it is to journal bearings. The tiltingpad type of thrust bearing (Fig. 3*a*) excels in low friction and in reliability. A typical commercial tthrust bearing (Fig. 3*b*) is made up of many tilting pads located in a circular position. One of the largest is on a hydraulic turbine at the Grand Coulee Dam. There, a bearing 96 in. (2.4 m) in diameter carries a load of 2,150,000 lb (9,560,000 newtons) with a coefficient of friction of about 0.0009.

Fluid-film hydrostatic bearings. Sleeve bearings of the self-generating pressure type, after being brought up to speed, operate with a high degree of efficiency and reliability. However, when the rotational speed of the journal is too low to maintain a complete fluid film, or when starting, stopping, or reversing, the oil film is ruptured, friction increases, and wear of the bearing accelerates. This condition can be eliminated by introducing high-pressure oil to the area between the bottom of the journal and the bearing itself, as shown schematically in Fig. 4. If the pressure and quantity of flow are in the correct proportions, the shaft will be raised and supported by an oil-film whether it is rotating or not. Friction drag may drop to one-tenth of its original value or even less, and in certain kinds of heavy rotational equipment in which available torque is low, this may mean the difference between starting and not starting. This type of lubrication is called hydrostatic lubrication and, as applied to a journal bearing in the manner indicated, it is called an oil lift. Hydrostatic lubrication in the form of a step bearing has also been used on various machines to carry thrust.

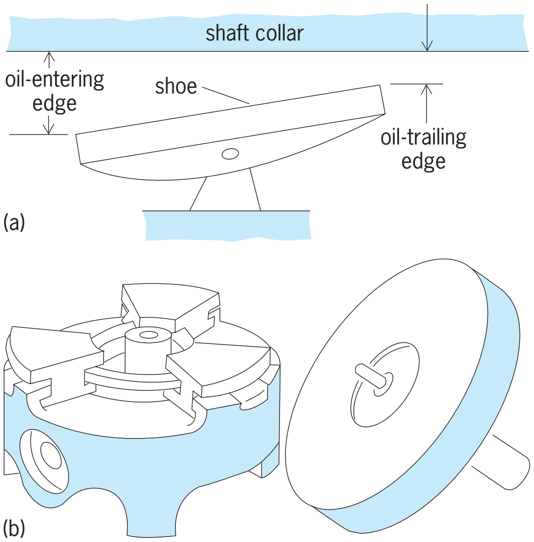

Fig. 3. Tilting-shoe-type bearing. (*a*) Schematic (*after W. Staniar, ed., Plant Engineering Handbook, 2d ed., McGraw-Hill, 1959*). (*b*) Thrust bearing (*after D. D. Fuller, Theory and Practice of Lubrication for Engineers, copyright © 1956 by John Wiley; used with permission*).

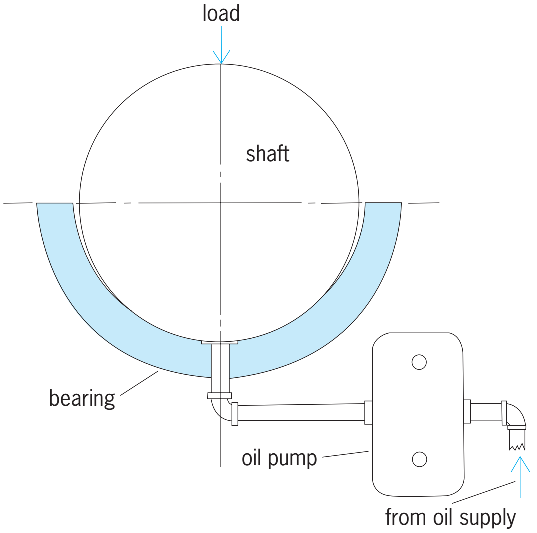

Fig. 4. Fluid-film hydrostatic bearing. Hydrostatic oil lift can reduce starting friction drag to less than one-tenth of usual starting drag. (*After W. Staniar, ed., Plant Engineering Handbook, 2d ed., McGraw-Hill, 1959*)

Large structures have been floated successfully on hydrostatic-type bearings. For example, the Hale 200-in. (5-m) telescope on Palomar Mountain (California Institute of Technology/Palomar

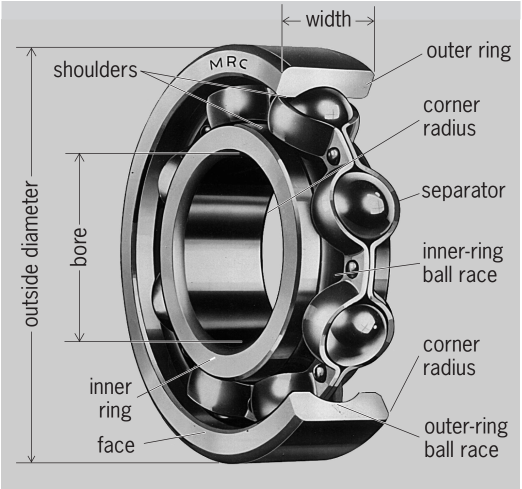

Fig. 5. Deep-groove ball bearing. (*Marlin-Rockwell*)

Observatory) weighs about 1,000,000 lb (450,000 kg); yet the coefficient of friction for the entire supporting system, because of the hydrostatic-type bearing, is less than 0.000004. The power required is extremely small and a $^{1}/_{12}$-hp (62-W) clock motor rotates the telescope while observations are being made.

Rolling-element bearings. Everyday experiences demonstrate that rolling resistance is much less than sliding resistance. This principle is used in the rolling-element bearing which has found wide use. In the development of the automobile, ball and roller bearings were found to be ideal for many applications, and today they are widely used in almost every kind of machinery.

These bearings are characterized by balls or cylinders confined between outer and inner rings. The balls or rollers are usually spaced uniformly by a cage or separator. The rolling elements are the most important because they transmit the loads from the moving parts of the machine to the stationary supports. Balls are uniformly spherical, but the rollers may be straight cylinders, or they may be barrel- or cone-shaped or of other forms, depending upon the purpose of the design. The rings, called the races, supply smooth, hard, accurate surfaces for the balls or rollers to roll on. Some types of ball and roller bearings are made without separators. In other types there is only the inner or the outer ring, and the rollers operate directly upon a suitably hardened and ground shaft or housing. Figure 5 shows a typical deep-grooved ball bearing, with the parts that are generally used.

These bearings may be classified by function into three groups: radial, thrust, and angular-contact bearings. Radial bearings are designed principally to carry a load in a direction perpendicular to the axis of rotation. However, some radial bearings, such as the deep-grooved bearings shown in Fig. 5, are also capable of carrying a thrust load, that is, a load parallel to the axis of rotation and tending to push the shaft in the axial direction. Some bearings, however, are designed to carry only thrust loads. Angular-contact bearings are especially designed and manufactured to carry heavy thrust loads and also radial loads.

A unique feature of rolling-element bearings is that their useful life is not determined by wear but by fatigue of the operating surfaces under the repeated stresses of normal use. Fatigue failure, which occurs as a progressive flaking or sifting of the surfaces of the races and rolling elements, is accepted as the basic reason for the termination of the useful life of such a bearing. [D.D.F.]

Antigen

A substance that initiates and mediates the formation of the corresponding immune body, termed antibody. Antigens can also react with formed antibodies. Antigen-antibody reactions serve as host defenses against microorganisms and other foreign bodies, or are used in laboratory tests for detecting the presence of either antigen or antibody. *See* ANTIBODY; ANTIGEN-ANTIBODY REACTION.

A protein immunogen (any substance capable of inducing an immune response) is usually composed of a large number of antigenic determinants. Thus, immunizing an animal with a protein results in the formation of a number of antibody molecules with different specificities. The antigenicity of a protein is determined by its sequence of amino acids as well as by its conformation. Antigens may be introduced into an animal by ingestion, inhalation, sometimes by contact with skin, or more regularly by injection into the bloodstream, skin, peritoneum, or other body part.

With a few exceptions, such as the autoantigens and the isoantigens of the blood groups, antigens produce antibody only in species other than the ones from which they are derived. All complete proteins are antigenic, as are many bacterial and other polysaccharides, some nucleic acids, and some lipids. Antigenicity may be modified or abolished by chemical treatments, including degradation or enzymatic digestion; it may be notably increased by the incorporation of antigen into oils or other adjuvants. *See* ISOANTIGEN.

Bacteria, viruses, protozoans, and other microorganisms are important sources of antigens. These may be proteins or polysaccharides derived from the outer surfaces of the cell (capsular antigens), from the cell interior (the somatic or O antigens), or from the flagella (the flagellar or H antigens). Other antigens either are excreted by the cell or are released into the medium during cell death and disruption; these include many enzymes and toxins, of which diphtheria, tetanus, and botulinus toxins are important examples. The presence of antibody to one of these constituent antigens in human or animal sera is presumptive evidence of past or present contact with specific microorganisms, and this finds application in clinical diagnosis and epidemiological surveys. *See* BOTULISM; DIPHTHERIA; TETANUS; TOXIN.

Microbial antigens prepared to induce protective antibodies are termed vaccines. They may consist of either attenuated living or killed whole cells, or extracts of these. Since whole microorganisms are complex structures, vaccines may contain 10 or more distinct antigens, of which generally not more than one or two engender a protective antibody. Examples of these are smallpox vaccine, a living attenuated virus; typhoid vaccine, killed bacterial cells; and diphtheria toxoid, detoxified culture fluid. Several independent vaccines may be mixed to give a combined vaccine, and thus reduce the number of injections necessary for immunization, but such mixing can result in a lesser response to each component of the mixture. *See* VACCINATION.

Allergens are antigens that induce allergic states in humans or animals. Examples are preparations from poison ivy, cottonseed, or horse dander, or simple chemicals such as formaldehyde or picryl chloride. *See* HETEROPHILE ANTIGEN; HYPERSENSITIVITY; IMMUNOLOGY. [M.J.Po.]

Antigen-antibody reaction

A reaction that occurs when an antigen combines with a corresponding antibody to produce an immune complex. A substance that induces the immune system to form a corresponding antibody is called an immunogen. All immunogens are also antigens because they react with corresponding antibodies; however, an antigen may not be able to induce the formation of an antibody and therefore may not be an immunogen. For instance, lipids and all low-molecular-weight substances are not immunogenic. However, many such substances, termed haptens, can be attached to immunogens, called carriers, and the complex then acts as a new immunogen. *See* ANTIBODY; ANTIGEN.

A molecule of antibody has two identical binding sites for one antigen or more, depending on its class. Each site is quite small and can bind only a comparably small portion of the surface of the antigen, which is termed an epitope. The specificity of an antibody for an antigen depends entirely upon the possession of the appropriate epitope by an antigen. The binding site on the antibody and the epitope on the antigen are complementary regions on the surface of the respective molecules which interlock in the antigen-antibody reaction. The intensity with which an antibody binds to the antigen depends on the exactitude of the fit between the respective binding site and epitope, as well as some inherent characteristics of the reacting molecules and factors in the environment. The epitope must be continuous spatially, but not structurally: in other words, if the molecule of the antigen consists of several chains, then an epitope may be formed by adjacent regions on two different chains, as well as by adjacent regions on the same chain. If the epitope is now modified either chemically (for example, by altering the hapten) or physically (for example, by causing the chains to separate), then its fit in the binding site will be altered or abolished, and the antigen will react with the antibody either less strongly or not at all.

The immune complex formed in the reaction consists of closely apposed, but still discrete, molecules of antigen and antibody. Therefore, the immune complex can dissociate into the original molecules. The proportion of the dissociated, individual molecules of antigen and antibody to those of the immune complex clearly depends on the intensity of the binding. These proportions can be measured in a standardized procedure, so that the concentration of antigen [Ag], antibody [Ab], and the immune complex [AgAb] becomes known. A fraction is then calculated and called either the dissociation constant or the association constant. The magnitude of either of these constants can be used subsequently to assess the intensity of the antigen-antibody reaction. *See* IMMUNOASSAY.

Only one epitope of its kind generally occurs on each molecule of antigen, other than that which consists of multiple, identical units, though many epitopes of different configuration are possible. Particles, however, either natural ones such as cells or suitably treated artificial ones made of, for example, latex or glass, typically carry multiple identical epitopes, as well as nonidentical ones, because their surfaces contain many molecules of the same antigen. Immune complexes comprising many molecules eventually reach sufficient size to scatter light, at which point they can be detected by nephelometry or turbidimetry; if their growth continues, they become visible as precipitates, which can also be assayed by such methods as immunodiffusion. Since particles typically carry many molecules of antigen, they can be, in principle, aggregated and the reaction can be detected by inspection. Antigen-antibody reactions can also be detected at very low concentration of reactants through special techniques such as immunofluorescence and radioimmunoassay. *See* IMMUNOASSAY; IMMUNOFLUORESCENCE; IMMUNONEPHELOMETRY; RADIOIMMUNOASSAY.

The reaction between antigen and antibody is followed by a structural change in the remainder of the antibody molecule. The change results in the appearance of previously hidden regions of the molecule. Some of these hidden regions have specific functions, such as binding complement. Fixation of complement by immune complexes has been used to detect and measure antigen-antibody reactions. *See* COMPLEMENT.

The chief use of antigen-antibody reactions has been in the determination of blood groups for transfusion, serological ascertainment of exposure to infectious agents, and development of immunoassays for the quantification of various substances. *See* BLOOD GROUPS; IMMUNOLOGY; SEROLOGY. [A.B.]

Antihistamine A type of drug that inhibits the combination of histamine with histamine receptors. These drugs are termed either H-1 or H-2 receptor antagonists depending on which type of histamine receptor is involved. H-1 receptor antagonists are used largely for treating allergies, and H-2 receptor antagonists are used to treat peptic ulcer disease and related conditions. *See* HISTAMINE.

The primary therapeutic use of H-1 receptor antagonists is to antagonize the effects of histamine released from cells by antigen-antibody reactions; they can thus inhibit histamine-induced effects, such as bronchoconstriction, skin reactions, for example, wheals and itching, and nasal inflammation. These drugs, therefore, are quite effective in reducing allergy signs and symptoms, especially if they are administered before contact with the relevant antigen; however they are not effective in treating asthma. Their effects vary widely, both among the drugs and from individual to individual; in young children excitement may be seen. Another common set of effects caused by many of these drugs, including dry mouth, blurred vision, and urinary retention, can be ascribed to their anticholinergic actions. H-1 receptor antagonists have low toxicity. The chief adverse effect is sedation. Overdoses of H-1 receptor antagonists may be associated with excitement or depression, and although there is no pharmacologic antidote for these drugs, good supportive care should be adequate in managing cases of poisoning. *See* ALLERGY; ANTIGEN-ANTIBODY REACTION; ASTHMA; SEDATIVE.

H-2 receptor antagonists are much newer. Histamine stimulates gastric acid secretion by combining with H-2 receptors. By preventing this combination, H-2 antagonists can reduce acid secretion in the stomach, an effect that makes these drugs useful in managing various conditions, such as peptic ulcer disease. *See* ULCER.

Other conditions in which H-2 antagonists are used to lower gastric acidity include reflux esophagitis, stress ulcers, and hypersecretory states such as the Zollinger-Ellison syndrome, in which tumor cells secrete large amounts of the hormone gastrin, which stimulates gastric acid secretion. In these conditions, administration of H-2 antagonists reduces symptoms and promotes healing.

The toxicity of H-2 antagonists is quite low, and adverse effects are reported by only 1-2% of patients. The most common side effects are gastrointestinal upsets, including nausea, vomiting, and diarrhea. [A.Bur.]

Antimatter Matter which is made up of antiparticles. At the most fundamental level every type of elementary particle has its anti-counterpart, its antiparticle. The existence of antiparticles was implied by the relativistic wave equation derived in 1928 by P. A. M. Dirac in his successful attempt to reconcile quantum mechanics and special relativity. The antiparticle of the electron (the positron) was first observed in cosmic rays by C. D. Anderson in 1932, while that of the proton (the antiproton) was produced in the laboratory and observed by E. Segré, O. Chamberlain, and their colleagues in 1955. *See* ELECTRON; ELEMENTARY PARTICLE; POSITRON; PROTON; QUANTUM MECHANICS; RELATIVITY.

The mass, intrinsic angular momentum (spin), and lifetime (in the case of unstable particles) of antiparticles and their particles are equal, while their electromagnetic properties, that is, charge and magnetic moment, are equal in magnitude but opposite in sign. Some neutrally charged particles such as the photon and π^0 meson are their own antiparticles. Certain other abstract properties such as baryon number (protons and neutrons are baryons and have baryon number +1) and lepton number (electrons and muons are leptons and have lepton number +1) are reversed in sign between particles and antiparticles. *See* ANGULAR MOMENTUM; BARYON; LEPTON.

The quantum-mechanical operation of turning particles into their corresponding antiparticles is termed charge conjugation (C), that of reversing the handedness of particles is parity conjugation (P), and that of reversing the direction of time is time reversal (T). A fundamental theorem, the *CPT* theorem, states that correct theories of particle physics must be invariant under the simultaneous operation of C, P, and T. Simply put, the description of physics in a universe of antiparticles with opposite handedness where time runs backward must be the same as the description of the universe. One consequence of the *CPT* theorem is that the above-mentioned properties of antiparticles (mass, intrinsic angular momentum, lifetime, and the magnitudes of charge and magnetic moment) must be identical to those properties of the corresponding particles. This has been experimentally verified to a high precision in many instances. *See* CPT THEOREM; PARITY (QUANTUM MECHANICS); TIME REVERSAL INVARIANCE.

When a particle and its antiparticle are brought together, they can annihilate into electromagnetic energy or other particles and their antiparticles in such a way that all memory of the nature of the initial particle and antiparticle is lost. Only the total energy and total angular momentum remain. In the reverse process, antiparticles can be produced in particle collisions with matter if the colliding particles possess sufficient energy to create the required mass. For example, a photon with sufficient energy which interacts with a nucleus can produce an electron-positron pair. *See* ELECTRON-POSITRON PAIR PRODUCTION.

Since mesons do not possess baryon or lepton number, only charge, energy, and angular momentum need be conserved in their production. Thus, a process such as a collision of a proton with a proton can produce a single neutral pi meson. Other quantum numbers, such as strangeness and charm, must be conserved if production of mesons possessing these quantum numbers is to proceed through strong or electromagnetic interactions. In these cases a particle with the negative values of the particular quantum number must also be produced. Such a process is termed associated production. *See* CHARM; QUANTUM NUMBERS.

Isolated neutral particles, notably K^0 and B^0 mesons, can spontaneously transform into their antiparticles via the weak interaction. These quantum-mechanical phenomena are termed K–$\overline{K}$ or $\overline{B}$ mixing, respectively. Mixing can lead to particle-antiparticle oscillations wherein a K^0 can become its antiparticle, a $\overline{K}^0$, and later oscillate back to a K^0. It was through this phenomenon that observation of *CP* violation first occurred. That observation, coupled to the *CPT* theorem, implies that physics is not exactly symmetric under time reversal, for example, that the probability of a K^0 becoming a $\overline{K}^0$ is not exactly the same as that in the reverse process.

Experimental observations, both ground- and balloon-based, indicate that the number of cosmic ray antiprotons is less than 1/10,000 that of protons. This number is consistent with the antibaryon production that would be expected from collisions of cosmic protons with the Earth's atmosphere, and is consistent with the lack of appreciable antimatter in the Milky Way Galaxy. Attempts to find antimatter beyond the Milky Way involve searches for gamma radiation resulting from matter-antimatter annihilation in the intergalactic gas that exists between galactic clusters. The null results of these searches suggests that at least the local cluster of galaxies consists mostly of matter. If matter dominates everywhere in the universe, a question arises as to how this came to be. In the standard model of cosmology, the big bang model, the initial condition of the universe was that the baryon number was zero; that is, there was no preference of matter over antimatter. The current theory of how the matter-antimatter asymmetry evolved requires three ingredients: interactions in which baryon number is violated, time reversal (or *CP*) violation, and a lack of thermodynamic equilibrium. The last requirement was satisfied during the first few microseconds after the big bang. Time reversal violation has been observed in the laboratory in K^0 decays, albeit perhaps not of sufficient size to explain the observed baryon-antibaryon asymmetry. But the first ingredient, baryon number violation, has not yet been observed in spite of sensitive searches. Thus, the origin of the dominance of matter over antimatter remains an outstanding mystery of particle and cosmological physics. *See* BIG BANG THEORY; COSMIC RAYS; COSMOLOGY; THERMODYNAMIC PROCESSES. [M.E.Z.]

Antimicrobial agents Chemical compounds biosynthetically or synthetically produced which either destroy or usefully suppress the growth or metabolism of a variety of microscopic or submicroscopic forms of life. On the basis of their primary activity, they are more specifically called antibacterial, antifungal, antiprotozoal, antiparasitic, or antiviral agents. Antibacterials which destroy are bactericides or germicides; those which merely suppress growth are bacteriostatic agents. *See* ANTIBIOTIC; FUNGISTAT AND FUNGICIDE.

Common antimicrobial agents and their uses

Use	Agents
Chemotherapeutics (animals and humans)	
Antibacterials	Sulfonamides, isoniazid, *p*-aminosalicylic acid, penicillin, streptomycin, tetracyclines, chloramphenicol, erythromycin, novobiocin, neomycin, bacitracin, polymyxin
Antiparasitics (humans)	Emetine, quinine
Antiparasitics (animal)	Hygromycin, phenothiazine, piperazine
Antifungals	Griseofulvin, nystatin
Chemotherapeutics (plants)	Captan (*N*-trichlorothio-tetrahydrophthalimide), maneb (manganese ethylene bisdithiocarbamate), thiram (tetramethylthiuram disulfide)
Skin disinfectants	Alcohols, iodine, mercurials, silver compounds, quaternary ammonium compounds, neomycin
Water disinfectants	Chlorine, sodium hypochlorite
Air disinfectants	Propylene glycol, lactic acid, glycolic acid, levulinic acid
Gaseous disinfectants	Ethylene oxide, β-propiolactone, formaldehyde
Clothing disinfectants	Neomycin
Animal-growth stimulants	Penicillin, streptomycin, bacitracin, tetracyclines, hygromycin
Food preservatives	Sodium benzoate, tetracycline

Of the thousands of antimicrobial agents, only a small number are safe chemotherapeutic agents, effective in controlling infectious diseases in plants, animals, and humans. A much larger number are used in almost every phase of human activity: in agriculture, food preservation, and water, skin, and air disinfection. A compilation of some common uses for antimicrobials is shown in the table.

The most important antimicrobial discovery of all time, that of the chemotherapeutic value of penicillin, was made in 1938. In the next 20 years, more than a score of new and useful microbially produced antimicrobials entered into daily use. New synthetic antimicrobials are found today by synthesis of a wide variety of compounds, followed by broad screening against many microorganisms. Biosynthetic antimicrobials, although first found in bacteria, fungi, and plants, are now being discovered primarily in actinomycetes.

Antimicrobial agents contain various functional groups. No particular structural type seems to favor antimicrobial activity. The search for correlation of structure with biological activity goes on, but no rules have yet appeared with which to forecast activity from contemplated structural changes. On the contrary, minor modifications may lead to unexpected loss of activity. [G.M.S.]

Antimony A chemical element, symbol Sb, atomic number 51. Antimony is not a naturally abundant element; it is occasionally found native, often in isomorphous mixture with arsenic, as allemonite. The symbol Sb is derived from the Latin name stibium.

The element is dimorphic, existing as a yellow, metastable form composed of Sb_4 molecules, as in antimony vapor and the structural unit in yellow antimony; and a gray, metallic form, which crystallizes with a layered rhombohedral structure. Antimony differs from normal metals in having a lower electrical conductivity as a solid than as a liquid (as does its congener, bismuth). Metallic antimony is quite brittle, bluish-white with a typical metallic luster, but a flaky appearance. Although stable in air at normal temperatures, it burns brilliantly when heated, with the formation of a white smoke of Sb_2O_3. Vaporization of the metal gives molecules of Sb_4O_6, which break down to Sb_2O_3 above the transition temperature.

Antimony occurs in nature mainly as Sb_2S_3 (stibnite, antimonite); Sb_2O_3 (valentinite) occurs as a decomposition product of stibnite. Antimony is commonly found in ores of copper, silver, and lead. The metal antimonides NiSb (breithaupite), NiSbS (ullmannite), and Ag_2Sb (dicrasite) also are found naturally; there are numerous thioantimonates such as Ag_3SbS_3 (pyrargyrite).

Antimony is produced either by roasting the sulfide with iron, or by roasting the sulfide and reducing the sublimate of Sb_4O_6 thus produced with carbon; high-purity antimony is produced by electrolytic refining.

Commercial-grade antimony is used in many alloys (1–20%), especially lead alloys, which are much harder and mechanically stronger than pure lead; batteries, cable sheathing, antifriction bearings, and type metal consume almost half of all the antimony produced. The valuable property of Sn-Sb-Pb alloys, that they expand on cooling from the melt, thus enabling the production of sharp castings, makes them especially useful as type metal. [J.L.T.W.]

Antioxidant A substance that, when present at a lower concentration than that of the oxidizable substrate, significantly inhibits or delays oxidative processes, while being itself oxidized. In primary antioxidants, such as polyphenols, this antioxidative activity is implemented by the donation of an electron or hydrogen atom to a radical derivative, and in secondary antioxidants by the removal of an oxidative catalyst and the consequent prevention of the initiation of oxidation.

Antioxidants have diverse applications. They are used to prevent degradation in polymers, weakening in rubber and plastics, autoxidation and gum formation in gasoline, and discoloration of synthetic and natural pigments. They are used in foods, beverages, and cosmetic products to inhibit deterioration and spoilage. Interest is increasing in the application of antioxidants to medicine relating to human diseases attributed to oxidative stress.

The autoxidation process is shown in reactions (1), (2), and (3). Lipids, mainly those containing unsaturated fatty acids, such

$$\mathrm{RH} + \text{initiator (L)} \rightarrow \mathrm{R}\cdot + \mathrm{LH} \tag{1}$$

$$\mathrm{R}\cdot + \mathrm{O_2} \rightarrow \mathrm{ROO}\cdot \tag{2}$$

$$\mathrm{ROO}\cdot + \mathrm{RH} \rightarrow \mathrm{ROOH} + \mathrm{R}\cdot \tag{3}$$

as linoleic acid [RH in reaction (1)], can undergo autoxidation via a free-radical chain reaction, which is unlikely to take place with atmospheric oxygen (ground state) alone. A catalyst (L) is required, such as light, heat, heavy-metal ions (copper or iron), or specific enzymes present in the biological system [reaction (1)]. The catalyst allows a lipid radical to be formed (alkyl radical $R\cdot$) on a carbon atom next to the double bond of the unsaturated fatty acid. This radical is very unstable and reacts with oxygen [reaction (2)] to form a peroxyl radical ($ROO\cdot$), which in turn can react with an additional lipid molecule to form a hydroperoxide [ROOH in reaction (3)] plus a new alkyl radical, and hence to start a chain reaction. Reactions (2) and (3), the propagation steps, continue unless a decay reaction takes place (a termination step), which involves the combination of two radicals to form stable products. *See* AUTOXIDATION; CATALYSIS; CHAIN REACTION (CHEMISTRY).

When lipid autoxidation occurs in food, it can cause deterioration, rancidity, bad odor, spoilage, reduction in nutritional value, and possibly the formation of toxic by-products. Oxidation stress in a lipid membrane in a biological system can alter its structure, affect its fluidity, and change its function, causing disease.

An antioxidant can eliminate potential initiators of oxidation and thus prevent reaction (1). It can also stop the process by donating an electron and reducing one of the radicals in reaction (2) or (3), thus halting the propagation steps. A primary antioxidant can be effective if it is able to donate an electron (or hydrogen atom) rapidly to a lipid radical and itself become more stable then the original radical. The ease of electron donation depends on the molecular structure of the antioxidant, which dictates the stability of the new radical. Many naturally occurring polyphenols, such as flavonoids, anthocyanins, and saponins, which can be found in wine, fruit, grain, vegetables, and almost all herbs and spices, are effective antioxidants that operate by this mechanism.

A secondary antioxidant can prevent reaction (1) from taking place by absorbing ultraviolet light, scavenging oxygen, chelating transition metals, or inhibiting enzymes involved in the formation of reactive oxygen species, for example, NADPH oxidase and xanthine oxidase (reducing molecular oxygen to superoxide and hydrogen peroxide), dopamine-β-hydroxylase, and lipoxygenases. The common principle of action in the above examples is the removal of the component acting as the catalyst that initiates and stimulates the free-radical chain reaction. *See* ENZYME.

Among antioxidants, the synthetic compounds butylated hydroxyanisole (BHA), propyl gallate, ethoxyquin, and diphenylamine are commonly used as food additives. Quercetin belongs to a large natural group of antioxidants, the flavonoid family, with more than 6000 known members, many acting through both mechanisms described above. Ascorbic acid is an important water-soluble plasma antioxidant; it and the tocopherols, the main lipid soluble antioxidants, represent the antioxidants in biological systems. β-Carotene belongs to the carotenoid family, which includes lycopene, the red pigment in tomatoes; the family is known to be very effective in reacting with singlet oxygen ($^1O_2$), a highly energetic species of molecular oxygen. *See* ASCORBIC ACID; CAROTENOID; FLAVONOID; FOOD PRESERVATION. [J.Va.; L.P.]

Antipatharia An order of the subclass Zoantharia. These animals are the black or horny corals which live in rather deep tropical and subtropical waters and usually form regular or irregularly branching plant-like colonies, often 6.6 or 9.9 ft (2 or 3 m) in height, with thorny, solid lamellar, horny axial skeletons (see illustration). *Stichopathes* forms an unbranching wirelike colony.

***Antipathes rhipidion.* (*After F. Pax*)**

The polyp or zooid has six unbranched, nonretractile tentacles with a warty surface due to the presence of nematocysts. Six primary, complete, bilaterally arranged mesenteries occur, of which only two lateral ones bear filaments and gonads. Adjacent zooids are united by a coenenchyme, but their gastrovascular cavities have no connection. The musculature is the most weakly developed in the anthozoans.

The polyps are dioecious. Schizopathidae are dimorphic; the gastrozooid has a mouth and two tentacles, while the gonozooid, the only fertile polyp, lacks a mouth. *See* COELENTERATA; ZOANTHARIA. [K.At.]

Antiresonance The condition for which the impedance of a given electric, acoustic, or dynamic system is very high, approaching infinity. In an electric circuit consisting of a capacitor and a coil in parallel, antiresonance occurs when the alternating-current line voltage and the resultant current are in phase. Under these conditions the line current is very small because of the high impedance of the parallel circuit at antiresonance. [J.Mar.]

Antiseptic A drug used to destroy or prevent the growth of infectious microorganisms on or in the human or animal body, that is, on living tissue. Many chemical substances have been employed as antiseptics.

Iodine is the most important of the halogens used as an antiseptic. Tincture of iodine (iodine in an alcohol solution) has been employed widely as a preoperative antiseptic and in first aid. Tincture of iodine is germicidal by laboratory test in 0.02% concentration, but 2.0% solutions are usually employed in surgery and first aid.

Compounds of mercury were used to prevent infection before the germ theory of disease was established. Because of their high toxicity and severe caustic action, such inorganic mercurials as mercuric chloride, mercuric oxycyanide, and potassium mercuric iodide have been largely replaced by certain organic mercury compounds. Organic mercurial compounds are far less toxic and are nonirritating in concentrated solutions. They are highly bacteriostatic, and in concentrated solutions germicidal as well. They are also nonspecific in antimicrobial activity.

Essential oils have been defined as odoriferous oily substances obtained from such natural sources as plants by steam distillation. Essential oils in alcoholic solutions also were early employed in place of the carbolic acid solution of Lister, and because of the toxic and corrosive action of mercury bichloride, they also replaced this compound. Alcoholic solution of essential oils was first developed in 1881 and was admitted as liquor antisepticus to the U.S. Pharmacopoeia in 1900 and to the National Formulary IV in 1916. Alcoholic solutions of essential oils as represented by liquor antisepticus have proved effective in a wide variety of clinical applications and in first aid.

Silver compounds have been widely used for a variety of purposes. Because of the bland nature of most of these compounds, they have been successfully used in the eyes, nose, throat, urethral tract, and other organs. The most widely used silver compounds are silver nitrate, ammoniacal silver nitrate solution, silver picrate, and certain colloidal silver preparations such as strong protein silver and mild silver protein. These are effective germicides of low tissue toxicity and are not counteracted by organic matter.

Such compounds as ethyl alcohol and isopropyl alcohol are germicidal rather than bacteriostatic and are effective against the vegetative forms of bacteria and virus, but do not kill spores. Ethyl alcohol in 62.5–70% solution is most commonly used, being widely employed for disinfecting the skin before hypodermic injections and other skin punctures. Isopropyl alcohol is equal, if not superior, to ethyl alcohol and is widely used for degerming the skin and for disinfecting oral thermometers. Alcohols are also widely used in other antiseptic preparations, in which they serve to lower the surface tension and to promote spreading and penetration.

Bisphenol compounds such as dichlorophene and tetrachlorophene are essentially bacteriostatic agents and are weaker as germicides. They have proved quite effective as skin-degerming agents, when used in soaps and other detergents, and as mildew-preventing formulations. The halogenated form, such as dichlorophene, tetrachlorophene, hexachlorophene, and bithionol, is most commonly employed. When used repeatedly on the skin, as in soaps and detergents, bisphenols have a tendency to remain for long periods, thus reducing skin bacteria to a significant degree. For this purpose they are especially useful in preoperative hand washing.

Quaternary ammonium compounds have high germicidal activity. Although they are more properly classified as surfaceactive disinfectants, some of them are employed in certain antiseptic formulations, for instance, Zephiran, especially suited for use on the skin, and Cepacol, for mucous surfaces. Nontoxic and nonirritating, they may be used in place of alcohol after preoperative scrub-up. *See* ANTIMICROBIAL AGENTS; BIOASSAY. [G.F.R./F.C.]

Antisubmarine warfare All measures required to combat enemy submarines, including strategy, operational employment of forces, tactics, and a wide variety of equipment and weapons to find and destroy submarines and to neutralize their weapons.

The key physical facts of antisubmarine warfare (ASW) are that submerged submarines are, effectively, invisible to surface observers and that sound is the only form of energy that travels any substantial distance underwater. All forms of antisubmarine warfare are based on strategies which cause the submarines to surrender either their invisibility (or stealth) or their mobility. Generally, since the submarine can be destroyed once it is located, the effort in antisubmarine warfare goes primarily into finding it.

Since invisibility is the key element of submarine operations, and since this is violated only by sound, sound sensor (that is, sonar) performance shapes the tactics of antisubmarine warfare. Sonars may be active, that is, the listening device may impose a signature on the target, or passive, in which case the device may listen for noise from the target. There are two limits on active sonar: water can transmit only a limited amount of energy, and active sensing will tend to alert the target submarine.

The distance that sound travels through the ocean depends on its frequency: under given conditions, the lower the frequency, the farther a sound signal will travel. The best low-frequency active sonars are the size of small boats, which is probably about the largest size that would be acceptable within a conventional hull. For lower frequencies, a towed array is employed. This is a line of passive transducers trailed far astern of a ship, at the optimum listening depth. Although the array can detect distant targets (perhaps positioned hundreds of miles away), it cannot provide range and bearing data that are sufficient for fire control. Therefore, an airplane or helicopter is generally used to search the area defined by the sensor quickly enough to detect the submarine before it leaves the area.

A major area of effort in antisubmarine warfare has been to distinguish ever fainter (more distant) submarine noises from the surrounding random ocean noise, so that attacks are not made against nonexistent targets; otherwise, weapons may be expended too quickly. This problem of identifying sounds of real objects is generally termed one of classification. It includes the challenge of distinguishing friendly from enemy submarines. *See* UNDERWATER SOUND.

The main weapons used in antisubmarine warfare are homing torpedoes (using active or passive sonars) and depth bombs, the latter generally fused to explode at a preset depth. In many cases, depth charges are propelled by rockets to the vicinity of the submarine. Because sonar range may exceed the range at which a torpedo can find a submarine target, several navies use missiles to carry homing torpedoes out to the point at which they are likely to find the target. Since World War II, torpedoes have generally replaced depth bombs or depth charges because the latter fall relatively slowly through the water so that a fast submarine can evade them.

Most antisubmarine warfare operations fall into three distinct categories: long-range detection (which may be followed by attacks, often by aircraft), interception by submarines, and counterattack by escorts.

If a submarine can be detected at very long range, it can be attacked by an airplane cued by the detection system. Until the end of the Cold War, much of United States antisubmarine strategy was based on the ability of fixed undersea arrays and strategic towed arrays to detect Russian submarines at great distances, of hundreds or even thousands of miles, in the open Atlantic and Pacific oceans. From the late 1970s on, the Russians began to silence their nuclear submarines far more efficiently, and alternative forms of antisubmarine operation became more important. In the aftermath of the Cold War, United States naval operations were likely to occur in areas not covered by the fixed systems, and possibly not accessible to the slow towed-array ships. A deployable submarine detection system became essential.

Because it is almost invisible, a submarine can lie near enemy submarine bases in hopes of intercepting emerging enemy craft. Such interception was an important United States tactic against the Russian submarine force throughout the Cold War. In the absence of effective long-range detectors, this sort of submarine blockade becomes an important tactic.

If the submarines are likely to concentrate on ships as targets, and if they cannot be located efficiently at long ranges, then antisubmarine ships can be concentrated around the potential targets, in a convoy. Convoys do not actively protect the escorted ships against attack. Rather, they act as a deterrent, since any submarines that attack must surrender their invisibility, inviting counterattacks from escort ships. Convoy escorts were responsible for the bulk of all German submarines destroyed at sea in World War II.

There are four main platforms for antisubmarine warfare: surface ships equipped with sonars; airplanes equipped with sonobuoys (which they drop into the water); helicopters carrying both sonobuoys and dipping sonars; and submarines. [N.F.]

Antitoxin An antibody that will combine with and generally neutralize a particular toxin. When the manifestations of a disease are caused primarily by a microbial toxin, the corresponding antitoxin, if available in time, may have a pronounced prophylactic or curative effect. Apart from this, the other properties of an antitoxin are those of the antibody family (lgG, IgA, IgM) to which it belongs. *See* Antibody; Biologicals; Immunoglobulin.

Antitoxins have been developed for nearly all microbial toxins. Diphtheria, tetanus, botulinus, gas gangrene, and scarlatinal toxins are important examples. Antitoxins may be formed in humans as a result of the disease or the carrier state, or following vaccination with toxoids, and these may confer active immunity. The status of this can be evaluated through skin tests, or by titration of the serum antitoxin level. *See* Botulism; Diphtheria; Gangrene; Immunity; Skin test; Tetanus; Toxin-antitoxin reaction. [H.P.T.]

Anura One of the three living orders (sometimes called Salientia) of the class Amphibia, which includes the frogs and toads. About 2400 species of frogs are known. Only the frozen polar regions and remote oceanic islands are without native frogs, and 80% of the species live in the tropics.

Frogs are short-bodied animals with a large mouth and protruding eyes. The externally visible part of the ear, absent in some forms, is the round, smooth tympanum situated on the side of the head behind the eye. There are five digits on the hindfeet and four on the front. Teeth may be present on the upper jaw and the vomerine bones of the roof of the mouth, but are found on the lower jaw of only one species. Often teeth are totally lacking, as in toads of the genera *Bufo* and *Rhinophrynus*. The short vertebral column consists of from 6 to 10 vertebrae, usually 9, and the elongate coccyx. The sacral vertebra precedes the coccyx and bears more or less enlarged lateral processes with which the pelvic girdle articulates. A characteristic feature of frogs is the fusion of the bones in the lower arm and lower leg, so that a single bone, the radioulna in the arm and the tibiofibula in the leg, occupies the position of two in most other tetrapods.

The one character of frogs that comes to the attention of most persons, including many who may never see a frog, is the voice. Most frogs have voices and use them in a variety of ways. In the breeding season great numbers of male frogs may congregate in favorable sites and call, each species giving its own characteristic vocalization. Because no two species breeding at the same time and place have identical calls, it is assumed that the call is important in aiding individuals to find the proper mate. In some species it appears that the female is active in selecting the mate and may be responding to the mating call, but the call may not act in exactly the same way in other species. The mating call is given with the mouth closed. Air is shunted back and forth between the lungs and the mouth, so frogs can call even though submerged. Many species possess one or two vocal sacs, which are expansible pockets of skin beneath the chin or behind the jaws. The sacs (Fig. 1), which may be inflated to a volume as great as that of the frog itself, serve as resonators.

Fig. 1. Toad of the genus *Bufo* giving mating call with vocal sac expanded. (*American Museum of Natural History*)

Other noises made by frogs include the so-called fright scream given with the mouth open, and the warning chirp, which evidently serve as a sex recognition signal when one male contacts another. Some calls evidently serve as territorial signals.

Breeding and development typically take place in the following manner. The male grasps the female about the body with the forelegs, a procedure called amplexus, and fertilizes the eggs externally as they are extruded. The number of eggs may be quite large (up to 20,000 in the bullfrog or 25,000 in a common toad) or may be as few as one in a frog of the West Indies. The larva, called a tadpole, is at first limbless and has external gills and a muscular tail with dorsal and ventral fins (Fig. 2). At hatching there is no mouth opening present, but one soon forms that develops a horny beak and several rows of labial teeth not at all like the true teeth of the adult frog. Shortly after the tadpole hatches, the gills become enclosed within chambers and are no longer visible externally. Except for the gradual development of the hindlimbs, no additional external changes take place as the tadpole grows until the time for metamorphosis. The anterior limbs, which have been forming hidden in the gill chambers, break through the covering skin as metamorphosis begins. The tail dwindles in size as it is absorbed, while the mouth assumes the shape of that of the adult frog. Many other changes are

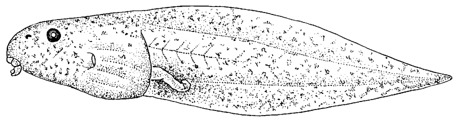

Fig. 2. The tadpole, or larval, stage of the frog *Rana pipiens*. (*After W. F. Blair et al., Vertebrates of the United States, 2d ed., McGraw-Hill, 1968*)

taking place internally, including shortening of the intestine and adapting it to the carnivorous diet of the adult frog.

All frogs are carnivorous. The kind of food seems to depend largely upon the size of the frog, whose capacious mouth permits somewhat astonishing feats of swallowing. A large bullfrog, for example, may snap up low-flying bats, ducklings, snakes, and turtles. Insects and other invertebrates form the bulk of the diet of most frogs. The tongue, moistened by a sticky secretion from the intermaxillary gland in the roof of the mouth, is used to catch smaller prey, while larger items of food may bring the front limbs into play. When swallowing, a frog will usually depress the eyeballs into the head to aid in forcing the food down the pharynx. In contrast to transformed frogs, most tadpoles are vegetarian and feed on algae. A few are largely carnivorous or sometimes cannibalistic, and even vegetarian species will scavenge for dead animal matter.

The habitats of frogs are as various as the places where fresh water accumulates. Lakes and streams are tenanted year-round by many species, and others migrate to these places in the breeding season. Any permanent source of water in the desert is likely to support a population of one or more species, and when rainstorms occur, the air around a temporary pool may be filled with mating calls for a few nights, while the frogs take advantage of the water for breeding. As often as not, the pool goes dry before the tadpoles metamorphose, and the adult frogs retreat underground to await another rain. Moist tropical regions provide an abundance of habitats little known to temperate regions, such as the air plants (bromeliads) that hold water and so provide a moist home and breeding site for frogs that may never leave the trees.

Although the majority of frogs fall into fairly well-defined familial categories, the arrangement of the families into subordinal groups by different authorities is not consistent, and there is controversy about the relationships of some smaller groups. [R.G.Z.]

Anxiety disorders A group of distinct psychiatric disorders characterized by marked emotional distress and social impairment, including generalized anxiety disorder, panic disorder, obsessive-compulsive disorder, and posttraumatic stress disorder.

Generalized anxiety disorder (GAD) is characterized by excessive worry, tension, and anxiety. Accompanying physical symptoms include muscle tension, restlessness, fatigability, and sleep disturbances. GAD occurs in around 4–6% of the population and is the most frequently encountered anxiety disorder in primary care, where sufferers may seek help for the physical symptoms of the disorder. Studies of fear in animals and clinical studies of people with GAD suggest that similar brain circuits are involved in both cases. For example, numerous complex connections to other brain areas allows the amygdala to coordinate cognitive, emotional, and physiological responses to fear and anxiety. Thus in the "fight or flight" response, the organism makes cognitive-affective decisions about how to respond to the perceived danger and has a range of somatic (increased heart and respiration rate) and endocrine (release of stress hormones) responses that act together to increase the likelihood of avoiding the danger. Various neurotransmitter systems are responsible for mediating the communication between the functionally connected regions. Medications acting on these systems are thus effective in treating GAD. Although benzodiazepines have often been used, selective serotonin reuptake inhibitors (SSRIs) and noradrenergic/serotonergic reuptake inhibitors (NSRIs) are currently viewed as first-line options because of their favorable safety profile. Psychotherapy has also proven effective in the treatment of GAD. Cognitive-behavioral psychotherapy focuses on using behavioral techniques and changing underlying thought patterns.

Panic disorder (PD) is characterized by repeated, sudden, and unexpected panic attacks. Panic attacks are accompanied by a range of physical symptoms, including respiratory (shortness of breath), cardiovascular (fast heart rate), gastrointestinal (nausea), and occulovestibular (dizziness) symptoms. The prevalence of PD is approximately 2% in the general population, is more common in women, and is often complicated by depression. The same brain circuits and neurotransmitters implicated in fear and GAD are also likely to play a role in PD. For treatment the first-line choice of medication should be an SSRI or NSRI. Benzodiazepines are effective alone or in combination with SSRIs, but their use as the only medication is generally avoided due to the potential for dependence and withdrawal. Cognitive-behavioral principles that address avoidance behavior and irrational dysfunctional beliefs are also effective.

Obsessive-compulsive disorder (OCD) is characterized by obsessions (unwanted, persistent, distressing thoughts) and compulsions (repetitive acts to relieve anxiety caused by obsessions). The disorder occurs in 2–3% of the population and often begins in childhood or adolescence. OCD is also seen in the context of certain infections, brain injury, and pregnancy. A range of evidence now implicates a brain circuit between the frontal cortex, basal ganglia, and thalamus in mediating OCD. Key neurotransmitters in this circuit include the dopamine and serotonin neurotransmitter system. SSRIs are current first-line treatments for OCD, with dopamine blockers added in those who do not respond to these agents. Behavioral therapy focuses on exposure and response prevention, while cognitive strategies address the distortions in beliefs that underlie the perpetuation of symptoms.

Social anxiety disorder (SAD) is characterized by persistent fears of embarrassment, scrutiny, or humiliation. People with SAD may avoid social situations and performance situations, resulting in marked disability. For some, symptoms are confined to one or more performance situations, while others may be generalized to include most social and performance situations. Generalized SAD is usually more severe and sufferers are more likely to have a family history of SAD. SAD is particularly common, with prevalence figures in some studies upwards of 10%. SAD is often complicated by depression, and people with SAD may self-medicate their symptoms with alcohol, leading to alcohol dependence. Brain-imaging studies have found that effective treatment with medication and psychotherapy normalizes activity in the amygdala and the closely related hippocampal region in SAD. SSRIs, NSRIs, and cognitive-behavioral therapy are all effective in the treatment of SAD. Monoamine oxidase inhibitors (MAOIs) and benzodiazepines are also known to be effective treatments, but have a number of disadvantages.

Posttraumatic stress disorder (PTSD) is an abnormal response to severe trauma. PTSD is characterized by distinct clusters of symptoms: reexperiencing of the event (for example, in flashbacks or dreams), avoidance (of reminders of the trauma), numbing of responsiveness to the environment, and increased arousal (for example, insomnia, irritability, and being easily startled). Although exposure to severe trauma occurs in more than 70% of the population, PTSD has a lifetime prevalence of 7–9% in the general population. Risk factors for developing PTSD following exposure to severe trauma include female gender, previous psychiatric history, trauma severity, and absence of social support after the trauma. Brain-imaging studies have suggested that in PTSD frontal areas of the brain may fail to effectively dampen the "danger alarm" of the amygdala. Whereas stress responses ordinarily recover after exposure to trauma, in PTSD they persist. There is growing evidence that functioning of the hypothalamic-pituitary-adrenal hormonal axis is disrupted in PTSD. However, other systems, such as serotonin and noradrenaline, may also be involved. Both SSRIs and cognitive-behavioral therapy are effective in decreasing PTSD symptoms. Behavioral techniques (using different forms of exposure in the safety of the consultation room) or cognitive retraining (addressing irrational thoughts on the trauma and its consequences) can both be helpful. [P.D.C.; D.J.St.]

Anyons Particles obeying unconventional forms of quantum statistics. For many years it was believed that only two possible forms of quantum statistics, Bose-Einstein and Fermi-Dirac statistics, were possible, but in fact a continuum of possibilities exists. Elementary excitations (quasiparticles) in the fractional quantum Hall effect are anyons.

In quantum mechanics, in the behavior of identical particles there are important dynamical effects that have no classical analog. Thus, in the case of two indistinguishable particles A and B, the amplitude for the process that leads to A arriving at point *x* while B arrives at point *y* must be added to the amplitude for the process that leads to A arriving at *y* while B arrives at *x*—the so-called exchange process—because the final states cannot be distinguished. Actually the recipe of adding the amplitude for the exchange process is appropriate only for particles obeying Bose-Einstein statistics (bosons); for particles obeying Fermi-Dirac statistics (fermions), this amplitude must be subtracted. *See* FERMI-DIRAC STATISTICS; NONRELATIVISTIC QUANTUM THEORY.

The definition of anyons posits other possible recipes for adding exchange processes, refining the analysis of exchange to take account of the direction in which the exchange takes place. These more general possibilities can be defined only for particles whose motion is restricted to two space dimensions. However, many important materials are effectively two-dimensional, including microelectronic circuitry and the copper oxide layers of high-temperature superconductors. The quantum statistics of the quasiparticles in these systems is under investigation, but the fractional quantized Hall states are known to be anyons. *See* HALL EFFECT; QUANTUM STATISTICS; SUPERCONDUCTIVITY. [F.Wil.]

Aorta The main vessel of the systemic arterial circulation arising from the left ventricle of the heart; it is divided into three parts for convenience only. The first portion, the ascending aorta, passes upward under the pulmonary artery; the coronary arteries arise at the base of the ascending aorta behind the aortic valves. The second part, or aortic arch, curves over the hilum of the left lung, giving off the innominate, left carotid, and left subclavian arteries, which supply the neck, head, and forelimbs. The third portion, or descending aorta, continues downward in the thorax on the left side of the vertebral column to the diaphragm, giving off small arteries to the bronchi, esophagus, and other adjacent tissues. Below the diaphragm this vessel, known as the abdominal aorta, descends to the level of the fourth lumbar vertebra where it bifurcates into the two common iliac arteries supplying the hindlimbs.

In the abdomen the major branches of the aorta include the single celiac, superior mesenteric and inferior mesenteric, and the paired renal and internal spermatic (male) or ovarian (female) arteries. In addition, many small branches go to other organs and to the body wall. *See* SYSTEM. [W.J.B.]

Apatite The most abundant and widespread of the phosphate minerals, crystallizing in the hexagonal system. The apatite structure type includes no less than 10 mineral species and has the general formula $X_5(YO_4)_3Z$, where X is usually Ca^{2+} or Pb^{2+}, Y is P^{5+} or As^{5+}, and Z is F^-, Cl^-, or $(OH)^-$. The apatite series takes X = Ca, whereas the pyromorphite series includes those members with X = Pb. Three end members form a complete solid-solution series involving the halide and hydroxyl anions. These are fluorapatite, $Ca_5(PO_4)F_3$; chlorapatite, $Ca_5(PO_4)_3Cl$; and hydroxyapatite, $Ca_5(PO_4)_3(OH)$. Thus, the general series can be written $Ca_5(PO_4)_3(F,Cl,OH)$, the fluoride member being the most frequent and often simply called apatite.

The apatite isomorphous series of minerals occurs as grains, blebs, or short to long hexagonal prisms terminated by pyramids, dipyramids, and the basal pinacoid. The minerals are transparent to opaque, and can be asparagus-green (asparagus stone), grayish-green, greenish-yellow, gray, brown, brownish-red, and more rarely violet, pink, or colorless. Apatites are brittle, with hardness 5 on Mohs scale, and specific gravity 3.1–3.2; they are also botryoidal, fibrous, and earthy.

Apatite occurs in nearly every rock type as an accessory mineral. It often crystallizes in regional and contact metamorphic rocks, especially in limestone and associated with chondrodite and phlogopite. It is very common in basic to ultrabasic rocks; enormous masses occur associated with nephelinesyenites in the Kola Peninsula, Russia, and constitute valuable ores which also contain rare-earth elements. Large beds of oolitic, pulverulent, and compact fine-grained carbonate-apatites occur as phosphate rock, phosphorites, or collophanes. Extensive deposits of this kind occur in the United States in Montana and Florida and in North Africa. The material is mined for fertilizer and for the manufacture of elemental phosphorus. *See* FERTILIZER; PHOSPHORUS; PYROMORPHITE. [P.B.M.]

Apes The group of primates most closely related to humans. They include the African great apes, the gorilla and two species of chimpanzee; the Asian great ape, the orangutan; and the lesser apes from Asia, the gibbon and siamang. The apes can be distinguished from the rest of the primates by a number of anatomical and behavioral traits, which indicate their common origin; thus they are termed a monophyletic group called the Hominoidea.

Apes are distinguished from other primates through such obvious features as absence of tail and presence of an appendix. They share a number of specializations (synapomorphies) of the skeleton, which are useful as diagnostic characters, particularly when it comes to distinguishing fossil apes, because bones and teeth are the most readily preserved parts in the fossil record. The distal end of the humerus is especially useful, both because it is one of the most robust body parts, and therefore readily preserved, and because it is diagnostic of the ape condition, with a large trochlea (ulnar forearm articulation) and a well-developed trochlea ridge. The wrist is also modified for mobility of the joint. There are few synapomorphies of the skull, which in general retains the primitive primate condition except in individual species, but two shared specializations are the deep arched palate and relatively small incisive foramina. The teeth also are generally primitive, except in the broad, low-crowned incisors and enlarged molars. *See* DENTITION; FOSSIL APES; SKELETAL SYSTEM.

Gibbons. Each group of ape differs from this basic ape pattern in varying degrees. The gibbons retain many of the primitive ape characteristics. They have also developed a number of unique characters that are different from any other ape: they have very elongated arms (relative to body weight) with many modifications of the musculature for a brachiating form of locomotion (swinging by the arms); their legs are also lengthened, so that they are quite efficient bipeds; they have adopted a monogamous family system, which is unusual in primates, and one of the outcomes is role sharing between males and females and lack of size variation between the sexes; and they have also developed a complex system of vocal communication related both to their close social bonds and to their thick tropical forest environment, which makes visual communication difficult. At present there are six species of gibbon (*Hylobates*) occupying most parts of Southeast Asia where primary forest still remains. *See* SOCIAL MAMMALS.

Orangutan. The sister group to the gibbons is the great ape and human group, which is readily distinguished by the shared presence of enlarged premolars in all its members. Within this group can be distinguished the orangutan and the African apes. The orangutan (*Pongo pygmaeus*) has a great many specializations that support this separation, although because of its common heritage with the chimpanzee and gorilla, and the great increase in body size of all three, the orangutan has a superficial similarity which has led in the past to all being grouped in the same family, the Pongidae. The differences separating the orangutan from other apes are in part biochemical—the structure of the blood proteins, for instance—and in part morphological. The deep face, enlarged premaxilla, narrow distance between the eyes, massive zygomatic bones, smooth floor of nose, and enlarged central incisors are all characters unique to the orangutan, and in all of these traits the African apes and humans retain the primitive ape condition. The orangutan is today confined to the tropical rain forests of Borneo and Sumatra, where it exists as a highly variable species. There are many biochemical and chromosomal differences both within and between populations, so that the possibility has been raised that, in fact, two separate species are present. This cannot be accepted on present evidence, but it would appear that the orangutan is a good example of ongoing evolution and incipient speciation. It is largely arboreal despite its great size, which ranges in body weight from 88 to 308 lb (40 to 140 kg). It leads a solitary or small-group existence, leading to the massive sexual-size variation indicated by its body weight variation. Little is known of its social structure.

African apes. The other part of the great ape group consists of the three African apes, the gorilla and two species of chimpanzee. They are distinguished from the orangutan (and other primates) by specializations of the wrist and frontal sinus and the development of massive brow ridges (all of which they also share with humans), and by a further series of unique modifications of the hand that are related to its unusual form of locomotion, called knuckle walking. Their legs are reduced in length (relative to body weight) so that their arms appear long in proportion to the rest of their body. The effects of this are further increased both by elongation of the hand and by the fact that when they walk quadrupedally on the ground they support their weight on the middle phalanges (finger bones) of the hand. This raises the body to a semiupright position even when the animals are walking on all fours.

The chimpanzee (*Pan troglodytes*) inhabits much of the forested region of tropical Africa, extending beyond the forest into more seasonal wooded habitats as well. The pygmy chimpanzee, or bonobo (*P. paniscus*), is confined to the southern loop of the Congo River where it inhabits mainly swamp forest. The gorilla is also confined to tropical Africa, but is divided into two rather distinct forms, the mountain gorilla (*Gorilla gorilla beringei*) and two lowland subspecies (*G. g. gorilla and G. g. manyeura*). The gorilla is the largest of the primates, with body weights ranging from 165 to 396 lb (75 to 180 kg), while the chimpanzee at 88–110 lb (40–50 kg) is much smaller. Gorilla social groups consist of a dominant male with several females and immature males and females, while chimpanzees live in fluctuating multimale or multifemale groups.

Relationship to humans. The orangutan is put into a separate group (or clade) from the other great apes (the chimpanzee, *Pan*, and the gorilla) because these have been shown to be more closely related to humans in evolutionary terms than they are to the orangutan. This signifies that the idea of the "great apes" encompassing all three is not valid, and the use of a single family, the Pongidae, to include them all is not correct. The great apes, however, have many superficial similarities to each other, mostly related to their large size, so that they may be said to be similar in grade, but in terms of clade (ancestral-descendant relationship) they are different. This could be recognized by restricting the use of the family Hominidae, but other classifications are also possible based on this set of relationships. *See* FOSSIL HUMANS.
[P.A.]

Aphasia Impairment in the use of spoken or written language caused by injury to the brain which cannot be accounted for by paralysis or incoordination of the articulatory organs, impairment of hearing or vision, impaired level of consciousness, or impaired motivation to communicate. The language zone in the brain includes the portion of the frontal, temporal, and parietal lobes surrounding the sylvian fissure and structures deep to these areas. In right-handed persons, with few exceptions, only injury in the left cerebral hemisphere produces aphasia. Lateralization of language function is variable in left-handers, and they are at greater risk for becoming aphasic from a lesion in either hemisphere. *See* HEMISPHERIC LATERALITY.

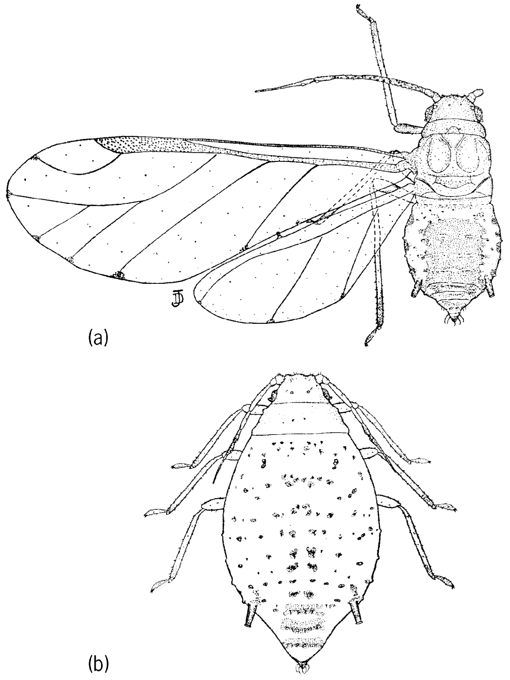
Distinctive recurring patterns of deficit are associated with particular lesion sites within the language zone. These patterns may entail selective impairment of articulation, ability to retrieve concept names, or syntactic organization. Other dissociations affect principally the auditory comprehension of speech, the repetition of speech, or the recognition of written words. The erroneous production of unintended words in speech (paraphasia), oral reading (paralexia), or writing (paragraphia) is a feature of some forms of aphasia.

Mixed forms of aphasia, caused by multiple lesions or lesions spanning anterior and posterior portions of the speech zone, are quite common, and massive destruction of the entire language area results in a global aphasia. Further, individual variations in behavioral manifestations of similar lesions have set limits on the strict assignment of function to structures within the language area.

Preadolescent children suffering aphasia after unilateral injury usually recover rapidly, presumably by virtue of the capacity of the right cerebral hemisphere early in life to acquire the language functions originally mediated by the left hemisphere. Capacity for recovery of function decreases during later adolescence and young adulthood.

Complete recovery in adults after a severe injury is much less common, and severe aphasia may persist unchanged for the duration of the person's life. Many patients are aided by remedial language training, while others continue severely impaired. *See* MEMORY.
[H.G.]

Aphid One of a group of mostly soft-bodied plant-feeding insects of the suborder Homoptera, superfamily Aphidoidea. The worldwide fauna of over 4000 species is most abundant in north temperate regions. Aphids feed on phloem sap from vascular plants, tapping it through a feeding tube formed from modified mandibles and maxillae called stylets. In so doing they



Viviparae of the tulip bulb aphid: (*a*) the winged form and (*b*) the wingless form. (*After J. Davidson, On some aphids infesting tulips, Bull. Entomol. Res., 18:51–62, 1927*)

may transmit viruses from plant to plant, spreading serious disease in crops such as potatoes, cereals, sugarbeet, and citrus. Plants sometimes react to aphid feeding by forming galls in which the aphids live protected from drought and enemies. The so-called Chinese gall is valued in commerce for its high tannin content.

Aphids have evolved complex life styles to exploit the changing growth phases of plants. Many divide their yearly cycle by flying between a primary host, on which sexual forms mate and lay winter eggs, and a secondary host, where only parthenogenetic females multiply. Only one generation of males and sexual oviparous females occurs each year, usually in autumn. Most parthenogenetic females are also viviparous, and reproduce very rapidly under favorable conditions. Viviparae are winged or wingless (see illustration). Development of young aphids can be switched toward either wingedness or sexuality by outside factors, such as crowding, decreasing temperature, or shortening days. Aphids in the tropics often remain wholly parthenogenetic. [H.L.G.S.]

Apiales An order of flowering plants, division Magnoliophyta (Angiospermae), in the subclass Rosidae of the class Magnoliopsida (dicotyledons). The order (also known as Umbellales) consists of two families, the Araliacea, with about 700 species, and the Umbelliferae, with about 3000. They are herbs or woody plants with mostly compound or conspicuously lobed or dissected leaves, well-developed secretory canals, and separate petals.

The Umbelliferae are mostly aromatic herbs, most numerous in temperate regions. The flowers consistently have an ovary of two carpels, ripening to form a dry fruit that splits into two halves, each containing a single seed. Some common garden vegetables and spice plants, including carrot (*Daucus carota*), parsnip (*Pastinaca sativa*), celery (*Apium graveolens*), parsley (*Petroselinum crispum*), caraway (*Carbum carvi*), and dill (*Anethum graveolens*), belong to the Umbelliferae, as do also such notorious poisonous plants as the poison hemlock (*Conium*) and water hemlock (*Cicuta*). *See* Anise; Carrot; Celery; Fennel; Magnoliopsida; Parsley; Parsnip; Rosidae. [A.Cr.]

Apical dominance Correlative inhibition of the growth of lateral (axillary) shoots exerted by the growing apical bud of the plant stem. Partial or complete apical dominance can also occur in the initiation of lateral roots and in the orientation of lateral organs such as branches, leaves, and stolons.

In the apical meristem, cell division occurs in the young forming leaves and along the flanks of the apical bud. As the number of cells increases, they elongate, pushing the apical meristem upward and leaving a small portion of the dividing cells behind the axil of each of the laterally forming leaves. This meristem, called the lateral meristem, may remain a small group of cells with little organization or may develop into an axillary bud possessing short internodes, unexpanded leaves, and an apical meristem. In roots, branching does not directly involve the apical meristem. Lateral roots do not form from organized buds but originate in the layer of cells between the endodermis and root vascular system (pericycle). *See* Lateral meristem; Root (botany).

The degree of apical dominance over the lateral buds varies with the plant species. Some plants, such as pea and sunflower, exhibit strong apical dominance, causing the formation of single branchless shoots. Other plants, such as tomato, have weak apical dominance, allowing axillary bud growth and a bushy growth habit. Apical dominance can be broken by several factors, including apical bud removal (decapitation), horizontal positioning of the plant's main axis (gravistimulation), shoot inversion, low light intensity, or short-day photoperiods. In some situations, apical dominance is weakened as the plant becomes older. *See* Photoperiodism; Plant movements.

Plant organs other than the main shoot are under the control of apical dominance. In roots, strong apical dominance causes taproot growth, whereas weak apical dominance results in a fibrous root system. Leaves and branches which grow at characteristic angles to the main axis of the stem will grow more upright after removal of the apical bud of the main stem. The growth form of some organs is also controlled by the presence of the apical bud. Rhizomes (underground axillary shoots lacking chlorophyll and having rudimentary leaves) will grow upright, forming green, leafy shoots if the apical bud and all the aboveground axillary buds are removed. Lower plants, such as mosses and ferns, as well as fungi and algae, also exhibit apical dominance.

One hypothesis for the mechanism of apical dominance is based on the competition of nutrients between centers of growth. According to this hypothesis, nutrients are preferentially transported to the apical bud, causing deficiencies in the axillary buds. A second hypothesis for the mechanism of apical dominance proposes that one or more plant hormones, such as auxin, cytokinin, and gibberellin, acts as correlative signals. *See* Auxin; Cytokinins; Gibberellin; Plant growth. [M.Ha.]

Apical meristem Permanently embryonic tissue involved in cell division at the apices of plant roots and stems, and forming dynamic regions of growth. These apical meristems, usually consisting of small, densely cytoplasmic cells, become established during embryo development. Thereafter they divide, producing the primary plant body of root and shoot. Below the apical meristems, tissue differentiation begins: the protoderm gives rise to the epidermal system, the procambium to the primary vascular system, and the ground meristem to the pith and cortex (see illustration). Plant apical meristems have been the object of experiments on development similar to those carried out on animal embryos.

Root apical meristem is covered by a root cap, a region of parenchymatous, cells which has a protective function and is responsible for perceiving gravitational changes. Root tips have been shown to possess a central region, usually hemispherical, which consists of cells which rarely divide or synthesize deoxyribonucleic acid (DNA), and have less ribonucleic acid (RNA) and protein than adjacent cells; this region is known as the quiescent center. The cells which divide and give rise to root tissues lie around the periphery of this region. Cells in the quiescent center are regarded as cells that are mitotically young and genetically sound; they can renew the initial cells from time to time.

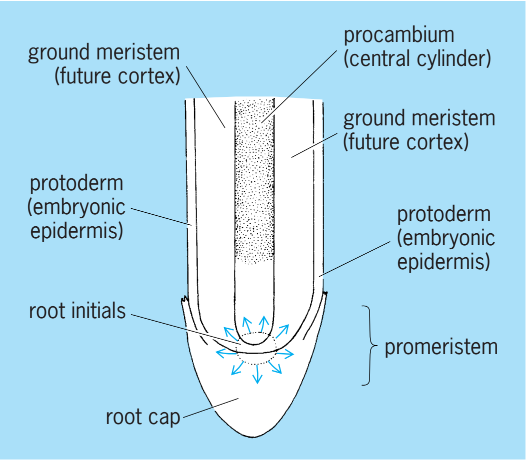


Diagram of a root apical meristem. Cortex and central cylinder have separate initials; epidermis and root cap have a common origin.

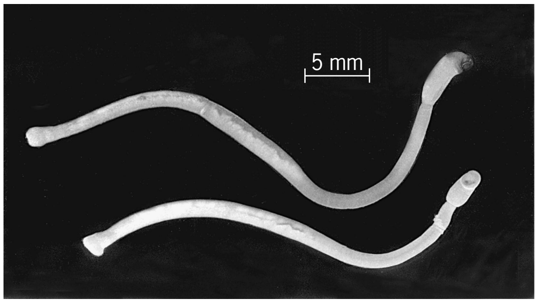
Shoot apices vary greatly in size and shape. The diameter can vary from about 50 micrometers to 0.14 in. (3.5 mm); the shape may be elongated and conical, dome-shaped, flat, or even slightly concave. The distance from the center of the apex to the youngest leaf primordium also varies considerably. Apices increase in size during the development of a single plant; for example, the apical meristem of flax *(Linum usitatissimum)* increases in area 20-fold from the seedling up to the time of flowering. Apices may also change in size during the time between the formation of one leaf primordium and the next. A single apical cell is present in shoot apices of bryophytes and vascular cryptogams; however, surrounding cells are also mitotically active, and these plants have multicellular apical meristems. In flowering plants, the outer layer or layers of cells (tunica) may divide predominantly by walls at right angles to the surface; the inner tissue (corpus), in less regular planes. Regions of the apical meristem may react differently to certain stains, reflecting so-called cytohistological zonation.

Cells in the central terminal region of the vegetative shoot apex divide less actively than those on the flanks or at the periphery, where leaf and bud primordia are formed. Various surgical experiments, involving incision of the apical meristem, have shown that new apices can be regenerated from portions of the flank. Excised apical meristems, devoid of leaf primordia, can be successfully grown on agar nutrient medium, in the presence of auxin, and will eventually yield new plants. *See* AUXIN; BUD; LEAF. [E.G.C.]

Aplacophora A class, also known as Solenogastres, of vermiform mollusks ubiquitous in the deep oceanic basins and trenches to 30,000 ft (9000 m) and common on the continental shelf and slope regions of the world, where they burrow through or creep upon the mud or wrap around alcyonarian corals. Most Aplacophora are less than 10.4 in. (10 mm) in length.

There are two distinct taxa: the subclass Chaetodermomorpha (= Caudofoveata; see illustration); and the subclass Neomeniomorpha (= Ventroplicida; Solenogastres).



Living *Chaetoderma nitidulum*. (*Courtesy of R. Robertson*)

Several features are common to all Aplacophora. The ladderlike nervous system consists of paired lateral and ventral cords with many cross-commissures, a buccal ring, and cerebral and suprarectal ganglia. The coelom is restricted to coelomoducts, a spacious pericardium, and gonads that uniquely connect to the pericardium. There is a mantle cavity into which empty the anus and coelomoducts. Other molluscan characters present, but not common to all families, are a radula and its supports; paired gills in the mantle cavity; a mucus-secreting vestigial foot used in creeping; and a style sac containing a mucoid rod which turns against a chitinous gastric shield. *See* MOLLUSCA. [A.H.S.]

Aplite A fine-grained, sugary-textured rock, generally of granitic composition; also any body composed of such rock. This light-colored rock consists chiefly of quartz, microcline, or orthoclase perthite and sodic plagioclase, with small amounts of muscovite, biotite, or hornblende and traces of tourmaline, garnet, fluorite, and topaz. Much quartz and potash feldspar may be micrographically intergrown in cuneiform fashion. *See* GRANITE; IGNEOUS ROCKS.

Aplites may form dikes, veins, or stringers, generally not more than a few feet thick, with sharp or gradational walls. Some show banding parallel to their margins. Aplites usually occur within bodies of granite and more rarely in the country rock surrounding granite. They are commonly associated with pegmatites and may cut or be cut by pegmatites. *See* PEGMATITE. [C.A.C.]

Apoda The smallest order (sometimes called Gymnophiona) of the class Amphibia, known as the caecilians. These are wormlike, legless animals with indistinct or even hidden eyes. A series of annular grooves is usually present along the length of the body, heightening the resemblance to an earthworm. Most caecilians lead a burrowing existence, though members of one genus, *Typhlonectes*, are aquatic. Some species have the eyes hidden beneath the bones of the skull and probably are blind, but others at least are able to distinguish movement. A unique feature of the caecilians among modern Amphibia is the presence of scales buried in the skin of some species. There are more than 160 species of caecilians confined to tropical regions of both Eastern and Western hemispheres. Many species are less than 1 ft (0.3 m) in length, but three species of the genus *Caecilia* grow to over 3 ft (0.9 m). Some species lay eggs, while others bring forth their young alive. The embryos of the species that bear living young are nourished in the later part of their embryonic development by “uterine milk,” which is secreted by the mother. In some of the species that lay eggs there is an aquatic larval stage. Caecilians are carnivorous, but little is known of their food habits. Captive specimens have fed on earthworms, and in the natural state caecilians have eaten lizards. *See* AMPHIBIA; ANURA; URODELA. [R.G.Z.]

Apodiformes An order of birds consisting of two dissimilar groups, the swifts (Apodi) and the hummingbirds (Trochili). These birds have been placed together because of several anatomical specializations of the wings and feathers. They are excellent fliers but have small, weak feet. The two groups share a unique crossover structure of a neck muscle which cannot be related to their ways of life.

The order Apodiformes is divided into the suborder Apodi, containing the families Aegialornithidae (fossils), Hemiprocnidae (crested swifts; 4 species), and Apodidae (swifts; 83 species), and the suborder Trochili, containing the single family Trochilidae (hummingbirds; 341 species).

Swifts are fast-flying, aerial birds with dull, hard plumage; long, curved, pointed wings; and a short, broad, weak bill and a wide gape, adapted to catching insects in flight. They rest by clinging to cliffs, hollow trees, and other vertical surfaces. Their nest is composed of sticks glued to these surfaces, with the extreme condition being a nest built completely of their gluelike mucus. Swifts are found worldwide except at high latitudes. True swifts never perch crosswise on branches, but crested swifts, found in tropical Asia to New Guinea, are able to perch on branches.

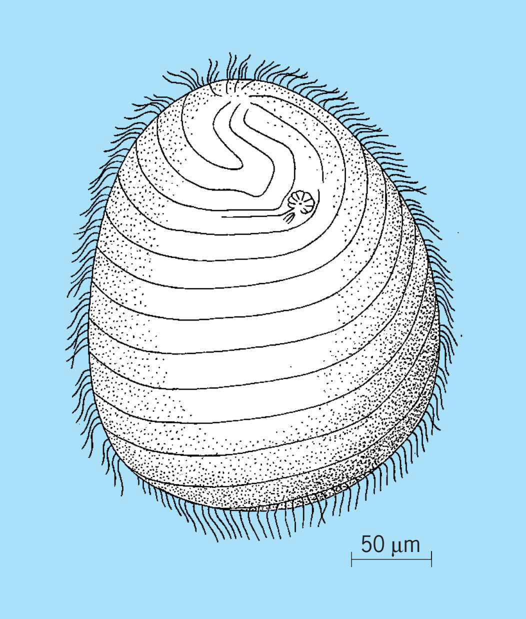
The hummingbirds are small, brightly colored, nectar-feeding birds, found only in the Western Hemisphere. The bill is slender and varies in length and shape, correlated closely with the shape of the flowers utilized by each species. They have a rapid wing beat and flight and are able to hover in front of a flower while feeding or even fly backward. Hummingbirds are attracted to the color red, and flowers specialized on hummingbirds for cross-pollination are red. They are among the smallest birds and include the bee hummingbird (*Mellisuga helenae*) of Cuba, the smallest of all birds. Hummingbirds can hibernate overnight to conserve energy. *See* AVES. [W.J.B.]

Apophyllite A hydrous calcium-potassium silicate containing fluorine. The composition is variable but approximates to

$KFCa_4(Si_2O_5)_4 \cdot 8H_2O$. It resembles the zeolites, with which it is sometimes classified, but differs from most zeolites in having no aluminum. It exfoliates (swells) when heated, losing water, and is named from this characteristic; the water can be reabsorbed. It is essentially white, with a vitreous luster, but may show shades of green, yellow, or red. The symmetry is tetragonal, and the crystal structure contains sheets of linked SiO_4 groups; this accounts for the perfect basal cleavage of the mineral. It occurs as a secondary mineral in cavities in basic igneous rocks, commonly in association with zeolites. The specific gravity is about 2.3–2.4, the hardness 4.5–5 on Mohs scale, the mean refractive index about 1.535, and the birefringence 0.002. *See* SILICATE MINERALS; ZEOLITE. [G.W.Br.]

Aporidea An order of tapeworms of uncertain composition and affinities, found in anseriform birds. The scolex may lack suckers and have only a simple rostellum with hooks, or it may have four large suckers and a complex glandular rostellum with small hooks. The small cylindroid body lacks segmentation, although some species have an internal serial arrangement of reproductive organs. Lack of reproductive ducts and openings to the outside prevents cross fertilization between strobilae. The life cycle is unknown. *See* CESTODA. [R.S.F.]

Apostomatida A group of ciliates comprising an order of the Holotrichia. The majority occur as commensals on marine crustaceans. Their life histories may become exceedingly complicated, and they appear to bear a direct relationship to the molting cycles of their hosts. Apostomes are particularly characterized by the presence of a unique rosette in the vicinity of an inconspicuous mouth opening and the possession of only a small number of ciliary rows wound around the body in a spiral fashion (see illustration). *See* CILIOPHORA; HOLOTRICHIA; PROTOZOA. [J.O.C.]



***Foettingeria*, an example of an apostomatid.**

Appendicitis An inflammation of the vermiform appendix. Acute appendicitis is the most common cause of emergency abdominal surgery, occurring in 5–6% of the population of the United States. It develops when the lumen of the appendix becomes obstructed, usually by fecal material, a foreign body, or hyperplasia of lymphatic tissue that is normally present in the wall of the appendix. The obstructed appendix becomes distended because of continued secretion of mucus by the lining cells. Typically, acute appendicitis progresses from obstruction of the lumen and distention of the appendix to spread of the inflammation beyond the appendix. Initially, there is localized peritonitis confined to the area of the appendix. If unrecognized and untreated, this may progress to an inflammatory mass or abscess, or to perforation of the appendix with resultant diffuse peritonitis, generalized toxic reaction, and even death. *See* APPENDIX (ANATOMY); PERITONITIS.

The usual progression of symptoms includes pain in the region around the navel; loss of appetite, nausea, and occasionally vomiting; localization of the pain to the right lower quadrant of the abdomen; and mild fever. Although the pain typically is localized in the right lower quadrant of the abdomen, there are variations because the appendix may be located in a number of other positions within the abdominal cavity. Fever is a fairly late sign, with mild elevation the rule; a high fever increases the suspicion of perforation or of some other inflammatory process. The diagnosis of appendicitis is generally made by history and physical examination, although laboratory and radiologic studies may be helpful in differentiating appendicitis from other conditions.

The treatment of acute appendicitis is prompt surgical removal of the inflamed appendix. Prior to surgery, the patient may be given intravenous fluids to correct dehydration and electrolyte imbalances. The use of antibiotics before surgery to decrease wound infection is often recommended. Antibiotics are continued after surgery in cases where the inflammation has extended beyond the appendix. Delay in removal of the appendix increases the chance of perforation. *See* ANTIBIOTIC; GASTROINTESTINAL TRACT DISORDERS. [A.L.I.]

Appendicularia A class of marine planktonic animals in the subphylum Tunicata. This class is characterized by the persistence of a tail, notochord, gill slits, and dorsal nerve cord throughout life and by a unique feeding structure, the "house." Appendicularians are free-swimming, solitary animals that are believed to have evolved through neoteny from the tadpole larvae of a bottom-dwelling, ascidianlike, ancestral tunicate. They resemble a bent tadpole with a flat, muscular tail and a trunk containing all major organs. Included are a complex digestive system, reproductive organs, two ciliated openings of the gill slits (the spiracles) leading to a mucus-lined pharynx, a mucus-producing gland called the endostyle, and a simple circulatory system with a single, muscular heart. *See* NEOTENY.

Appendicularians feed primarily on small particles from 0.1 to 30 micrometers in diameter. Larger individuals may filter up to several thousand milliliters of seawater per day. As one of the few metazoan groups capable of capturing bacteria and tiny phytoplankton, appendicularians are important marine grazers which may significantly reduce phytoplankton populations in the ocean. About 13 genera and 70 species of appendicularians are known. They are found in all oceans of the world and are a common component of plankton samples, particularly in coastal waters. The most abundant genera are *Oikopleura* and *Fritillaria*. *See* CHORDATA; TUNICATA. [A.L.Al.]

Appendix (anatomy) A narrow, elongated tube closed at one end, extending from the cecum, a blind pocket off the first part of the large intestine. It is found in only a few mammals. The size and detailed structure of the appendix vary markedly, depending on the species and the age of the individual. Most reptiles, birds, and mammals have a single or a paired cecum at the anterior end of the large intestine, but it is quite rare that this cecum has a thinner projection or true appendix.

In humans the appendix is about 3 in. (7.5 cm) long, but it varies greatly in both size and its specific location in the lower right quarter of the abdomen. The exact function of the human appendix is unknown, and it is considered to be a remnant of a portion of the digestive tract which was once more functional and is now in the process of evolutionary regression. The appendixes presumably function in digestion in forms with larger ones. [T.S.P.]

Apple Apples (genus *Malus*) belong to the family Rosaceae. There are about 30 *Malus* species in the North Temperate Zone. The fruits of most species are edible. More apples are consumed than any other temperate-zone tree fruit. Apples are eaten fresh, processed into jellies or preserves, cooked in pies and pastries, or made into sauces. Apple juice is drunk fresh, or at various stages of fermentation as cider, applejack, or brandy. Apple cider vinegar is popular for use in salads and in many processed foods.

The "European" cultivated apple is now thought to have been derived principally from M. *pumila*, a Eurasian species which occurs naturally from the Balkans eastward to the Tien Shan of central Asia. In the wild, some forms of *M. pumila* approach present cultivars in size and quality. Another Asian species, *M. sylvestris*, whose range extends into western Europe, grows side by side with *M. pumila* and hybridizes with it in the Caucasus Mountains. Thus *M. sylvestris* probably also had some genetic input into the cultivated apple.

Wild apples, mainly the edible *M. baccata*, grow so thickly east of Lake Baikal in Siberia that the region is called Yablonovy Khrebet ("Apple Mountains").

The success of the Delicious and Golden Delicious cultivars may be laid to the demand for better-quality fresh fruit. Both originated on farms as chance seedlings near the end of the 19th century. In spite of the dominance of such "chance" cultivars, cultivars such as Cortland and Idared that were produced by scientific breeding have begun to achieve prominence. Most of the apple breeding programs under way earlier this century have ceased, but the few remaining ones are now introducing some exciting new cultivars. Many of the new cultivars are of excellent quality and in addition are resistant to the most damaging diseases, such as scab, rust, and fire blight. These cultivars promise to revolutionize apple growing in the future.

The apple is probably the most widely distributed fruit crop in the world, although it ranks behind grapes, bananas, and oranges in total production. There are substantial apple-growing areas on all temperate-zone continents; the United States, Italy, France, and Germany are leading producers.

Apples can be grown as far north as 60° latitude in the maritime climate of northwestern Europe. In North America, apple culture does not extend much above 50° north latitude. Away from the coasts, the buffering effects of the Great Lakes on temperature extremes facilitate heavy apple production in New York, Michigan, and Ontario. Hardier cultivars are continuing to be developed for use in colder regions. Apples can be grown in the tropics at higher elevations where sufficient chilling to break dormancy is available. Cultivars with lower chilling needs are being developed.

The principal apple-growing regions in North America are, in order of importance: the Northwest (Washington, Oregon, Idaho, and British Columbia), the Northeast (New York, New Jersey, New England, Ontario, Quebec, and Nova Scotia), the Cumberland-Shenandoah area (Pennsylvania, Maryland, Virginia, West Virginia, and North Carolina), Michigan, California, the Ohio Basin (Ohio, Indiana, and Illinois), and Colorado.

Apples may be sold fresh immediately, or after a period of storage, or they may be processed into less perishable products such as canned, frozen, or dried slices or chunks for baking, applesauce, apple juice or cider, and vinegar.

Fresh apples may be sold locally at roadside stands or at farmers' markets, or sold in wholesale quantities to supermarkets. Often, large quantities of fruit are traded by cooperatives or independent buyers for sale in distant markets. Thousands of tons of apples are shipped annually from the state of Washington to the Midwest and the East Coast. Apples can be stored for long periods at low temperatures under controlled atmosphere (CA storage), so that fresh fruits are now available year round.

There is a large international trade in apples, particularly in Europe between the large producing countries of France and Italy and the net-importing countries of Germany, Britain, and Scandinavia, and from the United States to Canada. Apples grown in the Southern Hemisphere (Australia, New Zealand, South Africa, and Argentina) are shipped in large quantities to western Europe during the northern winter. *See* FRUIT, TREE; ROSALES. [H.S.A.; S.V.B.]

Apraxia An impairment in the performance of voluntary actions despite intact motor power and coordination, sensation and perception, and comprehension. The apraxic person knows the act to be carried out, and has the requisite sensory-motor capacities, yet performance is defective. The abnormality is highlighted when the act must be performed on demand and out of context. Defects in performance vary from total inability to initiate the action, to incorrect serial ordering of elements, to partial approximations. A common apraxic behavior is the use of a body part as an object. Pantomiming the act of brushing the teeth, for example, a person may run the index finger across the teeth as though it were a toothbrush, while in normal performance, the hand assumes the posture of holding and moving the brush.

Apraxia is usually observed in both upper extremities. When it occurs unilaterally, it is usually the left arm and hand that are affected. This has been explained by assuming that the left cerebral hemisphere is specialized in the organization of voluntary movements, just as it is in language. The left hand is under the immediate control of the right hemisphere, but for skilled voluntary actions, the right hemisphere is dependent on information transmitted from the dominant left hemisphere over the corpus callosum. Callosal lesions produce apraxia of the left hand, because the right hemisphere is incapable of organizing the plan of movement independently. With an appropriately placed left-hemisphere lesion, a bilateral apraxia will result. When the left-hemisphere lesion also destroys the primary motor zone, the right arm is paralyzed and the apraxia is masked. The observable apraxia on the left side is referred to as sympathetic apraxia. This is seen in many individuals with right hemiplegia (unilateral paralysis of the body) and Broca's aphasia. Another apraxia often coupled with Broca's aphasia is nonspeech oral apraxia (or buccofacial apraxia). Individuals with this disorder can be observed to struggle to perform such simple acts as protruding the tongue or licking the lips on command or imitation, even though these movements are executed easily as part of the act of eating. *See* APHASIA; HEMISPHERIC LATERALITY.

There are several disorders that are controversial with regard to their interpretation as forms of apraxia. The nonfluent speech pattern of Broca's aphasia, often riddled with speech-sound errors, is considered as apraxia of speech by some authorities, while others view it as an integral part of the linguistic deficit of the aphasia. In dressing apraxia and in some types of constructional apraxia, the defect appears to be perceptually based. Limb-kinetic apraxia is widely interpreted today as a mild spastic paresis, while ideational apraxia, commonly associated with dementia, is likely due to conceptual confusion rather than to a disturbance of motor organization. *See* AGNOSIA. [G.J.C.]

Apricot The stone fruit *Prunus armeniaca*, thought to be native to China and then distributed throughout Asia, Europe, and eventually to North and South America and Oceania. The species is genetically diverse and can grow in a wide range of climates depending upon the cultivar. Such diversity occurs in North America, where apricots are produced as far north as British Columbia, Canada, and as far south as Mexico. Most commercial production in the world is limited to areas where temperatures do not fall below −10 to −20°F (−23 to −29°C)

Castlebrite apricot branch with a fruit cluster.

for extended periods; however, certain cultivars can tolerate severer conditions. Many apricot cultivars can tolerate high summer temperatures in excess of 105°F (40°C). Some cultivars develop an internal browning of the flesh if high temperatures persist with fruit on trees. Apricots tend to bloom earlier than other stone fruit and are sensitive to frost. Frostfree areas are generally preferred.

Fruits for commerce are generally yellow to orange in skin color and flesh (Fig. 1). Apricot size ranges from small (about 25–30 g per fruit) to large (100–130 g). The fruit can be consumed fresh, dried, frozen, or processed as canned product, as juice, or as baby food (pureed). Flowers from most commercial cultivars are self-fertile, but examples of self-infertility are found in commercial cultivars. In those self-incompatible cultivars, cross-pollination with another cultivar is required. [S.M.So.]

Apsides In astronomy, the two points in an elliptical orbit that are closest to, and farthest from, the primary body about with the secondary revolves. In the orbit of a planet or comet about the Sun, the apsides are, respectively, perihelion and aphelion. In the orbit of the Moon, the apsides are called perigee and apogee, while in the orbit of a satellite of Jupiter, these points are referred to as perijove and apojove. The major axis of an elliptic orbit is referred to3 as the line of apsides. *See* Orbital motion. [R.L.Du.]

Apterygota A subclass of Insecta including the wingless orders Archaeognatha (bristletails), Thysanura (silverfish), and the fossil Monura. The general body form is elongate and usually tapered toward the tail, which is provided with a segmented median caudal filament and (in living forms) paired posterolateral cerci, serving a sensory function. Organs of the head are similar to those of winged insects with mandibles, and compound eyes are present in some, but are reduced or absent in many thysanurans. Archaeognathans and most thysanurans are free living and feed on lichens, algae, or vegetable detritus; some thysanurans dwell in ant or termite nests, and a few can live in very hot, dry habitats, such as deserts or domestic heating vents. The sexes are generally similar, but the female has a recognizable ovipositor and lays eggs. Fertilization occurs indirectly, often after a courtship in which the female is guided by the male over sperm placed on a thread or packaged in a spermatophore and picked up by the female. *See* Collembola; Diplura; Insecta; Pterygota; Thysanura. [W.L.Bro.]

Aqua regia A mixture of one part by volume of concentrated nitric acid and three parts of concentrated hydrochloric acid. Aqua regia was so named by the alchemists because of its ability to dissolve platinum and gold. Either acid alone will not dissolve these noble metals. [E.E.W.]

Aquaculture The cultivation of fresh-water and marine species (the latter type is often referred to as mariculture). Aquacultural ventures occur worldwide. China grows macroalgae (seaweeds) and carp. Japan cultures a wide range of marine organisms, including yellowtail, sea bream, salmonids, tuna, penaeid shrimp, oysters, scallops, abalone, and algae. Russia concentrates on the culture of fish such as sturgeon, salmon, and carp. North America grows catfish, trout, salmon, oysters, and penaeid shrimp. Europe cultures flatfish, trout, oysters, mussels, and eels. Presently, plant aquaculture is almost exclusively restricted to Japan, China, and Korea, where the national diets include substantial amounts of macroalgae.

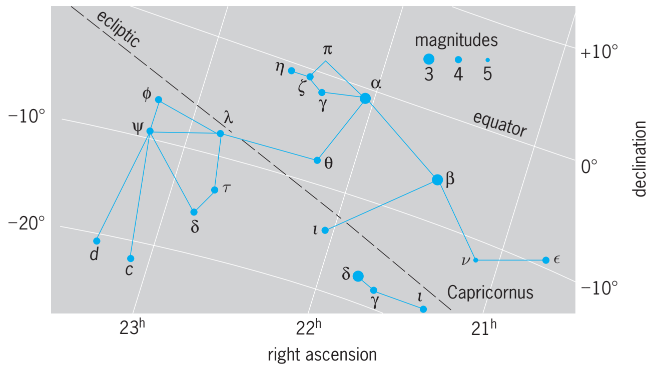
The worldwide practice of aquaculture runs the gamut from low-technology extensive methods to highly intensive systems. At one extreme, extensive aquaculture can be little more than contained stock replenishment, using natural bodies of water such as coastal embayments, where few if any alterations of the environment are made. Such culture usually requires a low degree of management and low investment and operating costs; it generally results in low yields per unit area. At the other extreme, intensive aquaculture, animals are grown in systems such as tanks and raceways, where the support parameters are carefully controlled and dependence on the natural environment is minimal. Such systems require a high degree of management and usually involve substantial investment and operating costs, resulting in high yields per unit area.

A unique combination of highly intensive and extensive aquaculture occurs in ocean ranching, as commonly employed with anadromous fish (which return from the ocean to rivers at the time of spawning). The two most notable examples are the ranching of salmon and sturgeon. In both instances, highly sophisticated hatchery systems are used to rear young fish, which are then released to forage and grow in their natural environment. The animals are harvested upon return to their native rivers.

Intensive aquaculture brings with it high energy costs, necessitating the design of energy-efficient systems. As this trend continues, aquaculture will shift more to a year-round, mass-production industry using the least amount of land and water possible. With this change to high technology and dense culturing, considerable knowledge and manipulation of the life cycles and requirements of each species are necessary. Specifically, industrialized aquaculture has mandated the development of reproductive control, hatchery technology, feeds technology, disease control, and systems engineering.

Regardless of the type of system used, aquacultural products are marketed as are fisheries products (which are caught in the ocean), except for some advantages. For one, fisheries products often must be transported on boats and may experience spoilage; whereas cultured products, which are land-based, can be delivered fresh to the various nearby markets. Also, intensively cultured products through genetic selection can result in a more desirable food than those caught in the wild, with uniform size and improved taste resulting from controlled feeding and rearing in pollution-free water. *See* Agriculture; Marine fisheries. [W.H.C.; A.B.McG.]

Aquarius The Water Bearer, in astronomy, a large zodiacal constellation visible in both summer and autumn. Aquarius is the eleventh sign of the zodiac. To ancients, the constellation resembled a man pouring a stream of water from a jar. Four



Line pattern of the constellation Aquarius. The grid lines represent the coordinates of the sky. The apparent brightness, or magnitude, of the stars is shown by the sizes of the dots, which are graded by appropriate numbers as indicated.

stars, η, ζ, π, and γ, arranged like a Y, form the head of the Water Bearer (see illustration). The stream of water flows into the Fish's Mouth (Fomalhaut) in the constellation Pisces Austrinus (Southern Fish). Fomalhaut, bright and solitary in this part of the sky, is one of the relatively important navigational stars. From earliest time this constellation has been associated with water, probably because the Sun is seen in Aquarius during the rainy season of February. *See* CONSTELLATION. [C.-S.Y.]

Aquifer A subsurface zone that yields economically important amounts of water to wells. The term is synonymous with water-bearing formation. An aquifer may be porous rock, unconsolidated gravel, fractured rock, or cavernous limestone.

Aquifers are important reservoirs storing large amounts of water relatively free from evaporation loss or pollution. If the annual withdrawal from an aquifer regularly exceeds the replenishment from rainfall or seepage from streams, the water stored in the aquifer will be depleted. This mining of groundwater results in increased pumping costs and sometimes pollution from sea water or adjacent saline aquifers. Lowering the piezometric pressure in an unconsolidated artesian aquifer by overpumping may cause the aquifer and confining layers of silt or clay to be compressed under the weight of the overlying material. The resulting subsidence of the ground surface may cause structural damage to buildings, altered drainage paths, increased flooding, damage to wells, and other problems. *See* ARTESIAN SYSTEMS. [R.K.Li.]

Arachnida The largest class of the subphylum Chelicerata in the phylum Arthropoda. Most familiar of the included orders are the spiders, scorpions, harvestmen, and mites and ticks. Arachnids are mainly terrestrial and may be the oldest of the Recent terrestrial animals; scorpions are known from the Silurian (over 4×10^8 years ago).

The arachnid body is divided into a cephalothorax (prosoma) and an abdomen (opisthosoma). The cephalothorax has six pairs of appendages: the chelicerae (jaws), a pair of pedipalps, and four pairs of walking legs. There are no antennae. The abdomen may be either segmented or unsegmented and usually lacks appendages, or the appendages may be modified into specialized structures, for example, the spinnerets of spiders.

As in other arthropods there is an exoskeleton, the outside layer of which (the epicuticle) consists mainly of lipids; it is water-repellent and prevents water loss. Respiration is by means of book lungs or tracheae or both. Arachnids have an open circulatory system. The heart lies in the anterior dorsal part of the abdomen. Blood enters the heart from the pericardial chamber through small openings (ostia). The blood is pumped into the prosoma through an anterior artery, and posteriorly through a posterior artery. It flows through vessels and chambers and around the book lungs and then into the pericardial cavity and back to the heart.

Digestion takes place outside the body. The captured prey is held by the chelicerae while digestive enzymes are secreted over it; then the broth is sucked up. (The arachnids are predominantly predacious. The main exceptions are among the mites, where herbivores and parasites of plants and animals are common.) Excretory organs may be either thin-walled coxal glands that open to the outside on the basal segment (coxa) of each leg, or Malpighian tubules which enter the midgut.

The nervous system is concentrated in the cephalothorax except in the primitive scorpions, which have ganglia in each segment. The brain encircles the esophagus; the protocerebrum lies above the esophagus, the remainder of the brain below. Sense organs include simple eyes (ocelli), hollow hairs located at the tips of palps and legs that may be olfactory, fine hairs (trichobothria) on the appendages that are sensitive to air currents and vibrations, and membrane-covered pits in the exoskeleton called slit sense organs, that respond to tension in the exoskeleton and to some vibrations.

The genital opening and gonads are on the underside at the anterior of the abdomen. Males of many species perform an elaborate courtship. Females produce yolk-rich eggs and may provide some care to their young.

The Arachnida comprise more than 10 Recent orders: Scorpiones, Palpigradi, Schizomida, Uropygi, Amblypygi, Araneae, Solifugae (or Solpugida), Pseudoscorpionida, Opiliones, Ricinulei, and Acari. *See* ACARI; AMBLYPYGI; ARANEAE; ARTHROPODA; CHELICERATA; OPILIONES; PALPIGRADI; PSEUDOSCORPIONIDA; RICINULEI; SCHIZOMIDA; SCORPIONES; SOLIFUGAE; UROPYGI. [H.W.L.]

Araeolaimida An order of nematodes in which the amphids are simple spirals that appear as elongate loops, shepherd's crooks, question marks, or circular forms. The cephalic sensilla are often separated into three circlets: the first two are papilliform or the second coniform, and the third is usually setiform; rarely are the second and third whorls combined. Body annulation is simple. The stoma is anteriorly funnel shaped and posteriorly tubular; rarely is it armed. Usually the esophagus ends in a bulb that may be valved. In all but a few taxa the females have paired gonads. Male preanal supplements are generally tubular, rarely papilloid.

There are three araeolaimid superfamilies: Araeolaimoidea, Axonolaimoidea, and Plectoidea. The distinguishing characteristics of the Araeolaimoidea are in the amphids (sensory receptors), stoma, and esophagus. The amphids are in the form of simple spirals, elongate loops, or hooks. Although araeolaimoids are chiefly found in the marine environment, many species have been collected from fresh water and soil.

The amphids in the Axonolaimoidea are generally prominent features of the anterior end, visible as a single-turn loop of a wide sausage shape. Feeding habits are unknown. All known species occur in marine or brackish-water environments.

Plectoidea comprise small free-living nematodes, found mainly in terrestrial habitats, frequently in moss; some are freshwater, and a few are marine. Those that inhabit moss cushions can withstand lengthy desiccation. For most, the feeding habit is unconfirmed; where it is known, they are microbivorous. Many are easily raised on agar cultures that support bacteria. *See* NEMATA. [A.R.M.]

Araeoscelida An order of Paleozoic diapsid reptiles including the families Petrolacosauridae and Araeoscelidae. Members of these families resemble primitive modern lizards, such as the green iguana, in size and most body proportions, but are distinguished by their elongate necks and distal limb elements. *Petrolacosaurus*, from the Upper Pennsylvanian of Kansas, is the earliest known diapsid. The skull shows well-developed upper and lateral temporal openings and a subor-bital fenestra that are characteristic of the diapsids.

The following derived features distinguish members of the Araeoscelida from other early diapsids: six to nine elongate neck vertebrae; a radius as long as the humerus and a tibia as long as the femur; expanded neural arches; posterior cervical and anterior dorsal neural spines with mamillary processes; a coracoid process; and enlarged lateral and distal pubic tubercles. In contrast to later diapsids, members of the Araeoscelida show no evidence of an impedance-matching middle ear. The stapes is massive, the quadrate is not emarginated for support of a tympanum, and there is no retroarticular process. *See* REPTILIA. [R.L.C.]

Aragonite One of three naturally occurring mineral forms of calcium carbonate ($CaCO_3$). The other forms (or polymorphs) are the abundant mineral calcite and the relatively rare mineral vaterite. Still other forms of calcium carbonate are known, but only as products of laboratory experiments. The name aragonite comes from Aragon, a province in Spain where especially fine specimens occur. *See* CALCITE.

Aragonite has an orthorhombic crystal structure in which layers of calcium (Ca) atoms alternate with layers of offset carbonate (CO_3) groups. A common crystallographic feature of aragonite is twinning, in which regions of crystal are misoriented as though they were mirror images of each other. This can give rise to a pseudohexagonal symmetry which is readily identified in large crystals (see illustration). Aragonite crystals are usually colorless or white if seen individually; however, aggregates of small crystals may exhibit different colors. Most aragonites are nearly pure calcium carbonate; however, small amounts of strontium (Sr) and less commonly barium (Ba) and lead (Pb) may be present as impurities.

At the low temperatures and pressures found near the Earth's surface, aragonite is metastable and should invert spontaneously to calcite, which is stable at these conditions. This, in part, explains why calcite is far more abundant than aragonite. However, at low temperatures the transformation of aragonite to calcite effectively occurs only in the presence of water, and aragonite may persist for long periods of geologic time if isolated from water. Increased temperature also promotes the transformation to calcite. Despite being metastable, aragonite rather than calcite is sometimes the favored precipitate from certain solutions, such as seawater, in which magnesium (Mg) ions inhibit precipitation of calcite.

Aragonite occurs most abundantly as the hard skeletal material of certain fresh-water and marine invertebrate organisms, including pelecypods, gastropods, and some corals. The accumulated debris from these skeletal remains can be thick and extensive, usually at the shallow sea floor, and with time may transform into limestone. Most limestones, however, contain calcite and little or no aragonite. The transformation of the aragonite to calcite is an important step in forming limestone and proceeds by the dissolution of aragonite followed by the precipitation of calcite in the presence of water. This process may take more than 100,000 years. *See* LIMESTONE.

Aragonite. Pseudohexagonally twinned specimen from Girgenti, Sicily. (*American Museum of Natural History specimens*)

Other occurrences of aragonite include cave deposits (often in unusual shapes) and weathering products of calcium-rich rocks. [R.J.Re.]

Arales An order of flowering plants, division Magnoliophyta (Angiospermae), in the subclass Arecidae of the class Liliopsida (monocotyledons). It consists of two families, the Araceae, with about 1800 species, and the Lemnaceae, with only about 30.

The Araceae are herbs (seldom woody climbers) with ordinary roots, stems, and leaves (often broad and net-veined) and with the vessels confined to the roots. They have numerous tiny flowers grouped together in a small to very large spadix. They are commonest in forested tropical and subtropical regions. *Anthurium* (elephant ear), *Arisaema* (jack-in-the-pul-pit), *Dieffenbachia* (dumb cane), *Monstera*, and *Philodendron* are some well-known members of the Araceae.

The Lemnaceae, or duckweeds, are small, free-floating, thalloid aquatics that are generally conceded to be derived from the Araceae. Their flowers, seldom seen, are much reduced and form a miniature spadix. *Pistia* (water lettuce), a free-floating aquatic (but not thalloid) aroid is seen as pointing the way toward *Spirodela*, the least reduced genus of the Lemnaceae. *See* ARECIDAE; LILIOPSIDA; MAGNOLIOPHYTA; PLANT KINGDOM. [A.Cr.]

Araneae A natural order of the class Arachnida, also called Araneida, commonly known as the spiders. These animals are widespread over most of the land areas of the world and are well adapted to many different habitats. They are known to be one of the oldest of all groups of arthropods, and their remains are known from the Devonian and Carboniferous geological deposits. Through successive geological periods spiders have become adapted to use insects as their chief source of food. On the other hand, certain insects consume the eggs of spiders, others parasitize the eggs, and still others capture adults and place them in their nests for food for their young.

Spiders have only two subdivisions of the body, the cephalothorax and the abdomen, joined by a slender pedicel. All parts of the body are covered by chitinous plates which often extend into curious outgrowths, such as spines, horns, and tubercles. Only simple paired eyes, ocelli, are present, with the number varying from eight, the most common number, to none in a few species inhabiting lightless habitats.

The first of six pairs of appendages are termed the chelicerae or jaws. The second pair of appendages is the six-segmented pedipalps, simple organs of touch and manipulation in the female, but curiously and often complexly modified in males for use in copulation. The four pairs of thoracic legs consist of seven segments each. Just in front of the genital opening in most females there is a more or less specific and often elaborately formed plate, the epigynum. This organ is of importance in the reproductive activities of the female. In most of the true spiders internal breathing tubules occur with ventral openings posterior to the genital apertures. Distinctive paired ventral spinnerets occur near the posterior end of the abdomen. In certain families a sieve-like plate lies immediately anterior to the foremost spinnerets. From this plate, the cribellum, a special kind of banded silk is extruded and used in conjunction with a comb on the fourth legs. The spinnerets and cribellum are directly associated with several types of abdominal glands and responsible for the production of the different types of silk characteristic of these animals.

Silk produced by spiders is a scleroprotein which is fine, light, elastic, and strong. It is used industrially only in the making of cross hairs in optical instruments. This use is diminishing as metal filaments and etched glass come into more common usage. In addition to the attractive orb webs, these animals also construct sheet webs, funnel webs, tube webs, and reticular webs. The spider's reliance upon silk extends its use to the making of egg cocoons, sperm webs by males, molting sheets, gossamer threads for ballooning, attachment disks, lining for burrows, hinges for trap doors, binding for captives, retreats, and drag lines.

No general agreement exists at present among araneologists concerning the classification and exact arrangement of the families of spiders. A. Petrunkevitch (1939) recognized 5 suborders: Liphistiomorphae containing only 2 families with a primitively segmented abdomen, and restricted to regions in the Eastern Hemisphere; Mygalomorphae with 8 families; Hypochilomorphae with a single relict family native to the southern Appalachian region; Dipneumonomorphae with 48 families; and finally the Apneumonomorphae with 3 families, which lack the book lungs and represent the most highly modified members of the order. There is now a tendency to increase the number of recognized families. *See* ARACHNIDA. [A.M.C.]

Arboretum An area set aside for the cultivation of trees and shrubs for educational and scientific purposes. An arboretum differs from a botanical garden in emphasizing woody plants, whereas a botanical garden includes investigation of the growth and development of herbaceous plants as well as trees and shrubs. The largest of the arboretums in the United States is the Arnold Arboretum of Harvard University, founded in 1872. *See* BOTANICAL GARDENS. [E.L.C.]

Arboriculture A branch of horticulture concerned with the selection, planting, and care of woody perennial plants. Knowing the potential form and size of plants is essential to effective landscape planning as well as to the care needed for plants. Arborists are concerned primarily with trees since they become large, are long-lived, and dominate landscapes both visually and functionally.

Plants can provide privacy, define space, and progressively reveal vistas; they can be used to reduce glare, direct traffic, reduce soil erosion, filter air, and attenuate noise; and they can be positioned so as to modify the intensity and direction of wind. They also influence the microclimate by evaporative cooling and interception of the Sun's rays, as well as by reflection and reradiation. Certain plants, however, can cause human irritations with their pollen, leaf pubescence, toxic sap, and strong fragrances from flowers and fruit. Additionally, trees can be dangerous and costly: branches can fall, and roots can clog sewers and break paving. *See* LANDSCAPE ARCHITECTURE. [R.W.Ha.]

Arborvitae A plant, sometimes called the tree of life, belonging to the genus *Thuja* of the order Pinales (Coniferales). It is characterized by flattened branchlets with two types of scalelike leaves. At the edges of the branchlets the leaves may be keeled or rounded; on the upper and lower surfaces they are flat, and often have resin glands. The cones, about 1/2 in. (1.25 cm) long, have the scales attached to a central axis. *See* PINALES; RESIN; SECRETORY STRUCTURES (PLANT).

The tree is valued both for its wood and as an ornamental. *Thuja occidentalis*, of the eastern United States, is known as the northern white cedar. It occurs in moist or swampy soil from Nova Scotia to Manitoba and in adjacent areas of the United States, and extends south in the Appalachians to North Carolina and Tennessee. Other important species include the giant arborvitae (*T. plicata*); oriental arborvitae (*T. orientalis*); and Japanese arborvitae (*T. standishii*). Among the horticultural forms are the dwarf pendulous and juvenile varieties. *See* FOREST AND FORESTRY; TREE. [A.H.G./K.P.D.]

Arboviral encephalitides A number of diseases, such as St. Louis, Japanese B, and equine encephalitis, which are caused by arthropod-borne viruses (abbreviated "arboviruses"). In their most severe human forms, the diseases invade the central nervous system and produce brain damage, with mental confusion, convulsions, and coma; death or serious aftereffects are frequent in severe cases. Inapparent infections are common.

The arbovirus "group" comprises more than 250 different viruses, many of them differing fundamentally from each other except in their ecological property of being transmitted through the bite of an arthropod. A large number of arboviruses of antigenic groups A and B are placed in the family Togaviridae, in two genera, alphavirus (serological group A) and flavivirus (serological group B). Still other arboviruses, related structurally and antigenically to one another but unrelated to Togaviridae, are included in the family Bunyaviridae, consisting chiefly of the numerous members of the Bunyamwera supergroup—a large assemblage of arboviruses in several antigenic groups which are cross-linked by subtle interrelationships between individual members. The nucleic acid genomes of all arboviruses studied thus far have been found to be RNA.

Members of serological group A include western equine encephalitis, eastern equine encephalitis, and Venezuelan equine encephalitis viruses; and Mayaro, Semliki Forest, Chikungunya, and Sindbis viruses, which have nonencephalitic syndromes. Group A viruses are chiefly mosquito-borne. Serological group B viruses include Japanese B, St. Louis, and Murray Valley encephalitis viruses (mosquito-borne), and the viruses of the Russian tick-borne complex, some of which produce encephalitis (Russian spring-summer), whereas others cause hemorrhagic fevers (Omsk, Kyasanur Forest) or other syndromes, such as louping ill. Also in group B are the nonneurotropic viruses of West Nile fever, yellow fever, dengue, and other diseases. *See* LOUPING ILL; YELLOW FEVER.

There is no proved specific treatment. In animals, hyperimmune serum given early may prevent death. Killed virus vaccines have been used in animals and in persons occupationally subjected to high risk. A live, attenuated vaccine against Japanese B encephalitis virus, developed in Japan, has been used experimentally with some success, not only in pigs to reduce amplification of the virus in this important vertebrate reservoir but also in limited trials in humans. In general, however, control of these diseases continues to be chiefly dependent upon elimination of the arthropod vector. *See* VIRUS. [J.L.Me.]

Arc discharge A type of electrical conduction in gases characterized by high current density and low potential drop. The electric arc was discovered by Humphry Davy in 1808, when he connected a piece of carbon to each side of an electric battery, touched the two pieces of carbon together, then drew them slightly apart. The result is a dazzling steam of ionized air, or plasma, at a temperature of 6000°C (10,800°F), the surface temperature of the Sun. A typical arc runs at a voltage drop of 100 V with a current drain of 10 A. The arc has negative resistance—the voltage drop decreases as the current increase—so a stabilizing resistor or inductor in series is required to maintain it. The high-temperature gas rises like a hot-air balloon while it remains anchored to the current-feeding electrodes at its ends. It thereby acquires an upward-curving shape, which accounts for its being called an arc.

There are many applications of such an intensely hot object. The brilliant arc and the incandescent carbon adjacent to it form the standard light source for movie theater projectors. The electronic flashgun in a camera uses an intense pulsed arc in xenon gas, simulating sunlight. Since no solid-state material can withstand this temperature for long, the arc is used industrially for welding steel and other metals. Alternatively, it can be used for cutting metal very rapidly. Electric arcs form automatically when the contacts in electrical switches in power networks are opened, and much effort goes into controlling and extinguishing them.

Lightning is an example of a naturally occurring electric arc. *See* Arc heating; Arc lamp; Arc welding; Circuit breaker; Lightning; Optical projection systems; Stroboscopic photography; Welding and cutting of materials.

The arc has been pushed to extremely high temperatures in the search for thermonuclear fusion, the record temperature being $4 \times 10^5\,^\circ$C in a long pulse in helium. The arc temperature appears to be limited by the energy lost in intense radiation from the interface region between the intensely hot, fully ionized plasma core and the surrounding cooler, un-ionized gas. [I.A.; K.E.Lo.]

Arc heating The heating of matter by an electric arc. The matter may be solid, liquid, or gaseous. When the heating is direct, the material to be heated is one electrode; for indirect heating, the heat is transferred from the arc by conduction, convection, or radiation.

At atmospheric pressure, the arc behaves much like a resistor operating at temperatures of the order of thousands of kelvins. The energy source is extremely concentrated and can reach many millions of watts per cubic meter. Almost all materials can be melted quickly under these conditions, and chemical reactions can be carried out under oxidizing, neutral, or reducing conditions.

In a direct-arc furnace, the arc strikes directly between the graphite electrodes and the charge being melted. These furnaces are used in steelmaking, foundries, ferroalloy production, and some nonferrous metallurgical applications. Although an extremely large number of furnace types are available, they are all essentially the same. They consist of a containment vessel with a refractory lining, a removable roof for charging, electrodes to supply the energy for melting and reaction, openings and a mechanism for pouring the product, a power supply, and controls. The required accessory components include water-cooling circuits, gas cleaning and extraction equipment, cranes for charging the furnace, and ladles to remove the product. Because the electrodes are consumed by volatilization and reaction, a mechanism must be provided to feed them continuously through the electrode holders.

In submerged-arc furnaces, the arcs are below the solid feed and sometimes below the molten product. Submerged-arc furnaces differ from those used in steelmaking in that raw materials are fed continuously around the electrodes and the product and slag are tapped off intermittently. The furnace vessel is usually stationary. Submerged-arc furnaces are often used for carbothermic reductions (for example, to make ferroalloys), and the gases formed by the reduction reaction percolate up through the charge, preheating and sometimes prereducing it. Because of this, the energy efficiency of this type of furnace is high. The passage of the exhaust gas through the burden also filters it and thus reduces air-pollution control costs.

Although carbon arcs are plasmas, common usage of the term plasma torch suggests the injection of gas into or around the arc. This gas may be inert, neutral, oxidizing, or reducing, depending on the application and the electrodes used. Plasma torches are available at powers ranging from a few kilowatts to over 10 MW; usually they use direct-current electricity and water-cooled metallic electrodes.

Direct-current carbon arc furnaces operate on the basis that a direct-current arc is more stable than its alternating-current counterpart, and can, therefore, be run at lower current and higher voltage by increasing the arc length. This reduces both the electrode diameter and the electrode consumption compared to alternating-current operation at similar powers. Tests have also shown that injecting gas through a hole drilled through the center of the electrode further increases stability and reduces wear. Powdered ore and reductants may be injected with this gas, reducing the need for agglomerating the arc furnace feed.

In most cases, direct-current carbon arc furnaces have one carbon electrode, with the product forming the second electrode. The current is usually removed from the furnace through a bottom constructed of electrically conducting material. Several direct-current plasma furnaces with powers ranging from 1 to 45 MW are in operation. [R.J.Mun.]

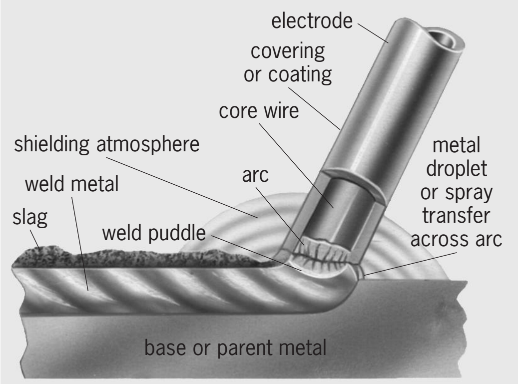
Arc lamp A type of electric-discharge lamp in which an electric current flows between electrodes through a gas or vapor. In most arc lamps the light results from the luminescence of the gas; however, in the carbon arc lamp the light is produced by the incandescence of one or both electrodes. The color of the arc depends upon the electrode material and the surrounding atmosphere. Most lamps have a negative resistance characteristic so that the resistance decreases after the arc has been struck. Therefore some form of current-limiting device is required in the electric circuit. For other electric-discharge lamps *see* Vapor lamp.

The carbon arc lamp was the first practical commercial electric lighting device, but the use of arc lamps at present is limited. In many of its previous functions, the carbon arc lamp has been superseded by the high-intensity mercury vapor lamp. Arc lamps are now used to obtain high brightness from a concentrated light source, where large amounts of radiant energy are needed, and where spectral distribution is an advantage. Typical uses of arc lamps are in projectors, searchlights, blueprinting, photography, therapeutics, and microscope lighting, and for special lighting in research. [J.O.K.]

Arc welding A welding process utilizing the concentrated heat of an electric arc to join metal by fusion of the parent metal and the addition of metal to the joint usually provided by a consumable electrode (see illustration). Electric current for the welding arc may be either direct or alternating, depending upon the material to be welded and the characteristics of the electrode used. The current source may be a rotating generator, rectifier, or transformer and must have transient and static volt-ampere characteristics designed for arc stability and weld performance.

There are three basic welding methods: manual, semiautomatic, and automatic. Manual welding is the oldest method, and though its proportion of the total welding market diminishes yearly, it is still the most common. Here an operator takes an electrode, clamped in a hand-held electrode holder, and manually guides the electrode along the joint as the weld is made. Usually the electrode is consumable; as the tip is consumed, the operator manually adjusts the position of the electrode to maintain a constant arc length.

Semiautomatic welding is becoming the most popular welding method. The electrode is usually a long length of small-diameter bare wire, usually in coil form, which the welding operator manually positions and advances along the weld joint. The consumable electrode is normally motor-driven at a preselected speed through the nozzle of a hand-held welding gun or torch.



Metallic welding arc.

Automatic welding is very similar to semiautomatic welding, except that the electrode is automatically positioned and advanced along the prescribed weld joint. Either the work may advance below the welding head or the mechanized head may move along the weld joint.

There are, in addition to the three basic welding methods, many welding processes which may be common to one or more of these methods. A few of the more common are described below.

Carbon-electrode arc welding is in limited use for welding ferrous and nonferrous metals. Normally, the arc is held between the carbon electrode and the work. The carbon arc serves as a source of intense heat and simply fuses the base materials together, or filler material may be added from a separate source.

Shielded metal arc welding is the most widely used arc-welding process. A coated stick electrode is consumed during the welding operation, and therefore provides its own filler metal. The electrode coating burns in the intense heat of the arc and forms a blanket of gas and slag that completely shields the arc and weld puddle from the atmosphere. Its use is generally confined to the manual welding method.

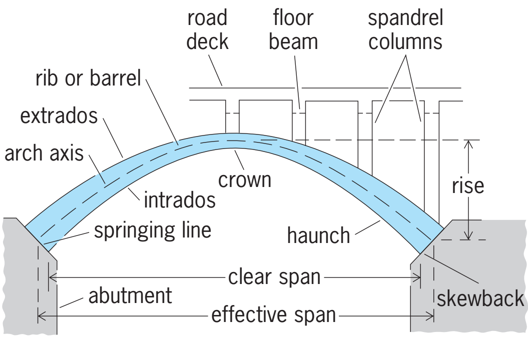
Submerged-melt arc welding uses a consumable bare metal wire as the electrode, and a granular fusible flux over the work completely submerges the arc. This process is particularly adapted to welding heavy work in the flat position. High-quality welds are produced at greater speed with this method because as much as five times greater current density is used. Automatic or semiautomatic wire feed and control equipment is normally used for this process.

Tungsten-inert gas welding, often referred to as TIG welding, utilizes a virtually nonconsumable electrode made of tungsten. Impurities, such as thorium, are often purposely added to the tungsten electrode to improve its emissivity for direct-current welding. The necessary arc shielding is provided by a continuous stream of chemically inert gas, such as argon, helium, or argon-helium mixtures, which flows axially along the tungsten electrode that is mounted in a special welding torch. This process is used most often when welding aluminum and some of the more exotic space-age materials. When filler metal is desired, a separate filler rod is fed into the arc stream either manually or mechanically. Since no flux is required, the weld joint is clean and free of voids.

Metal-inert gas welding, often referred to as MIG welding, saw its greatest growth in the 1960s. It is similar to the TIG welding process, except that a consumable metal electrode, usually wire in spool form, replaces the nonconsumable tungsten electrode. This process is adaptable to either the semiautomatic or the automatic method. In addition to the inert gases, carbon dioxide has become increasingly common as a shielding means. [E.F.S.]

Arcellinida An order of Lobosia. The shell (test) of these protozoa has a single, well-defined aperture through which slender fingerlike pseudopodia (lobopodia) can be extended. The test often has an internal chitinous layer known as a glycocalyx and an external layer composed of secreted siliceous elements, organic hollow platelets, or collected sand grains and other matter cemented together by an adhesive secretion. Most arcellinidans are uninucleate, but *Arcella* is binucleate. Food consists of bacteria and smaller protistans. The order includes *Arcella*, *Centropyxis*, *Cochliopodium*, *Difflugia*, and many other genera. *See* LOBOSIA; PROTOZOA; SARCODINA; SARCOMASTIGOPHORA. [O.R.A.]

Arch A structure, usually curved, that when subjected to vertical loads causes its two end supports to develop reactions with inwardly directed horizontal components. The designations of the various parts of an arch are given in the illustration. The commonest uses for an arch are as a bridge, supporting a roadway, railroad track, or footpath, and as part of a building, where it provides a large open space unobstructed by columns. Arches are usually built of steel, reinforced concrete, or timber.



An open-spandrel, concrete, fixed-arch bridge.

On the basis of structural behavior, arches are classified as fixed (hingeless), single-hinged, two-hinged, or three-hinged. An arch is considered to be fixed when rotation is prevented at its supports. Reinforced concrete ribs are almost always fixed. For long-span steel structures only fixed solid-rib arches are used. Because of its greater stiffness, the fixed arch is better suited for long spans than hinged arches.

Concrete is relatively weak in tension and shear but strong in compression and is therefore ideal for arch construction. Precast reinforced concrete arches of the three-hinged type have been used in buildings for spans up to 160 ft (49 m).

Steel arches are solid-rib or braced-rib arches. Solid-rib arches usually have two hinges but may be hingeless. The braced-rib arch has a system of diagonal bracing replacing the solid web of the solid-rib arch. The world's longest arch spans are two-hinged arches of the braced-rib type. The spandrel-braced arch is essentially a deck truss with a curved lower chord, the truss being capable of developing horizontal thrust at each support. This type of arch is generally constructed with two or three hinges because of the difficulty of adequately anchoring the skewbacks.

Wood arches may be of the solid-rib or braced-rib type. Solid-rib arches are of laminated construction and can be shaped to almost any required form. Arches are usually built up of nominal 1- or 2-in. (2.5- or 5-cm) material because bending on individual laminations is more readily accomplished. Because of ease in fabrication and erection, most solid-rib arches are of the three-hinged type. This type has been used for spans of more than 200 ft (60 m). The lamella arch has been widely used to provide wide clear spans for gymnasiums and auditoriums. The wood lamella arch is more widely used than its counterpart in steel. The characteristic diamond pattern of lamella construction provides a unique and pleasing appearance. *See* BRIDGE; BUILDINGS; TRUSS. [C.N.G.]

The masonry arch can provide structure and beauty, is fireproof, requires comparatively little maintenance, and has a high tolerance for foundation settlement and movement due to other environmental factors. Most arches are curved, but many hectares (acres) of floor in highrise office and public buildings are supported by hollow-tile jack (flat) arches. If a curved arch is wide (dimension normal to span), the arch is referred to as a barrel arch or vault. The vault cross section may have several different shapes. Contiguous vaults may be individual, may intersect, or may cross. A four-part vault is termed quadripartite. Contiguous quadripartite vaults that are supported at the corners by columns are masonry skeletons of large cathedrals.

Stone for masonry skeletons is cut from three classes of rock; igneous (granite, traprock), metamorphic (gneiss, slate, quartzite), and sedimentary (limestone, sandstone). The primary requirements for brick as a structural material are compressive strength and weathering resistance. Hollow clay tiles (terra-cotta) for floor arches are made semiporous in order to improve fire resistance. *See* BRICK; METAMORPHIC ROCKS; SEDIMENTARY ROCKS. [C.Bi.]

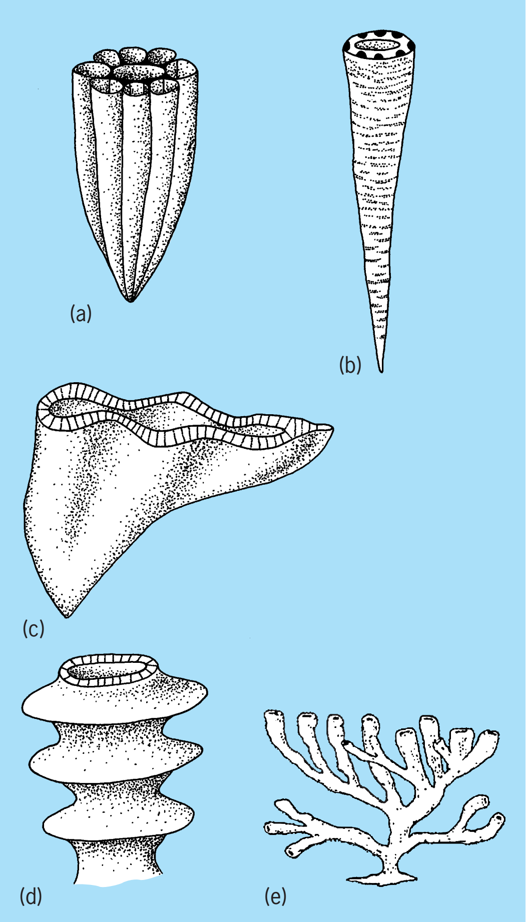
Archaebacteria A group of prokaryotic organisms that are more closely related to eukaryotes than bacteria. Based on comparative analyses of small subunit ribosomal ribonucleic acid (rRNA) sequences and selected protein sequences, the three primary lines of descent from the common ancestor are the Archaea (archaebacteria), the Bacteria, and the Eucarya (eukaryotes). Although the Archaea look like Bacteria cytologically (they are both prokaryotes), they are not closely related to them.

The Archaea can be divided into two evolutionary lineages on the basis of rRNA sequence comparisons, the Crenarchaeotae and the Euryarchaeotae. The crenarchaeotes are organisms that grow at high temperatures (thermophiles) and metabolize elemental sulfur. Most are strict anaerobes that reduce sulfur to hydrogen sulfide (sulfidogens), but a few can grow aerobically and oxidize sulfur to sulfuric acid. The euryarchaeotes have a number of different phenotypes. *Thermococcus* and *Pyrococcus* are sulfidogens like many crenarchaeotes. *Archaeoglobus* reduces sulfate to sulfide. *Thermoplasma* grows under acidic conditions aerobically or anaerobically (as a sulfidogen). Many euryarchaeotes are methane-producing anaerobes (methanogens) and some grow aerobically in the presence of very high concentrations of salt (halophiles). *See* METHANOGENESIS (BACTERIA).

The thermophilic archaea are found in high-temperature environments around the world. They have been isolated from soils and shallow marine sediments heated by nearby volcanoes and from deep-sea hydrothermal vents. Some are used as a source for heat-stable enzymes useful for industrial applications. The methanogenic archaea inhabit the digestive tracts of animals (especially ruminants like cows), sewage sludge digesters, swamps (where they produce marsh gas), and sediments of marine and fresh-water environments. They are of interest commercially because of their ability to produce methane from municipal garbage and some industrial wastes. Halophilic archaea live in the Great Salt Lake, the Dead Sea, alkaline salt lakes of Africa, and salt-preserved fish and animal hides. They are also commonly found in pools used to evaporate seawater to obtain salt.

The discovery of the Archaea caused a major revision in the understanding of evolutionary history. It had previously been thought that all prokaryotes belonged to one evolutionary lineage. Since their cellular organization is simpler, prokaryotes were assumed to be ancestors of eukaryotes. The discovery of the relationship of the Archaea to the Eucarya revealed that prokaryotes do not comprise a monophyletic group since they can be divided into two distinct lineages. Although the three descended from a common ancestor, modern eukaryotes may have arisen from fusions of bacterial and archaeal endosymbionts with ancestral eukaryotes. Chloroplasts and mitochondria arose from free-living bacteria which became endosymbionts. The discovery of the Archaea has also given microbiologists a better picture of the common ancestor. The deepest-branching eukaryotes (like *Giardia*) are strict anaerobes that lack mitochondria, and they diverged much later than the deepest-branching bacteria and archaea. The earliest archaea and bacteria (*Thermotoga* and *Aquifex*) are also anaerobes and are also extreme thermophiles. Therefore the common ancestor of these groups was probably also an extremely thermophilic anaerobe. Therefore, it is possible that life may have arisen in a relatively hot environment, perhaps like that found in deep-sea hydrothermal vents. *See* BACTERIA; EUKARYOTAE; PROKARYOTAE. [K.M.N.]

Archaeocyatha An extinct group of mainly Lower Cambrian marine sponges which, although lacking spicules, possessed an intricate, highly porous skeleton of calcite. It was probably a monophyletic group; that is, all representatives were derived from a single ancestor. The position of the Archaeocyatha within the Porifera is uncertain, but they were probably most closely related to the class Demospongiae. Their fossil record is well known, as archaeocyaths represent the first large skeletal animals to have been associated with reefs; they were widespread in the shallow, warm waters that surrounded the many continents that occupied tropical latitudes during the Cambrian.



Some growth forms in the Archaeocyatha: (*a*) ribbed; (*b*) tubular conical; (*c*) asymmetric, conical; (*d*) annulated; (*e*) branching.

Archaeocyath sponges displayed a great variety of sizes and growth forms. They ranged from a few millimeters to over 500 mm in length and width, and included open cups, convoluted plates, and complex branching forms (see illustration). Archaeocyatha has been traditionally subdivided into two subclasses, the Regulars and Irregulars, according to differences in the early development of the skeleton. It has now been demonstrated, however, that these skeletal characters are a function of differences in soft-tissue distribution, which are independent of systematic placing. Regulars (orders Monocyathida, Ajacicyathida, Coscniocyathida, and Tabulacyathida) generally show no tabulae or dissepiments, and they are inferred to have had intervalla that were completely filled with soft tissue. By contrast, the skeletons of Irregulars (orders Archaeocyathida and Kazachstanicyathida) are believed to have borne soft tissue in their upper parts only, as they possessed abundant structures such as tabulae which served to section off abandoned areas of the skeleton as the soft tissue migrated upward. *See* PARAZOA; PORIFERA. [R.Wo.]

Archaeognatha An order of ancestrally wingless insects, commonly known as bristletails, in the subclass Apterygota; about 350 species are known in two families, Machilidae and Meinertellidae. All have slender, spindle-shaped bodies of about 0.4–0.8 in. (1–2 cm) in length, tapered tail-ward to a long, multisegmented median caudal filament and paired cerci. The relatively thin integument is covered with pigmented scales after the first instar. The antennae are long and filiform, without intrinsic musculature in the flagellum, as in all true insects; and large, contiguous compound eyes are accompanied by a trio of ocelli. The mandibles are exposed and attached to the cranium by a single joint (condyle), and the maxillary palpi are extended, with seven segments, while the labial palpi have only three segments. Each leg has a large coxa, two-segmented trochanter, femur, tibia, and a two- or three-segmented tarsus terminating in a two-clawed pretarsus. The posterior pair or two pairs of coxae and most of the ventral abdominal coxites bear styles, which may represent modified legs. Outwardly projecting vesicles that are apparently water absorbing also occur on most coxites. Internally, the gut is relatively simple, with small crop, digestive ceca, and a dozen or more Malpighian tubules. The nervous system is primitive, with three thoracic and eight abdominal ganglia and twin connectives. Tracheae are well developed.

In mating, the male deposits sperm on a thread or in a spermatophore that is picked up by the female, but in at least one species sperm is placed directly on the female ovipositor. Immature forms are similar to adults in body form, though the first instar may lack cerci. Sexual maturity is attained after eight or more molts.

Bristletails live in a variety of habitats worldwide, often on stones or tree trunks where they find the algae and lichens that appear to be their principal sources of food. Most species are primarily nocturnal feeders. *See* Apterygota. [W.L.Bro.]

Archaeopteridales An order of extinct, free-sporing plants (cryptogams) that lived during the Late Devonian through Early Mississippian. The order includes the genera *Archaeopteris* which has been extensively investigated, *Actinoxylon*, *Actinopodium*, *Svalbardia*, *Eddya*, and *Siderella*. *Archaeopteris* had a worldwide distribution on what today are Northern Hemisphere continents, as well as on Australia. The genus is characterized by an arborescent habit and large, determinate, deciduous, frondlike lateral branch systems that bear simple, oval to fan-shaped leaves, with dichotomous venation, which vary in different species from highly dissected to nearly entire. Archaeopteridales belongs to the class Progymnospermopsida. The progymnosperms are thought by some botanists to be ancestral to seed plants. *See* Plant kingdom. [C.B.B.]

Archaeornithes One of the two subclasses of birds, the ancient birds, containing the single order Archaeopterygiformes, the most primitive taxon of birds. This taxon was established for the seven specimens (one feather impression and six skeletons) of the oldest known fossil bird, *Archaeopteryx lithographica* from the Late Jurassic limestones of Bavaria. All other fossil and living birds are placed in the second subclass, the Neornithes or modern birds.

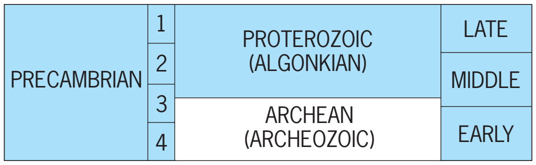
Archaeopteryx is an outstanding example of an intermediate form demonstrating the pattern of mosaic evolution. It is pigeon-sized with a long feathered tail, a pair of feathers attached to each tail vertebra, and a fully feathered wing. The feathers are completely modern avian feathers. The skull has reptilian jaws with small sharp teeth; cranial kinesis is very similar to that of modern birds. The brain and eyes are somewhat larger than those features in most reptiles. The forelimb is modified to a wing, but with the three clawed fingers still unfused. The pectoral girdle is weak and reptilian except for the presence of a stout furcula (wishbone). A bony, keeled sternum is lacking, but ventral ribs (gastralia) exist. The body is moderately long and flexible. The sacrum is small, and the bones of the pelvic girdle are not fused strongly together. The pubis is not fully reversed. The bones of the tarsometatatsus are not fused together. The long tail is formed of a number of individual vertebrae.

Archaeopteryx probably was aboreal for part of its life, going into trees for hiding, sleeping, and nesting. It could descend to the ground with a controlled glide and most likely foraged for food on the ground. There is no evidence that *Archaeopteryx* had the ability of powered flight or that flight in birds evolved to enable the bird to fly up from the ground. All evidence suggests that active, powered flight in birds evolved from the gliding stage and was to permit the animal to reach the ground from an elevated position in trees. *Archaeopteryx* climbed up tree trunks by using the sharp claws on its hands and feet to grip the tree. It is most likely that *Archaeopteryx* was an obligatory homoiotherm with feathers covering its body to reduce heat loss.

Archaeopteryx has many similarities with small carnivorous dinosaurs, and many workers have argued that birds evolved from this group of dinosaurs. *See* Aves; Dinosaur; Neornithes; Reptilia. [W.J.B.]

Archaic ungulate The most diverse group of early Tertiary mammals are the archaic ungulates (condylarths). Although closely related, they are not a monophyletic group but, along with various extinct and extant mammals, form the taxon Ungulata. They are ancestral to as many as 7 of 18 living orders of mammals: Artiodactyla, Cetacea, Hyracoidea, Perissodactyla, Proboscidea, Sirenia, and possibly Tubulidentata. Along with the Late Cretaceous zhelestids, best known from Asia, Ungulata forms the taxon Ungulatomorpha. Fossil (and molecular) evidence suggests that Ungulatomorpha separated from other placentals 85 million years ago. Early ungulatomorphs had lower-crowned, more squared molars compared to contemporary placentals, which have a more slicing dentition, indicating a trend toward omnivory and herbivory. Although "ungulate" implies hooves, most archaic ungulates had at best rudimentary hooves or even claws. *See* Artiodactyla; Cetacea; Hyracoidea; Perissodactyla; Proboscidea; Sirenia; Tubulidentata. [J.D.Ar.]

Archean A period of geologic time from about 3.8 to 2.5 billion years ago (Ga). During the Archean Eon a large percentage of the Earth's continental crust formed, plate tectonics began, very warm climates and oceans existed, and life appeared on Earth in the form of unicellular organisms.



The occurrence of rock assemblages typical of arcs, oceanic plateaus, and oceanic islands and the presence of accretionary orogens in the very earliest vestiges of the geologic record at 4–3.5 Ga strongly supports some sort of plate tectonics operating on the Earth by this time. By 3 Ga, cratons, passive margins, and continental rifts were also widespread. Although plate tectonics appears to have occurred since 4 Ga, there are geochemical differences between Archean and younger rocks that indicate that Archean tectonic regimes must have differed in some respects from modern ones. The degree that Archean plate tectonics differed from modern plate tectonics is unknown; however, these differences are important in terms of the evolution of the Earth. *See* Plate tectonics.

The oldest rocks occur as small, highly deformed terranes tectonically incorporated within Archean crustal provinces. Although the oldest known igneous rocks on Earth are the 4 Ga Acasta gneisses of northwest Canada, the oldest minerals are detrital zircons (zircons in sediments) from the 3 Ga Mount Narryer quartzites in western Australia.

The oldest isotopically dated rocks on Earth are the Acasta gneisses, which are a heterogeneous assemblage of highly deformed granitic rocks, tectonically interleaved with mafic and ultramafic rocks, and metasediments. Uranium-lead zircon ages from the granitic components of these gneisses range from 4 to 3.6 Ga, and thus it would appear that this early crustal segment evolved over about 400 million years and developed a full range in composition of igneous rocks. The chemical compositions of Acasta mafic rocks are very much like less deformed Archean greenstones representing various oceanic tectonic settings. *See* DATING METHODS; ROCK AGE DETERMINATION.

The largest and best-preserved fragment of early Archean continental crust is the Itsaq Gneiss Complex in southwest Greenland. In this area, three terranes, each with its own tectonic and magmatic history, collided about 2.7 Ga, forming the continental nucleus of Greenland. Although any single terrane records less than 500 million years of precollisional history, collectively the terranes record over 1 billion years of history before their amalgamation.

The Archean is known for its reserves of iron, copper, zinc, nickel, and gold. Some of the world's largest copper-zinc deposits occur as massive sulfide beds associated with submarine volcanics in Archean greenstones in Canada and western Australia.

The Earth's first atmosphere was probably composed chiefly of gases such as helium and hydrogen inherited from the solar nebula from which the solar system formed, as well as from the asteroidlike bodies that collided to form Earth. As Earth heated up from core formation, it released gases and formed a secondary atmosphere composed chiefly of CO_2, methane (CH_4), nitrogen (N_2), and water (H_2O). In support of this view, the surviving rock record includes carbonates that reflect a carbon dioxide-rich atmosphere; and also one or more greenhouse gases (carbon dioxide, methane) must have been present to prevent the surface of the Earth from freezing over.

There are three lines of evidence for life in the Archean: (1) fossil stromatolites, which are laminated structures deposited by microorganisms; (2) fossils of cells or cellular tissue; and (3) carbonaceous matter identifiable from its carbon isotopic composition as a product of biologic activity. Some of the oldest fossil stromatolites occur in the 3.5 Ga Barberton greenstone in southern Africa and in the 3.5 Ga Pilbara greenstone in western Australia. [K.C.C.]

Archeoastronomy The interdisciplinary study that attempts to determine how much astronomy prehistoric people knew and how it influenced their lives. It involves multiple disciplines: astronomy to chart the heavens, archeology to probe the cultural context, engineering to survey sites, and ethnology to provide clues to the cultural past. Archeoastronomy has prompted valuable insights into the astronomy of the past, even to revolutionizing some models of prehistoric cultures. It has been suggested that archeoastronomy and its loose family of disciplines should be subsumed under a broader study, cultural astronomy. The reason to do cultural astronomy is that the sky can perform a special role in the scheme of cultural systems. The sky then serves as a cultural resource of many uses. The cultural context is the key to understanding the findings of archeoastronomers. Finding astronomical orientations at sites is easy; interpreting these as intentional alignments is hard. It is necessary to consider what their purpose might be (to keep a seasonal calendar? to regulate sacred time? both or neither?). The great danger is the imposition of modern astronomy and culture upon an alien culture of the past. *See* ARCHEOASTRONOMY; ASTRONOMY.

Every prehistoric culture appears to have developed its own astronomy. The traditional navigators of Oceania needed to memorize guide stars and to employ them as the bearing markers for island-to-island travel over thousands of kilometers of water. The Carib people of northern South American developed a calendar that relied on the positions of stars relative to each other and to the Sun at times of rising and setting. A bone from the shores of Lake Edward, Zaire and Uganda, may have markings of a lunar calendar, tallied at a time over 8000 years ago, perhaps used to forecast marine activity or the weather; a focus on the Moon continues in Africa today. Chinese astronomical records cut into bones and shells may have begun as early as the twelfth century B.C., well before the Babylonians incised their earliest records on clay.

By the time the Spanish invaded Mesoamerica and South America, the use of astronomy went well beyond complex systems of cycles and calendars. For instance, in some Mayan cities knowledge of the cycles of Venus timed the onset of warfare. In others, key political events incorporated the summer solstice and perhaps conjunctions of Jupiter and Saturn. Ancient Inca city planning and politics embodied astronomy, such as the ceque system of radial lines from the Temple of the Sun in the valley of Cuzco. These lines mark the directions to sacred places as well as to specific astronomical phenomena. The ceque system had a calendric manifestation in knotted cords that tallied the days of the agricultural year. [M.Ze.]

Archeological chemistry The application of chemical techniques to the study of archeological finds, natural or anthropogenic, in order to ascertain their composition or age. Traditional chemical analysis uses wet methods, in which a sample is brought into solution and its components are assayed by precipitation or titration. These methods were applied to ancient coins as early as the late eighteenth centuary. The obvious need to minimize damage to an irreplaceable object spurred the development of microchemical techniques. Modern analysis relies on instrumental methods that require only very small samples or are entirely nondestructive. Although these methods rely on physical phenomena rather than chemical transformation, all procedures that are capable of the qualitative and quantitative determination of the atomic or molecular composition of the object under study are usually included under the broad heading of archeological chemistry.

Various analytical methods are utilized in archeological chemistry, including optical emission spectography, atomic absorption spectroscopy, inductively coupled plasma, neutron activation analysis, x-ray fluorescence spectrometry, electron microprobe analysis, proton-induced x-ray emission, Auger electron spectroscopy, and x-ray photoelectron spectroscopy. It should be noted that these methods of analysis are not competing but complementary. The choice of method depends on the nature of the object, on the elements to be determined, and on the accuracy required. *See* ACTIVATION ANALYSIS; ATOMIC SPECTROMETRY; AUGER EFFECT; PROTON-INDUCED X-RAY EMISSION (PIXE); RADIOISOTOPE; X-RAY FLUORESCENCE ANALYSIS.

Organic materials constitute only a small portion of archeological finds, but since they include such basic necessities as food, drink, and clothing, they have the potential of revealing much about past life. Because they consist of covalently bound, complex, and sensitive molecules, their study requires special methods of analysis. Organic archeometry is the newest and most rapidly expanding field of archeological chemistry. Organic dyes have long been determined qualitatively and quantitatively by absorption spectroscopy in the visible and ultraviolet ranges. The extension into the infrared range allows not only the identification of organic materials by visual or computer-aided comparison of infrared spectra ("fingerprinting") but also some structural interpretation. Since organic residues typically consist of mixtures of dozens or even hundreds of individual compounds, the progress of organic archeometry has crucially depended on the development of chromatographic separation procedures. These include column chromatography, paper and thin-layer chromatography, gas chromatography, with or without prior pyrolysis, and liquid chromatography. All of these techniques not only separate mixtures into individual components but permit their identification if the rate at which they travel through the chromatographic substrate, the retention time, can be matched to those of authentic reference compounds.

Another method that is gaining use in organic archeometry is nuclear magnetic resonance spectrometry (NMR), which detects a limited number of atomic nuclei, among them ordinary hydrogen, carbon-13, nitrogen-15, fluorine-19, and phosphorus-31, by their simultaneous interaction with an external magnetic field and a radio-frequency field. *See* GAS CHROMATOGRAPHY; INFRARED SPECTROSCOPY; MASS SPECTROMETRY; NUCLEAR MAGNETIC RESONANCE (NMR); SPECTROSCOPY.

The determination of the chemical composition of an archeological find is not an end in itself, but provides the archeologist with factual evidence not otherwise obtainable and touching on many aspects of early human life. The changing elemental composition of coins detects progressive debasement and reveals economic history and fiscal policy. The metals added to copper to make bronze and brass outline the history and spread of technology. The foodstuffs consumed are indicators of the advent and progress of agriculture and animal husbandry. Together, all these paint a picture of prehistoric social, cultural, and economic stratification. The composition of an object also offers clues to its geographic origin, which may be far from the excavation site. This provides evidence of trade and exchange in commodities and raw materials. *See* PREHISTORIC TECHNOLOGY.

While the most widely used methods for dating archeological material—radioactive decay, thermoluminescence, and archeomagnetism—deal with physical processes, three depend on the progress of conventional chemical reactions. (1) Amino acid dating uses the rate of racemization of optically active organic molecules. (2) Hydration dating measures the thickness of the weathering layer produced by the action of water on natural and artificial glass, including obsidian and flint. (3) NFU dating of bone relies on the loss of nitrogen (N) from the organic collagen component and on the uptake of fluorine (F) and uranium (U) by the inorganic hydroxyapatite component. Like all nonnuclear chemical reactions, these changes are a function not only of time but also of temperature, of acidity and, in the case of fluorine and uranium uptake, of the concentrations of these elements in the surrounding soil. Chemical methods cannot produce absolute dates unless these other variables are known or can be estimated reasonably closely. They are, however, useful in establishing relative ages of finds within a single site in which the depositional characteristics are likely to have been uniform. *See* AMINO ACID DATING; ARCHEOLOGICAL CHRONOLOGY; CHEMICAL MICROSCOPY; DATING METHODS; PALEOMAGNETISM; RACEMIZATION; RADIOCARBON DATING; THERMOLUMINESCENCE. [C.W.Be.]

Archeological chronology The establishment of the temporal sequence of human cultures. Prior to the discovery of nuclear and chemical dating methods, which provide an absolute time scale, archeologists used stratigraphy, lithic and ceramic typology, seriation, index fossils, and a limited range of chemical techniques to establish relative chronologies for cultural remains. The major chemical techniques used in dating of bones in relative sequence have been labeled F-U-N (for fluorine-uranium-nitrogen). In a single site or environment, bones of the same age usually absorb the same amount of fluorine and uranium while losing the same amount of nitrogen.

Since the mid-twentieth century numerous absolute (sometimes called chronometric) dating techniques have been devised by natural scientists. Some of these techniques can give results in calendar years, whereas others yield dates which are expressed in years but which cannot always be correlated precisely with the calendar. The major methods for absolute dating of archeological materials used include radiocarbon dating, dendrochronology, thermoluminescence dating, hydration dating, racemization, potassium-argon dating, lead-210 dating, and archeomagnetism. Many other techniques, for example, fission track dating, have been used to establish archeological chronology, and a host of physical and, to a lesser degree, chemical dating methods have been investigated. *See* DATING METHODS; DENDROCHRONOLOGY; FISSION TRACK DATING; PALEOMAGNETISM; RACEMIZATION; RADIOCARBON DATING; ROCK AGE DETERMINATION; THERMOLUMINESCENCE. [G.R.]

Archeology The scientific study of past material culture. The initial objective of archeology is to construct cultural chronologies, attempting to order past material culture into meaningful temporal segments. The intermediate objective is to breathe life into these chronologies by reconstructing past lifeways. The ultimate objective of contemporary archeology is to determine the cultural processes that underlie human behavior, both past and present.

The material culture of the past is of infinite variety. The scientific study of this evidence is such a broad task that there is no such thing as any single archeological method, although over the past century archeologists have evolved what can be termed an overall archeological approach. By constant confirmation, the archeologist often attempts to establish synchronism with what has already been established historically.

Archeologists use a number of types in order to categorize similar artifacts. Most common is the temporal type, a principle similar to the index fossil concept used by the geologist. A temporal type can be any kind of archeological artifact or feature, but ideally it is some object of common use in which the form is subject to change, due to either the whim of fashion or technological improvement. One example is the simple flint arrowhead with side barbs and central tang. It is typical of the British Bronze Age and was not in fashion earlier or later. Ceramic types have been established by archeologists working around the world, and a thoroughly tested ceramic chronology is invaluable as a temporal ordering device, no matter where the archeologist is working. The nature of the artifact employed as a temporal type is irrelevant, and its use may not even be known. Archeologists also establish other kinds of types. Functional types attempt to group artifacts on the basis of known or presumed functions. Technological types, divisions which reflect the mode of manufacture, are particularly helpful when studying stone tool manufacture.

The concept of culture is used in two different ways by contemporary archeologists. When dealing with cultural chronologies, the archeologist most commonly uses a modal or shared view of culture. It is this normative collection of shared ideas which causes artifacts to change in systematic ways through time, and temporal types can be established on the basis of this shared culture. When attempting to reconstruct lifeways, however, the archeologist can no longer rely on the shared aspects of culture. When transcending temporal associations, contemporary archeologists tend to view culture systematically, as people's extrasomatic (that is, learned) method of dealing with the social and cultural environment.

The principles of stratigraphy are applied to archeology in terms of the law of superposition, which states that, all else being equal, older deposits will tend to be buried beneath younger ones. Mere stratigraphic equivalence, however, does not necessarily indicate contemporaneity, as there can be misleading mixtures of successive occupational debris on one surface. Archeologists must therefore study the processes of cultural deposition in order to recognize the difference between intact and disturbed strata.

Contemporary excavation must be conducted with a plan, a firm research design that attempts to provide answers to definite questions. Archeology is one of the few sciences which destroys its own data in the process of generating them. Archeologists must therefore be extremely careful to make the appropriate observations at the time of excavation.

The task of deciphering meaning from past material culture is so complex that the archeologist is often required to borrow from allied disciplines in the physical and natural sciences, including geology, climatology, paleobotany, paleontology, mineralogy, physics, chemistry, and anthropology. The archeologist must have some understanding of all these sciences to extract from sites and materials every possible piece of information which may lead to a better understanding of prehistory. The archeologist must be able to record and publish every minor fact for the benefit of colleagues and successors, because the writing of prehistory requires the synthesis of all archeological discovery and interpretation. *See* Archeological chemistry; Physical anthropology. [D.H.Th.]

Archiacanthocephala An order of the phylum Acanthocephala. The adult worms are parasitic in terrestrial vertebrates. Some common archiacanthocephalans are *Oncicola canis, Moniliformis moniliformis*, and *Macracanthorhynchus hirudinaceus*.

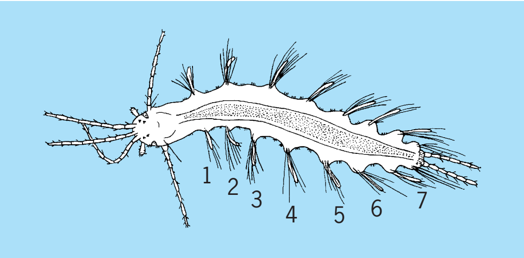
Oncicola canis is a short plump acanthocephalan, primarily parasitic in dogs and other Canidae. It occurs also in cats. The body of the adult, 0.24–0.56 in. (6–14 mm) long, is short and heavy with irregular cross furrows. The globular proboscis has six spiral rows of six hooks each. The arthropod intermediate host is unknown. Cystacanths have been found in armadillos and in the esophageal walls of turkeys, which indicates a transport host in the life cycle.

Moniliformis moniliformis is an elongate acanthocephalan which is parasitic in house rats. The females are 4–12 in. (10–30 cm) long, whereas the males measure 2.4–5.2 in. (6–13 cm). The body of both sexes exhibits conspicuous pseudosegmentation except on the extremities. The proboscis is cylindrical with 12–15 rows of 10 or 11 hooks each. Cockroaches (*Periplaneta americana*) serve as the intermediate host; however, in Europe a beetle, *Blaps* mucronata, is the intermediate host. Occasionally infections have been found in humans.

Macracanthorhynchus hirudinaceus is the giant thornheaded worm of hogs and is probably the best known of all acanthocephalans because of its cosmopolitan distribution. Females measure 10–24 in. (25–60 cm) in length and the males 2–4 in. (5–10 cm). The worms are pinkish with a transversely wrinkled body which tapers from a rather broad anterior end to a slender posterior end. The proboscis is globular with six spiral rows of six hooks each. At least 25 species of scarabaeid beetle larvae have been reported as intermediate hosts. In addition to their occurrence in the domestic pig, adults have been reported to occur in squirrels, chipmunks, moles, and occasionally humans. This acanthocephalan is of considerable economic importance to the hog-raising industry. *See* Acanthocephala. [D.V.Mo.]

Archiannelida A name applied to a small group of unrelated annelids, probably not primitive as the name implies. Some resemble existing families of polychaetes (see illustration). Most live in marine or brackish water and occur in intertidal and estuarine habitats. They are characterized by their vermiform body and small sizes. Lengths range from less than 0.04 in. (1 mm) to 0.4 in. (10 mm), rarely to 4 in. (100 mm). The number of segments varies from five to many, or segmentation is obscure. Parapodia with setae may be altogether lacking, and the epithelium may be ciliated. Cephalic and anal structures may be modified as holdfast organs to maintain existence in turbulent, intertidal zones and shifting sands. *See* Polychaeta.

Three families with about 82 species in 15 genera are recognized. The Nerillidae have well-developed parapodia and setae; they are known for 20 species in 7 genera, all but one limited to Europe and western Africa; *Nerilla* is worldwide. The Protodrilidae are known through 47 species in 5 genera; the best known are *Polygordius*, *Protodrilus*, and *Saccocirrus*, which are recorded from cosmopolitan areas. The Dinophilidae are known through 17 species in 3 genera, of which the best known is *Dinophilus*, with 6 or 7 species. *See* Annelida. [O.H.]



Nerilla antennata **(Nerillidae) with segments 1 to 7. (*After Schlieper, Zool. Anz. Leipzig, 62:233, 1925*)**

Archidiidae A subclass of the plant class Bryopsida (mosses). The Archidiidae consists of a single genus, *Archidium*, with 26 species, occurring in ephemeral habitats, especially in wet, grassy places. The small gametophytes consist of erect, simple or forked stems, and elongate, singly co-state leaves in numerous rows. The capsules, usually terminal, are globose, immersed, and irregularly rupturing. The capsule wall consists of a single layer of cells; stomota, peristome, and columella are lacking. The spores are few, large (50–310 micrometers), and thick-walled. The calyptra is scarcely differentiated. *See* Bryidae; Bryophyta; Bryopsida; Buxbaumiidae; Dawsoniidae; Polytrichidae; Tetraphididae. [H.Cr.]

Archigregarinida An order of the protozoan subclass Gregarinia, class Telosporea, subphylum Sporozoa. All gregarines are parasites of the digestive tract and body cavity of invertebrates or lower chordates; their large, mature trophozoites (vegetative stages) live outside the host's cells. The Archigregarinida are primitive gregarines and live in marine worms (annelids and lower chordates—enteropneustids, sipunculids, and ascidians). Their life cycle includes sexual and asexual phases and involves three periods of schizogony (multiple fission). There are only 28 named species in five genera. The most important genus is *Selenidium*, which has 24 species. Its members occur in the intestine of marine polychaete annelids, sipunculids, enteropneustids, and ascidians. *See* Gregarinia; Protozoa; Sporozoa; Telosporea. [N.D.L.]

Archimedes' principle The principle that the net fluid force on a body submerged (or floating) in a stationary fluid is an upward force equal to the weight of the fluid displaced by the body. This concept, perhaps the oldest stated principle in fluid mechanics, was first put forth by Archimedes in the third century B.C.

In a static fluid, the weight of the fluid causes an increase in pressure with depth. Thus, at the surface of the fluid, the pressure is atmospheric pressure ($p_0 = 14.7$ lb/in.^{2} = 101 kilonewtons/m^2), while at a depth h the pressure has a larger value of p_1, given by Eq. (1), where γ is the specific weight

$$p_1 = p_0 + \gamma h \tag{1}$$

of the fluid (weight/volume). The difference in pressure force between the bottom and the top of a water column is therefore given by Eq. (2), where h' and A are the height and area

$$(p_b - p_t)A = \gamma h' A \tag{2}$$

of the column, and p_b and p_t are the pressures at the bottom and top of the column. This difference is precisely equal to the weight W of the water within the column, given by Eq. (3). If

$$W = \gamma(\text{volume}) = \gamma h' A \tag{3}$$

the water column were replaced with a solid object, the pressure forces on the object would be the same as on the original water column. That is, the net hydrostatic pressure force on the object, termed the buoyant force, would be equal to the weight of the water displaced (which is the statement of Archimedes' principle). The same concept holds for a body of arbitrary shape, which can be thought of a consisting of many small vertical columns fastened together. Archimedes' principle is valid for submerged or floating bodies in liquids or gases. *See* Buoyancy; Specific gravity. [B.R.M.]

Architectural acoustics The science of sound as it pertains to buildings. There are three major branches of architectural acoustics. (1) Room acoustics involves the design of the interior of buildings to project properly diffused sound at appropriate levels and with appropriate esthetic qualities for music and adequate intelligibility for speech. (2) Noise control or noise management involves the reduction and control of noise between a potentially disturbing sound source and a listener. (3) Sound reinforcement and enhancement systems use electronic equipment to improve the quality of sounds heard in rooms.

Room acoustics. One essential component of room acoustics is an understanding of psychoacoustics and the qualitative evaluation of sounds heard by people in rooms. Psychoacoustics is the study of the psychology of sounds. It includes studies conducted in laboratories and in actual listening rooms of how people react to the level, frequency content, direction, and arrival time of sounds. These studies have established a set of relationships among the acoustical qualities that have been found to be important in the perception of sound, the room surfaces that contribute to these qualities, and the physical components of the sound field in a room that contribute to these properties. *See* Psychoacoustics.

Several important design concepts are used to provide good listening conditions in rooms for speech and music. First is to provide good access to the direct sound for all people in the room. This usually involves raising the source of sound on an elevated stage, altar, or podium at the front of the room and sloping the floor surface to elevate the ears of people above the heads of those seated in front of them. The width and depth of the room should also be limited so that the natural direct sound can project from the speaker or instruments at the front of the room to the listeners. Second is to limit the background noise level in the room so that people can hear the sound they want to hear above the level of the ambient sound. Third is to limit the reverberation time in the room so that sounds are heard clearly and fully, while providing enough reverberant sound energy that sounds are heard as "full" and "live." If there is too much reverberation in a room, the persistence of an initial syllable will cover up or mask the one that follows it, making it difficult to understand what is being said.

Noise control. Acoustical planning concepts for buildings include placing noisy activities away from activities that require relative quiet and locating noise-sensitive activities away from major sources of noise. Buffer spaces such as corridors or storage spaces are often used to separate two rooms that require acoustical privacy such as music rehearsal rooms in a school. Intruding noises from the exterior or from adjoining rooms can be reduced by using walls, ceilings, windows, and doors with appropriate transmission losses. A compound or double wall assembly can be used to reach a relatively high transmission loss with low mass per unit wall area. The separation between the two leaves or surfaces of the wall must be maintained as completely as possible for this to occur.

It is essential to control noise from building services. The location of air-conditioning plants on a site should be chosen so as to reduce propagation of noise to neighbors. Mechanical rooms in buildings that house air handling units, pumps, and other equipment should be located away from noise-sensitive rooms. Noise control treatments in the air-conditioning system include providing vibration isolators for equipment; providing flexible connections between ducts, conduits, and pipes to equipment; designing air ducts to operate with air velocities that will not create turbulent flow noise; and installing silencers or attenuators in the ducts to reduce noise produced by fans from traveling through the duct work. *See* Mechanical vibration; Vibration isolation.

Sound reinforcement. Sound reinforcement systems, electronic enhancement systems, and sound amplification systems are used in many buildings. A sound reinforcement system amplifies the natural acoustic sounds in a room that is too large for people to hear with just "natural" room acoustics. This type of system reinforces the natural sounds that come from the room, increasing their apparent loudness with a series of loudspeakers.

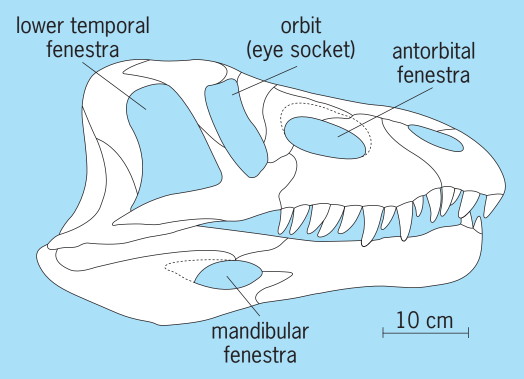
In an electronic enhancement system, loudspeakers act as virtual room surfaces to create the perception that sounds are reflected from these surfaces at the proper times and with the proper loudness. These systems usually have a network of loudspeakers located throughout a room and connected to a microprocessor. The microprocessor can delay the signals to arrive at times corresponding to reflected sounds from the virtual room surfaces. It can also add reverberation and other special acoustic effects to create a virtual acoustic space.

A sound amplification system makes all sounds played in a space louder. It is usually not designed to supplement the natural room acoustics or to provide subtle virtual room effects to the amplified sounds. [G.W.Sie.]

Architectural engineering A discipline that deals with the technological aspects of buildings, including the properties and behavior of building materials and components, foundation design, structural analysis and design, environmental system analysis and design, construction management, and building operation. Environmental systems, which may account for 45–70% of a building's cost, include heating, ventilating and air conditioning, illumination, building power systems, plumbing and piping, storm drainage, building communications, acoustics, vertical and horizontal transportation, fire protection, alternate energy sources, heat recovery, and energy conservation. In addition, to help protect the public from unnecessary risk, architectural engineers must be familiar with the various building codes, plumbing, electrical, and mechanical codes, and the Life Safety Code. The latter code is similar to a building code and is designed to require planning and construction techniques in buildings which will minimize possible hazards to the occupants. *See* Electrical codes; Fire technology.

Architectural engineering differs from other engineering disciplines in two important aspects. Most engineers work with other engineers, while most architectural engineers work or consult with architects. Furthermore, an architectural engineer not only must be fully qualified in engineering, but must also be thoroughly versed in all architectural considerations involved in design and construction. An architectural engineer designing a structural or environmental system is expected to be familiar not only with that system, but also with the multitude of architectural considerations which may affect its design, installation, and operation. *See* Buildings; Engineering. [T.S.D.]

Archosauria A subclass of reptiles more easily defined by listing its five component orders, four of them extinct, than by its anatomical characters. The earliest, most primitive archosaurs were the Thecodontia, from which arose independently the Saurischia ("lizard-hipped" dinosaurs), the Omithischia ("bird-hipped" dinosaurs), the Pterosauria (flying reptiles, including the pterodactyls), and the Crocodilia (including the living crocodiles,



Skull of *Chasmatosaurus*, a primitive archosaur (order Thecodontia), from the Early Triassic of South Africa. (*After Broili and Schroeder*)

alligators, caimans, and gavials). *See* Crocodylia; Ornithischia; Pterosauria; Saurischia.

Many Archosauria are certainly bipeds. They have two pairs of openings (fenestrae) in the temporal region of the skull (diapsid condition) and never lose the bony arcades around those openings. Typically there are also one or more antorbital openings in front of the orbit, a character which is virtually confined to this subclass (see illustration).

The earliest archosaurs are Lower Triassic, with a single species in the uppermost Permian. The Archosauria were undoubtedly a highly successful group, with locomotor systems, sense organs, and probably physiological adaptations far superior to those of any otherreptiles. *See* Reptilia. [A.J.C.]

Arctic and subarctic islands Defined primarily by climatic rather than latitudinal criteria, arctic islands are those in the Norhern Hemisphere where the mean temperature of the warmest month does not exceed 50°F (10°C) and that of the coldest is not above 32°F (0°C). Subarctic islands are those in the Northern Hemisphere where the mean temperature of the warmest month is over 50°F (10°C) for less than 4 months and that of the coldest is less than 32°F (0°C). Such islands generally are in high latitudes. Distribution of land and sea masses, ocean currents, and atmospheric circulation greatly modifies the effect of latitude so that it is often misleading to use location relative to the Arctic Circle as a significant criterion of arctic or subarctic. The largest proportion by area of the islands lies in the Western Hemisphere, primarily in Greenland and in the Canadian Arctic Archipelago. Within this general description, individual islands vary considerably (see table).

Physiographically, the islands include all the varied major landforms found elsewhere in the world, from rugged mountains over 8000 ft (2500 m) high, through plateaus and hills, to level plains only recently emerged from the sea. All have been glaciated except Sakhalin and some of the islands in the Bering Sea sector. Removal of the weight of ice sheets and the resultant crustal rebound has exposed prominent marine beaches and wave-cut cliffs on many of the islands. These now commonly occur at elevations of over 300 ft (150 m) above sea level.

The general climatic pattern of these islands is set by their location relative to the two semipermanent centers of low pressure over the Aleutian Islands and over Iceland. Most of the precipitation is cyclonic in origin. Because they are marine areas, the islands receive more precipitation than they otherwise would, yet even so this is very light for most of the arctic islands removed from the zone of cyclonic activity. Also, because they are marine areas, the islands, regions of low temperatures by definition, are not regions of extreme low temperatures. In general, the larger the island and the closer its proximity to a continental landmass, the higher are the summer temperatures and the lower its winter temperature. *See* Polar meteorology.

The climatic differences between arctic and subarctic islands are reflected in their natural vegetation. The arctic islands are treeless. Natural vegetation consists of the tundra—mosses, sedges, lichens, grasses, and creeping shrubs. Bare ground is often exposed and in some places plant growth may be lacking completely except for a few rock-encrusting lichens. In such places the ground surface may consist of frost-shattered rock fragments, tidal mud flats, boulder-strewn fell fields, or snow patches and ice. Permafrost (permanently frozen ground) occurs throughout the Arctic (and in parts of the subarctic) and is reflected in impeded drainage and patterned ground. *See* Permafrost; Tundra.

The natural vegetation of subarctic islands characteristically is the boreal forest or taiga, composed predominantly of conifers such as spruce, fir, pine, and larch with deciduous trees such as birch, aspen, and willow; the latter are especially common in regrowth of clearings in the forest. Impeded drainage because of permafrost or glaciation gives rise to numerous ponds and muskeg areas. A transitional type of vegetation, the forest-tundra, is recognized on some subarctic islands in sectors where smaller trees are widely spaced and abundant mosses cover the ground. *See* Muskeg; Taiga.

Size of larger arctic and subarctic Islands*

	Area	
Name	mi^2	km^2
Aleutian Is.		
Unimak I.	15,500	40,100
Unalaska I.	10,800	28,000
St. Lawrence I.	18,200	47,100
Nunivak I.	16,000	41,400
Kodiak I.	37,400	96,900
Canadian Arctic Archipelago	500,000	1,295,000
Baffin I.	196,000	507,000
Ellesmere I.	76,000	197,000
Victoria	84,000	217,000
Banks	27,000	70,000
Devon	21,000	55,000
Axel Heiberg	17,000	43,000
Melville	16,000	42,000
Southhampton	16,000	42,000
Prince of Wales	13,000	33,033
Newfoundland	42,734	109,000
Greenland	840,000	2,176,000
Iceland	39,961	102,000
Svalbard (archipelago)	24,100	62,000
Vest-Spitsbergen	15,250	39,000
Franz Josef Land (archipelago)	7,000	18,000
Novaya Zemlya (archipelago)	36,000	93,000
Severny I.	21,000	54,000
Yughny I.	15,000	39,000
Severnaya Zemlya (archipelago)	14,000	36,000
New Siberian Is.	12,000	31,000
Wrangel I.	2,000	5,000
Sakhalin I.	27,000	70,000
Kuriloe Is.	6,000	16,000

*Approximate only in some cases because of incomplete mapping.

The typical soils of the subarctic islands are podzols—the grayish-white surface soil beneath the raw humus layer and highly acidic in nature. The tundra soils of the arctic islands really consist only of a dark-brown peaty surface layer over poorly defined thin horizons, and much of the ground cannot properly be termed soil. [W.C.Wo.]

Arctic Circle The parallel of latitude approximately $66^{1}/_{2}{}^{\circ}$ (66.55°) north of the Equator, or $23^{1}/_{2}{}^{\circ}$ from the North Pole. The Arctic Circle has the same angular distance from the Equator as the inclination of the Earth's axis from the plane of the ecliptic. Thus, when the Earth in its orbit is at the Northern Hemisphere summer solstice, June 21, and the North Pole is tilted $23^{1}/_{2}{}^{\circ}$ toward the Sun, the Sun's rays extend beyond the pole $23^{1}/_{2}{}^{\circ}$ to the Arctic Circle, giving that parallel 24 h of sunlight. On this same date the Sun's rays at noon will just reach the horizon at the Antarctic Circle, $66^{1}/_{2}{}^{\circ}$ south. The highest altitude of the noon Sun at the Arctic Circle is on June 21, when it is 47° above the horizon.

At the Arctic Circle the Sun remains above the horizon continuously only 24 h at the longest period. However, with twilight considered, it remains daylight or twilight continuously for about 5 months. Twilight can be considered to last until the Sun drops 18° below the horizon. *See* Mathematical geography; Solstice. [V.H.E.]

Arctic Ocean The north polar ocean lying between North Armerica and Asia, extending over about 386,000 mi^2 (10^6 km^2). It is nearly completely covered by 6–9 ft (2–3 m) of ice in winter, and in summer it becomes substantially open only at its peripheries. Its extent has been variably defined, but it is oceanogaphically appropriate to consider it bounded on the south by a line running from northern Greenland through Smith, Jones, and Lancaster sounds, along northwestern Baffin Island to the Canadian mainland, thence to the Alaskan coast, across Bering Strait, along the Siberian coast to Novaya Zemlya, across to Franz Josef Land and Spitsbergen, and over to northern Greenland. This definition omits the Barents, Norwegian, and Greenland seas and Baffin Bay, which have a pronounced North Atlantic character.

The central polar basin, somewhat triangular in shape, is surrounded by continental shelves which are interrupted only by the deep passage running through Fram Strait. The upper 650 ft (200 m) of the Arctic Ocean, referred to as Surface Water or Arctic Water, is characterized by a significant density stratification produced by the strong increase in salinity downward from the surface. This density stratification is of considerable importance, for it prevents a deep-reaching convection from developing within the Arctic Ocean and also prevents the heat of the underlying warm Atlantic Water from reaching the surface. The relatively low salinity at the surface is maintained against the upward diffusion of salt by the addition of fresh water, principally through river outflow. The upper 100–160 ft (30–50 m) of Surface Water tends to be relatively uniform vertically in temperature and salinity. Except for areas which become ice-free in summer, the water will be near the freezing point. Currents in the upper waters tend to be relatively slow (4 in./s or 10 cm/s or less), and they are similar in both speed and direction to the ice motion. The overall circulation in the upper waters has its ultimate cause in the prevailing wind pattern over the Arctic Ocean.

As in other oceans, the current at any instant can vary greatly from the mean condition. The most spectacular example observed in the Arctic Ocean occurs on an occasional basis in the Canadian Basin, consisting of a high-speed current core. *See* Ocean circulation; Seawater.

Below the Surface Water, the temperature increases to a maximum, which over most of the region is about 33°F (0.5°C) and lies between 1000 and 1500 ft (300 and 500 m). The salinity is nearly uniform, and since at low temperatures the density of seawater depends almost solely on salinity, there is virtually no density stratification beneath the upper waters. Significant deviations from the stated temperature occur only in the southern Eurasian Basin closest to Spitsbergen, for it is there that the warm and saline water (called Atlantic Water) which maintains the temperature maximum throughout the Arctic Ocean first enters. This water has its origin in the North Atlantic. Once into the Arctic Ocean it sinks because of its high salinity and moves eastward along the Eurasian continental slope. Beneath the Atlantic Water lies cold, nearly uniform Bottom Water. These two water masses together constitute over 90% of the volume of the Arctic Ocean. The Bottom Water is formed in the Greenland Sea. [K.A.]

Arcturus The brightest star in the northern sky, apparent magnitude -0.10, also known as α Boötis. It is a yellow giant star of spectral type K2, one of the nearest giants to the Earth at a distance of 11.3 parsecs (2.15×10^{14} mi or 3.47×10^{14} km). Unlike the Sun, which is currently converting hydrogen into helium in its core, Arcturus has already exhausted its central hydrogen and has evolved away from the main sequence. It is approximately 25 times larger in diameter than the Sun, and more than 100 times more luminous. Its effective temperature is estimated to be 7700°F (4300 K). *See* Spectral type; Stellar evolution.

Arcturus has a large space motion relative to the Sun, and it is a member of the high-velocity group of stars known as population II, associated with the halo of the Milky Way Galaxy. The pattern of chemical abundances is also quite typical of population II. *See* Stellar population.

Precise measurements have revealed small variations in the radial velocity of Arcturus with a period close to 2 days, which are believed to be due to pulsation. Variations with much longer periods of 1 or 2 years have also been reported. Similar variations have also been found in other giant stars. *See* Star. [D.W.L.]

Area The superficial contents of a geometrical figure of two dimensions. The area of any rectangle or square is the product of two adjacent sides, one of which may be called the base and the other the altitude. In general, any line segment that partially bounds a plane geometric figure may be called a base if its line does not separate the figure, and a perpendicular drawn to the base line from one of its points at greatest distance may be called the altitude. Some area formulas are given in the table. *See* Euclidean geometry. [J.S.F.]

Area formulas

Figure	Formula
Triangle	$\frac{hb}{2}$, where h = altitude, b = base; $\sqrt{s(s-a)(s-b)(s-c)}$, where $s = {}^1\!/_2(a+b+c)$, and a, b, and c are sides of the triangle
Rectangle	ab, where a and b are adjacent sides
Square	a^2, where a = side
Parallelogram	$ab \sin\theta$, where a and b are adjacent sides, and θ is the angle between the sides
Trapezoid	${}^1\!/_2(a+b)h$, where a and b are the parallel sides, and h is the altitude
Quadrilateral	${}^1\!/_2 ab \sin\theta$, where a and b are the diagonals, and θ is the angle between them
Regular polygon	${}^1\!/_4 nl^2 \cot \frac{180^\circ}{n}$, where n is the number of sides, each of length l
Circle	πr^2, where r = radius
Ellipse	πab, where a and b are semiaxes
Sphere	$4\pi r^2$, where r = radius
Spherical triangle	$(A+B+C-\pi)r^2$, where A, B, and C are angles (radians), and r is the radius

Arecales An order of flowering plants, division Magnoliophyta (Angiospermae), of the subclass Arecidae in the class Liliopsida (monocotyledons). The name of the subclass is derived from the ordinal name. The order consists of the single family Arecaceae (Palmae), the palms, with more than 200 genera and nearly 3000 species, largely confined to tropical and subtropical regions. The order Arecales has also been called Palmales or Principes. Most palms are trees with an unbranched trunk and a terminal crown of large leaves. The plicate structure of all palm leaves relates to a complex ontogeny shared only by some of the Cyclanthaceae (Cyclanthales), in which new tissue continues to develop along the folds after the flanking tissues have matured. *See* Arecidae; Carnauba wax; Coconut; Cyclanthales; Date; Liliopsida; Magnoliophyta; Plant kingdom; Vegetable ivory. [A.Cr.; T.M.Ba.]

Arecidae A subclass of the class Liliopsida (monocotyledons) of the division Magnoliophyta (Angiospermae), the flowering plants, consisting of four orders (Arecales, Cyclanthales, Pandanales, and Arales), five families, and nearly 6000 species. Except for the highly reduced family Lemnaceae (Arales), they have an inflorescence of usually numerous, small flowers, generally subtended by a prominent spathe and often aggregated into a spadix. Except in the Araceae (Arales), the endosperm seldom contains much starch. More than 80% of the species have broad, petiolate leaves that do not have the typical parallel venation commonly associated with monocotyledons, and more than half of the species are arborescent (likewise an unusual character among the monocotyledons). *See* Arales; Arecales; Cyclanthales; Liliopsida; Magnoliophyta; Pandanales; Plant kingdom. [A.Cr.; T.M.Ba.]

Arenaceous rocks The arenaceous rocks (arenites) include all those classic rocks whose particle sizes range from 0.8 to 0.0025 in. (2 to 1/16 mm), or if silt is included, to 1/256 mm. Some arenites are composed primarily of carbonate particles, in which case they are called calcarenites and grouped with the limestones. Some oolitic iron ores and glauconite beds are properly classified as arenites. But the vast majority of arenites are commonly called sandstones, and the two words are almost synonymous. *See* Graywacke; Oolite; Sandstone; Sedimentary rocks. [R.Si.]

Argillaceous rocks The argillaceous rocks (lutites) include shales, argillites, siltstones, and mudstones; they are clastic sediments whose constituent particles are less than 0.0025 in. or 1/16 mm (if siltstones are included) or less than 0.00015 in. or 1/256 mm (if siltstones are excluded). They are the most abundant sedimentary rock type, varying according to different estimates from 44 to 56% of the total sedimentary rock column. Claystone is indurated clay, which consists dominantly of fine material of which at least a major proportion is clay mineral (hydrous aluminum silicates). Shale is a laminated or fissile claystone or siltstone, in general more consolidated than claystone. Mudstone is a claystone that is blocky and massive. The term argillite is used for rocks which are more indurated than claystone or shale but not metamorphosed to slate. All these argillaceous rocks are consolidated equivalents of muds, oozes, silts, and clays. Loess is a finegrained, unconsolidated, wind-blown deposit. The term shale has been used by many authors generically to denote all of these types of rock. *See* Bentonite; Clay; Clay minerals; Loess; Sedimentary rocks; Shale. [R.Si.]

Argon A chemical element, Ar, atomic number 18, and atomic weight 39.948. Argon is the third member of group 0 in the periodic table. The gaseous elements in this group are called the noble, inert, or rare gases, although argon is not actually rare. The Earth's atmosphere is the only natural argon source; however, traces of this gas are found in minerals and meteorites. Argon constitutes 0.934% by volume of the Earth's atmosphere. Of this argon, 99.6% is the argon-40 isotope; the remainder is argon-36 and argon-38. There is good evidence that all the argon-40 in the air was produced by the radioactive decay of the radioisotope potassium-40. *See* Inert gases; Periodic table.

Argon is colorless, odorless, and tasteless. The element is a gas under ordinary conditions, but it can be liquefied and solidified readily. Some salient properties of the gas are listed in the table. Argon does not form any chemical compounds in the ordinary sense of the word, although it does form some weakly bonded clathrate compounds with water, hydroquinone, and phenol. There is one atom in each molecule of gaseous argon.

The oldest large-scale use for argon is in filling electric light bulbs. Welding and cutting metal consumes the largest amount of argon. Metallurgical processing constitutes the most rapidly growing application. Argon and argon-krypton mixtures are used, along with a little mercury vapor, to fill fluorescent lamps. Argon mixed with a little neon is used to fill luminous electric-discharge tubes employed in advertising signs (similar to neon signs) when a blue or green color is desired instead of the red color of neon. Argon is also used in gas-filled thyratrons, Geiger-Müller radiation counters, ionization chambers which measure cosmic radiation, and electron tubes of various kinds. Argon atmospheres are used in dry boxes during manipulation of very reactive chemicals in the laboratory and in sealed-package shipments of such materials.

Most argon is produced in air-separation plants. Air is liquefied and subjected to fractional distillation. Because the boiling point of argon is between that of nitrogen and oxygen, an argon-rich mixture can be taken from a tray near the center of the upper distillation column. The argon-rich mixture is further distilled and then warmed and catalytically burned with hydrogen to remove oxygen. A final distillation removes hydrogen and nitrogen, yielding a very high-purity argon containing only a few parts per million of impurities. [A.W.F.]

Properties of argon

Property	Value
Atomic number	18
Atomic weight (atmospheric argon)	39.948
Melting point (triple point), °C	−189.4
Boiling point at 1 atm pressure, °C	−185.9
Gas density at 0°C and 1 atm (101.325 kPa) pressure, g/liter	1.7840
Liquid density at normal boiling point, g/ml	1.3998
Solubility in water at 20°C, ml argon (STP) per 1000 g water at 1 atm (101.325 kPa) partial pressure of argon	33.6

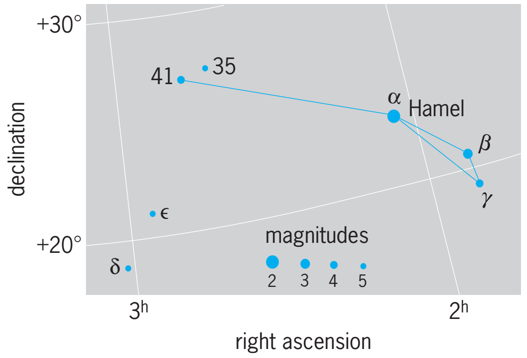
Arhynchobdellae An order of the class Hirudinea (the leeches) which do not have an eversible proboscis, but frequently have three jaws armed with sharp teeth. The blood of these annelids contains hemogloblin. They may be divided into the Gnathobdellae, with jaws, and the Pharyngobdellae, without jaws.

Erpobdella punctata.

Gnathobdellae have bodies which are oval in cross section and have a conspicuous posterior sucker. The anterior sucker does not project beyond the sides of the body but forms a deep cup on the underside of the head in which the jaws can work to make their incision in the host. This group contains most of the important bloodsucking leech parasites of humans and other warm-blooded animals. The land leeches are members of this group. They occur in great numbers on vegetation in swamp and jungle areas and attach themselves to passing warm-blooded animals.

Pharyngobdellae are specialized for carnivorous diets, and in many cases have completely lost the jaws. They have a strong muscular pharynx which extends nearly half the length of the body. *Erpobdella* (*see* illustration) is common in lakes and streams in the Northern Hemisphere, while *Trocheta* tends to leave the water and forage in moist soil. *See* Hirudinea; Rhynchobdellae. [K.H.M.]

Aries The Ram, in astronomy, a zodiacal and autumnal constellation (see illustration). Among the 12 zodiacal constellations, Aries was considered as the first, because about 2000 years ago when the zodiacal constellations were organized, the Sun was in Aries where it crossed the equator at vernal equinox. Today, because of the precession of the equinoxes, this reference point has moved into the constellation Pisces. However, Aries remains the first sign of the zodiac. *See* Constellation. [C.-S.Y.]



Line pattern of constellation Aries. Grid lines represent the coordinates of the sky. Apparent brightness, or magnitudes, of stars are shown by sizes of the dots, which are graded by appropriate numbers as indicated.

Aristolochiales An order of flowering plants, division Magnoliophyta (Angiospermae), in the subclass Magnoliidae of the class Magnoliopsida (dicotyledons). It contains only the family Aristolochiaceae, with seven genera and about 600 species, most of them in tropical and subtropical regions. Within its subclass the order is marked by the presence of ethereal oil cells, by its uniaperturate or nonaperturate pollen, and especially by its strongly perigynous to epigynous flowers, usually with united carpels, that typically lack petals and have the sepals joined into a highly irregular, corolloid calyx. Many of the species are climbing vines. *Aristolochia* (birthwort or Dutchman's pipe) and *Asarum* are well-known genera of the order. *See* Flower; Magnoliidae; Magnoliophyta; Magnoliopsida; Pollen; Rafflesiales. [A.Cr.]

Arithmetic A branch of mathematics dealing with numbers, operations on numbers, and computation. Arithmetic is useful in solving many practical problems, such as buying, selling, budgets, sports statistics, and measurement. The usual numbers of arithmetic are whole numbers, fractions, decimals, and percents. Beyond the numbers of arithmetic are negative numbers, rational numbers, and irrational numbers. The rational and irrational numbers together constitute the real numbers.

Whole numbers. The whole numbers include the infinite sequence of counting numbers—one, two, three, four, five,. . . — and the number zero. For numbers to ten, a single symbol is used, and for larger numbers a combination of symbols.

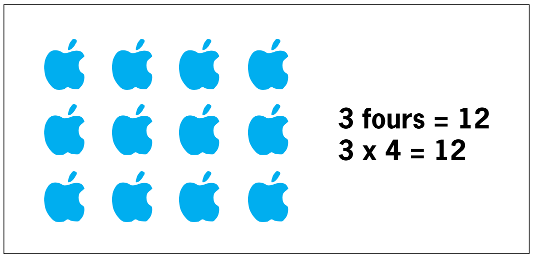
Numbers to ten are designated with a single digit: 0, 1, 2, 3, 4, 5, 6, 7, 8, and 9. Numbers ten and greater are expressed by using a combination of the ten digits, with the place of the digit indicating the value of the digit. This place-value system, named the Hindu-Arabic numeration system, is now used around the world.

In a multidigit numeral, the value of each place from right to left is a successive power of ten, and the total values for all places are combined or added.

Operations. The basic operations are addition (+) and multiplication (× or ·), with subtraction (−) and division (÷) defined, respectively, by using addition and multiplication.

If two numbers, *a* and *b*, are combined or added, the result is a number, *c*, called the sum. In the example 4 + 6 = 10, 4 and 6 are addends and 10 is the sum. The whole amount, 10, is the result of combining two parts, 4 and 6.

If a given number, *n*, sets of objects with the same number in each set, *r*, are combined, then multiplication of *n* and *r* is the total number of objects. In 3 × 4 = 12, 3 and 4 are factors and 12 is the product (see illustration).



One meaning of multiplication.

Subtraction is the inverse operation to addition, finding an addend when a sum and one addend are known. If there are 18 children on the playground and 10 are boys, then the number of girls is 18 − 10 or 8, illustrating that the whole minus a part leaves the other part. Subtraction is used also to find the difference, for example, to see how many more are in one group of 18 children than in a group of 10 children. Subtraction is checked with addition; 18 − 10 = 8 because 8 + 10 = 18.

Division is the inverse operation to multiplication, that is, finding a factor when a product and a factor are known. In 12 ÷ 3 = 4, 12 is called the dividend, 3 is called the divisor, and 4 is the quotient.

Fractions and decimals. Understanding fractions and decimals, as well as operations on these numbers, is essential for practical uses and for long-term memory.

The initial and most basic idea is that a fraction shows "part of a whole." In the fraction 3/4, read "three-fourths," the 4 shows the number of equal-size pieces in each whole unit as well as the size of one piece, "fourth." The 3 shows the number of equal-size pieces being taken or considered. The top number, 3, "numbers" the parts and is called the numerator. The bottom number, 4, "names" the parts and is called the denominator.

To show decimals less than one, the place value system for whole numbers is extended to the right of the ones place. The value of each place to the right is a successive power of 1/10. The decimal point is needed to designate the ones place because the place on the right is no longer the ones place. The decimal point also separates the whole number from the decimal part.

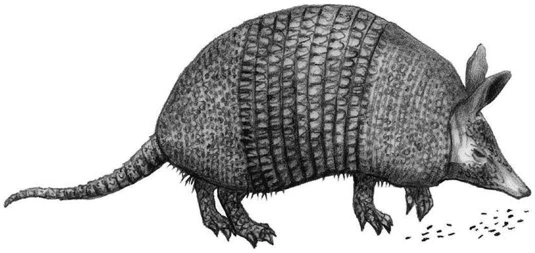
Percent is another way to express fractions and decimals that show hundredths. For example, 7 hundredths can be expressed as 7/100, as 0.07, or as 7%. All three expressions show the same part of a whole. *See* Percent. [J.N.P.]

Arkose An arenaceous rock that contains a high proportion of feldspar in addition to quartz and other detrital minerals. Arkose is also known as feldspathic sandstone. Although there is no universal agreement, many geologists consider a minimum of 25% feldspar a requisite for calling sandstone an arkose. Other geologists accept a lower value. Arkoses may contain a high proportion of other nonquartz detritus, such as igneous and metamorphic rock fragments, micas, amphiboles, and pyroxenes. Frequently the accessory heavy mineral suite consists of a variety of species.

Sedimentary structures of arkoses are similar in kind to those of the orthoquartzites. Cross-bedding, the major feature, may be displayed on a huge scale, some cross-bedded units being many feet thick. Arkoses are associated with a variety of clastic rocks, dominantly conglomerates, and reddish-colored shales. Arkoses also are found with basic lava flows. Most arkoses are found in geosynclinal areas, but the thin, reworked, granite wash arkoses can be found on stable continental platforms. *See* GEOSYNCLINE.

The granite-wash arkoses appear to have formed as the result of a transgression of the sea over a land area underlain by granite. The fragmented granite in the soil and mantle rock is incorporated in the basal sediment. In some areas the original granite is changed so slightly that the arkose is called recomposed granite and may be almost indistinguishable from the original granite. Since high relief and climatic extremes generally are associated with orogenic movements, arkoses are usually interpreted as sediments that result from tectonically active regions. *See* ARENACEOUS ROCKS; FELDSPAR; GRAYWACKE; SANDSTONE; SEDIMENTARY ROCKS. [R.Si.]

Armadillo The name for 21 species of mammals of the order Edentata, a group characterized by the lack of enamel on their teeth. They are indigenous to the New World, especially South America.



Nine-banded armadillo (*Dasypus novemcinctus*).

Armadillos range in size from the lesser pichiciego or fairy armadillo (*Chlamyphorus truncatus*), in which the adult is about 5 in. (7.5 cm) long, to the giant armadillo (*Priodontes giganteus*), which is about 4 ft (1.2 m) in length. The body is covered with horny dermal scales that replace the hair common to most mammals and overlay bony plates. These structures fuse to form rigid shields covering the anterior and posterior ends of the animal, whereas in the midregion they form jointed bands allowing a certain amount of flexibility. The giant armadillo has about 100 teeth, more than any other land mammal. The snout is long, and the tongue is cylindrical and viscous to assist in capturing food. The toes are clawed and are used by the animal to dig into ant and termite colonies for food, as well as for burrowing. When disturbed, many species roll into a ball or wedge themselves into the opening of a burrow.

The nine-banded armadillo (*Dasypus novemcinctus*; see illustration) is the best-known species and ranges from South America to the southwestern and southern United States. It is the only edentate which inhabits the United States, ranging from the Rio Grande area to Oklahoma and eastward along the coast to Louisiana. The nine-banded armadillo has been studied because of its unusual life cycle. Four young are born in a den or chamber at the end of the burrow. The young are always of the same sex and are identical quadruplets. *See* DENTITION; EDENTATA. [C.B.C.]

Armature That part of an electric rotating machine which includes the main current-carrying winding. The armature winding is the winding in which the electromotive force (emf) produced by magnetic flux rotation is induced. In electric motors this emf is known as the counterelectromotive force.

On machines with commutators, the armature is normally the rotating member. On most ac machines, the armature is the stationary member and is called the stator. The core of the armature is generally constructed of steel or soft iron to provide a good magnetic path, and is usually laminated to reduce eddy currents. The armature windings are placed in slots on the surface of the core. On machines with commutators, the armature winding is connected to the commutator bars. On ac machines with stationary armatures, the armature winding is connected directly to the line. *See* COMMUTATOR; CORE LOSS; WINDINGS IN ELECTRIC MACHINERY. [A.R.E.]

Armature reaction The effects of the magnetomotive force (mmf) of the armature on the air-gap field of direct-current (dc) and synchronous alternating-current (ac) machines. Since armature current varies directly with the electrical or mechanical load on the machine, armature-reaction effects are load-dependent. In dc machines, the armature reaction causes a distorted flux-density distribution in the air gap. Due to the saturation of the armature teeth, the flux density is decreased by a greater amount under one pole tip than it is increased under the other, and therefore the armature reaction produces a demagnetizing effect, and the generated voltage or countervoltage will be reduced when the armature is loaded. In a generator this degrades the voltage regulation. In a motor it tends to increase the speed and may cause instability.

For dc machines subject to heavy overloads, rapidly reversing loads, or operation with a weak field, the resultant flux-distribution distortion by excessive armature reaction will cause nonuniform distribution of voltage between commutator segments, and may result in flashover between commutator segments. A pole-face (or compensating) winding, embedded in slots in the pole face and excited by armature current, is provided to neutralize the armature mmf under the pole faces. [G.McP.]

Army armament The weapons, equipment, and supplies that permit lethal or nonlethal devices to strike their targets. Armaments can be classified as field artillery, individual and crew-served weapons (infantry), armor and antiarmor, antiaircraft, helicopter armaments, and mines and countermines.

Field artillery. Artillery can deliver highly lethal warheads to ranges well beyond the reach of infantry weapons. Artillery includes rockets, missiles, and self-propelled and towed howitzers (cannon). Artillery fire support is designed to meet adversarial forces by attacks on personnel and on medium and hard targets such as troop carriers and tanks. This mission is conducted at extended ranges with high-explosive projectiles, projectiles with shaped-charge submunitions, and the Copperhead guided projectile. Artillery can also channel, delay, and destroy oncoming forces by delivery of antipersonnel and antitank mines. Future goals include the use of smart munitions; increased range, lethality, and firing rates; new propulsion techniques; cartridge course correction in flight; and systems which permit much greater battlefield versatility.

Individual and crew-served weapons (infantry). Infantry armament is composed largely of line-of-sight, direct-fire weapons and indirect-fire mortar weapons used by nonmechanized light infantry (60-mm and 81-mm mortars) and mechanized infantry and armor divisions (120-mm mortars).

Many small-caliber weapons have been introduced as replacements or additions to the inventory. Improvements in hit probability, combat load, and target acquisition of small-caliber weapons over those of the current systems are being pursued. The long-term objective is a family of small arms that may feature composite materials, bursting ammunition, laser fire control, night-vision devices, and microelectronics.

The U.S. Army uses three mortar weapon systems: the 60-mm M224 lightweight company mortar, the 81-mm improved M252 mortar, and the 120-mm M120 mortar. The 107-mm M30 mortar has been replaced by the 120-mm M120 mortar (towed and ground mounted) and the 120-mm M121 mortar (carrier mounted). Each type of mortar fires a family of projectiles, including high-explosive, smoke, illuminating, and full-range and short-range practice cartridges.

The primary shoulder-launched infantry munitions consist of the AT4 recoilless rifle and the shoulder-launched multipurpose assault weapon-disposable (SMAW-D) bunker defeat munition.

Armor and antiarmor. The primary armored weapon systems consist of the M1 and M1A1 main battle Abrams tanks; the more lightly armored Bradley M2 infantry and M3 cavalry fighting vehicles; and the M113 family of armored personnel carriers. Major thrusts in armament development have resulted in conversion of the rifled 105-mm cannon in the M1 tank to the 120-mm smoothbore cannon in the M1A1 tank, and the utilization of tungsten and depleted-uranium long-rod penetrators for maximum antiarmor effectiveness. Increased protection against penetration by kinetic-energy and shaped-charge ammunition has been provided by the use of laminate Chobham-type armor and reactive armor.

Air defense. There are a number of air defense weapons. These include the Avenger Air Defense System, the hand-held Stinger rocket, and the Patriot system.

The Stinger is a human-portable, shoulder-fired, two-stage, infrared homing missile, designed to attack and destroy at short range any low-altitude, fixed- and rotary-wing aircraft with a high-explosive fragmentation warhead. The Stinger is to be replaced by the Linebacker Air Defense System.

The Avenger Air Defense System is mounted on a Humvee (high-mobility multipurpose wheeled vehicles; HMMWV). It is lightweight and transportable and designed to counter enemy cruise missiles, crewless aerial vehicles, and low-flying fixed-wing or rotary aircraft.

The Patriot system fires MIM-104 surface-to-air missiles at attacking aircraft and missiles at ranges up to 37.3 mi (62.3 km), providing medium- and high-altitude defense. It was used in the first Persian Gulf War to defend against Iraqi-launched SCUD missiles.

Helicopter armaments. The major combat aircraft used in support of ground operations are the AH-64 Apache and the AH-1 Cobra attack helicopters. Both helicopters are highly mobile and are capable of destroying moving armored columns and other point and area targets on the modern battlefield. *See* HELICOPTER.

Mines. The U.S. Army places great emphasis on the use of mines in modern warfare. A family of mines and modes of delivery have been developed, which include scatterable antipersonnel and antitank mines (family of scatterable mines; FASCAM) that have high utility because they can be emplaced by artillery, aircraft, and ground vehicles at close-in and extended ranges. They are autonomous after deployment, are effective over a time period, and self-destruct to permit occupation of the area by friendly forces. [J.Ru.; G.Pa.; J.We.]

Aromatic hydrocarbon

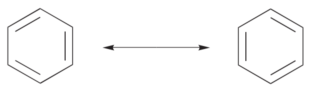
A hydrocarbon with a chemistry similar to that of benzene. Aromatic hydrocarbons are either benzenoid or nonbenzenoid. Benzenoid aromatic hydrocarbons contain one or more benzene rings and are by far the more common and the more important commercially. Nonbenzenoid aromatic hydrocarbons have carbon rings that are either smaller or larger than the six-membered benzene ring. Their importance arises mainly from a theoretical interest in understanding those structural features that impart the property of aromaticity.

Benzenoid aromatic hydrocarbons are also called arenes. Benzene itself is the prototypical arene. The properties associated with aromaticity have little to do with aroma, although the aromatic hydrocarbons were first studied in connection with naturally occurring fragrances. Instead, these compounds possess special stability; take part in certain types of reactions; and exhibit persistence of the structural integrity of aromatic rings during chemical reactions, while groups attached to those rings are chemically altered or manipulated.

Benzene. With molecular formula (**1**), benzene is highly unsaturated; it has three double bonds, alternating with single bonds. The double bonds in the benzene structure can be arranged in two ways, (**1′**) and (**1″**). Benzene is a resonance hybrid of these two structures, called Kekulé structures; the double-headed arrow is used to signify that the benzene structure is neither (**1′**) nor (**1″**), but a single structure that is a hybrid of the two. That is, the bonds between adjacent carbon atoms are neither double nor single, but of some intermediate or hybrid type.

C_6H_6

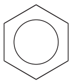
(**1**)



(**1′**) (**1″**)

Each carbon atom in benzene is connected to three atoms, two adjacent carbon atoms and a hydrogen atom. These three bonds lie in a single plane and use three of the carbon's four valence electrons. The fourth valence electron of each carbon is located in a *p* orbital, extending perpendicularly above and below the plane of the other three bonds. These electrons, one from each carbon atom and called π electrons, form three molecular orbitals located above and below, but parallel to, the plane of the ring.

The symbol of a hexagon with an inscribed circle (**2**) is often used to express the delocalized nature of the π electrons in benzene and other arenes. There is physical evidence that the π electrons circulate around the ring carbons, as implied by this formula. For example, in the nuclear magnetic resonance (NMR) spectra of arenes, the chemical shifts of arene hydrogen atoms (protons) are characteristically at lower magnetic fields than those of protons attached to carbon-carbon double bonds. This difference is due to an induced magnetic field caused by circulation of the π electrons in the molecular orbitals above and below the arene ring plane. Indeed, this chemical shift difference, due to a diamagnetic ring current, is sometimes used as evidence for aromaticity in nonbenzenoid aromatic hydrocarbons. *See* DELOCALIZATION.

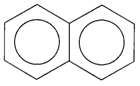


(**2**)

Other arenes. Besides benzene itself, several alkylbenzenes are commercially important and produced on a large scale—millions of pounds annually. Production is commonly by the cyclodehydrogenation of alkanes at high temperatures over metallic catalysts such as platinum.

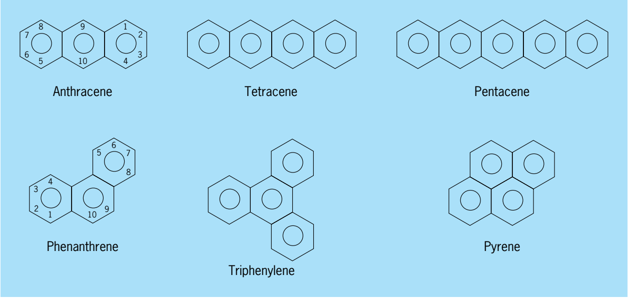
Benzene, toluene, and the xylenes are added to unleaded gasoline to raise the octane number. These arenes are also essential to the petrochemical industry. Products derived from them include polyesters, polyurethanes, polystyrene, and synthetic rubber; alkylbenzenesulfonate detergents; phenol and acetone; pharmaceuticals, flavors, and perfumes; plasticizers; and many others. *See* PETROCHEMICAL.

Arenes with fused rings are also known as polynuclear aromatic hydrocarbons. Rings are said to be fused when they share two carbon atoms. The simplest example is naphthalene (**3**), a colorless crystalline compound found in coal tar, best known as a moth repellent.



(**3**)

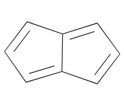
Additional arene rings can be fused. For example, anthracene, tetracene, and pentacene are linearly fused, while phenanthrene, triphenylene, and pyrene are angularly fused (see illustration). In general, angular fusion results in more stable systems than linear fusion. Phenanthrene, for example, is about 6 kcal/mol more stable than its linear isomer anthracene. Stability falls off



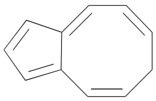
Structures of some fused-ring (polynuclear) aromatic hydrocarbons.

sharply in the linearly fused series, and compounds with more than seven such rings are unknown.

Hückel rule. From molecular orbital theory, E. Hückel derived the rule that planar, cyclic conjugated (alternate single and double bonds) systems with $4n + 2\pi$ electrons (n is an integer, 0, 1, 2 . . .) will be aromatic and have substantial resonance energy, whereas those with $4n$ such electrons will not; indeed, it was later shown that $4n$ systems are often destabilized, hence antiaromatic. Benzene is a $4n + 2$ system ($n = 1$) and aromatic. As striking confirmation of these ideas, pentalene (**4**), a planar analog of cyclooctatetraene, is exceptionally reactive, unstable, and antiaromatic (a $4n$ system, $n = 2$), whereas the purple hydrocarbon azulene (**5**; a $4n = 2$ system, $n = 2$, and an isomer of naphthalene) is stable and undergoes substitution reactions analogous to those of benzenoid arenes. [H.Ha.]



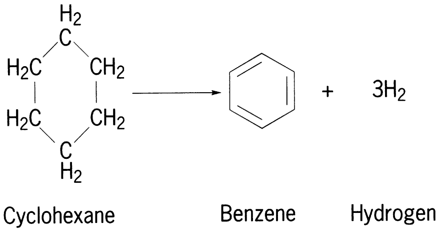
(**4**)



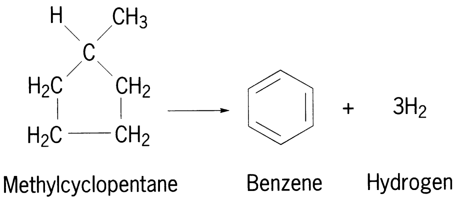
(**5**)

Aromatization

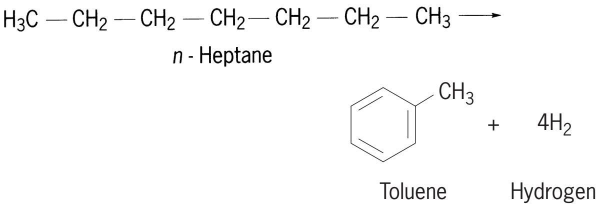
Aromatization The conversion of any nonaromatic hydrocarbon structures, especially those found in petroleum, to aromatic hydrocarbons. There are numerous routes and means to accomplish this transformation, the simplest and most important of which are direct dehydrogenation of naphthenes to aromatics, reaction (1); dehydroisomerization of naphthenes to aromatics, reaction (2); dehydrocyclization of aliphatics to aromatics, reaction (3); and high-temperature condensation of hydrocarbons to aromatics, reaction (4).



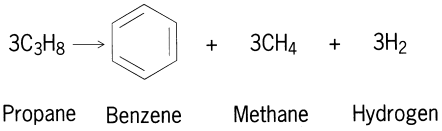
(1)



(2)



(3)



(4)

Reforming of naphthas with catalysts comprising small amounts of platinum on an acidified alumina support accomplishes reactions (1), (2), and (3) readily and simultaneously. It is a major process for benzene, toluene, and other aromatics from petroleum sources.

Reaction (4) illustrates one type of reaction that may occur in the high-temperature (600–800°C or 1100–1500°F) thermal cracking of petroleum fractions. *See* PETROLEUM PROCESSING AND REFINING. [B.S.G.; M.Sou.]

Arsenic

Arsenic A chemical element, symbol As, atomic number 33. Arsenic is found widely distributed in nature (approximately 5×10^{-4} of the Earth's crust). It is one of the 22 known elements composed of only one stable nuclide, $_{33}^{75}\mathrm{As}$; the atomic weight is 74.92158. There are 17 other radioactive arsenic nuclides known.

There are three polymorphic modifications of arsenic. The yellow cubic α-form is made by condensing the vapor at very low temperatures. The black β-polymorph is isostructural with black phosphorus. Both these modifications revert to the stable γ-form, gray or metallic, rhombohedral arsenic, on heating or exposure to light. The metallic form is a moderately good thermal and electric conductor and is brittle, easily fractured, and of low ductility.

Arsenic is found native as the mineral scherbenkobalt, but generally occurs among surface rocks combined with sulfur or metals such as Mn, Fe, Co, Ni, Ag, or Sn. The principal arsenic mineral is FeAsS (arsenopyrite, mispickel); other metal arsenide ores are $FeAs_2$ (löllingite), NiAs (nicolite), CoAsS (cobalt glance), NiAsS (gersdorffite), and $CoAs_2$ (smaltite). Naturally occurring arsenates and thioarsenates are common, and most sulfide ores contain arsenic. As_4S_4 (realgar) and As_4S_6 (orpiment) are the most important sulfur-containing minerals. The oxide, arsenolite, As_4O_6 is found as the product of the weathering of other arsenical minerals, and is also recovered from flue dusts collected during the extraction of Ni, Cu, and Sn from their ores; it also results when the arsenides of Fe, Co, or Ni are roasted in air or oxygen. The element may be obtained by roasting FeAsS or $FeAs_2$ in the absence of air or by reduction of As_4O_6 carbon, when As_4 may be sublimed away.

Elemental arsenic has few uses. It is one of the few minerals available in 99.9999+% purity, which is largely used in the laser material GaAs and as a doping agent in the manufacture of various solid-state devices. Arsenic oxide is used in glass manufacture. The arsenic sulfides are used as pigments and in pyrotechnics. Dihydrogen arsenate is used in medicine, as are several other arsenic compounds. Most of the medicinal uses of arsenic compounds depend on their toxic nature. *See* ANTIMONY; PHOSPHORUS. [J.L.T.W.]

Arsenopyrite

Arsenopyrite A mineral having composition FeAsS and crystallizing in the monoclinic system. Crystals have pseudo-orthorhombic symmetry because of twinning. The Mohs hardness is 5.5–6.0, and the specific gravity is 6.0. The luster is metallic and the color silver-white. Arsenopyrite is the most widespread arsenic-bearing mineral. It is commonly found in veins containing gold (Lead, South Dakota; Deloro, Ontario), tin or tungsten minerals (Bolivia; Cornwall, England), or nickel-cobalt-silver minerals (Cobalt, Ontario; Freiberg, Germany). *See* ARSENIC. [L.Gr.]

Art conservation chemistry The application of chemistry to the technical examination, authentication, and preservation of cultural property. Chemists working in museums engage in a broad range of investigations, most frequently studying the chemical composition and structure of artifacts, their corrosion products, and the materials used in their repair, restoration, and conservation. The effects of the museum environment, including air pollutants, fluctuations in temperature and relative humidity, biological activity, and ultraviolet and visible illumination, represent a second major area of research. A third area of interest is the evaluation of the effectiveness, safety, and long-term stability of materials and techniques for the conservation of works of art. Though analytical techniques appear to dominate, many other areas of chemistry, biology, physics, and engineering, including polymer chemistry, kinetic studies, imaging methodologies, biodegradation studies, dating methods, computer modeling, metallography, and corrosion engineering, play active roles in conservation science.

Methods of examination may be divided into two classes: those that provide an image of the entire object (holistic examination) or a section of it; and those that provide an analysis at a point on the object, with or without sampling. Nondestructive methods, not requiring sampling, are always preferable. However, modern methods of analysis can be employed on such minute samples that they are in effect nondestructive. In some cases, samples must be taken for methods that are in principle nondestructive because the object is too large to fit into a sample chamber. The ability to analyze minute samples introduces the serious concern that the sample may not be representative of the composition of the artifact but may be an inclusion or contaminant introduced by the experimentalist. With specimens from painted surfaces, great care must be taken to identify areas of restoration.

A further concern arises from the differing depths from which signals originate. On a metal surface, ion scattering spectrometry (ISS) would see the initial fraction-of-a-nanometer, predominantly adsorbed species and contaminants. Secondary ion mass spectrometry (SIMS) would begin to penetrate the oxidized area; Auger electron spectrometry (AES) would examine the bulk of the oxidized layer; and x-ray-induced photoelectron spectrometry (XPS) would give data on the bulk sample some 10 nm below the specimen surface. *See* ACTIVATION ANALYSIS; ANALYTICAL CHEMISTRY; AUGER EFFECT; SURFACE PHYSICS; X-RAY.

The most commonly employed holistic method is x-ray radiography, where variations in the density and average atomic number of the sample attenuate an x-ray beam, leaving a negative image on film. Other methods, such as ultraviolet and infrared reflectance and fluorescence, are used to show areas of compositional difference indicating restoration or variation in the pigments used by the artist. *See* INFRARED IMAGING DEVICES; INFRARED RADIATION; LUMINESCENCE ANALYSIS; RADIOGRAPHY; ULTRAVIOLET RADIATION.

In the examination of paintings, small samples are taken under the binocular microscope, embedded in transparent resin, and polished to produce a cross section for microscopic examination. This permits a study of the artist's painting technique and shows how several layers may have been built up to achieve a desired effect. Conservation studies of the composition and technique embrace the entire spectrum of modern chemical analysis. *See* CHEMICAL MICROSCOPY; IMAGE PROCESSING; MICROSCOPE.

The separation of the fake from the authentic is a small but often spectacular aspect of the technical examination of artifacts. In some cases, direct age determination (dendrochronology for panel paintings, fission track dating for uranium glass, radiocarbon dating for organic materials, thermoluminescence dating for ceramics) is possible. *See* ARCHEOLOGICAL CHRONOLOGY; DATING METHODS; DENDROCHRONOLOGY; FISSION TRACK DATING; RADIOCARBON DATING.

More commonly, the issue of authenticity turns upon anachronisms in composition or technique when the artifact in question is compared to accepted artifacts of the period. Thus, the greater part of the work in the conservation laboratory concerns the building of databases of analyses of composition, trace-element distributions, and studies of technique.

Many artifacts are sensitive to destructive agents in the museum atmosphere. Rapid changes in relative humidity will cause dimensional changes in wood furniture, polychrome sculpture, and panel paintings, leading to cracking and splitting of the wood with loss of painted surface decoration. High relative humidity can lead to mold growth and foxing on books and prints, while low relative humidity will cause photographic prints and films to become brittle.

Oxidation of iron objects, tarnishing of silver plate, and the development of corrosion products on lead artifacts by the action of formic and acetic acids emitted by wooden display cases have regularly been observed in museums.

The common air pollutants sulfur dioxide (SO_2) and ozone (O_3) have been monitored at elevated levels in museums, libraries, and archives. These pollutants cause the degradation of leather, spotting of photographic prints, and fading of dyes and pigments. Chemical methods of analysis are used to identify degradation products and to study the kinetics of degradation mechanisms. Specialists in air-pollution monitoring use analytical instrumentation to measure ambient pollution levels in museums. [N.S.B.]

Arteriosclerosis The name given a group of degenerative diseases of arteries characterized by thickening and hardening of their walls. The group includes three types of lesions: (1) atherosclerosis involves the aorta and its major branches; (2) medial sclerosis involves the muscular arteries of the legs; and (3) arteriolosclerosis involves the small branches of the arterial tree, called the arterioles.

Atherosclerosis is by far the most common and important form of arteriosclerosis, and the two terms are often used interchangeably. Atherosclerosis has global distribution and occurs in virtually epidemic proportions in the Western industrialized nations. Factors associated with the high incidence and severity of atheromas (anatomic lesions of atherosclerosis) include a high total caloric intake, high fat intake, sedentary living, aggressive personality, emotional stress, and cigarette smoking. Hypertension (high blood pressure) does not induce arteriosclerosis, but it augments its development and accelerates the progress of the disease if it is present. The excessive incidence of myocardial infarction (heart attack) in cigarette smokers has been clearly documented. High blood lipid levels especially of cholesterol and triglycerides are also associated with higher incidence. The strong supposition thus arose that environmental and nutritional factors are of prime etiologic importance in the development of the disease, although the specific cause has not been identified. *See* HEART DISORDERS; HYPERTENSION.

Atheromas begin within the lining layer of the aorta (intima) or its branches and subsequently extend into the middle layer (media) of these vessels. The basic lesion has been shown to be a focal overgrowth of the smooth muscle cells of these layers, possibly following from a mutation. The cells subsequently degenerate, producing an accumulation of lipids in their cytoplasm, then necrosis, and finally calcification and scarification. As these lesions enlarge in the intima, the overlying endothelial cells may become disrupted, and fibrin clots are deposited on the surface. The lumen of the vessel is diminished in diameter (stenosis) by both the atheromatous plaque and the overlying clot. The occurrence of successive layers of clots and enlarging plaque produces narrowing of the lumen. If the process involves all layers of the arterial wall, it may weaken the wall, and an aneurysm may result.

When the atherosclerotic process occurs in the smaller branches of the aorta, complete occlusion may occur. If the process takes place in the vessels supplying blood to the heart muscle (coronary arteries), the blood supply may be restricted or stopped completely, producing a myocardial infarction. If the process involves the arteries supplying the brain, hemorrhage and stroke may occur. If arteries leading to the legs, arms, or internal organs are occluded, gangrene may result. Because of these sequelae, atherosclerosis assumes awesome importance as the major cause of death in the United States. *See* HEMORRHAGE.

Although the vast majority of cases of atherosclerosis appear to be principally caused by environmental factors, there are some specific genetic defects associated with the genesis of the process. Individuals with primary diabetes mellitus develop severe arteriosclerosis at an earlier age than nondiabetic individuals do. Familial hypercholesterolemia, homocystinuria, and hypothyroidism are other examples of metabolic defects associated with arteriosclerosis. *See* DIABETES; THYROID GLAND DISORDERS.

Medial sclerosis is an uncommon type of arteriosclerotic lesion, affecting arteries of the arms, legs, and genital tracts of both sexes. The disorder is characterized by ringlike calcifications within the media (middle layer) of affected vessels. The endothelial lining of the vessel is not altered, and occlusion of the vessel seldom occurs.

Arteriolosclerosis is an increased generalized thickening of the walls of arterioles related to hypertension. The change is often most prominent in the kidneys, although other internal organs may be similarly affected. Individuals with diabetes mellitus have an increased incidence of the lesion. *See* CIRCULATION DISORDERS.

[N.K.M.]

Artesian systems Groundwater conditions formed by water-bearing rocks (aquifers) in which the water is confined above and below by impermeable beds. Because the water table in the intake area of an artesian system is higher than the top of the aquifer in its artesian portion, the water is under sufficient head to cause it to rise in a well above the top of the aquifer. Many of the systems have sufficient head to cause the water to overflow at the surface, at least where the land surface is relatively low. Flowing artesian wells were extremely important during the early days of the development of groundwater from drilled wells, because there was no need for pumping. Their importance has diminished with the decline of head that has occurred in many artesian systems and with the development of efficient pumps and cheap power with which to operate the pumps. [A.N.S./R.K.Li.]

Arthritis A group of diseases affecting joints or their component tissues. Several types of arthritis are recognized, and these can be divided into groups by their clinical course and pathologic appearance. There are four basic types of arthritis: inflammatory arthritis, degenerative joint disease, nonarticular rheumatism, and miscellaneous arthritis.

Inflammatory arthritis is characterized by inflammation of tissues associated with joints. Connective tissue diseases, crystal deposition diseases, infectious arthritis, and spondyloarthropathies are examples of inflammatory arthritis. Connective tissue diseases are a group of acute and chronic diseases characterized by involvement of joints, connective tissue, serosal membranes, and small blood vessels. These diseases are divided into acquired disorders (for example, rheumatoid arthritis, systemic lupus erythematosus, scleroderma, polymyositis, vasculitis) and rare hereditary diseases (for example, Ehlers-Danlos syndrome). Rheumatoid arthritis is the most common variety of inflammatory arthritis. It occurs in younger and middle-aged persons and is characterized by noninfectious inflammation of the synovium (joint-lining membrane) frequently associated with extraarticular manifestations other than in the joints. The etiology is unknown, but genetic, immunologic, infectious, and psychologic disturbances have all been suggested. The systemic disease follows a variable but slowly progressive course, marked by spontaneous flares and remissions. There are three groups of crystal deposition disease classified according to type of crystal involvement: gout (monosodium urate), pseudogout (calcium pyrophosphate), and calcific tendonitis (hydroxyapatite). Infectious arthritis is an inflammatory joint disease caused by the invasion of the synovial joint by living microorganisms such as gonorrheal, streptococcal, and staphylococcal bacteria. Such arthritis usually results from a generalized infection but may appear following local spread or after trauma. The spondyloarthropathies are types of inflammatory arthritis characterized by involvement of the axial (central) skeleton (for example, the spine rather than the limbs). Ankylosing spondylitis and Reiter's syndrome are examples of the spondyloarthropathies. *See* CONNECTIVE TISSUE DISEASE; GONORRHEA; GOUT; STAPHYLOCOCCUS; STREPTOCOCCUS; URIC ACID.

Degenerative joint disease (osteoarthritis) is a ubiquitous joint disease characterized pathologically by deterioration of cartilage lining the joints and new bone formation beneath the cartilage. The disease is very common in older persons and is thought to be inherent in the aging process. Degenerative joint disease is marked by a progressive stiffness, loss of function, and destruction of the larger, weight-bearing joints of the body. With advancing age, the continued slow damage causes increasing disability. *See* AGING.

Nonarticular rheumatism is a group of diseases, also called soft-tissue rheumatisms, that includes tendonitis, bursitis, tenosynovitis, and fibrositis. The etiology is unclear, but the disorder may relate to psychobiologic or sleep disturbances or muscular and soft-tissue abnormalities. *See* BURSITIS; RHEUMATISM.

Systemic diseases of other or unknown etiology may produce arthritis or joint destruction. There are neurologic, blood, and endocrine examples of these unusual rheumatic diseases.

Disability can often result from arthritis but can be curtailed by general health maintenance, rest, and rehabilitation. Occupational and physical therapies can be helpful. Diagnosis of the particular type of arthritis is extremely important in choosing drug therapy. Rheumatoid arthritis can be treated with nonsteroidal anti-inflammatory drugs such as aspirin. Disease-modifying antirheumatic drugs and immunosuppressive drugs are also frequently used. Osteoarthritis is treated with anti-inflammatory and analgesic drugs. Cortisone compounds are also used to treat arthritis, but the dosage and duration of treatment must be carefully monitored because of significant side effects. Surgical treatment includes arthroscopic surgery and joint replacement. *See* AUTOIMMUNITY; JOINT DISORDERS. [R.Se.]

Arthropoda A phylum that includes the well-known insects, spiders, ticks, and crustaceans, as well as many smaller groups, some of which are known only as fossils. Arthropodous animals make up about 75% of all animals that have been described. The estimated number of known species exceeds 780,000. Of this number the class Insecta alone contains about 700,000 described species. Arthropods vary in size from the microscopic mites to the giant decapod crustaceans, such as the Japanese crab with an appendage span of 5 ft (1.5 m) or more.

The adult arthropod typically has a body composed of a series of ringlike segments, muscularly movable on each other. The integument is sclerotized by the formation of hardening substances in the cuticle, and the segmental limbs are many-jointed. These characteristics, taken together, distinguish the arthropods from all other animals. Young stages may be quite different from the adults, and some parasitic species differ very radically from their relatives.

Arthropod evolution is no longer the clear-cut subdivision of a single phylum, Arthropoda, into three structurally divergent subphyla. Advances in functional morphology, comparative embryology, spermatology, serology, and paleontology have brought an array of new hypotheses about relationships of arthropodous animals. At the center of debate is the question of monophyly versus polyphyly: Did all arthropodous animals evolve from a common ancestor or did several distinct lineages evolve along similar pathways? Two opposing classification schemes are presented; numerous variations on these schemes can be found in the literature. The first pair of classifications is as follows:

Phylum Uniramia
Subphylum: Onychophora
Myriapoda
Hexapoda (Insecta)
Phylum Trilobita (Trilobitomorpha)
Phylum Crustacea
Phylum Chelicerata

Versus

Phylum Arthropoda
Subphylum Arachnata
Superclass: Trilobita
Chelicerata
Subphylum Mandibulata
Superclass: Crustacea
Myriapoda
Insecta
Phylum Onychophora

Alternatively, a slightly different and expanded pair of classifications is as follows:

Phylum Uniramia
Subphylum Onychophora
Subphylum Myriapoda
Class: Chilopoda
Diplopoda
Symphyla
Pauropoda
Arthropleurida
Subphylum Hexapoda
Class: Protura
Collembola
Diplura
Thysanura
Pterygota (Insecta)
Phylum Crustacea
Class: Cephalocarida
Remipedia
Branchiopoda
Ostracoda
Tantulocarida
Maxillopoda
Malacostraca
Phylum Cheliceriformes
Subphylum Pycnogonida
Subphylum Chelicerata
Class: Merostomata
Arachnida
Phylum Trilobitomorpha
Class: Trilobitoidea
Trilobita

Versus

Phylum Onychophora
Phylum Arthropoda
Subphylum Cheliceromorpha
Infraphylum: Pycnogonida
Chelicerata
Superclass: Xiphosurida
Cryptopneustida
Class: Eurypterida
Archnida
Subphylum Ganthomorpha
Infraphylym: Trilobitomorpha
Class: Trilobita
Trilobitodea
Infraphylum: Mandibulata
Class: Cheloniellida
Crustacea
Myriapoda
Insecta

Body segmentation, or metamerism, is the most fundamental character of the arthropods, but it is shared by the annelid worms, so there can be little doubt that these two groups of animals are related. The limbs of all modern arthropods develop in the embryo from small lateroventral outgrowths of the body segments that lengthen and become jointed. Hence it may be inferred that the arthropods originated from some segmented worm that acquired similar lobelike limb rudiments and thus, as a crawling or walking animal, became distinguished from its swimming relatives. Then, with sclerotization of the integument, the limbs could lengthen and finally become jointed, providing greater locomotor efficiency. In their later evolution, some of these limbs became modified for many other purposes, such as feeding, grasping, swimming, respiration, silk spinning, egg laying, and sperm transfer. The body segments, corresponding to specialized sets of appendages, tend to become consolidated or united in groups, or tagmata, forming differentiated body regions, such as head, thorax, and abdomen. Annelida; Metameres.

Sclerotization of the cuticle may be continuous around the segments. More usually, it forms discrete segmental plates, or sclerites. A back plate of a segment is a tergum, or notum; a ventral plate is a sternum; and lateral plates are pleura. The consecutive tergal and sternal plates, unless secondarily united, are connected by infolded membranes, and are thus movable on each other by longitudinal muscles attached on anterior marginal ridges of the plates. Since nearly all the body and limb muscles are attached on integumental sclerites, there is little limit to the development of skeletomuscular mechanisms.

All arthropods have all the internal organs essential to any complex animal. An alimentary canal extends either straight or coiled from the subapical ventral mouth to the terminal anus. Its primary part is the endodermal stomach, or mesenteron, but there are added ectodermal ingrowths that form a stomodeum anteriorly and a proctodeum posteriorly. The nervous system includes a brain and a subesophageal ganglion in the head, united by connectives around the stomodeum, and a ventral nerve cord of interconnected ganglia. Some of the successive ganglia, however, may be condensed into composite ganglionic masses. Nerves proceed from the ganglia. Internal proprioceptors and surface sense organs of numerous kinds are present, chiefly tactile, olfactory, and optic. A usually tubular pulsatory heart lies along the dorsal side of the body and keeps the blood in circulation. In some arthropods arteries distribute the blood from the heart; in others it is discharged from the anterior end of the tube directly into the body cavity. The blood reenters the heart through openings along its sides.

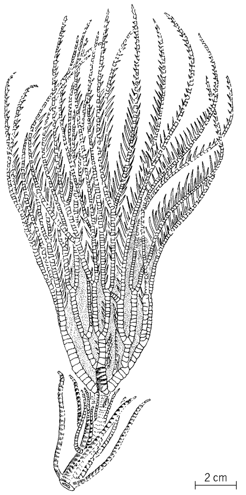
Aquatic arthropods breathe by means of gills. Most terrestrial species have either flat air pouches or tubular tracheae opening from the outside surface; some have both. A few small, soft-bodied forms respire through the skin. Excretory organs open either at the bases of some of the appendages or into the alimentary canal. Most arthropods have separate sexes, but some are hermaphroditic, and parthenogenesis is of common occurrence. The genital openings differ in position in different groups and are not always on the same body segment in the two sexes. *See* ARACHNIDA; CHELICERATA; CRUSTACEA; INSECTA; ONYCHOPHORA; TRILOBITA. [J.C.Ro.]

Artichoke *Cynara scolymus*, a herbaceous perennial plant, in the family Compositae; also called globe artichoke. Its origin is in the Mediterranean region. Artichoke requires a mild winter and cool summer with fog and little bright sunshine. It is a delicacy in Europe, Africa, and North and South America. Artichoke is also a medicinal plant; it is rich in the cynarin and ortho-phenol constituents. In the United States, artichokes are grown in the Pacific Coast area between south San Francisco and Los Angeles, mainly Monterey County.

Green Globe artichoke. (*Burpee Seeds*)

The marketable portion of the plant, the so-called bud, is actually the immature flower head, made up of numerous closely overlaid bracts or scales (see illustration). The edible portion consists of the tender bases of the bracts, the young flowers, and the receptacle or fleshy base upon which the flowers are borne. The bud can be various shapes, from round to oblong to flat, and the color can be light green to dark green, often with purple or red. [A.M.I.]

Articulata (Echinodermata) The only surviving subclass of the Crinoidea. It differentiated during Triassic times. The calyx is dicyclic, but considerable reduction of the infrabasals and basals may occur. The uniserial arms bear pinnules and usually branch, and the arm retains its movable articulation with the radial plate, despite the incorporation of the lower brachial ossicles into the calyx. Extant stalked forms with nodal rings of cirri (*Metacrinus*) are included in the order Isocrinida (see illustration). They do not tolerate turbulent waters and live at depths below current action, although they do inhabit shallow water when the conditions are suitable. The feather stars, of the order Comatulida, discard the stem when young, and thereafter remain free, either as swimming animals or as creeping benthic forms. They prefer shallow, clear water, rich in nutrients, and therefore abound on tropical coasts and in polar seas rather than in temperate waters. Four other orders have been defined. *See* CRINOIDEA; ECHINODERMATA. [H.B.F.]



***Metracrinus cyaneus*, a living, articulate stalked crinoid.**

Artificial intelligence The subfield of computer science concerned with understanding the nature of intelligence and constructing computer systems capable of intelligent action. It embodies the dual motives of furthering basic scientific understanding and making computers more sophisticated in the service of humanity.

Many activities involve intelligent action—problem solving, perception, learning, planning and other symbolic reasoning, creativity, language, and so forth—and therein lie an immense diversity of phenomena. Scientific concern for these phenomena is shared by many fields, for example, psychology, linguistics, and philosophy of mind, in addition to artificial intelligence. The starting point for artificial intelligence is the capability of the computer to manipulate symbolic expressions that can represent all manner of things, including knowledge about the structure and function of objects and people in the world, beliefs and purposes, scientific theories, and the programs of action of the computer itself.

Artificial intelligence is primarily concerned with symbolic representations of knowledge and heuristic methods of reasoning, that is, using common assumptions and rules of thumb. Two examples of problems studied in artificial intelligence are planning how a robot, or person, might assemble a complicated device, or move from one place to another; and diagnosing the nature of a person's disease, or of a machine's malfunction, from the observable manifestations of the problem. In both cases, reasoning with symbolic descriptions predominates over calculating.

The approach of artificial intelligence researchers is largely experimental, with small patches of mathematical theory. As in other experimental sciences, investigators build devices (in this case, computer programs) to carry out their experimental investigations. New programs are created to explore ideas about how intelligent action might be attained, and are also developed to test hypotheses about concepts or mechanisms involved in intelligent behavior.

The foundations of artificial intelligence are divided into representation, problem-solving methods, architecture, and knowledge. To work on a task, a computer must have an internal representation in its memory, for example, the symbolic description of a room for a moving robot, or a set of features describing a person with a disease. The representation also includes all the knowledge, including basic programs, for testing and measuring the structure, plus all the programs for transforming the structure into another one in ways appropriate to the task. Changing the representation used for a task can make an immense difference, turning a problem from impossible to trivial.

Given the representation of a task, a method must be adopted that has some chance of accomplishing the task. Artificial intelligence has gradually built up a stock of relevant problem-solving methods (the so-called weak methods) that apply extremely generally.

An important feature of all the weak methods is that they involve search. One of the most important generalizations to arise in artificial intelligence is the ubiquity of search. It appears to underlie all intelligent action. In the worst case, the search is blind. In heuristic search extra information is used to guide the search.

Some of the weak methods are generate-and-test (a sequence of candidates is generated, each being tested for solutionhood); hill climbing (a measure of progress is used to guide each step); means-ends analysis (the difference between the desired situation and the present one is used to select the next step); impasse resolution (the inability to take the desired next step leads to a subgoal of making the step feasible); planning by abstraction (the task is simplified, solved, and the solution used as a guide); and matching (the present situation is represented as a schema to be mapped into the desired situation by putting the two in correspondence).

An intelligent agent—person or program—has multiple means for representing tasks and dealing with them. Also required is an architecture or operating framework within which to select and carry out these activities. Often called the executive or control structure, it is best viewed as a total architecture (as in computer architecture), that is, a machine that provides data structures, operations on those data structures, memory for holding data structures, accessing operations for retrieving data structures from memory, a programming language for expressing integrated patterns of conditional operations, and an interpreter for carrying out programs. Any digital computer provides an architecture, as does any programming language. Architectures are not all equivalent, and one important scientific question is what architecture is appropriate for a general intelligent agent.

In artificial intelligence, the basic paradigm of intelligent action is that of search through a space of partial solutions (called the problem space) for a goal situation. Each step offers several possibilities, leading to a cascading of possibilities that can be represented as a branching tree. The search is thus said to be combinatorial or exponential. For example, if there are 10 possible actions in any situation, and it takes a sequence of 12 steps to find a solution (a goal state), then there are 10^{12} possible sequences in the exhaustive search tree. What keeps the search under control is knowledge, which suggests how to choose or narrow the options at each step. Thus the fourth fundamental concern is how to represent knowledge in the memory of the system so it can be brought to bear on the search when relevant.

An intelligent agent will have immense amounts of knowledge. This implies another major problem, that of discovering the relevant knowledge as the solution attempt progresses. Although this search does not include the combinatorial explosion characteristic of searching the problem space, it can be time consuming and hard. However, the structure of the database holding the knowledge (called the knowledge base) can be carefully tailored to suit the architecture in order to make the search efficient. This knowledge base, with its accompanying problems of encoding and access, constitutes the final ingredient of an intelligent system.

An example of artificial intelligence is computer perception. Perception is the formation, from a sensory signal, of an internal representation suitable for intelligent processing. Though there are many types of sensory signals, computer perception has focused on vision and speech. Perception might seem to be distinct from intelligence, since it involves incident time-varying continuous energy distributions prior to interpretation in symbolic terms. However, all the same ingredients occur: representation, search, architecture, and knowledge. Speech perception starts with the acoustic wave of a human utterance and proceeds to an internal representation of what the speech is about. A sequence of representations is used: the digitization of the acoustic wave into an array of intensities; the formation of a small set of parametric quantities that vary continuously with time (such as the intensities and frequencies of the formants, bands of resonant energy characteristic of speech); a sequence of phons (members of a finite alphabet of labels for characteristic sounds, analogous to letters); a sequence of words; a parsed sequence of words reflecting grammatical structure; and finally a semantic data structure representing a sentence (or other utterance) that reflects the meaning behind the sounds.

A class of artificial intelligence programs called expert systems attempt to accomplish tasks by acquiring and incorporating the same knowledge that human experts have. Many attempts to apply artificial intelligence to medicine, government, and other socially significant tasks take the form of expert systems. Even though the emphasis is on knowledge, all the standard ingredients are present.

In careful tests, a number of expert systems have shown performance at levels of quality equivalent to or better than average practicing professionals (for example, average practicing physicians) on the restricted domains over which they operate. Nearly all large corporations and many smaller ones use expert systems. A common application is to provide technical assistance to persons who answer customers' trouble calls. Computer companies use expert systems to assist in configuring components from a parts catalog into a complete system that matches a customer's specifications, a kind of application that has been replicated in other industries tailoring assembled products to customers' needs. Troubleshooting and diagnostic programs are commonplace. Another widespread use of this technology is in software for home computers that assists taxpayers. One important lesson learned from incorporating artificial intelligence software into ongoing practice is that its success depends on many other aspects besides the intrinsic intellectual quality, for example, ease of interaction, integration into existing workflow, and costs.

Expert systems have sparked important insights in reasoning under uncertainty, causal reasoning, reasoning about knowledge, and acceptance of computer systems in the workplace. They illustrate that there is no hard separation between pure and applied artificial intelligence; finding what is required for intelligent action in a complex applied area makes a significant contribution to basic knowledge. *See* EXPERT SYSTEMS.

In addition to the subject areas mentioned above, significant work in artificial intelligence has been done on puzzles and reasoning tasks, induction and concept identification, symbolic mathematics, theorem proving in formal logic, natural language understanding and generation, vision, robotics, chemistry, biology, engineering analysis, computer-assisted instruction, and computer-program synthesis and verification, to name only the most prominent. As computers become smaller and less expensive, more and more intelligence is built into automobiles, appliances, and other machines, as well as computer software, in everyday use. *See* AUTOMATA THEORY; COMPUTER; CONTROL SYSTEMS; CYBERNETICS; DIGITAL COMPUTER; INTELLIGENT MACHINE; ROBOTICS. [A.N.; B.G.Bu.]

Artificially layered structures Manufactured, reproducibly layered structures with layer thicknesses approaching interatomic distances. Modern thin-film techniques are at a stage at which it is possible to fabricate these structures, also known as artificial crystals or superlattices, opening up the possibility of engineering new desirable properties into materials. In addition, a variety of solid-state physics problems can be studied which are otherwise inaccessible. The various possibilities include: the application of negative pressure, that is, stretching of the crystalline lattice; the study of dimensional crossover, that is, the transition from a situation in which the layers are isolated and two-dimensional in character to where the layers couple together to form a three-dimensional material; the study of collective behavior, that is, properties which depend on the cooperative behavior of the whole superlattice; and the effect and physics of multiple interfaces and surfaces. For a discussion of semiconductor superlattices *see* SEMICONDUCTOR HETEROSTRUCTURES; CRYSTAL.

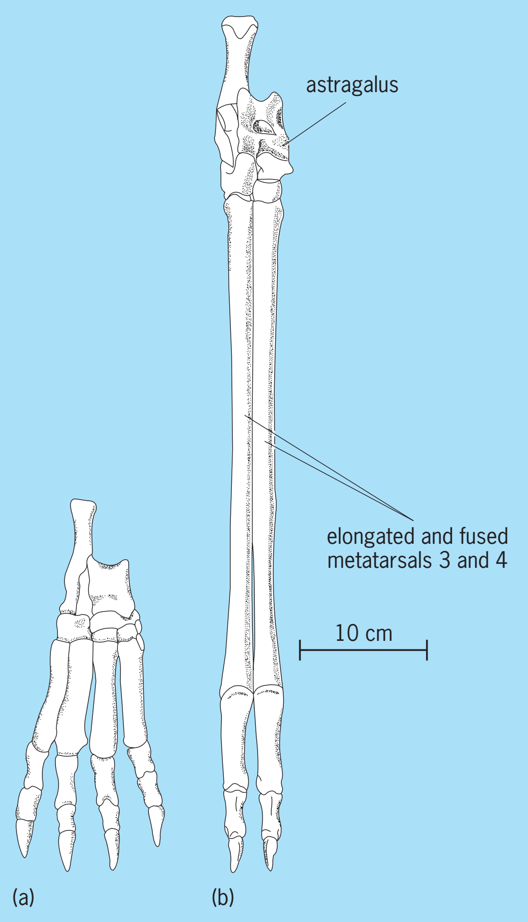
The preparation techniques can be conveniently classified into two groups: evaporation and sputtering. In the evaporation system, two or more particle sources (thermal or electron beam gun) are aimed at a heated substrate where the artificially layered structure is grown. The sputtering method relies on bombarding targets of the proper materials with an inert gas, such as argon, thus producing the beams of the various elements. *See* SPUTTERING.

Once the artificially layered structure is prepared, it is necessary to characterize whether the layer structure is stable at the growth temperature. This is of considerable importance, since the interdiffusion of the constituents in many cases eliminates the layered growth. One of the most successful methods of characterizing layered growth has been x-ray diffraction. *See* ELECTRON MICROSCOPE.

Artificially layered structures are especially useful for the construction of mirrors for soft x-rays since there are no suitable, naturally occurring crystals for this purpose. Superlattices with zero temperature coefficient of resistivity are useful as resistor material, and high-critical-field-magnet tapes using superconducting-insulator superlattices have been proposed. *See* ELECTRICAL INSULATION; NEUTRON OPTICS; X-RAYS. [I.K.S.]

Artiodactyla An order comprising the even-toed ungulates (hoofed mammals). There are two main radiations: the predominantly omnivorous Bunodontia, including suoids (such as pigs, peccaries, and hippos); and the more herbivorous Selenodontia, including camels and ruminants (such as deer, giraffe, cattle, sheep, and antelope). Artiodactyla contains about 213 living species, making it the fifth most speciose order of mammals. First known from the early Eocene, artiodactyls have proliferated during the last 55 million years to reach great diversity (especially among the family Bovidae). Their radiation is often contrasted with that of the odd-toed ungulates, or Perissodactyla (horses, rhinos, and tapirs). Artiodactyls are also important for human economy and agriculture, comprising most of the domestic animals, providing milk, wool, and most of the meat supply. *See* PERISSODACTYLA.

Artiodactyls are defined by a unique morphology of the ankle joint, possessing a "double-pulley" astragalus (see illustration). This morphological feature is frequently considered to be a key innovation of artiodactyls, but its precise functional significance is poorly understood. Artiodactyls also have a paraxonic foot structure, where the axis of limb support passes between the third and fourth digits. The first toe is usually completely lost. In primitive artiodactyls and in suoids, the foot is four-toed, and the metapodials (hand and foot bones) are short and unfused as in the generalized mammalian condition (illus. *a*). In more derived artiodactyls, digits 2 and 5 have been reduced or lost entirely, and metapodials 3 and 4 are lengthened and fused to form a "cannon bone" (illus. *b*). It is this fusion of the metapodials with digits 3 and 4 free that gives ruminants their cloven-hoofed appearance (in contrast with the single and solid hoof of horses).



Representative left hindfeet of artiodactyls, showing the double-pulley astragalus. (*a*) Primitive condition, as in the Oligocene oreodont *Agriochoerus* (although the clawed condition in this animal is a secondary one). (*b*) Derived condition, as in the Miocene camelid *Oxydactylus*. (*After A. S. Romer, Vertebrate Paleontology, 3d ed., University of Chicago Press, 1966*)

Despite their host of unique features, in terms of branching patterns artiodactyls represent an early divergence from the main stem of ungulate evolution. The earliest artiodactyls, rabbit-sized animals found in the Eocene of North America and Europe, are commonly known as dichobunids. By the late middle Eocene the earliest members of the two modern radiations, the Bunodontia and the Selenodontia, had arisen from among different groups of dichobunids. The three main types of living artiodactyls—suoids, camelids, and ruminants—can trace their roots back to this Eocene divergence. There has been much debate as to whether whales (order Cetacea) should be included among the Artiodactyla. Whales are clearly the sister taxon to artiodactyls among modern mammals, but some molecular studies imply that they are closely allied with the hippos. Morphologists and paleontologists would generally prefer to keep whales separate from artiodactyls. *See* CETACEA. [C.J.]

Asbestos Any of six naturally occurring minerals characterized by being extremely fibrous (asbestiform), being incombustible, and having high tensile strength. Historically they were utilized in commerce for fire protection; for fiber-reinforcing material in tiles, plastics, and cements; for friction materials; and for thousands of other uses. Currently the vast majority of asbestos used worldwide is chrysotile type, which is used for asbestos cement, friction products, coating and compounds, and roofing products. Because of great concern over the health effects of asbestos, many countries have promulgated strict regulations or bans on its use.

The six naturally occurring minerals exploited commercially for their desirable physical properties, which are in part derived from their asbestiform habit, are chrysotile asbestos—a member of the serpentine mineral group; and anthophyllite asbestos, grunerite asbestos (known historically by the commercial name amosite), riebeckite asbestos (known historically by the commercial name crocidolite), tremolite asbestos, and actinolite asbestos—all members of the amphibole mineral group. Populations of these mineral fibers, however processed, can be demonstrated to be asbestos if the length varies independently of the diameter. The six minerals designated as asbestos also occur in a nonfibrous form.

The three principal diseases associated with exposure to the asbestos minerals are lung cancer; mesothelioma, a rare cancer of the pleural and peritoneal membranes that enclose the chest and abdominal cavities; and asbestosis, a nonmalignant disease characterized by a diffuse interstitial fibrosis of the lung, which causes the lung tissue to become stiff and exchange oxygen poorly. Excessive exposure to all the asbestos fiber types is associated with asbestosis and increased risk of lung cancer. Mesothelioma, a rare tumor accounting for approximately 1 in 10,000 deaths in the general population, can be dramatically increased by exposure to amosite, crocidolite, or tremolite asbestos. These last two fiber types are strongly associated with an increased incidence of nonoccupational mesothelioma and therefore are thought to present a risk at rather low exposures. *See* MUTAGENS AND CARCINOGENS; ONCOLOGY. [M.Ro.; R.P.N.]

Ascaridida An order of nematodes in which the oral opening is generally surrounded by three or six labia; in some taxa labia are absent, but the cephalic sensilla are always evident. Usually there are eight cephalic or labial sensilla; the submedians may be fused and then only four sensilla are seen. The stoma varies from being completely reduced to spacious or globose. The esophagus varies from club shaped to nearly cylindrical, never rhabditoid. There may be posterior esophageal or anterior intestinal ceca. The collecting tubules of the excretory system may extend posteriorly and anteriorly. Males generally have two spicules; however, in some taxa there may be none or only one. The gubernaculum may also be present or absent. Though females generally have two ovaries, multiple ovaries do occur. The number of uteri is also variable: two, three, four, or six. Phasmids are sometimes large and pocketlike. Reportedly, the larvae lack a stomatal hook or barb.

The order probably comprises seven superfamilies: Ascaridoidea, Seuratoidea, Camallanoidea, Dracunculoidea, Subuluroidea, Dioctophymatoidea, and Muspiceoidea (*incertae sedis*).

The Ascaridoidea include about 65 genera which comprise large parasitic roundworms whose adult stages usually occur in the stomach or small intestine of terrestrial and aquatic mammals, birds, reptiles, and fishes; the parasitic larval stages of many species occur, either temporarily or indefinitely, in other parts of the host's body.

Many species have a direct life cycle. Others, mainly species with marine mammals, birds, and fishes as definitive hosts, require an intermediate host, such as a fish, amphibian, insect, crustacean, or small mammal. Infestation is typically characterized by pulmonary damage and distress initially, and digestive disturbances later. Damage may also occur during larval migration to other parts of the body, including the liver and brain.

Dracunculoidea, the superfamily of parasitic nematodes, comprise obligate tissue parasites of fishes, reptiles, and mammals. All known species require an intermediate host in order to complete their life cycle, and that host is always a water flea (*Cyclops*). The most widely known example is *Dracunculus medinensis*, the guinea worm.

Ingestion of water containing infective *Cyclops* is the only known source of infection. The encysted nematode larvae are released from *Cyclops* by the digestive juices of the duodenum. Then the larvae burrow through the intestinal wall, and upon reaching the loose connective tissue, they develop to adulthood in 8 months to 1 year.

The gravid females, 28–48 in. (70–120 cm) long, migrate from the site of development to the surface of the skin, and a papule is formed, then a blister, usually on the lower extremities. When the blister comes in contact with fresh water, the uterus bursts through the anterior part of the nematode's body, and the worm also bursts, releasing cloudlike swarms of motile larvae. These larvae are then filtered from the water by *Cyclops* and subsequently ingested.

The formation of the blister and subsequent rupturing of the female produce a profound allergic reaction. This reaction results from the release of large amounts of toxic by-products from the worm. Upon discharge of larvae in fresh water, much of the allergic reaction abates. The reactions and systemic prodromes include erythema, urticarial rash, pruritus, vomiting, diarrhea, and giddiness. Septicemia, suppurating cysts, and chronic abscesses are not uncommonly associated with these infections. The worms can be removed surgically, or in the native manner of winding upon a stick. Chemotherapy is also available.

Control in endemic areas includes keeping infected persons from wading or bathing in water used for drinking purposes, and the education to avoid drinking suspect water. *See* NEMATA. [A.R.M.]

Ascidiacea A class of Tunicata which occurs as solitary zooids or, by a process of asexual budding, develops into colonies.

Zooids vary in length from about 0.1 to 10 in. (a few millimeters to 25 cm). Individuals or colonies are invested by a protective covering, the tunic or test, made of polysaccharide material structurally close to cellulose. Beneath the test is the body wall or mantle. Each zooid has two apertures: inhalant (oral) and exhalant (atrial). Water currents, created by cilia on the margins of stigmata in the pharyngeal wall, draw water into the branchial sac, where it is filtered and passed out through the exhalant aperture. Digestive enzymes are secreted into the stomach, and a pyloric gland, of unknown function, enters at the junction of stomach and intestine. Gonads are hermaphroditic, and may be situated in the loop of the intestine or in the mantle wall.

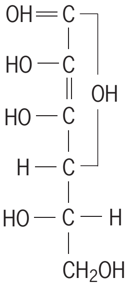
Three orders of ascidian are recognized. Ascidians occur throughout the seas of the world and at all depths, including the abyssal region. Most species feed on minute particulate matter, but a few are carnivores and engulf small zooplankters. *See* TUNICATA. [I.Go.]

Ascomycota A phylum in the kingdom Fungi, representing the largest of the major groups of fungi, and distinguished by the presence of the ascus, a specialized saclike cell in which fusion of nuclei and reduction division occur and the resulting nuclei form ascospores. In most ascomycetes, each ascus contains eight ascospores, but the number may vary from one to several hundred. In the simplest ascomycetes (yeasts), the vegetative body (thallus) is unicellular; however, in the majority of ascomycetes, the thallus is more complex and consists of a tubular, threadlike hypha with cross walls which grows in or on the substrate. These hyphae eventually form structures called ascomata (ascocarps), on or in which the asci are formed. In addition to their sexual reproduction, most ascomycetes reproduce asexually by means of conidia.

Traditionally, the structure of the ascoma and ascus has served as the basis for subdividing the Ascomycota into five classes: Hemiascomycetes, Plectomycetes, Pyrenomycetes, Discomycetes, Loculoascomycetes. The introduction of molecular data, however, is changing concepts of the relationships of different groups of ascomycetes and will eventually lead to a much-revised classification scheme. *See* DISCOMYCETES; HYMENOMYCETES; LOCULOASCOMYCETES; PLECTOMYCETES; PLECTOMYCETES.

The ascomycetes occur throughout the world in all types of habitats and on both living and dead substrates. An estimated 33,000 species are arranged in about 3300 genera, with new species being described regularly. Ecologically ascomycetes function as primary decomposers of plant materials, but they also are important as plant and human pathogens; in baking, brewing, and winemaking; in enzyme and acid production; and as sources of antibiotics and other drugs. *See* EUMYCOTA; FUNGI; PLANT PATHOLOGY; YEAST. [R.T.Ha.]

Ascorbic acid A white, crystalline compound, also known as vitamin C. It is highly soluble in water, which is a stronger reducing agent than the hexose sugars, which it resembles chemically. Vitamin C deficiency in humans has been known for centuries as scurvy. The compound has the structural formula shown below.



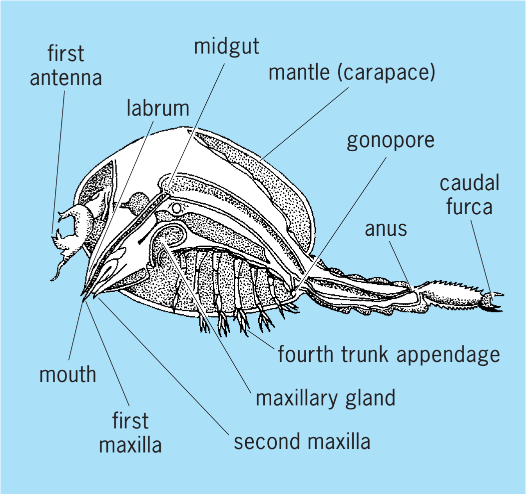
The stability of ascorbic acid decreases with increases in temperature and pH. This destruction by oxidation is a serious problem in that a considerable quantity of the vitamin C content of foods is lost during processing, storage, and preparation.

While vitamin C is widespread in plant materials, it is found sparingly in animal tissues. Of all the animals studied, only a few, including humans, require a dietary source of vitamin C. The other species are capable of synthesizing the vitamin in such tissues as liver and kidneys. Some drugs, particularly the terpene-like cyclic ketones, stimulate the production of ascorbic acid by rat tissues.

Vitamin C–deficient animals suffer from defects in their mesenchymal tissues. Their ability to manufacture collagen, dentine, and osteoid, the intercellular cement substances, is impaired. This may be related to a role of ascorbic acid in the forma- tion of hydroxy-proline, an amino acid found in structural proteins, particularly collagen. People with scurvy lose weight and are easily fatigued. Their bones are fragile, and their joints sore and swollen. Their gums are swollen and bloody, and in advanced stages their teeth fall out. They also develop internal and subcutaneous hemorrhages.

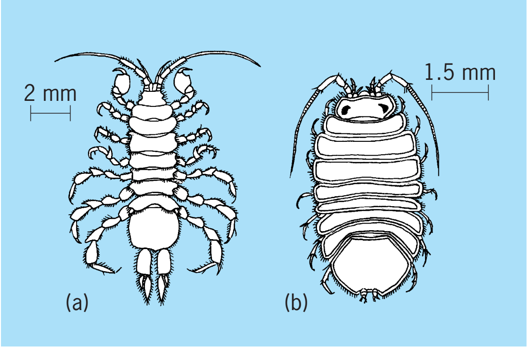
There is evidence that vitamin C may play roles in stress reactions, in infectious disease, or in wound healing. Therefore, many nutritionists believe that the human intake of ascorbic acid should be many times more than that intake level which produces deficiency symptoms. The recommended dietary allowances of the Food and Nutrition Board of the National Research Council are 30 mg per day for 1- to 3-month infants, 80 mg per day for growing boys and girls, and 100 mg per day for pregnant and lactating women. These values represent an intake which tends to maintain tissue and plasma concentrations in a range similar to that of other well-nourished species of animals. *See* VITAMIN. [S.N.G.; W.A.Li.]

Ascothoracica An order of the subclass Cirripedia. Members are ecto- or endoparasites of coelenterates and echinoderms. The body is enclosed in a voluminous saclike mantle up to 0.8 in. (20 mm) long, whereas the body is only about one-fourth of this length (see illustration). Ascothoracica are not attached permanently to the host by the antennular region, but the antennules may be modified as a clasping organ. Up to six pairs of thoracic appendages are present, reduced in number and development in the endoparasites. The mouth parts are modified for piercing and sucking. Unlike all other Cirripedia, Ascothoracica retain a more or less segmented abdomen in the adult. There are no cement glands present. Diverticula of the alimentary canal extend into the mantle. *See* CIRRIPEDIA. [H.G.St.]



***Ascothorax ophioctenis*, a parasite in the bursae of brittle stars. (*After R. D. Barnes, Invertebrate Zoology, 2d ed., Saunders, 1968*)**

Asellota A suborder of the Isopoda containing aquatic species of considerable morphologic and ecologic diversity. These crustaceans are usually divided into three major groups, the Paraselloidea, Aselloidea, and Stenetrioidea. Asellotes such as *Asellus* (see illustration) are found in freshwater streams; *Caecidotea*, in subterranean water; *Caeioniropsis*, in the interstices of marine sands as commensals with other isopods such as *Caecijaera* and *Jaera* and in shallow waters of the seas; and *Macrostylus*, in the greatest depth of the seas. *See* CRUSTACEA; ISOPODA. [R.J.Me.]



***Asellus communis*. (*After H. S. Pratt, Manual of the Common Invertebrate Animals, rev. ed., McGraw-Hill, 1951*)**

Ash A genus, *Fraxinus*, of deciduous trees of the olive family Oleaceae, order Scrophulariales, which have opposite, pinnate leaflets, except in one species, *F. anomala*, which has only a single leaflet. There are about 65 species in the Northern Hemisphere. This tree occurs in America south to Mexico, in Asia south to Java, and in Europe. *See* SCROPHULARIALES.

The white ash (*F. americana*), of the eastern United States, has stalked leaflets, rusty-colored winter buds, and an erect trunk that is valuable for lumber. The wood is light, strong, but flexible, and is used for oars, baseball bats, furniture, motor vehicle parts, boxes, baskets, and crates. The black ash (*F. nigra*) grows in wet soils in the northeastern United States and Canada and has sessile leaflets and friable outer bark. The wood of black ash is used for the same purposes as that of white ash. The red ash (*F. pennsylvanica*), also of the eastern United States and adjacent Canada, has pubescent (hairy) twigs and leafstalks. The uses of the wood of this species are also similar to those of white ash. Some species of ash are ornamental trees, such as the flowering ash (*F. ornus*) with gray winter buds and white flowers, and the European ash (*F. excelsior*) with black buds and sessile leaflets. *See* FOREST AND FORESTRY; TREE. [A.H.G./K.P.D.]

Asia The largest of the world's continents. With its peninsular extension, commonly called the continent of Europe, it is the major portion of the broad east-west extent of the Northern Hemisphere land masses. In many ways Asia is more a cultural concept than a physical entity. There is no logical physical separation between Asia and Europe, and even Africa is separated from Asia merely by the width of the Suez Canal. For convenience, however, the Eurasian land mass is considered to be divided by the Ural Mountains into Europe in the west and Asia in the east. Thus restricted, Asia has an area of about 17,700,000 mi^2 (45,800,000 km^2), about one-third of the land area of the Earth. In the north, Siberia reaches past the 80th latitude. Southward, India and Sri Lanka (Ceylon) reach nearer than 10°N of the Equator, while the Indonesian islands extend more than 10°S of the Equator. The continental heart of Asia is more than 2000 mi (3200 km) from the nearest ocean. *See* CONTINENT; EUROPE.

Topography. In the topographic framework of Asia, the great mountain systems are the most impressive features. From the central knot of the mighty Pamirs and Kopet Dagh in the heart of the continent originate chains radiating in several directions. In the Peter the First Range there are such heights as Qullai Ismoili Somoni, 24,584 ft (7493 m), and Lenin Peak, 23,377 ft (7125 m), above sea level. Running westward through Afghanistan is the Hindu Kush, reaching elevations over 20,000 ft (6100 m). The mountain trendline continues, after a jog northwestward, in the Elburz of northern Iran and thence in the Armenian highlands and the Caucasus, each with elevations reaching 18,000 ft (5500 m), decreasing thereafter to the Pontus and Taurus ranges of northern and southern Turkey. In western and southern Iran are the massive Zagros and Makran ranges.

Southeastward from the Pamir knot run the three most imposing mountain chains on Earth: the Karakorum, which continues the line of the Hindu Kush eastward in an arc convex to the north; the Himalaya in an arc convex to the south; and the shorter Trans-Himalaya, or Nyen-chen Tangla, north of the Himalaya, with higher average elevations but peaks of lesser height. In all of these, the average elevations exceed 4 mi (6400 m), with several scores of peaks reaching a height in excess of 25,000 ft (7600 m) above sea level. Everest, 29,141 ft (8882 m), and Kinchinjunga, 28,146 ft (8579 m), lie in the Himalaya, while the peak designated as K2, 28,250 ft (8611 m), rises in the Karakorum.

In eastern Tibet the Himalaya and Nyen-chen Tangla bend sharply toward the south, and the former is cut through by the gorge of the Brahmaputra River. From the bend zone, great ridges divided by deep gorges run south to form the Burma-China frontiers and the mountain backbones of the Malay peninsula and Vietnam. The Nan-ling system of south China diverges eastward to divide the Yang-tzu (Yangtze) from the Hsi (Si) drainage.

From the western Himalaya, the 11,000-ft (3400-m) Sulaiman Range runs south and, together with the Kirthar Range, divides West Pakistan from Afghanistan.

Beginning at heights over 20,000 ft (6100 m) and branching off from the Karakorum south of Kashgar, the Kuen-lun Mountains run eastward across western China. Genetically they form the longest mountain system of China. With their eastward extensions in the 12,000 ft (3700 m) Ch'in-ling and the lesser Ta-pieh mountains and Huai-yang hills, they reach almost to the Pacific. Together with the northeastward arc of the Altyn Tagh and the Nan Shan branching from it, the Kuen-lun forms the northern wall of the Tibetan plateau. Near the eastern end of the Kuen-lun proper lie the Amne Machin Mountains, with peaks up to 25,000 ft (7600 m) in elevation.

Northeastward of the Pamir knot runs the east-west oriented Tien Shan, over 1000 mi (1600 km) long and maintaining heights of 18,000–20,000 ft (5500–6100 m) over much of its length. Roughly parallel and trending east and west is a series of great ranges to its north, with mutual connections in the west. These include the Altai-Sayan, the Tannu Ola, and the Kentei, which form natural boundaries for Outer Mongolia. They continue the systems of young mountains crossing central Asia; farther northeast, they extend further in the Stanovoi Mountains of Eastern Siberia.

The Asian plateaus are in various stages of erosion and thus present a great variety of landscapes. The Tibetan plateau is a prime example. The western half, because of little rainfall, exhibits a rolling topography with relatively slight local relief except where mountain chains cross it; it is a land of internal drainage basins. Average elevations are over 16,000 ft (4900 m). The eastern half is humid or subhumid and is cut by numerous rivers, producing deep canyons and great ridges. In contrast to this is the Mongolian plateau. This plateau consists mostly of vast, rather level plains 3000–5000 ft (900–1500 m) high, surmounted in places by mountains, and containing broad, shallow basins divided by land swells of low elevation.

Other major topographic units of Asia are blocs of hill lands. Most of southern China and much of southeastern Asia comprise hills which may be roughly defined as slope lands with local relief under 1000–1500 ft (300–450 m) although in absolute elevation they may rise many thousands of feet above sea level. Hilly lands are found to predominate in the northern part of the Indian peninsula and along both flanks of the Indian plateau, where they are called ghats. In southern India are the Nilgiri and Cardomom hills, rising to mountainous elevations of 8000 ft (2400 m). Many parts of different plateaus have hilly regions where erosion has produced uneven local relief, as in the Shan or North Vietnam plateau. Hills are prominent features of southwestern Asia, including eastern Mediterranean regions, such as Israel, Syria, and Lebanon.

The most significant topographic units of Asia are the great alluvial plains and river deltas. The gross drainage pattern of Asia is radial; the rivers flow from the highlands in the heart of the continent and run outward in all directions. Only in the south, east, and north sectors of the continent do the rivers reach the sea. Flowing into the peripheral seas of the Pacific are such mighty rivers as the Mekong, the Hsi, the Yang-tzu, the Huai, the Yellow, and the Amur, each building large, heavily populated plains and, with the exception of the Amur, densely settled deltas. The Yellow Plain (North China Plain), with some 125,000 mi^2 (324,000 km^2) of area, and the Yangtzu Plain, with about 75,000 mi^2 (194,000 km^2), are among the most extensive alluvial plains of the Earth. In the shallow South China, East China, and Yellow seas, the deltas of the first five rivers mentioned above are pushing steadily seaward.

Important sectors of Asia, containing some 200,000,000 people, are completely insular. The most important are the Japanese, Philippine, and Indonesian islands and Taiwan. Almost all of Asia's islands lie in great volcanic arcs bounding large seas off the continent's Pacific coast. At least 160 active volcanoes are found here and in Kamchatka. Few islands lie along the Asiatic coasts of the Indian Ocean, although the Sunda chain of Indonesia has perhaps more of a claim to Indian Ocean frontage than to Pacific frontage. Sri Lanka is the only significant island in the northern part of the Indian Ocean west of Sumatra. In the Persian Gulf off the north coast of Arabia lies the small island Bahrein.

Few islands lie off the alluviated coastlands of northern Siberia. Some moderately large ones are included in the barren and rocky Severnaya Zemlya group, the New Siberian Islands, and Wrangel Island. The Commander Islands and Karaginski Island lie in the Bering Sea only a short distance from the Aleutians.

Climates. Five major climatic types may be distinguished in the Asian region: (1) the monsoonal system of eastern Asia, (2) the monsoonal system of southern Asia, (3) the equatorial regions of southeastern Asia and their extension into the Southern Hemisphere as they are influenced by the Australian monsoon, (4) the winter rainfall areas of southwestern Asia, and (5) the cyclonic and convectional storm systems of central and northern Asia.

Fundamental to understanding the climates of Asia are the vastness of the unbroken landmass and the long latitudinal stretch from the polar realm to south of the Equator. These are responsible for the great temperature and humidity extremes that occur. The greatest ranges of temperatures in the world have been recorded in interior Asia. Continentality, therefore, is the outstanding feature of climates of interior Asia. In coastal and insular areas of east Asia, however, winds moving over the warm, northward-flowing Japan Current and the western Pacific waters moderate the coastland and island climates. *See* MONSOON METEOROLOGY.

The driest portions of Asia include the vast areas of southern Mongolia, Hsin-chiang, former Soviet Central Asia, and southwestern Asia. Except for small, favored mountain areas, most of this region from the Gobi to the Red Sea gets less than 10 in. (25 cm) of precipitation per year. With the exception of southern Arabia, which is subtropical desert, these are mid-latitude desert and dry steppe regions. Favored with higher rainfall are the Yemen Mountains and the coastal mountains of Turkey, together with Lebanon, Syria, and northern Israel. The highlands of Armenia and the Elburz of Iran are favored also with more abundant rainfall, which may range from 25 to 50 in. (64 to 127 cm) or more per year.

The northeastern Siberian mountains and the Arctic coastal lands also receive meager rainfall, less than 8 in. (20 cm), but are not dry because evaporation is low and the water table is high. Most of Siberia has permafrost below a few feet of surface soil, so that rainwater does not filter far down into the earth. Between the arid belt of central Asia and the northeast Siberian low-precipitation zone, the annual rainfall ranges between 10 and 18 in. (25 and 45 cm).

In eastern Asia the precipitation increases in a southeasterly direction from interior Asia to the coast. The annual maximum seldom exceeds 80 in. (203 cm) in the wetter southeast coastal regions, whereas this drops to less than 30 in. (76 cm) in the North China Plain and less than 15 in. (38 cm) at the Great Wall. In some mountainous parts of Japan and Taiwan, the yearly average may be more than 100 in. (254 cm).

In the Indian subcontinent rainfall is heaviest along the western plateau fringe and in East Bengal, where it may average over 100 in. (254 cm) per year. The interior of the peninsula is relatively dry. Northwestern India and Pakistan share the drought of southwestern Asia. With the exception of the extreme north, Ceylon generally has abundant rainfall.

Southeastern Asia has the heaviest rainfall of the entire Asiatic region. The mainland mountains facing the southwest summer monsoon crossing the Bay of Bengal, and parts of the Vietnamese and Laotian cordilleras facing the humidified northeast winter monsoons of eastern Asia, regularly get average rainfalls of 120–150 in. (305–381 cm) or even more. Equally heavy rainfalls occur in the southwestern half of Sumatra, southwestern Java, the northwestern half of Borneo, and the Pacific fringe of the Philippine Islands. With a few small exceptions, southeastern Asia has no areas that are subject to severe drought.

Vegetation. Asia's vegetation belts and zones follow, in general, the climatic patterns from desert lands through tropical to Arctic margins.

A wide belt of tundra made irregular by topography occupies the entire Arctic lowland of Siberia with widths varying from 250 to 500 mi (400 to 800 km) north and south. It is widest in the extreme northeast and it extends southward and inland with higher elevations. The frozen subsoil permits the growth of little more than mosses, lichens, dwarfed trees, and scrub. *See* PERMAFROST; TUNDRA.

The largest unbroken expanse of forest in the world is the Siberian taiga, a dominantly coniferous forest of larches, spruce, fir, and pines, with such deciduous trees as birch and aspen occurring intermixed with the conifers or taking over as a secondary growth in burnt-over areas. The width of this belt in Siberia is more than 1000 mi (1600 km) and it stretches about 4000 mi (6400 km) from the Sea of Okhotsk to the Urals. *See* TAIGA.

Various admixtures of coniferous and deciduous trees compose the vegetation of mid-latitude mixed forests. In the west Siberian plain there is a narrow zone of mixed taiga and deciduous forests including oaks, maples, ash, and lindens. This zone, with a width of 50–100 mi (80–160 km), lies somewhat south of the parallel of 60°N and fades into the steppelands that form the great spring-wheat region of Siberia. Mixed midlatitude deciduous and coniferous forest areas of a similar type occupy most of Korea, the northern half of Honshu in Japan, and the hill lands surrounding the Yellow Plain, as well as the Ch'in-ling Mountains. In southern Asia these forests are found chiefly in a narrow belt of mountain land in the outer ranges of the Himalaya. The remaining areas of these mixed forests run from the Elburz Mountains through the Armenian highlands and the Black Sea fringe of Turkey to the Aegean coast, and in southwestern Asia in the Elburz of northern Iran.

From the mixed and deciduous forests of the west Siberian plain southward, an increasingly dry steppeland is encountered. It extends for 400–500 mi (640–800 km) in a belt about 1000 mi (1600 km) long between the Urals and the Altai-Sayan and associated uplands. The northern half of this belt with its higher annual precipitation of 12–16 in. (30–40 cm) is the agricultural heart of the plain. The southern part gradually changes to desert steppe and then to desert along about the 50th parallel. Eastward of Lake Baikal a broadened steppe zone occupies the Trans-Baikal region extending southward to the Gobi Desert of southern Mongolia and eastward to the Great Hsing-an Mountains, where the zone, about 200 mi (320 km) wide, runs southward in Inner Mongolia. The steppe zone in Inner Mongolia widens with the increasing moisture south of the Great Wall to include most of China's loess plateau. Grasses also form the natural vegetation of the Manchurian plain, with tall grass in the eastern portion thinning out to short-grass steppe in the Hsing-an Mountain flanks. The Gobi Desert is flanked by steppelands to its north, east, and south, as well as by mountain steppe zones in the eastern Altai and eastern T'ien Shan.

Mixed evergreen forests appear to be limited mostly to interior southern China and to Japan from the Kwanto Plain southward, South of the Yang-tzu Valley, this forest type extends from the coast at Shanghai to the gorge lands of eastern Tibet. In Asia the characteristic trees of the mixed forest include broad-leafed evergreen trees such as banyans and camphor, and coniferous trees such as pines, cedars, and cypresses, as well as varieties of bamboo.

Tropical and subtropical rainforest is restricted to warm or hot regions of southern and southeastern Asia which get ample rainfall the year round or get so much rain during a large part of the year that a high groundwater table is maintained during the short dry season. The subtropical sectors are found along the southeastern China coast, in Taiwan, and in northern Burma; they merge with the tropical rainforest farther south, where rainfall and temperature increase. *See* RAINFOREST.

Monsoon tropical deciduous forests comprise the tropical parts of Asia which have a moderately high rainfall but a long dry season (usually in the low-sun period or winter). These forests consist mostly of mixed species, but sometimes a single species becomes dominant as a result of selection from frequent burnings.

A large region of savanna grassland surrounds the Thar Desert of northwestern India and occupies most of the Indus Valley, the Punjab, and the Kathiawar peninsula. Much of the drier interior peninsular Deccan of India also has this as a natural vegetation. Other Asian regions with similar cover are found in Yemen and the region in southeastern Arabia from Oman as far westward as the Qatar peninsula; and similar vegetation extends over the Korat plateau of Thailand, lower Thailand west of Bangkok, southern Cambodia, and small areas in interior Borneo and the Philippines. *See* SAVANNA.

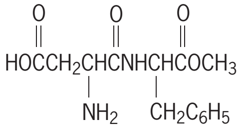
Immense areas of central and southwestern Asia have little or no vegetative cover, and bare rock alternates with sand veneering. In places shifting sand dunes are formed. Although the deserts are not necessarily lifeless, the vegetation is so widely spaced that much bare ground is exposed. The tropical desert areas generally receive their meager rainfall in torrential downpours on rare occasions. After such rains numerous herbs may spring to life and flower, while the bunch grass here and there may become green for a short season. [H.J.Wi.]

Asparagales A large, widespread order of petaloid monocotyledons consisting of 29 families and about 26,000 species. Asparagales are clearly circumscribed in deoxyribonucleic acid (DNA) sequence analyses but are difficult to define morphologically, and separation from Liliales has proved particularly problematic. Phytomelan, a dark seedcoat pigment present in most families of Asparagales but not found in other plants, is an obvious characteric of this order, although seeds of the largest family, Orchidaceae, and a few other taxa lack phytomelan. Most Asparagales are herbaceous perennials, but there are some vines including some species of asparagus (Asparagaceae), and woody taxa including aloes (Asphodelaceae). The order contains many horticultural taxa, including members of Orchidaceae (orchids), Amaryllidaceae (daffodils, belladonna lilies, and others), Iridaceae (irises, gladiolus, freesias), Convallariaceae (lily of the valley, Solomon's seal), and Hemerocallidaceae (daylilies), in addition to food crops including onions, leeks, and garlic (Alliaceae). *See* FLOWER; LILIIDAE; LILIOPSIDA; MAGNOLIOPHYTA; ORCHID; ORCHIDALES; PLANT KINGDOM. [M.F.F.; M.W.C.]

Asparagus A dioecious perennial monocot (*Asparagus officinalis*) of Mediterranean origin belonging to the plant order Liliales. Asparagus is grown for its young shoots or spears, which are canned, frozen, or cooked fresh as a vegetable. These aerial stems arise from rhizomes (underground stems). The rhizomes and the fleshy and fibrous roots constitute the massive underground part of the plant. Blanched or white asparagus is grown by ridging soil over the rows and cutting the spears beneath the soil surface. Chemical weed control is commonly used.

Commercial production is limited to areas where crowns will have a dormant period of 3–5 months each year. Dormancy in the northern states is induced by low temperatures and in California by withholding irrigation. California, New Jersey, and Washington are important asparagus-producing states. *See* LILIALES. [H.J.C.]

Aspartame A white, crystalline compound, 1-aspartyl-1-phenylalanine methyl ester (APM), with formula (**1**). It is slightly soluble in water. Its sweetening properties were discovered accidentally in 1965 when the compound, a dipeptide, was produced as an intermediate in the synthesis of the C-terminal tetrapeptide of gastrin. Aspartame is the L,L-diastereoisomer; the three other possible diastereoisomers are not sweet. The taste of aspartame would not have been predictable based on its component amino acids, aspartic acid and phenylalanine.

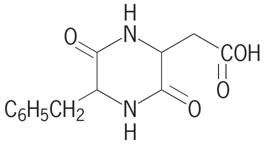


$$\mathrm{HO\overset{O}{\overset{\|}{C}}CH_2\underset{\underset{NH_2}{|}}{CH}\overset{O}{\overset{\|}{C}}NH\underset{\underset{CH_2C_6H_5}{|}}{CH}\overset{O}{\overset{\|}{C}}OCH_3}$$

(**1**)

The sweetness of aspartame relative to sucrose is a function of the latter's concentration, and is also dependent upon the presence of other flavors and materials. In a number of applications, such as chewing gum and various fruit-flavored products, aspartame favorably extends and enhances the flavor perception, and it shows synergy with other sweeteners. The sweetness perception may also last longer with aspartame than with sucrose or other sweeteners. *See* SUCROSE; TASTE.

Aspartame is metabolized to its component amino acids, which are further metabolized by the usual metabolic pathways. Under certain conditions of heat and pH in aqueous solution, aspartame is transformed into its diketopiperazine derivative, 3,6-dioxo-5-benzyl-2-piperazineacetic acid (**2**), which is tasteless.



(**2**)

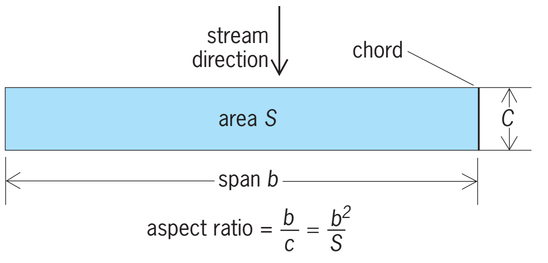
This property limits the use of aspartame when it is exposed to high temperatures, such as in baking. The stability of aspartame in aqueous solution is pH-dependent; it is most stable at a pH of approximately 4. The rate of conversion (its half-life is 262 days at 77°F or 25°C) is sufficiently slow under the conditions of normal use that aspartame has found an increasing number of applications in various food products, and is particularly successful in soft drinks. The safety of aspartame has been established by studies in animals and human beings. Aspartame has been approved in many countries for uses in both dry and wet applications. *See* FOOD ENGINEERING. [D.L.A.]

Aspect ratio As originally conceived, the ratio of the span of a wing or airfoil to the chord of a wing, where the span is the maximum cross-stream dimension and the chord is the dimension in the streamwise direction, as illustrated. This definition is unambiguous only in the case of a rectangular wing.

Because early wings were usually nearly rectangular, no confusion resulted from the original definition. Later, when wings were tapered or had complex planforms, another definition became necessary. It was desirable that the new and more general definition correspond to the old definition for the special case of the rectangular wing. The more general definition of geometrical aspect ratio which is now universally used is given in the equation below, where A is the aspect ratio and b and S are

$$A = b^2/S$$

defined in the illustration. Because S is equal to bc for a wing of



Aspect ratio of a wing.

rectangular planform, the definition of aspect ratio given in the equation corresponds to the original idea of the ratio of the span to the chord for a rectangular wing. [A.E.V.D./R.L.Bi.]

Asphalt and asphaltite Varieties of naturally occurring bitumen. Asphalt is also produced as a petroleum byproduct. Both substances are black and largely soluble in carbon disulfide. Asphalts are of variable consistency, ranging from a highly viscous fluid to a solid, whereas asphaltites are all solid. Asphalts fuse readily, but asphaltites fuse only with difficulty. Asphalts may, moreover, occur with or without appreciable percentages of mineral matter, but asphaltites usually have little or no associated mineral matter. *See* Bitumen; Impsonite; Wurtzilite.

Many asphalts occur as viscous impregnations in sandstones, siltstones, and limestones. Most such deposits are thought to be petroleum reservoirs from which volatile constituents have been stripped by exposure of the rock. Relatively pure asphalt occurs in Kern, San Luis Obispo, and Santa Barbara counties, California. Occurrences of asphalt are also known in Kentucky and Oklahoma. Although asphalt seeps have long been known in France, Greece, Russia, Cuba, and other countries, the best known and largest are those of Venezuela and Trinidad.

The asphaltites (gilsonite, grahamite, and glance pitch) were probably derived from a saline lacustrine sapropel and owe their variable properties to differences in environment of deposition. These substances occur on a large scale in the Uinta Basin of northeastern Utah, where they are derived from upper Eocene Green River sediments, most of which are oil shales high in carbonate content. *See* Oil shale; Sapropel. [I.A.B.]

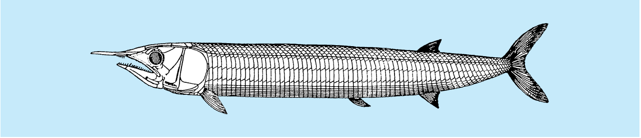
Asphalt is derived from petroleum in commercial quantities by removal of volatile components. It is an inexpensive construction material used primarily as a cementing and waterproofing agent. *See* Petroleum products.

Asphalt is composed of hydrocarbons and heterocyclic compounds containing nitrogen, sulfur, and oxygen; its components vary in molecular weight from about 400 to 5000. It is thermoplastic and viscoelastic; at high temperatures or over long loading times it behaves as a viscous fluid, while at low temperatures or short loading times it behaves as an elastic body.

The three distinct types of asphalt made from petroleum residues are straight-run, air-blown, and cracked. Straight-run asphalt, characterized by a nearly viscous flow, is used in the construction of pavement surfaces for roads and airport runways. Air-blown asphalt is resilient and has a viscosity that is less susceptible to temperature change than that of straight-run asphalt. It is used mainly for roofing, pipe coating, paints, underbody coatings, and paper laminates. Cracked asphalt, with limited applications such as dust laying or as an insulation board saturant, has a nearly viscous flow, and its viscosity is more susceptible to temperature change than straight-run asphalt. [T.K.M.]

Aspidogastrea A group of entoparasites considered to be a subclass or order of the Trematoda. They have strongly developed ventral holdfasts. Two families, Aspidogastridae and Stichocotylidae, are recognized. Aspidogastridae, which are the commonest, occur in various cavities of mollusks and in digestive tracts of fishes and turtles. Elongate Stichocotylidae occur in the digestive tracts of skates. Little is known of the physiology of aspidogastreids, but they appear less host-specific than other trematodes. *See* Digenea; Trematoda. [W.J.Ha.]

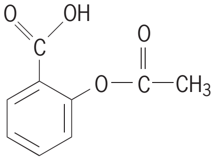
Aspidorhynchiformes A small order of specialized holostean fishes which are first recorded from Middle Jurassic deposits of Europe, and probably had a worldwide distribution in the warm seas of the Cretaceous Period. The order contains one family, Aspidorhynchidae, and two genera: *Aspidorhynchus* and *Belonostomus*. These fishes, some of which reached a length of over 3 ft (0.9 m), are characterized by a ganoid scale covering with much deepened scales along the flank, by an elongate fusiform body and head with long slender snout, and by an externally symmetrical tail. All the fins are small and fringing fulcra are reduced or absent. The dorsal and anal fins are positioned opposite one another far back on the body, and the pelvic fins are inserted closer to the anal than to the pectorals (see illustration). *See* Holostei.



***Aspidorhynchus acutirostris*, Upper Jurassic, Bavaria. (*After Assmann*)**

In the body form, fin position, and elongated snout, the aspidorhynchiforms resemble some of the living teleostean Exocoetoidei (needlefishes and sauries). It seems likely that these two widely separated and unrelated groups of fishes shared a similar mode of life, being predacious open-water forms that utilized their long snouts and strong swimming ability in capturing prey. *See* Osteichthyes; Teleostei. [T.M.C.]

Aspirin The acetyl ester of salicylic acid, also known as 2-(acetyloxy)-benzoic acid and acetylsalicylic acid (see structure below). Aspirin is prepared by the acetylation of salicylic acid with acetic anhydride.



Aspirin is effective as an analgesic, antipyretic, and anti-inflammatory drug. It prevents the aggregation of platelets, and there is some evidence that it can prevent stroke. Aspirin, if tolerated, is the preferred drug for the treatment of rheumatoid arthritis, and it has been used in the treatment of osteoarthritis. Aspirin lowers fever, probably by acting on the hypothalamus. Salicylates inhibit aldose reductase in the lens; it has been suggested that they might retard the development of cataracts. Aspirin might encourage the development of Reye's syndrome, an acute encephalopathy which occurs in children who recover from viral disease, but this cause-and-effect relationship remains to be confirmed. *See* Analgesic; Arthritis.

Intolerance to aspirin is not uncommon. It tends to develop in middle age and involve the skin or the respiratory tract, or both. Death rarely ensues because people rapidly become aware of their intolerance. [M.S.]

Assembly machines Machines that take discrete components as they come into an assembly department and bring them together so as to produce a configuration of some practical value. Such machines differ from packaging machinery in two ways: in assembly machinery, components must be inserted in specific sequence and spatial attitude; and they must often be tested functionally as part of the assembly process.

Assembly machinery was originally conceived for situations where volume or hazard of production, parts size, or availability of labor made manual assembly impractical from an operational or economic viewpoint. The early applications of assembly machinery and the majority of modern applications are found in the automotive industry, consumer products, manufacturing, or hazardous assembly.

Assembly machinery can be classified in several ways, including work path (rotary, carrousel, or linear, index-dwell ratios (continuous motion, intermittent motion, or power and free); actuation (mechanical, fluid power, or electronically programmable); work nest configuration (pallet or walking beam); and design (special or standard modular). The engineers who specify assembly machinery will usually select from one or more of these categories based on product size and weight, volume of production, product life cycle, future and present flexibility needs, human resources, and return on investment.

Rotary dial machines have a number of pallets fastened to a rotating dial or ring. Transfer devices are usually mounted to the machine base, while feeders are placed outside the periphery of the dial. Carrousel machines are usually configured in race track shape. Work-holding nests (the machine elements used to hold all of the parts being assembled) are secured to one another (a configuration known as precision link) or fastened to a chain. Linear machines have an open-loop configuration in which pallets transport the product being assembled along one or more linear paths, rather than in a closed circuit such as rotary or carrousel machines.

In any form of automatic assembly, production rates will be controlled by the single longest operation. If new parts can be added to the assembly without the fixture being stopped, the machine can be operated in a continuous motion.

Assembly machines perform several tasks: parts feeding (including orientation, separation, and transfer); parts joining (for example, welding, riveting, and soldering); parts inspection (condition, parameters, presence, and position); functional testing (for example, capacitance, torque, and pressure decay); marking (date coding, model number, and operational characteristics); and ejection (in controlled or uncontrolled positions). Many of the tasks of assembly machinery use commercial units identical to those used on manual lines. The unique task of automatic assembly machinery is that of parts feeding, which consists of accepting the component parts as they come to the assembly area and taking one of these components, separating that component from other parts, changing its spatial orientation to a usable insertion attitude, and transferring it from the orientation device into the work-holding fixture or into a partially completed assembly. *See* MANUFACTURING ENGINEERING; PRODUCTION METHODS. [F.Ri.]

Astatine A chemical element, At, atomic number 85. Astatine is the heaviest of the halogen groups, filling the place immediately below iodine in group VII of the periodic table. Astatine is a highly unstable element existing only in short-lived radioactive forms. About 25 isotopes have been prepared by nuclear reactions of artificial transmutation. The longest-lived of these is ^{210}At, which decays with a half-life of only 8.3 h. It is unlikely that a stable or long-lived form will be found in nature or prepared artificially. The most important isotope, used for tracer studies, is ^{211}At. Astatine exists in nature in uranium minerals, but only in the form of trace amounts of shortlived isotopes, continuously replenished by the slow decay of uranium, The total amount of astatine in the Earth's crust is less than 1 oz (28 g).

In aqueous solution, astatine resembles iodine except for differences attributable to the fact that astatine solutions are of necessity extremely dilute. Like the halogen iodine, when astatine exists as a free element in solution, it is extracted by benzene. The element in solution is reduced by agents such as sulfur dioxide and is oxidized by bromine. It is more electropositive than the other halogens. It has oxidation states with coprecipitation characteristics similar to those of the iodide ion, free iodine, and the iodate ion. Powerful oxidizing agents produce an astatate ion, but not a perastatate ion. The free state is most readily obtained and is characterized by high volatility and high extractability into organic solvents. *See* HALOGEN ELEMENTS. [E.K.H.]

Asterales An order of flowering plants, division Magnoliophyta (Angiospermae), which gives its name to the subclass Asteridae in the class Magnoliopsida (dicotyledons). The Asterales have often been included in the order Campanulales, but they are perhaps more closely allied to the Rubiales and Dipsacales. The order consists of only the very large family Asteraceae (Compositae), with about 20,000 species, occurring in nearly all parts of the world but most abundant and conspicuous in areas which are not densely forested. *See* CAMPANULALES; DIPSACALES; RUBIALES.

New England aster (*Aster novae-angliae*), a characteristic member of the order Asterales. (*Courtesy of Alvin E. Staffen, National Audubon Society*)

The Asterales are marked by their inferior ovary, single basal ovule, specialized pollen presentation mechanism, and pseudanthial, centripetally flowering heads which often have specialized marginal flowers with a strap-shaped corolla resembling the petal of an ordinary flower. Most members of the order are herbaceous, but some, such as the sagebrush (*Artemisia tridentata*), are shrubs, and a few tropical species are trees. Many well-known garden ornamentals, such as aster (see illustration), chrysanthemum, dahlia, daisy, sunflower (*Helianthus*), and zinnia, belong to the Asterales. A few garden vegetables, for example, lettuce (*Lactuca*) and artichoke (*Cynara*), and some common weeds, such as dandelion (*Taraxacum*), thistle (*Cirsium*), and ragweed (*Ambrosia*), also belong to the order. *See* ARTICHOKE; ASTERIDAE; LETTUCE; MAGNOLIOPHYTA; MAGNOLIOPSIDA; ORNAMENTAL PLANTS; PLANT KINGDOM; SUNFLOWER. [A.Cr.; T.M.Ba.]

Asteridae A large subclass of the class Magnoliopsida (dicotyledons) of the division Magnoliophyta (Angiospermae), the flowering plants, consisting of 11 orders, 49 families, and more than 60,000 species. The Asteridae are mostly sympetalous with unitegmic, tenuinucellate ovules and with the stamens usually as many as, or fewer than, the corolla lobes and alternate with them. Most of them have two carpels, but a few have as many as five or even more carpels, and a few others are pseudomonomerous. The largest orders of the group are the Asterales (about 20,000 species), Scrophulariales (about 11,000 species), Lamiales (about 7800 species), and Rubiales (about 6500 species). Other orders are the Gentianales, Plantaginales, Solanales, Callitrichales, Campanulales, Calycerales, and Dipsacales. See individual articles on each order. *See* MAGNOLIOPHYTA; MAGNOLIOPSIDA; PLANT KINGDOM. [A.Cr.; T.M.Ba.]

Asteroid One of the many thousands of small planets (minor planets) revolving around the Sun, mainly between the orbits of Mars and Jupiter. Newly discovered asteroids are assigned a catalog number and name (such as 433 Eros) only after they are observed often enough to compute an accurate orbit. There are over 73,000 cataloged asteroids. *See* PLANET.

The majority of asteroids have semi-major axes (mean distances to the Sun; symbolized a) between 2.2 and 3.2 astronomical units (1 AU = distance from Earth to the Sun = 1.496×10^8 km = 9.3×10^7 mi). However, numerous small asteroids orbit between Venus and Mars, and two large groups, the Trojan asteroids, orbit at Jupiter's distance from the Sun. *See* TROJAN ASTEROIDS.

In 1992, the first of the trans-Neptunian "asteroids" was discovered. Called Kuiper Belt objects (KBOs), about 900 had been found by mid-2004. They represent a population of bodies much more numerous than the main-belt or Trojan asteroids, but are more properly thought of as comets. There are also a modest number of minor planets orbiting the Sun in temporary orbits beyond Jupiter but well inside the Kuiper Belt; they are termed Centaurs. *See* COMET; KUIPER BELT.

Most asteroid orbits are more elliptical and inclined to the plane of the ecliptic than the orbits of major planets. A number of small asteroids (Amor objects) cross, but do not intersect, the orbit of Mars, and a few even cross the Earth's orbit (Apollo objects) or orbit inside the Earth's orbit (Aten objects).

Improvements in radar technology make it possible to image small asteroids that pass close to the Earth almost as well as by spacecraft flybys. For more distant asteroids the chief technique used to measure asteroid diameters is radiometry, which compares the brightness of reflected visible sunlight from an asteroid with the brightness of the asteroid's emitted thermal radiation in the infrared. *See* ALBEDO; INFRARED ASTRONOMY; OCCULTATION.

There are about 30 asteroids larger than 124 mi (200 km) in diameter; about 75% of them are soot black (geometric albedos of 3–5%). Asteroids are much more numerous at smaller sizes, generally following a size distribution characteristic of fragmentation processes, as would be expected if the asteroids were smashing into each other. Indeed, there are so many large asteroids confined in the volume of the asteroid belt that collisions sufficient to fragment all but the larger asteroids occur every few billion years, and much more often for smaller ones. Thus all asteroids have been extensively battered and many are collisional fragments.

Spectra of sunlight reflected from asteroids have shapes, including absorption bands, characteristic of different rock-forming minerals. Combined with the albedo data from radiometry, the spectral colors of surfaces of over 2000 asteroids show that more than three-quarters of them have very low albedos and are composed of carbon-rich material (often with hydrated, or water-rich, minerals). The black asteroids located in the middle and outer parts of the belt (called C type) resemble carbonaceous meteorites, which are believed to be among the most primitive materials in the solar system, little altered since the planets were forming. The black asteroids near the outer edge of the main belt have a reddish tinge and are not represented by known meteorites on the Earth; they are called P types, and may be even richer in organic components. Still farther out, many of the Trojans are even redder and more mysterious; they are termed D types. Closer to the inner edge of the belt, most asteroids are so-called S types, characterized by moderately high albedos and by absorption bands due to the common silicate minerals pyroxene and olivine. They also contain considerable metal, and probably are akin to either the stony-iron meteorites or the ordinary chondritic meteorites. The general progression of asteroid compositions is thought to reflect the variation with distance from the Sun in the composition of the original nebular dust from which the planets were formed. *See* COSMOCHEMISTRY; METEORITE; SOLAR SYSTEM.

Apollo, Amor, and Aten asteroids are of special interest, particularly because they stand a chance of striking the Earth. Indeed, Meteor Crater (Arizona), and other craters on the Earth and the Moon, testify to the potential for collisions with near-Earth asteroids. Many scientists believe that just such a collision 6.5×10^7 years ago rendered most species of life, including the dinosaurs, extinct. A huge, eroded crater of that age on the Yucatán peninsula in Mexico must have been caused by the impact of an asteroid or comet about 10 mi (16 km) in diameter. In 1908, a small asteroid, perhaps 160 ft (50 m) across, exploded over the Tunguska region of Siberia with energy equivalent to 15 megatons of TNT. Only about one-third of the potentially threatening objects have been discovered so far.

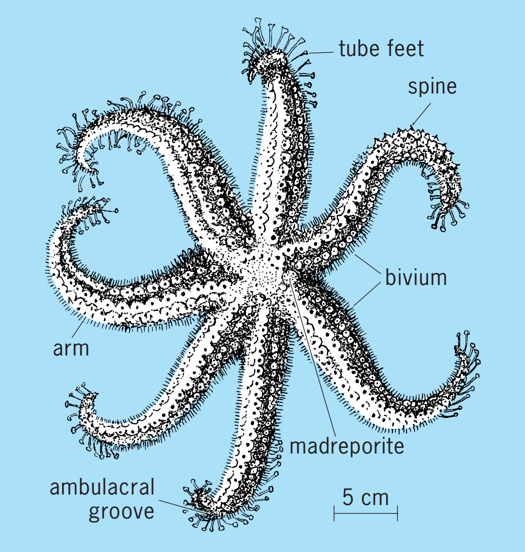
After some tens of millions of years, most of the current crop of near-Earth asteroids will have struck the Earth, the Moon, the Sun, or one of the other inner planets, or will have been ejected from the solar system. Most are probably fragments of main-belt asteroids, traveling in chaotic orbits, just like their smaller cousins, the meteorites.

Current cosmogonical models for the origin of planets involve accretion from myriads of asteroidlike planetesimals. It is likely that asteroids are a remnant of the planetesimals that failed to accrete into a planet between Mars and Jupiter. Perhaps bombardment of the asteroid zone by large planetesimals scattered from massive, nearby Jupiter increased the relative velocities of asteroids to the present value of 3 mi/s (5 km/s) so that asteroids fragment rather than accrete when they meet each other. Instead of forming a planet, the asteroids have been smashing each other to bits.

Evidently some asteroids of primitive, nonvolatile solar composition were heated within the first few hundred million years after the origin of the solar system, perhaps by the solar wind or extinct radionuclides, and they melted. While the unmelted, weak, C-type asteroids may have been depleted by a large factor by collisions, most of the strong stony-iron cores of the melted proto-asteroids have survived; perhaps they are among the M- and S-type asteroids observed today. The asteroids still collide and fragment, occasionally spraying the inner solar system with chips that produce craters or fall as meteorites. [C.R.C.]

Asteroidea A subclass of the class Stelleroidea in the subphylum Asterozoa; asteroids are known as starfish (see illustration). The arms are not sharply demarcated from the rest of the body. The ambulacral ossicles never fuse to form vertebrae. The tube feet are locomotor organs, usually suctorial, emerging from an open ambulacral groove. The dominant growth gradients are such as to cause the skeletal ossicles to lie in longitudinal rows known as series (for example, adambulacral series, ventrolateral series, and inferomarginal series).

For many years the Asteroidea and the Ophiuroidea were accorded separate class status, but in 1951 W. K. Spencer showed that they have a common origin. Most differences between these groups disappear when fossil forms are considered. Thus both groups are now ranked as subclasses of Asterozoa. The 1700 or so known fossil and recent species of Asteroidea are now grouped into six orders: Platyasterida, Paxillosida,



A representative asteroid, *Astrostole scabra*.

Valvatida, Forcipulatida, Notomyotida, and Trichasteropsida. Asteroids range in size from about 0.4 to 40 in. (10 mm to 1 m) across. Many starfish are brightly colored and attractive animals, but some are dowdy and cryptic. Their conjugated carotenoid pigments fade on preservation. Like most echinoderms, starfish have a lifespan of about 5 years. *See* OPHIUROIDEA.

Starfish inhabit all types of bottom throughout the world's seas and oceans. Some burrow in sand and mud, and others live on rocks and coral reefs, where they are at their most diverse. Most families show well-defined bathymetrical preferences, but there are exceptions. There are 12 families which occur at depths greater than 2 mi (3 km), and several genera extend below 4 mi (6.5 km).

The outer surface is coated with a thin layer of ciliated epithelium. Below this lies connective and muscle tissue which forms the body wall and in which the skeletal ossicles are embedded, forming the test. Some of the ossicles, notably the spines, protrude to the exterior. The arms can be slowly moved by the body wall musculature. Although 5 arms are common, up to 12 occur in a number of genera, and more than 12 may occur, as in *Acanthaster*.

Pedicellariae, small seizing organs used to grip intruders, occur in some starfish. They probably assist in protecting the delicate epithelium from predators and sediments. Pedicellariae are formed from two or four modified spines which are snapped together by adductor muscles like minute tongs. Their shape and type is important in classification because different orders of starfish have evolved different forms of pedicellariae. The well-developed water-vascular system follows the pattern for the phylum, with the following features. With the exception of some Paleozoic genera, the madreporite is always on the upper (aboral) side. There is usually only one madreporite situated interradially, but *Allostichaster* has 2 to 4 and *Acanthaster* up to 16 or more. The tube feet may be peglike and suckerless or columnar and suckered. The nervous system also follows the pattern for the phylum. Starfish cannot see, but they clearly detect changes in light intensity such as those caused by shadows. They have photosensitive eyespots located at the tip of each arm. The terminal tube feet of each ambulacrum appear to be especially sensitive to water-borne chemicals which may be emitted by prey species, and they are thus used in food detection.

Starfish are voracious feeders. The prey is detected by water-borne odors or by direct contact as the result of random movement. Small food, such as amphipods and young mollusks, may be engulfed whole. *Acanthaster* everts part of its stomach out of the mouth and wraps it over coral polyps, which are thus digested outside the predator's body. The mouth is in the middle of the lower (oral) surface of the disk and leads through a short esophagus to the cardiac stomach. The number of lobes of this organ correspond to the arm number of the starfish. Above the cardiac stomach lies the pyloric stomach, again with as many branches as there are arms. In most species, a short intestine leads upward to the rectum and anus, generally situated near the middle of the upper (aboral) surface. In starfish which lack an anus, the feces are extruded through the mouth.

Asteroids are generally mature and able to reproduce at 1 year. They normally continue to grow for about 4 years, growth taking place when food is abundant. The sexes are usually separate, but in a few genera, such as *Fromia*, hermaphrodites occur, the sex changing with age. Regeneration of lost or damaged parts is a characteristic of most genera. In *Linckia* this is most marked, and a whole new individual can be regenerated from a fragment of an arm. *See* ECHINODERMATA. [A.C.C.]

Asteroxylales A small extinct order of the class Lycopsida that bridges the evolutionary gap between the primitive Zosterophyllopsida and relatively advanced Lycopsida; hence the asteroxylaleans are often termed prelycopsids. The best-known asteroxylalean species are of Early Devonian age, although similar forms survived to the Late Devonian. All possessed at least some hydrophytic features; together with a paucity of strengthening tissues, this characteristic suggests that they largely relied on hydrostatic pressure for structural support.

With the exception of *Asteroxylon*, asteroxylalean fossils are not well preserved. The asteroxylaleans are regarded as the most primitive lycopsids, but they can also be considered as the most advanced zosterophyllopsids; some authorities prefer to disperse the prelycopsids among other taxa.

The pivotal plant in this order is *A. mackiei*, which originated from the remarkable biotic communities petrified in Lower Devonian volcanigenic cherts at Rhynie, Scotland. This species had naked horizontal rhizomes that produced primitive roots and aerial branches up to 20 in. (50 cm) high and 0.4 in (1 cm) in diameter. The radially symmetrical actinostele (a star-shaped protostele) is typical of primitive lycopsids rather than zosterophyllopsids. Vascular traces extended toward, but did not enter, the densely packed clasping tissue outgrowths termed protomicrophylls.

The sporangia were homosporous, kidney shaped, and distributed singly and randomly among the leaves on the more distal axes. Like the zosterophyllopsids, *Asteroxylon* bore sporangia on stalks with a vascular supply that was independent of, and more extensive than, that of the surrounding enations. These reproductive structures are generally regarded as homologous with vegetative lateral branches. [R.M.Ba.; W.A.DiM.]

Asthenosphere A layer in the Earth's interior occurring approximately 50 mi (80 km) below the surface and extending to a depth of about 180 mi (300 km); it consists of rocks possessing less mechanical strength than the rocks above or below it. The asthenosphere is a relatively thin layer contained in a much larger region known as the mantle. The mantle is the solid portion of the Earth's interior that is located between the bottom of the Earth's crust (at about 15 mi or 25 km depth) and the top of the liquid outer core (at 1800 mi or 2900 km depth). The layers in the mantle that are above and below the asthenosphere are known as the lithosphere and the mesosphere respectively. The lithosphere is broken into 12 major tectonic plates that possess much greater mechanical strength than the underlying asthenosphere. *See* LITHOSPHERE.

The thermal structure of the asthenosphere, and indeed the very existence of this layer, is determined by the thermal convection process in the mantle. The convective flow in the mantle transports heat vertically upward from the deep interior, and it drives the observed horizontal motions of the tectonic plates. In the deep mantle, below the lithosphere, the vertical advection of heat by the convective flow is sufficiently rapid to create an adiabatic depth variation of mantle temperature. In the lithosphere the velocities of the vertical flows are much smaller than in the deep mantle; therefore the depth variation of temperature in this region is determined by a balance between the horizontal advection of heat (due to the horizontal flow associated with the tectonic plate motions) and the vertical conduction of heat to the surface. The asthenosphere is, in effect, a layer in which the depth variation of temperature changes from a steep gradient in the lithosphere to a relatively flat gradient in the deep mantle.

Since the mantle flow occurs over geological time scales, the long-term mechanical strength of the mantle rocks may be defined as the amount of stress that must be applied to produce some specified flow velocity. The flow of the solid mantle is made possible by the presence of naturally occurring microscopic defects in the crystal grains that constitute mantle rocks. The movement of these defects, due to thermally generated internal stresses, allows the mantle to creep as though it were a fluid with an extremely high viscosity. The effective viscosity of mantle rocks is a direct measure of their long-term mechanical strength, and it is strongly dependent on the ratio between the temperature (T) and the melting temperature (T_m) of the rocks. An increase of the scaled temperature T/T_m (also called the homologous temperature) produces exponentially large decreases in the effective viscosity of rocks. In the asthenosphere the average mantle temperature is closest to the melting temperature; thus the effective viscosity (that is, mechanical strength) is lower there than above or below the asthenosphere. There is a smooth transition between the zone of reduced mechanical strength in the asthenosphere and the zone of greater strength in the adjoining portions of the mantle. Therefore it is not possible, or meaningful, to specify precise locations for the upper and lower boundaries of the asthenosphere. *See* RHEOLOGY.

The analysis of seismic data (for example, the travel times of seismic waves) has provided the only direct indication of the presence of the asthenosphere. Seismologists usually refer to the asthenosphere as a low-velocity zone on account of the reduction of seismic wave speeds in this layer. *See* SEISMOLOGY.

Seismologists have made considerable progress in the application of tomographic imaging techniques to map the three-dimensional variation of seismic wave speed in the mantle. A tomographic model of the relative perturbations of seismic shear velocity has been constructed; at a depth of 120 mi (200 km), this model indicates that the shear-velocity perturbations range from -2.5 to $+4.5\%$. The coldest (that is, largest negative perturbation of) temperature is found below the continents. This local reduction of mantle temperature, and the corresponding increase of mechanical strength, may be sufficiently great that the concept of the asthenosphere (as a hotter and mechanically weak region) ceases to be valid below the continents. The concept of the asthenosphere is valid below the oceans, and there is an obvious concentration of hotter material below the plate boundaries, which are zones of active spreading (the so-called mid-oceanic ridges). This pattern suggests that the observed spreading at the mid-oceanic ridges is fed, and perhaps partially driven, by the upward ascent of hotter mantle material across the asthenosphere. When the ascent of this hotter material is sufficiently rapid (that is, adiabatic), the material begins to melt (and may thus produce surface eruptions of lava), because the temperature of this ascending material exceeds the local melting temperature. This partial melting can occur in the asthenosphere. *See* ISOSTASY; PLATE TECTONICS. [A.M.Fo.]

Asthma An allergic inflammatory disease of the airways, involving mast cells, eosinophils, macrophages, fibroblasts, and neutrophils. Such inflammatory changes are associated with widespread airflow obstruction, which is variable and improves (reverses) spontaneously or with appropriate therapy. Inflammation progresses to increased airway irritability (hyperresponsiveness) induced by the inhalation of allergens, cold air, and occupational factors. Although bronchospasm can be induced immediately after exposure to a specific allergen in an appropriately sensitized recipient, it is the late allergic response that most resembles the inflammatory reaction occurring in asthma. Central to this reaction is the release from mast cells, eosinophils, and lymphocytes of chemical mediators such as histamine, leukotrienes (potent bronchoconstricting agents), and various cytokines which perpetuate the response. Potent neurohumoral agents derived from neural pathways contribute further to the bronchospasm. *See* CYTOKININS; HYPERSENSITIVITY.

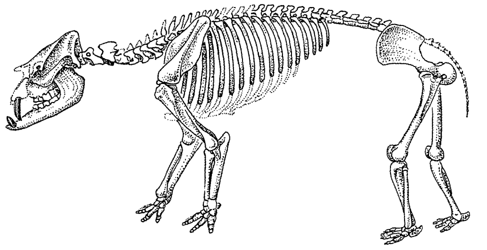
Wheezing, nocturnal breathlessness, coughing, and chest tightness often relieved by expectoration are highly suggestive of asthma. Episodes of breathlessness which result from exposure to an irritant (such as cold air) or an allergen (such as dust mites) following exercise or a viral infection and which are reversed spontaneously or with therapy are diagnostic of asthma. Eczema and edema in the folds of the nasal chambers are suggestive of a hereditary allergy, the major predictor of asthma. Objective measures of airflow obstruction which improved spontaneously or with therapy are also central to establishing an asthma diagnosis. Atopy, the genetic predisposition for developing an immunoglobulin-E (IgE) mediated (allergic) response to inhaled environmental allergens, is the strongest predisposing factor for developing asthma. Asthma may be classified, therefore, according to severity, etiology, or pattern of airflow obstruction. It is helpful to differentiate those factors that induce inflammation from those that incite acute bronchospasm in susceptible individuals. The association of an elevated serum IgE and the occurrence of asthma in all age groups, including those who are not atopic, makes antigenic stimulation causal in all instances of asthma. The severity of asthma can best be defined in terms of peak-flow monitoring (monitoring the severity of the allergy). Such evaluations as mild, moderate, and severe are useful in applying therapy in a stepwise manner contingent on severity. *See* IMMUNOGLOBULIN.

Successful management of asthma requires education of the sick individual coupled with the development of a partnership with an asthma management health-care team; assessing and monitoring the severity of asthma, with utilization of objective parameters of assessment (for example, the peak-flow meter, a device that measures the amount of air that enters and leaves the lungs); environmental management to avoid asthma triggers; and establishment of a drug regimen that controls asthma (medications include bronchodilators, which act as relievers, and bronchodilators, which act as preventers), as well as a written plan to prevent the condition from becoming worse. Adequate management of asthma should control the symptoms, prevent asthma attacks, return and maintain pulmonary function as close to normal as possible, maintain normal activity levels including exercise, avoid adverse side effects from the drugs, reduce and prevent irreversible airway changes, and prevent mortality. *See* ALLERGY; RESPIRATORY SYSTEM DISORDERS. [A.L.She.]

Astomatida An order of protozoans, subclass Holotrichia, in which all species are mouthless. All species are parasitic in other animals, typically oligochaete annelids. Many astomatids possess an elaborate holdfast organelle. *Anoplophyra* is a typical example. *See* CILIOPHORA; HOLOTRICHIA; OLIGOCHAETA. [J.O.C.]

Astrapotheria A relatively small group of extinct South American ungulates, ranging from the late Paleocene to the late Miocene. They are customarily divided into two suborders: the late Paleocene–Eocene Trigonostylopoidea, and the early Eocene–late Miocene Astrapotheroidea.

One of the most spectacular and advanced members of the order was *Astrapotherium* (see illustration). This animal, known from the late Oligocene to the late Miocene, averaged 9–10 ft (2.7–3 m) in length, although some other forms grew even larger. The anterior part of the skull was striking with the huge,



Astrapotherium magnum **skeleton.**

persistently growing, curving canines, whose function is unexplained. The retracted, chopped-off appearance of the snout region strongly suggests that this animal had a moderately large trunk. The front legs were somewhat more strongly constructed than the hind ones, and this makes the habits of this animal a puzzle. *See* MAMMALIA. [F.S.S.]

Astrometry That part of astronomy dealing with the position and motion of celestial objects, including solar system objects, stars, radio sources, and galaxies.

In 1994 the International Astronomical Union (IAU) adopted the International Celestial Reference Frame (ICRF), based on about 400 extragalactic radio sources, as the fundamental reference frame. This replaced the previous fundamental catalogs, such as the FK5, which were based on positions and proper motions of bright stars. The *Hipparcos Star Catalog*, based on observations of that astrometric satellite, provides an accurate optical catalog based on the International Celestial Reference Frame. Other star catalogs provide a denser coverage of the sky and can reach fainter magnitudes, but with reduced accuracies. The positions and proper motions of the stars provide a two-dimensional map of the sky for a given time. To provide the three-dimensional aspect, the parallaxes (which give the distances to the stars) and the radial velocities are necessary. With that information, it is possible to determine a three-dimensional position and velocity for each star. *See* ABERRATION (ASTRONOMY); CELESTIAL REFERENCE SYSTEM; FUNDAMENTAL STARS; PARALLAX (ASTRONOMY).

An extragalactic reference frame, defined by radio sources, has the advantage that since such sources are so distant they have no apparent motion. These sources are observed by means of very long baseline interferometry (VLBI), using radio antennas so that their positions can be determined to milliarcsecond accuracies. This accuracy compares favorably with the 0.1-arc-second accuracy of bright-star catalogs, which degrade with time because of the inaccuracies of proper motions. *See* RADIO TELESCOPE.

Observations can be made at different wavelengths, such as the radio, optical, and infrared, and the resulting star catalogs must be related to each other. Observations can be divided into those involving large-angle measurements and those employing small-angle measurements. *See* TELESCOPE.

Large-angle measurements determine the difference in position between objects over large angular distances in the sky. Transit circles, which made such observations in the past, are being replaced by more accurate observational techniques. Interferometers, observing radio, optical, or infrared wavelengths, combine the reception of the emission from a source at two separate detectors. By measuring the time difference between the two detections, a very accurate measurement of the angle to the source can be provided. In addition, the *Hipparcos Astrometric Satellite* used a technique for observing pairs of stars separated by approximately 60° to form a catalog of stars located throughout the sky.

Small-angle measurements provide accurate relative positions of the observed objects. They can also provide, by means of multiple observations, the parallaxes and motions of the stars with respect to the reference stars in the field. The charge-coupled device (CCD) has replaced the photographic plate for small-angle measurements. *See* ASTRONOMICAL PHOTOGRAPHY; CHARGE-COUPLED DEVICES.

The speckle interferometer takes very rapid exposures (approximately 30 per second) to freeze atmospheric effects. These short exposures can then be added together to measure the separation, relative position, and magnitude between pairs of stars that could not be observed with such accuracy through the atmosphere. Thus, speckle interferometry is used primarily for double stars. *See* SPECKLE.

The atmosphere is the primary limitation on astrometric accuracy, and thus provides the impetus for plans to make observations from space or the lunar surface. *See* SATELLITE ASTRONOMY. [P.K.S.]

Astronautical engineering The engineering aspects of flight and navigation in space, also known as astronautics. Astronautical engineering deals with vehicles, instruments, and other equipment used in space, but not with the sociological or economic aspects of space flight, except as they influence the equipment.

There is a lack of parallelism between astronautic and aeronautic vehicle terminology. An aircraft is a self-contained vehicle, having within its structure essentially all the equipment required to transport its payload from one place to another. A spacecraft, in the more restricted sense, is the container for the payload. Sometimes the word is used to denote the container and payload. Most spacecraft, to date, have had either very limited propulsion or none at all. Since enormous speeds are the hallmark of all astronautic missions, unpowered spacecraft require a "booster," or "launch vehicle," usually a rocket many times as large as the spacecraft. The weight of the spacecraft, in fact, seldom exceeds 5% of the total launch vehicle weight.

It is extremely expensive to put a pound of payload into Earth orbit. Thus designers have been justified in going to great lengths to convert a pound of structure into a pound of payload. Great improvement appears possible in this respect; only the cost of the propellant seems to be irreducible. In view of the high cost of space operations, it is especially important that space vehicles operate long enough to successfully fulfill their missions. A severe reliability requirement is thus imposed upon vehicles and equipment intended for missions, such as journeys to the planets, which may require up to a year or more to accomplish. For complex equipment in space vehicles, operating lifetimes of this order of magnitude are difficult to attain. The requirements for high reliability and low weight add tremendously to the cost of the payloads themselves, to the extent that their cost approaches that of the launch vehicle. All space missions through 1975 used expendable launch vehicles. The space shuttle, a reusable launch vehicle, is expected to reduce the costs of Earth-to-orbit transportation. *See* SPACE SHUTTLE.

Gravity is a dominating influence in the design of space launch vehicles. Despite the fact that the pull of gravity extends to infinity, it is nonetheless possible to escape permanently from the Earth's gravity in the sense of never being drawn back to the ground. The key is speed. Circular velocity is the minimum at which a space vehicle can remain permanently above the Earth. At low altitudes, this velocity is about 25,000 ft/s (7.9 km/s). As the speed is increased above the circular velocity, the path of a vehicle becomes a larger circle or an elongated ellipse. When the speed reaches 37,000 ft/s, or about 7 mi/s (11.2 km/s), the path becomes a parabola and the vehicle will travel along one of the legs to infinity without further propulsion. *See* ESCAPE VELOCITY; SATELLITE.

These velocities are tremendous by any previous standard. To reach them, a vehicle must carry the corresponding amount of energy in the form of propellant.

Even with the most energetic propellants and the lightest structures, it has not yet been possible to reach orbital velocity with a single rocket. To overcome this seemingly insurmountable obstacle, one rocket is carried as the payload of a larger one. When the larger burns out, the second is ignited and adds its velocity to that of the first. This is known as the step-rocket or staging technique. For lunar and planetary missions, lightweight vehicles, powerful propellants, and many stages are used. The lunar orbit rendezvous method required a total of six stages to take the Apollo astronauts to the Moon and back. *See* ROCKET STAGING; SPACECRAFT PROPULSION.

Although propulsion is the key to space flight, other elements are essential and present numerous new problems. One such element is guidance and control. For the ascent phase of space vehicle flight, guidance systems similar to those used for ballistic missiles are employed. Another control requirement of many types of space vehicles is that of maintaining the desired vehicle attitude over long periods of time. Displacement gyroscopes, even excellent ones with very low drift rates, cannot provide an accurate reference for days or weeks. Such devices must be corrected frequently by an external reference.

At least two such references are available: sources of electromagnetic radiation, and the gravitational gradient. The first might be used by such devices as a Sun seeker, a star tracker, or a horizon scanner. In the vicinity of the Earth (or any large celestial body) the difference in the pull of gravity between points on the craft having different distances from the Earth can be usefully employed.

Reaction wheels or other devices capable of storing angular momentum may be used to provide the torque to effect or maintain a given orientation. Such devices are very efficient, both from a weight and an energy standpoint, where disturbing torques on the spacecraft are small, random, and long continued. At the opposite end of the torque spectrum, torques that are large and uncompensating, rocket engines are the most suitable.

Vehicle and payload equipment require electric power. For small amounts of energy, chemical sources, such as batteries or chemically fueled generators, may be used. A great deal more energy can be obtained from a nuclear reactor. Energy also comes continuously from the Sun but at a fairly low density at Earth's distance.

Communications equipment comprises an essential item of nearly all space vehicles. This equipment is designed for light weight, low power consumption, and, usually, long life.

Although a large percentage of the problems of space flight are associated with the vehicles, it would be a mistake to assume that these constitute even a major fraction of the total operating system. Indeed, the cost of overcoming the Earth's gravity is so great that any portion of the total operation which can be performed on the ground should be done there. The supporting ground equipment consists of the preparation and launching equipment, and the tracking, communications, and payload-oriented equipment for turning the received data into usable form. For missions which involve return of space vehicles or booster rockets, recovery equipment may also be required. *See* LAUNCH COMPLEX; SPACECRAFT GROUND INSTRUMENTATION.

In their interaction with the terrestrial and atmospheric environment during reentry, space vehicles resemble ballistic missiles. However, although ballistic reentry techniques have been proved successful, the use of winged vehicles also has certain attractive aspects. There is a basic difference in these two methods in respect to the way atmospheric heat is handled. The ballistic approach absorbs the heat in the reentry body or rejects it back to the air by mass transfer. The winged vehicle dissipates the heat by radiation. Considerable research has been done on compromise reentry vehicles, such as the lifting body approach. The orbital stage of the shuttle is a winged craft designed to land like an airplane. It utilizes a combination of techniques to overcome the reentry heating problems: lift, temperature-resistant materials, and local ablative cooling. *See* ATMOSPHERIC ENTRY.

Astronautical engineering must contend with the unique environment of space outside the Earth's atmosphere. Although gravity is present in space, whenever a vehicle is coasting unpropelled, the shell and everything in it are acted on equally by gravity and therefore appear weightless. Fluids do not flow naturally, but must be confined and extruded. Liquids exposed to the vacuum of space evaporate or freeze. External transfer of heat takes place only by radiation. Metals exposed to the ultraviolet rays of the Sun emit electrons. Small particles of cosmic dust strike external surfaces at fantastic velocities and gradually erode them. Cosmic radiation creates a spectrum of secondary radiation that may reach levels damaging to equipment or personnel.

[R.C.Tr.]

Astronautics The application of scientific principles and engineering techniques to flight in space. Astronautics deals with space vehicles in the sense that aeronautics deals with aircraft. The distinguishing feature between astronautics and aeronautics is the extent to which the vehicles are influenced by the Earth's atmosphere. Astronautics encompasses both crewed and uncrewed missions. *See* AERONAUTICS; ASTRONAUTICAL ENGINEERING; SPACE TECHNOLOGY.

The subject matter of astronautics is flight in regions where a vehicle overcomes gravitational attraction and controls its course by reactive propulsion. Aeronautics concerns flight in regions where a vehicle resists gravitational attraction and controls its course by aeromechanical forces. The distinction is convenient but not clear cut. Rockets, by their reaction, assist airplanes to take off. Space vehicles may glide back to Earth. *See* INTERPLANETARY PROPULSION. [R.C.Tr.]

Astronomical atlases Sets of maps of celestial phenomena. Often developed in conjunction with catalogs that list position, brightness, and other features, maps provide a clear picture of the spatial relations between the phenomena.

In the nineteenth century the introduction of larger telescopes, steadier mounts, better graduated circles, and filar micrometers led to more extensive and precise star catalogs and atlases. Premier among these was the *Atlas des nordlichen gestirnten Himmels* (Bonn, 1863), organized by F. W. A. Argelander. These 40 charts showed the positions and magnitudes of 324,198 stars in the northern hemisphere. The charts, along with their companion star catalog, the *Bonner Durchmusterung*, or "B.D.," are still in use today. *See* ASTRONOMICAL CATALOGS.

By the 1880s photography was sufficiently well developed for astronomers to begin considering a photographic atlas of the heavens. In 1949, under sponsorship of the National Geographic Society, was begun the *Palomar Observatory Sky Survey*—the first photographic atlas that showed the sky in two colors. Taken with the 48-in. (1.2-m) Schmidt telescope, it reveals stars brighter than magnitude 20 situated north of −33°. A new *Palomar Observatory Sky Survey* was begun in 1985. This atlas will use improved photographic plates to reach magnitude 22, in three colors. *See* ASTRONOMICAL PHOTOGRAPHY.

In addition to the photographic atlases, printed atlases continue to be published, usually in conjunction with star catalogs. Among the more popular atlases of this type are the *Smithsonian Astrophysical Observatory Star Catalog* and *Star Atlas of Reference Stars and Nonstellar Objects* (Washington, 1966); Antonin Becvar's *Skalnate Pleso Atlas* (Cambridge, 1949) and its successors; *Norton's Star Atlas* (Cambridge, 1979); and W. Tirion's *Sky Atlas 2000.0* (Cambridge, 1982).

Edwin Hubble, known as the founder of modern extragalactic astronomy, charted the distribution of galaxies in space and their morphology. The *Hubble Atlas of Galaxies* appeared in 1961, edited by Allan Sandage. *See* GALAXY, EXTERNAL; MILKY WAY GALAXY; NEBULA.

G. P. Kuiper's *Photographic Lunar Atlas* (Chicago, 1960) contains the best set of Moon plates based on terrestrial observations to date. Lunar probes have generated countless closeups of the lunar surface. A particularly beautiful photographic atlas of the Moon is the NASA publication *The Moon as Viewed by Lunar Orbiter* (Washington, 1970). As spacecraft explore more of the solar system, atlases of more objects are becoming available. *See* MOON. [D.J.Wa.; C.T.K.]

Astronomical catalogs Lists or enumerations of astronomical data, generally ordered by increasing right ascension of the objects listed. Astronomical catalogs vary a great deal in form and content depending upon their use, which may be purely astronomical, or for navigation, time determination, geodesy, or space science applications. In some catalogs the essential data are stellar positions and motions, while in others astrophysical data, such as magnitudes, spectra, and radial velocities of stars, are important. There are also catalogs of special stellar and of nonstellar objects. *See* ASTRONOMICAL COORDINATE SYSTEMS.

A catalog regarded as the best representation of the celestial coordinate system at the time of its publication is called a fundamental star catalog.

The *Fifth Fundamental Catalogue*, designated *FK5*, was published by the Astronomisches Rechen-Institut in Heidelberg, Germany, in 1988. The catalog contains the positions (right ascensions and declinations) and their changes with time (proper motions and precession) of the 1535 stars in *FK4*, and an additional 3117 stars, down to an apparent visual magnitude of about 9.5. These catalogs, and other modern catalogs, have the standard epoch J2000.0, which is the date January 1, 2000, at 12 hours Universal Time.

The positions and proper motions of the stars in *FK5* provide a fundamental system for measurements of other star positions and proper motions, which may be carried out for a variety of problems arising in stellar astronomy.

Moderately bright stars (seventh to ninth magnitude), selected on the basis of one star per square degree of the sky, are related to the fundamental system by meridian circle observations. These stars form a system of sufficient density to serve as position references for photographic observations. Typical of catalogs of such reference stars is the *International Reference System (IRS)* catalog covering the entire sky from pole to pole with one star per square degree. It is the current world standard reference system.

A photographic survey of the northern celestial hemisphere resulted in the *AGK3* (*Dritter Astronomische Gesellschaft Katalog*, 1975), the third in a series of catalogs published by the German Astronomical Society. A revised version of this catalog has been published by the Astronomisches Rechen-Institut in Heidelberg as the *Position and Proper Motion (PPM) Catalog* of 181,731 stars north of -2.5° declination. A similar photographic catalog for the southern celestial hemisphere with plates taken at the Royal Cape Observatory in South Africa is the *Second Cape Photographic Catalog (CPC2)*, published in 1970. It contains the positions of 250,000 stars.

An important photographic catalog covering the entire sky to a limiting magnitude of 13 is the result of an international undertaking involving 19 observatories, with each assigned zones of declination and observing with nearly identical telescopes. The catalog, known as the *Carte du Ciel (CdC)* or *Astrographic Catalogue (AC)*, finally completed for all zones in 1964, provides the positions of the stars in the form of rectangular coordinates, as measured on the plates.

Among the numerous catalogs of astrophysical data is the monumental *Henry Draper Catalog (HD)* of spectral classification, which with its extension includes data for 275,000 stars published in 10 volumes. The general acceptance of the U, B, V photometric system since its inception in the 1950s is shown by the compilation of a general catalog containing data for 87,000 stars (*Astronomy and Astrophysics*, suppl., vol. 71, 1987).

L. E. Dreyer's *New General Catalogue of Nebulae and Starclusters* (1888) contains the objects originally classified as nonstellar, with galaxies included as nebulae. The catalog contains 7840 objects, and was supplemented by two index catalogs in 1895 and 1908 with an additional 5386 objects. The NGC and IC numbers assigned in these catalogs remain the most commonly used designations. *See* NEBULA; STAR CLUSTERS; VARIABLE STAR.

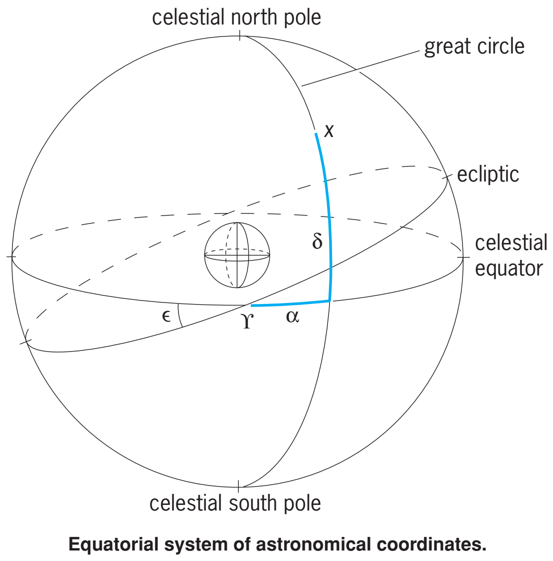
Since Dreyer's time, the number of known nonstellar optical objects has increased by an order of magnitude, and the data are scattered through the astronomical literature. R. S. Dixon and G. Sonneborn compiled *A Master List of Nonstellar Astronomical Objects* (1980) with approximately 185,000 listings from 270 catalogs, with multiple listings of objects appearing in several catalogs. [K.A.S.]

Astronomical coordinate systems Schemes for locating astronomical objects in space. To an observer on the Earth's surface, the stars of the night sky appear to be placed upon a spherical shell of infinite radius with the observer at the center. Celestial objects appear to move with respect to the stars, and at any given time their position on this imaginary sphere, called the celestial sphere, can be specified by two angles, called celestial coordinates, whose values depend upon what coordinate system is used. *See* CELESTIAL SPHERE.

Each coordinate system is defined by a fundamental plane and a principal axis. For example, on the Earth's surface, longitude and latitude coordinates are used to determine positions. In this system, which is analogous to astronomical coordinate systems, the fundamental plane is that of the Earth's Equator, and the principal axis is defined by a line running from the Earth's center to a point on the Equator at the longitude of Greenwich, England. *See* EQUATOR; LATITUDE AND LONGITUDE.

Horizon system. The boundary between the hemisphere of the sky that is visible and the hemisphere which is hidden from view by the Earth is called the horizon. The observer is located at the center of the horizon system, the pole directly overhead is termed the zenith, and the opposite pole, the nadir. These pole directions are aligned with a plumb line, which is determined by the observer's local gravity. The fundamental horizon plane is 90° from the poles, and for astronomical applications the principal axis is most often taken to pass through the north point. Great circles that pass through the zenith and nadir are termed vertical circles; the one passing through the east and west points is termed the prime vertical, and that passing through the north and south points is called the celestial meridian. The longitudinal coordinate of a celestial object is termed its azimuth and is most often measured eastward from the north point to the object's vertical circle; and the latitudinal coordinate, termed its altitude, is measured along the object's vertical circle, north or south from the horizon plane to the object. *See* HORIZON; ZENITH.

Equatorial system. The fundamental plane of the equatorial coordinate system can be visualized by imagining that the



Equatorial system of astronomical coordinates.

Earth's equatorial plane is extended to intersect the celestial sphere. An alternate fundamental plane, the ecliptic plane, is the extension of the Earth's mean orbital plane onto the celestial sphere (see illustration). These planes intersect at two points, called equinoxes, with the angle between them ϵ being termed the obliquity of the ecliptic. This angle is about 23.4°. *See* Ecliptic; Equinox.

Due to the Earth's motion about the Sun, observers on Earth see an apparent motion of the Sun along the ecliptic plane. The point where the Sun's annual apparent motion takes it northward across the equatorial plane is called the vernal equinox Υ, and the line between the Earth's center and this point defines the principal axis for both the equatorial and ecliptic coordinate systems. The apparent passage of the Sun through the vernal equinox, on about March 21, marks the beginning of spring in the Northern Hemisphere. Because of disturbing effects of the Sun and Moon on the Earth's figure, the Earth's rotation axis precesses, causing the celestial pole to describe an approximate circular motion about the ecliptic pole once every 26,000 years. This causes the location of the vernal equinox to drift westward along the ecliptic about 50 arc-seconds each year. Hence for an inertial coordinate system, where the principal axis is not moving, an epoch must be specified at which time the coordinate system is held fixed. In practice, the beginning of the year 2000 is most often used as an epoch. *See* Earth rotation and orbital motion; Precession of equinoxes.

The north and south celestial poles represent the extension of the Earth's North and South poles onto the celestial sphere. For a celestial object (for example, object X in the illustration), the longitudinal coordinate is termed the right ascension α and is measured eastward along the celestial equator from the vernal equinox Υ to the great circle passing through the object and the north and south celestial poles. The latitudinal coordinate, called the declination δ, is then measured along the object's great circle, north or south from the Equator to the object.

Ecliptic system. The ecliptic coordinate system is often used when representing the orbital motions of the planets, asteroids, and comets. The fundamental plane is that of the ecliptic, and as in the equatorial system, the principal axis is the line extending from the Earth's center to the vernal equinox.

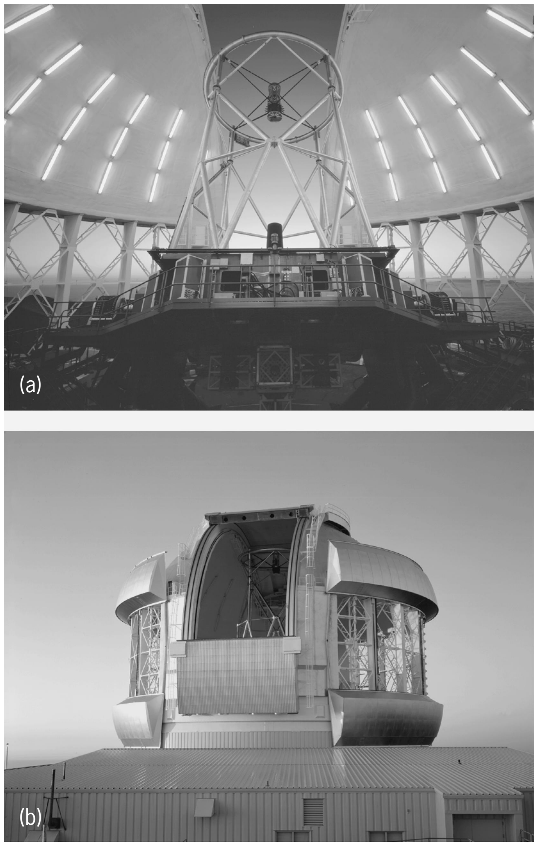
Galactic system. Astronomers working with stars and other objects within the Milky Way Galaxy often find it convenient to use the galactic disk as the fundamental plane of their coordinate system, and the line extending from the galactic center to the Sun's location as the principal axis. *See* Milky Way Galaxy.

[D.K.Y.]

Astronomical observatory A telescope or telescopes, their protective enclosures (if any), support and headquarters buildings, and the staff of astronomers, engineers, technicians, and other support personnel. The telescopes can be optical or infrared (reflecting or refracting) inside a corotating dome, or radio dishes without enclosures.

The on-site support building contains the control room with the computers and control electronics to operate and point the telescope, as well as the data acquisition computers and electronics for detector instruments. It houses laboratories for testing and calibrations, a machine shop for emergency repair and fabrication of parts, and storage for inactive instruments or telescope optics. These areas are often incorporated into a single building along with the telescope and dome. Since telescopes are generally located at remote sites to maximize their usefulness, the administration and support offices are often located in a separate headquarters building miles away in a town or university.

Optical and infrared observatories are the most common types of observatory. They are often located in remote mountains to minimize the effects of contaminating artificial lights and atmospheric blurring. Some countries place their largest telescopes at the best sites in the world such as the 13,800-ft-high (4200-m) volcanic mountain Mauna Kea in Hawaii (see illustration) and La Palma in the Canary Islands.



Gemini North Observatory in Mauna Kea. (*a*) Telescope and interior of dome. (*b*) Exterior of dome. Vent gates surrounding the dome allow air to flow throughout the dome, thereby minimizing distortion of images due to swirling. (*Neelon Crawford, Polar Fine Arts and Gemini Observatory*)

Optical observatories study planets, stars, nebulae, and galaxies. A large aperture is needed to collect the faint light of these sources. Sizes typically range from 0.5 to 10 m (20–400 in.). The smaller telescopes can use glass lenses, the largest refractor being the University of Chicago 1.0-m (40-in.) Yerkes. For the largest telescopes, engineering and manufacturing constraints dictate the reflecting design. The 9.8-m (386-in.) Keck Telescope is the world's largest reflector. The Very Large Telescope Project seeks to combine the light from four 8.1-m (319-in.) telescopes to effectively have the light-gathering capability of a 16-m (630-in.) telescope.

Most optical observatories can also observe in the near-infrared region. Infrared observatories have been optimized to work farther into the longer (thermal) infrared. Since glass absorbs infrared light, all infrared telescopes are of the reflecting type. Special design techniques must be used, as the telescope itself glows in the infrared.

Radio observatories have become an essential complement to optical observatories. With their longer wavelengths, the radio telescopes can see through cosmic clouds and measure the properties (temperature, pressure, chemical composition, and velocities) of gases which pervade the universe. Since the wavelengths are so long, the telescopes must be large to achieve a high resolution (the ability to discriminate between two nearby sources), and radio dishes are typically tens to hundreds of meters wide.

The longer radio wavelengths allow the use of interferometers, where the signal from several small radio telescopes can be mathematically combined to yield results as if they had been collected from a very large dish. The Very Large Array radio observatory in Socorro, New Mexico, has twenty-seven 25-m (82-ft) antennas arranged in a Y pattern, which can yield the resolution of a single telescope 36 km (22 mi) wide. The Very Long Baseline Array uses ten 25-m (82-ft) antennas spread from Hawaii to the Virgin Islands, allowing the resolution of a telescope dish that distance across.

Crewless balloons have been used to hoist telescopes above the absorbing atmosphere for gamma-ray, x-ray, and ultraviolet observations. Their lower cost (compared to space missions) is offset by the short duration of the observations. The National Aeronautics and Space Administration (NASA) successfully operated the Kuiper Airborne Observatory for 20 years. Space observatories have amply proven their worth despite their initial high cost and limited mission lifetimes. *See* SATELLITE (ASTRONOMY).

An astronomical instrument is the working heart of an observatory. The telescope exists solely to collect and funnel light into the instrument. Astronomical instruments range from a simple eyepiece for direct viewing (with different magnifications), to a camera for imaging on film or electronic detectors, to a spectrograph which records the wavelength distribution of light energy (analogous to a rainbow). The charge-coupled device (CCD) has now virtually supplanted the photographic plate. For radio telescopes the instrument is an amplifier that isolates and boosts the weak celestial electric signal. *See* ASTRONOMICAL SPECTROSCOPY; CAMERA; CHARGE-COUPLED DEVICES; SPECTROGRAPH.

Besides observing light (electromagnetic radiation), astronomers are mapping the universe via neutrinos, particles that can transverse matter with a minimum of interaction. Gravitational wave observatories attempt to detect ripples (gravitational waves or gravitons) in the fabric of space-time itself. *See* GRAVITATIONAL WAVES; NEUTRINO ASTRONOMY; TELESCOPE. [J.Ham.]

Astronomical photography

The application of the photographic process to astronomy, including monochrome photography and color photography.

Monochrome photography. Monochrome photography was one of the premiere tools of astronomical research during most of the twentieth century. It offered two major advantages: the integration of signal (through time exposure) allowed the accumulation of photons from very faint objects which could not otherwise be seen; and the storage of information in an efficient and permanent form allowed protracted, in-depth study of astronomical objects away from the telescope. Monochrome astronomical photography became a standard technique that was applied to direct imaging, spectroscopy, photometry, polarimetry, and astrometry. *See* ASTROMETRY; PHOTOMETRY; POLARIMETRY.

Nonetheless, because astronomers were continually searching for increased sensitivity and wavelength coverage, the aggressive attempts to improve photographic emulsions had, by the 1970s, begun to reach the limits of what was reasonably attainable. At the same time a new type of electronic imager, the charge-coupled device (CCD), developed for military applications, began to become available to the scientific community. Space-based imaging applications of the charge-coupled device, particularly the development of the TI 800 × 800-px chip for use in the *Galileo* spacecraft, stimulated expanded use of this mode of imaging at ground-based observatories. By the end of the twentieth century, charge-coupled devices had become so pervasive in astronomical observatories that it was clear that monochrome astronomical photography was, in many respects, a technique of the past. Rarely used now by professional astronomers, the techniques of high-quality monochrome astrophotography are primarily preserved by amateur astronomers. Some advances are still being achieved, primarily through computer-processing of digitized photographic images. [E.R.Cr.]

Color photography. The language of astronomy abounds with references to color, and the concept of color is implicit in many of the measurements that astronomers make. Color index, for example, is a quantity related to the temperature of a star, while the redshift of a galaxy is used to indicate its recessional velocity. More directly, stars may be described as red giants or white dwarfs or even blue stragglers. *See* BLUE STRAGGLER STAR; COLOR INDEX; REDSHIFT; STAR.

These names reflect the underlying importance of color in astrophysics and cosmology, and though the colors involved are subtle and difficult to distinguish by the eye in its dark-adapted state, special photographic techniques can be used to display them. A realistic representation of the true colors of celestial bodies can reveal new relationships in familiar objects and add an important third dimension to the morphology and brightness information of the more usual monochrome representations.

Special photographic materials are necessary to accommodate the unusual requirements of photography in astronomy. Not only is the amount of incoming radiation to be detected extremely small, but it is accompanied by unwanted light from the night sky (the airglow). The materials must therefore combine extreme sensitivity at long exposures with high contrast. The ability to detect faint objects is ultimately more dependent on the contrast and resolution of the photographic material than on the light grasp of the telescope or available observing time. On the other hand, color films are designed for general use at levels of illumination where high contrast and low-light-level efficiency are unimportant. In addition, these films are intended primarily to reproduce the broadband colors of everyday life, and for this the rather uneven spectral response of their individual layers is unimportant. Unfortunately, gaseous nebulae emit most of their visible radiation in the form of monochromatic emission lines from the ionized elements present. Color films always show gaseous nebulae as red, largely irrespective of the contribution from the green oxygen line, whereas yellow (red + green) would be a more realistic representation in many cases. *See* NEBULA.

A further problem is the effect of long exposures on the relative sensitivity of the three layers, which are differently affected by low-intensity reciprocity failure. Changes in both sensitivity and contrast of the layers are found, and exposures which are long enough to be astronomically useful often produce severe color-balance distortion.

Low-intensity reciprocity failure of both color and monochrome films is reduced if the long exposure is made at a low temperature. Most experiments have been made with cameras designed for fairly small formats and cooled to about −103°F (−75°C) with solid carbon dioxide.

Some of the techniques which are used for spectroscopic plates may also be applied to color films. Baking both in nitrogen and in forming gas, a 2–4% hydrogen-in-nitrogen mixture, is useful. Films are baked for several hours in a flow of the gas at 150°F (65°C) just prior to exposure and then (preferably) exposed in a nitrogen atmosphere.

These user-applied processes reduce some of the disadvantages of color films for astrophotography, and push development may be used in addition to the above, to increase both speed and contrast. However, the basic problem of uneven spectral response remains. As a result, color films can reproduce only realistic colors of the brighter, continuous-spectrum objects, such as planets, stars, and galaxies. Faint objects and emission nebulae are not well recorded.

An alternative approach is to use the oldest system of color photography, the three-color separation technique. In this system, three exposures are made with combinations of photographic emulsions and filters chosen to record the red, green, and blue parts of the spectrum on separate plates or film. Filter-emulsion passbands are chosen to ensure adequate overlap between adjacent colors so that hues intermediate between red, green, and blue are well recorded. With care in selection of these parameters, coverage of the visible region is much more uniform than is possible with conventional color film.

The same principles are used with digital detectors such as charge-coupled devices, which are much more sensitive than hypersensitized silver-based photographic materials. As yet, they lack the essentially unlimited area and small pixels that give conventional materials their "photographic" characteristics that translate into a distinctive esthetic quality. Charge-coupled-device images are usually combined into three-color images with a computer, and similar methods can be used to combine digitized versions of photographic red, green, and blue exposures.

Two methods are possible to recover the color information in three-color separations. The subtractive process involves image-wise combinations of yellow, magenta, and cyan dyes or pigments and is now rarely practiced outside professional printing applications. Much more flexible in the astronomical application is the additive process, which allows several levels of image manipulation before the monochromes are combined. Additive color photography involves mixing colored light, rather than colored compounds, and its most common manifestation is the color television or computer screen image, which a magnifier shows to be made up of blue, green, and red dots or strips. When used photographically, monochrome positive copies are made by contact copying the three original separation negatives onto a suitable film material. A wide range of image-manipulation techniques can be applied to enhance small or faint features and to adjust the contrast of the original images. *See* ELECTRONIC DISPLAY. [D.F.M.]

Astronomical spectroscopy The use of spectroscopy (the analysis of light as a function of wavelength) as a tool for obtaining observational data on the chemical compositions, physical conditions, and radial velocities of astronomical objects. Astronomical applications of optical spectroscopy from ground-based observatories cover the electromagnetic spectrum from the near-ultraviolet (wavelengths around 0.3 micrometer) through the visible (0.4–0.7 μm) and into the near-infrared (2 μm). Space-based observatories extend spectroscopic observations from the far-ultraviolet (0.1 μm) to the far-infrared (100 μm). Work at shorter wavelengths (x-ray and gamma-ray spectroscopy) and longer wavelengths (submillimeter and radio wavelengths) requires techniques other than those discussed here. *See* GAMMA-RAY ASTRONOMY; RADIO ASTRONOMY; SATELLITE ASTRONOMY; ULTRAVIOLET ASTRONOMY; X-RAY ASTRONOMY.

Usually a spectrograph is fitted to a reflecting telescope, which serves as a light collector. The image of the celestial body being studied is focused on the spectrograph slit, which limits the region under study (thus improving the spectral resolution) and reducing the contribution by the night sky. The diverging light beam then passes from the slit to a collimator (either a lens or mirror). This produces parallel light, which is then dispersed by a diffraction grating or prism. The dispersed light enters a camera, which focuses the spectrum onto a detector, either a charge-coupled device (CCD) in the case of an optical spectrograph, or an electronic array sensitive to infrared light. *See* CHARGE-COUPLED DEVICES; DIFFRACTION GRATING; SPECTROGRAPH; SPECTROSCOPY; TELESCOPE.

It is often desirable to obtain spectroscopy of many of the objects within a telescope's field of view in a single exposure. A variety of methods are available to accomplish such surveys, including slitless spectroscopy, slitlet masks, and fiber-fed spectroscopy.

It is possible to take spectra of all of the brighter objects within the field of view by not using a spectrograph at all, but by combining a low-dispersing element directly with the telescope. For instance, an objective prism may be placed in front of the telescope, which is often a Schmidt camera. Slitless spectroscopy has been used for large stellar surveys. *See* ASTRONOMICAL CATALOGS.

In the technique of slitlet masks, a picture is usually taken of a region containing several astronomical objects of interest; the exact locations of these objects are determined, and small slits (slitlets) are then milled in the corresponding locations in a metal plate. This plate is substituted for the slit in a conventional spectrograph.

Rather than milling slitlets in a plate, holes may be drilled, which are then plugged with optical fibers. (Such an arrangement is often referred to as a plugboard.) The light is then transported via the fibers to a spectrograph mounted on an optical bench in a laboratorylike environment adjacent to the telescope. Alternatively, robotics may be used to position fibers in the focal plane; the fibers are then anchored to a metal plate via magnets. At the spectrograph, the fibers are arrayed in a line and act as the spectrograph slit. Hundreds of objects can be observed simultaneously, leading to very effective use of the telescope. *See* OPTICAL FIBERS.

Normal spectrographs employ diffraction gratings that are intended to be used in low orders ($n = 1$, 2, or 3), with colored glass filters used to prevent overlap of adjacent orders. Echelle spectrographs differ from conventional systems in that they employ gratings intended to be used in very high orders ($n > 10$), resulting in very high resolving power. Normally these orders would fall on top of one another, rendering the data useless. An echelle uses a second dispersal element, usually another grating but sometimes a prism, at right angles to the first, in order to separate the successive spectral strips from each other. A large range of wavelengths can be obtained in the format of nearly parallel segments, well suited for charge-coupled devices.

In integral field spectroscopy, a close-knit bundle of optical fibers is placed in the focal plane and is used to observe an extended astronomical object, such as a gaseous nebula or a galaxy. The light is transmitted via the fibers to a bench-mounted spectrograph. Although the fibers are in a linear array at the spectrograph, their locations in the focal plane are known, and sophisticated data reduction techniques allow the astronomer to reconstruct a spectral "image" of the object.

Fourier transform spectroscopy is used particularly in the near-infrared. Instead of being dispersed in a spectrograph, the light of a wide band of wavelengths is passed through a Michelson interferometer with variable spacing of its two apertures. The resulting interferogram, which is an electronic record of the interference signal produced by the interferometer as the separation of the apertures is varied, is converted into a record of intensity versus wavelength by a computer, and is of extremely high spectral resolution. *See* INFRARED SPECTROSCOPY; INTERFEROMETRY.

The application of astronomical spectroscopy extends from solar system objects (the Sun, planets, and comets) to Milky Way objects (stars, including binary stars, ordinary novae, and cataclysmic variables; and gaseous nebulae, such as supernova remnants, H II regions, and planetary nebulae) and to distant galaxies and quasars. [P.Ma.; L.H.Al.]

Astronomical transit instrument A telescope adapted to the observation of the passage, or transit, of an astronomical object across the meridian of the observer. The astronomical transit instrument is the classic instrument of positional astronomy, which is the study of the positions and motions of astronomical objects. The chief variants of the classic design include the vertical circle, the horizontal transit circle, the broken or prism transit, the photographic zenith tube and, most commonly, the meridian or transit circle.

The modern transit instrument has an objective (lens) with a diameter of 6–10 in. (15–25 cm) and a focal length of 72–90 in. (180–230 cm). The instrument consists of a telescope mounted on a single fixed horizontal axis of rotation. The horizontal axis has a central hollow cube (or sometimes a sphere) and two conical semiaxes ending in cylindrical pivots. The objective and imaging halves of the telescope are also fastened to the cube of the instrument, perpendicular to the horizontal axis. Rotation of the instrument in its bearings, or wyes, permits the optical axis to sweep only in the plane of the meridian. Because

Carlsberg Meridian Circle, La Palma, Canary Islands. (*University of Copenhagen*)

it is constrained to a single plane, it can be solidly mounted on massive piers, creating a stability not present in other telescope designs.

Meridian or transit circle. For many years, the major observatories of the world had astronomical transit instruments called meridian or transit circles. These instruments are similar to the transit instrument described above except that they are also capable of measuring the distance of the object along the meridian to obtain its declination, using a large, accurately calibrated circle attached to the horizontal axis. An accurate (atomic) clock is used as the scale for determining the right ascension of the object. *See* ATOMIC CLOCK.

Electronic detection systems, most commonly charge-coupled devices have improved the accuracy and efficiency of the observations, but they cannot be used far from the Equator due to the curved paths that the stars follow across the charge-coupled devices, and it is difficult to observe objects that are not point sources, such as the Sun and planets. *See* CHARGE-COUPLED DEVICES.

Applications. In 1997 the European Space Agency published the results of observations made with the *Hipparcos* satellite. The accuracy of the 100,000 star positions far exceeds anything obtainable with transit circles. In addition, modern astrographs with charge-coupled-device cameras can measure far more star positions than the transit circle and with greater accuracy. Nevertheless, transit circles still carry on specialized observing programs. The Carlsburg Meridian Telescope at La Palma in the Canary Islands is an example of a modern transit circle used to provide additional accurate star positions to improve the proper motions of previously measured stars and for the measurement of solar system bodies, especially asteroids (see illustration). It is completely automatic, being operated remotely via the Internet. Use of a charge-coupled device as the detector generally limits these instruments to areas near the Equator. *See* ASTEROID. [F.S.Ga.]

Astronomical unit The basic unit of length in the solar system. The astronomical unit (AU) is also used to a limited extent for interstellar distances through the definition of the parsec (1 pc = 206,265 AU). It is nearly equal to the mean distance a between the center of mass of the Sun and the center of mass of the Earth-Moon system ($a = 1.00\ 000\ 23$ AU), and for that reason it is often convenient to think of it as the mean distance between the Sun and Earth. *See* PARSEC.

The most accurate determination of the length of the astronomical unit in physical units, such as meters, is obtained from phase-modulated continuous-wave (CW) radio signals beamed to other planets. The round-trip travel times of the signals are determined by cross-correlating the returned signal from the planet with the transmitted signal, and as a result, planetary distances are measured directly. Continuous-wave signals returned from the National Aeronautics and Space Administration (NASA) landers on the surface of Mars resulted in a determination of the astronomical unit to an accuracy of 20 m (65 ft). With an adopted value of 299,792,458 m/s (186,282.397051 mi/s) for the speed of electromagnetic propagation in vacuum, the value of the astronomical unit from NASA's Viking and Pathfinder missions is 149,597,870,692 m (92,955,807.268 mi). [J.D.A.]

Astronomy The study of the universe and the objects in it through scientific investigation. Since much of contemporary astronomy uses the laws and methods of physics, the terms "astronomy" and "astrophysics" are usually used interchangeably. However, modern astronomy also uses techniques from many other scientific disciplines, including chemistry, geology, and biology, for which the terms astrochemistry, planetary science, and astrobiology are increasingly used.

The use of geological knowledge and methods in analyzing close-up observations from spacecraft of planets and their satellites and of comets and asteroids closely links the disciplines of astronomy and planetary science. Indeed, the discovery of planets around distant stars holds for even closer relations in the future. Methods of studying molecules in interstellar clouds involve chemical knowledge. Planetary science and astrochemistry come together with astronomy in the search for life outside the solar system, part of the search for extraterrestrial intelligence (SETI). The National Aeronautics and Space Administration (NASA), the United States space agency, has placed a priority on astrobiology, including the investigation of Mars and the bringing of samples back to Earth from Mars. *See* ASTEROID; COMET; COSMOCHEMISTRY; EXTRATERRESTRIAL INTELLIGENCE; INTERSTELLAR MATTER; PLANET; PLANETARY PHYSICS; SOLAR SYSTEM.

Astronomers often lead in employing new technologies, pushing them to the limit in exploring extremely faint signals in various parts of the electromagnetic spectrum. Nearly all astronomical research is now heavily dependent on computers. Astronomical imagery is now dominated by light-sensitive silicon chips known as charge-coupled devices (CCDs), which are approximately 100 times more sensitive than film. Fiber optics are used for a variety of astronomical purposes, including the taking of hundreds of galaxy images simultaneously from the field of view of a telescope and bringing the light to a spectrograph that can produce simultaneous spectra of all the objects. The technology of active optics, in which the shape of a mirror is changed slightly at a high rate (often faster than 1 Hz) to compensate for the blurring of astronomical images caused by the Earth's atmosphere, is being increasingly pursued to eliminate the twinkling of stars. *See* ADAPTIVE OPTICS; FIBER-OPTICS IMAGING.

The opening of the 5-m (200-in.) Hale telescope at the Palomar Observatory on Palomar Mountain, California, in 1948 marked the beginning of a great period of development in optical astronomy. The light-gathering power of this telescope allowed cosmological study that extended most of the way to the beginning of time in the universe. It was joined in the task by several 4-m-class (160-in.) telescopes and by one less successful larger telescope. In the 1990s, new techniques of telescope making allowed the completion of several telescopes in the 10-m (400-in.) class, twice the diameter and thus four times the collecting area of the Hale telescope. The large telescopes have proven useful in taking spectra of the optical counterparts of gamma-ray bursts, proving that they are very far away; and in analyzing the distances to faraway galaxies and in measuring the redshifts of their spectra, leading to the current cosmological models of the expansion of the universe and the tentative conclusion that the rate of expansion is accelerating. *See* COSMOLOGY; HUBBLE CONSTANT; TELESCOPE.

The 1990s saw the thorough use of the vantage points of space for astronomical observation, exemplified by NASA's series of Great Observatories. In 1991 the *Compton Gamma-Ray Observatory* was launched, and in the following years mapped about one gamma-ray burst per day in addition to many other objects and events. The Hubble Space Telescope was launched in 1990 to study the ultraviolet and visible parts of the spectrum. Its repair in 1993, with secondary mirrors compensating for a focusing problem with the main mirror, brought it to full working order, and a 1996 upgrade included an improved two-dimensional spectrograph and infrared capability. The *Chandra X-Ray Observatory*, launched in 1999, provides high-resolution x-ray images, and is the same size and scope as Hubble. It studies various types of celestial objects and processes, such as black holes of stellar and galactic sizes. The *Space Infrared Telescope Facility*, the fourth of this series of Great Observatories, was launched in 2004 and renamed the *Spitzer Space Telescope*. Smaller spacecraft have also made valuable contributions. *See* BLACK HOLE; INFRARED ASTRONOMY; X-RAY ASTRONOMY; X-RAY TELESCOPE.

The atmosphere blocks most of the electromagnetic spectrum from reaching the Earth's surface, leaving windows of transparency mostly in the optical and radio parts of the spectrum. Radio astronomers have made the most of their window of transparency with such telescopes as the 100-m (328-ft) fully steerable telescope outside Bonn, Germany; the 330-m (1083-ft) Arecibo dish in Puerto Rico, which has some limited tracking ability, the Very Large Array of radio telescopes in New Mexico, and the Very Long Baseline Array. The ozone layer and other constituents of the atmosphere block the shortest wavelengths from penetrating to the Earth's surface, so observations of gamma rays, x-rays, and most of the ultraviolet region require telescopes in space. *See* OZONE; RADIO ASTRONOMY; RADIO TELESCOPE.

Much of astronomy involves breaking down the incoming celestial radiation into its component wavelengths, a process known as spectroscopy. Spectroscopic studies can reveal the temperature of an object, the identity and proportions of its chemical elements, and the velocities of its constituents toward and away from the Earth. Light from the Sun and other objects is sometimes polarized, and studies of such polarization can tell about the magnetic fields present or about scattering processes. *See* ASTRONOMICAL SPECTROSCOPY; POLARIMETRY.

The expansive definition of a telescope includes anything used in astronomy to observe the sky. Several neutrino telescopes have been used to detect neutrinos from the Sun and, in one instance, from a supernova. The pace of observation of secondary cosmic rays as well as the few primary cosmic rays that reach the Earth is increasing. A pair of interferometers are being built on Earth to attempt direct detection of such gravitational waves, which should result from such distant events as the merger of two neutron stars. *See* COSMIC RAYS; NEUTRINO; SOLAR NEUTRINOS.

Theoretical calculations of the nature of astronomical objects or processes are known as theoretical astrophysics. The availability of supercomputers, powerful and fast computers capable of handling large amounts of data, has led to three-dimensional simulations of, for example, the formation of large-scale structure in the early universe. Models of the oscillations detectable on the Sun's surface through long-time-series observations are used to improve understanding of the solar interior, a process known as helioseismology. *See* HELIOSEISMOLOGY; SIMULATION; SUPERCOMPUTER; UNIVERSE.

Laboratory astrophysics involves the measurement of basic parameters that are used in calculations of physical or chemical processes relevant to astronomy, such as cross sections of atomic and molecular collisional excitation and ionization. *See* MOLECULAR STRUCTURE AND SPECTRA. [J.M.P.]

Astrophysics, high-energy

The study of the universe as revealed by high-energy, invisible forms of light: x-rays and gamma rays. These radiations are produced in the cosmos when gas is heated to millions of degrees Kelvin or electrons have been accelerated to near the speed of light by violent and extreme conditions. Exploding stars, neutron stars, black holes, and galaxy clusters, the most massive objects in the universe, are among the objects studied.

The high energies of x-rays and gamma rays have two important consequences for astronomical research. First, these forms of light are absorbed by the atmosphere, so telescopes to detect them must be placed on spacecraft above the atmosphere. Second, the telescopes must be constructed differently. Gamma rays have such high energy that they cannot be focused by traditional techniques, although indirect methods can give a rough estimate of their direction. *See* SATELLITE ASTRONOMY.

X-rays will reflect off mirrors, but only if they strike at grazing angles, like a stone skipping across a pond. For this reason, x-ray mirrors have to be carefully shaped and aligned nearly parallel to the incoming x-rays. These barrel-shaped mirrors are nested one inside the other to increase the collection area, and therefore the sensitivity, of the telescope.

The *Chandra X-ray Observatory*, launched by the National Aeronautics and Space Administration (NASA) in July 1999, is the premier focusing x-ray telescope. It is an assembly of four pairs of mirrors. *Chandra's* mirrors are the smoothest mirrors ever constructed. The largest of the mirrors is almost 4 feet (1.2 m) in diameter and 3 ft (0.9 m) long. *See* X-RAY TELESCOPE.

The European Space Agency's *XMM*, a powerful telescope launched in December 1999, has 58 mirrors. These mirrors are not as smooth as *Chandra*'s mirrors, so *XMM* cannot make images of the same crispness, but it can detect fainter sources and measure the energies of x-rays very accurately.

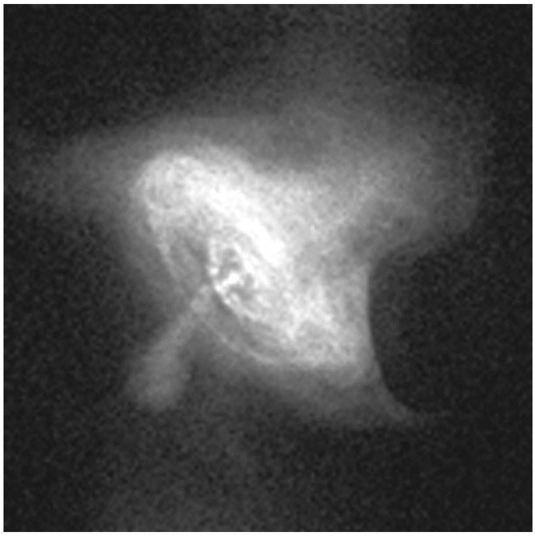
The new era of gamma-ray astronomy was inaugurated by the launches of NASA's *Compton Gamma-Ray Observatory*, and *Granat*, a Russian-French mission. *Granat*, launched in 1989, has two instruments that cover the x-ray through the gamma-ray region. *Compton* was launched in 1991 as one of NASA's Great Observatories, along with the Hubble Space Telescope and the *Chandra X-ray Observatory*. It has four instruments on board that go from high-energy x-ray to high-energy gamma-ray energies. The capabilities of the instruments aboard these observatories are more than ten times that of any previous gamma-ray mission. *See* GAMMA-RAY ASTRONOMY.

Supernovae. A massive star explodes about once every 50 years in the Milky Way Galaxy. The shell of matter thrown off by the supernova creates a bubble of multimillion-degree gas called a supernova remnant. The hot gas expands and produces x-rays for thousands of years. Gamma rays from radioactive elements have also been detected from supernova remnants by gamma-ray telescopes such as those on the *Compton Gamma-Ray Observatory* and the SIGMA telescope on board *Granat*.

The study of remnants of exploded stars, or supernovae, is essential for understanding the origin of life on Earth. The cloud of gas and dust that collapsed to form the Sun, Earth, and other planets was composed mostly of hydrogen and helium, with a small amount of heavier elements such as carbon, nitrogen, oxygen, and iron. The only place where these and other heavy elements necessary for life are made is deep in the interior of a massive star. There they remain until a supernova explosion spreads them throughout space. *See* NUCLEOSYNTHESIS; SUPERNOVA.

Neutron stars. When a massive star explodes, most of it is flung into space, but the core of the star is compressed to form a rapidly rotating dense ball of neutrons that is about 12 mi (20 km) in diameter. The collapse and rapid rotation of the neutron star cause it to become highly magnetized. A magnetized, rapidly rotating neutron star can produce electric voltages of 10^{16} V.

Neutron star gravity, which is more than 10^{11} times stronger than gravity on Earth, is overwhelmed by the electric field, and particles are pulled off the neutron star and accelerated to speeds near the speed of light. An intense shower of electrons and antimatter electrons, or positrons, is produced by these particles. The pulsed emission from the Crab Nebula, observed at all wavelengths from radio through gamma rays, is thought to be caused by this process (see illustration). *See* Crab nebula; Pulsar.



Chandra X-ray Observatory **image of the Crab Nebula, a supernova remnant and pulsar in the constellation Taurus. The image shows the central pulsar, a rapidly spinning neutron star, or pulsar that emits pulses of radiation 30 times a second, surrounded by tilted rings of high-energy particles that appear to have been flung outward over a distance of more than a light-year from the pulsar. (*NASA*/*Chandra X-ray Observatory Center*/ *Smithsonian Astrophysical Observatory*)**

Black holes and quasars. When a very massive star collapses, it forms a black hole. A black hole does not have a surface in the usual sense of the word. There is simply a region in space around a black hole beyond which nothing can be seen, because nothing can escape from inside this region. This region is called the event horizon.

Anything that passes beyond the event horizon is doomed to be crushed as it descends ever deeper into the gravitational well of the black hole. Neither visible light, nor x-rays, nor any other form of electromagnetic radiation given off by the particle can escape.

A black hole cannot be seen directly. The only way to find one is by observing the energy released by matter that is falling toward the black hole. As gas and dust particles swirl toward a black hole, they speed up and form a flattened disk. Friction caused by collisions between the particles heats them to extreme temperatures. Just before the particles pass beyond the event horizon, they produce x-rays and gamma rays as their temperatures approach 10^8 K.

Black holes grow when matter falls into them. A black hole in the center of a galaxy where stars are densely packed may grow to the mass of 10^9 suns. Energy released from large clouds of gas as they fall into these supermassive black holes can be stupendous. This is the accepted explanation for quasars, sources in which the power output at the center of a galaxy is a thousand times greater than an entire galaxy of 10^{11} stars. *See* Quasar.

One of the most intriguing features of supermassive black holes is that they do not suck up all the matter that falls within their sphere of influence. Some of the matter falls inexorably toward the black hole, and some explodes away from the black hole in high-energy jets that move at near the speed of light. These jets produce radio, optical, x-ray, and gamma radiation. The matter swirling around the black hole must somehow be producing enormous electric and magnetic fields that accelerate electrons to extremely high energies. Exactly how this happens is unknown and is a major focus of research. *See* Black hole.

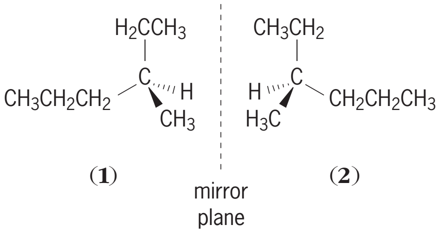
Galaxy clusters and dark matter. More than half of all galaxies in the universe are members of groups of galaxies or larger collections of galaxies, called clusters. X-ray observations have shown that most clusters of galaxies are filled with vast clouds of multimillion-degree gas. The mass of this gas, which was heated when it collapsed from a much larger size, is greater than all the stars in all the galaxies in a cluster of a thousand galaxies. Galaxy clusters are the largest and most massive gravitationally bound objects in the universe.

The x-ray-producing hot gas found in a typical cluster of galaxies presents a great mystery. Over time this extremely hot gas should escape the cluster, since the galaxies and gas do not provide enough gravity to hold it in. Yet the gas remains in clusters of all ages. Scientists have concluded that some unobserved form of matter, called dark matter, is providing the gravity needed to hold the hot gas in the cluster. An enormous amount of dark matter is needed—about three to ten times as much matter as that observed in the gas and galaxies. This means that most of the matter in the universe may be dark matter.

The dark matter could be collapsed stars, planet-like objects, black holes, or exotic subatomic particles that produce no light, and can be detected only through their gravity. Detailed measurements of the size and temperature of the hot gas clouds in galaxy clusters with x-ray telescopes could help solve the dark matter mystery. *See* Cosmology; Galaxy, external; Satellite astronomy; Universe; X-ray astronomy. [W.T.]

Asymmetric synthesis

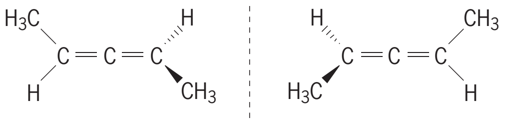
Asymmetric synthesis A reaction or series of reactions leading to predominant or exclusive formation of a single enantiomer, that is, a stereoisomer that is not superimposable on its mirror image. Among the organic compounds that are usually the target of asymmetric synthesis, the most common structural element that makes one exist as an enantiomer is a carbon atom with a single bond to four different atoms or groups (a stereogenic center), as the two enantiomers of 3-methylhexane, (R)-3-methylhexane (**1**) and (S)-3-methylhexane (**2**).



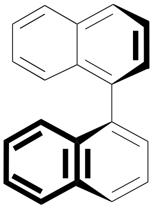
(**1**) (**2**)

Enantiomers are said to be chiral. They are asymmetric; symmetric molecules, possessing a plane or point of symmetry, are superimposable on their mirror images. Not all molecules exist as enantiomers. *See* Prochirality.

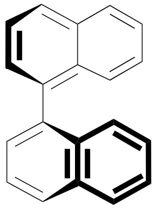
Other structural elements can give rise to asymmetry, for example substituted allene functional groups, as in (S)-2,3-pentadiene (**3**) and (R)-2,3-pentadiene (**4**), and binaphthyl systems, as in (R)-1,1′-binaphthyl (**5**) and (S)-1,1′-binaphthyl (**6**),



(**3**) (**4**)



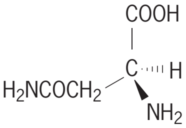
(**5**)



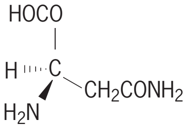
(**6**)

which are said to have axial chirality. Rules exist for unambiguously designating the three-dimensional orientations (configurations) of the atoms attached to such structural elements; these designations are the R versus S terms. *See* Stereochemistry.

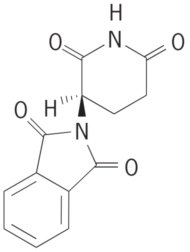
Asymmetry in molecules is very important to the biological activity of the molecule. Because almost all of the molecules in an organism, such as occur in cell membranes, enzymes, receptors, and nucleic acids (which mediate all life processes) are asymmetric, they interact differently with different enantiomers. For example, the S enantiomer of asparagine (**7**; a common amino acid) has a bitter flavor, while the R enantiomer (**8**) has a sweet flavor, due to the fact that each of the two enantiomers binds differently to chemoreceptors in the tongue. Thalidomide, a drug once prescribed to counteract pregnancy-related morning sickness, is an effective sedative as the R enantiomer (**9**), but the S enantiomer (**10**) is a potent teratogen (it causes birth defects). In general, only one enantiomer of a drug, agrochemical (herbicide, pesticide), flavoring agent, or other molecule (when asymmetric) has the desired biological effect, while the other enantiomer has very different effects or, at least, places a metabolic burden on the body. For this reason, asymmetric synthesis to produce only one enantiomer of a molecule for such uses is extremely important. *See* Amino acids; Chemoreception; Protein.



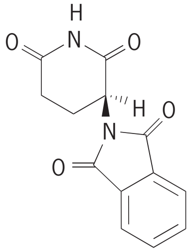
(**7**)



(**8**)



(**9**)



(**10**)

The two enantiomers of an asymmetric molecule have identical physical properties, except that they rotate plane-polarized light in opposite directions. The ability to rotate plane-polarized light (referred to as optical activity) is a property that only asymmetric molecules possess: one pure enantiomer will rotate the plane of polarization in one direction [clockwise, thus behaving as a d (dextrorotatory) or + enantiomer], and the opposite enantiomer will rotate the plane of polarization the same number of degrees but in the opposite direction [counterclockwise, thus an l (levorotatory) or − enantiomer]. A 50:50 mixture of two enantiomers of a molecule is called a racemic mixture (designated dl or ±); it will not rotate the plane of plane-polarized light. By knowing the specific rotation of a pure enantiomer, it is possible to calculate the relative amounts of each enantiomer (the so-called optical purity) in an unequal mixture. *See* Optical activity; Racemization.

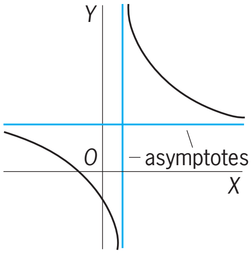
Another distinguishing property of two enantiomers is that each will react with a single enantiomer of another chiral molecule at a different rate. This process is related to the existence of diastereomers, which are stereoisomers that are not enantiomers. Diastereomers can occur in many forms. One common manifestation is the case where a molecule possesses two (or more) stereogenic carbon centers. Diastereomers, unlike enantiomers, possess different physical and chemical properties; they have different free energies while enantiomers are identical in energy. Therefore, if a reaction is designed so that it passes through two possible pathways, each involving transition states which are diastereomeric, to produce two possible stereoisomers of the product, then the pathway which involves the lower-energy transition state will proceed faster; thus one stereoisomer of the product will predominate in the product mixture. The greater the difference between the energies of the transition states, the greater the predominance of one product stereoisomer. This is the basis of asymmetric synthesis. *See* Free energy.

A common strategy to achieve asymmetric synthesis is to place a chiral center in proximity to the location where the new stereogenic center is to be introduced. When the reaction proceeds, the configuration of the new stereogenic centers being formed are influenced by the chirality of the chiral reactant; the chiral reactant "induces" chirality at the newly formed stereogenic centers.

In some cases, a chiral solvent or a chiral catalyst is used to induce chirality. In all cases, the existing chiral entity in the reaction (reactant or solvent or catalyst) is involved in the transition state, resulting in diastereomeric transition states of which the lower-energy one is favored.

Another strategy for synthesizing predominantly one enantiomer of a product is to react a racemic mixture of a starting material with a chiral reagent or catalyst that reacts faster with one of the enantiomers of the starting material than the other so that one enantiomer is consumed and the other is not. Such processes are known as kinetic resolutions. A kinetic resolution strategy for asymmetric synthesis is not as desirable as an asymmetric reaction strategy, because half of the starting material is left behind as the unwanted stereoisomer. *See* Enzyme. [R.D.Wa.]

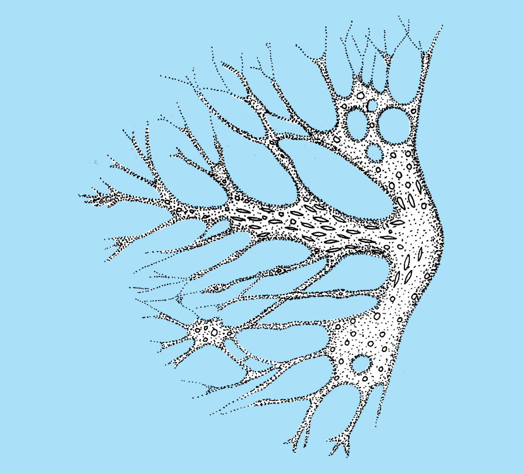
Asymptote A line that is a limit of lines tangent to a curve as the contact points of those tangents approach infinity along the curve. Thus, an asymptote of a curve is an ordinary line (that is, not the "line at infinity") that is tangent to a curve at the points in which the curve intersects the line at infinity (see illustration). [L.M.Bl.]



Asymptotes of a hyperbola.

Atelostomata A superorder of the Echinoidea, subclass Euechinoidea, characterized by having a rigid, exocyclic test, and lacking a lantern, or jaw, apparatus. The included orders are the Holasteroida and Spatangoida. *See* Echinodermata; Echinoidea; Euechinoidea; Holasteroida; Spatangoida. [H.B.F.]

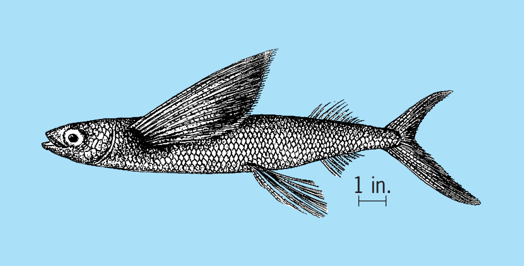
Athalamida An order of Granuloreticulosia in which the naked amebas form branched, threadlike interconnected pseudopodia (reticulopodia; see illustration). Species are known from fresh, salt, and brackish water. General characteristics are difficult to select. Heterogeneity may extend even to a genus; described species of *Biomyxa* differ appreciably in morphology and exhibit, for example, uninucleate and multinucleate conditions in different species (although these may represent young and mature stages in life cycles). In addition to *Biomyxa*, the genera *Arachnula*, *Gymnophrys*, and *Pontomyxa* have been assigned to this order. *See* GRANULORETICULOSIA; PROTOZOA; RHIZOPODEA; SARCODINA; SARCOMASTIGOPHORA. [R.P.H.]



***Biomyxa vagans*. (*After R. P. Hall, Protozoology, Prentice Hall, 1953*)**

Athecanephria An order of Pogonophora, a group of elongate, tentaculated, tube-dwelling, sedentary, nonparasitic marine worms lacking a digestive system. The coelom in the tentacular region is sac-shaped, with the two ducts set far apart from one another, and their excretory (osmoregulatory) sections lie close to the lateral cephalic blood vessels. The Athecanephria contain two families: Siboglinidae and Oligobrachiidae, with two and five genera respectively. *See* POGONOPHORA; THECANEPHRIA. [E.B.Cu.]

Atheriniformes An order of actinopterygian fishes that includes the flyingfishes, needlefishes, killifishes, silversides, and their allies. Atheriniform fishes date from the Upper Cretaceous. Modern forms are grouped in 3 suborders, 16 families, about 170 genera, and probably 700–800 species. They chiefly inhabit fresh, brackish, and oceanic surface waters of the tropics and subtropics, but some enter the temperate zones, both in fresh water and the sea. They are circumtropical in distribution, abounding in fresh waters of Africa and the Americas and in all warm seas. None lives in deep oceanic waters. Atheriniformes are mostly small, although some needlefishes reach 5 ft (1.5 m) or more in length; most have a single dorsal fin of soft rays, but the silversides have a short anterior spinous dorsal; the pectoral fin is placed high on the side; the pelvic fin, if present, is abdominal, subabdominal, or thoracic and has six (occasionally seven) or fewer rays, one of which may be a spine; scales are usually cycloid, sometimes ctenoid, and rarely absent. The most familiar families include flyingfishes (see illustration) and halfbeaks (Exocoetidae), the former with stiffened, elongated rays on the paired fins that permit gliding in air; killifishes (Cyprinodontidae); live-bearers (Poeciliidae), among them guppies, swordtails, platyfishes, mollies, and mosquito fishes; and silversides (Atherinidae), that abound on marine beaches and reefs. Viviparity is more frequent and better understood in Atheriniformes than in any other order of bony fishes, occurring in no fewer than eight families. *See* ACTINOPTERYGII; OSTEICHTHYES; TELEOSTEI. [R.M.B.]



California flyingfish (*Cypselurus californicus*). (*After G. B. Goode, Fishery Industries of the U.S., 1884*)

Atlantic Ocean The large body of sea water separating the continents of North and South America in the west from Europe and Africa in the east and extending south from the Arctic Ocean to the continent of Antarctica. The Atlantic is the second largest ocean water body and in area covers nearly one-fifth of the Earth's surface. The two major divisions, North and South Atlantic oceans, have the Equator as the common boundary. The North Atlantic, because of projecting land areas and island arcs, has numerous subdivisions. These include three large mediterranean-type seas, the Mediterranean Sea, the Gulf of Mexico plus Caribbean Sea, and the Arctic Ocean; two small mediterranean-type seas, the Baltic Sea and Hudson Bay; and four marginal seas, the North Sea, English Channel, Irish Sea, and Gulf of St. Lawrence. Parts of the Atlantic are given special names but lack precise boundaries, such as the Bahama Sea, Irminger Sea, Labrador Sea, and Sargasso Sea.

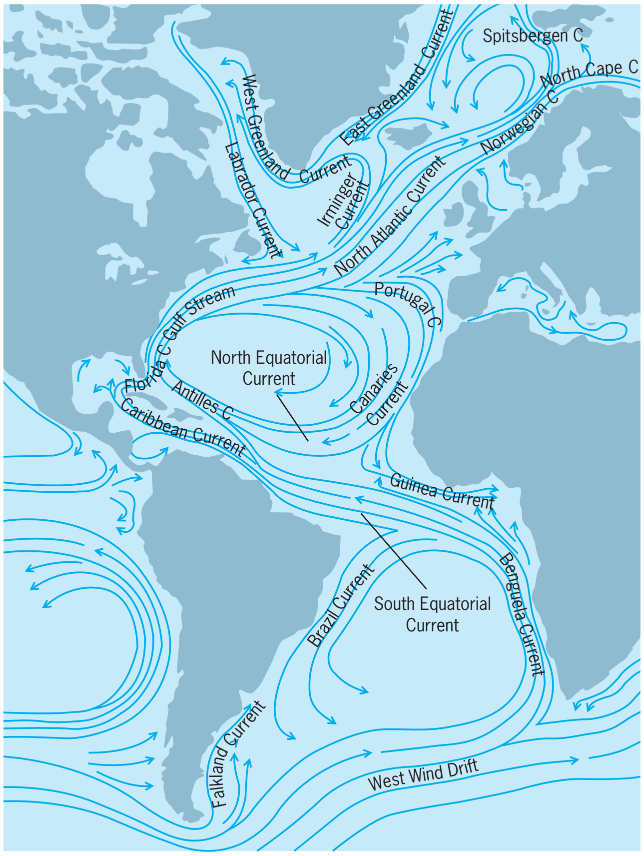
The mean depth of the Atlantic Ocean is 12,960 ft (3868 m), and its volume is 76,300,000 mi^3 (318,000,000 km^3). Broad shelves with depths less than 660 ft (200 m) are found in the region of the North Sea and the British Isles, on the Grand Banks of Newfoundland, and off the coasts of northeastern South America and Patagonia. The Mid-Atlantic Ridge, which extends from the Arctic Ocean to 55°S, is less than 9800 ft (3000 m) beneath the surface and is characterized by a pronounced relief. It separates the east and west Atlantic troughs, both of which have relatively uniform relief.

Three marked east-west ridges—the Greenland-Scotland Ridge in the North Atlantic and the Walvis and Rio Grande Ridges in the South Atlantic—and several less-conspicuous east-west rises separate the two Atlantic troughs into a series of basins including the West European, Canary, and Angola in the eastern Atlantic and the North American, Brazilian, and Argentine basins in the western Atlantic.

Islands in the Atlantic are mostly of volcanic origin. The Bermudas are the northernmost coral reefs, rising from an old submarine volcanic cone. Some islands, such as the British Isles, are continental in character. *See* OCEANIC ISLANDS; WEST INDIES.

The primary circulation of surface winds over the Atlantic Ocean is characterized by a zonal distribution pattern oriented in an east-west direction. The greatest storm frequency, more than 30% in winter, is in the zone of the prevailing westerlies. Air temperatures also follow a zonal pattern of distribution. They are lower in the South Atlantic than in the North Atlantic, and lower in the tropics and subtropics over the eastern Atlantic, than they are in the same latitudes over the western Atlantic. Maximum precipitation occurs in the doldrum zone (80 in. or 2000 mm/year). Precipitation also is relatively great in the zone of westerlies but is low in the trade-wind zones.

Sea ice is formed in the northernmost and southernmost parts of the Atlantic Ocean. From these areas drift ice moves equatorward into neighboring regions where it becomes a hazard to sea



Currents of the Atlantic Ocean. (*Adapted from J. Bartholomew Advanced Atlas of Modern Geography, McGraw-Hill, 3d ed., 1957*)

traffic and limits fishing. Many icebergs drift southward into the sea lanes of the North Atlantic. Most of these have their origin in the valley glaciers of western Greenland. Icebergs generally drift south of the Grand Banks, and some are known to have drifted southeast of Bermuda. In the South Atlantic large, tabular icebergs separate from the Antarctic ice shelf and drift northward. *See* Iceberg; Sea ice.

Surface currents in the Atlantic Ocean flow in much the same direction as the prevailing surface winds (see illustration). Deflections from these directions are caused by the bottom topography and the latitude or increased effect of Coriolis forces. The fairly constant flow of the North and South Equatorial currents is sustained largely by the trade winds. As a result, warm water is piled up along the poleward borders of these currents and on the western sides of the Atlantic Ocean. *See* Antarctic; Ocean; Arctic; Ocean; Sea; Gulf of; Gulf; Stream; Ocean circulation.

The surface water in certain areas takes on a particularly high density in winter under the influence of climatic conditions. These water masses sink to a depth where the surrounding waters have a corresponding density and then spread out at that level. At the same time they are constantly mixing with the surrounding waters. In this way a multistoried stratification arises. Compared with that of the Indian and Pacific oceans, the deep circulation in the Atlantic Ocean is very vigorous, and the deeper water is therefore rich in oxygen. The abundance of nutrients permits a greater rate of organic production where the nutrient-rich waters nearly reach the surface, as in the Antarctic waters. *See* Seawater; Seawater fertility.

The semidiurnal tidal form predominates in the Atlantic Ocean. The mean tidal range is about 3.3 ft (1 m) in the open ocean, but it decreases to 6.3 in. (16 cm) off Rio Grande do Sul in southern Brazil and to 3.5 in. (9 cm) off Puerto Rico. Tidal ranges increase beyond broad shelves under favorable physical conditions. The tides of the mediterranean and marginal seas are cooscillations of the tides of the Atlantic Ocean. *See* Tide.

The Atlantic Ocean, especially the North Atlantic, is by far the most important bearer of the world's sea traffic. Favorable trend include increased transportation capacities for handling bulk goods, regular weather observations for the safety of air and sea traffic by weather ships in selected positions, and the observation and reporting of drifting icebergs by the International Ice Patrol. Communication facilities, including telegraph and telephone cables and radio stations, have been improved and increased in number. [G.O.D.]

Atmosphere

A gaseous layer that envelops the Earth and most other planets in the solar system. Earth, Venus, Mars, Jupiter, Saturn, Uranus, Neptune, and Titan (Saturn's largest satellite) are all known to possess substantial atmospheres that are held by the force of gravity. The structure and properties of the various atmospheres are determined by the interplay of physical and chemical processes. Structural features of Earth's atmosphere detailed below can often be identified in the atmospheres of other planetary bodies. *See* Planetary physics.

The composition of the Earth's atmosphere is primarily nitrogen (N_2), oxygen (O_2), and argon (Ar) [see table]. The concentration of water vapor (H_2O) is highly variable, especially near the surface, where volume fractions can vary from nearly 0% to as high as 4% in the tropics. There are many minor constituents or trace gases, such as neon (Ne), helium (He), krypton (Kr), and xenon (Xe), that are inert, and active species such as carbon dioxide (CO_2), methane (CH_4), hydrogen (H_2), nitrous oxide (NO), carbon monoxide (CO), ozone (O_3), and sulfur dioxide (SO_2), that play an important role in radiative and biological processes.

In addition to the gaseous component, the atmosphere suspends many solid and liquid particles. Aerosols are particulates usually less than 1 micrometer in diameter that are created by gas-to-particle reactions or are lifted from the surface by the wind. A portion of these aerosols can become centers of condensation or deposition in the growth of water and ice clouds. Cloud droplets and ice crystals are made primarily of water with some trace amounts of particles and dissolved gases. Their diameters range from a few micrometers to about 100 μm. Water or ice particles larger than about 100 μm begin to fall because of gravity and may result in precipitation at the surface. *See* Aerosol; Cloud physics; Precipitation (meteorology).

One of the remarkable properties of the Earth's atmosphere is the large amount of free molecular oxygen in the presence of gases such as nitrogen, methane, water vapor, hydrogen, and others that are capable of being oxidized. The atmosphere is in a highly oxidizing state that is far from chemical equilibrium. This is in sharp contrast to the atmospheres of Venus and Mars, the planets closest to the Earth, which are composed almost entirely of the more oxidized state, carbon dioxide. The chemical disequilibrium on the Earth is maintained by a continuous source of reactive gases derived from biological processes. Life plays a vital role in maintaining the present atmospheric composition. *See* Atmospheric chemistry; Mars; Venus.

The total mass of the Earth's atmosphere is about 5.8×10^{15} tons (5.3×10^{15} metric tons). The vertical distribution of gaseous mass is maintained by a balance between the downward force of gravity and the upward pressure gradient force. The balance is known as the hydrostatic balance or the barometric law. Hence, the declining atmospheric pressure that is measured while ascending in the atmosphere is a result of gravity. The globally averaged pressure at mean sea level is 1013.25 millibars (101,325 pascals).

Below about 60 mi (100 km) in altitude, the atmosphere's composition of major constituents is very uniform. This region is known as the homosphere to distinguish it from the heterosphere above 60 mi (100 km), where the relative amounts of the major

Composition of the atmosphere*

Molecule	Fraction volume near surface	Vertical distribution
Major constituents		
N_2	7.8084×10^{-1}	Mixed in homosphere; photochemical dissociation high in thermosphere
O_2	2.0946×10^{-1}	Mixed in homosphere; photochemically dissociated in thermosphere, with some dissociation in mesosphere and stratosphere
Ar	9.34×10^{-3}	Mixed in homosphere with diffusive separation increasing above
Important radiative constituents		
CO_2	3.5×10^{-4}	Mixed in homosphere; photochemical dissociation in thermosphere
H_2O	Highly variable	Forms clouds in troposphere; little in stratosphere; photochemical dissociation above mesosphere
O_3	Variable	Small amounts, 10^{-8}, in troposphere; important layer, 10^{-6} to 10^{-5}, in stratosphere; dissociated above
Other constituents		
Ne	1.82×10^{-5}	
He	5.24×10^{-6}	Mixed in homosphere with diffusive separation increasing above
Kr	1.14×10^{-6}	
CH_4	1.15×10^{-6}	Mixed in troposphere; dissociated in upper stratosphere and above
H_2	5×10^{-7}	Mixed in homosphere; product of H_2O photochemical reactions in lower thermosphere, and dissociated above
NO	$\sim 10^{-8}$	Photochemically produced in stratosphere and mesosphere

*Other gases, for example, CO, N_2O, NO_2, and many by-products of atmospheric pollution also exist in small amounts.

constituents change with height. In the homosphere there are sufficient atmospheric motions and a short enough molecular free path to maintain uniformity in composition. Above the boundary between the homosphere and the heterosphere, known as the homopause or turbopause, the mean free path of the individual molecules becomes long enough that gravity is able to partially separate the lighter molecules from the heavier ones. The mean free path is the average distance that a particle will travel before encountering a collision. Hence the average molecular weight of the heterosphere decreases with height as the lighter atoms dominate the composition.

The vertical structure of the atmosphere is in large part determined by the transfer properties of the solar and terrestrial radiation streams. The energy of the smallest unit of radiation, the photon, is directly proportional to its frequency. The type of interaction that occurs between photons and the atmosphere depends on the energy of the photons. *See* PHOTON.

The most energetic of the photons are x-rays and extreme ultraviolet radiation of the eletromagnetic spectrum, which are capable of dissociating and ionizing the gaseous molecules. The less energetic near-ultraviolet photons are able to excite molecules and atoms into higher electronic levels. As a result, most of the ultraviolet and x-ray radiation is attenuated by the upper atmosphere. A cloudless atmosphere, however, is relatively transparent to visible light, where most of the solar energy resides. At the opposite end of the spectrum toward the lower frequencies of radiation is the infrared part, which is capable of inducing various vibrational and rotational motions in triatomic and polyatomic molecules.

In order to maintain an energy balance, the Earth must emit about the same amount of radiation as it absorbs from the Sun. The terrestrial radiation occurs in the infrared part of the spectrum and hence is strongly affected by water vapor, clouds, carbon dioxide, and ozone and other trace gases. The ability of these gases to absorb and emit in the infrared allows them to effectively trap some of the outgoing radiation that is emitted by the surface, creating the so-called greenhouse effect. *See* INSOLATION.

The atmospheric layer that extends from the surface to about 7 mi (11 km) is called the troposphere. The tropopause, which is the top of the troposphere, has an average altitude that varies from about 11 mi (18 km) near the Equator to about 5 mi (8 km) near the Poles. The actual tropopause height varies considerably on time scales from a few days to an entire year. The troposphere contains about 80% of the atmospheric mass and exhibits most of the day-to-day weather fluctuations that are observed from the ground. Temperatures generally decrease with increasing altitude at an average lapse rate of about 17°F/mi (6°C/km), although this rate varies considerably, depending on time and location. *See* TROPOPAUSE; TROPOSPHERE.

The stratosphere is the atmospheric layer that extends from the tropopause up to the stratopause at about 30 mi (50 km) above the surface. It is characterized by a nearly isothermal layer in the first 6 mi (10 km) overlaid by a layer in which the temperature increases with height to a maximum of about 32°F (0°C) at the stratopause. The reversal in the temperature lapse rate is a result of direct absorption of solar radiation, mainly by ozone and oxygen at the ultraviolet frequencies. *See* STRATOSPHERE.

The reversal of the temperature lapse rate makes the stratosphere vertically stable. This stability limits the amount of vertical mixing and results in molecular residence times of many months to years. Another consequence of a stable stratosphere is that it acts as a lid on the troposphere, confining the strong vertical overturning and hence most of the surface-based weather phenomena. *See* WEATHER.

The mesosphere is the atmospheric layer extending from the stratopause up to the mesopause at an altitude of about 53 mi (85 km). The mesosphere is characterized by temperatures decreasing with height at a rate of about 12°F/mi (4°C/km). Although the mesosphere has less vertical stability than the stratosphere, it is still more stable than the troposphere and does not experience rapid overturning. The coldest temperatures of the entire atmosphere are encountered at the mesopause, with values as low as −150°F (−100°C). The temperature lapse rate found in the mesosphere is a result of the gradual weakening with height of the direct absorption of solar radiation by ozone. The radiative infrared cooling to space by the carbon dioxide molecules is responsible for the low temperatures near the mesopause. *See* MESOSPHERE.

The thermosphere is found above the mesopause. The thermosphere is characterized by rising temperatures with height up to an altitude of about 190 mi (300 km) and then is nearly isothermal above that. Although there is no clear upper limit to the thermosphere, it is convenient to consider it extending several thousand kilometers. Embedded within the thermosphere is the ionosphere, comprising those atmospheric layers in which the ionized molecules and atoms are dominating the processes.

Molecular species dominate the lower thermosphere, while atomic species are dominant above 190 mi (300 km). The distribution of the constituents is controlled by diffusive equilibrium in which the concentration of each constituent decreases exponentially with height according to its molecular weight. Hence the concentration of the heavier constituents such as nitrogen, oxygen, and carbon dioxide will decrease with height faster than the lighter constituents such as helium and hydrogen. At an altitude of 560 mi (900 km) helium becomes the dominant constituent while hydrogen dominates above 1900 mi (3000 km).

The ionosphere can be defined operationally as that part of the atmosphere that is sufficiently ionized to affect the propagation of radio waves. In the ionosphere, the dominant negative ion is the electron, and the main positive ions include O^+, NO^+, and $O_2{}^+$. The ionosphere is classified into four subregions. The D region extends from 40 to 60 mi (60 to 90 km) and contains complex ionic chemistry; most of the ionization is caused by ultraviolet ionization of NO and by galactic cosmic rays. This region is responsible for the daytime absorption of radio waves, which prevents distant propagation of certain frequencies. The E region extends from 60 to 90 mi (90 to 150 km) and is caused primarily by the x-rays from the Sun. The F1 region from 90 to 125 mi (150 to 200 km) is caused by the extreme ultraviolet radiation from the Sun and disappears at night. Finally, the F2 region includes all the ionized particles above 125 mi (200 km), with the peak ion concentrations occurring near 190 mi (300 km). *See* COSMIC RAYS; IONOSPHERE.

The exosphere is the atmosphere above 300 mi (500 km) where the probability of interatomic collisions is so low that some of the atoms traveling upward with sufficient velocity can escape the Earth's gravitational field. The dominant escaping atom is hydrogen since it is the lightest constituent. Calculations of the thermal escape of hydrogen (also known as the Jeans escape) yield a value of about 3×10^8 atoms $\cdot$ $\mathrm{cm}^{-2} \cdot \mathrm{s}^{-1}$. This is a very small amount since at this rate less than 0.5% of the oceans would disappear over the current age of the Earth.

The magnetosphere is the region surrounding the Earth where the movement of ionized gases is dominated by the geomagnetic field. The lower boundary of the magnetosphere, which occurs at an altitude of nearly 75 mi (120 km), can be roughly defined as the height where there are enough neutral atoms that the ion-neutral particle collisions dominate the ion motion. The dynamics of the magnetosphere is dictated in part by its interaction with the plasma of ionized gases that blows away from the Sun, the solar wind. The solar wind interacts with the Earth's magnetic field and severely deforms it, producing a magnetosphere around the Earth. It extends about 40,000 mi (60,000 km) toward the Sun but extends beyond the orbit of the Moon away from the Sun. *See* MAGNETOSPHERE; SOLAR WIND; VAN ALLEN RADIATION. [G.B.L.]

Atmospheric acoustics The science of sound in the atmosphere. The atmosphere has a structure that varies in both space and time, and these variations have significant effects on a propagating sound wave. In addition, when sound propagates close to the ground, the type of ground surface has a strong effect.

Atmospheric sound attenuation. As sound propagates in the atmosphere, several interacting mechanism attenuate and change the spectral or temporal characteristics of the sound received at a distance from the source. The attenuation means that sound propagating through the atmosphere decreases in level with increasing distance between source and receiver. The total attenuation, in decibels, can be approximated as the sum of three nominally independent terms, as given in the equation below,

$$A_{\mathrm{total}} = A_{\mathrm{div}} + A_{\mathrm{air}} + A_{\mathrm{env}}$$

where A_{div} is the attenuation due to geometrical divergence, A_{air} is the attenuation due to air absorption, and A_{env} is the attenuation due to all other effects and includes the effects of the ground, refraction by a nonhomogeneous atmosphere, and scattering effects due to turbulence.

Sound energy spreads out as it propagates away from its source due to geometrical divergence. At distances that are large compared with the effective size of the sound source, the sound level decreases at the rate of 6 dB for every doubling of distance. The phenomenon of geometrical divergence, and the corresponding decrease in sound level with increasing distance from the source, is the same for all acoustic frequencies. In contrast, the attenuation due to the other two terms in the equation depends on frequency and therefore changes the spectral characteristics of the sound.

Air absorption. Dissipation of acoustic energy in the atmosphere is caused by viscosity, thermal conduction, and molecular relaxation. The last arises because fluctuations in apparent molecular vibrational temperatures lag in phase the fluctuations in translational temperatures. The vibrational temperatures of significance are those characterizing the relative populations of oxygen (O_2) and nitrogen (N_2) molecules. Since collisions with water molecules are much more likely to induce vibrational state changes than are collisions with other oxygen and nitrogen molecules, the sound attenuation varies markedly with absolute humidity. *See* MOLECULAR STRUCTURE AND SPECTRA; VISCOSITY.

The total attenuation due to air absorption increases rapidly with frequency. For this reason, applications in atmospheric acoustics are restricted to sound frequencies below a few thousand hertz it the propagation distance exceeds a few hundred meters. *See* SOUND ABSORPTION.

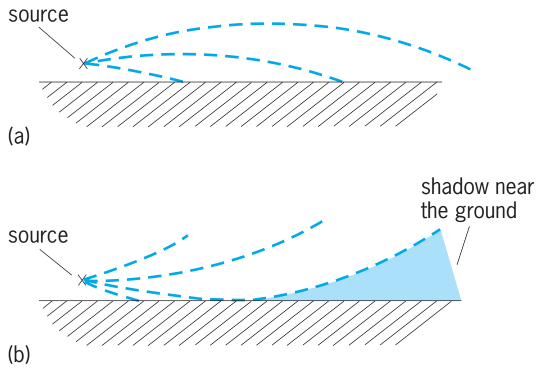
Effects of the ground. When the sound source and receiver are above a large flat ground surface in a homogeneous atmosphere, sound reaches the receiver via two paths. There is the direct path from source to receiver and the path reflected from the ground surface. Most naturally occurring ground surfaces are porous to some degree, and their acoustical property can be represented by an acoustic impedance. The acoustic impedance of the ground is in turn associated with a reflection coefficient that is typically less than unity. In simple terms, the sound field reflected from the ground surface suffers a reduction in amplitude and a phase change.

When the source and receiver are both relatively near the ground and are a large distance apart, the direct and reflected fields become nearly equal and cancel each other.

Refraction of sound. Straight ray paths are rarely achieved outdoors. In the atmosphere, both the wind and temperature vary with height above the ground. The velocity of sound relative to the ground is a function of wind velocity and temperature; hence it also varies with height, causing sound waves to propagate along curved paths.

The speed of the wind decreases with decreasing height above the ground because of drag on the moving air at the surface. Therefore, the speed of sound relative to the ground increases with height during downwind propagation, and ray paths curve downward. For propagation upwind, the sound speed decreases with height, and ray paths curve upward (see illustration). In the case of upward refraction, a shadow boundary forms near the ground beyond which no direct sound can penetrate. Some acoustic energy penetrates into a shadow zone via creeping waves that propagate along the ground and that continually shed diffracted rays into the shadow zones. The dominant feature of shadow-zone reception is the marked decrease in a sound's higher-frequency content. The presence of shadow zones explains why sound is generally less audible upwind of a source.

Refraction by temperature profiles is analogous. During the day, solar radiation heats the Earth's surface, resulting in warmer air near the ground. This condition is called a temperature lapse and is most pronounced on sunny days. A temperature lapse is the common daytime condition during most of the year, and also causes ray paths to curve upward. After sunset there is



Curved ray paths. (*a*) Refraction downward, during temperature inversion or downwind propagation. (*b*) Refraction upward, during temperature lapse or upwind propagation.

often radiation cooling of the ground, which produces cooler air near the surface. In summer under clear skies, such temperature inversions begin to form about 2 hours after sunset. Within the temperature inversion, the temperature increases with height, and ray paths curve downward.

The effects of refraction by temperature and wind are additive and produce rather complex sound speed profiles in the atmosphere.

Effects of turbulence. Turbulence in the atmosphere causes the effective sound speed to fluctuate from point to point, so a nominally smooth wave front develops ripples. One result is that the direction of a received ray may fluctuate with time in random manner. Consequently, the amplitude and phase of the sound at a distant point will fluctuate with time. The acoustical fluctuations are clearly audible in the noise from a large aircraft flying overhead. Turbulence in the atmosphere also scatters sound from its original direction. *See* TURBULENT FLOW. [G.A.Da.]

Atmospheric chemistry A scientific discipline concerned with the chemical composition of the Earth's atmosphere. Topics include the emission, transport, and deposition of atmospheric chemical species; the rates and mechanisms of chemical reactions taking place in the atmosphere; and the effects of atmospheric species on human health, the biosphere, and climate.

A useful quantity in atmospheric chemistry is the atmospheric lifetime, defined as the mean time that a molecule resides in the atmosphere before it is removed by chemical reaction or deposition. The atmospheric lifetime measures the time scale on which changes in the production or loss rates of a species may be expected to translate into changes in the species concentration. The atmospheric lifetime can also be compared to the time scales for atmospheric transport to infer the spatial variability of a species in the atmosphere; species with lifetimes longer than a decade tend to be uniformly mixed, while species with shorter lifetimes may have significant gradients reflecting the distributions of their sources and sinks.

The principal constituents of dry air are nitrogen (N_2; 78% by volume), oxygen (O_2; 21%), and argon (Ar; 1%). The atmospheric concentrations of N_2 and Ar are largely determined by the total amounts of N and Ar released from the Earth's interior since the origin of the Earth. The atmospheric concentration of O_2 is regulated by a slow atmosphere-lithosphere cycle involving principally the conversion of O_2 to carbon dioxide (CO_2) by oxidation of organic carbon in sedimentary rocks (weathering), and the photosynthetic conversion of CO_2 to O_2 by marine organisms which precipitate to the bottom of the ocean to form new sediment. This cycle leads to an atmospheric lifetime for O_2 of about 4 million years. *See* ATMOSPHERE, EVOLUTION OF; BIOSPHERE; LITHOSPHERE; PHOTOSYNTHESIS.

Water vapor concentrations in the atmosphere range from 3% by volume in wet tropical areas to a few parts per million by volume (ppmv) in the stratosphere. Water vapor, with a mean atmospheric lifetime of 10 days, is supplied to the troposphere by evaporation from the Earth's surface, and it is removed by precipitation. Because of this short lifetime, water vapor concentrations decrease rapidly with altitude, and little water vapor enters the stratosphere. Oxidation of methane represents a major source of water vapor in the stratosphere, comparable to the source contributed by transport from the troposphere.

The most abundant carbon species in the atmosphere is CO_2. It is produced by oxidation of organic carbon in the biosphere and in sediments. The atmospheric concentration of CO_2 is rising, and there is concern that this may cause significant warming of the Earth's surface because of the ability of CO_2 to absorb infrared radiation emitted by the Earth (the greenhouse effect). The total amount of carbon present in the atmosphere is small compared to that present in the other geochemical reservoirs, and therefore it is controlled by exchange with these reservoirs. Equilibration of carbon between the atmosphere, biosphere, soil, and surface ocean reservoirs takes place on a time scale of decades. *See* CARBON DIOXIDE; GREENHOUSE EFFECT.

Methane is the second most abundant carbon species in the atmosphere and an important greenhouse gas. It is emitted by anaerobic decay of biological carbon (for example, in wetlands, landfills, and stomachs of ruminants), by exploitation of natural gas and coal, and by combustion. It has a mean lifetime of 12 years against atmospheric oxidation by the hydroxyl (OH) radical, its principal sink. *See* METHANE.

Many hydrocarbons other than methane are emitted to the atmosphere from vegetation, soils, combustion, and industrial activities. The emission of isoprene [$H_2C{=}C(CH_3){-}CH{=}CH_2$] from deciduous vegetation is particularly significant. Nonmethane hydrocarbons have generally short lifetimes against oxidation by OH (a few hours for isoprene), so that their atmospheric concentrations are low. They are most important in atmospheric chemistry as sinks for OH and as precursors of tropospheric ozone, organic nitrates, and organic aerosols.

Carbon monoxide (CO) is emitted to the atmosphere by combustion, and it is also produced within the atmosphere by oxidation of methane and other hydrocarbons. It is removed from the atmosphere by oxidation by OH, with a mean lifetime of 2 months. Carbon monoxide is the principal sink of OH and hence plays a major role in regulating the oxidizing power of the atmosphere.

Nitrous oxide (N_2O) is of environmental importance as a greenhouse gas and as the stratospheric precursor for the radicals NO and NO_2. The principal sources of N_2O to the atmosphere are microbial processes in soils and the oceans; the main sinks are photolysis and oxidation in the stratosphere, resulting in an atmospheric lifetime for N_2O of about 130 years.

About 90% of total atmospheric ozone (O_3) resides in the stratosphere, where it is produced by photolysis of O_2. The ultraviolet photons ($\lambda < 240$ nm) needed to photolyze O_2 are totally absorbed by ozone and O_2 as solar radiation travels through the stratosphere. As a result, ozone concentrations in the troposphere are much lower than in the stratosphere. *See* PHOTOLYSIS; STRATOSPHERE; TROPOSPHERE.

Tropospheric ozone plays a central role in atmospheric chemistry by providing the primary source of the strong oxidant OH. It is also an important greenhouse gas. In surface air, ozone is of great concern because of its toxicity to humans and vegetation. Ozone is supplied to the troposphere by slow transport from the stratosphere, and it is also produced within the troposphere by a chain reaction involving oxidation of CO and hydrocarbons by OH in the presence of NO_x. Ozone production by this mechanism is particularly rapid in urban areas, where emissions of NO_x and of reactive hydrocarbons are high.

Sulfuric acid produced in the atmosphere by oxidation of sulfur dioxide (SO_2) is a major component of aerosols in the atmosphere and an important contributor to acid deposition. Sources of SO_2 to the atmosphere include emission from combustion, smelters, and volcanoes, and oxidation of oceanic dimethylsulfide [$(CH_3)_2S$] emitted by phytoplankton. It is estimated that about 75% of total sulfur emission to the atmosphere is anthropogenic. *See* AEROSOL; AIR POLLUTION. [D.J.J.]

Atmospheric electricity The electrical processes constantly taking place in the lower atmosphere. This activity is of two kinds, the intense local electrification accompanying storms, and the much weaker fair-weather electrical activity over the entire globe, which is produced by the many electrified storms continuously in progress over the Earth. The mechanisms by which storms generate electric charge are unknown, and the role of atmospheric electricity in meteorology has not been determined.

Almost all precipitation-producing storms throughout the year are accompanied by energetic electrical activity. The most intense of these are the thunderstorms, in which the electrification attains values sufficient to produce lightning. Electrical measurements show that most other storms, even though they do not give lightning, are also quite strongly electrified. The electric fields of thunderstorms cause three currents to flow, each of a few amperes: lightning, point discharge from the ground beneath, and conduction in the surrounding air. Because the external field and conductivity are greatest over the top of the cloud, most of the conduction current flows to the ionosphere, the upper, highly conductive layer of the atmosphere. *See* THUNDERSTORM.

Fair-weather measurements, irrespective of place and time, show the invariable presence of a weak negative electric field caused by the estimated several thousand electrified storms continually in progress. Together these storms cause a 2000-A current from the earth to the ionosphere that raises the ionosphere to a positive potential of about 300,000 V with respect to the earth. This potential difference is sufficient to cause a return flow of positive charge to the earth by conduction through the intervening lower atmosphere equal and opposite to the thunderstorm supply current. The fair-weather field is simply the voltage drop produced by the flow of this current through the atmosphere. Because the electrical resistance of the atmosphere decreases with altitude, the field is greatest near the Earth's surface and gradually decreases with attitude until it vanishes at the ionosphere.

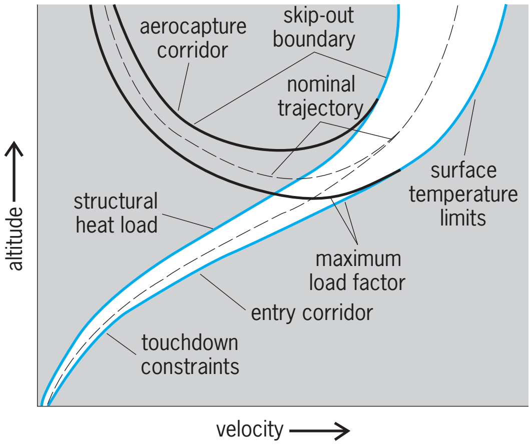
No importance is presently attached to fair-weather atmospheric electricity except that according to some theories it is responsible for the initiation of the thunderstorm electrification process. *See* CLOUD PHYSICS; LIGHTNING; SFERICS; STORM DETECTION; TORNADO. [B.V.]

Atmospheric entry The motion of a body traveling from space through the atmosphere surrounding a planet. Entry bodies can be natural bodies, such as meteors or comets, or vehicles, such as ballistic missiles or the space shuttle orbiter. Entry begins when the body reaches the sensible atmosphere (defined as 400,000 ft or 122 km altitude for Earth).

The primary forces acting on an entry body are aerodynamic lift and drag, gravity, propulsion, and centrifugal acceleration. Of particular concern to the designer of entry vehicles is the control of the trajectory to minimize the effects of heating on the thermal protection system and aerodynamic loading on the vehicle structure. From Newton's law of motion, the forces on the vehicle determine the resulting trajectory as the body traverses the atmosphere.

Aerocapture vehicles use the atmosphere to deplete energy prior to orbit capture in order to significantly reduce the amount of propellant required and thus reduce the mass requirements.

For controllable vehicles, the concept of trajectory control refers to the management of the kinetic and potential energy so as to maneuver from the initial entry conditions to the desired final conditions with due regard to system constraints and dispersions. One manner of accomplishing this is to establish a guidance corridor (see illustration). Initially, the flight path is steep enough to prevent skipping out of the atmosphere but shallow enough to keep the maximum temperature and structural load factor within limits. Later in flight, the total heat load into the structure, which increases with time of flight, becomes a constraint.



Guidance corridor. Constraints on the trajectory, which determine the boundaries of the corridor, are indicated.

The most dominant aerodynamic force is the vehicle drag, which provides the deceleration. High-drag bodies are characterized by large, blunt reference profiles. The lift force is perpendicular to the drag force, works perpendicular to the velocity vector, and is the primary force vector for trajectory control. The ratio of lift to drag (L/D) determines the amount of trajectory control available. For the space shuttle this ratio is 1.1, while for the Apollo entry capsule this ratio was 0.3. *See* AERODYNAMIC FORCE.

Vehicles entering the atmosphere experience heat transferred from the hot air surrounding the spacecraft to the colder wall of the spacecraft. The transfer of heat or energy is accomplished by conduction, radiation, and convection. A vehicle traveling at supersonic or hypersonic velocities deflects the air and forms a shock wave. The air between the detached bow shock and the vehicle is heated to very high temperatures by molecular collisions converting the kinetic energy to thermal energy. Approximately 97–98% of this energy flows past the vehicle into the free stream. The remaining 2% has to be managed by the thermal protection system on the spacecraft. *See* AEROTHERMODYNAMICS; HYPERSONIC FLIGHT; SHOCK WAVE; SUPERSONIC FLIGHT.

The flow within the thin boundary layer next to the surface of the vehicle can be either laminar or turbulent. Turbulent flow has faster-moving particles and higher rates of heat transfer to the surface than laminar flow. Thus, it is desirable for entry vehicles to maintain laminar flow as long as possible to minimize the surface temperature. *See* FLUID FLOW.

Ablator materials, which were used on Mercury, Gemini, and Apollo spacecraft, accommodated the convective heating through absorption, vaporization, and the resultant char layer that reradiated the heat to the atmosphere. Ablators, however, are not reusable. *See* NOSE CONE.

The reuse requirement for the shuttle orbiter necessitated development of new concepts of thermal protection. One concept is an external low-density insulator that can withstand high temperatures for multiple orbiter entries for at least 100 flights. The insulator is a tile fabricated from high-purity silica fibers reinforced with silica binder.

The temperature on the wing leading edges and on the nose of the shuttle orbiter was predicted to exceed 2300°F (1533 K). A reinforced carbon-carbon system was developed to withstand up to 3000°F (1922 K). Reinforced carbon-carbon is a laminate of woven graphite cloth with a carbon binder and a silicon carbide coating which prevents oxidation. [R.L.Ba.; D.B.L.; J.D.Ga.]

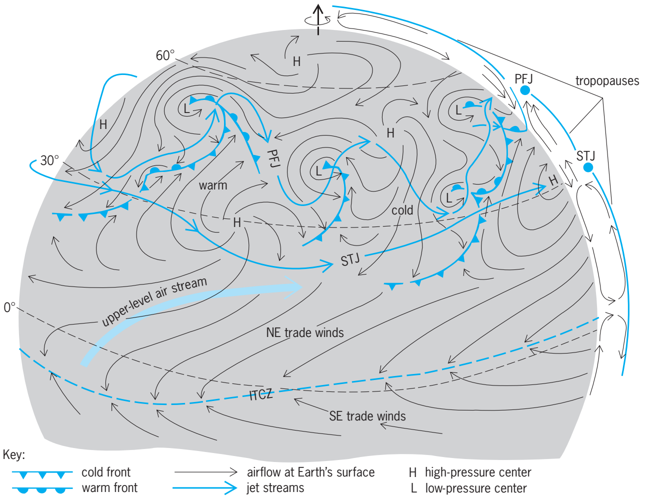
Atmospheric general circulation

The statistical description of atmospheric motions over the Earth, their role in transporting energy, and the transformations among different forms of energy. Through their influence on the pressure distributions that drive the winds, spatial variations of heating and cooling generate air circulations, but these are continually dissipated by friction. While large day-to-day and seasonal changes occur, the mean circulation during a given season tends to be much the same from year to year. Thus, in the long run and for the global atmosphere as a whole, the generation of motions nearly balances the dissipation. The same is true of the long-term balance between solar radiation absorbed and infrared radiation emitted by the Earth-atmosphere system, as evidenced by its relatively constant temperature. Both air and ocean currents, which are mainly driven by the winds, transport heat. Hence the atmospheric and oceanic general circulations form cooperative systems. *See* MARITIME METEOROLOGY.

Owing to the more direct incidence of solar radiation in low latitudes and to reflection from clouds, snow, and ice, which are more extensive at high latitudes, the solar radiation absorbed by the Earth-atmosphere system is about three times as great in the equatorial belt as at the poles, on the annual average. Infrared emission is, however, only about 20% greater at low than at high latitudes. Thus in low latitudes (between about 35°N and 35°S) the Earth-atmosphere system is, on the average, heated by radiation, and in higher latitudes cooled by radiation. The Earth's surface absorbs more radiative heat than it emits, whereas the reverse is true for the atmosphere. Therefore, heat must be transferred generally poleward and upward through processes other than radiation. At the Earth-atmosphere interface, this transfer occurs in the form of turbulent flux of sensible heat and through evapotranspiration (flux of latent heat). In the atmosphere the latent heat is released in connection with condensation of water vapor. *See* CLIMATOLOGY.

Considering the atmosphere alone, the heat gain by condensation and the heat transfer from the Earth's surface exceed the net radiative heat loss in low latitudes. The reverse is true in higher latitudes. The meridional transfer of energy, necessary to balance these heat gains and losses, is accomplished by air currents. These take the form of organized circulations, whose dominant features are notably different in the tropical belt (roughly the half of the Earth between latitudes 30°N and 30°S) and in extratropical latitudes. *See* METEOROLOGY; STORM.

Characteristic circulations over the Northern Hemisphere are shown in the illustration. In the upper troposphere, there are two principal jet-stream systems: the subtropical jet (STJ) near latitude 30°, and the polar-front jet (PFJ), with large-amplitude long waves and superimposed shorter waves associated with cyclone-scale disturbances. The long waves on the polar-front jet move slowly eastward, and the shorter waves move rapidly. At the Earth's surface, northeast and southeast trade winds of the two hemispheres meet at the intertropical convergence zone (ITCZ), in the vicinity of which extensive lines and large clusters of convective clouds are concentrated. Westward-moving waves and vortices form near the intertropical convergence zone and, in summer, within the trades. Heat released by condensation in convective clouds of the intertropical convergence zone, and the mass of air conveyed upward in them, drive meridional circulations (right side of the illustration), whose upper-level poleward branches generate the subtropical jet stream at their poleward boundaries.



Schematic circulations over the Northern Hemisphere in winter. The intertropical convergence zone (ITCZ) lies entirely north of the Equator in the summer. Eastward acceleration in the upper-level tropical airstream is due to Earth rotation and generates the subtropical jet stream (STJ). The vertical section (right) shows the dominant meridional circulation in the tropics and shows airstreams relative to the polar front in middle latitudes.

In extratropical latitudes, the circulation is dominated by cyclones and anticyclones. Cyclones develop mainly on the polar front, where the temperature contrast between polar and tropical air masses is concentrated, in association with upper-level waves on the polar-front jet stream. In winter, cold outbreaks of polar air from the east coasts of continents over the warmer oceans result in intense transfer of heat and water vapor into the atmosphere. Outbreaks penetrating the tropics also represent a sporadic exchange in which polar air becomes transformed into tropical air. Tropical airstreams, poleward on the west sides of the subtropical highs, then supply heat and water vapor to the extratropical disturbances. *See* CYCLONE; FRONT.

The characteristic flow in cyclones takes the form of slantwise descending motions on their west sides and ascent to their east in which extensive clouds and precipitation form. Heat that is released in condensation drives the ascending branch, and the descending branch consists of polar air that has been cooled by radiation in higher latitudes. When viewed relative to the meandering polar-front zone (right side of the illustration), the combined sinking of cold air and ascent of warm air represents a conversion of potential energy into kinetic energy. This process maintains the polar jet stream. The branches of the circulation transfer heat both upward, to balance the radiative heat loss by the atmosphere, and poleward, to balance the radiative heat deficit in high latitudes. [C.W.N.]

Atmospheric tides

Those oscillations in any or all atmospheric fields whose periods are integral fractions of either lunar or solar days. Oscillations with a period of a day are called diurnal, with a period of a half day semidiurnal, and with a period of a third of a day terdiurnal. The sum of all tidal variations is referred to as the daily variation. As a practical matter, the subject of atmospheric tides is generally restricted to oscillations on a global spatial scale (thus excluding sea breezes). The bulk of attention is devoted to migrating tides, which are those tidal oscillations that depend only on local time.

Atmospheric tides tend to be rather small in the troposphere, although the tidal oscillations in rainfall are surprisingly large. Their importance stems from two primary factors: (1) Tidal oscillations tend to increase in amplitude with height and become major components of the total meteorology above about 50 km (30 mi). (2) The subject has played a prominent role in the intellectual history of meteorology, and it still provides a remarkable example of scientific methodology in an observational science. Tides are unique among meteorological systems in that they have perfectly known periods and relatively well known sources of forcing.

The determination of an oscillation by means of data requires at least two measurements per period. Since most meteorological upper air soundings are taken only twice each day, such data can be used only to marginally determine diurnal oscillations. Occasionally, stations obtain soundings four times per day, which in turn permits determinations of semidiurnal oscillations. Rain gages assign rainfall to specific hours, and averages over many years allow the determination of the daily variation of rainfall. Surface pressure is monitored at a great many stations with effectively (from the point of view of tidal analyses) continuous time resolution. Therefore, surface pressure has traditionally been the field most thoroughly analyzed for tides.

The lunar semidiurnal tide in surface pressure is similar in distribution to the migrating part of the solar semidiurnal tide but only about one-twentieth its strength; maximum lunar semidiurnal surface pressure typically occurs about 1 lunar hour and 13 lunar hours after lunar transit. Clearly, the solar semidiurnal tide dominates the surface pressure. The solar diurnal component is not only smaller but also far more irregular.

Rainfall is commonly observed to have a daily variation. The diurnal component, though often quite large, has a very irregular phase; on the other hand, the solar semidiurnal component is surprisingly uniform, amounting to about 10–20% of the mean daily rainfall in the tropics with maximum rainfall at about 4 A.M. and 4 P.M. local time. Maximum semidiurnal rainfall appears to occur somewhat later in middle latitudes. *See* PRECIPITATION (METEOROLOGY).

Data become more sparse when attempts are made to analyze tides above the surface. Analyses of radiosonde wind measurements have shown that solar semidiurnal oscillations in horizontal wind are primarily in the form of migrating tides. Diurnal oscillations, on the other hand, are significantly affected by regional, nonmigrating components up to at least 20 km (12 mi). Above this height, the diurnal oscillations also tend to be dominated by migrating components. There is a tendency for the diurnal oscillations to have more phase variation with height, especially at low latitudes. As a rough rule of thumb, oscillations in temperature tend to have magnitudes in kelvins comparable to the amplitudes in wind in meters per second. There is also no longer a clear dominance of the semidiurnal oscillations over the diurnal oscillations once the upper-level fields are considered. The amplitude increase with height renders the detection of tidal oscillations at greater altitudes somewhat easier since the tides are becoming a larger feature of the total fields. *See* OSCILLATION.

While the classical theory of atmospheric tides is adequate for many purposes, recent years have seen a substantial development of theory well beyond the classical theory to include the effects of mean winds, viscosity, and thermal conductivity. *See* ATMOSPHERE; EARTH TIDES; TIDE. [R.S.L.]

Atmospheric waves, upper synoptic Horizontal wavelike oscillations in the pattern of wind flow aloft, usually with reference to the stronger portion of the westerly current in mid-latitudes. The flow is anticyclonically curved in the vicinity of a ridge line in the wave pattern, and is cyclonically curved in the vicinity of a trough line.

Any given hemispheric upper flow pattern may be represented by the superposition of sinusoidal waves of various lengths in the general westerly flow. Analysis of a typical pattern discloses the presence of prominent long waves, of which there are usually three or four around the hemisphere, and of distinctly evident short waves, of about half the length of the long waves.

Typically, each short-wave trough and ridge is associated with a particular cyclone and anticyclone, respectively, in the lower troposphere. The development and intensification of one of these circulations depends in a specific instance upon the details of this association, such as the relative positions and intensities of the upper trough and the low-level cyclone. These circulations produce the rapid day-to-day weather changes which are characteristic of the climate of the mid-latitudes.

The long waves aloft do not generally correspond to a single feature of the circulation pattern at low levels. They are relatively stable, slowly moving features which tend to guide the more rapid motion of the individual short waves and of their concomitant low-level cyclones and anticyclones. Thus, by virtue of their position and amplitude the long waves can exert an indirect influence on the character of the weather over a given region for a period of the order of weeks.

A blocking situation is one in which waves do not progress through the latitude belt of the westerlies. Blocking situations are frequently accompanied by extreme meteorological events; precipitation and cool temperatures persist near upper-level cyclones, and dry, warm weather persists near upper-level anticyclones. A blocking pattern usually consists of a ridge (anticyclone) over a trough (cyclone), a high-amplitude ridge, or flow shaped like an uppercase Greek omega (Ω). Because of the preference for blocking off the west coasts of Europe and North America, it appears that topography must play an important role in blocking. *See* ATMOSPHERE; JET STREAM; STORM; VORTEX; WIND. [F.S.; H.B.B.]

Atoll An annular coral reef, with or without small islets, that surrounds a lagoon without projecting land area. Most atolls are isolated reefs rising from the deep sea, and vary considerably in size. Small rings, usually without islets, may be less than a mile in diameter, but many atolls have a diameter of about 20 mi (32 km) and bear numerous islets.

The reefs of the atoll ring are flat, pavementlike areas, large parts of which, particularly along the seaward margin, may be exposed at times of low tide. The reefs vary in width from narrow ribbons to broad bulging areas more than a mile (1.6 km) across. The structures form a most effective baffle that robs the incoming waves of much of their destructive power, and at the same time brings a constant supply of refreshing sea water with oxygen, food, and nutrient salts to wide expanses of the reef.

Atolls, like other types of coral reefs, require strong light and warm waters and are limited in the existing seas to tropical and near-tropical latitudes. A large percentage of the world's atolls are contained in an area known as the former Darwin Rise that covers much of the central and southwestern Pacific. Atolls are also numerous in parts of the Indian Ocean and a number are found, mostly on continental shelves, in the Caribbean area. *See* OCEANIC ISLANDS; REEF. [H.S.L.]

Atom A constituent of matter consisting of z negatively charged electrons bound predominantly by the Coulomb force to a tiny, positively charged nucleus consisting of Z protons and $(A - Z)$ neutrons. Z is the atomic number, and A is the mass or nucleon number. The atomic mass unit is $\mathrm{u} = 1.6605397 \times 10^{-24}$ g. Electrically neutral atoms ($z = Z$) with the range $Z = 1$ (hydrogen) to $Z = 92$ (uranium) make up the periodic table of the elements naturally occurring on Earth. Isotopes of a given element have different values of A but nearly identical chemical properties, which are fixed by the value of Z. Certain isotopes are not stable; they decay by various processes called radioactivity. Atoms with Z greater than 92 are all radioactive but may be synthesized, either naturally in stellar explosions or in the laboratory using accelerator techniques. *See* ATOMIC MASS UNIT; ELECTRON; ISOTOPE; MASS NUMBER; NUCLEAR STRUCTURE; RADIOACTIVITY; TRANSURANIUM ELEMENTS.

Atoms with $Z - z$ ranging from 1 to $Z - 1$ are called positive ions. Those having $z - Z = 1$ are called negative ions; none has been found with $z - Z$ greater than 1. *See* ION. [P.M.K.]

Atom cluster Clusters are aggregates of atoms (or molecules) containing between three and a few thousand atoms that have properties intermediate between those of the isolated monomer (atom or molecule) and the bulk or solid-state material. The study of such species has been an increasingly active research field since about 1980. This activity is due to the fundamental interest in studying a completely new area that can bridge the gap between atomic and solid-state physics and also shows many analogies to nuclear physics. However, the research is also done for its potential technological interest in areas such as catalysis, photography, and epitaxy. A characteristic of clusters which is responsible for many of their interesting properties is the large number of atoms at the surface compared to those in the cluster interior. For many kinds of atomic clusters, all atoms are at the surface for sizes of up to 12 atoms. As the clusters grow further in size, the relative number of atoms at the surface scales as approximately $4N^{-1/3}$, where N is the total number of atoms. Even in a cluster as big as 10^5 atoms, almost 10% of the atoms are at the surface. Clusters can be placed in the following categories:

1. Microclusters have from 3 to 10–13 atoms. Concepts and methods of molecular physics are applicable.
2. Small clusters have from 10–13 to about 100 atoms. Many different geometrical isomers exist for a given cluster size with almost the same energies. Molecular concepts lose their applicability.
3. Large clusters have from 100 to 1000 atoms. A gradual transition is observed to the properties of the solid state.
4. Small particles or nanocrystals have at least 1000 atoms. These bodies display some of the properties of the solid state.

The most favored geometry for rare-gas (neon, argon, and krypton) clusters of up to a few thousand atoms is icosahedral. However, the preferred cluster geometry depends critically on the bonding between the monomers in the clusters. For example, ionic clusters such as those of sodium chloride [$(NaCl)_N$] very rapidly assume the cubic form of the bulk crystal lattice, and for metallic clusters it is the electronic structure rather than the geometric structure which is most important. *See* CHEMICAL BONDING; CRYSTAL STRUCTURE.

There are two main types of sources for producing free cluster beams. In a gas-aggregation source, the atoms or molecules are vaporized into a cold, flowing rare-gas atmosphere. In a jet-expansion source, a gas is expanded under high pressure through a small hole into a vacuum.

In most situations, the valence electrons of the atoms making up the clusters can be regarded as being delocalized, that is, not attached to any particular atom but with a certain probability of being found anywhere within the cluster. The simplest and most widely used model to describe the delocalized electrons in metallic clusters is that of a free-electron gas, known as the jellium model. The positive charge is regarded as being smeared out over the entire volume of the cluster, while the valence electrons are free to move within this homogeneously distributed, positively charged background. [E.Ca.]

Atom laser A device that generates an intense coherent beam of atoms through a stimulated process. It does for atoms what an optical laser does for light. The atom laser emits coherent matter waves, whereas the optical laser emits coherent electromagnetic waves. Coherence means, for instance, that atom laser beams can interfere with each other. *See* COHERENCE.

Laser light is created by stimulated emission of photons, a light amplification process. Similarly, an atom laser beam is created by stimulated amplification of matter waves. The conservation of the number of atoms is not in conflict with matter-wave amplification: The atom laser takes atoms out of a reservoir and transforms them into a coherent matter wave similar to the optical laser, which converts energy into coherent electromagnetic radiation (but, in contrast, the number of photons need not be conserved). *See* LASER.

Elements. A laser requires a cavity (resonator), an active medium, and an output coupler (see table).

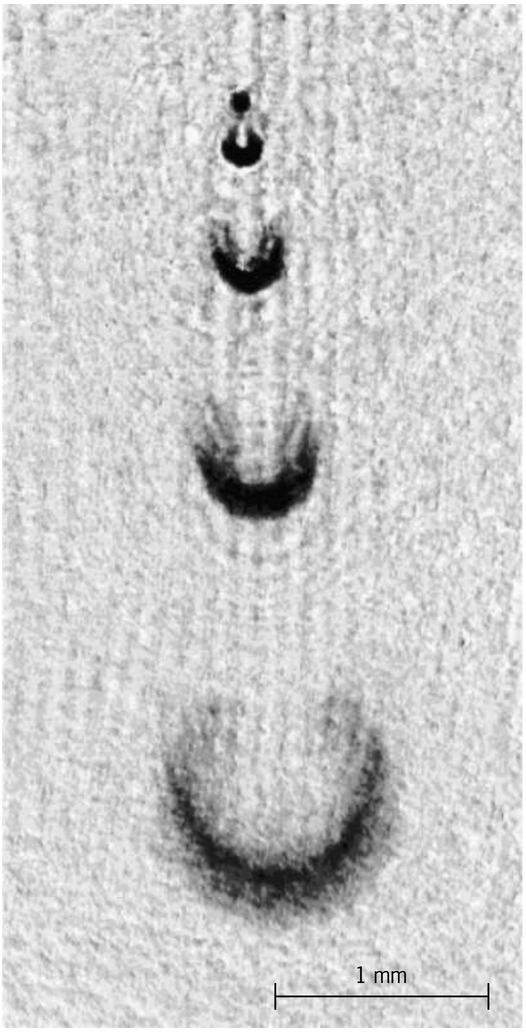
Analogies between an atom laser and the optical laser

Atom laser*	Optical laser
Atoms	Photons
Matter waves	Electromagnetic waves
Atom trap	Laser cavity
Atoms in the Bose condensate	Photons in the lasing mode
Thermal atoms	Gain medium
Evaporative cooling	Excitation of the gain medium
Stimulated scattering of atoms	Stimulated emission of photons
Critical temperature for Bose-Einstein condensation	Laser threshold

* Based on evaporative cooling.

Cavity. Various analogs of laser cavities for atoms have been realized. The most important ones are magnetic traps (which use the force of an inhomogeneous magnetic field on the atomic magnetic dipole moment) and optical dipole traps (which use the force exerted on atoms by focused laser beams). *See* PARTICLE TRAP.

Active medium. The active medium is a reservoir of atoms which are transferred to one state of the confining potential, which is the analog of the lasing mode. The reservoir can be atoms confined in other quantum states of the atom cavity or an ultraslow atomic beam. The atoms are transferred to the lasing mode either by collisions or by optical pumping. The transfer of



Pulsed atom laser in operation, with pulses of coherent sodium atoms coupled out from a Bose-Einstein condensate that is confined in a magnetic trap.

atoms is efficient only for an ultracold sample, which is prepared by laser cooling or evaporative cooling. This cooling ensures that the atoms in the reservoir occupy only a certain range of quantum states which can be efficiently coupled to the lasing mode.

Output coupler. The output coupler extracts atoms from the cavity, thus generating a pulsed or continuous beam of coherent atoms. A simple way to accomplish this step is to switch off the atom trap and release the atoms. This method is analogous to cavity dumping for an optical laser, and extracts all the stored atoms into a single pulse. A more controlled way to extract the atoms requires a coupling mechanism between confined quantum states and propagating modes.

Such a beam splitter for atoms can be realized by applying the Stern-Gerlach effect to atoms in a magnetic trap. Initially, all the atoms have their electron spin parallel to the magnetic field, say spin up, and in this state they are confined in the trap. A short radio-frequency pulse rotates (tilts) the spin of the atoms by a variable angle. Quantum-mechanically, a tilted spin is a superposition of spin up and spin down. Since the spin-down component experiences a repulsive magnetic force, the cloud of atoms is split into a trapped cloud and an out-coupled cloud. By using a series of radio-frequency pulses, a sequence of coherent atom pulses can be formed. These pulses are accelerated downward by gravity and spread out. *See* QUANTUM MECHANICS.

The illustration shows such a sequence of coherent pulses. In this case, sodium atoms are coupled out from a magnetic trap by radio-frequency pulses every 5 ms. The atom pulses are observed by illuminating them with resonant laser light and imaging their shadows, which are caused by absorption of the light. Each pulse contains 10^5–10^6 sodium atoms.

Potential applications. Although a basic atom laser has now been demonstrated, major improvements are necessary before it can be used for applications, especially in terms of increased output power and reduced overall complexity. The atom laser provides ultimate control over the position and motion of atoms at the quantum level, and might find use where such precise control is necessary, for example, for precision measurements of fundamental constants, tests of fundamental symmetries, atom optics (in particular, atom interferometry and atom holography), and precise deposition of atoms on surfaces. *See* FUNDAMENTAL CONSTANTS; NANOTECHNOLOGY; SYMMETRY LAWS (PHYSICS). [W.Ket.]

Atom optics

The use of laser light and nanofabricated structures to manipulate the motion of atoms in the same manner that rudimentary optical elements control light. The term refers to both an outlook in which atoms in atomic beams are thought of and manipulated like photons in light beams, and a collection of demonstrated techniques for doing such manipulation. Two types of atom optics elements have existed for some time: slits and holes used to collimate molecular beams (the analog of the pinhole camera), and focusing lenses for atoms and molecules (for example, hexapole magnets and quadrupole electrostatic lenses). However, in the 1980s the collection of optical elements for atoms expanded dramatically because of the use of near-resonant laser light and fabricated structures to make several types of mirrors as well as diffraction gratings. The diffraction gratings are particularly interesting because they exploit and demonstrate the (de Broglie) wave nature of atoms in a clear fashion. *See* LASER.

Diffraction gratings. Diffraction gratings for atoms have been made by using either a standing wave of light or a slotted membrane. The standing light wave makes a phase grating (that is, it advances or retards alternate sections of the incident wavefront but does not absorb any of the atom wave), so that the transmitted intensity is high. This approach requires the complexity of a single-mode laser, and introduces the complication that the light acts differently on the various hyperfine states of the atom. The slotted membrane, however, absorbs (or backscatters) atoms which strike the grating bars, but does not significantly alter the phase of the transmitted atoms; it is therefore an amplitude grating. It works for any atom or molecule, regardless of internal quantum state, but with total transmission limited to about 40% by the opacity of the grating bars and requisite support structure. *See* DIFFRACTION GRATING.

Atom interferometers. Atom interferometers have been demonstrated through several different experimental routes, involving both microscopic fabricated structures and laser beams. These interferometers are the first examples of optical systems composed of the elements of atom optics like those discussed above. Atom interferometers, like optical interferometers, are well suited for application to a wide range of fundamental and applied scientific problems. Scientific experiments with atom interferometers divide naturally into three major categories: measurements of atomic and molecular properties, fundamental tests and demonstrations, and inertial effects. *See* FRAME OF REFERENCE; INTERFERENCE OF WAVES; INTERFEROMETRY; OPTICS. [D.E.P.]

Atomic beams

Unidirectional streams of neutral atoms passing through a vacuum. These atoms are virtually free from the influence of neighboring atoms but may be subjected to electric and magnetic fields so that their properties may be studied. The technique of atomic beams is identical to that of molecular beams. For historical reasons the latter term is most generally used to describe the method as applied to either atoms or molecules.

The method of atomic beams yields extremely accurate spectroscopic data about the energy levels of atoms, and hence detailed information about the interaction of electrons in the atom with each other and with the atomic nucleus, as well as information about the interaction of all components of the atom with external fields. *See* MOLECULAR BEAMS. [P.Ku.]

Atomic bomb

A device for suddenly producing an explosive neutron chain reaction in a fissile material such as uranium-235 (^{235}U) or plutonium-239 (^{239}Pu). In a wider sense, any explosive device that derives its energy from nuclear reactions, including not only the foregoing fission weapon but also a fusion weapon, which gets its energy largely from fusion reactions of heavy hydrogen isotopes, and a fission-fusion weapon, which derives its energy from both fission and fusion. Because an atomic bomb derives its energy from nuclear reactions, it is properly called a nuclear explosive or nuclear weapon. *See* NUCLEAR FISSION; NUCLEAR REACTION; PLUTONIUM; URANIUM.

Of the two principal fissile materials, the cheaper but less potent ^{235}U is present in natural uranium usually in the proportion of 1 part to 139 parts of ^{238}U and is separated from it by various enrichment processes. Weapons-grade plutonium is manufactured from ^{238}U in a special military production reactor that has enough excess neutrons for the reaction below.

$$\mathrm{U} + n \rightarrow {}^{239}\mathrm{U}\ \text{(23-min half-life)} \rightarrow {}^{239}\mathrm{Np}\ \text{(2.3-day half-life)} \rightarrow {}^{239}\mathrm{Pu}$$

Weapon cores are made of very high fractions of fissile materials: highly enriched 93% uranium-235 or weapon-grade 94% plutonium-239. *See* ISOTOPE SEPARATION.

A fission bomb before ignition consists of a mass of fissile material and surrounding tamper—beryllium oxide or other reflector of neutrons intended ultimately to improve the neutron multiplication factor k—arranged in a geometry so favorable to neutron leakage that k is less than 1. These materials are suddenly compressed into a geometry where k substantially exceeds 1. This is done with chemical explosives that either implode a spherical subcritical mass of fission material or else drive two subcritical sections together in a gun-barrel type of arrangement. At the same time, enough neutrons are artificially introduced to start an explosively divergent (expanding) chain reaction. Fission-explosive devices intended for military application are highly sophisticated combinations of pure materials, precise design, and reliable electronics.

The explosive energy (yield) of a nuclear weapon is usually expressed in kilotons or megatons. A kiloton is the amount of energy liberated in the explosion of 1000 tons of TNT (10^{12} calories or 4.18×10^{12} J), and a megaton is a thousand times as large. The fission bombs that destroyed Hiroshima (gun-barrel type) and Nagasaki (implosion type) had estimated explosive yields of 13 and 22 kilotons, respectively. Fractional kiloton yields can be obtained (tactical nuclear weapons). Fission weapons have been tested up to approximately 500 kilotons, overlapping the yield of multistage fusion explosives (strategic nuclear weapons).

The nuclear explosive energy is communicated by mechanical shock and radiative transport to the surrounding water, earth, or air, ionizing it out to a radius which, in the case of explosions in air, is known as the fireball radius (150 yd or 140 m in about 1 s after a 20-kiloton nuclear explosion). Energy goes out from such a fireball into the surrounding relatively transparent air, in not very different orders of magnitude in the form of a shock wave and in the form of heat radiation that may continue for a number of seconds. *See* NUCLEAR EXPLOSION; RADIOACTIVE FALLOUT. [A.DeV.]

Atomic clock A device that uses an internal resonance frequency of atoms (or molecules) to measure the passage of time. The terms atomic clock and atomic frequency standard are often used interchangeably. A frequency standard generates pulses at regular intervals. It can be made into a clock by the addition of an electronic counter, which records the number of pulses. *See* DIGITAL COUNTER.

Most methods of timekeeping rely on counting some periodic event, such as the rotation of the Earth, the motion of a pendulum in a grandfather clock, or the vibrations of a quartz crystal in a watch. An atomic clock relies on counting periodic events determined by the difference of two different energy states of an atom. A transition between two energy states with energies E_1 and E_2 may be accompanied by the absorption or emission of a photon (particle of electromagnetic radiation). The frequency ν of this radiation is given by the equation

$$h\nu = |E_2 - E_1|$$

where h is Planck's constant. A basic advantage of atomic clocks is that the frequency-determining elements, atoms of a particular isotope, are the same everywhere. Thus, atomic clocks constructed and operated independently will measure the same time interval. *See* ATOMIC STRUCTURE AND SPECTRA; ENERGY LEVEL (QUANTUM MECHANICS); QUANTUM MECHANICS.

An atomic frequency standard can be either active or passive. An active standard uses as a reference the electromagnetic radiation emitted by atoms as they decay from a higher energy state to a lower energy state. A passive standard attempts to match the frequency of an electronic oscillator or laser to the resonant frequency of the atoms by means of a feedback circuit. Either kind of standard requires some kind of frequency synthesis to produce an output near a convenient frequency that is proportional to the atomic resonance frequency. *See* FEEDBACK CIRCUIT; LASER; MASER; OSCILLATOR.

Two different gages of the quality of a clock are accuracy and stability. The accuracy of a frequency standard is defined in terms of the deviation of its frequency from an ideal standard. The stability of frequency standard is defined in terms of the constancy of its average frequency from one interval of time to the next.

The three most commonly used types of atomic clock are the cesium atomic beam, the hydrogen maser, and the rubidium gas cell. The cesium clock has high accuracy and good long-term stability. The hydrogen maser has the best stability for periods of up to a few hours. The rubidium cell is the least expensive and most compact and also has good short-term stability.

The cesium atomic-beam clock uses a 9193-MHz transition between two hyperfine energy states of the cesium-133 atom. Both the atomic nucleus and the outermost electron have magnetic moments; that is, they are like small magnets, with a north and a south pole. The two hyperfine energy states differ in the relative orientations of these magnetic moments. The cesium atoms travel in a collimated beam through a series of evacuated regions, where they are exposed to microwave radiation near their resonance frequency and are deflected into different trajectories by nonuniform magnetic fields. *See* ELECTRON SPIN; HYPERFINE STRUCTURE; MAGNETIC MOMENT; MOLECULAR BEAMS; NUCLEAR MOMENTS.

Cesium has become the basis of the international definition of the second; the duration of 9,192,631,770 periods of the radiation corresponding to the transition between the two hyperfine states of the ground state of the cesium-133 atom. The cesium clock is especially well suited for applications such as timekeeping, where absolute accuracy without recalibration is necessary. Measurements from many cesium clocks throughout the world are averaged together to define an international time scale that is uniform to parts in 10^{14}, or about 1 microsecond in a year. *See* ATOMIC TIME; DYNAMICAL TIME; PHYSICAL MEASUREMENT.

The hydrogen maser is based on the hyperfine transition of atomic hydrogen, which has a frequency of 1420 MHz. Atoms in the higher hyperfine energy state enter an evacuated storage bulb inside a microwave cavity, and are induced to make a transition to the lower hyperfine state by a process called stimulated emission.

The rubidium gas cell is based on the 6835-MHz hyperfine transition of rubidium-87. The rubidium atoms are contained in a glass cell together with a buffer gas, where they are subjected to optical pumping and microwave radiation at the hyperfine transition frequency; this results in a detectable decrease in the light transmitted through the cell.

Many other kinds of atomic clocks, such as thallium atomic beams and ammonia and rubidium masers, have been demonstrated in the laboratory. The first atomic clock, constructed at the National Bureau of Standards in 1949, was based on a 24-GHz transition in the ammonia molecule. Some laboratories have tried to improve the cesium atomic-beam clock by replacing the magnetic state selection with laser optical pumping and fluorescence detection. One such standard, called NIST-7, is in operation at the U.S. National Institute of Standards and Technology and is the primary frequency standard for the United States. Atomic frequency standards can also be based on optical transitions. One of the best-developed optical frequency standards is the 3.39-micrometer (88-THz) helium-neon laser, stabilized to a transition in the methane molecule. Frequency synthesis chains have been built to link the optical frequency to radio frequencies.

Atomic clocks are used in applications for which less expensive alternatives, such as quartz oscillators, do not provide adequate performance. In addition to maintaining a uniform international time scale, atomic clocks are used to keep time in the Global Positioning System, various digital communications systems, radio astronomy, and navigation of space probes. *See* ELECTRICAL COMMUNICATIONS; RADIO ASTRONOMY; SATELLITE NAVIGATION SYSTEMS; SPACE NAVIGATION AND GUIDANCE. [W.M.I.]

Atomic mass The mass of an atom or molecule on a scale where the mass of a carbon-12 (^{12}C) atom is exactly 12.0. The mass of any atom is approximately equal to the total number of its protons and neutrons multiplied by the atomic mass unit, $u = 1.6605397 \times 10^{-24}$ gram. (Electrons are much lighter, about 0.0005486 u.) No atom differs from this simple formula by more than 1%, and stable atoms heavier than helium all lie within 0.3%. *See* ATOMIC MASS UNIT.

This simplicity of nature led to the confirmation of the atomic hypothesis—the idea that all matter is composed of atoms, which are identical and chemically indivisible for each chemical element. In 1802, G. E. Fischer noticed that the weights of acids needed to neutralize various bases could be described systematically by assigning relative weights to each of the acids and bases. A few years later, John Dalton proposed an atomic theory in which elements were made up of atoms that combine in simple ways to form molecules.

In reality, nature is more complicated, and the great regularity of atomic masses more revealing. Two fundamental ideas about atomic structure come out of this regularity: that the atomic nucleus is composed of charged protons and uncharged neutrons, and that these particles have approximately equal mass. The number of protons in an atom is called its atomic number, and equals the number of electrons in the neutral atom. The electrons, in turn, determine the chemical properties of the atom. Adding a neutron or two does not change the chemistry (or the name) of an atom, but does give it an atomic mass which is 1 u larger for each added neutron. Such atoms are called isotopes of the element, and their existence was first revealed by careful study of radioactive elements. Most naturally occurring elements are mixtures of isotopes, although a single isotope frequently predominates. Since the proportion of the various isotopes is usually about the same everywhere on Earth, an average atomic mass of an element can be defined, and is called the atomic weight. Atomic weights are routinely used in chemistry in order to determine how much of one chemical will react with a given weight of another. *See* Isotope; Relative atomic mass.

In contrast to atomic weights, which can be defined only approximately, atomic masses are exact constants of nature. All atoms of a given isotope are truly identical; they cannot be distinguished by any method. This is known to be true because the quantum mechanics treats identical objects in special ways, and makes predictions that depend on this assumption. One such prediction, the exclusion principle, is the reason that the chemical behavior of atoms with different numbers of electrons is so different. *See* Quantum mechanics. [F.L.P.; D.E.P.]

Atomic mass unit An arbitrarily defined unit in terms of which the masses of individual atoms are expressed. One atomic mass unit is defined as exactly $^1/_{12}$ of the mass of an atom of the nuclide ^{12}C, the predominant isotope of carbon. The unit, also known as the dalton, is often abbreviated amu, and is designated by the symbol u. The relative atomic mass of a chemical element is the average mass of its atoms expressed in atomic mass units. *See* Relative atomic mass. [J.F.We.]

Atomic nucleus The central region of an atom. Atoms are composed of negatively charged electrons, positively charged protons, and electrically neutral neutrons. The protons and neutrons (collectively known as nucleons) are located in a small central region known as the nucleus. The electrons move in orbits which are large in comparison with the dimensions of the nucleus itself. Protons and neutrons possess approximately equal masses, each roughly 1840 times that of an electron. The number of nucleons in a nucleus is given by the mass number A and the number of protons by the atomic number Z. Nuclear radii r are given approximately by $r = 1.2 \times 10^{-15}\ \text{m}\ A^{1/3}$. [H.E.D.]

Atomic number The number of elementary positive charges (protons) contained within the nucleus of an atom. It is denoted by the letter Z. Correspondingly, it is also the number of planetary electrons in the neutral atom.

The concept of atomic number emerged from the work of G. Moseley, done in 1913–1914. He measured the wavelengths of the most energetic rays (K and L lines) produced by using the elements calcium to zinc as targets in an x-ray tube. The square root of the frequency, ν, of these x-rays increased by a constant amount in passing from one target to the next. These data, when extended, gave a linear plot of atomic number versus ν for all elements studied, using 13 as the atomic number for aluminum and 79 for that of gold. *See* X-ray spectrometry.

Moseley's atomic numbers were quickly recognized as providing an accurate sequence of the elements, which the chemical atomic weights had sometimes failed to do. Additionally, the atomic number sequence indicated the positions of elements that had not yet been discovered.

The atomic number not only identifies the chemical properties of an element but facilitates the description of other aspects of atoms and nuclei. Thus, atoms with the same atomic number are isotopes and belong to the same element, while nuclear reactions may alter the atomic number. *See* Isotope; Radioactivity.

When specifically written, the atomic number is placed as a subscript preceding the symbol of the element, while the mass number (A) precedes as a superscript, for example, $^{27}_{13}\text{Al}$, $^{238}_{92}\text{U}$. *See* Element (chemistry); Mass number. [H.E.D.]

Atomic physics The study of the structure of the atom, its dynamical properties, including energy states, and its interactions with particles and fields. These are almost completely determined by the laws of quantum mechanics, with very refined corrections required by quantum electrodynamics. Despite the enormous complexity of most atomic systems, in which each electron interacts with both the nucleus and all the other orbiting electrons, the wavelike nature of particles, combined with the Pauli exclusion principle, results in an amazingly orderly array of atomic properties. These are systematized by the Mendeleev periodic table. In addition to their classification by chemical activity and atomic weight, the various elements of this table are characterized by a wide variety of observable properties. These include electron affinity, polarizability, angular momentum, multiple electric moments, and magnetism. *See* Periodic table; Quantum electrodynamics; Quantum mechanics.

Each atomic element, normally found in its ground state (that is, with its electron configuration corresponding to the lowest state of total energy), can also exist in an infinite number of excited states. These are also ordered in accordance with relatively simple hierarchies determined by the laws of quantum mechanics. The most characteristic signature of these various excited states is the radiation emitted or absorbed when the atom undergoes a transition from one state to another. The systemization and classification of atomic energy levels (spectroscopy) has played a central role in developing an understanding of atomic structure. [B.B.]

Atomic spectrometry A branch of chemical analysis that seeks to determine the composition of a sample in terms of which chemical elements are present and their quantities or concentrations. Unlike other methods of elemental analysis, however, the sample is decomposed into its constituent atoms which are then probed spectroscopically.

In routine atomic spectrometry, a device called the atom source or atom cell is responsible for producing atoms from the sample; there are many different kinds of atom sources. After atomization of the sample, any of several techniques can determine which atoms are present and in what amounts, but the most common are atomic absorption, atomic emission, atomic fluorescence (the least used of these four alternatives), and mass spectrometry.

Most atomic spectrometric measurements (all those just mentioned except mass spectrometry) exploit the narrow-line spectra characteristic of gas-phase atoms. Because the atom source yields atomic species in the vapor phase, chemical bonds are disrupted, so valence electronic transitions are unperturbed by bonding effects. As a result, transitions among atomic energy levels yield narrow spectral lines, with spectral bandwidths commonly in the 1–5-picometer wavelength range. Moreover, because each atom possesses its unique set of energy levels, these narrow-band transitions can be measured individually, with little mutual interference. Thus, sodium, potassium, and scandium can all be monitored simultaneously and with minimal spectral influence on each other. This lack of spectral overlap remains one of the most attractive features of atomic spectrometry. *See* ATOMIC STRUCTURE AND SPECTRA; LINE SPECTRUM; SPECTRUM.

In atomic absorption spectrometry, light from a primary source is directed through the atom cell, where a fraction of the light is absorbed by atoms from the sample. The amount of radiation that remains can then be monitored on the far side of the cell. The concentration of atoms in the path of the light beam can be determined by Beer's law, which can be expressed as the equation below, where P_0 is the light intensity incident on the

$$\log \frac{P_0}{P} = kC$$

atom cell, P is the amount of light which remains unabsorbed, C is the concentration of atoms in the cell, and k is the calibration constant, which is determined by means of standard samples having known concentrations.

The two most common kinds of atom cells employed in atomic absorption spectrometry are chemical flames and electrical furnaces. Chemical flames are usually simple to use, but furnaces offer higher sensitivity.

The most common primary light source employed in atomic absorption spectrometry is the hollow-cathode lamp. Conveniently, the hollow-cathode lamp emits an extremely narrow line spectrum of one, two, or three elements of interest. As a result, the atomic absorption spectrometry measurement is automatically tuned to the particular spectral lines of interest.

In atomic emission spectrometry, atomic species are measured by their emission spectra. For such spectra to be produced, the atoms must first be excited by thermal or nonthermal means. Therefore, the atom sources employed in atomic emission spectrometry are hotter or more energetic than those commonly used in atomic absorption spectrometry. Although several such sources are in common use, the dominant one is the inductively coupled plasma. From the simplest standpoint, the inductively coupled plasma is a flowing stream of hot, partially ionized (positively charged) argon. Power is coupled into the plasma by means of an induction coil.

There are two common modes for observing emission spectra from an inductively coupled plasma. The less expensive and more flexible approach employs a so-called slew-scan spectrometer, which accesses spectral lines in rapid sequence, so that a number of chemical elements can be measured rapidly, one after the other. Moreover, because each viewed elemental spectral line can be scanned completely, it is possible to subtract spectral emission background independently for each element. The alternative approach is to view all spectral lines simultaneously, either with a number of individual photo-detectors keyed to particular spectral lines or with a truly multichannel electronic detector driven by a computer. This approach enables samples to be analyzed more rapidly and permits transient atom signals (as from a furnace-based atomizer) to be recorded. *See* EMISSION SPECTROCHEMICAL ANALYSIS.

Elemental mass spectrometry has been practiced for many years in the form of spark-source mass spectrometry and, more recently, glow-discharge-lamp mass spectrometry. However, a hybrid technique that combines the inductively coupled plasma with a mass spectrometer has assumed a prominent place.

At the high temperatures present in an inductively coupled plasma, many atomic species occur in an ionic form. These ions can be readily extracted into a mass spectrometer.

The advantages of the combination of inductively coupled plasma and mass spectrometry are substantial. The system is capable of some of the best detection limits in atomic spectrometry, typically 10^{-3} to 10^{-2} ng/ml for most elements. Also, virtually all elements in the periodic table can be determined during a single scan. The method is also capable of providing isotopic information, unavailable by any other atomic spectrometric method for such a broad range of elements. *See* MASS SPECTROMETRY.

[G.M.H.]

Atomic structure and spectra

The idea that matter is subdivided into discrete building blocks called atoms, which are not divisible any further, dates back to the Greek philosopher Democritus. His teachings of the fifth century B.C. are commonly accepted as the earliest authenticated ones concerning what has come to be called atomism by students of Greek philosophy. The weaving of the philosophical thread of atomism into the analytical fabric of physics began in the late eighteenth and the nineteenth centuries. Robert Boyle is generally credited with introducing the concept of chemical elements, the irreducible units of which are now recognized as individual atoms of a given element. In the early nineteenth century John Dalton developed his atomic theory, which postulated that matter consists of indivisible atoms as the irreducible units of Boyle's elements, that each atom of a given element has identical attributes, that differences among elements are due to fundamental differences among their constituent atoms, that chemical reactions proceed by simple rearrangement of indestructible atoms, and that chemical compounds consist of molecules which are reasonably stable aggregates of such indestructible atoms. *See* CHEMISTRY.

Electromagnetic nature of atoms. The work of J. J. Thomson in 1897 clearly demonstrated that atoms are electromagnetically constituted and that from them can be extracted fundamental material units bearing electric charge that are now called electrons. The electrons of an atom account for a negligible fraction of its mass. By virtue of overall electrical neutrality of every atom, the mass must therefore reside in a compensating, positively charged atomic component of equal charge magnitude but vastly greater mass. *See* ELECTRON.

Thomson's work was followed by the demonstration by Ernest Rutherford in 1911 that nearly all the mass and all of the positive electric charge of an atom are concentrated in a small nuclear core approximately 10,000 times smaller in extent than an atomic diameter. Niels Bohr in 1913 and others carried out some remarkably successful attempts to build solar system models of atoms containing planetary pointlike electrons orbiting around a positive core through mutual electrical attraction (though only certain "quantized" orbits were "permitted"). These models were ultimately superseded by nonparticulate, matter-wave quantum theories of both electrons and atomic nuclei. *See* NONRELATIVISTIC QUANTUM THEORY; QUANTUM MECHANICS.

The modern picture of condensed matter (such as solid crystals) consists of an aggregate of atoms or molecules which respond to each other's proximity through attractive electrical interactions at separation distances of the order of 1 atomic diameter (approximately 10^{-10} m) and repulsive electrical interactions at much smaller distances. These interactions are mediated by the electrons, which are in some sense shared and exchanged by all atoms of a particular sample, and serve as an interatomic glue that binds the mutually repulsive, heavy, positively charged atomic cores together. *See* SOLID-STATE PHYSICS.

Bohr atom. The hydrogen atom is the simplest atom, and its spectrum (or pattern of light frequencies emitted) is also the simplest. The regularity of its spectrum had defied explanation until Bohr solved it with three postulates, these representing a model which is useful, but quite insufficient, for understanding the atom.

Postulate 1: The force that holds the electron to the nucleus is the Coulomb force between electrically charged bodies.

Postulate 2: Only certain stable, nonradiating orbits for the electron's motion are possible, those for which the angular momentum associated with the motion of an electron in its orbit is an integral multiple of $h/2\pi$ (Bohr's quantum condition on the orbital angular momentum). Each stable orbit represents a discrete energy state.

Postulate 3: Emission or absorption of light occurs when the electron makes a transition from one stable orbit to another, and the frequency ν of the light is such that the difference in the orbital energies equals $h\nu$ (A. Einstein's frequency condition for the photon, the quantum of light).

Here the concept of angular momentum, a continuous measure of rotational motion in classical physics, has been asserted to have a discrete quantum behavior, so that its quantized size is related to Planck's constant h, a universal constant of nature. Velocity v, in rotational motion about a central body, is defined as the product of the component.

Modern quantum mechanics has provided justification of Bohr's quantum condition on the orbital angular momentum. It has also shown that the concept of definite orbits cannot be retained except in the limiting case of very large orbits. In this limit, the frequency, intensity, and polarization can be accurately calculated by applying the classical laws of electrodynamics to the radiation from the orbiting electron. This fact illustrates Bohr's correspondence principle, according to which the quantum results must agree with the classical ones for large dimensions. The deviation from classical theory that occurs when the orbits are smaller than the limiting case is such that one may no longer picture an accurately defined orbit. Bohr's other hypotheses are still valid.

According to Bohr's theory, the energies of the hydrogen atom are quantized (that is, can take on only certain discrete values). These energies can be calculated from the electron orbits permitted by the quantized orbital angular momentum. The orbit may be circular or elliptical, so only the circular orbit is considered here for simplicity. Let the electron, of mass m and electric charge $-e$, describe a circular orbit of radius r around a nucleus of charge $+e$ and of infinite mass. With the electron velocity v, the angular momentum is mvr, and the second postulate becomes Eq. (1). The integer n is called the principal quantum number.

$$mvr = n\,(h/2\pi) \qquad (n = 1, 2, 3, \ldots) \tag{1}$$

The possible energies of the nonradiating states of the atom are given by Eq. (2). Here ε_0 is the permittivity of free space, a con-

$$E = -\frac{me^4}{8\epsilon_0^2 h^2}\cdot\frac{1}{n^2} \tag{2}$$

stant included in order to give the correct units to the statement of Coulomb's law in SI units.

The same equation for the hydrogen atom's energy levels, except for some small but significant corrections, is obtained from the solution of the Schrödinger equation, as modified by W. Pauli, for the hydrogen atom. *See* QUANTUM NUMBERS.

The frequencies of electromagnetic radiation or light emitted or absorbed in transitions are given by Eq. (3), where E' and E''

$$\nu = \frac{E' - E''}{h} \tag{3}$$

are the energies of the initial and final states of the atom. Spectroscopists usually express their measurements in wavelength λ or in wave number σ in order to obtain numbers of a convenient size. The wave number of a transition is shown in Eq. (4).

$$\sigma = \frac{\nu}{c} = \frac{E'}{hc} - \frac{E''}{hc} \tag{4}$$

If $T = E/(hc)$, then Eq. (5) results. Here T is called the spectral term.

$$\sigma = T'' - T' \tag{5}$$

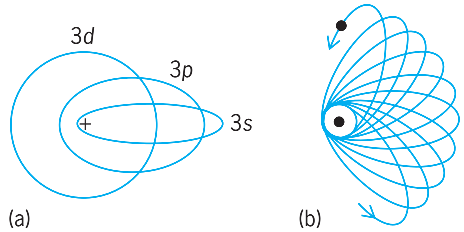
The allowed terms for hydrogen, from Eq. (2), are given by Eq. (6). The quantity R is the important Rydberg constant. Its

$$T = \frac{me^4}{8\epsilon_0^2 ch^3}\cdot\frac{1}{n^2} = \frac{R}{n^2} \tag{6}$$

value, which has been measured to a remarkable and rapidly improving accuracy, is related to the values of other well-known atomic constants, as in Eq. (6). *See* RYDBERG CONSTANT.

The effect of finite nuclear mass must be considered, since the nucleus does not actually remain at rest at the center of the atom. Instead, the electron and nucleus revolve about their common center of mass. This effect can be accurately accounted for and requires a small change in the value of the effective mass m in Eq. (6).

In addition to the circular orbits already described, elliptical ones are also consistent with the requirement that the angular momentum be quantized. A. Sommerfeld showed that for each value of n there is a family of n permitted elliptical orbits, all having the same major axis but with different eccentricities. Illustration *a* shows, for example, the Bohr-Sommerfeld orbits for $n = 3$. The orbits are labeled *s*, *p*, and *d*, indicating values of the azimuthal quantum number $l = 0$, 1, and 2. This number determines the shape of the orbit, since the ratio of the major to the minor axis is found to be $n/(l = 1)$. To a first approximation, the energies of all orbits of the same n are equal. In the case of the highly eccentric orbits, however, there is a slight lowering of the energy due to precession of the orbit (illus. *b*). According to Einstein's theory of relativity, the mass increases somewhat in the inner part of the orbit, because of greater velocity. The velocity increase is greater as the eccentricity is greater, so the orbits of higher eccentricity have their energies lowered more. The quantity l is called the orbital angular momentum quantum number or the azimuthal quantum number. *See* RELATIVITY.



Possible elliptical orbits, according to the Bohr- Sommerfeld theory. (*a*) The three permitted orbits for $n = 3$. (*b*) Precession of the 3*s* orbit caused by the relativistic variation of mass. (*After A. P. Arya*, *Fundamentals of Atomic Physics*, *Allyn and Bacon*, *1971*)

Multielectron atoms. In attempting to extend Bohr's model to atoms with more than one electron, it is logical to compare the experimentally observed terms of the alkali atoms, which contain only a single electron outside closed shells, with those of hydrogen. A definite similarity is found but with the striking difference that all terms with $l > 0$ are double. This fact was interpreted by S. A. Goudsmit and G. E. Uhlenbeck as due to the presence of an additional angular momentum of $\frac{1}{2}(h/2\pi)$ attributed to the electron spinning about its axis. The spin quantum number of the electron is $s = \frac{1}{2}$.

The relativistic quantum mechanics developed by P. A. M. Dirac provided the theoretical basis for this experimental observation. *See* ELECTRON SPIN.

Implicit in much of the following discussion is W. Pauli's exclusion principle, first enunciated in 1925, which when applied to atoms may be stated as follows: no more than one electron in a multielectron atom can possess precisely the same quantum numbers. In an independent, hydrogenic electron approximation to multielectron atoms, there are $2n^2$ possible independent choices of the principal (n), orbital (l), and magnetic (m_l, m_s) quantum numbers available for electrons belonging to a given n, and no more. Here m_l and m_s refer to the quantized projections of l and s along some chosen direction. The organization of atomic electrons into shells of increasing radius (the Bohr radius scales as n^2) follows from this principle. *See* EXCLUSION PRINCIPLE.

The energy of interaction of the electron's spin with its orbital angular momentum is known as spin-orbit coupling. A charge in motion through either "pure" electric or "pure" magnetic fields, that is, through fields perceived as "pure" in a static laboratory, actually experiences a combination of electric and magnetic fields, if viewed in the frame of reference of a moving observer with respect to whom the charge is momentarily at rest. For example, moving charges are well known to be deflected by magnetic fields. But in the rest frame of such a charge, there is no motion, and any acceleration of a charge must be due to the presence of a pure electric field from the point of view of an observer analyzing the motion in that reference frame. *See* RELATIVISTIC ELECTRODYNAMICS.

A spinning electron can crudely be pictured as a spinning ball of charge, imitating a circulating electric current. This circulating current gives rise to a magnetic field distribution very similar to that of a small bar magnet, with north and south magnetic poles symmetrically distributed along the spin axis above and below the spin equator. This representative bar magnet can interact with external magnetic fields, one source of which is the magnetic field experienced by an electron in its rest frame, owing to its orbital motion through the electric field established by the central nucleus of an atom. In multielectron atoms, there can be additional, though generally weaker, interactions arising from the magnetic interactions of each electron with its neighbors, as all are moving with respect to each other and all have spin. The strength of the bar magnet equivalent to each electron spin, and its direction in space are characterized by a quantity called the magnetic moment, which also is quantized essentially because the spin itself is quantized. Studies of the effect of an external magnetic field on the states of atoms show that the magnetic moment associated with the electron spin is equal in magnitude to a unit called the Bohr magneton.

The energy of the interaction between the electron's magnetic moment and the magnetic field generated by its orbital motion is usually a small correction to the spectral term, and depends on the angle between the magnetic moment and the magnetic field or, equivalently, between the spin angular momentum vector and the orbital angular momentum vector (a vector perpendicular to the orbital plane whose magnitude is the size of the orbital angular momentum). Since quantum theory requires that the quantum number j of the electron's total angular momentum shall take values differing by integers, while l is always an integer, there are only two possible orientations for s relative to l: s must be either parallel or antiparallel to l.

For the case of a single electron outside the nucleus, the Dirac theory gives Eq. (7) for the spin-orbit correction to the spectral

$$\Delta T = \frac{R\alpha^2 Z^4}{n^3} \times \frac{j(j+1) - l(l+1) - s(s+1)}{l(2l+1)(l+1)} \tag{7}$$

terms. Here $\alpha = e^2/(2\epsilon_0 hc) \cong 1/137$ is called the fine structure constant.

In atoms having more than one electron, this fine structure becomes what is called the multiplet structure. The doublets in the alkali spectra, for example, are due to spin-orbit coupling; Eq. (7), with suitable modifications, can still be applied.

When more than one electron is present in the atom, there are various ways in which the spins and orbital angular momenta can interact. Each spin may couple to its own orbit, as in the one-electron case; other possibilities are orbit-other orbit, spin-spin, and so on. The most common interaction in the light atoms, called *LS* coupling or Russell-Saunders coupling, is described schematically in Eq. (8). This notation indicates that the l are

$$\{(l_1, l_2, l_3, \ldots)(s_1, s_2, s_3, \ldots)\} = \{L, S\} = J \tag{8}$$

coupled strongly together to form a resultant L, representing the total orbital angular momentum. The s_i are coupled strongly together to form a resultant S, the total spin angular momentum. The weakest coupling is that between L and S to form J, the total angular momentum of the electron system of the atom in this state.

Coupling of the *LS* type is generally applicable to the low-energy states of the lighter atoms. The next commonest type is called *jj* coupling, represented in Eq. (9). Each electron has its

$$\{(l_1, s_1)(l_2, s_2)(l_3, s_3)\ldots\} = \{j_1, j_2, j_3, \ldots\} = J \tag{9}$$

spin coupled to its own orbital angular momentum to form a j_i for that electron. The various j_i are then more weakly coupled together to give J. This type of coupling is seldom strictly observed. In the heavier atoms it is common to find a condition intermediate between *LS* and *jj* coupling; then either the *LS* or *jj* notation may be used to describe the levels, because the number of levels for a given electron configuration is independent of the coupling scheme.

Nuclear magnetism and hyperfine structure. Most atomic nuclei also possess spin, but rotate about 2000 times slower than electrons because their mass is on the order of 2000 or more times greater than that of electrons. Because of this, very weak nuclear magnetic fields, analogous to the electronic ones that produce fine structure in spectral lines, further split atomic energy levels. Consequently, spectral lines arising from them are split according to the relative orientations, and hence energies of interaction, of the nuclear magnetic moments with the electronic ones. The resulting pattern of energy levels and corresponding spectral-line components is referred to as hyperfine structure. *See* NUCLEAR MOMENTS.

Nuclear properties also affect atomic spectra through the isotope shift. This is the result of the difference in nuclear masses of two isotopes, which results in a slight change in the Rydberg constant. There is also sometimes a distortion of the nucleus, which can be detected by ultrahigh precision spectroscopy. *See* MOLECULAR BEAMS; PARTICLE TRAP.

Doppler spread. In most cases, a common problem called Doppler broadening of the spectral lines arises, which can cause overlapping of spectral lines and make analysis difficult. The broadening arises from motion of the emitted atom with respect to a spectrometer. Several ingenious ways of isolating only those atoms nearly at rest with respect to spectrometric apparatus have been devised. The most powerful employ lasers and either involve saturation spectroscopy, utilizing a saturating beam and probe beam from the same tunable laser, or use two laser photons which jointly drive a single atomic transition and are generated in lasers so arranged that the first-order Doppler shifts of the photons cancel each other. *See* DOPPLER EFFECT.

Radiationless transitions. It would be misleading to think that the most probable fate of excited atomic electrons consists of transitions to lower orbits, accompanied by photon emission. In fact, for at least the first third of the periodic table, the preferred decay mode of most excited atomic systems in most states of excitation and ionization is the electron emission process first observed by P. Auger in 1925 and named after him. For example, a singly charged neon ion lacking a 1*s* electron is more than 50 times as likely to decay by electron emission as by photon emission. In the process, an outer atomic electron descends to fill an inner vacancy, while another is ejected from the atom to conserve both total energy and momentum in the atom. The ejection usually arises because of the interelectron Coulomb repulsion. *See* AUGER EFFECT.

Cooling and stopping atoms and ions. Despite impressive progress in reducing Doppler shifts and Doppler spreads, these quantities remain factors that limit the highest obtainable spectroscopic resolutions. The 1980s and 1990s saw extremely rapid development of techniques for trapping neutral atoms and singly charged ions in a confined region of space, and then cooling them to much lower temperatures by the application of laser-light cooling techniques. Photons carry not only energy but also momentum; hence they can exert pressure on neutral atoms as well as charged ions. *See* LASER COOLING.

Schemes have been developed to exploit these light forces to confine neutral atoms in the absence of material walls, whereas various types of so-called bottle configurations of electromagnetic fields developed earlier remain the technique of choice for similarly confining ions. Various ingenious methods have been invented to slow down and even nearly stop neutral atoms and singly charged ions, whose energy levels (unlike those of most more highly charged ions) are accessible to tunable dye lasers. These methods often utilize the velocity-dependent light pressure from laser photons of nearly the same frequency as, but slightly less energetic than, the energy separation of two atomic energy levels to induce a transition between these levels.

The magnetooptic trap combines optical forces provided by laser light with a weak magnetic field whose size goes through zero at the geometrical center of the trap and increases with distance from this center. The net result is a restoring force which confines sufficiently laser-cooled atoms near the center. Ingenious improvements have allowed cooling of ions to temperatures as low as 180×10^{-9} K.

For more highly ionized ions, annular storage rings are used in which radial confinement of fast ion beams (with speeds of approximately 10% or more of the speed of light) is provided by magnetic focusing. Two cooling schemes are known to work on stored beams of charged particles, the so-called stochastic cooling method and the electron cooling method. In the former, deviations from mean stored particle energies are electronically detected, and electronic "kicks" that have been adjusted in time and direction are delivered to the stored particles to compensate these deviations. In electron cooling, which proves to be more effective for stored heavy ions of high charge, electron beams prepared with a narrow velocity distribution are merged with the stored ion beams. When the average speeds of the electrons and the ions are matched, the Coulomb interaction between the relatively cold (low-velocity-spread) electrons and the highly charged ions efficiently transfers energy from the warmer ions, thereby reducing the temperature of the stored ions. [I.A.S.]

Atomic theory The study of the structure and properties of atoms based on quantum mechanics and the Schrödinger equation. These tools make it possible, in principle, to predict most properties of atomic systems. A stationary state of an atom is governed by a time-independent wave function which depends on the position coordinates of all the particles within the atom. To obtain the wave function, the time-independent Schrödinger equation, a second-order differential equation, has to be solved. The potential energy term in this equation contains the Coulomb interaction between all the particles in the atom, and in this way they are all coupled to each other. *See* DIFFERENTIAL EQUATION; NONRELATIVISTIC QUANTUM THEORY; QUANTUM MECHANICS.

A many-particle system where the behavior of each particle at every instant depends on the positions of all the other particles cannot be solved directly. This is not a problem restricted to quantum mechanics. A classical system where the same problem arises is a solar system with several planets. In classical mechanics as well as in quantum mechanics, such a system has to be treated by approximate methods. *See* CELESTIAL MECHANICS.

Independent particle model. As a first approximation, it is customary to simplify the interaction between the particles. In the independent particle model the electrons are assumed to move independently of each other in the average field generated by the nucleus and the other electrons. In this case the potential energy operator will be a sum over one-particle operators. The simplest wave function which will satisfy the resulting equation is a product of one-particle orbitals. To fulfill the Pauli exclusion principle, the total wave function must, however, be written in a form such that it will vanish if two particles are occupying the same quantum state. This is achieved with an antisymmetrized wave function, that is, a function which, if two electrons are interchanged, changes sign but in all other respects remains unaltered. The antisymmetrized product wave function is usually called a Slater determinant. *See* EXCLUSION PRINCIPLE.

Hartree-Fock method. In the late 1920s, only a few years after the discovery of the Schrödinger equation, D. Hartree showed that the wave function to a good approximation could be written as a product of orbitals, and also developed a method to calculate the orbitals. Important contributions to the method were also made by V. Fock and J. C. Slater (thus, the Hartree-Fock method). The Hartree-Fock model thus gives the lowest-energy ground state within the assumption that the electrons move independently of each other in an average field from the nucleus and the other electrons.

To simplify the problem even further, it is common to add the requirement that the Hartree-Fock potential should be spherically symmetric. This leads to the central-field model and the so-called restricted Hartree-Fock method.

The Hartree-Fock method gives a qualitative understanding of many atomic properties. Generally it is, for example, able to predict the configurations occupied in the ground states of the elements. Electron binding energies are also given with reasonable accuracy.

Electron correlation. Correlation is commonly defined as the difference between the full many-body problem and the Hartree-Fock model. More specifically, the correlation energy is the difference between the experimental energy and the Hartree-Fock energy. There are several methods developed to account for electron correlation, including the configuration-interaction method, the multi* figuration Hartree-Fock method, and perturation theory.

Strongly correlated systems. Although the Hartree-Fock model can qualitatively explain many atomic properties, there are systems and properties for which correlation is more important, such as negative ions, doubly-excited states, and some open-shell systems. If the interest is not in calculating the total energy of a state but in understanding some other properties, such as the hyperfine structure, effects beyond the central field model can be more important. *See* HYPERFINE STRUCTURE; NEGATIVE ION.

Relativistic effects. The Schrödinger equation is a nonrelativistic wave equation. In heavy elements the kinetic energy of the electrons becomes very large, and calculations are based on the relativistic counterpart to the Schrödinger equation, the Dirac equation. It is possible to construct a Hartree-Fock model based on the Dirac equation, where the electron-electron interaction is given by the Coulomb interaction, a magnetic contribution, and a term which corrects for the finite speed (retardation) with which the interaction propagates. *See* ANTIMATTER; RELATIVISTIC QUANTUM THEORY.

Radiative corrections. Radiative corrections, which arise when the electromagnetic field is quantized within the theory of quantum electrodynamics, For many-body systems, calculations of radiative effects are usually done within some independent-particle model, and the result is added to a correlated relativistic calculation based on the Dirac equation. *See* QUANTUM ELECTRODYNAMICS; ATOMIC STRUCTURE AND SPECTRA. [Eva Li.]

Atomic time Time based on the frequency determined by the energy of quantum transitions. Atomic time is obtained from the continuous operation of atomic clocks since mid-1955. The only relativistic correction to atomic time is for gravitational potential (related to height above sea level). *See* ATOMIC CLOCK.

An atom which drops from an energy level, E_2, to a lower one, E_1, emits radiation of frequency $f = (E_1 - E_2)/h$, where h is Planck's constant. The second in the International System of Units (SI) was defined in 1967 as the duration of 9,192,631,770 cycles of the radiation from a selected transition of cesium-133. *See* ATOMIC STRUCTURE AND SPECTRA; QUANTUM MECHANICS.

International Atomic Time (TAI) is generated by the International Bureau of Weights and Measures (BIPM) in Sèvres, France. It is based on approximately 200 commercial atomic clocks and up to 8 laboratory-built, cesium primary-frequency standards at approximately 44 laboratories around the world. The clock data are collected through use of the Global Positioning System (GPS) with a process called common-view time transfer. The primary physical frequency standards, with accuracy as good as 2.2 parts in 10^{15}, provide the accuracy and long-term stability of TAI, which reproduces the SI second to better than 1 part in 10^{14}. The highest-accuracy standards now use laser-cooled atoms. The function of the commercial clocks is to provide redundancy and short-term stability. *See* ATOMIC CLOCK; SATELLITE NAVIGATION SYSTEMS.

TAI is a highly precise atomic time used, for example, in determining variations in the Earth's speed of rotation, computing orbits, and tracking celestial objects, including spacecraft. TAI provides not only the SI unit of time but also the unit of length, the meter, now defined as the distance that light travels in 1/299,792,458 of a second in vacuum. *See* PHYSICAL MEASUREMENT. [T.E.P.; M.We.]

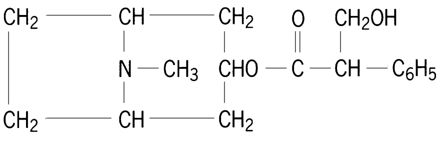
Atomization The process whereby a bulk liquid is transformed into a multiplicity of small drops. This transformation, often called primary atomization, proceeds through the formation of disturbances on the surface of the bulk liquid, followed by their amplification due to energy and momentum transfer from the surrounding gas.

Spray formation processes are critical to the performance of a number of technologies and applications. These include combustion systems (gas turbine engines, internal combustion engines, incinerators, furnaces, rocket motors), agriculture (pesticide and fertilizer treatments), paints and coatings (furniture, automobiles), consumer products (cleaners, personal care products), fire suppression systems, spray cooling (materials processing, computer chip cooling), medicinal (pharmaceutical), and spray drying (foods, drugs, materials processing). Current concerns include how to make smaller drops (especially for internal combustion engines), how to make larger drops (agricultural sprays), how to reduce the number of largest and smallest drops (paints and coatings, consumer products, medicinals, spray drying), how to distribute the liquid mass more uniformly throughout the spray, and how to increase the fraction of liquid that impacts a target (paints and coatings, spray cooling, fire suppression).

Spray devices (that is, atomizers) are often characterized by how disturbances form. The most general distinction is between systems where one or two fluids flow through the atomizer. The most common types of single-fluid atomizers are pressure (also called plain-orifice, hydraulic, or pneumatic), pressure-swirl, rotary, ultrasonic (sometimes termed whistle or acoustic), and electrostatic. Twin-fluid atomizers include internal-mix and external-mix versions, where these terms describe the location where atomizing fluid (almost always a gas) first contacts fluid to be sprayed (almost always a liquid).

While primary atomization is important, because of its role in determining mean drop size and the spectrum of drop sizes, subsequent processes also play key roles in spray behavior. They include further drop breakup (termed secondary atomization), drop transport to and impact on a target, drop evaporation (and perhaps combustion), plus drop collisions and coalescence. In addition, the spray interacts with its surroundings, being modified by the adjacent gas flow and modifying it in turn. *See* AEROSOL; PARTICULATES. [P.E.So.]

Atropine An alkaloid, $C_{17}H_{23}NO_3$, with the chemical structure below. The systematic chemical name is endo-(±)-α-(hydroxymethyl)phenylacetic acid 8-methyl-8-azabicyclo[3.2.1] oct-3-yl ester, and in phamacy it is sometimes known as *dl*-hyoscyamine. It occurs in minute amounts in the leaves of *Atropa belladonna, A. betica, Datura stramonium, D. innoxia,* and *D. sanguinea*, as well as many related plants. It is chiefly manufactured by racemization of *l*-hyoscyamine, which is isolated from the leaves and stems of the henbane, *Hyoscyamus niger*. It melts at 114–116°C (237–241°F) and is poorly soluble in water. The nitrate and sulfate are used in medicine instead of the free base.



Atropine is used clinically as a mydriatic (pupil dilator). Dilation is produced by paralyzing the iris and ciliary muscles. Atropine is also administered in small doses before general anesthesia to lessen oral and air-passage secretions. Its ability to reduce these secretions is also utilized in several preparations commonly used for symptomatic relief of colds. *See* ALKALOID. [F.W.]

Attention deficit hyperactivity disorder A common psychiatric disorder of childhood characterized by attentional difficulties, impulsivity, and hyperactivity; known earlier as attention deficit disorder. Other older names for this disorder include minimal brain dysfunction, minimal brain damage, hyperactivity, hyperkinesis, and hyperactive child syndrome. Over time, these names were modified due to their implications about etiology and core symptoms: minimal brain dysfunction seemed to imply that children with this disorder were brain-damaged, while hyperactivity and its synonyms named a feature seen in many but not all of these children.

The three defining symptoms of attention deficit disorder are as follows:

(1) *Attentional deficits.* The child is described as having a short attention span. The child often fails to finish things he or she starts, does not seem to listen, and is easily distracted or disorganized. In more severe instances the child is unable to focus attention on anything, while in less severe cases attention can be focused on things of interest to the child.

(2) *Impulsivity.* The child is often described as acting before thinking, shifting excessively and rapidly from one activity to another, or having difficulty waiting for a turn in games or group activities.

(3) *Hyperactivity.* Many children with this disorder are hyperactive—and indeed, may have been noted to be so prior to birth. They may fidget, wiggle, move excessively, and have difficulty keeping still. This excessive activity is not noticeable when the children are playing; however, in the classroom or other quiet settings, the child cannot decrease his or her activity appropriately. Some affected children are active at a normal level or even sluggish. On the basis of the predominating symptoms, children with attention deficit hyperactivity disorder are subcategorized as having hyperactive symptoms (hyperactive type), lacking hyperactivity (inattentive type), and having both inattention and hyperactivity or impulsivity (combined type).

Many children with attention deficit hyperactivity disorder frequently show an altered response to socialization. They are often described by their parents as obstinate, impervious, stubborn, or negativistic. With peers, many affected children are domineering or bullying, and thus may prefer to play with younger children. Another characteristic often seen in children with the disorder is emotional lability. Their moods change frequently and easily, sometimes spontaneously, and sometimes reactively. Because of their behavioral difficulties, children with the disorder often have conflicts with parents, teachers, and peers. Commonly, difficulties in discipline and inadequacies in schoolwork lead to reproof and criticism. As a consequence, children with the disorder usually also have low self-esteem. Attention deficit hyperactivity disorder is frequently associated with other disorders, including disruptive behavior disorders, internalizing (mood and anxiety) disorders, and developmental disorders. *See* AFFECTIVE DISORDERS.

Formerly believed to be largely caused by brain damage, and more recently believed by some to be caused by food allergy, attention deficit hyperactivity disorder is now considered to be mainly hereditary. It is estimated that 3–10% of children of elementary school age (roughly 6–19 years) manifest significant symptoms of attention deficit hyperactivity disorder. About twice as many boys as girls are affected with the disorder. The girls are much less likely than the boys to be aggressive and have serious behavioral difficulties, making the girls vulnerable to underidentification and undertreatment. It was formerly believed that attention deficit hyperactivity disorder was out-grown during adolescence. Although some signs of the disorder such as excessive activity may diminish or disappear in some affected children, other signs such as attentional difficulties, impulsivity, and interpersonal problems may persist. Despite the fact that this disorder is not uncommon in adults, the lower rates of hyperactivity in adults may result in the condition being frequently overlooked.

The treatment of the child or adult with this disorder involves three steps: evaluation, explanation of the problem to parents and child, and therapeutic intervention. Evaluation requires a detailed history of the child's psychological development and current functioning. Next, because the disorder is frequently associated with learning problems in school, it is desirable to obtain an individual intelligence test as well as a test of academic achievement. Since attention deficit hyperactivity disorder is often associated with other psychiatric disorders, it is important to carefully evaluate the presence of these other conditions. If a diagnosis of attention deficit hyperactivity disorder is confirmed, the parents or family should be educated regarding the nature of the condition and other associated conditions. Medication and guidance are the mainstays of the treatment. Approximately 70–80% of the children manifest a therapeutic response to one of the major stimulant drugs, such as amphetamines and methylphenidate. When effective, these medications increase attention, decrease impulsivity, and usually make the child more receptive to parental and educational requests and demands. Hyperactivity, when present, is usually diminished as well. Although usually less effective, other medications can be helpful to individuals who cannot tolerate or do not respond to stimulants. The common mechanism of action for such medications is their impact upon the neurotransmitters dopamine and norepinephrine. [J.Bi.]

Attenuation

The reduction in level of a transmitted quantity as a function of a parameter, usually distance. It is applied mainly to acoustic or electromagnetic waves and is expressed as the ratio of power densities. Various mechanisms can give rise to attenuation. Among the most important are geometrical attenuation, absorption, and scattering.

For unconfined radiation from a point source in free space, the power density (watts per square meter) decreases in proportion to the square of the distance. The power densities, I_1 and I_2, at distances r_1 and r_2 from the source, are related by Eq. (1).

$$I_2 = I_1 \left(\frac{r_1}{r_2}\right)^2 \qquad (1)$$

See INVERSE-SQUARE LAW.

If the signal, in a parallel beam so that there is no geometrical attenuation, passes through a lossy medium, absorption reduces the power level, I, exponentially with distance, x, according to Eq. (2), where a is the attenuation coefficient.

$$I(x) = I(0)e^{-ax} \qquad (2)$$

See ABSORPTION; ABSORPTION OF ELECTROMAGNETIC RADIATION; SOUND ABSORPTION.

Scattering is said to occur if the power is not absorbed in the medium but scattered from inhomogeneities. *See* SCATTERING OF ELECTROMAGNETIC RADIATION.

More complicated situations occur with guided waves, such as acoustic waves in pipes or electromagnetic waves in transmission lines or waveguides, where absorption may take place and irregularities may cause reflection of some power. *See* TRANSMISSION LINES; WAVEGUIDE.

In electric circuits, constituent elements are often described as attenuators when they reduce the level of signals passing through them. *See* ATTENUATION (ELECTRICITY).

Attenuation is usually measured in terms of the logarithm of the power ratio, the units being the neper or the decibel. *See* DECIBEL; NEPER. [A.E.Ba.]

Attenuation (electricity)

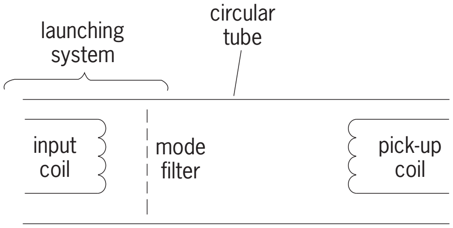
The exponential decrease with distance in the amplitude of an electrical signal traveling along a very long uniform transmission line, due to conductor and dielectric losses. If the peak voltage at the sending end of the transmission line is denoted by V_0, the peak voltage at a distance x from the sending end is given by the equation below, where α is the attenuation constant of the line.

$$V_x = V_0 e^{-\alpha x}$$

Attenuators find numerous applications, typical examples being: in a signal generator, to vary the amplitude of the output signal; and in the input line to a television receiver that is very close to a television transmitter, so that overloading can be avoided. *See* SIGNAL GENERATOR; TELEVISION RECEIVER.

Attenuators for the dc (steady voltage) to very high-frequency (VHF) range (frequencies from 0 to 300 MHz) often contain resistors arranged in T or π configurations.

Piston attenuators (sometimes called waveguide-beyond-cutoff attenuators) are used at both intermediate and microwave frequencies (see illustration). The attenuation is varied by altering the separation between the two coils. The circular tube acts as a waveguide beyond cutoff, and the launching system is designed so that only one mode is excited in it.



Piston attenuator.

A variable waveguide attenuator can be produced by moving a lossy vane either sideways across the waveguide or into the waveguide through a longitudinal slot.

The rotary vane attenuator is a very popular instrument. At the input end, there is a rectangular-to-circular waveguide taper containing a fixed lossy vane perpendicular to the incident electric vector. The central section contains a lossy vane diametrically across a circular waveguide that can be rotated, and the output section is a mirror image of the input section.

Many different techniques for measuring attenuation have been devised. The power-ratio method is widely used. The simplest configuration requires only a stable well-matched filtered source and a well-matched low-drift power meter. Substitution methods of attenuation measurement are also very popular.

Low values of attenuation can be determined accurately by making reflection coefficient measurements on the device under test with a sliding short behind it. Several bridge techniques for measuring attenuation have been devised.

The attenuation in a waveguide can be found by making Q measurements on resonant sections of different lengths.

When only moderate accuracy (on the order of ± 0.5 dB) is required over a wide frequency range, a leveled swept source can be connected to the device under test, and the emerging signal can be fed to a diode detector that is followed by a logarithmic amplifier and oscilloscope. *See* AMPLITUDE–MODULATION DETECTOR.

Network analyzers yield both the magnitude and phase angle of the transmission and reflection coefficients of the device under test over a wide frequency range. By using ingenious calibration and computer-correction techniques, high accuracy can be achieved. *See* TRANSMISSION LINES. [F.L.W.]

Audio amplifier An electronic circuit for amplification of signals within or somewhat beyond the audio frequency range (generally regarded as 20 to 20,000 Hz). Audio amplifiers may function as voltage amplifiers (sometimes called preamplifiers), power amplifiers, or both. In the last case, they are often called integrated amplifiers. *See* POWER AMPLIFIER.

The function of integrated amplifiers (or of the combination of separate voltage amplifiers and power amplifiers used together) is to amplify a weak signal, such as from a microphone, phonograph pickup, tape player, radio tuner, or compact disc player, to a level capable of driving a loudspeaker or other type of transducer such as headphones at the desired sound level. Power amplifiers may have power ratings ranging from less than 1 W to several hundreds of watts. Stereo amplifiers consist of two identical, but electrically independent, amplifier circuits housed in a single chassis, often sharing a common power supply. Audio amplifiers are commonly constructed with solid-state devices (transistors and integrated circuits), although some amplifiers using vacuum tubes as the active, amplifying devices are still manufactured. *See* AMPLIFIER; INTEGRATED CIRCUITS; LOUDSPEAKER; TRANSISTOR; VACUUM TUBE.

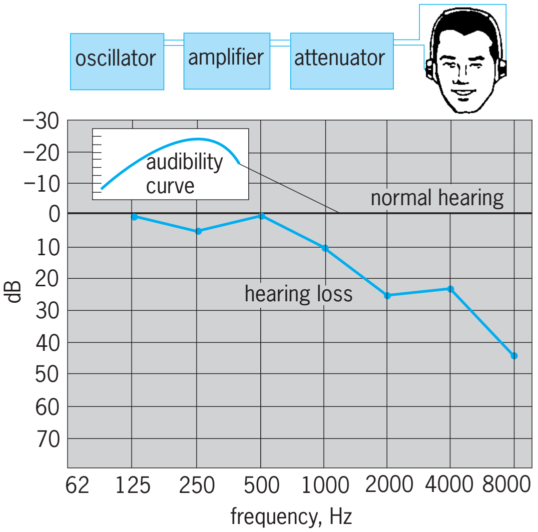
The ideal amplifier delivers an output signal that, aside from its higher power level, is identical in relative spectral content to the input signal. Normally, various forms of distortion are generated by the amplifier, such as harmonic distortion (multiples of the desired signal frequency), intermodulation distortion (spurious sum or difference frequencies created when multiple tones are applied to the amplifier simultaneously, as in the case of music or speech amplification), and transient intermodulation distortion (caused by rapid fluctuations of the input signal level). All forms of distortion are measured as percentages of the desired signal amplitude. Generally, distortion levels of under 1% or 0.5% are considered to be low enough for high-fidelity applications. *See* FIDELITY.

Other parameters used to define an amplifier's characteristics include frequency response and signal-to-noise ratio (S/N). The frequency response is the range of frequencies that the amplifier can handle, usually quoted with a tolerance in decibels, for example: "frequency response: 20 to 20,000 Hz, ±0.5 dB." Signal-to-noise ratio, also quoted in decibels, is indicative of the amount of residual noise generated by the amplifier itself, as compared with the desired output signal level. Signal-to-noise levels greater than 70 dB are generally considered to be acceptable, although some amplifiers offer much better values. *See* RESPONSE; SIGNAL-TO-NOISE RATIO. [L.Fel.]

Audiometry The quantitative assessment of individual hearing, either normal or defective. Three types of audiometric tests are used: pure tone, speech, and bone conduction tests. Such tests may serve various purposes, such as investigation of auditory fatigue under noise conditions, human engineering study of hearing aids and communication devices, screening of individuals with defective hearing, and diagnosis and treatment of defective hearing. In all of these situations, individual hearing is measured relative to defined standards of normal hearing.

The pure-tone audiometer is the instrument used most widely in individual hearing measurement. It is composed of an oscillator, an amplifier, and an attenuator to control sound intensity. For speech tests of hearing, word lists called articulation tests are reproduced on records or tape recorders. Measurements of detectability or intelligibility can be made by adjusting the intensity of the test words. To make bone conduction tests, sound vibrations from the audiometer activate a vibrator located on the forehead or mastoid bone.

Scientific advance in audiometry demands careful control of all environmental sound. Two types of rooms especially constructed for research and measurement of hearing are the random diffusion, or reverberation, chamber and the anechoic room. In the reverberation chamber, sounds are randomly reflected from heavy nonparallel walls, floor, and ceiling surfaces. In the anechoic room, the fiber glass wedges absorb all but a small percent of the sound.



Audiogram for determining the audibility curve for pure-tone hearing loss at various frequency levels.

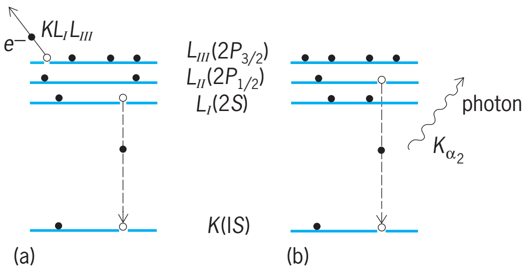
The measurement of hearing loss for pure tones in defective hearing is represented by the audiogram (see illustration). Sounds of different frequencies are presented separately to each ear of the individual, and the intensity levels of the absolute thresholds for each frequency are determined. The absolute threshold is the lowest intensity which can be detected by the individual who is being tested.

In clinical audiometry the status of hearing is expressed in terms of hearing loss at each of the different frequency levels. In the audiogram the normal audibility curve, representing absolute thresholds at all frequencies for the normal ear, is represented as a straight line of zero decibels. Amount of hearing loss is then designated as a decibel value below normal audibility. The audiogram in the illustration reveals a hearing loss for tones above 500 Hz. Automatic audiometers are now in use which enable individuals to plot an audiogram for themselves.

Articulation tests are speech perception or speech hearing tests used to assess hearing and loss of hearing for speech. The threshold of intelligibility for speech is defined as the intensity level at which 50% of the words, nonsense syllables, or sentences used in the articulation test are correctly identified. The hearing loss for speech is determined by computing the difference in decibels between the individual intelligibility threshold and the normal threshold for that particular speech test. Discrimination loss for speech represents the difference between the maximum articulation score at a high intensity level (100 dB), expressed in percent of units identified, and a score of 100%. The measure of discrimination loss is important in distinguishing between conduction loss and nerve deafness.

Bone conduction audiograms are compared with air conduction audiograms in order to analyze the nature of deafness. Losses in bone conduction hearing generally give evidence of nerve deafness, as contrasted to middle-ear or conduction deafness. *See* EAR; HEARING IMPAIRMENT. [K.U.S.]

Auger effect One of the two principal processes for the relaxation of an inner-shell electron vacancy in an excited or ionized atom. The Auger effect is a two-electron process in which an electron makes a discrete transition from a less bound shell to the vacant, but more tightly bound, electron shell. The energy gained in this process is transferred, via the electrostatic interaction, to another bound electron which then escapes from the atom. This outgoing electron is referred to as an Auger electron and is labeled by letters corresponding to the atomic shells involved in



Two principal processes for the filling of an inner-shell electron vacancy. (*a*) Auger emission; a KL_IL_{III} Auger process in which an L_I electron fills the *K*-shell vacancy with the emission of a KL_IL_{III} Auger electron from the L_{III} shell. (*b*) Photon emission; a radiative process in which an L_{II} electron fills the *K*-shell vacancy with the emission of a K_{α_2} photon.

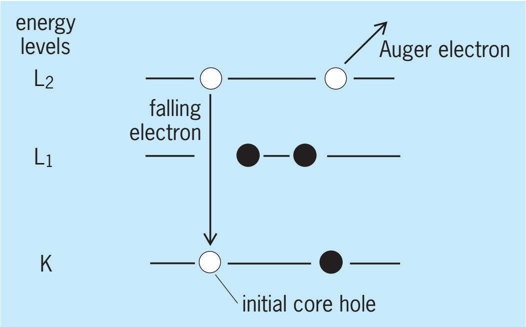
the process. For example, a KL_IL_{III} Auger electron corresponds to a process in which an L_I electron makes a transition to the *K* shell and the energy is transferred to an L_{III} electron (illus. *a*). By the conservation of energy, the Auger electron kinetic energy *E* is given by $E = E(K) - E(L_I) - E(L_{III})$ where $E(K,L)$ is the binding energy of the various electron shells. Since the energy levels of atoms are discrete and well understood, the Auger energy is a signature of the emitting atom. *See* Electron configuration; Energy level (quantum mechanics).

The other principal process for the filling of an inner-shell hole is a radiative one in which the transition energy is carried off by a photon (illus. *b*). Inner-shell vacancies in elements with large atomic number correspond to large transition energies and usually decay by such radiative processes; vacancies in elements with low atomic number or outer-shell vacancies with low transition energies decay primarily by Auger processes. [L.C.F.]

Auger electron spectroscopy

Auger electron spectroscopy (AES) is a widely used technique that detects the elements in the first atomic layers of a solid surface. Although many elements can be detected, hydrogen usually cannot be observed. Excellent spatial resolution can be achieved. Auger electron spectroscopy is important in many areas of science and technology, such as catalysis, electronics, lubrication, and new materials, and also understanding chemical bonding in the surface region. Auger spectra can be observed with gas-phase species.

Basic principles. In Auger electron spectroscopy an electron beam, usually 2–20 kV in energy, impinges on a surface, and a core-level electron in an atom is ejected. An electron from a higher level falls into the vacant core level. Two deexcitation processes are possible: An x-ray can be emitted, or a third electron is ejected from the atom (see illustration). This electron is an Auger electron; the effect is named after its discoverer, Pierre Auger. Auger electrons for surface analysis can be created from other sources, such as, x-rays, ion beams, and positrons. K capture (radioactive decay) is another source of Auger electrons. The Auger yield (the ratio of Auger electrons to the number of core holes created) depends upon the element, the initial core level, and the excitation conditions. *See* Auger effect.



Schematic diagram of an Auger electron being ejected from a carbon atom for a KL_2L_2 transition. Round forms are electrons.

The surface sensitivity of Auger electron spectroscopy is based upon the fact that electrons with kinetic energy in the range of 30–2500 eV have an inelastic mean free path (IMFP) of about 0.5–3 nanometers for most materials. The inelastic mean free path is defined as the average distance that an electron will travel before it undergoes an inelastic collision with another electron or nucleus of the matrix constituent atoms. Very few Auger electrons created at depths greater than two to three times the IMFP will leave the bulk with their initial kinetic energy. Those electrons formed at greater depths undergo collisions with atoms and electrons in the bulk and lose part or all of the initial creation energy. In this energy range, all elements with an atomic number of 3 or more have detectable Auger electrons. Most elements can be detected to 1 atomic percent in the analysis volume, and relative atomic amounts usually can be determined.

X-ray notation is used to signify Auger transitions. For example, if a K (1*s*) electron in silicon is ejected and an L_3 ($2p_{3/2}$) electron falls into the K-level hole and another L_3 is ejected as the Auger electron, the transition is KL_3L_3. If a valence electron is involved, it often is denoted with a V. [N.H.T.]

Augite

A group of monoclinic calcic pyroxenes which have the general chemical formula $(Ca,Mg,Fe)(Mg,Fe)Si_2O_6$, in which calcium is the dominant cation in the first cation position. Monoclinic pyroxene with substantial iron or magnesium in place of calcium is called pigeonite, and has a different crystal structure from augite. Augite is generally considered a combination of the four end members diopside ($CaMgSi_2O_6$), hedenbergite ($CaFe^{2+}Si_2O_6$), enstatite ($Mg_2Si_2O_6$), and ferrosilite ($Fe^{2+}{}_2Si_2O_6$), but it almost always has substantial aluminum and minor to substantial amounts of sodium, ferric iron, chromium, and titanium.

Augite occurs in both igneous and metamorphic rocks. It is nearly universal in basalts and gabbros, and occurs somewhat less frequently in less mafic igneous rocks. Magnesium-rich augite is a characteristic mineral in many ultramafic rocks and in rocks of the Earth's mantle. Augite and pigeonite are also rather common constituents of lunar basalts and basaltic meteorites. *See* Diopside; Eclogite; Enstatite; Pigeonite; Pyroxene. [R.J.Tr.]

Aurora

An optical manifestation of a large-scale electrical discharge process which surrounds the Earth. The discharge is powered by the so-called solar wind-magnetosphere generator. The Sun continuously blows out its upper atmosphere, the corona, with a supersonic speed. This fully ionized and magnetized gas flow interacts with the Earth's magnetic field, resulting in a comet-shaped cavity (the magnetosphere) carved around the Earth, while the lines of force of the Earth's magnetic field and of the solar wind magnetic field interconnect. Electric power of as much as 10^{12} W is generated as the solar wind blows across the interconnected field lines near the comet-shaped boundary. A part of the electric current (carried mainly by electrons) thus generated flows between the magnetospheric boundary and an annular, ring-shaped region of the polar upper atmosphere along the lines of force of the Earth's magnetic field. *See* Magnetosphere.

As these electrons descend toward the Earth, they themselves develop an electrical potential drop of the order of a few kilovolts along the lines of force. As a result, the current-carrying electrons acquire energies of as much as a few kiloelectronvolts, sufficient to ionize and excite a few hundred atoms and molecules before they are stopped by the atmosphere at an altitude of about 60 mi (100 km).

Two curtain-shaped auroras stretching across the sky near Fairbanks, Alaska. (*Courtesy of Lee Snyder*)

Two ring-shaped glows, one in each hemisphere, are produced by upper atmospheric atoms and molecules which emit their own characteristic light after colliding with the current-carrying electrons. The most common light of the aurora (the greenish-white light) comes from excited oxygen atoms. Excited and ionized molecular nitrogen adds several band emissions. Imaging devices aboard satellites have successfully "photographed" both the northern and southern auroral rings. *See* SCIENTIFIC SATELLITES.

From a point on the ground, only a small part of the ring-shaped glow can be observed. It is seen as a curtain-shaped glow, stretching from horizon to horizon across the sky (see illustration). The bottom of the auroral curtain is sharply bounded and is located at about 60 mi (100 km) altitude. The upper boundary diffuses and extends to well above 180 mi (300 km).

The aurora becomes active during geomagnetic storms which occur often about 40 h after an intense solar flare. This is because the efficiency of the solar wind-magnetosphere generator becomes high and variable when the solar wind becomes gusty after a solar flare. During a great magnetic storm, the auroral ring expands from its usual latitude of about 67 to 50° or a little less. It is on such an occasion when the aurora can be seen widely across the continental United States. *See* ATMOSPHERE; ATOMIC STRUCTURE AND SPECTRA; GEOMAGNETISM; IONOSPHERE; PLASMA (PHYSICS). [S.I.A.]

Australia An island continent in the Southern Hemisphere with a total area of 2,941,526 mi^2 (7,618,552 km^2). It is bounded on the west by the Indian Ocean and on the east by the Pacific Ocean and the Tasman Sea. Numerous small and several large islands lie off the coast, including Tasmania and New Zealand. Australia is generally of remarkably low elevation and moderate relief. Three-fourths of the land mass lies between 600 and 1500 ft (180 and 450 m) in the form of a huge plateau. A cross section from east to west shows first a narrow belt of coastal plain, then the steep escarpments of the eastern face of the Great Dividing Range, stretching 1200 mi (1900 km) from the north of Queensland to the south of Victoria. The descent on the western slope of the Dividing Range is gradual until often elevation in the inland basins is below sea level, rising gradually again across the great plateau until the low ranges of western Australia fringing the plateau are reached, and beyond these lies another coastal plain. With the exception of the Gulf of Carpentaria and Cape York peninsula in the north and the Great Australian Bight in the south, there are few striking features in the configuration of the coast. Australia may conveniently be divided into three great structural and landform regions.

The region called East Australian Highlands consists of a narrow plain extending north and south along the eastern coast. Flanking the plain are the series of ranges and tablelands making up the Great Dividing Range. The East Australian Highlands is the best-watered region in Australia, and some of the river systems are of considerable size. On the flanks of the East Australian Highlands are Australia's principal coal deposits—in the vicinity of Sydney and Newcastle and in the Bowen and Ipswich fields in Queensland. Petroliferous basins at Surat (Roma), flanking the divide in Queensland and off the coast of Victoria in Bass Strait, are Australia's most promising deposits of petroleum and natural gas.

The region known as the Interior Lowland Basins comprises a region of sedimentary rocks that occupy one-third of the continent between the western slope of the eastern highlands and the inner eastern margin of the ancient shield which forms the Western Plateau. Little land is over 500 ft (150 m), and some is below sea level. The rivers of the Murray-Darling Basin, draining the western slopes of the Great Dividing Range, have a marked seasonal variation in flow but never dry up in the lower reaches. South Australia's shallow lakes are more often dry expanses of encrusted white salt than bodies of water—the result of low rainfall and high evaporation. In most parts of the region water from deep artesian wells is available.

The region known as the Western Plateau is the largest area, occupying almost three-fifths of the continent, and is a great shield of ancient rocks standing 750–1500 ft (225–450 m) high. Much of it is buried in desert sand, and only a few ridges of ancient mountains (such as the Macdonnel and Musgrave ranges) break the monotony of the plateau surface. Only in the southwestern corner of the continent and along the northwestern coast is rainfall sufficient to support a sclerophyll forest of eucalypts and a monsoon woodland, respectively. In the north, coastal rivers are of considerable size but change from flooded torrents after rains to a succession of water holes in dry seasons.

Tasmania is a small mountainous island lying 150 mi (240 km) southeast of Australia across Bass Strait, with a total area of 26,383 mi^2 (68,332 km^2). The island is structurally similar to the East Australian Highlands. The dominant feature is the central plateau, falling from a general level of 3500 ft (1070 m) in the northwest toward the southeast. A dense eucalyptus forest covers most of the island except along the wetter west coast, where beech forest predominates. The rivers have short, rapid courses with little seasonal variation in flow. *See* NEW ZEALAND. [K.B.C.]

Australopithecine Any of the seven extinct species that belong to the family Hominidae (comprising humans and their closest relatives). These species are not attributable to the genus *Homo*, but belong to at least three genera that existed between about 4.4 million years ago (Ma) and 1.2 Ma during the Pliocene and early Pleistocene epochs. All seven species are known only from Africa. Although some workers regard all of them as belonging to one genus, *Australopithecus*, it is clear that a second genus, *Ardipithecus*, should be recognized for the earliest known hominid fossils, and that the three "robust" species belong to a third genus, *Paranthropus*.

The name australopithecine comes from the taxon *Australopithecus* ("southern ape") *africanus*, which was coined by Raymond Dart for a fossil skull discovered in 1924 in Taung, South Africa (see illustration). The Taung skull had several distinctly hominid, or humanlike, features, but the claim that *A. africanus* was a human forebear was disputed by many of the leading paleoanthropologists of that time. The hominid status of *A. africanus* became widely accepted more than a decade later, largely because of work on *Australopithecus* fossils from Sterkfontein. Specimens of *A. africanus* are known also from the sites of Makapansgat and Gladysvale in southern Africa. Faunal comparison with radiometrically dated sites in eastern Africa indicates that this species existed between about 3.0 and 2.3 Ma. The name *Paranthropus*

Lateral view of the Taung skull of *Australopithecus africanus*, the type specimen of *Australopithecus* and the first early hominid specimen to be discovered in Africa. (*Courtesy of F. E. Grine*)

(“beside human”) was coined in 1938 when fossils from Kromdraai, South Africa, were attributed to the taxon *P. robustus*. Fossils of this species are also known from the nearby sites of Swartkrans and Drimolen. These bones are dated, also by faunal comparisons with radiometrically dated sites in eastern Africa, to between about 1.8 and 1.5 Ma.

At least seven australopithecine species, belonging to at least three genera, can be recognized in the Pliocene and early Pleistocene of Africa: *Ardipithecus ramidus* (?5.0–4.4 Ma), *Australopithecus anamensis* (3.9–4.2 Ma), *Australopithecus afarensis* (?4.0–2.9 Ma), *Australopithecus africanus* (3.0–2.3 Ma), *Paranthropus aethiopicus* (2.8–2.3 Ma), *Paranthropus boisei* (2.3–1.2 Ma), and *Paranthropus robustus* (1.8–1.5 Ma). All are defined on the basis of craniodental morphology.

Paleoanthropologists disagree over the assignment of early hominid fossils to different genera and species. Such arguments over what is known as Alpha Taxonomy are to be expected, as different workers view the fossil record from different philosophical perspectives. Such differences also account for disagreements over the phylogenetic relationships of these species, including the issue of which (if any) is most closely related to the human genus, *Homo*. Every phylogenetic hypothesis that has been put forward since the 1950s has been either falsified outright or at least substantially altered by ongoing research and new discoveries.

At present, no scientifically rigorous phylogenetic analysis has been undertaken that incorporates all seven of the australopithecine species. The most comprehensive study of “australopithecine” evolutionary relationships to date does not include *Ar. ramidus* or *A. anamensis*. Nevertheless, it is evident from the descriptive account of *Ar. ramidus* that it very likely resembles the stem hominid taxon in its morphology. *Australopithecus anamensis* shares some evolved (derived) traits with later species such as *A. afarensis*, but retains some primitive features that are displayed also by *Ar. ramidus*. Thus, *A. anamensis* most likely evolved from a species that was at least morphologically similar to *Ar. ramidus* in some respects. For the moment, *Ar. ramidus* represents the best candidate for the ancestor of *A. anamensis*. *Australopithecus anamensis*, in turn, possesses some unique features that make it unlikely to be the immediate ancestor of *A. afarensis*, but it is probable that *A. afarensis* evolved from a species that had a strong morphological resemblance to *A. anamensis*.

Australopithecus afarensis likely gave rise to a lineage that provided the ancestry of both *A. africanus* and another lineage that included the common ancestor of the genera *Paranthropus* and *Homo*. Although *A. africanus* shares a number of derived morphological characters with species that are part of the *Paranthropus* and *Homo* lineage, it is not considered to be directly ancestral to that line because it exhibits derived morphology in several characters that are more primitive in both *A. afarensis* and *P. aethiopicus*. It is perhaps more likely that the derived traits which *A. africanus* shares with some species of *Paranthropus* and *Homo* were evolved in parallel. Other workers, however, have argued that *A. africanus* constitutes a reasonable morphotype for the last common ancestor of the lineage that leads to *Homo* and *Paranthropus*. In this case, the primitive features displayed by *P. aethiopicus* would represent evolutionary reversals. At present, then, it is safest to conclude that the phyletic position of *A. africanus* remains ambiguous.

Paranthropus aethiopicus is considered to be a likely candidate for the ancestry of both *P. boisei* and *P. robustus*. The reason is that *P. aethiopicus* shares a number of primitive features with *A. afarensis*, but at the same time it shares a host of derived features with the later species of *Paranthropus*, namely *P. robustus* and *P. boisei*.

The lineage leading to *Paranthropus* shares a number of morphological features with that leading to *Homo*. For example, all species of *Homo* and *Paranthropus* share a coronally oriented petrous temporal bone, a foramen magnum that is roughly horizontal in disposition, and a vertically oriented mandibular symphysis. Thus, it is most parsimonious to assume that these two lineages shared a common ancestor at some time prior to 2.8 Ma.

The apparent increase in cranial capacity that is shown by some species of *Paranthropus* (*P. robustus* and *P. boisei*) would appear to parallel the increase in brain size that characterized the evolutionary history of the lineage that led to *Homo sapiens*. Tools made of stone or bone are not known to be associated with *Ardipithecus* or the three species of *Australopithecus*. Stone tools are known from sites that contain *P. boisei* fossils, and both bone and stone tools are known from sites that preserve *P. robustus* remains. However, early members of the genus *Homo* are known also from these same localities. Thus, it is difficult to determine whether *Paranthropus* species may have been responsible for some of the late Pliocene and early Pleistocene archeological record. Indeed, it has been argued that the later species of *Paranthropus* may have been driven to extinction through competition with early *Homo*, because the latter possessed a distinct ecological advantage through the utilization of lithic technology in the procurement of food. While the evidence for this is not compelling, it is possible that ecological interactions between *Paranthropus* and early members of *Homo* may have influenced the evolutionary course of the human genus. *See* APES; FOSSIL HUMANS. [F.E.Gr.]

Authigenic minerals Minerals that are formed in sediment or a sedimentary rock. Their in-place origin distinguishes them from minerals that are formed elsewhere and transported to the site of deposition (detrital minerals). Authigenic minerals form at the Earth’s surface as well as during subsequent burial. The postdepositional processes are referred to as diagenesis, and the resulting minerals are important clues to postdepositional physical and chemical changes in the rock. *See* DIAGENESIS; SEDIMENTARY ROCKS.

Authigenic minerals precipitate from the overlying water column, pore fluids in the sediment, recrystallization or alteration of preexisting minerals, and structural transformation of one mineral to another. The minerals change in an attempt to equilibrate to the physical and chemical conditions present at any given time. Critical factors in their formation are initial mineral assemblage, temperature, pressure, ionic concentration, pH, electron availability, and the fluid flux through the rock.

In sedimentary rocks it is common to find a record of multiple diagenetic events based on the authigenic minerals. For example, in sediments near the surface, meteoric water may displace original marine pore water, resulting in distinct types of cements. Iron oxide can result from oxidizing fluid. Depletion of oxygen by bacteria may result in the formation of iron sulfides, such as pyrite. During burial, the sediments respond to increasing temperature (up to 200°C; 390°F), pressure (up to 2.5 kilobars; 250 megapascals), and fluid movement from compaction-driven waters or influx of water from the basin flanks. As a result, the sedimentary rock may contain authigenic minerals that record a sequence of events ranging from processes occurring near the sediment-water interface to those forming during deep burial. Unlike metamorphic rocks, the preexisting (detrital) mineral assemblage is at least partially retained, in part due to the sluggish reaction rates at diagenetic conditions. Early cementation processes often seal up the rock, preventing subsequent diagenetic reactions and preserving the original detrital mineral assemblage.

Authigenic minerals occur in all sedimentary rock and can vary from trace amounts to virtually the total rock (see table). The carbonate minerals calcite, dolomite, and siderite are some of the most common types. They form in a wide range of depositional environments and at varying burial depths. Calcite and dolomite form the principal minerals in limestones and dolostones, respectively, as well as cements in sandstones or shales. Carbonate cements result from recrystallization of detrital carbonates and from dissolution of other calcium, iron, and magnesium minerals with carbon dioxide from organic reactions. Much of the calcite in limestones initially consisted of aragonite or magnesium-rich calcite, whereas most dolomite has been formed by the chemical alteration of calcite. Recrystallization may change aragonite to calcite. Aragonite (orthorhombic) is a naturally unstable form of calcium carbonate. With the passage of geologic time, aragonite normally inverts to the more stable calcite (hexagonal). The substitution of magnesium for calcium is responsible for the conversion of calcite or aragonite to dolomite, and it has been shown that dedolomitization (replacement of magnesium by calcium) is also possible. *See* ARAGONITE; CALCITE; CARBONATE MINERALS; CEMENT; DOLOMITE. [J.R.B.]

Common authigenic minerals

Mineral	Formula
Albite	$NaAlSi_3O_8$
Anatase	TiO_2
Anhydrite	$CaSO_4$
Apatite*	$Ca_5(PO_4)_3(F,Cl,OH)$
Aragonite (orthorhombic)	$CaCO_3$
Barite	$BaSO_4$
Boehmite	$AlO(OH)$
Calcite (hexagonal)	$CaCO_3$
Celestite	$SrSO_4$
Clay minerals	
Chlorites*	$(Mg,Fe^{2+},Fe^{3+})_6(Al,Si_3)O_{10}(OH)_8$
Illites*	$K(Al)_2(AlSi_3)O_{10}(OH)_2$
Kaolinite	$Al_2Si_2O_5(OH)_4$
Smectites*	$(Na,0.5Ca)_{0.5}(Al,Mg,Fe)_2(Al,Si_3)O_{10}(OH)_2 \cdot nH_2O$
Dolomite	$CaMg(CO_3)_2$
Gibbsite	$Al(OH)_3$
Glauconite*	$K(Al,Mg,Fe^{2+},Fe^{3+})_2(Al,Si_3)O_{10}(OH)_2$
Goethite	$Fe_2O_3 \cdot n(H_2O)$
Gypsum	$CaSO_4 \cdot 2(H_2O)$
Halite	$NaCl$
Hematite	Fe_2O_3
Leucoxene	TiO_2
Limonite	$FeO(OH) \cdot n(H_2O)$
Opal (amorphous)	$SiO_2 \cdot n(H_2O)$
Orthoclase	$KAlSi_3O_8$
Pyrite (isometric)	FeS_2
Pyrolusite	MnO_2
Quartz	SiO_2
Siderite	$FeCO_3$
Zeolites*	$X_y{}^{1+,2+}Al_xSi_{1-x}O_z \cdot nH_2O$
Clinoptilolite*	$(Na,0.5Ca,K)_{3.5}\,Al_{3.5}\,Si_{14.5}O_{36} \cdot nH_2O$
Analcime	$NaAlSi_2O_6 \cdot H_2O$
Laumontite	$CaAl_2Si_4O_{12} \cdot 4H_2O$

*Group of minerals characterized by considerable chemical variation.

Autistic disorder A severe neuropsychiatric disorder of early childhood onset, historically regarded as a psychosis of childhood but now classified as a pervasive developmental disorder. While autism has been the most intensively studied pervasive developmental disorder, other conditions are now included in this class of conditions: Asperger's syndrome (sometimes referred to as autistic psychopathy), Rett's syndrome, and childhood disintegrative disorder (Heller's syndrome).

Symptoms of autism generally are apparent within the first 2 years of life and may occasionally be noted from the time of birth. Characteristic disturbances include disruption of social, cognitive, linguistic, motor, and perceptual development. Affected individuals fail to develop appropriate interpersonal relationships. In about half of the cases, language fails to develop; when it does develop, it is characterized by pronoun confusion (for example, the use of "you" for "I"), abnormal speech tone or rhythm, and an impaired ability to use abstract terms or communicate symbolic information. Unusual responses to the environment are common and may include resistance to change, exaggerated reactions to sensory stimuli or changes in the environment, ritualistic behavior, and peculiar attachments to inanimate objects. Motor abnormalities include unusual posturing and stereotyped (purposeless and repetitive) movements; self-injurious behavior (for example, head banging) is also common. Although some islets of unusual ability (in memory, drawing, or calculation) may be present, about 80% of individuals score in the mentally retarded range on tests of intelligence. Autistic individuals do not experience delusions and hallucinations; however, the metaphorical and bizarre language of verbal individuals may mistakenly suggest the kind of thought disturbance that is found in schizophrenia. *See* SCHIZOPHRENIA.

In Rett's syndrome, a short period of normal development is followed by loss of developmental skills and marked psychomotor retardation. A brief autisticlike phase may be observed during the preschool period, but the subsequent course and clinical features are markedly different from those of autism. Rett's syndrome has been observed only in females. The validity of Asperger's syndrome apart from autism has been more controversial. Individuals with Asperger's syndrome appear to have relatively much more preserved verbal and cognitive skills. Unusual circumscribed interests are common (for example, in maps, the weather, or train or bus schedules). In childhood disintegrative disorder, development in the first several years of life is unequivocally normal and is followed by a marked developmental regression (a child who previously had been speaking in sentences becomes totally mute), and various autistic features develop.

Autism is chronic and incapacitating. Only one autistic individual in six is able to make a good adjustment in adulthood and engage in regular, gainful employment. Approximately two-thirds of children remain severely handicapped as adults and need constant supervision and support. Even for those autistic individuals who make the best adjustment as adults, residual deficits in social, affective, and cognitive development remain. Factors related to better prognosis include the development of communication skills by age 5 and intellectual achievement. In Asperger's syndrome, the prognosis is apparently better than in autism, probably reflecting, in some part, the preservation of cognitive abilities in this condition. In Rett's syndrome and childhood disintegrative disorder, the prognosis is worse than in autism.

The "purest" form of autism, where the child has higher IQ, some islets of normal or near-normal behavior, and profound social detachment, affects only 1 child in 2000; however, the broader spectrum of communication and developmental disorders associated with autism and requiring similar care may affect 1 in every 750 children. Although males outnumber females (by four or five times), females with autism tend to be more severely affected. Predisposing factors include congenital infections (for example, maternal rubella) and metabolic and genetic illnesses (for example, phenylketonuria). A history of prenatal or perinatal complication is not uncommon, but in many cases no specific predisposing factor or associated mental condition is found. *See* PHENYLKETONURIA; RUBELLA.

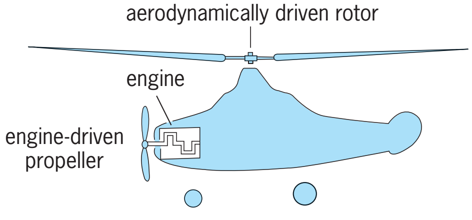
For the majority of cases of autism, the cause remains unknown. Theoretical explanations have emphasized either a primary psychological or biological vulnerability in the child, the role of environmental factors, and an interaction between an inborn vulnerability and the child's environment. The high incidence of neurological signs, electroencephalographic abnormalities, and the fact that seizures develop in 25% of children during adolescence (especially in lower-IQ children) tend to support the role of a biological vulnerability. The final behavioral expression of the syndrome may be a function of multiple factors. Individuals with Rett's syndrome and childhood disintegrative disorder also are at increased risk for developing seizures, and exhibit other signs of central nervous system dysfunction. The history of a prolonged period of normal development in childhood disintegrative disorder often prompts extensive medical investigation, which usually does not reveal a specific medical condition that might account for the deterioration.

Treatment modalities that have been used in the management of individuals with autism and related conditions include psychotherapy, pharmacotherapy, behavior therapy, various somatic treatments, and educational interventions. Certain drugs may be effective in controlling certain maladaptive behavioral features, such as hyperactivity, aggression, and stereotyped behaviors. Behavior modification procedures may be quite useful. Educational interventions with highly structured, intensive remediation are of greatest overall benefit. However, even with the best of interventions there are no cures and most autistic individuals remain severely impaired. *See* PSYCHOTHERAPY; TRANQUILIZER. [D.J.C.; F.R.Vo.]

Autogiro A type of aircraft which utilizes a rotating wing (rotor) to provide lift. An autogiro is similar to a helicopter, but uses a conventional engine-propeller combination in addition to the rotor to pull the vehicle through the air like a fixed-wing aircraft (see illustration),

Unlike the helicopter, the autogiro rotor maintains its speed of rotation in the air because of the aerodynamic forces acting upon the rotor blades, and is without direct mechanical drive from the engine (autorotation). All the power required to maintain flight is supplied through the propeller of the autogiro at the front (tractor type) or rear (pusher type) of the fuselage. The rotor is thereby pulled through the air and creates a lifting force.

The autogiro has several inherent advantages. It is capable of takeoff and landing in a shorter distance than the fixed-wing airplane, and is capable of level controlled flight at extremely slow speed, on the order of 20 mi/h (30 km/h). It is mechanically simpler than the helicopter. An autogiro, unlike an airplane, cannot be stalled. Among the disadvantages of the vehicle is that its speed performance is limited as compared to an airplane, although it is capable of flying slightly faster than the helicopter. It cannot hover as can a helicopter. *See* HELICOPTER. [L.G.]



In-flight loaded dynamic components of a typical autogiro.

Autoimmunity The occurrence in an organism of an immune response to one of its own tissues, that is, a response to a self constituent. Efficient discrimination between self and nonself, the basis of normal immune function, depends upon a function known as immune tolerance (inertness to substances that could be capable of provoking an immune response). Failure of immune tolerance to self constituents results in an autoimmune response which is often, although not invariably, associated with autoimmune disease. Autoimmune disease occurs when the autoimmune response to self constituents has damaging effects of a structural or functional character.

Lymphocytes that participate in immune responses belong to two major groups. One group, which matures in the thymus gland, comprises thymic or T lymphocytes, of which there are several subsets. These subsets have different functions and carry unique surface molecules: (1) helper T lymphocytes, marked by the CD4 molecule, respond to antigens by releasing stimulatory cytokines (intercellular hormones) that can amplify the number and activity of lymphocytes participating in the immune response; (2) cytolytic T lymphocytes, marked by the CD8 molecule, can directly recognize and kill cellular targets, usually virus-infected cells; and (3) suppressor T lymphocytes, which also carry the CD8 molecule, release molecules that reduce the intensity of immune responses, or switch these off altogether. The other major group of lymphocytes, which mature in the bone marrow, are B lymphocytes. After stimulation with antigen molecules, and under the influence of factors released by helper T cells, B lymphocytes proliferate and later secrete the antibody molecules which, when circulating in the blood, provide for humoral immune responses. The normal immune system remains in a state of balance conditioned by positive signals and negative signals. Positive signals are provided by antigen in low dose and the amplifying factors released by activated helper T lymphocytes, while negative signals are provided by antigen present in excess, which causes an overload paralysis, and by suppressor T lymphocytes which are generated preferentially when self antigens are presented. There is still a lack of full understanding of the mechanism by which immune responses to self antigens are suppressed so as to provide for natural tolerance to self. The major processes are (1) permanent deletion, or functional inactivation in early life, of cells capable of responding to self antigens; and (2) regulatory controls, which inhibit the activity of self-reactive lymphocytes that escape the deletion process. The relative contribution of these two mechanisms for specific self antigens appears to differ, and both probably operate to control autoimmunity. There are low background levels of immunologic reactivity to many self antigens in healthy subjects, indicating that suppressor activity over immune responses to autoantigens must be continuously operative. *See* IMMUNITY.

Failure of immune regulation is responsible for autoimmune disease. Inheritance may account for 25–50% of the risk for autoimmune diseases. It is known that autoimmune disease, or at least the tendency to produce autoantibodies, runs in families. There are many genetic determinants, and they are poorly understood. One set is in some way associated with major histocompatibility complex (MHC; called HLA in humans), a gene complex that codes for cell-surface molecules which confer biological uniqueness on cells of an individual. Since products of HLA genes normally function to direct T lymphocytes to cells with which they should interact, it is not surprising that autoimmune diseases are associated with the presence of particular HLA types; examples include B8 (thyrotoxicosis), DR4 (rheumatoid arthritis, type 1 diabetes mellitus), and DR2 (multiple sclerosis). The reason may be that the autoantigen readily associates with the MHC (HLA) molecule on cells which present antigen to helper T lymphocytes. The MHC influences the occurrence of autoimmunity in other ways. Release of cytokines by T lymphocytes may induce aberrant expression of molecules on tissue cells which then can present their own antigens, and these become inducers of an autoimmune response. In addition to the MHC, there are other inherited determinants of autoimmunity, including genes specifying immunoglobulin structure and genes specifying weakness in the down-regulation of immune reactions. There may also be somatic genetic causes of autoimmunity (random mutations in later life) among genes that code for immunoglobulins that function as recognition structures on the surface of B lymphocytes; such a mutation may generate a cell with a receptor structure with exquisite specificity for a self antigen which is resistant to regulation. Environmental causes could include infection with microorganisms that carry antigenic structures closely resembling those of self; these could provoke an uncontrolled response to the related self structures of the body. *See* IMMUNOGENETICS.

Any autoimmune response must become self-sustaining, which implies coexisting failure of normal regulatory processes, either by reason of genetic predisposition or by an acquired disruption of immune function. Once self-sustaining, the autoimmune reaction can cause damage or dysfunction in one of several ways. First, autoantibody molecules circulate in the blood and, by attaching to self antigens on cell surfaces, either damage cells or interfere with important cell-surface receptor molecules. Second, antibodies can unite with their autoantigen, which results in the binding of a serum factor, complement, to form immune complexes that are capable of provoking inflammatory responses. Third, there may be generated T lymphocytes with the capacity for cellular destruction, and these may cause the progressive inflammatory damage that characterizes autoimmune reactions in solid organs. Many human diseases can be attributed to autoimmune reactions. Circulating autoantibodies are responsible for diseases in which there is intravascular destruction of elements of the blood, for example, the red blood cells in hemolytic anemia. T lymphocytes may be responsible for some types of thyroid goiter, such as Hashimoto's disease; a stomach mucosal degeneration that results in nonabsorption of vitamin B_{12} and thus the blood disease pernicious anemia; the insulin-dependent or juvenile type of diabetes mellitus; and one type of chronic hepatitis. Immune complexes cause glomerulonephritis and most of the features of systemic lupus erythematosus, in which autoantibodies are formed to various constituents of cell nuclei. In Sjogren's disease, in which salivary and lacrimal glands are destroyed, damage by T lymphocytes within the glands may be accompanied by damage by immune complexes throughout the body. Some autoimmune diseases are caused by antibodies to cell receptors, which either block neuromuscular transmission, as in myasthenia gravis, or stimulate thyroid cells to overactivity, as in Graves' disease. Some important human diseases may be autoimmune disorders, although demonstration of an autoimmune basis is not yet adequate: these include rheumatoid arthritis, multiple sclerosis, and ulcerative colitis. *See* ANEMIA; ARTHRITIS; DIABETES; HEPATITIS; MULTIPLE SCLEROSIS; MYASTHENIA GRAVIS.

Autoimmune diseases are alleviated by treatment, though these diseases are seldom curable. At the simplest level, replacement of the specific secretions of tissues or organs damaged by autoimmune reactions may help. For multisystem autoimmune disease, such as lupus, there are drugs, particularly cortisone derivatives, that modify the harmful effects of humoral or cellular autoimmune attack on tissues and so allow the body to reestablish immunologic homeostasis. Also used are cytotoxic immunosuppressive drugs, which are given specifically to inhibit the activity of immunologically active cells responsible for autoantibody formation or for cytolytic damage to tissues. *See* IMMUNOLOGY. [I.R.M.]

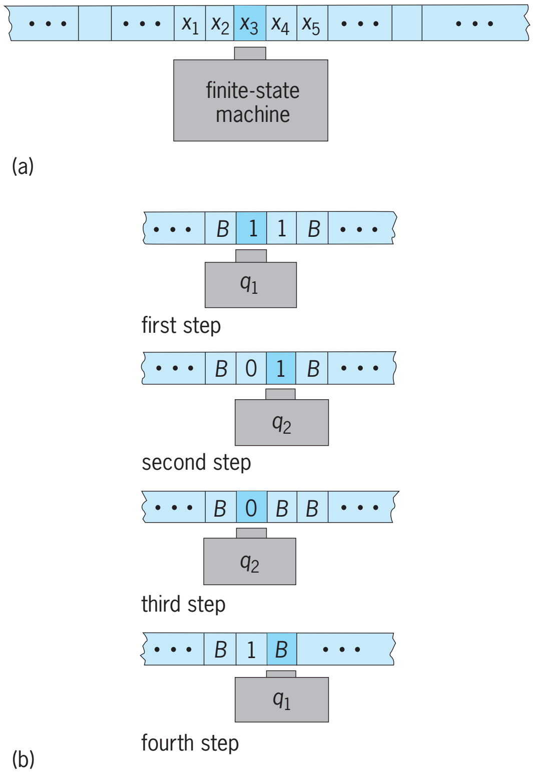
Automata theory

Automata theory A theory concerned with models (automata) used to simulate objects and processes such as computers, digital circuits, nervous systems, cellular growth, and reproduction. Automata theory helps engineers design and analyze digital circuits which are parts of computers, telephone systems, or control systems. It uses ideas and methods of discrete mathematics to determine the limits of computational power for models of existing and future computers. Among many known applications of finite automata are lexical analyzers and hardware controllers.

The concept now known as the automaton was first examined by A. M. Turing in 1936 for the study of limits of human ability to solve mathematical problems in formal ways. His automaton, the Turing machine, is too powerful for simulation of many systems. Therefore, some more appropriate models were introduced.

Turing machines and intermediate automata. The Turing machine is a suitable model for the computational power of a computer. A Turing machine has two main parts: a finite-state machine with a head, and a tape (*see* illustration). The tape is infinite in both directions and is divided into squares. The head sees at any moment of time one square of the tape and is able to read the content of the square as well as to write on the square. The finite-state machine is in one of its states. Each square of the tape holds exactly one of the symbols, also called input symbols or machine characters. It is assumed that one of the input symbols is a special one, the blank, denoted by *B*.

At any moment of time, the machine, being in one of its states and looking at one of the input symbols in some square, may act or halt. The action means that, in the next moment of time, the machine erases the old input symbol and writes a new input symbol on the same square (it may be the same symbol as before, or a new symbol; if the old one was not *B* and the new one is *B*, the machine is said to erase the old symbol), changes the state to a new one (again, it is possible that the new state will be equal to the old one), and finally moves the head one square to the



Turing machine. (*a*) General idea. (*b*) An example of a computation.

left, or one square to the right, or stays on the same square as before.

For some pairs of states and input symbols the action is not specified in the description of a Turing machine; thus the machine halts. In this case, symbols remaining on the tape form the output, corresponding to the original input, or more precisely, to the input string (or sequence) of input symbols. A sequence of actions, followed by a halt, is called a computation. A Turing machine accepts some input string if it halts on it. The set of all accepted strings over all the input symbols is called a language accepted by the Turing machine. Such languages are called recursively enumerable sets.

Another automaton is a nondeterministic Turing machine. It differs from an ordinary, deterministic Turing machine in that for a given state and input symbol, the machine has a finite number of choices for the next move. Each choice means a new input symbol, a new state, and a new direction to move its head.

A linear bounded automaton is a nondeterministic Turing machine which is restricted to the portion of the tape containing the input. The capability of the linear bounded automaton is smaller than that of a Turing machine.

A computational device with yet smaller capability than that of a linear bounded automaton is a push-down automaton. It consists of a finite-state machine that reads an input symbol from a tape and controls a stack. The stack is a list in which insertions and deletions are possible, both operations taking place at one end, called the top. The device is nondeterministic, so it has a number of choices for each next move. Two types of moves are possible. In the first type, a choice depends on the input symbol, the top element of the stack, and the state of the finite-state machine. The choice consists of selecting a next state of the finite-state machine, removing the top element, leaving the stack without the top element, or replacing the top element by a sequence of symbols. After performing a choice, the input head reads the next input symbol. The other type is similar to the first one, but now the input symbol is not used and the head is not moved, so the automaton controls the stack without reading input symbols. *See* ABSTRACT DATA TYPE.

Finite-state machines. A finite-state automaton, or a finite-state machine, or a finite automaton, is a computational device having a fixed upper bound on the amount of memory it uses (unlike Turing and related machines). One approach to finite automata is through the concept of an acceptor. The finite automaton examines an input string (that is, a sequence of input symbols, located on the tape) in one pass from left to right. It has a finite number of states, among which one is specified as initial. The assumption is that the finite automaton starts scanning of input standing in its initial state. Some of the states are called accepting states. The finite automaton has a transition function (or next-state function) which maps each state and input symbol into the next state. In each step the finite automaton computes the next state and reads the next input symbol. If after reading the entire input string the last state is accepting, the string is accepted; otherwise it is rejected. [J.W.G.B.]

Automated decision making The use of computers to automate decision tasks. A decision task is any task requiring the generation or selection of options.

Related to automated decision making (ADM) are techniques for automated control. The term “control” is usually applied to continuously operating systems that are constantly monitored and adjusted. The term “decision making” usually refers to comparatively high-level tasks with discrete decision points. For example, continuous monitoring and adjustment of operating factory equipment may be considered a control task, while the scheduling of factory operations may be considered a decision task. *See* CONTROL SYSTEMS; PROCESS CONTROL.

Another related area is decision support systems. Decision support systems are intended to support human decision making, while automated decision making concentrates on completely computer-automated decision making. Nevertheless, there is a close connection between these two areas since many decision support systems are designed as advisory systems, where the decision support system recommends decisions. To generate a recommendation, the decision support system invokes an ADM model. *See* DECISION SUPPORT SYSTEM.

Techniques for automated decision making are drawn from several disciplines, including optimization, artificial intelligence, and decision theory. Alternative approaches to automated decision making can be characterized in terms of a trade-off between power and generality. An ADM technique is general to the extent that it can be applied to diverse problems. It is powerful to the extent that it quickly generates good answers. *See* DECISION THEORY; OPTIMIZATION.

There is a trend toward integration of ADM techniques. Decision-theory approaches now strongly influence artificial intelligence research in automated decision making, and there has also been an active interest in integrating optimization and artificial intelligence problem-solving approaches. [P.E.L.]

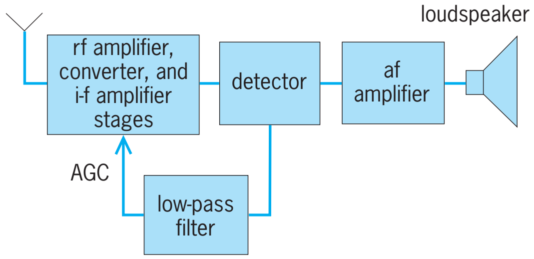
Automatic frequency control (AFC) The automatic control of the intermediate frequency in a radio, television, or radar receiver, to correct for variations of the frequency of the transmitted carrier or the local oscillator. In high-fidelity broadcast receivers, AFC keeps distortion due to detuning to a low figure. In the reception of long-haul telegraph signals, AFC reduces the error rate due to signal pulse distortion or interference from lower-intensity signals in the same frequency band.

AFC techniques are varied but are mainly of two types. One uses a discriminator to furnish a voltage whose magnitude and polarity are determined by the frequency change. This voltage is used to adjust the frequency of the local oscillator of the receiver, thereby keeping the intermediate frequency constant. The other uses two-polarity pulse accumulation which furnishes a dc potential proportional to frequency error. [W.Lyo.]

Automatic gain control (AGC) The automatic maintenance of a nearly constant output level of an amplifying circuit by adjusting the amplification in inverse proportion to the input field strength, also called automatic volume control (AVC). Almost all radio receivers in use employ AGC. In broadcast receivers, AGC makes it possible to receive incoming signals of widely varying strength, yet have the sound remain at nearly the same volume. In communications receivers a type of AGC circuit called a squelch circuit is used to prevent noise during periods of no transmission, such as in the reception of on-off keying, frequency-shift keying (FSK), and phone. AGC is also useful in accelerating the switching action between receivers in diversity connection. *See* RADIO RECEIVER.

AGC action depends on the characteristic, possessed by most electronic tubes and transistors, of adjustment of gain by the variation of the applied bias voltage. If the dc voltage applied to the control grid of a vacuum tube is made more negative, the amplification of that stage will be reduced.

In most broadcast receivers the AGC voltage is taken from the detector. This dc voltage, proportional to the average level



Block diagram of broadcast receiver using AGC.

of the carrier, adjusts the gain of the radio-frequency (rf) and intermediate-frequency (i-f) amplifiers and the converter, as shown in the illustration. AGC tends to keep the input signal to the audiofrequency (af) amplifier constant despite variations in rf signal strength. There are several modifications of this basic circuit.

AGC circuits are also used in dictation recording equipment, public address systems, and similar equipment where a constant output level is desirable. *See* Amplifier. [W.Lyo.]

Automatic horizon A device that provides the pilot with symbols representative of the attitude of an aircraft relative to an artificial horizon. In an automatic or artificial horizon a vertical gyro moves a horizon bar relative to a fixed aircraft index. Motion of the bar simulates changes in pitch or roll of the aircraft. As the pilot views the indicator, the horizon is seen relative to the aircraft as the horizon would appear if the pilot could see it through the windscreen. *See* Gyroscope. [J.W.A.]

Automatic landing system The means for guiding and controlling aircraft from an initial approach altitude to a point where safe contact is made with the landing surface. Such systems differ from low-approach systems in three major respects: (1) They furnish not only guidance but control of the aircraft as well. (2) They furnish information on the aircraft's position with respect to the terrain below it, and the rate at which the landing surface is being approached. (3) They do not require the pilot to assume manual control near the ground.

Two automatic landing systems have been developed. One, a radar-beam type, detects the position and rate of change in position of the landing aircraft by means of a radar beam emitted from a ground derived-control complex. The other, a fixed-beam type, derives position and rate of change in position by instrumentation within the landing aircraft, but it makes use of instrument landing system (ILS) type equipment on the ground. In the aircraft are accelerometers (which may be part of an inertial navigation system) and a radio altimeter. Essential to both systems is an autopilot in the aircraft, commanded by a computer on the ground in the radar-beam system and by a computer in the aircraft for the fixed-beam system. *See* Instrument landing system (ILS). [J.L.Lo.]

Automatic sprinkler system An integrated arrangement of fixed facilities for protection from combustion by use of water extinguishment. The system comprises an adequate water supply, hydraulically designed internal piping, and sprinklers connected in a systematic pattern over the protected area; the system is activated by a fire to discharge a fine spray of water over the heat.

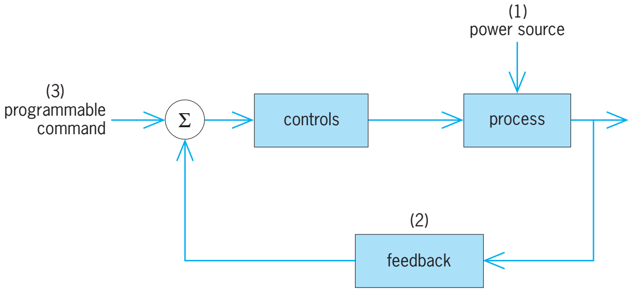
Essential features of a system are its self-detection of fire, prior installation, and built-in activation. In these respects, the automatic sprinkler system is among the earliest-used architectural features that contribute actively to maintenance of the internal environment (in contrast to the passive fire-resistant contribution of the static structure). Auxiliary to an automatic sprinkler system may be a fire alarm. *See* Fire detector.

The principal component of the system is a thermally sensitive sprinkler with a linkage assembly that holds closed the discharge opening. In various designs the assembly is disrupted through a low-melting-point chemical, a frangible bulb filled with liquid, a bimetallic disk, or—usually—a low-melting-point alloy link. The sprinkler abruptly opens to discharge water against a deflector so that water falls in a hemispherical spray across the area below.

Water reaches the sprinklers variously in five basic setups. In the usual wet-pipe system, for heated buildings, all pipes contain water under pressure for immediate release through any sprinkler that opens. In a dry-pipe system—for unheated buildings in freezing climates or for cold-storage rooms—branch lines and other distribution pipes contain dry air or nitrogen under pressure. For occupancies where flash fires are possible, a deluge system is appropriate. All sprinklers are continuously open while the pipes are empty. In a preaction system, both heat-sensitive sprinklers and separate detectors guard the area; the separate detectors open a preaction valve and sound an alarm in the event of fire. Another adaptation is the recycling preaction system, applicable to unattended buildings, in which the water flow recycles if necessary to follow the fire cycle. *See* Fire extinguisher; Fire technology. [F.H.R.]

Automation The process of having a machine or machines accomplish tasks hitherto performed wholly or partly by humans. As used here, a machine refers to any inanimate electromechanical device such as a robot or computer. As a technology, automation can be applied to almost any human endeavor, from manufacturing to clerical and administrative tasks. An example of automation is the heating and air-conditioning system in the modern household. After initial programming by the occupant, these systems keep the house at a constant desired temperature regardless of the conditions outside.

The fundamental constituents of any automated process are (1) a power source, (2) a feedback control mechanism, and (3) a programmable command (see illustration) structure. Programmability does not necessarily imply an electronic computer. For example, the Jacquard loom, developed at the beginning of the nineteenth century, used metal plates with holes to control the weaving process. Nonetheless, the advent of World War II and the advances made in electronic computation and feedback have certainly contributed to the growth of automation. While feedback is usually associated with more advanced forms of automation, so-called open-loop automated tasks are possible. Here, the automated process proceeds without any direct and continuous assessment of the effect of the automated activity. For example, an automated car wash typically completes its task with no continuous or final assessment of the cleanliness of the automobile. *See* Control systems; Digital computer.



Elements of an automated system.

Because of the growing ubiquity of automation, any categorization of automated tasks and processes is incomplete. Nonetheless, such a categorization can be attempted by recognizing two distinct groups, automated manufacturing and automated information processing and control. Automated manufacturing includes automated machine tools, assembly lines, robotic assembly machines, automated storage-retrieval systems, integrated computer-aided design and computer-aided manufacturing (CAD/CAM), automatic inspection and testing, and automated agricultural equipment (used, for example, in crop harvesting). Automated information processing and control includes automatic order processing, word processing and text editing, automatic data processing, automatic flight control, automatic automobile cruise control, automatic airline reservation systems, automatic mail sorting machines, automated planet exploration (for example, the rover vehicle, *Sojourner*, on the *Mars Pathfinder* mission), automated electric utility distribution systems, and automated bank teller machines. *See* Assembly machines; Computer-aided design and manufacturing;

COMPUTER-INTEGRATED MANUFACTURING; FLEXIBLE MANUFACTURING SYSTEM; INSPECTION AND TESTING; SPACE PROBE; WORD PROCESSING.

A major issue in the design of systems involving both human and automated machines concerns allocating functions between the two. This allocation can be static or dynamic. Static allocation is fixed; that is, the separation of responsibilities between human and machine do not change with time. Dynamic allocation implies that the functions allocated to human and machine are subject to change. Historically, static allocation began with reference to lists of activities which summarized the relative advantages of humans and machines with respect to a variety of activities. For example, at present humans appear to surpass machines in the ability to reason inductively, that is, to proceed from the particular to the general. Machines, however, surpass humans in the ability to handle complex operations and to do many different things at once, that is, to engage in parallel processing. Dynamic function allocation can be envisioned as operating through a formulation which continuously determines which agent (human or machine) is free to attend to a particular task or function. In addition, constraints such as the workload implied by the human attending to the task as opposed to the machine can be considered. *See* HUMAN-FACTORS ENGINEERING.

It has long been the goal in the area of automation to create systems which could react to unforeseen events with reasoning and problem-solving abilities akin to those of an experienced human, that is, to exhibit artificial intelligence. Indeed, the study of artificial intelligence is devoted to developing computer programs that can mimic the product of intelligent human problem solving, perception, and thought. For example, such a system could be envisioned to perform much like a human copilot in airline operations, communicating with the pilot via voice input and spoken output, assuming cockpit duties when and where assigned, and relieving the pilot of many duties. Indeed, such an automated system has been studied and named a pilot's associate. Machines exhibiting artificial intelligence obviously render the sharp demarcation between functions better performed by humans than by machines somewhat moot. While the early promise of artificial intelligence has not been fully realized in practice, certain applications in more restrictive domains have been highly successful. These include the use of expert systems, which mimic the activity of human experts in limited domains, such as diagnosis of infectious diseases or providing guidance for oil exploration and drilling. Expert systems generally operate by (1) replacing human activity entirely, (2) providing advice or decision support, or (3) training a novice human in a particular field. *See* EXPERT SYSTEMS. [R.A.He.]

Automobile A self-propelled land vehicle, usually having four wheels and an internal combustion engine, used primarily for personal transportation. Other types of motor vehicles include buses, which carry large numbers of commercial passengers, and medium- and heavy-duty trucks, which carry heavy or bulky loads of freight or other goods and materials. Instead of being carried on a truck, these loads may be placed on a semitrailer, and sometimes also a trailer, forming a tractor-trailer combination which is pulled by a truck tractor. *See* BUS; TRUCK.

The automobile body is the assembly of sheet-metal, fiberglass, plastic, or composite-material panels together with windows, doors, seats, trim and upholstery, glass, and other parts that form enclosures for the passenger, engine, and luggage compartments. The assembled body structure may attach through rubber mounts to a separate or full frame (body-on-frame construction), or the body and frame may be integrated (unitized-body construction). In the latter method, the frame, body parts, and floor pan are welded together to form a single unit that has energy-absorbing front and rear structures, and anchors for the engine, suspension, steering, and power-train components. A third type of body construction is the space frame which is made of welded steel stampings. Similar to the tube chassis and roll cage combination used in race-car construction, non-load-carrying plastic outer panels fasten to the space frame to form the body. *See* COMPOSITE MATERIAL; SHEET-METAL FORMING.

The frame is the main structural member to which all other mechanical chassis parts and the body are assembled to make a complete vehicle. In older vehicle designs, the frame is a separate rigid structure; newer passenger-car designs have the frame and body structure combined into an integral unit, or unitized body. Subframes and their assembled components attach to the side rails at the front and rear of the unitized body. The front subframe carries the engine, transmission or transaxle, lower front suspension, and other mechanical parts. The rear subframe, if used, carries the rear suspension and rear axle.

The suspension supports the weight of the vehicle, absorbs road shocks, transmits brake-reaction forces, helps maintain traction between the tires and the road, and holds the wheels in alignment while allowing the driver to steer the vehicle over a wide range of speed and load conditions. The action of the suspension increases riding comfort, improves driving safety, and reduces strain on vehicle components, occupants, and cargo. The springs may be coil, leaf, torsion bar, or air. Most automotive vehicles have coil springs at the front and either coil or leaf springs at the rear. *See* AUTOMOTIVE SUSPENSION.

The steering system enables the driver to turn the front wheels left or right to control the direction of vehicle travel. The rotary motion of the steering wheel is changed to linear motion in the steering gear, which is located at the lower end of the steering shaft. The linear motion is transferred through the steering linkage to the steering knuckles, to which the front wheels are mounted. Steering systems are classed as either manual steering or power steering, with power assist provided hydraulically or by an electric motor.

A brake is a device that uses a controlled force to reduce the speed of or stop a moving vehicle, or to hold the vehicle stationary. The automobile has a friction brake at each wheel. When the brake is applied, a stationary surface moves into contact with a moving surface. The resistance to relative motion or rubbing action between the two surfaces slows the moving surface, which slows and stops the vehicle.

The engine supplies the power to move the vehicle. The power is available from the engine crankshaft after a fuel, usually gasoline, is burned in the engine cylinders. Most automotive engines are located at the front of the vehicle and drive either the rear wheels or the front wheels through a drive train or power train made up of gears, shafts, and other mechanical and hydraulic components. Most automotive vehicles are powered by a spark-ignition four-stroke-cycle internal combustion engine. The inline four-cylinder engine and V-type six-cylinder engine are the most widely used, with V-8 engines also common. Other automotive engines have three, five, ten, and twelve cylinders. Some passenger cars and trucks have diesel engines. Some automotive spark-ignition and diesel engines are equipped with a supercharger or turbocharger. *See* AUTOMOTIVE ENGINE; DIESEL ENGINE; ENGINE; IGNITION SYSTEM; SUPERCHARGER; TURBOCHARGER.

Most automotive engines have electronic fuel injection instead of a carburetor. A computer-controlled electronic engine control system automatically manages various emissions devices and numerous functions of engine operation, including the fuel injection and spark timing. This allows optimizing power and fuel economy while minimizing exhaust emissions. *See* CARBURETOR; CONTROL SYSTEMS; FUEL INJECTION.

The power available from the engine crankshaft to do work is transmitted to the drive wheels by the power train, or drive train. In the front-engine rear-drive vehicle, the power train consists of a clutch and manual transmission, or a torque converter and an automatic transmission; driveshafts and Hooke (Cardan) universal joints; and rear drive axle that includes the final drive, differential, and wheel axle shafts. In the typical front-engine front-drive vehicle, the power train consists of a clutch and manual transaxle, or a torque converter and an automatic transaxle. The final drive and differential are designed into the transaxle, and drive the wheels through half-shafts with constant-velocity (CV) universal joints. *See* Clutch; Gear; Universal joint.

The transmission is the device in the power train that provides different forward gear ratios between the engine and drive wheels, as well as neutral and reverse. The two general classifications of transmission are manual transmission, which the driver shifts by hand, and automatic transmission, which shifts automatically. To shift a manual transmission, the clutch must first be disengaged. However, some vehicles have automatic clutch disengagement for manual transmissions, while other vehicles have a limited manual-shift capability for automatic transmissions. *See* Automotive transmission.

In the power train, the final drive is the speed-reduction gear set that drives the differential. The final drive is made up of a large ring gear driven by a smaller pinion, or pinion gear. This provides a gear reduction of about 3:1; the exact value can be tailored to the engine, transmission, weight of the vehicle, and performance or fuel economy desired.

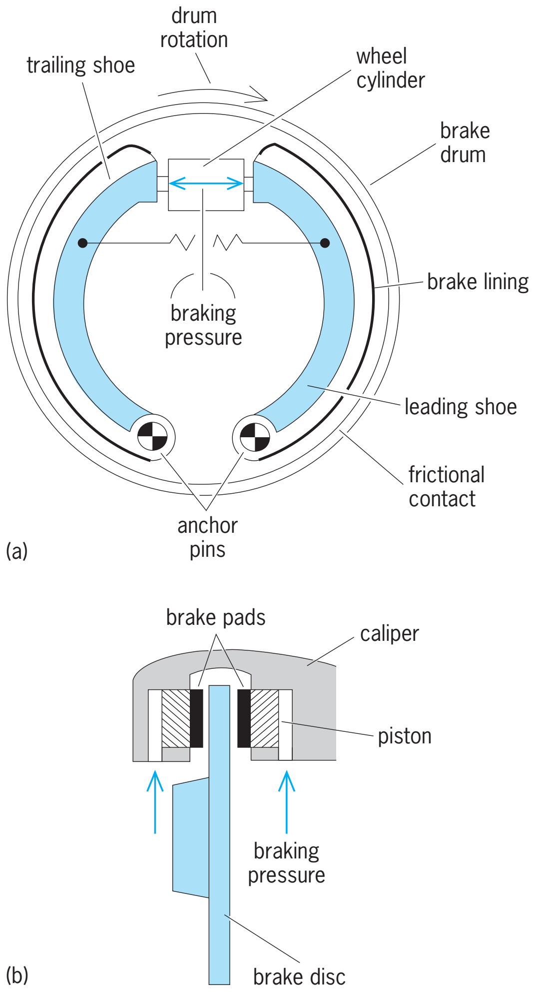
In drive axles, the differential is the gear assembly between axle shafts that permits one wheel to rotate at a speed different from that of the other (if necessary), while transmitting torque from the final-drive ring gear to the axle shafts. When the vehicle is cornering or making a turn, the differential allows the outside wheel to travel a greater distance than the inside wheel; otherwise, one wheel would skid, causing tire wear and partial loss of control. *See* Differential.

A wheel is a disc or a series of spokes with a hub at the center and a rim around the outside for mounting of the tire. The wheels of a vehicle must have sufficient strength and resiliency to carry the weight of the vehicle, transfer driving and braking torque to the tires, and withstand side thrusts over a wide range of speed and road conditions. Wheel size is primarily determined by the load-bearing strength of the tire.

The use of solid-state electronic devices in the automobile began during the 1960s, when the electromechanical voltage regulator of the alternator, was replaced by a transistorized voltage regulator. This was followed in the 1970s by electronic ignition, fuel injection, and cruise control. Since then, electronic devices and systems on the automobile have proliferated. These include engine and power train control, air bags, antilock braking, traction control, suspension and ride control, remote keyless entry, memory seats, driver information and navigation systems, cellular telephone and mobile communications systems, and onboard diagnostics. *See* Electronic display; Feedback circuit; Satellite navigation systems.

The self-diagnostic capability of the vehicle computer, powertrain or engine control module, or system controller may be aided by a memory that stores information about malfunctions that have occurred and perhaps temporarily disappeared. When recalled from the memory, this information can help the service technician diagnose and repair the vehicle more quickly, accurately, and reliably. [D.L.An.]

Automotive brake An energy conversion device used to slow a vehicle, stop it, or hold it in position. The two systems are the service brake and the parking brake, both of friction type. The service brake includes a hydraulically operated brake mechanism at each wheel. These wheel brakes are controlled by movement of the brake pedal, providing braking proportional to the applied pedal force. The parking brake is a mechanical brake operated through a separate hand lever or pedal; it applies parking-brake mechanisms usually at the two rear wheels. Most automotive vehicles have power-assisted braking, where a hydraulic or vacuum booster increases the force applied by the driver to the service-brake pedal. *See* Brake.



Friction brakes of (*a*) drum type and (*b*) disk type used in automotive vehicles. (*Robert Bosch Corp.*)

The two types of wheel-brake mechanisms are drum brakes and disk brakes (see illustration). Drum brakes are used at all four wheels on older vehicles, and at the rear wheels of many vehicles with front disk brakes. Some vehicles have disc brakes at all four wheels.

The four wheel brakes are hydraulically interconnected so they operate together from one control. When the driver depresses the brake pedal, pistons are forced into fluid chambers in the master cylinder. The resulting hydraulic pressure is transmitted through steel pipe and rubber hose to hydraulic cylinders in the wheel brakes. The pressure forces pistons in the cylinders to move outward, pushing brake friction material, or lining, into contact with the rotating drum or disk to apply the brakes. *See* Hydraulics.

In a drum brake, two nonrotating curved steel shoes, faced with heat- and wear-resistant lining, are forced against the inner surface of a rotating brake drum as the driver depresses the brake pedal. When the pedal is released, return springs pull the shoes away from the drum.

In a disk brake, a nonrotating caliper containing one or more pistons and carrying two brake pads, or lined flat shoes, straddles the rotating disk. As the driver depresses the brake pedal, the piston and hydraulic reaction push the brake pads against each side of the disk. When the brake pedal is released, the piston seal, which was deflected as the piston moved out, provides piston retraction. Two types of caliper are the fixed or nonmoving, and the floating or sliding. The floating or sliding type depends on slight inward movement of the caliper, resulting from hydraulic reaction, to force the outer brake pad against the disk.

Power-assisted braking is provided by a hydraulic or vacuum booster. As the brake pedal is depressed, the booster furnishes most of the force to push a pushrod into the master cylinder. The power piston in the hydraulic booster is operated by oil pressure from the power-steering pump or from a separate pump driven by an electric motor. In the vacuum booster, a diaphragm usually is suspended in a vacuum supplied from the engine intake manifold or from a vacuum pump driven by the engine or an electric motor. Depressing the brake pedal allows atmospheric pressure to act against one side of the diaphragm. The resulting pressure differential moves the diaphragm and power piston, which forces the pushrod into the master cylinder. [D.L.An.]

Automotive climate control A system for providing a comfortable environment within the passenger compartment of a vehicle. Controlled ventilation is utilized, along with a heater, an air conditioner, or an integrated heater and air-conditioner system. Linked to the setup is a windshield defrosting and defogging system capable of clearing the windshield. Some vehicles have a ventilation-air filter which cleans the outside air that enters the passenger compartment through the fresh-air inlet. The increasing glass area of many passenger vehicles places an additional load on the air conditioner. Many vehicles incorporate solar-control glass to reduce solar transmission to the interior.

Heating. There are two types of passenger-compartment heaters: engine-dependent and engine-independent. The engine-dependent heater utilizes waste heat from the engine. The engine-independent heater includes a small combustion chamber in which fuel is burned.

Most vehicles have a liquid-cooled engine and an engine-dependent heater through which hot engine coolant flows. The coolant passes through the tubes of a tube-and-fin heater core (see illustration) while air flows between the fins. Heat output into the passenger compartment is regulated by controlling either the coolant flow or the airflow. An electric blower motor may run at various speeds to help move the air. When the heater is turned off, a coolant flow-control valve may close to stop the flow of coolant through the heater core. *See* DEWAR FLASK; ENGINE COOLING.

Air conditioning. When the outside temperature is above 68°F (20°C), the passenger compartment may be uncomfortable for the occupants unless the inside air is cooled. Cooling is provided by a mobile, vehicle-mounted refrigeration system known as an automotive air conditioner. The automotive air conditioner combines the refrigeration system with an air-distribution system and a temperature-control system to cool, clean, dry, and circulate passenger-compartment air. Cooling is provided by a mechanical vapor-compression refrigeration system with five major components: compressor, condenser, refrigerant flow-control valve, evaporator, and a receiver or accumulator that includes a desiccant. *See* COMPRESSOR; DESICCANT; EVAPORATOR; FLUOROCARBON; HEAT EXCHANGER; REFRIGERATION.

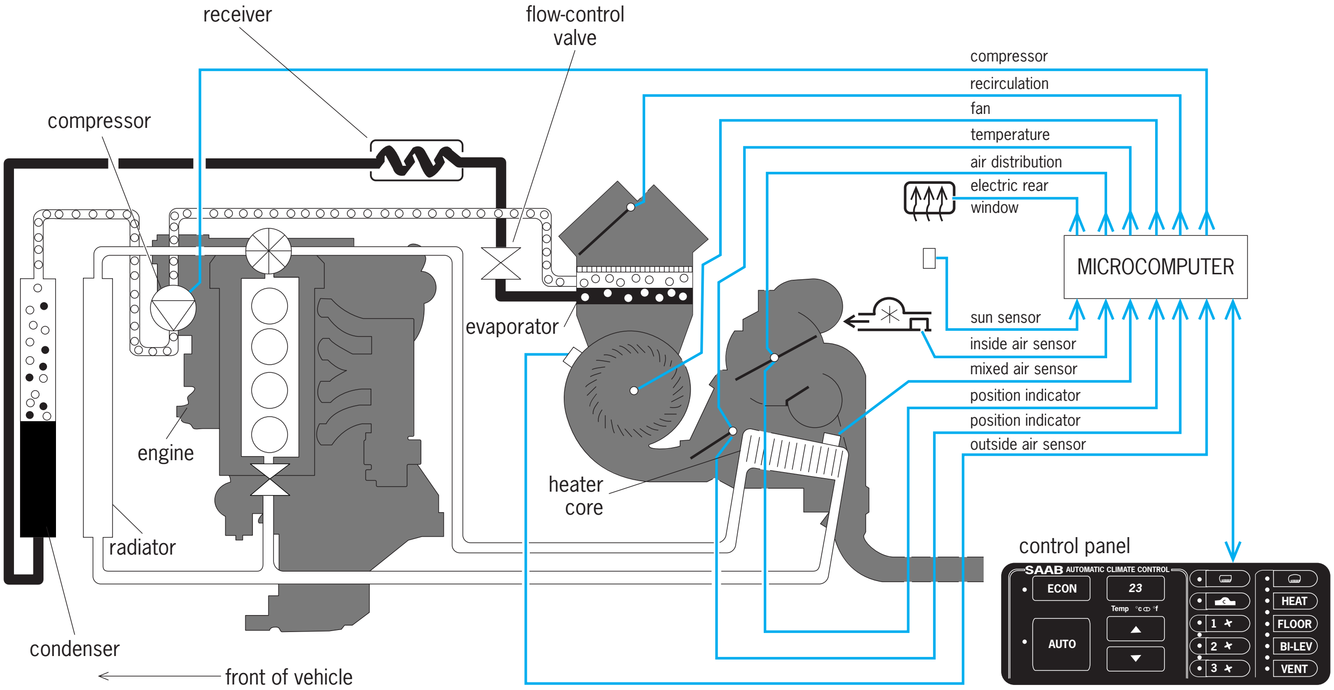
Operation, air temperature, and air distribution through the passenger compartment may be controlled either automatically or manually by the driver. In some vehicles, conditioned air distribution can be controlled for each seat or seating position. *See* AIR CONDITIONING. [D.L.An.]

Automotive drive axle A theoretical or actual crossbar or assembly which supports a motor vehicle and on which one or more wheels turn. The axle is either a live axle or a dead axle. A live axle, or drive axle, drives the wheels connected to it while supporting part of the weight of the vehicle. A dead axle, or nondrive axle, carries part of the weight of the vehicle but does not drive the wheels. *See* AUTOMOBILE.

A drive axle on which the wheels can pivot for steering, such as on the front axle of a four-wheel-drive truck, is a steerable drive axle. The rear axle in most automotive vehicles is a non-steering drive axle.

The rear drive axle is suspended from the vehicle body or frame by springs attached to the axle housing. The housing encloses the final-drive gears, differential gears, and wheel axle shafts. *See* AUTOMOTIVE SUSPENSION.

Most four-wheel-drive vehicles have a steerable front drive axle that is usually similar in construction and function to the rear drive axle. The principal difference is in the provisions made for steering. *See* AUTOMOTIVE STEERING.



Schematic of an automotive air conditioner. (*Saab Cars USA, Inc.*)

Automobiles with front-engine and front-wheel drive have independent front suspension and do not use a front drive-axle housing. Instead, a separate transaxle combines the functions of the transmission and the drive axle. *See* AUTOMOTIVE TRANSMISSION. [D.L.An.]

Automotive electrical system The system in a motor vehicle that furnishes the electrical energy to crank the engine for starting, recharge the battery after cranking, create the high-voltage sparks to fire the compressed air-fuel charges, and power the headlamps, light bulbs, and electrical accessories.

The vehicle electrical system includes the battery, wiring, starting motor and controls, generator and voltage regulator, electronic ignition, and electronic fuel metering. Also included may be a computerized electronic engine control system, an electronically displayed driver information system, various types of radios and sound systems, and many other electrically operated and electronically controlled systems and devices. *See* ALTERNATING-CURRENT GENERATOR; BATTERY; COMMUTATION; COMMUTATOR; COMPUTER; CONDUCTOR (ELECTRICITY); CONTROL SYSTEMS; CURRENT MEASUREMENT; DIRECT CURRENT; DIRECT-CURRENT MOTOR; ELECTRIC SWITCH; ELECTRONIC DISPLAY; ELECTRONICS; FUSE (ELECTRICITY); GENERATOR; PARALLEL CIRCUIT; REGULATOR; SPARK PLUG; SPEEDOMETER; STEPPING MOTOR; VOLTAGE REGULATOR. [D.L.An.]

Automotive engine The component of the motor vehicle that converts the chemical energy in fuel into mechanical energy for power. The automotive engine also drives the generator and various accessories, such as the air-conditioning compressor and power-steering pump. *See* AUTOMOTIVE CLIMATE CONTROL; AUTOMOTIVE ELECTRICAL SYSTEM; AUTOMOTIVE STEERING.

Otto-cycle engine. An Otto-cycle engine, the dominant automotive engine in use today, is an internal combustion piston engine that may be designed to operate on either two strokes or four strokes of a piston that moves up and down in a cylinder. Generally, the automotive engine uses four strokes to convert chemical energy to mechanical energy through combustion of gasoline or similar hydrocarbon fuel. The heat produced is converted into mechanical work by pushing the piston down in the cylinder. A connecting rod attached to the piston transfers this energy to a rotating crankshaft. *See* GASOLINE; INTERNAL COMBUSTION ENGINE; OTTO CYCLE.

Engines having from 1 to 16 cylinders in in-line, flat, horizontally opposed, or V-type cylinder arrangements have appeared in production vehicles. Increased vehicle size and weight played a major role in this transition, requiring engines with additional displacement and cylinders to provide acceptable performance. *See* ENGINE.

In many automotive engines, the camshaft, which operates the intake and exhaust valves, has been moved from the cylinder block to the cylinder head. This overhead-camshaft arrangement allows the use of more than two valves per cylinder, with various multivalve engines having three to five. Some overhead-camshaft engines have only one camshaft, while others have two camshafts, one for the intake valves and one for the exhaust valves. A V-type engine may have four camshafts, two for each bank of cylinders.

Most engines have fixed valve timing, regardless of the number of camshafts or their location. Variable valve timing can improve fuel economy and minimize exhaust emissions, especially on multivalve engines. At higher speeds, volumetric efficiency can be increased by opening the intake valves earlier. One method drives the camshaft through an electrohydraulic mechanism that, on signal from the engine computer, rotates the intake camshaft ahead about 10°. Another system varies both valve timing and valve lift by having two cam lobes, each with a different profile, that the computer can selectively engage to operate each valve. Computer-controlled solenoids for opening and closing the valves will allow elimination of the complete valve train, including the camshaft, from the automotive piston engine while providing variable valve timing and lift.

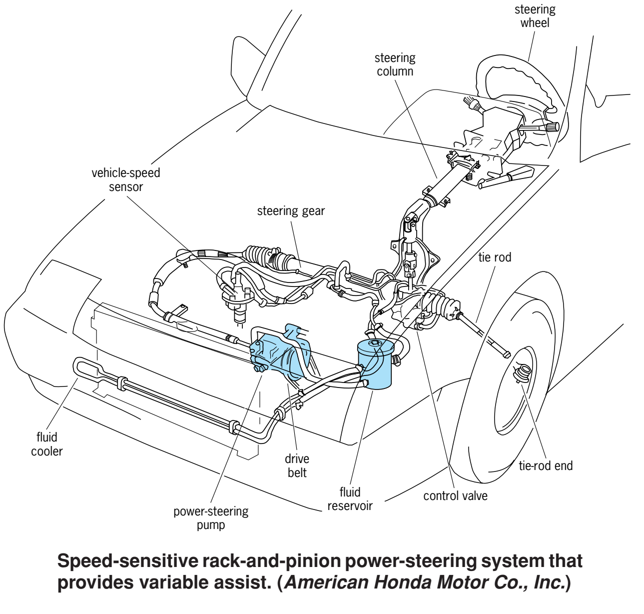
Alternative engines. Alternative engine designs have been investigated as replacements for the four-stroke Otto-cycle piston engine, including the two-stroke, diesel, Stirling, Wankel rotary, gas turbine, and steam engines, as well as electric motors and hybrid power plants. However, only two engines are in mass production as automotive power plants: the four-stroke gasoline engine described above, and the diesel engine. *See* DIESEL ENGINE; ROTARY ENGINE; STIRLING ENGINE. [D.L.An.]

Automotive steering The means by which a motor vehicle is controlled about the vertical axis. It allows the driver to control the course of vehicle travel by turning the steering wheel, which turns the input shaft in the steering gear. The steering system has three major components: (1) the steering wheel and attached shaft in the steering column which transmit the driver's movement to the steering gear; (2) the steering gear that increases the mechanical advantage while changing the rotary motion of the steering wheel to linear motion; and (3) the steering linkage (including the tie rod and tie-rod ends) that carries the linear motion to the steering-knuckle arms. *See* MECHANICAL ADVANTAGE.

When the only energy source for the steering system is the force that the driver applies to the steering wheel, the vehicle has manual steering. When the driver's effort is assisted by hydraulic pressure from an electric or engine-driven pump, or by an electric motor, the vehicle has power-assisted steering, commonly known as power steering. Power steering allows manual steering to always be available, even if the engine is not running or the power-assist system fails.

Two types of automotive steering gears are rack-and-pinion and recirculating-ball. In a rack-and-pinion steering gear (see illustration), a tubular housing contains the toothed rack and a pinion gear. The housing is mounted rigidly to the vehicle body or frame to take the reaction to the steering effort. The pinion gear is attached to the lower end of the steering shaft, and meshes with rack teeth. Tie rods connect the ends of the rack to the steering-knuckle arms at the wheels. As the steering wheel turns, the pinion gear moves the rack right or left. This moves the tie rods and steering-knuckle arms, which turn the wheels in or out for steering.

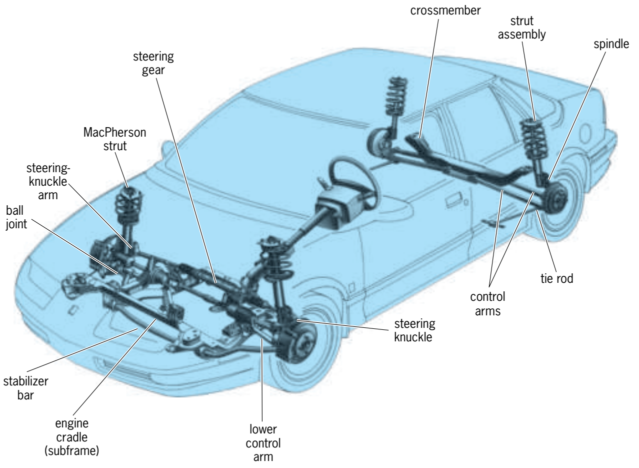
In a recirculating-ball steering gear, a worm gear is attached to the lower end of the steering shaft. The worm gear turns inside a ball nut which rides on a set of recirculating ball bearings. These



Speed-sensitive rack-and-pinion power-steering system that provides variable assist. (*American Honda Motor Co., Inc.*)

ball bearings roll in the grooves in the worm and inside the ball nut. Gear teeth on one outside flat of the ball nut mesh with a sector of teeth on the output or sector shaft to which the pitman arm is attached. As the steering wheel is turned, the rotary motion of the worm gear causes the ball nut to move up or down, forcing the sector shaft and pitman arm to rotate. This action moves the steering linkage to the right or left, turning the front wheels in or out for steering. *See* Antifriction bearing; Gear. [D.L.An.]

Automotive suspension The springs and related parts intermediate between the wheels and the frame, subframe, or side rails of a unitized body. The suspension supports the weight of the upper part of a vehicle on its axles and wheels, allows the vehicle to travel over irregular surfaces with a minimum of up-and-down body movement, and allows the vehicle to corner with minimum roll or loss of traction between the tires and the road. *See* Automobile; Spring (machines).



Front-wheel-drive car with MacPherson-strut front suspension and strut-type independent rear suspension. (*Saturn Corp.*)

In a typical suspension system for a vehicle with front-engine and front-wheel drive (see illustration), the weight of the vehicle applies an initial compression to the coil springs. When the tires and wheels encounter irregularities in the road, the springs further compress or expand to absorb most of the shock. The suspension at the rear wheels is usually simpler than for the front wheels, which require multiple-point attachments so the wheels can move up and down while swinging from side to side for steering.

A telescoping hydraulic damper, known as a shock absorber, is mounted separately or in the strut at each wheel to restrain spring movement and prevent prolonged spring oscillations. The shock absorber contains a piston that moves in a cylinder as the wheel moves up and down with respect to the vehicle body or frame. As the piston moves, it forces a fluid through an orifice, imposing a restraint on the spring. Spring-loaded valves open to permit quicker flow of the fluid if fluid pressure rises high enough, as it may when rapid wheel movements take place. Most automotive vehicles use gas-filled shock absorbers in which the air space above the fluid is filled with a pressurized gas such as nitrogen. The gas pressure on the fluid reduces the creation of air bubbles and foaming. *See* Shock absorber.

Most automotive vehicles have independent front suspension, usually using coil springs as part of either a short-arm long-arm or a MacPherson-strut suspension system. A MacPherson-strut suspension (see illustration) combines a coil spring and shock absorber into a strut assembly that requires only a beam-type lower control arm.

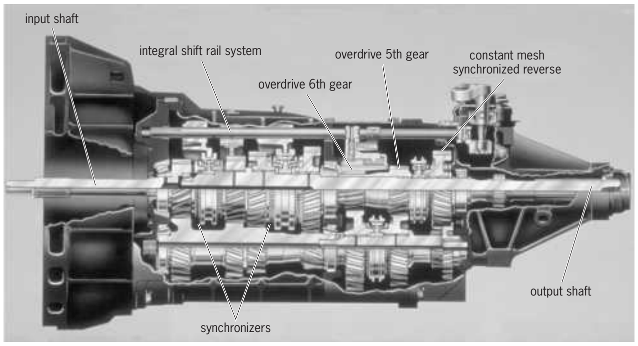
Some vehicles with short-arm long-arm front suspension use either longitudinal or transverse torsion bars for the front springs. One end of the torsion bar is attached to the lower control arm, and the other end is anchored to the vehicle body or frame. As the tire and wheel move up and down, the torsion bar provides springing action by twisting about its long axis. Turning an adjustment bolt at one end of the torsion bar raises or lowers the vehicle ride height. *See* Torsion bar.

Most automobiles and many light trucks have coil springs at the rear. These may mount on the rear drive axle, on struts, or on various types of control or suspension arms in an independent suspension system. Some rear-drive vehicles have leaf springs at the rear. Others use transverse torsion bars. [D.L.An.]

Automotive transmission The device in the power train of a motor vehicle that provides different gear ratios between the engine and drive wheels, as well as neutral and reverse. An internal combustion engine develops relatively low torque at low speed and maximum torque at only one speed, with the crankshaft always rotating in the same direction. To meet the tractive-power demand of the vehicle, the transmission converts the engine speed and torque into an output speed and torque in the selected direction for the final drive. This arrangement permits a smaller engine to provide acceptable performance and fuel economy while moving the vehicle from standstill to maximum speed. The transmission may be a separate unit as in front-engine rear-drive vehicles or may be combined with the drive axle to form a transaxle as in most front-drive vehicles. *See* Automobile; Automotive drive axle; Differential.

The two general classifications are manual transmissions that the driver shifts by hand after disengaging the foot-operated clutch, and automatic transmissions that shift with no action by the driver. However, manual transmissions can have a clutch that is automatically disengaged by an actuator when the driver moves the shift lever, and automatic transmissions can have manual-shift capability which allows the driver to select the shift to the next lower or higher gear ratio by movement of the shift lever. *See* Clutch.

The manual transmission is an assembly of gears, shafts, and related parts contained in a metal case or gearbox partially filled with lubricant. The transmission input shaft connects through the clutch and flywheel to the engine crankshaft (see illustration). The transmission output shaft connects through a driveshaft to the final-drive gearing in the drive axle. To get the vehicle into motion, reduction or underdrive gearing in the transmission allows the engine crankshaft to turn fast while the drive wheels turn much more slowly but with greatly increased torque. As the vehicle accelerates, and less torque and more speed are needed, the driver shifts the transmission into successively lower numerical gear ratios, known as higher gears. In a typical five-speed manual transmission, gear ratios are approximately 3.35:1 for first gear, 2:1 for second gear, 1.35:1 for third gear, 1:1 (direct drive) for fourth gear, and 0.75:1 (overdrive) for fifth gear. Most transmissions with four or more forward speeds are operated by a floor-mounted shift lever. *See* Gear; Gear train.



Six-speed manual transmission for a rear-drive car. (*Pontiac-GMC Division, General Motors Corp.*)

Automatic transmission provides automatic control of drive-away, gear-ratio selection, and gear shifting through four or five forward speeds. A typical automotive automatic transmission includes a hydrodynamic three-element torque converter with locking clutch, a planetary-gear system that provides overdrive in fourth or higher gear, and a hydraulic or electrohydraulic control system. Shifts are made without loss of tractive power. *See* Hydraulics; Hydrodynamics; Planetary gear train; Torque converter. [D.L.An.]

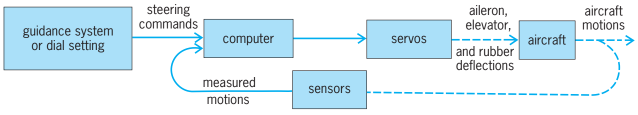
Autonomic nervous system The part of the nervous system that innervates smooth and cardiac muscle and the glands, and regulates visceral processes including those associated with cardiovascular activity, digestion, metabolism, and thermoregulation. The autonomic nervous system functions primarily at a subconscious level. It is traditionally partitioned into the sympathetic system and the parasympathetic system, based on the region of the brain or spinal cord in which the autonomic nerves have their origin. The sympathetic system is defined by the autonomic fibers that exit thoracic and lumbar segments of the spinal cord. The parasympathetic system is defined by the autonomic fibers that either exit the brainstem via the cranial nerves or exit the sacral segments of the spinal cord. *See* Parasympathetic nervous system; Sympathetic nervous system.

The defining features of the autonomic nervous system were initially limited to motor fibers innervating glands and smooth and cardiac muscle. This definition limited the autonomic nervous system to visceral efferent fibers and excluded the sensory fibers that accompany most visceral motor fibers. Although the definition is often expanded to include both peripheral and central structures (such as the hypothalamus), contemporary literature continues to define the autonomic nervous system solely as a motor system. However, from a functional perspective, the autonomic nervous system includes afferent pathways conveying information regarding the visceral organs and the brain areas (such as the medulla and the hypothalamus) that interpret the afferent feedback and exert control over the motor output back to the visceral organs. *See* Homeostasis. [S.W.P.]

Autopilot An automatic means for steering an aircraft or other vehicle. The original use of an autopilot, or automatic pilot, was to provide pilot relief during cruise modes. Autopilots now perform functions more rapidly and with greater precision than the human pilot. The functions, designs, and uses of autopilots vary widely depending on the type of vehicle. In addition to controlling various types of aircraft and spacecraft, autopilots are used to control ships or sea-based vehicles and in some cases land-based vehicles. This article discusses autopilots used in aircraft and space vehicles.

An autopilot is unique equipment in that it is expected to make the aircraft fly in the same manner as a highly trained, proficient pilot. It must provide smooth control and avoid sudden and erratic behavior. The intelligence for control must come from sensors such as gyroscopes, accelerometers, altimeters, airspeed indicators, automatic navigators, and various types of radio-controlled data links. The autopilot supplies the necessary scale factors, dynamics (timing), and power to convert the sensor signals into control surface commands. These commands operate the normal aerodynamic controls of the aircraft. *See* Accelerometer; Aircraft instrumentation; Altimeter; Gyroscope; Inertial guidance system.

Autopilots come in varying degrees of sophistication. A simple attitude hold (wing leveler) just barely justifies the term autopilot, while a top-of-the-line system that automatically takes the aircraft from one location to another exceeds the normal capabilities of an autopilot. Sophisticated autopilots are no longer limited to military aircraft but are now common in commercial aircraft and are available for general aviation. In modern fly-by-wire aircraft the autopilot and the flight control system often reside together in the same digital computer, and it is difficult to separate their functions. These advanced systems provide the pilot relief functions plus help to stabilize the aircraft, protect the aircraft from undesirable maneuvers, and provide automatic landings (in some cases on a moving ship). Research aircraft are being tested with backup automatic control concepts that continue to control the aircraft even if the primary controls are damaged and no longer function. *See* Flight controls.



Basic elements of an autopilot system.

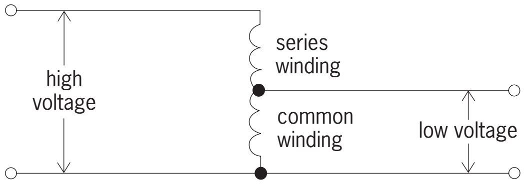
Aircraft motion is usually sensed by a gyro, which transmits a signal to a computer (see illustration). The computer commands a control servo to produce aerodynamic forces to remove the sensed motion. The computer may be a complex digital computer, an analog computer (electrical or mechanical), or a simple summing amplifier, depending on the complexity of the autopilot. The control servo can be a hydraulically powered actuator or an electromechanical type of surface actuation. Signals can be added to the computer that supply altitude commands or steering commands. For a simple autopilot, the pitch loop controls the elevators and the roll loop controls the aileron. A directional loop controlling the rudder may be added to provide coordinated turns. *See* Aileron; Amplifier; Analog computer; Control systems; Digital computer; Elevon; Guidance systems; Servomechanism. [L.L.K.]

Autoradiography A photographic technique used to localize a radioactive substance within a solid specimen; also known as radioautography.

A photographic emulsion is placed in contact with the object to be tested and is left for several hours, days, or weeks, depending on the suspected concentration of the radioactive material to be measured. The emulsion, which is a gel containing silver halide, is then developed, fixed, and washed as in the usual photographic process. At sites where the emulsion was close enough to the radioactive substance, it appears dark because of the presence of silver grains. When the number of grains is insufficient to darken the film to the unaided eye, the film may be examined with the aid of a microscope. The individual silver grains may then be seen. The pattern formed by the grains depends on the type of radiation and the nature of the photographic emulsion. Alpha particles produce short, straight rows or tracks of grains. Beta particles as well as x-rays and gamma rays, which affect film by producing beta particles, produce tortuous tracks whose lengths and grain densities depend on the energy of the beta particles. Low-energy particles produce shorter tracks with higher grain densities. Very low energy particles like those from tritium (3-hydrogen) may produce only a single grain very close to the site of decay.

Autoradiography can be used to detect, and measure semi-quantitatively, the radioactive materials in almost any object that can be placed in contact with film or photographic emulsion in some form. However, in biological research the object may be (1) a whole plant or animal that can be flattened against a film; (2) the cut surface of a plant or animal, or one of its organs; (3) thin sections of tissues or cells; (4) squashed or otherwise flattened cells; (5) surface films produced by spreading on water the protein monolayers containing DNA or ribonucleic acid (RNA) that are picked up on grids for electron microscopy; (6) sheets of paper or other materials on which radioactive substances have been separated by chromatography or electrophoresis; or (7) acrylamide gels in which DNA, RNA, or proteins have been separated by electrophoresis. *See* Radiography. [J.H.T.]

Autotransformer A special form of transformer having one winding, a portion of which is common to both the primary and the secondary circuits. The current in the high-voltage circuit flows through the series and common windings (see illustration).



Typical autotransformer circuit.

The current in the low-voltage circuit flows through the common winding and adds vectorially to the current in the high-voltage circuit to give the common winding current. Thus, an electrical connection exists between high-voltage and low-voltage windings. Because of this sharing of parts of the winding, an autotransformer having the same kilovolt-ampere (kVA) output rating is generally smaller in weight and dimensions than a two-winding transformer. One possible disadvantage of autotransformers is that the windings are not insulated from each other and that the autotransformer provides no isolation of the primary and secondary circuits.

Autotransformers of large sizes are used for interconnecting high-voltage power systems. They are used in small sizes for intermittent-duty starting of motors. For this use the motor is connected for a short time to the common winding voltage, and then connected to the full line voltage. Small, variable-ratio autotransformers are used in testing and as components of other apparatus. [J.R.Su.]

Autoxidation The slow, flameless combustion of materials by reaction with oxygen; it is sometimes spelled autooxidation. Autoxidation is important because it is a useful reaction for converting compounds to oxygenated derivatives, and also because it occurs in situations where it is not desired (as in the destructive cracking of the rubber in automobile tires). *See* COMBUSTION; OXIDATION PROCESS.

Although virtually all types of organic materials can undergo air oxidation, certain types are particularly prone to autoxidation, including unsaturated compounds that have allylic hydrogens or benzylic hydrogens; these materials are converted to hydroperoxides by autoxidation.

Autoxidation is a free-radical chain process. Such reactions can be divided into three stages: initation, propagation, and termination. In the initiation process, some event causes free radicals to be formed. For example, free radicals can be produced purposefully by the decomposition of a free-radical initiator, such as benzoyl peroxide. In some cases, initiation occurs by a process that is not well understood but is thought to be the spontaneous reaction of oxygen with a material with a readily abstractable hydrogen. Destructive autoxidation processes also are initiated by pollutants such as those in smog.

Once free radicals are formed, they react in a chain to convert the material to a hydroperoxide. The chain is ended by termination reactions in which free radicals collide and combine their odd electrons to form a new bond. *See* FREE RADICAL; ORGANIC REACTION MECHANISM.

Autoxidation is a process of enormous economic impact, since all foods, plastics, gasolines, oils, rubber, and other materials that must be exposed to air undergo continuous destructive reactions of this type. All plastics and rubber and most processed foods contain antioxidants to protect them against the attack of oxygen. *See* ANTIOXIDANT; FAT AND OIL (FOOD); FOOD MANUFACTURING; PLASTICS PROCESSING; RUBBER. [Wi.A.P.]

Auxin Any of a group of organic compounds which, when applied in low concentration, are able to promote elongation growth of plant shoots excised from a growing region of a young seedling. The ability to increase the rate of shoot elongation is a key to the designation of a synthetic or naturally occurring compound as an auxin. However, auxins, and the other plant hormones, influence a variety of plant processes during various stages of plant development.

The major naturally occurring auxin, indole-3-acetic acid (IAA) has been found in almost all plant tissues that have been studied. It occurs in minute quantity, usually in less than micromolar amounts. Auxins occur in plant tissue in several chemical forms. They may occur as the free active hormone (such as indoleacetic acid), and they may also be present in plant tissue as a number of so-called bound auxins. The bound forms are auxins linked by a covalent chemical bond to some other chemical compound. These bound forms are thought to be important reserve forms which function to regulate the levels of free hormone in tissue, especially during certain developmental stages such as seedling growth. In addition, it is possible that the compound to which the auxin is linked (usually a sugar or an amino acid) is important in the transport of the hormone within the plant. Conjugation also renders the auxin immune to many of the enzymes which would normally degrade the free auxin.

Auxin responses in plant tissue can be artificially divided into two groups, based on the time of their appearance. First, there are a number of very rapid responses which can be measured within minutes after the addition of auxin. Included in these responses are auxin-induced increases in protoplasmic streaming, cell elongation, and an increase in the acidity of the cell-wall free space. The second group of responses includes the long-term effects in which the observable response can be measured only after hours or even days of hormone treatment. Examples of these responses are auxin-induced increases in ribonucleic acid and protein synthesis, initiation of xylem differentiation, and an inhibition of lateral bud growth.

The generalized model for auxin action begins when a membrane receptor responds to auxin by releasing phosphoinositides from the pool of membrane-bound phospholipids. These signals are carried through the cytosol and initiate release of calcium stored in vacuole and endoplasmic reticulum compartments. This sudden increase in calcium initiates a response from at least two cell systems. First, the active removal of calcium from cytosol back to the vacuole is begun through the pumping of calcium in exchange for protons in the vacuole. These protons are in turn pumped out of the cytosol and into the cell-wall where acidification occurs. Second, the increase of calcium in cytosol acts to stimulate enzymes known as protein kinases which modify other proteins by phosphorylation. One protein that is modified by phosphorylation in this way is the proposed auxin-binding protein mediator that becomes receptive to auxin and can thus act on plant DNA to promote transcription of mRNAs that are critical for enzymes involved in cell growth.

The most widespread agricultural use of auxins is for weed and vegetation control. Synthetic auxins, such as 2,4-D and 2,4,5-trichlorophenoxy-acetic acid (2,4,5-T) and their homologs, are commonly used as herbicides. Synthetic auxins have found practical use for other agricultural needs as well. For example, auxin applications are effective for floral thinning of overproductive orchard trees. Synthetic auxins have also been used to prevent premature fruit drop and to improve fruit quality in tree crops. Auxin treatments have been used to enhance rooting of over 1000 different plant species, and have been applied on a practical scale to over 30 different species throughout the world. Auxin preparations designed to enhance root formation in cuttings are also available for home use. The production of large numbers of genetically identical (clonal) plants is now possible by use of plant cell culture techniques. Additions of auxins as well as another type of plant hormone, cytokinin, are usually necessary for the growth of such cultures. In addition, ongoing research on the production of new varieties of agriculturally important plants, using the emerging techniques of molecular biology, rely on cell culture methods and a detailed knowledge of the role of auxins and other plant hormones in the developmental life of plants. *See* CYTOKININS; HERBICIDE; MOLECULAR BIOLOGY; PLANT GROWTH; PLANT HORMONES; TISSUE CULTURE. [J.D.Coh.; B.G.Ba.]

Avalanche In general, a large mass of snow, ice, rock, earth, or mud in rapid motion down a slope or over a precipice. In the English language, the term avalanche is reserved almost exclusively for snow avalanche. Minimal requirements for the occurrence of an avalanche are snow and an inclined surface, usually a mountainside. Most avalanches occur on slopes between 30 and 45°.

Two basic types of avalanches are recognized according to snow cover conditions at the point of origin. A loose-snow avalanche originates at a point and propagates downhill by successively dislodging increasing numbers of poorly cohering snow grains, typically gaining width as movement continues downslope. This type of avalanche commonly involves only those snow layers near the surface. The mechanism is analogous to dry sand. The second type, the slab avalanche, occurs when a distinct cohesive snow layer breaks away as a unit and slides because it is poorly anchored to the snow or ground below. A clearly defined gliding surface as well as a lubricating layer may be identifiable at the base of the slab, but the meteorological conditions which create these layers are complex.

In the case of the loose avalanche, release mechanisms are primarily controlled by the angle of repose, while slab releases involve complex strength-stress problems. A release may occur simply as a result of the overloading of a slope during a single snowstorm and involve only snow which accumulated during that specific storm, or it may result from a sequence of meteorological events and involve snow layers comprising numerous precipitation episodes. Most large snow slides are believed to be caused by an unstable layer of ice grains that develop deep in mountain snow. Called depth hoar by students of avalanche dynamics, these crystals owe their formation to heat from earth and rock which are buried by the snow, and which in late autumn are warmer than the surrounding air. Snow nearest the ground vaporizes, causing growth of angular ice grains that exhibit poor bonding qualities. Gravity combining with the weakness of the depth hoar crystals loosens the upper stable layers. Once the stable layers begin to slide, the depth hoar acts in a manner similar to ball beatings to speed the descent of the slide.

Where snow avalanches constitute a hazard, that is, where they directly threaten human activities, various defense methods have evolved. Attempts are made to prevent the avalanche from occurring by artificial supporting structures or reforestation in the zone of origin. The direct impact of an avalanche can be avoided by construction of diversion structures, dams, sheds, or tunnels. Hazardous zones may be temporarily evacuated while avalanches are released artificially, most commonly by explosives. Finally, attempts are made to predict the occurrence of avalanches by studying relationships between meteorological and snow cover factors. [R.L.A.]

Aves Modern birds are a class of vertebrates characterized by being feathered, warm-blooded (endothermic), and bipedal (two-legged); and by having very high metabolic rates and a forelimb modified into a wing which, together with a long tail, forms part of a flight mechanism. Such a definition, however, as with any group of vertebrates, characterizes the living forms and is blurred by the fossil record, which contains species with characteristics close to those of the reptilian ancestors of birds. The feathers of birds are filamentous, lightweight modifications of the outer skin that have remarkable aerodynamic qualities. They serve not only as flight structures by generating lift and thrust but also as insulation to maintain high body temperatures. In addition, birds have lightweight hollow bones, a well-developed air-sac system and flow-through lungs, a wishbone or furcula (fused clavicles), and a hand reduced to three digits (comparable to digits 2, 3, and 4 of the human hand). Birds are known to have evolved from some group of reptiles within the larger group of ancient diapsid reptiles known as archosaurs. However, debate still centers on whether they are derived from a common ancestor with the theropod (meat-eating) dinosaurs (a group known as basal archosaurs), or later in time directly from theropod dinosaurs.

Feathers are unique to birds. These lightweight structures made of keratin are the most complex appendages produced by the skin of any vertebrate. The bird wing comprises two sets of flight feathers, the outer primary feathers which are attached to the hand, and the inner secondary feathers which are attached to the ulna. The vanes of the wing feathers are asymmetric with a smaller outer vane and larger inner vane, producing lift in flight. The body feathers provide small aerodynamic contours which result in laminar airflow in flight. Most of the vane is stiff and tightly bound, like flight feathers. However, the basal portion can by fluffed up to trap body heat next to the skin. In warm conditions the body feathers can be flattened to allow heat to escape. Thus, feathers form an insulatory pelt to cover the surface of the avian body. The tail feathers resemble the flight feathers of the wing and provide lift in flight. The tail feathers of modern birds are attached to a specialized bone known as the pygostyle, which is formed by a number of fused tail vertebrae. The pygostyle (sometimes called the plowshare bone) also accommodates the uropygial gland, or oil gland, an essential part of the anatomy of birds that provides a rich waterproofing oil for preening the feathers. In addition to their primary functions of flight and insulation, feathers can serve other functions, ranging from the production of color patterns and structural forms that allow for species recognition and courtship displays, to color patterns that serve a cryptic purpose for protection. *See* FEATHER.

The once-toothed jaws of birds have evolved into the lighter beak in which the upper and lower jaws are covered by a horny rhamphotheca, which may vary in texture from the rock-solid beaks of predatory raptors to relatively soft beaks of shorebirds and ducks. Beaks have a great variety of adaptive forms, including the flesh-tearing hooked beaks of hawks and eagles, the filter-feeding straining beaks of flamingos and ducks, the fish-trapping beaks of pelicans, the climbing and nut-cracking beaks of parrots, the hammering beaks of woodpeckers, and the seed-eating beaks of finches. Birds have developed a muscular gizzard (also found in their relatives, crocodiles and dinosaurs) for grinding and processing food into small pieces. The grinding is often assisted by the addition of gizzard stones, which are ingested.

Birds have varied feet. The most primitive avian foot, found in the earliest known bird, *Archaeopteryx*, is the perching foot also found in most modern tree-dwelling birds. Three toes point forward, and a reversed first toe, or hallux, opposes them in perching on a branch. This type of foot is called anisodactyl. Other modifications include the zygodactyl feet of woodpeckers with two forward and two rearward pointing toes, and the webbed feet of ducks with the three forward pointing toes united by a web that serves as a paddle. The varied birds in the order Pelecaniformes have a foot in which all four toes are united by webbing, a totipalmate foot. Ostriches are unique in the bird world in having a foot with only two toes. The ankle and foot bones are fused and elongated in birds, so that the avian leg consists of a femur, tibiotarsus, and fibula, then a fusion of three bones into a tarsometatarsus, and finally the toes. Thus, birds walk on their toes, and the equivalent to the human foot is a long bone, the tarsometatarsus, which is off the ground.

Birds have keen senses of vision and hearing. The sense of smell (olfaction) is not particularly well developed, although in some birds there is a good sense of smell. Birds have developed a flow-through lung and an extensive air-sac system. Modern flying birds have a well-developed sternum with a keel, or carina, for the attachment of the large flight musculature.

Birds are found over the entire Earth. One of the most intriguing aspects of bird biology is the ability to migrate exceptional distances. Birds possess highly specialized directional senses for orientation, navigation, homing, and migration, including the ability to detect the Earth's magnetic field. These uncanny abilities permit birds to occupy distinctive wintering and nesting grounds, thus expanding their usable habitats. Some migrations, such as that of the Arctic tern, involve a circumatlantic migration from Alaska to the South Pole. *See* FLIGHT.

There are some 9700 species of birds living today, and most species are particularly well known. However, the relationships of the higher categories of birds are still debated. Of the 9700 species, some 5000 species belong to the order Passeriformes, the perching birds or songbirds. The number of avian orders is still controversial, and texts show different arrangements. Because the situation is in flux, a fairly conservative system is used below (fossil groups are designated by a dagger). *See* PASSERIFORMES.

- Class Aves
  - Subclass Sauriurae
    - Infraclass Archaeopterygiformes†
      - Order Archaeopterygiformes (late Jurassic reptile-birds)†
      - Order Confuciusornithiformes (lower Cretaceous, beaked reptile-birds)†
    - Infraclass Enantiornithes (archaic Mesozoic land birds)
  - Subclass Ornithuriae
    - Infraclass Odontornithes (or Odontoholcae)†
      - Order Hesperornithiformes (Cretaceous toothed divers)†
    - Infraclass Neornithes (or Carinata)
  - Superorder Ambiortimorphae (gull-like, Mesozoic toothed birds)†
  - *Incertae sedis* (*Gansus*, *Chaoyangia*, etc., archaic modern-type birds)†
  - Palaeognathae (ostrich and allies)
  - Neognathae (modern birds)
    - Order: Sphenisciformes (penguins, 17 species)
      - Procellariiformes (tube-nose seabirds, 114)
      - Pelecaniformes (pelicans and allies, 66)
      - Ciconiiformes (storks and allies, 86)
      - Falconiformes (hawks, eagles, and vultures, 309)
      - Galliformes (chickens and allies, 282)
      - Gruiformes (rails, cranes and allies, 214)
      - Podicipediformes (grebes, 22)
      - Charadriiformes (shorebirds, gulls and allies, 349)
      - Pteroclidiformes (sand grouse, 16)
      - Threskiornithiformes (ibis, spoonbills, 33)
      - Anseriformes (waterfowl, 161)
      - Phoenicopteriformes (flamingos, 5 or 6)
      - Gaviiformes (loons, 5)
      - Columbiformes (pigeons and doves, 316)
      - Psittaciformes (parrots, 360)
      - Coliiformes (mousebirds, 6)
      - Musophagiformes (turacos, or plaintain-eaters, 23)
      - Cuculiformes (cuckoos, 142)
      - Opisthocomiformes (hoatzin, 1)
      - Strigiformes (owls, barn owls, 173)
      - Caprimulgiformes (nightjars and allies, 116)
      - Apodiformes (hummingbirds and swifts, 425)
      - Trogoniformes (trogons, quetzals, 39)
      - Coraciiformes (kingfishers, bee-eaters and allies, 219)
      - Piciformes (woodpeckers and allies, 407)
      - Passeriformes (perching birds, songbirds, passerines, 5739)

The classification system presented above coordinates with most major treatises on birds. The subclass Sauriurae contains the archaic birds of the Mesozoic Era, the Age of Reptiles, which includes the toothed fossil *Archaeopteryx*, or *Urvogel*, the oldest known bird (150 million years ago). Other Mesozoic birds included the ancient ornithurine birds more closely allied with the modern radiation of birds, among them such forms as the hesperornithiforms, the Cretaceous toothed divers, which superficially resembled loons. They became extinct at the end of the Cretaceous along with their gull-like contemporaries, the Ambiortimorphae. Also included in this group is the Lower Cretaceous *Ambiortus* from Mongolia, which was a fully volant ornithurine bird about the size of a pigeon. It possessed a well-developed sternal keel and other features of the pectoral region typical of modern birds, indicating that true flying birds existed some 12 million years after the appearance of *Archaeopteryx*. *See* ARCHAEORNITHES; HESPERORNITHIFORMES; ICHTHYORNITHIFORMES.

The extinction of the dinosaurs 65 million years ago is now believed to have been due to the collision of a large extraterrestrial body, a meteor or some other object, with Earth, causing catastrophic effects, including the extinction of numerous bird species. It is likely that the very few types that survived, possibly related to shorebirds, were the wellspring of the modern evolution of birds; and modern birds, like their mammalian counterparts, probably evolved explosively during the early part of the Tertiary Period, perhaps over a period of some 5–10 million years. Among the first birds to appear were the strange *Diatrymas*, large, predatory, flightless birds that had a head the size of that of a horse. They are thought to have taken over the niche left vacant by predatory dinosaurs, and they fed on the small archaic mammals of the Paleocene and Eocene.

By the Eocene, approximately 50 million years ago, all the major orders of modern birds were present. By the Oligocene, most of the families were present, and by the Miocene, the genera of modern birds were well established. [A.Fe.]

Avian leukosis A complex of several related and unrelated viruses (both C-type retroviruses and herpesviruses) that are collectively responsible for a variety of benign and malignant neoplasms in chickens and, to a lesser extent, in other avian species. Although most neoplasms observed in avian species are induced by viruses, there are some of unknown etiology.

The neoplastic diseases induced by the leukosis-sarcoma group of retroviruses include lymphoid leukosis, myeloid or erythroid leukemias or solid tumors, tumors of connective tissue origin (for example, sarcomas, fibromas, and chondromas), epithelial carcinomas, and endothelial tumors. The many viral strains involved have similar physical and chemical characteristics and share a group-specific antigen; some can cause more than one type of neoplasm. The viruses are about 100 nanometers in diameter; have a core composed of ribonucleic acid; contain a reverse transcriptase; mature by budding from the cell membrane; and are divided into subgroups based on envelope glycoproteins. Some strains carry their own specific oncogenes that induce neoplasms within days or weeks. Others lack an oncogene and cause neoplasms less frequently and only after several months, probably by activating a specific cellular oncogene. *See* CANCER (MEDICINE); ONCOGENES; ONCOLOGY.

Lymphoid leukosis is the most important of the leukosis sarcoma diseases. The lymphoid leukosis virus is transmitted vertically from hen to chick through the egg. Infection can result in leukotic neoplasms in various visceral organs following metastasis from primary tumors in the bursa of Fabricius. Large-scale transmission of the lymphoid leukosis virus can be eradicated by eliminating individual infected breeders.

Reticuloendotheliosis virus strains constitute another retrovirus group, unrelated to the lymphoid-sarcoma group, and also may carry a specific oncogene. They can cause a chronic neoplastic form of reticuloendotheliosis or other neoplasms in turkeys, chickens, ducks, geese, quail, and pheasants, and a runting disease has been seen in chickens after accidental contamination of vaccines with reticuloendotheliosis virus.

Marek's disease in chickens is caused by an oncogenic, cell-associated, lymphotrophic, highly contagious herpesvirus. Inhalation of the virus causes an active infection in lymphoid organs; after about 1 week, a latent infection develops in lymphocytes. T-cell lymphomas may develop within a few weeks or months, depending on age, genetic makeup, virus virulence, and other factors. Degenerative, inflammatory and lymphoproliferative lesions occur principally in the peripheral nerves (causing paralysis), lymphoid tissues, visceral organs, muscle, and skin. Eye involvement (gray eye) can cause blindness. The disease is of great economic importance in chickens, and several vaccines, injected at 1 day of age, have been in worldwide use since about 1970. *See* ANIMAL VIRUS; TUMOR VIRUSES. [B.W.C.]

Aviation A general term including the science and technology of flight through the air. Aviation also applies to the mode of travel provided by aircraft as carriers of passengers and cargo, and as such is part of the total transportation system. Aviation also describes the employment of aircraft in such fields as military aviation. The world of the airplane, including the people who manufacture, market, and repair aircraft or who work in allied industries, is frequently spoken of as aviation. *See* AIRPLANE; MILITARY AIRCRAFT.

Aviation is broadly grouped into three classes: general aviation, air transport aviation, and military aviation. General aviation comprises all aviation not included in military or air-transport aviation. Military aviation includes all forms of aviation in military activities, and air-transport aviation is primarily the operation of commercial airlines essentially as a public utility for the movement of persons and commodities. *See* GENERAL AVIATION. [L.A.B.]

Avocado A tropical and subtropical fruit tree, *Persea americana*, in the Lauraceae family. It originated in Central America or adjoining regions of North or South America. It has now spread to much of the near-tropical world.

The species is divided into three horticultural races with differing commercial qualities. The so-called West Indian race is least tolerant of cold, the Mexican most tolerant, and the Guatemalan intermediate. This same gradation is found in salt tolerance (West Indian highest) and oil content (West Indian lowest). But in some other respects the West Indian race is intermediate (skin thickness), or one of the races is different from the other two (the West Indian fruit is less tolerant of cold storage; the Mexican has smaller fruit with a unique aniselike odor; the Guatemalan has a smaller seed ratio, and takes twice as long to mature—14 months or more in California).

Mexico is the world's leading producer, followed by Brazil and California, then Colombia and Venezuela, countries of eastern South America, Central America, Caribbean Islands, Florida, Philippines, and Zaire (central West Africa). South Africa and Israel have important export industries, primarily to Europe. Many other countries have begun development. The California industry is expanding rapidly, and the avocado has become one of the state's leading fruit crops. *See* FRUIT; FRUIT, TREE. [B.O.B.]

Avogadro number The number of elementary entities in one mole of a substance. A mole is defined as an amount of a substance that contains as many elementary entities as there are atoms in exactly 12 g of ^{12}C; the elementary entities must be specified and may be atoms, molecules, ions, electrons, other particles, or specified groups of such particles. Experiments give 6.0221367×10^{23} as the value of the Avogadro number. In most calculations the coefficient is rounded off to 6.02. Thus, a mole of ^{12}C atoms has 6.02×10^{23} carbon atoms, a mole of water molecules contains 6.02×10^{23} H_2O molecules, a mole of electrons contains 6.02×10^{23} electrons, and so forth. *See* MOLE (CHEMISTRY).

The atomic weight (relative atomic mass) of ^{12}C is exactly 12, by definition. Consider 12 g of ^{12}C (which is one mole and contains the Avogadro number of atoms) compared with 4 g of He, whose atomic weight is 4. The 12 g to 4 g ratio of the masses of the two samples is the same as the 12 to 4 ratio of the masses of the atoms of ^{12}C and He. Therefore the two samples must contain the same number of atoms, and 4 g of He contains the Avogadro number of atoms. The same argument holds for any element. Thus, for an element with atomic weight x, a sample with mass x grams contains the Avogadro number of atoms. Similarly, for a substance with molecular weight y, a sample whose mass is y grams must contain the Avogadro number of molecules. For example, 18 g of water contains 6.02×10^{23} H_2O molecules.

The Avogadro number is a dimensionless number. The Avogadro constant is defined as the Avogadro number divided by the unit "mole." The Avogadro constant is usually symbolized by N_A, N_0, or L. Since N_A gives the number of molecules per mole, $N_A = N/n$, where N is the number of molecules present in n moles of a substance.

The Avogadro number relates the mass of a mole of a substance to the mass of a single molecule. For example, for H_2O (whose molecular weight is 18) the mass of one mole is 18 g and the mass of one molecule is $(18\text{ g})/(6.02 \times 10^{23}) \approx 3 \times 10^{-23}$ g. The mass m of one molecule of a substance with molar mass M is $m = M/N_A$.

The Avogadro constant N_A is related to other fundamental physical constants. The Faraday constant F is the absolute value of the charge on one mole of electrons. Therefore $F = N_A e$, where e is the absolute value of the charge on one electron. Also, $R = N_A k$, where R is the gas constant and k is the Boltzmann constant. *See* BOLTZMANN CONSTANT; GAS CONSTANT.

Widespread use of the mole concept began only around 1900. The nineteenth-century concept most closely related to the Avogadro number is the number of molecules per unit volume in a gas at 0°C and 1 atm. [The ideal-gas law $PV = nRT = (N/N_A)RT$ gives $N/V = N_A P/RT$, so N/V, the number of gas molecules per unit volume, is proportional to the Avogadro constant N_A at fixed pressure P and temperature T.] Avogadro hypothesized in 1811 that at a fixed temperature and pressure the number of molecules per unit volume is the same for different gases, but he had no way of estimating this number. [I.N.L.]

Avogadro's law The principle that equal volumes of all gases and vapors, under the same conditions of temperature and pressure, contain identical number of molecules; also known as Avogadro's hypothesis. From Avogadro's law the converse follows that equal numbers of molecules of any gases under identical conditions occupy equal volumes. Therefore, under identical physical conditions the gram-molecular weights of all gases occupy equal volumes. *See* GAS; KINETIC THEORY OF MATTER. [T.C.W.]

Axenic culture The growth and maintenance of a single species in isolation, free from foreign or contaminating species. Isolation is usually achieved by growing the species in an environment that was previously sterilized, and was thereby rid of contaminating organisms. Since, from a practical viewpoint, the contaminating organisms usually encountered are microorganisms, axenic cultures, whether of invertebrates or vertebrates, are often referred to as germ-free. Indeed, the terms axenic and germ-free are occasionally used interchangeably. Gnotobiotic is also often used interchangeably with axenic; however, in common practice gnotobiotic specifically refers to germ-free conditions. *See* GNOTOBIOTICS.

A principal goal of early studies with axenic cultures was the establishment of nutritional requirements for individual species. Historically, axenic cultures have also been employed to demonstrate that organisms growing in close association can have both direct and indirect effects on each other. Direct effects include competition for nutrients, attacks (for example, by a parasite), or production by one species of toxic compounds that affect a second species. Indirect effects include such phenomena as the production by intestinal microflora of vitamin K (germ-free animals therefore require it as a dietary supplement).

The two methodological challenges associated with developing axenic culture methods are formulating an appropriate culture medium and designing a functional habitat. Formulating a culture medium for small organisms, including microorganisms and many invertebrates, is the more difficult of the two challenges. For larger organisms, a culture medium is replaced by a carefully formulated diet, which is usually a relatively straightforward task. Initiating the axenic cycle and maintaining a sterile environment can, however, be a formidable endeavor for larger organisms.

For axenic culture of small organisms, such as bacteria, protozoa, and fungi, a typical strategy is to add to a minimal medium [which usually contains only a carbon source (such as glucose), nitrogen, sulfur, and phosphorus, as well as various salts and trace minerals] several supplements that are rich in a large number of growth factors. Such supplements often include water-soluble extracts of meat or yeast containing vitamins and other organic compounds. Once successful growth is achieved, it is usual to attempt to simplify the culture medium by deleting, in a stepwise fashion, each of the more esoteric ingredients (for example, individual vitamins).

Initiating the axenic cycle and designing an appropriate habitat for larger organisms require special effort. First, organisms free of contaminating species need to be obtained; in some cases, cesarean births are employed. Second, sterile containers that have entry and exit ports as well as a comfortable living environment must be constructed.

Axenic culture has been achieved for a broad range of organisms. The method employed to remove contaminating organisms in a starter culture or for the initiation of an experiment depends upon the type of organism to be decontaminated and the nature of the contaminating organism.

Since bacteria represent the single most important potential contaminant in axenic cultures, antibiotic therapy is usually employed to maintain the cultures. There is no single antibiotic that inhibits all bacteria, however, so combinations of up to four to six antibiotics are usually added either directly to the culture fluid for axenic stocks of protozoa, plant cells, or nematodes, or to the food or beverage for larger, germ-free animals such as small mammals. Axenic cultures need to be continually monitored for the presence of contaminating microorganisms. *See* BACTERIOLOGY.

One problem is that it is not always possible to be certain that viruses and mycoplasmas are not present as a contaminant in axenic cultures. Another limitation is that since axenic cultures are designed to be pure it is almost impossible to construct a holistic or comprehensive view of an organism with data from axenic cultures alone. Nevertheless, the benefits that have been obtained from the use of axenic cultures have far outweighed the limitations. Indeed, virtually all aspects of research on pharmaceuticals, nutrition, ecology, agricultural production, and parasitology have benefited enormously from the use of axenic cultures. [G.M.M.]

Axinellida An order of sponges of the class Demospongiae, subclass Tetractinomorpha, with monactinal or diactinal megascleres or both arranged in plumose tracts bearing more or less spongin (see illustration). The axial skeleton may be dense, with an abundance of spongin especially near the base of the sponge. Axinellidan sponges vary in form from branching or massive to cup-shaped or lamellate. Most occur in shallower waters down to 330 ft (100 m), but a few descend to abysmal depths of at least 14,500 ft (4400 m). *See* DEMOSPONGIAE. [W.D.H.]

***Axinella polycapella*, a representative axinelline sponge.**

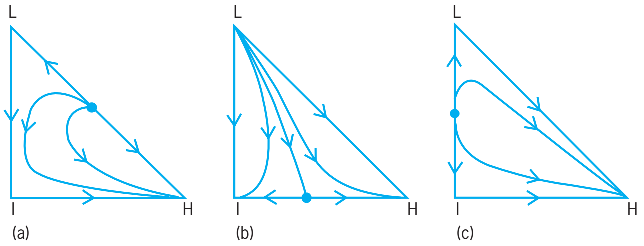
Aye-aye A rare prosimian primate indigenous to eastern Madagascar. A single living species, *Daubentonia madagascariensis*, makes up the family Daubentoniidae (see illustration). The aye-aye is a nocturnal, arboreal animal. A single young is produced in early spring in a special nest, which is constructed by the female. The hindtoes are opposable, and the fingers are quite long and slender, especially the middle one. Using its middle finger or its sharp incisors, the aye-aye digs insect larvae out of tree bark or extracts the contents of sugarcane.

The aye-aye, *Daubentonia madagascariensis*.

The phylogenetic relationship of this species is obscure; however, the general consensus is that this animal is an aberrant or divergent form of a lemuroid ancestral stock. *See* MAMMALIA; PRIMATES. [C.B.C.]

Azeotropic distillation Any of several processes by which liquid mixtures containing azeotropes may be separated into their pure components with the aid of an additional substance (called the entrainer, the solvent, or the mass separating agent) to facilitate the distillation. Distillation is a separation technique that exploits the fact that when a liquid is partially vaporized the compositions of the two phases are different. By separating the phases, and repeating the procedure, it is often possible to separate the original mixture completely. However, many mixtures exhibit special states, known as azeotropes, at which the composition, temperature, and pressure of the liquid phase become equal to those of the vapor phase. Thus, further separation by conventional distillation is no longer possible. By adding a carefully selected entrainer to the mixture, it is often possible to "break" the azeotrope and thereby achieve the desired separation. *See* AZEOTROPIC MIXTURE; DISTILLATION.

Entrainers fall into at least four distinct categories that may be identified by the way in which they make the separation possible. These categories are: (1) liquid entrainers that do not induce liquid-phase separation, used in homogeneous azeotropic distillations, of which classical extractive distillation



Schematic representation of the residue curve maps for ternary mixtures with one minimum- boiling binary azeotrope. (*a*) Azeotrope between the lowest- (L) and highest-boiling (H) pure components. (*b*) Azeotrope between the intermediate-(I) and highest-boiling components. (*c*) Azeotrope between the intermediate- and lowest-boiling components.

is a special case; (2) liquid entrainers that do induce a liquid-phase separation, used in heterogeneous azeotropic distillations; (3) entrainers that react with one of the components; and (4) entrainers that dissociate ionically, that is, salts. *See* SALT-EFFECT DISTILLATION.

Within each of these categories, not all entrainers will make the separation possible, that is, not all entrainers will break the azeotrope. In order to determine whether a given entrainer is feasible, a schematic representation known as a residue curve map for a mixture undergoing simple distillation is created. The path of liquid compositions starting from some initial point is the residue curve. The collection of all such curves for a given mixture is known as a residue curve map (see illustration). These maps contain exactly the same information as the corresponding phase diagram for the mixture, but they represent it in such a way that it is more useful for understanding and designing distillation systems.

Mixtures that do not contain azeotropes have residue curve maps that all look the same. The presence of even one binary azeotrope destroys the structure. If the mixture contains a single minimum-boiling binary azeotrope, three residue curve maps are possible, depending on whether the azeotrope is between the lowest- and highest-boiling components, between the intermediate- and highest-boiling components, or between the intermediate- and lowest-boiling components.

Nonazeotropic mixtures may be separated into their pure components by using a sequence of distillation columns because there are no distillation boundaries to get in the way. The situation is quite different when azeotropes are present, as can be seen from the illustration. It is possible to separate mixtures that have residue curve maps similar to those shown in illus. *a* and *c* by straightforward sequences of distillation columns. This is because these maps do not have any distillation boundaries. These, and other feasible separations for more complex mixtures, are referred to collectively as homogeneous azeotropic distillations. Without exploiting some other effect (such as changing the pressure from column to column), it is impossible to separate mixtures that have residue curve maps like illus. *b*.

A large number of mixtures have residue curve maps similar to illus. *c*, and therefore the corresponding distillation is given the special name extractive distillation.

Heterogeneous entrainers cause liquid-liquid phase separations to occur in such a way that the composition of each phase lies on either side of a distillation boundary. In this way, the entrainer allows the separation to “jump” over a boundary that would otherwise be impassable. [M.F.D.]

Azeotropic mixture A solution of two or more liquids, the composition of which does not change upon distillation. The composition of the liquid phase at the boiling point is identical to that of the vapor in equilibrium with it, and such mixtures or azeotropes form constant-boiling solutions. The exact composition of the azeotrope changes if the boiling point is altered by a change in the external pressure. A solution of two components which form an azeotrope may be separated by distillation into one pure component and the azeotrope, but not into two pure components. *See* DISTILLATION; SOLUTION. [F.J.J.]

Azide A compound containing the group —N_3, which can be represented as a resonance hybrid of two structures, as shown in expression (1). Sodium azide, from which most other azides are prepared, is manufactured by passing nitrous oxide over heated sodium amide, reaction (2). It is a water-soluble, stable compound. Heavy-metal azides are highly explosive and very shock sensitive; lead azide, $Pb(N_3)_2$, is used as a detonator to set off explosives. Sodium azide, in combination with an oxidizing agent, may be used as a gas generator in motor-vehicle passive-restraint systems. *See* EXPLOSIVE.

$$-\overset{\ominus}{N}-\overset{\oplus}{N}\equiv N \longleftrightarrow -N=\overset{\oplus}{N}=\overset{\ominus}{N} \qquad (1)$$

$$2NaNH_2 + N_2O \rightarrow NaN_3 + NaOH + NH_3 \qquad (2)$$

A variety of organic azides are known. The most important of these are aryl azides (ArN_3), azidoformates ($ROCON_3$), and sulfonyl azides (RSO_2N_3).

These lose N_2 when heated or exposed to ultraviolet light to generate species known as nitrenes, which are so reactive that they will react with almost any organic compound to form amine derivatives, as shown in reaction (3). Aryl azides are widely used to probe the active sites of biological targets by photoaffinity labeling. Difunctional aryl azides are used commercially to prepare photoresists, the nitrenes reacting with a polymer containing double bonds to insolubilize the polymer in the light-struck areas. The insoluble polymer protects the underlying metal from being attacked by an etching solution. Difunctional azidoformates and sulfonyl azides can be used to cross-link polymers, to prepare polymeric foams, and to adhere tire cord to rubber in the manufacture of automobile tires. Compounds containing a sulfonyl azide group and a hydrolyzable silane group, such as —$Si(OCH_3)_3$, in the same molecule are used to bond silaceous fillers (glass fibers, silica, mica, and so forth) to almost any organic polymer. Such coupled systems have much superior properties to simple mechanical mixtures.

$$RN_3 \xrightarrow[-N_2]{\text{heat or light}} R\overset{\cdot\cdot}{\underset{\cdot\cdot}{N}} \xrightarrow{R'CH_3} RNHCH_2R' \qquad (3)$$

Simple acyl azides (R = alkyl or aryl) undergo a Curtius rearrangement on heating to form an isocyanate, reaction (4).

$$RCON_3 \xrightarrow{\text{heat}} RN=C=O + N_2 \qquad (4)$$

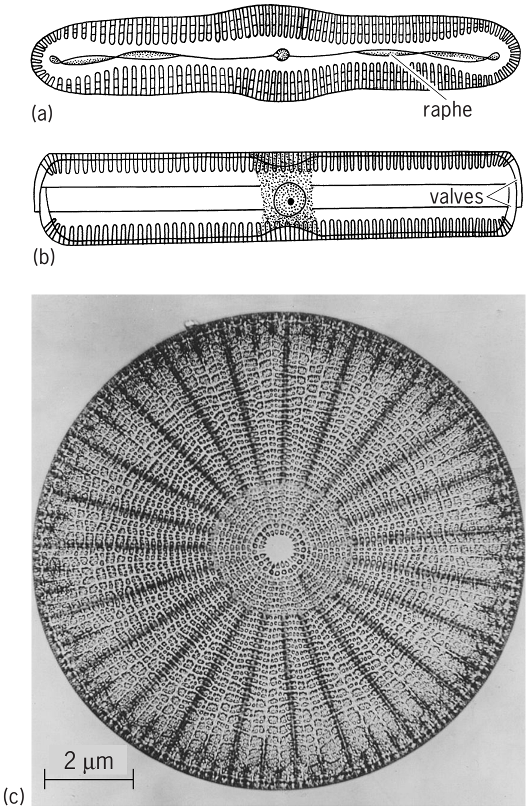
See NITROGEN; POLYMERIZATION; RUBBER. [D.S.Br.]

Azurite A basic carbonate of copper with the chemical formula $Cu_3(OH)_2(CO_3)_2$. Azurite is normally associated with copper ores and often occurs with malachite. Azurite is mono-clinic. It may be massive or may occur in tabular, prismatic, or equant crystals. Invariably blue, azurite was originally used extensively as a pigment. Hardness is $3^{1}/_{2}$–4 (Mohs scale) and specific gravity is 3.8. Notable localities for azurite are at Tsumeb, Southwest Africa, and Bisbee, Arizona. *See* COPPER. [R.I.Ha.]

B

Bacillariophyceae A class of nonflagellate unicellular algae, commonly called diatoms, with boxlike silicified walls. Diatoms range in maximum dimension from 4 micrometers to more than 1 millimeter. The diatom wall or frustule (illus. *a* and *b*) comprises several interlocking, usually elaborately sculptured, lightly or heavily silicified pieces overlying a thin polysaccharide layer. The two largest pieces are the upper and lower valves, which fit together like the top and bottom of a petri dish or shoe box. Between the valves (along the side or girdle of the cell), several smaller pieces—hooplike girdle bands—are intercalated. Depending upon which dimension is larger, breadth or depth, a diatom tends to lie on the valve side or on the girdle side.

Valves are honeycombed by perforate chambers arranged in patterns characteristic of individual species. The overall symmetry of the valves and details of their structure and ornamentation provide the basis for classification. More than 200 genera and 12,000 species of living diatoms have been described. Two main groups are recognized: those in which structural features of the valve are arranged with reference to a central pole (centric valve; illustration *c*) or to two or more poles (gonioid valve); and those in which the features are arranged with respect to a line, often symmetrically (pennate valve).



Diatoms. (*a*) *Pinnularia*, top view; (*b*) side view. (*c*) *Arachnoidiscus ehenbergii*.

Most diatoms are photosynthetic. Many, however, are auxotrophic, requiring an external source of certain vitamins. Diatoms are likely to occur wherever there is moisture. They are free-living or attached, solitary or colonial. Marine planktonic diatoms have been important primary producers for at least 100 million years, and over the millennia their frustules have accumulated on the ocean floor. From the abundant fossil record, it is known that centric diatoms evolved first (Cretaceous), followed by pennate diatoms (Paleocene). Uplifted deposits (diatomaceous earth) are mined at several locations. *See* ALGAE; CHRYSOPHYCEAE. [P.C.Si; R.L.Moe.]

Bacillary dysentery A highly contagious intestinal disease caused by rod-shaped bacteria of the genus *Shigella*. Bacillary dysentery is a significant infection of children in the developing world, where it is transmitted by the fecal-oral route. The global disease burden is estimated as 165 million episodes and 1.3 million deaths annually. Common-source outbreaks occasionally occur in developed countries, usually as a result of contaminated food. The most common species isolated in developed countries is *S. sonnei*, while *S. flexneri* serotypes predominate in endemic areas. Epidemics of *S. dysenteriae* 1 occur in equatorial regions, and these outbreaks can involve adults as well as children.

When ingested even in very small numbers, shigellae multiply in the intestine and invade the epithelial lining of the colon. Infection of this tissue elicits an acute inflammatory response (colitis) that is manifested as diarrhea or bloody, mucoid stools (dysentery). The virulence of all *Shigella* species, and *Shigella*-like enteroinvasive *Escherichia coli*, depends on an extrachromosomal genetic element (virulence plasmid) that encodes four invasion plasmid antigen (Ipa) proteins and a secretory system (Type III) for these proteins. Secreted Ipa proteins help shigellae to initiate colonic invasion through specialized endocytic intestinal cells (M cells). After shigellae pass through these M cells, they are phagocytized by tissue macrophages in the underlying lymphoid tissue. Ipa proteins then induce apoptosis (programmed cell death) in infected macrophages, releasing cytokines (primarily IL-1) that initiate an acute, localized inflammatory infiltrate. This infiltrate of polymorphonuclear leukocytes destabilizes tight junctions between absorptive epithelial cells (enterocytes), making the tissue more susceptible to additional *Shigella* invasion. Secreted Ipa proteins induce uptake of shigellae by the colonic enterocytes. The virulence plasmid also encodes an intercellular spread protein (IcsA) that recruits mammalian cytoskeletal elements (primarily actin) to the bacterial surface. This actin is organized into a cytoplasmic motor that facilitates spread of shigellae to adjacent enterocytes. *See* DIARRHEA; ESCHERICHIA.

In otherwise healthy individuals, bacillary dysentery is typically a short-term disease lasting less than a week. The symptoms can be truncated by appropriate antibiotic therapy (such as oral ampicillin or cyprofloxacin) that rapidly eliminates shigellae from the intestinal lumen and tissues. When *S. dysenteriae* 1 is the etiologic agent, however, hemolytic uremic syndrome can be manifested as a serious consequence of disease. This species produces a cytotoxin (Shiga toxin or Stx) that is functionally identical to the toxin of enterohemorrhagic *E. coli* (for example, O157:H7). Stx inhibits protein synthesis, damaging endothelial cells of the intestinal capillary bed; the toxin may also damage renal tubules, causing acute renal failure with chronic sequela in up to one-third of hemolytic uremic syndrome patients. *See* MEDICAL BACTERIOLOGY. [T.L.Ha.]

Background count The number of counts recorded by a radiation detector from background radiation. The term background radiation refers to the natural ionizing radiation on the Earth. Ionizing radiation refers to all radiations, waves, and particles that are energetic enough to remove electrons from stable atoms; they are stronger than infrared radiation, radio waves, or visible light, which cannot separate electrons from stable atoms. Radiation strong enough to cause ionization of atoms is measured in electrical units which range from 32 electronvolts up to millions of electronvolts. *See* ELECTROMAGNETIC RADIATION.

A radiation detector at sea level would detect the radiation from both cosmic and terrestrial sources. The measurement of background radiation is in absorbed dose units known as sieverts (Sv). (Previously the unit was the millirem, and 100 millirem = 1 mSv.) The chief concern is with the amount of background radiation absorbed by people's tissues. Most people absorb about 0.3 mSv per year at sea level, roughly 1 microsievert per day. About 10% of this is external radiation from cosmic radiation, and 10% is external radiation from terrestrial sources. Internal radiation from inhaled and ingested radionuclides constitutes the rest. Some 13% of the background radiation comes from the natural terrestrial radionuclide (radioisotope) potassium-40, which is uniformly concentrated in all living cells and is present as 1 in every 2000 potassium atoms. The remaining two-thirds of the background dose comes from inhalation of radon daughter products. Radon is a radioactive noble gas which is derived from the decay of radium, a decay product of uranium. In regions where the geology is such that there is a relatively high concentration of uranium, the radon concentration may be elevated, and the background dose rate can be quite high. *See* ENVIRONMENTAL RADIOACTIVITY; RADIOACTIVITY; RADON; UNITS OF MEASUREMENT. [M.Gol.]

Bacteria Extremely small—usually 0.3 to 2.0 micrometers in diameter—and relatively simple microorganisms possessing the prokaryotic type of cell construction. Although traditionally classified within the fungi as Schizomycetes, they show no phylogenetic affinities with the fungi, which are eukaryotic organisms. The only group that is clearly related to the bacteria are the blue-green algae. Bacteria are found almost everywhere, being abundant, for example, in soil, water, and the alimentary tracts of animals. Each kind of bacterium is fitted physiologically to survive in one of the innumerable habitats created by various combinations of space, food, moisture, light, air, temperature, inhibitory substances, and accompanying organisms. Dried but often still living bacteria can be carried into the air. Bacteria have a practical significance for humans. Some cause disease in humans and domestic animals, thereby affecting health and the economy. Some bacteria are useful in industry, while others, particularly in the food, petroleum, and textile industries, are harmful. Some bacteria improve soil fertility. As in higher forms of life, each bacterial cell arises either by division of a preexisting cell with similar characteristics or through a combination of elements from two such cells in a sexual process. *See* FOOD MICROBIOLOGY; INDUSTRIAL MICROBIOLOGY; PETROLEUM MICROBIOLOGY; SOIL MICROBIOLOGY.

Descriptions of bacteria are preferably based on the studies of pure cultures, since in mixed cultures it is uncertain which bacterium is responsible for observed effects. Pure cultures are sometimes called axenic, a term denoting that all cells had a common origin in being descendants of the same cell, without implying exact similarity in all characteristics. Pure cultures can be obtained by selecting single cells, but indirect methods achieving the same result are more common.

If conditions are suitable, each bacterium grows and divides, using food diffused through the gel, and produces a mass of cells called a colony. Colonies always develop until visible to the naked eye unless toxic products or deficient nutrients limit them to microscopic dimensions. *See* CULTURE.

The morphology, that is, the shape, size, arrangement, and internal structures, of bacteria can be distinguished microscopically and provides the basis for classifying the bacteria into major groups. Three principal shapes of bacteria exist, spherical (coccus), rod (bacillus), and twisted rod (spirillum). The coccus may be arranged in chains of cocci as in *Streptococcus*, or in tetrads of cocci as in *Sarcina*. The rods may be single or in filaments. Stains are used to visualize bacterial structures otherwise not seen, and the stain reaction with Gram's stain provides a characteristic used in classifying bacteria.

Many bacteria are not motile. Of the motile bacteria, however, some move by means of tiny whirling hairlike flagella extending from within the cell. Others are motile without flagella and have a creeping or gliding motion. Many bacteria are enveloped in a capsule, a transparent gelatinous or mucoid layer outside the cell wall. Some form within the cell a heat- and drought-resistant spore, called an endospore. Cytoplasmic structures such as reserve fat, protein, and volutin are occasionally visible within the bacterial cell.

The nucleus of bacteria is prokaryotic, that is, not separated from the rest of the cell by a membrane. It contains the pattern material for forming new cells. This material, deoxyribonucleic acid (DNA), carrying the information for synthesis of cell parts, composes a filament with the ends joined to form a circle. The filament consists of two DNA strands joined throughout their length. The joining imparts a helical form to the double strand. The double-stranded DNA consists of linearly arranged hereditary units, analogous and probably homologous with the "genes" of higher forms of life. During cell division and sexual reproduction, these units are duplicated and a complete set is distributed to each new cell by an orderly mechanism.

The submicroscopic differences that distinguish many bacterial genera and species are due to structures such as enzymes and genes that cannot be seen. The nature of these structures is determined by studying the metabolic activities of the bacteria. Data are accumulated on the temperatures and oxygen conditions under which the bacteria grow, their response in fermentation tests, their pathogenicity, and their serological reactions. There are also modern methods for determining directly the similarity in deoxyribonucleic acids between different bacteria. *See* FERMENTATION; PATHOGEN; SEROLOGY.

Bacteria are said to be aerobic if they require oxygen and grow best at a high oxygen tension, usually 20% or more. Microaerophilic bacteria need oxygen, but grow best at, or may even require, reduced oxygen tensions, that is, less than 10%. Anaerobic bacteria do not require oxygen for growth. Obligatorily anaerobic bacteria can grow only in the complete absence of oxygen. Some bacteria obtain energy from the oxidation of reduced substances with compounds other than oxygen (O_2). The sulfate reducers use sulfate, the denitrifiers nitrate or nitrite, and the methanogenic bacteria carbon dioxide as the oxidizing agents, producing H_2S, nitrogen (N_2), and methane (CH_4), respectively, as reduction products.

Interrelationships may be close and may involve particular species. Examples are the parasitic association of many bacteria with plant and animal hosts, and the mutualistic association of nitrogen-fixing bacteria with leguminous plants, of cellulolytic bacteria with grazing animals, and of luminous bacteria with certain deep-sea fishes. *See* NITROGEN FIXATION; POPULATION ECOLOGY. [R.E.H.]

Endospores are resistant and metabolically dormant bodies produced by the gram-positive rods of *Bacillus* (aerobic or facultatively aerobic), *Clostridia* (strictly anaerobic), by the coccus *Sporosarcina*, and by certain other bacteria. Sporeforming bacteria are found mainly in the soil and water and also in the intestines of humans and animals. Some sporeformers are found as pathogens in insects; others are pathogenic to animals and humans. Endospores seem to be able to survive indefinitely. Spores kept for more than 50 years have shown little loss of their capacity to germinate and propagate by cell division. The mature spore has a complex structure which contains a number of layers. The unique properties of bacterial spores are their extreme resistance to heat, radiation from ultraviolet light and x-rays, organic solvents, chemicals, and desiccation. The capacity of a bacterial cell to form a spore is under genetic control, although the total number of genes specific for sporulation is not known. The actual phenotypic expression of the spore genome depends upon a number of external factors. For each species of sporeforming bacteria, there exist optimum conditions for sporogenesis which differ from the optimal conditions for vegetative growth. These conditions include pH, degree of aeration, temperature, metals, and nutrients. The three processes involved in the conversion of the spore into a vegetative cell are (1) activation (usually by heat or aging), which conditions the spore to germinate in a suitable environment; (2) germination, an irreversible process which results in the loss of the typical characteristics of a dormant spore; and (3) outgrowth, in which new classes of proteins and structures are synthesized so that the spore is converted into a new vegetative cell. [H.O.H.; K.Hu.; C.O.]

Bacterial genetics The study of gene structure and function in bacteria. Genetics itself is concerned with determining the number, location, and character of the genes of an organism. The classical way to investigate genes is to mate two organisms with different genotypes and compare the observable properties (phenotypes) of the parents with those of the progeny. Bacteria do not mate (in the usual way), so there is no way of getting all the chromosomes of two different bacteria into the same cell. However, there are a number of ways in which a part of the chromosome or genome from one bacterium can be inserted into another bacterium so that the outcome can be studied. *See* GENETICS.

All organisms have diverged from a common ancestral prokaryote whose precise location in the evolutionary tree is unclear. This has resulted in three primary kingdoms, the Archaebacteria, the Eubacteria, and the Eukaryotae. All bacteria are prokaryotes, that is, the "nucleus" or nucleoid is a single circular chromosome, without a nuclear membrane. Bacteria also lack other membrane-bounded organelles such as mitochondria or chloroplasts, but they all possess a cytoplasmic membrane. Most bacteria have a cell wall that surrounds the cytoplasmic membrane, and some bacteria also contain an outer membrane which encompasses the cell wall. Duplication occurs by a process of binary fission, in which two identical daughter cells arise from a single parent cell. Every cell in a homogeneous population of bacterial cells retains the potential for duplication. Bacteria do not possess the potential for differentiation (other than spore formation) or for forming multicellular organisms. *See* ARCHAEBACTERIA; BACTERIA; PROKARYOTAE; RIBONUCLEIC ACID (RNA).

One of the most frequently used organisms in the study of bacterial genetics is the rod-shaped bacillus *Escherichia coli*, whose normal habitat is the colon. Conditions have been found for growing *E. coli* in the laboratory, and it is by far the best understood of all microorganisms. The single circular chromosome of *E. coli* contains about 4.5×10^6 base pairs, which is enough to make about 4500 average-size genes (1000 base pairs each). In regions where mapping studies are reasonably complete, the impression is obtained of an efficiently organized genome. Protein coding regions are located adjacent to regulatory regions. There is no evidence for significant stretches of nonfunctional deoxyribonucleic acid (DNA), and there is no evidence for introns [regions that are removed by splicing the messenger RNA (mRNA) before it is translated into protein] in the coding regions. Very little repetitive DNA exists in the *E. coli* chromosome other than the seven sequence-related rRNA genes that are dispersed at different locations on the chromosome. *See* CHROMOSOME; DEOXYRIBONUCLEIC ACID (DNA); GENETIC CODE.

The first step in performing genetic research on bacteria is to select mutants that differ from wild-type cells in one or more genes. Then crosses are made between mutants and wild types, or between two different mutants, to determine dominance-recessive relationships, chromosomal location, and other properties. Various genetic methods are used to select bacterial mutants, antibiotic-resistant cells, cells with specific growth requirements, and so on.

Certain genes that have the function of modulating the expression of other genes are known as regulatory genes. Mutations that affect the action of regulatory proteins are of two types: those that occur in the genes that encode the regulatory proteins, and those that affect the genetic loci where the regulatory protein interacts to modulate the level of gene expression. Some regulatory gene mutations cause overproduction and some cause underproduction of gene products. This is the hallmark of a mutation that influences the functioning of a regulatory protein or regulatory factor-binding site; it affects the quantity but not the quality of other gene products. Furthermore, regulatory gene mutations are frequently pleiotropic, that is, they influence the rate of synthesis of several gene products simultaneously. *See* GENE ACTION; PROTEIN.

Frequently, geneticists want to increase the number or types of mutants that can be obtained as a result of spontaneous mutagenesis. In such instances, they treat a bacterial population with a mutagenic agent to increase the mutation frequency. This is called induced mutagenesis. The simplest techniques of induced mutagenesis involve measured exposure of the bacteria to a mutagenic agent, such as x-rays or chemical mutagenic agents. Such procedures have a general effect on the increase in the mutation rate. More sophisticated procedures involve isolating the gene of interest and making a change in the desired location. This is called site-directed mutagenesis. The goal is usually to determine the effects of a change at a specific gene locus. The gene in question is isolated, modified, and reinserted into the organism. Discrete alterations can be made in a variety of ways on any DNA in cell-free culture, and the effect of such alterations can be subsequently tested in the organism. *See* GENETIC ENGINEERING; MUTAGENS AND CARCINOGENS.

Bacteria do not mate to form true zygotes, but they are able to exchange genetic information by a variety of processes in which partial zygotes (merozygotes) are formed. The first type of genetic exchange between bacteria to be observed was transformation. Naturally occurring transformation involves the uptake of DNA. This phenomenon is observed only for a limited number of bacterial species and is a relatively difficult technique to use for gene manipulation. In 1946 direct chromosomal exchange by conjugation between *E. coli* cells was discovered by J. Lederberg and E. Tatum, and in 1951 transduction, the virus-mediated transfer of bacterial genes, was discovered. Both conjugation and transduction provide facile, generally applicable methods for moving part of the bacterial chromosome from one cell to another. The discovery of bacterial transposons (a class of mobile genetic elements commonly found in bacterial populations) in the 1970s has been useful in marking and mobilizing genes of interest. The purely genetic approaches to mapping have been supplemented by the biochemical approaches of hybrid plasmid construction and DNA sequence analysis. *See* GENETIC MAPPING; TRANSFORMATION (BACTERIA); TRANSPOSONS.

At any given time, only a small percentage of the *E. coli* genome is being actively transcribed. The remainder of the genome is either silent or being transcribed at a very low rate. When growth conditions change, some active genes are turned off and other, inactive genes are turned on. The cell always retains its totipotency, so that within a short time (seconds to minutes), and given appropriate circumstances, any gene can be fully turned on. The maximal activity for transcription varies from gene to gene. For example, a β-galactosidase gene makes about one copy per minute, and a fully turned-on biotin synthase gene makes about one copy per 10 min. In the maximally repressed state, both of these genes express less than one transcript per 10 min. The level of transcription for any particular gene usually results from a complex series of control elements organized into a hierarchy that coordinates all the metabolic activities of the cell. For example, when the rRNA genes are highly active, so are the genes for ribosomal proteins, and the latter are regulated in such a way that stoichiometric amounts of most of the ribosomal proteins are produced. When glucose is abundant, most genes involved in processing more complex carbon sources are turned off in a process called catabolite repression. If the glucose supply is depleted and lactose is present, the genes involved in lactose breakdown (catabolism) are expressed. In *E. coli* the production of most RNAs and proteins is regulated exclusively at the transcriptional level, although there are notable exceptions. [G.Z.]

Bacterial growth The processes of both the increase in number and the increase in mass of bacteria. Growth has three distinct aspects: biomass production, cell production, and cell survival. Biomass production depends on the physical aspects of the environment (water content, pH, temperature), the availability of resources (carbon and energy, nitrogen, sulfur, phosphorus, minor elements), and the enzymatic machinery for catabolism (energy trapping), anabolism (biosynthesis of amino acid, purines, pyrimidines, and so forth), and macromolecular synthesis [proteins, ribonucleic acid (RNA), and deoxyribonucleic acid (DNA)]. Cell production is contingent on biomass production and involves, in addition, the triggering of chromosome replication and subsequent cell division. The cells may or may not separate from each other, and the division may partition the cell evenly or unevenly. Alternatively, growth may occur by budding (unequal division). Most cells so produced are themselves capable of growing and dividing; consequently, viability is usually very high when growth conditions are favorable. Moreover, in many cases the incidence of death is surprisingly low in the absence of needed nutrients. Many bacteria differentiate into resistant resting forms (such as spores); others may simply reduce their rate of metabolism and persist in the vegetative state for long times. [A.L.Ko.]

Bacterial luminescence The production of visible light by bacteria; with very few exceptions this light is blue-green. The phenomenon is seen in many species of several genera, including *Vibrio, Photobacterium, Alteromonas*, and *Xenorhabdus*. Luminous bacteria are primarily marine, but there are some genera with terrestrial (*Xenorhabdus*) and fresh-water (*Vibrio*) species. In the marine environment the bacteria are found in various habitats, including planktonic (free-floating), saprophytic (on a variety of marine proteinaceous materials), parasitic (on a number of marine invertebrates), and symbiotic. The symbiotic habitat can take one of several forms. The symbiotic bacteria may be loosely associated as gut symbionts in many different marine organisms; they may be specifically and more tightly associated in the light organs of marine fishes and squids; or they may be very tightly associated as intracellular symbionts in luminescent pyrosomes (light-omitting organelles). When associated as light-organ symbionts, the bacteria are used by the host fish or squid as a biological light bulb. Under these conditions the bacteria are maintained in specialized organs where they are cultured by the host organism, kept free from contaminants, and continuously emit light. The actual light emission is then controlled physically by the host's use of shutters, chromatophores, or other mechanisms. These symbiotic relationships are probably the most common habitats in which bacterial luminescence is observed in the ocean.

The chemistry of bacterial luminescence is unique among luminous organisms. The enzyme that catalyzes light emission is luciferase; it combines with a riboflavinlike substance called flavin mononucleotide ($FMNH_2$). This complex then reacts with a long-chain aldehyde, and with molecular oxygen to form an excited state capable of emitting light. The molecule that actually emits the light is an altered form of the flavin. This unique biochemistry has been used as an indicator of the presence of luminous bacteria in cases where the symbiotic bacteria could not be obtained in pure culture or could not be grown free from their host. *See* BACTERIAL PHYSIOLOGY AND METABOLISM; BIOLUMINESCENCE; RIBOFLAVIN. [K.H.N.]

Bacterial physiology and metabolism The biochemical reactions that together enable bacteria to live, grow, and reproduce. Strictly speaking, metabolism describes the total chemical reactions that take place in a cell, while physiology describes the role of metabolic reactions in the life processes of a bacterium. The study of bacteria has significance beyond the understanding of bacteria themselves. Since bacteria are abundant, easily grown, and relatively simple in cellular organization, they have been used extensively in biological research. Functional analyses of bacterial systems have provided a foundation for much of the current detailed knowledge about molecular biology and genetics. Bacteria are prokaryotes, lacking the complicated cellular organization found in higher organisms; they have no nuclear envelope and no specialized organelles. Yet they engage in all the basic life processes—transport of materials into and out of the cell, catabolism and anabolism of complex organic molecules, and the maintenance of structural integrity. To accomplish this, bacteria must obtain nutrients and convert them into a form of energy that is useful to the cell. [M.R.J.S.]

Enzymes. A list of bacterial enzymes (organic catalysts) includes many of the enzymes found in mammalian tissues, as well as many enzymes not found in higher forms of life. By combining with such enzymes, many antibiotics are able to exert a selective killing or inhibition of bacterial growth without causing toxic reactions in the mammalian host. The great capability of the bacterial cell to metabolize a wide variety of substances, as well as to control to some extent the environment in which the cell lives, is reflected in its ability to form inducible enzymes. The majority of bacterial enzymes require cofactors for activity. These cofactors may be inorganic cations of organic molecules called coenzymes. *See* COENZYME; ENZYME.

Bacterial enzymes may be classified in numerous ways, for example, on the basis of (1) whether they are inducible or constitutive (constitutive enzymes are defined as those enzymes formed by the bacterial cell under any or all conditions of growth, whereas inducible enzymes are formed by the bacterial cell only in response to an inducer); (2) whether they are degradative (catabolic; resulting in the release of energy) or synthetic (anabolic; using energy to catalyze the formation of macromolecules); or (3) whether they are exoenzymes (enzymes secreted from the cell to hydrolyze insoluble polymers—wood, starch, protein, and so on—into smaller, soluble compounds which can be taken into the cytoplasm of the bacterium).

In addition, bacterial enzymes are involved in the transport of substrates across the cell wall, in the oxidation of inorganic molecules to provide energy for the cell, and in the destruction of a large number of antibiotics.

Many pathogenic microorganisms excrete enzymes which may play an important role in pathogenesis in some cases (see table). The α-toxin (lecithinase) of *Clostridium perfringens* illustrates a highly active enzyme which is responsible for the necrotizing action associated with gas gangrene infections due to this microorganism. *Streptococcus pyogenes* excretes hyaluronidase which degrades ground substance (polymer of hyaluronic acid), and streptokinase, which activates plasmin resulting in a system that lyses fibrin. Other examples include coagulase of the *Staphylococcus*, which activates clotting of plasma, urease of *Proteus*

Enzymes excreted by microorganisms of medical importance

Organism	Enzyme	Substrate	End products
Clostridium	Lecithinase	Lecithin	Diglyceride, phosphoryl choline
	Collagenase	Collagen	?
Streptococcus	Hyaluronidase	Hyaluronic acid polymer	Hyaluronic acid
	Streptodornase	Deoxyribonucleic acid	Nucleotides
	Streptokinase	Activates plasminogen to plasmin	Results in lysis of fibrin clots
Staphylococcus	Coagulase	Coagulase reacting factor	Results in coagulation of plasma
Proteus	Urease	Urea	Ammonia and carbon dioxide
Corynebacterium diphtheriae	Diphtheria toxin	Nicotinamide dinucleotide (NAD)	Splits NAD and adds ADP-ribose to elongation factor 2 to prevent protein synthesis by freezing ribosome movement

vulgaris, which splits urea to ammonia and carbon dioxide, and collagenase of *Clostridium*, which hydrolyzes collagen. *See* DIPHTHERIA; GANGRENE; STAPHYLOCOCCUS.

Many bacteria are able to synthesize enzymes which will hydrolyze or modify an antibiotic so that it is no longer effective. Essentially all of these enzymes are coded by DNA that exists in bacterial plasmids. As a result, the ability to produce enzymes which destroy antibiotics can be rapidly passed from one organism to another either by conjugation in gram-negative organisms or by transduction in both gram-negative and gram-positive bacteria. [W.A.V.]

Bacterial catabolism. Bacterial catabolism comprises the biochemical activities concerned with the net breakdown of complex substances to simpler substances by living cells. Substances with a high energy level are converted to substances of low energy content, and the organism utilizes a portion of the released energy for cellular processes. Endogenous catabolism relates to the slow breakdown of nonvital intracellular constituents to secure energy and replacement building blocks for the maintenance of the structural and functional integrity of the cell. This ordinarily occurs in the absence of an external supply of food. Exogenous catabolism refers to the degradation of externally available food. The principal reactions employed are dehydrogenation or oxygenation (either represents biological oxidation), hydrolysis, hydration, decarboxylation, and intermolecular transfer and substitution. The complete catabolism of organic substances results in the formation of carbon dioxide, water, and other inorganic compounds and is known as mineralization. Catabolic processes may degrade a substance only part way. The resulting intermediate compounds may be reutilized in biosynthetic processes, or they may accumulate intra- or extracellularly. Catabolism also implies a conversion of the chemical energy into a relatively few energy-rich compounds or “bonds,” in which form it is biologically useful; also, part of the chemical energy is lost as heat.

Bacterial intermediary metabolism relates to the chemical steps involved in metabolism between the starting substrates and the final product. Normally these intermediates, or precursors of subsequent products, do not accumulate inside or outside the bacterial cell in significant amounts, being transformed serially as rapidly as they are formed. The identification of such compounds, the establishment of the coenzymes and enzymes catalyzing the individual reaction steps, the identity of active forms of the intermediates, and other details of the reaction mechanisms are the objectives of a study of bacterial intermediary metabolism. [J.W.Fo./R.E.K.]

Many bacteria are able to decompose organic compounds and to grow in the absence of oxygen gas. Such anaerobic bacteria obtain energy and certain organic compounds needed for growth by a process of fermentation. This consists of an oxidation of a suitable organic compound, using another organic compound as an oxidizing agent in place of molecular oxygen. In most fermentations both the compounds oxidized and the compounds reduced (used as an oxidizing agent) are derived from a single fermentable substrate. In other fermentations, one substrate is oxidized and another is reduced. Different bacteria ferment different substrates. Many bacteria are able to ferment carbohydrates such as glucose and sucrose, polyalchohols such as mannitol, and salts of organic acids such as pyruvate and lactate. Other compounds, such as cellulose, amino acids, and purines, are fermented by some bacteria. [H.A.B.]

Bacterial anabolism. Bacterial anabolism comprises the physiological and biochemical activities concerned with the acquisition, synthesis, and organization of the numerous and varied chemical constituents of a bacterial cell. Clearly, when a cell grows and divides to form two cells, there exists twice the amount of cellular components that existed previously. These components are drawn, directly or indirectly, from the environment around the cell, and (usually) modified extensively in the growth processes when new cell material is formed (biosynthesis). This build-up, or synthesis, begins with a relatively small number of low-molecular-weight building blocks which are either assimilated directly from the environment or produced by catabolism. By sequential and interrelated reactions, they are fashioned into different molecules (mostly of high molecular weight, and hence called macromolecules), for example, lipids, polysaccharides, proteins, and nucleic acids, and many of these molecules are in turn arranged into more complex arrays such as ribosomes, membranes, cell walls, and flagella. Other typical anabolic products, of lower molecular weight, include pigments, vitamins, antibiotics, and coenzymes. The enzymes responsible for the sequential reactions in any one biosynthetic pathway or assembly sequence are often located on or in cellular structures and thus in physical proximity to the preceding and succeeding enzymes, and their products, and to the site(s) where cellular structures are to be formed. Anabolism also includes the transport of molecules into cells, of building blocks to reaction sites, energetic activations, and the transfer and incorporation of the finished products to their ultimate sites in or outside the cell. [E.R.L.]

Bacterial taxonomy

The classification, nomenclature, and identification of bacteria; sometimes used as a term to indicate the theory of classification. The bacteria are members of the kingdom Prokaryotae, which is defined in terms of the unique structural and biochemical properties of their cells; more specifically, the organization of the deoxyribonucleic acid (DNA) in the nucleus, the lack of a nuclear membrane, the lack of independent membrane-bounded cytoplasmic organelles, the lack of endocytosis and exocytosis, and the chemical nature of some components of plasma membrane and cell walls.

Classification involves the recognition of similarities and relationships as a basis for the arrangement of the bacteria into taxonomic groups or taxa. The basic taxon is the species. Identification involves the recognition of a bacterium as a member of one of the established taxa, appropriately named, by the comparison of a number of characters with those in the description. *See* BACTERIA; TAXONOMIC CATEGORIES.

A bacterial species is a conceptual entity that is hard to define, despite its role as the basic taxonomic grouping. Bacteriologists accept the imprecision and recognize that a species represents a cluster of clones exhibiting some variations in minor properties.

They have developed a formal approach to the description of the taxon while trying to solve the problems encountered in the process of recognizing and naming species. The description is an assembly of such structural, chemical, physiologic, genetic, and ecologic characteristics as can be determined for the available strains that closely resemble each other. A strain is any pure culture of an organism isolated from nature, and the collected strains may then be conserved as cultures in the laboratory for study and comparison. In addition to the description, one strain must be designated by the author and preserved in a culture collection as a type strain, or permanent example, of the species and available to all who study bacteria. If that type strain is lost or succumbs, a formal proposal of a substitute strain (neotype) must be published. In general, bacterial taxonomy is built around the living type specimen: a species consists of the type strain and, whenever available, all other strains sufficiently similar to the type strain to be considered as included in the species. There is a provision for the description and naming of a distinctive species that is not yet cultivable, with the requirement for a suitably preserved type specimen.

A new species, validly described, must be assigned to a genus in order to accord with the binomial system of nomenclature initiated by C. Linnaeus. Thus, a species assigned to the genus *Bacillus* would be referred to as, for example, *Bacillus subtilis*. Such formal names of taxa are italicized to indicate that they are considered to accord with the formal description. If there is no appropriate genus available, a new genus must be named in accord with the *International Code of Nomenclature of Bacteria* and provided with a description that circumscribes the included species, and a type species must be designated as the exemplary representative of the genus.

The lowest nomenclatural rank that is recognized by the *Code* is subspecies, which is a subdivision of the species recognizing consistent variations in otherwise stable characters in the species description, for example, *Bacillus cereus* ssp. *mycoides*. There are times, however, when even finer but unofficial subdivisions of the species are useful and contribute to science, for example, for the epidemiology of pathogenic species. Then, groups of strains may be recognized by some special character as a variety of the species. These may be based on a biological property (biovar), antigenic variation (serovar), pathogenicity (pathovar), or susceptibility to particular bacterial viruses (phagovar). These characters have no formal standing in nomenclature.

Several new techniques are presently used in modern approaches to taxonomy. Numerical taxonomy (taxometrics) is a first approach for the analysis of phenotype. It implies the existence of programs for computer-assisted identification, either as recognizable phenons or by relation into a computer-stored classification and key program. Either of these methods has found considerable application in dealing with masses of isolates (for example, in studies of pollution or of sediments), or in dealing with results of automated systems for identification of pathogens in clinical bacteriology. *See* NUMERICAL TAXONOMY.

Chemotaxonomy applies systematic data on the molecular architecture of components of the bacterial cell to the solution of taxonomic problems. This has been a powerful tool since the 1950s, and a number of chemotaxonomic markers have been identified, ranging from molecules unique to the Prokaryotae or specific groups of bacteria to mechanisms or products of metabolism that characterize genera or species. The availability, and relative simplicity of techniques for amino acid analysis, for sequential analysis of polymers, for gas and thin-layer chromatography, for fermentation products and lipids, and so on, have made the systematic studies possible. These have led to a more effective definition of taxonomic groups based on biochemical assessment of cell wall composition, lipid composition of membranes, the types of isoprenoid quinones, the amino acid sequences of select proteins, and the characterization of proteins, such as the cytochromes and many other macromolecules. *See* CHEMOTAXONOMY.

Nucleic acid studies have been by far the most potent generators and arbiters of data on relatedness, with distinct capability for applications to the phylogenetic assessment of taxonomic arrangements. *See* DEOXYRIBONUCLEIC ACID (DNA); RIBONUCLEIC ACID (RNA). [R.G.E.M.]

Bacteriology The science and study of bacteria, and hence a specialized branch of microbiology. It deals with the nature and properties of the bacteria as living entities, their morphology and developmental history, ecology, physiology and biochemistry, genetics, and classification.

The major subjects that have consecutively occupied the forefront of bacteriological research have been the origin of bacteria, the constancy or variability of their properties, their role as causative agents of disease and of spoilage of foods, their significance in the cycle of matter, their classification, and their physiological, biochemical, and genetic features. *See* BACTERIA; MICROBIOLOGY. [C.B.V.N.]

Bacteriophage Any of the viruses that infect bacterial cells. They are discrete particles with dimensions from about 20 to about 200 nanometers. A given bacterial virus can infect only one or a few related species of bacteria; these constitute its host range. Bacteriophages consist of two essential components: nucleic acid, in which genetic information is encoded (this may be either ribonucleic acid or deoxyribonucleic acid), and a protein coat (capsid), which serves as a protective shell containing the nucleic acid and is involved in the efficiency of infection and the host range of the virus.

The description of a bacterial virus involves a study of its shape and dimensions by electron microscopy (see illustration), its host range, the serological properties of its capsid, the kind of nucleic acid it contains, and the characters of the plaques it forms on a given host. Both the nucleic acid and the capsid proteins are specific to the individual virus; in the case of the capsid proteins this specificity is the basis for serological identification of the virus.

The most striking form of phage infection is that in which all of the infected bacteria are destroyed in the process of the formation of new phage particles. This results in the clearing of a turbid liquid culture as the infected cells lyse. When lysis occurs in cells fixed as a lawn of bacteria growing on a solid

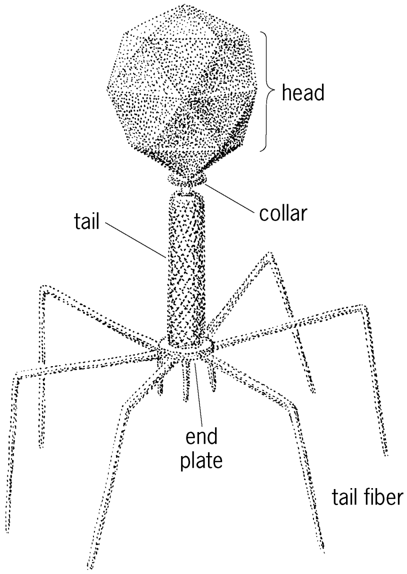


Diagram of a T4 bacteriophage.

medium, it produces holes, or areas of clearing, called plaques. These represent colonies of bacteriophage. The size and other properties of the plaque vary with individual viruses and host cells. *See* ACTINOPHAGE; COLIPHAGE; LYSOGENY; LYTIC INFECTION; VIRUS. [L.B.]

Badger The name for a number of species of heavily built omnivorous mammals assigned to the subfamily Melinae of the weasel family, Mustelidae. There are eight species in six genera (see table). *Taxidea taxus*, the American badger, is the only representative in North America. It tends to be more carnivorous with a diet consisting of small rodents, rabbits, prairie dogs, and ground squirrels in addition to vegetation. The American badger is more frequently found in open terrain than is the Eurasian species, which prefers wooded regions. Badgers live in burrows, called sets.

Names and geographic distribution of badgers

Species	Common name	Geographic distribution
Taxidea taxus	American badger	North America, especially United States
Meles meles	Eurasian or common badger	Europe, Asia
Arctonyx collaris	Hog or sand badger	Sumatra, southern Asia
Suillotaxus marchei	Philippines badger	Philippines
Mydaus javanensis	Malay or stinking badger, teledu	Malay Archipelago
Melogale moschata	Chinese ferret, badger	China, especially forested areas
Melogale orientalis	Javanese ferret, badger	Java, Borneo
Melogale personate	Burmese ferret, badger	Malayasia

Badgers are essentially nocturnal animals which have nonretractile claws on each of the five digits. Anal scent glands are present. The badgers walk on their feet and toes, and therefore are plantigrade. They have 38 teeth. Although little is known about the breeding behavior of the animal, the usual litter is three or four, and the gestation period for the Eurasian badger is known to be 7 months. In the colder regions of their range, badgers hibernate for varying periods from October on, with the exception of *Meles meles*, which is active during the winter. *See* CARNIVORA; HIBERNATION. [C.B.C.]

Balance An instrument used for the precise measurement of small weights or masses in amounts ranging from micrograms up to a few kilograms. *See* MASS; WEIGHT.

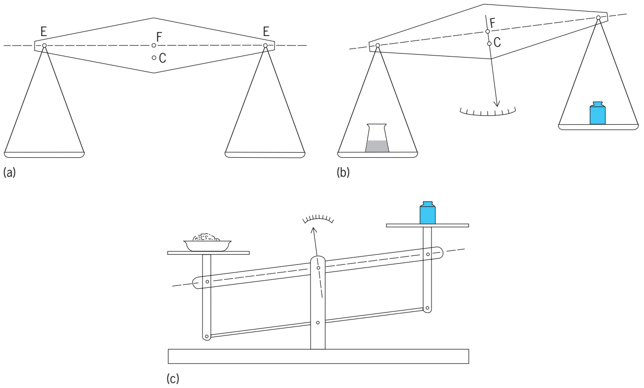
Balances are differentiated according to design, weighing principle, and metrological criteria (see table). For a given weighing task, a balance is selected primarily for its maximum weighing load (Max) and for the finest graduation or division (*d*) of its weight-reading device (scale dial, digital display, readout).

Balances can be roughly differentiated from scales by their resolution or number of scale divisions, $n = \mathrm{Max}/d$. Balances typically have a resolution of more than 10,000 divisions, and scales for the most part have less.

A traditional mechanical balance consists of a symmetric lever called a balance beam, two pans suspended from its ends, and a pivotal axis (fulcrum) at its center (see illustration). The object to be weighed is placed on one pan, whereupon the balance is brought into equilibrium by placing the required amount of weights on the opposite pan. Thus the weight of an object is defined as the amount represented by the calibrated standard masses that will exactly counterbalance the object on a classic equal-arm balance. Although this is not self-evident with modern balances and scales, the measurement of weight continues to be based on this original understanding.

Classification of balances

Type	Division (*d*)	Typical capacity (Max)
Ultramicroanalytical	0.1 μg	3 g
Microanalytical	1 μg	3 g
Semimicroanalytical	0.01 mg	30 g
Macroanalytical	0.1 mg	160 g
Precision	$\geq$1 mg	160 g–60 kg



Mechanical balance design. (*a*) Critical design aspects for an equal-arm balance. (*b*) Weighing small weight differentials with an equal-arm balance. (*c*) Top-loading equal-arm balance. F, fulcrum; E, end pivot; C, center of gravity.

The substitution principle represented the conclusive step in the evolution of the mechanical balance. Substitution balances have only one hanger assembly, incorporating both the load pan and a built-in set of weights on a holding rack. The hanger assembly is balanced by a counterpoise which is rigidly connected to the other side of the beam. The weight of an object is determined by lifting weights off the holding rack until the balance returns to an equilibrium position within its angular, differential weighing range. Small increments of weight in between the discrete dial weight steps are read from the projected screen image of a graduated optical reticle which is rigidly connected to the balance beam.

The evolution of electronic (more accurately, electromechanical) balances started in the late 1960s and has extended over several generations of electronic technology. Among a number of technical possibilities, one operating principle, electromagnetic force compensation, emerged early as the standard in high-precision weighing. First described by K. Ångström in 1895, the principle of electromagnetic force compensation became feasible for technical application as a result of the advancements in solid-state electronic components.

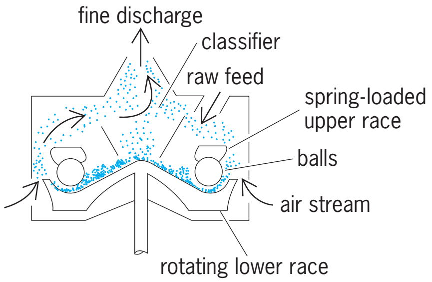
In every electromechanical weighing system, there are three basic functions: (1) The load-transfer mechanism, composed of the weighing platform or pan, levers, and guides, receives the weighing load on the pan as a randomly distributed pressure force and translates it into a measurable single force. (2) The electromechanical force transducer, often called load cell, converts the mechanical input force into an electrical output, for example, voltage, current, or frequency. (3) The electronic signal-processing part of the balance receives the output signal, converts it to numbers, performs computation, and displays the final weight data on the readout.

Besides improved accuracy, reliability, and speed of operation, the main benefits from this technology are human-engineered design for optimized interaction between operator and instrument, and numerous operating conveniences such as push-button zero setting, automatic calibration, built-in computing capabilities for frequently used work procedures, and data output to printers and computers. *See* PHYSICAL MEASUREMENT; WEIGHT MEASUREMENT. [W.E.Kup.]

Balanomorpha A suborder of the Thoracica. This group includes the common acorn barnacles. The mantle secretes a highly calcified test forming the bilaterally symmetrical conical shell, consisting typically of anterior rostrum, posterior carina, and one to three pairs of lateral plates. The broad basis is membranous or calcified. The shell (mantle) opening is closed by paired valves, each formed of two interlocking plates. These animals are hermaphroditic, and cross-fertilization is normal. Dwarf males have been recorded.

Balanomorph barnacles are found on almost every possible site for attachment, inanimate or living. They are most abundant intertidally and in shallow water. Some species occur at great depths. A few have become an economic problem as fouling organisms on ship hulls and in marine installations. *See* Barnacle; Thoracica. [H.G.St.]

Ball-and-race-type pulverizer A grinding machine in which balls rotate under pressure to crush materials, such as coal, to a fine consistency. The material is usually fed through a chute to the inside of a ring of closely spaced balls. In most designs the upper spring-loaded race applies pressure to the balls, and the lower race rotates and grinds the coarse material between it and the balls (see illustration). Two or more rings of balls can be cascaded in one machine to obtain greater capacity or output. Counterrotating top and bottom rings also are used to increase pulverizer capacity. Such pulverizers are compact and the power required per ton of material ground is relatively low. *See* Crushing and pulverizing. [G.W.K.]



Coarse raw material is ground by crushing and attrition between balls and races and is then withdrawn from the pulverizer by an airstream.

Ballast resistor A resistor that has the property of increasing in resistance as current flowing through it increases, and decreasing in resistance as current decreases. Therefore the ballast resistor tends to maintain a constant current flowing through it, despite variations in applied voltage or changes in the rest of the circuit. *See* Resistor.

The ballast action is obtained by using resistive material that increases in resistance as temperature increases. Any increase in current then causes an increase in temperature, which results in an increase in resistance and reduces the current. Ballast resistors may be wire-wound resistors. Other types, also called ballast tubes, are usually mounted in an evacuated envelope to reduce heat radiation.

Ballast resistors have been used to compensate for variations in line voltage, as in some automotive ignition systems, or to compensate for negative volt-ampere characteristics of other devices, such as fluorescent lamps and other vapor lamps. *See* Fluorescent lamp; Vapor lamp; Voltage regulator. [D.L.An.]

Ballistic missile A weapon that consists of integral rocket propulsion, means of pointing or guiding the weapon's velocity vector to a prescribed orientation at the position and time of rocket engine shutoff or burnout, and a warhead. In certain applications, means of deploying multiple warheads or submunitions may be incorporated. Ballistic missiles are conceptually simple weapons whose implementation becomes more complex with increasing accuracy, range, and defense penetration requirements.

The term ballistic means that part or most of the missile's trajectory is not subject to propulsion or control. In its ballistic phase of flight, a missile's motion is affected only by gravitation and uncontrolled aerodynamic interactions with the atmosphere.

The ballistic missile follows an elliptical path due to action of the Earth's gravitational field. If both the burnout velocity and burnout altitude are large, then an upwardly slanted flight path will cause the missile's trajectory to rise high above the sensible atmosphere, thereby eliminating the retarding and disturbing influences of the Earth's atmosphere for most of the trajectory. *See* Ballistics; Celestial mechanics.

All ballistic missiles incorporate means of pointing or guiding their velocity vectors so that their trajectories end coincidentally with the intended target. The simplest instance involves launching a missile from a guide rail or tube which the weapon operator points toward the intended target and upward at predetermined elevation angle that will result in a missile impact in the target area. The Army's Multiple Rocket Launching System (MRLS) is a good example of simple pointing as the means of initial-conditions guidance. Intercontinental ballistic missiles (ICBMs) wherein propulsion durations of several minutes are typical and precise pointing of the velocity vector at propulsion burnout is essential to achieve the desired accuracy in hitting the target area after intercontinental flight. ICBMs and theater nuclear weapons typically employ control over the direction of thrust from their rocket motors to change the orientation of the missile in response to guidance commands. Guidance is based upon the principles of inertial navigation. *See* Guidance systems; Inertial guidance system.

Ballistic missiles are either land-based or sea-based.

Land-based versions are commonly categorized according to the distance they can fly. *See* Army armament.

1. Battlefield ballistic missiles can hit targets from 12 to 300 mi (20 to 500 km) from the launch point, and generally employ conventional (nonnuclear) or submunition warheads.
2. Intermediate-range ballistic missiles (IRBM), which are sometimes referred to as intermediate nuclear forces (INF) or theater nuclear weapons, come in a variety of sizes, and can hit targets 300 to 3000 mi (500 to 5000 km) from the launch site. These missiles invariably carry one to three nuclear warheads.
3. ICBMs have flyout ranges between 5500 and 7500 mi (9000 and 12,000 km). Modern ICBMs carry from one to ten nuclear warheads in reentry vehicles that are independently targetable (multiple independently targeted reentry vehicles, or MIRVs).

Sea-based ballistic missiles are invariably based on submarines (submarine-launched ballistic missiles, or SLBMs), providing considerable uncertainty as to their location as an important element of survivability. The flyout range of SLBMs has systematically increased from a few thousand kilometers to more than 5500 mi (9000 km), equaling the capability of ICBMs. SLBMs have employed MIRV warheads since the early 1970s, and accuracy enhancements of the 1980s provide SLBMs with effectiveness levels comparable to those of their land-based counterparts. *See* Guided missile; Missile; Naval armament; Submarine. [M.M.Br.]

Ballistic range A long, instrumented enclosure wherein tests of gun-launched projectiles are conducted. Ballistic ranges were originally used for study of projectile flight characteristics such as the rate of velocity loss and the dispersion of trajectories, that is, the imperfect following of the bore sight line of the gun. Ballistic ranges are now used for the measurement of aerodynamic characteristics of projectiles and of scale models of

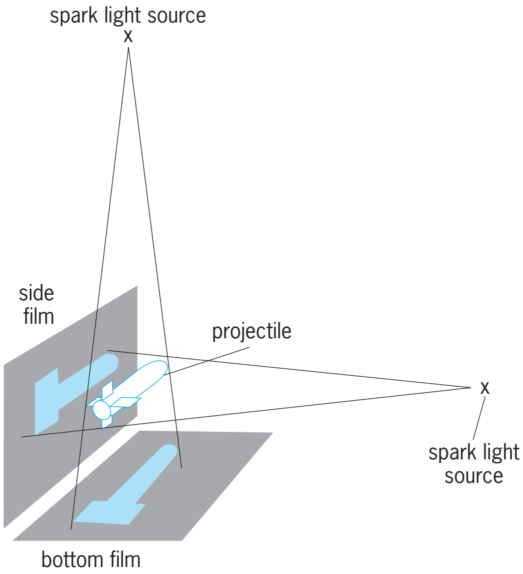


Fig. 1. Simple shadowgraph system.

vehicles intended for flight through the atmosphere, including missiles, aircraft, and space-flight capsules.

Ballistic ranges may vary in length from less than 10 ft (3 m), for limited investigations of small arms projectiles, to greater than 1000 ft (300 m), for detailed studies of projectiles from large-bore guns. Instrumentation may be as simple as a series of sheets of paper hung normal to the flight path (yaw cards) in which the projectile, by punching its outline, gives evidence of its vertical and lateral position and its angular orientation at the instant of penetration. The more refined instruments required in modern practice are usually photographic. A spark of extremely short duration (from 1 to 0.1 microsecond) is discharged when the projectile reaches a position between the spark and a piece of film (Fig. 1). The resulting shadow photograph (shadowgraph) records in projection two components of the linear position of the projectile and one component of angular orientation. Two orthogonal pictures, as in the simple system shown, completely define the position in space of the model. A number of shadowgraph stations placed in sequence along the flight path will define, as a function of distance flown, the history of position and attitude of the projectile in flight. Corollary timing apparatus is used to measure the precise times, frequently accurate within microseconds, at which the pictures are recorded.

The shadowgraph pictures further aid aerodynamic studies by making visible certain details of the airflow about the projectile (Fig. 2). Refraction, or bending, of light rays by the variable-air-density field about the model makes visible the shock waves, turbulence, boundary layers, and boundaries of expansion fans. The flow visualization is most valuable for the study of aerodynamics.

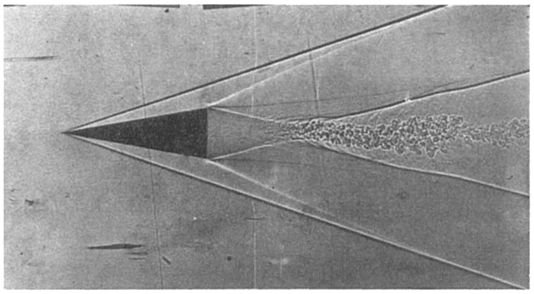

Fig. 2. Shadowgraph of a cone in supersonic flight. (*NASA, Ames Research Center*)

In modern practice the velocity performance of ballistic ranges has sometimes been enhanced by placing the instrumented range within the test section of a supersonic wind tunnel, which provides a high-velocity airflow opposite in direction to the model's flight direction. The earliest facility of this type used a conventional supersonic wind tunnel with a very long test section, driven by a high-pressure reservoir of air at room temperature. Later devices have been driven by high-temperature air generated in a shock tube. *See* WIND TUNNEL. [A.Se.]

Ballistics That branch of applied physics which deals with the motion of projectiles and the conditions governing that motion. Commonly called the science of shooting, it is, for practical purposes, subdivided into exterior and interior ballistics. Exterior ballistics begins at the instant the projectile leaves the muzzle of the gun barrel; interior ballistics, logically, deals with the events preceding this instant, that is, the events inside the gun barrel. [W.L./D.Wo.]

Balloon A nonporous envelope of thin material filled with a lifting gas and capable of lifting any surrounding material and usually a suspended payload into the atmosphere. A balloon which is supported chiefly by buoyancy imparted by the surrounding air is often referred to as an aerostat. The balloon rises because of a differential displacement of air according to Archimedes' principle, which states that the total upward buoyant force is equal to the weight of the air displaced. The upper practical limit for useful ballooning is approximately 34 mi (55 km). Beyond this altitude, the exponential nature of the atmosphere would require balloons of enormous size and delicately thin skin. A record altitude of 32.2 mi (51.8 km) has been recorded.

Balloons have been configured in many geometrical shapes, but the most common are spheres, oblate spheroids, and aerodynamic configurations. The materials used in the manufacture of the balloon envelope have been paper, rubber, fabric, and various plastics. Several types of lifting gases have been used to inflate balloons, but the most common in use are helium, hydrogen, and heated air.

The many types of balloons in use fall into twin main categories: extensible (expandable) and nonextensible. There are three methods of balloon operation: free balloons which are released into the atmosphere, tethered or moored balloons, and powered or controlled free balloons. The various types of balloons in use are the hot-air balloon, meteorological balloon, zero-pressure balloon, superpressure balloon, tethered balloon, and powered balloon (airship). *See* AIRSHIP. [W.R.N.]

Balsa A fast-growing tree, *Ochroma lagopus*, widely distributed in tropical America, especially in Ecuador. The leaves are simple, angled, or lobed, and the flowers are large and yellowish-white or brownish, and they are terminal on the branches. *See* MALVALES.

With plenty of room for growth in a rich, well-drained soil at low elevations, the wood is very light and soft. However, under adverse conditions, the wood is heavier. Culture is important, for if the trees are injured only slightly, the wood develops a hard and fibrous texture, thereby losing its commercial value. To secure a uniform product the trees must be grown in plantations.

The wood decays easily in contact with the soil and is subject to sap stain if not promptly dried. Seasoned lumber absorbs water quickly, but this can be largely overcome by waterproofing.

Balsa owes most of its present commercial applications to its insulating properties. Balsa also has sound-deadening qualities, and is also used under heavy machinery to prevent transmission of vibrations. The heartwood of balsa is pale brown or reddish, whereas the sapwood is nearly white, often with a yellowish or pinkish hue. Luster is usually rather high, and the wood is odorless and tasteless. [A.H.G./K.P.D.]

Baltic Sea A semienclosed brackish sea located in a humic zone, with a positive water balance relative to the adjacent ocean (the North Sea and the North Atlantic). The Baltic is connected to the North Sea by the Great Belt (70% of the water exchange), the Øresund (20% of the water exchange), and the Little Belt. The total area of the Baltic is 147,414 mi^2 (381,705 km^2), its total volume 4982 mi^3 (20,764 km^3), and its average depth 181 ft (55.2 m). The greatest depth is 1510 ft (459 m), in the Landsort Deep.

The topography of the Baltic is characterized by a sequence of basins separated by sills and by two large gulfs, the Gulf of Bothnia (40,100 mi^2 or 104,000 km^2) and the Gulf of Finland (11,400 mi^2 or 29,500 km^2). More than 200 rivers discharge an average of 104 mi^3 (433 km^3) annually from a watershed area of 637,056 mi^2 (1,649,550 km^2). The largest river is the Newa, with 18.5% of the total fresh-water discharge. From December to May, the northern and eastern parts of the Baltic are frequently covered with ice. On the average, the area of maximum ice coverage is 82,646 km^2 (214,000 km^2). The mean maximum surface-water temperature in summer is between 59 and 63°F (15 and 17°C).

As the Baltic stretches from the boreal to the arctic continental climatic zone, there are large differences between summer and winter temperature in the surface waters, ranging from about 68 to 30°F (20 to −1°C) in the Western Baltic and 57 to 32°F (14 to −0.2°C) in the Gulf of Bothnia and the Gulf of Finland.

The salt content of the Baltic waters is characterized by two major water bodies; the brackish surface water and the more saline deep water. Salinities for the surface water range from 8 to 6‰ in the Western and Central Baltic and 6 to 2000 in the Gulf of Bothnia and the Gulf of Finland; salinities for the deep water range from 18 to 13‰ in the Western and Central Baltic and 10 to 4‰ in the Gulf of Bothnia and the Gulf of Finland.

The surface currents of the Baltic are dominated by a general counterclockwise movement and by local and regional wind-driven circulations. A complex system of small- and medium-scale gyres develops especially in the central parts of the Baltic. The currents in the Belt Sea are dominated by the topography; they are due to sea-level differences between the Baltic proper and the North Sea. Tides are of minor importance, ranging between 0.8 and 4.7 in. (2 and 12 cm). Water-level changes of more than 6 ft (2 m) occur occasionally as a result of onshore or offshore winds and the passage of cyclones over the Baltic Sea area. The frequency of longitudinal sea-level oscillations is about 13.5 h. *See* Ocean circulation.

The flora and fauna of the Baltic are those of a typical brackish-water community, with considerably reduced numbers of species compared to an oceanic community. The productivity is relatively low compared to other shelf seas. The major commercially exploited species are cod, herring, sprat, flounder, eel, and salmon, and some fresh-water species such as whitefish, pike, perch, and trout. The total annual catch amounts to about 880,000 tons (800,000 metric tons). The Baltic is completely divided into fishery zones, with exclusive fishing rights belonging to the respective countries.

Other than fish the only major resources that have been exploited are sand and gravel in the Western Baltic Sea. It is believed that the deeper layer under the Gotland Basin contains mineral oil, but so far only exploratory drilling has been carried out in the near-coastal regions. Limited amounts of mineral oil have also been located in the Gulf of Kiel. [K.G.]

Bamboo The common name of various perennial, ornamental grasses (Gramineae). There are five genera with approximately 280 species. They have a wide distribution, but occur mainly in tropical and subtropical parts of Asia, Africa, and America, extending from sea level to an elevation of 15,000 ft (4600 m). Their greatest development occurs in the monsoon regions of Asia. Most plants are woody; a few are herbaceous or climbing. The economic uses of bamboo are numerous and varied. The seeds and young shoots are used as food, and the leaves make excellent fodder for cattle. In varying sizes, the stems are used for pipes, timber, masts, bows, furniture, bridges, cooking vessels, buckets, wickerwork, paper pulp, cordage, and weaving. Entire houses are made of bamboo stems. Certain bamboos have been naturalized in California, Louisiana, and Florida. *See* Cyperales. [P.D.St./E.L.C.]

Banana A large tropical plant of the family Musaceae; also its edible fruit, which occurs in hanging clusters, is usually yellow when ripe, and is about 6–8 in. (15–20 cm) long. The banana of commerce (*Musa sapientum*), believed to have originated in the Asian tropics, was one of the earliest cultivated fruits. For commercial production the plant requires a tropical climate within the temperature range 50–105°F (10–40°C) and a constant supply of moisture by rainfall or irrigation.

The plant portion above the ground is a false stem (pseudostem) consisting of several concentrically formed leaves, from the center of which develops the inflorescence stalk. The rhizome or true stem is underground. Near the tip of the flower stalk are several groups of sterile male flowers subtended by brilliant purple bracts. The lower female flower clusters on the same stalk give rise to the fruit and contain aborted stamens (male organs). The single fruits are called fingers, a single group of 8–12 fingers is termed a hand, and the several (6–18) hands of the whole inflorescence make up the stem.

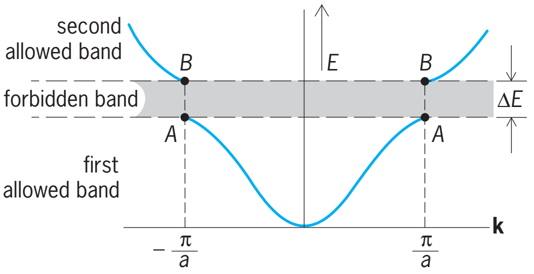
The fruit bunch requires 75–150 days to mature and must be removed from the plant to ripen properly. Chilled banana fruits do not soften normally; hence for best edibility the fruit is kept well ventilated at room temperature. Banana fruits of commerce set without pollination, by parthenocarpy, and hence are seedless. When mature, most varieties are yellow, although fine red-skinned types are well known. There are several hundred varieties grown throughout the world. The Cavendish banana (*M. nana*, variety Valery) is becoming important in the American tropics. The more starchy bananas, known as plantains, must be cooked before they can be eaten. *See* Fruit; Fruit, tree; Zingiberales. [C.A.Sch.]

Band spectrum A spectrum consisting of groups or bands of closely spaced lines. Band spectra are characteristic of molecular gases or chemical compounds. When the light emitted or absorbed by molecules is viewed through a spectroscope with small dispersion, the spectrum appears to consist of very wide asymmetrical lines called bands. These bands usually have a maximum intensity near one edge, called a band head, and a gradually decreasing intensity on the other side. In some band systems the intensity shading is toward shorter waves, in others toward longer waves. Each band system consists of a series of nearly equally spaced bands called progressions; corresponding bands of different progressions form groups called sequences.

When spectroscopes with adequate dispersion and resolving power are used, it is seen that most of the bands obtained from gaseous molecules actually consist of a very large number of lines whose spacing and relative intensities, if unresolved, explain the appearance of bands of continua. For the quantum-mechanical explanations of the details of band spectra *see* Molecular structure and spectra. [W.F.M./W.W.W.]

Band theory of solids A quantum-mechanical theory of the motion of electrons in solids which predicts certain restricted ranges, or bands, for the electron energies.

If the atoms of a solid are separated from each other to such a distance that they do not interact, the energy levels of the electrons will then be those characteristic of the individual free atoms, and thus many electrons will have the same energy. As the distance between atoms is decreased, the electrons in the outer



Electron energy *E* versus wave vector k for a monatomic linear lattice of lattice constant *a*. (*After C. Kittel, Introduction to Solid State Physics, 7th ed., 1995*)

shells begin to interact, thus altering their energy and broadening the sharp energy level out into a range of possible energy levels called a band. One would expect the process of band formation to be well advanced for the outer, or valence, electrons at the observed interatomic distances in solids. Once the atomic levels have spread into bands, the valence electrons are not confined to individual atoms, but may jump from atom to atom with an ease that increases with the increasing width of the band.

Although energy bands exist in all solids, the term energy band is usually used in reference only to ordered substances, that is, those having well-defined crystal lattices. In such a case, an electron energy state can be classified according to its crystal momentum $\mathbf{p}$ or its electron wave vector $\mathbf{k} = \mathbf{p}/\hbar$ (where $\hbar$ is Planck's constant h divided by 2π). If the electrons were free, the energy of an electron whose wave vector is $\mathbf{k}$ would be as shown in the equation below, where E_0 is the energy of the lowest state of a

$$E(\mathbf{k}) = E_0 + \hbar^2 k^2/2m_0$$

valence electron and m_0 is the electron mass. In a crystal, however, the electrons are not free because of the effect of the crystal binding and the forces exerted on them by the atoms; consequently, the relation $E(\mathbf{k})$ between energy and wave vector is more complicated. The statement of this relationship constitutes the description of an energy band.

The bands of possible electron energy levels in a solid are called allowed energy bands. There are also bands of energy levels which it is impossible for an electron to have in a given crystal. Such bands are called forbidden bands, or gaps. The allowed energy bands sometimes overlap and sometimes are separated by forbidden bands. The presence of a forbidden band immediately above the occupied allowed states (such as the region A to B in the illustration) is the principal difference in the electronic structures of a semiconductor or insulator and a metal. In the first two substances there is a gap between the valence band or normally occupied states and the conduction band, which is normally unoccupied. In a metal there is no gap between occupied and unoccupied states. The presence of a gap means that the electrons cannot easily be accelerated into higher energy states by an applied electric field. Thus, the substance cannot carry a current unless electrons are excited across the gap by thermal or optical means.

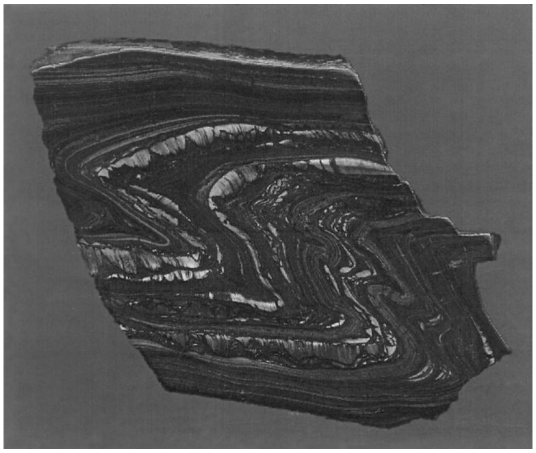
Under external influences, such as irradiation, electrons can make transitions between states in the same band or in different bands. The interaction between the electrons and the vibrations of the crystal lattice can scatter the electrons in a given band with a substantial change in the electron momentum, but only a slight change in energy. This scattering is one of the principal causes of the electrical resistivity of metals. *See* Electrical resistivity.

An external electromagnetic field (for example, visible light) can cause transitions between different bands. Here momentum must be conserved. Because the momentum of a photon $h\upsilon/c$ (where υ is the frequency of the light and c its velocity) is quite small, the momentum of the electron before and after collision is nearly the same. Such a transition is called vertical in reference to an energy band diagram. Conservation of energy must also hold in the transition, so absorption of light is possible only if there is an unoccupied state of energy $h\upsilon$ available at the same $\mathbf{k}$ as the initial state. These transitions are responsible for much of the absorption of visible and near-infrared light by semiconductors.

The results of energy-band calculations for ordinary metals usually predict Fermi surfaces and other properties that agree rather well with experiment. In addition, cohesive energies and values of the lattice constant in equilibrium can be obtained with reasonable accuracy, and, in the case of ferromagnetic metals, calculated magnetic moments agree with experiment. However, there are significant discrepancies between theoretical calculations and experiments for certain types of systems, including heavy-fermion systems (certain metallic compounds containing rare-earth or actinide elements), superconductors, and Mott-Hubbard insulator (compounds of $3d$ transition elements, for which band calculations predict metallic behavior). Also band calculations for semiconductors such as silicon, germanium and gallium arsenide (GaAs) predict values for the energy gap between valence and conduction bands in the range one-half to two-thirds of the measured values. In all these cases, the failures of band theory are attributed to an inadequate treatment of strong electron-electron interactions. [J.C.]

Banded iron formation Banded iron formation is a sedimentary rock that was commonly deposited during the Precambrian. It was probably laid down as a colloidal iron-rich chemical precipitate, but in its present compacted form it consists typically of equal proportions of iron oxides (hematite or magnetite) and silica in the finely crystalline form of quartz known as chert. Its chemical composition is 50% silicon dioxide (SiO_2) and 50% iron oxides (Fe_2O_3 and Fe_3O_4), to give a total iron content of about 30%. Banding is produced by the concentration of these two chemical components into layers about 1–5 cm (1/2–2 in.) thick; typical banded iron formation consists of pale silica-rich cherty bands alternating with black to dark red iron-rich bands (see illustration). These contrasting layers are sharply defined, so that the rock has a striped appearance; banded iron formation is normally a hard, tough rock, highly resistant both to erosion and to breaking with a hammer.

The world's iron and steel industry is based almost exclusively on iron ores associated with banded iron formation. Banded iron formation itself may be the primary ore, from which hematite or magnetite is concentrated after crushing. But the main ore now



Folded banded iron formation from the Ord Range, Western Australia. The distance between top and bottom of the polished face of the sample is about 15 cm (6 in.). Chert jasper bands alternate with dark magnetite-rich bands. The thin pale layers of irregular thickness are bands of asbestiform amphibole, now replaced by silica, to give the semiprecious material "tiger-eye." (*Photo courtesy of John Blockley*)

mined globally is high-grade (greater than 60% iron) material that formed within banded iron formation by natural leaching of its silica content. [A.F.T.]

Bandwidth requirements (communications)

The channel bandwidths needed to transmit various types of signals, using various processing schemes. Every signal observed in practice can be expressed as a sum (discrete or over a frequency continuum) of sinusoidal components of various frequencies. The plot of the amplitude versus frequency constitutes one feature of the frequency spectrum (the other being the phase versus frequency). The difference between the highest and the lowest frequencies of the frequency components of significant amplitudes in the spectrum is called the bandwidth of the signal, expressed in the unit of frequency, hertz. Every communication medium (also called channel) is capable of transmitting a frequency band (spectrum of frequencies) with reasonable fidelity. Qualitatively speaking, the difference between the highest and the lowest frequencies of components in the band over which the channel gain remains reasonably constant (or within a specified variation) is called the channel bandwidth. *See* FOURIER SERIES AND TRANSFORMS; WAVEFORM.

Clearly, to transmit a signal with reasonable fidelity over a communication channel, the channel bandwidth must match and be at least equal to the signal bandwidth. Proper conditioning of a signal, such as modulation or coding, however, can increase or decrease the bandwidth of the processed signal. Thus, it is possible to transmit the information of a signal over a channel of bandwidth larger or smaller than that of the original signal.

Amplitude modulation (AM) with double sidebands (DSB), for example, doubles the signal bandwidth. If the audio signal to be transmitted has a bandwidth of 5 kHz, the resulting AM signal bandwidth using DSB is 10 kHz. Amplitude modulation with a single sideband (SSB), on the other hand, requires exactly the same bandwidth as that of the original signal. In broadcast frequency modulation (FM), on the other hand, audio signal bandwidth is 15 kHz (for high fidelity), but the corresponding frequency-modulated signal bandwidth is 200 kHz. *See* FREQUENCY MODULATION; FREQUENCY-MODULATION RADIO; SINGLE SIDEBAND.

C. E. Shannon proved that over a channel of bandwith B the rate of information transmission, C, in bits/s (binary digits per second) is given by the equation below, where SNR is the

$$C = B \log_2(1 + \text{SNR}) \qquad \text{bits/s}$$

signal-to-noise power ratio. This result assumes a white gaussian noise, which is the worst kind of noise from the point of view of interference. *See* INFORMATION THEORY; SIGNAL-TO-NOISE RATIO.

It follows from Shannon's equation that a given information transmission rate C can be achieved by various combinations of B and SNR. It is thus possible to trade B for SNR, and vice versa.

A corollary of Shannon's equation is that, if a signal is properly processed to increase its bandwidth, the processed signal becomes more immune to interference or noise over the channel. This means that an increase in transmission bandwidth (broadbanding) can suppress the noise in the received signal, resulting in a better-quality signal (increased SNR) at the receiver. Frequency modulation and pulse-code modulation are two examples of broadband schemes where the transmission bandwidth can be increased as desired to suppress noise.

Broadbanding is also used to make communication less vulnerable to jamming and illicit reception by using the so-called spread spectrum signal. *See* ELECTRICAL COMMUNICATIONS; ELECTRONIC WARFARE; SPREAD SPECTRUM COMMUNICATION. [B.P.L.; M.Wr.]

Barbiturates A group of drugs widely used for the suppression of anxiety, the induction of sleep, and the control of seizures. Some of them, when injected intravenously, produce a general anesthesia. *See* ANESTHESIA.

Barbituric acid, from which the various barbiturate congeners come, is a malonyl urea. Following the synthesis of this compound, a dozen or more closely related compounds were synthesized by adding or substituting various radicals to the general formula. The names of many of them have become familiar; examples are Phenobarbital, Meberal, Seconal, Nembutal, Amytal, and Pentothal.

These drugs act by suppressing the excitability of all tissues; but all tissues are not equally sensitive. Low dosages induce drowsiness, and high dosages coma and death. The spread between the therapeutic and fatal doses varies with the different barbiturates.

The prolonged use of these drugs results in habituation; and insomnia, agitation, confusional psychosis, and seizures may occur within 24 to 36 hours of withdrawal. Overdose is one of the commonest means of suicide in Western countries, and life can be saved only by admission to a hospital where respiration can be maintained and cerebral anoxia prevented. [R.D.A.]

Barite An orthorhombic mineral with chemical composition $BaSO_4$. It possesses one perfect cleavage, and two good cleavages, as do the isostructural minerals. The mineral has a specific gravity of approximately 4.5, and is relatively soft, approximately 3 on Mohs scale. The color ranges through white to yellowish, gray, pale blue, or brown, and a thin section is colorless.

Barite is often an accessory mineral in hydrothermal vein systems, but frequently occurs as concretions or cavity fillings in sedimentary limestones. It also occurs as a residual product of limestone weathering and in hot spring deposits. It occasionally occurs as extensive beds in evaporite deposits. Occurrences of barite are extensive. It is found as a vein mineral associated with zinc and lead ores in Derbyshire, England. Large deposits occur at Andalusia, Spain. Commercial residual deposits occur in limestones throughout the Appalachian states such as Georgia, Tennessee, and Kentucky. It also occurred in substantial amounts in the galena ore deposits in Wisconsin and Missouri.

Since barite is dense and relatively soft, its principal use is as a weighting agent in rotary well-drilling fluids. It is the major ore of barium salts, used in glass manufacture, as a filler in paint, and, owing to the presence of a heavy metal and inertness, as an absorber of radiation in x-ray examination of the gastrointestinal tract. [P.B.M.]

Barium A chemical element, Ba, with atomic number 56 and atomic weight of 137.34. Barium is eighteenth in abundance in the Earth's crust, where it is found to the extent of 0.04%, making it intermediate in amount between calcium and strontium, the other alkaline-earth metals. Barium compounds are obtained from the mining and conversion of two barium minerals. Barite, barium sulfate, is the principal ore and contains 65.79% barium oxide. Witherite, sometimes called heavy spar, is barium carbonate and is 72% barium oxide. *See* BARITE; PERIODIC TABLE; WITHERITE.

The metal was first isolated by Sir Humphry Davy in 1808 by electrolysis. Industrially, only small amounts are prepared by aluminum reduction of barium oxide in large retorts. These are used in barium-nickel alloys for spark-plug wire (the barium increases the emissivity of the alloy) and in frary metal, which is an alloy of lead, barium, and calcium used in place of babbitt metal because it can be cast.

The metal reacts with water more readily than do strontium and calcium, but less readily than sodium; it oxidizes quickly in air to form a surface film that inhibits further reaction, but in moist air it may inflame. The metal is sufficiently active chemically to react with most nonmetals. Freshly cut pieces have a lustrous

Properties of barium

Property	Value
Atomic number	56
Atomic weight	137.34
Isotopes (stable)	130, 132, 134, 135, 136, 137, 138
Atomic volume	36.2 cm^3/g-atom
Crystal structure	Face-centered cubic
Electron configuration	2 8 18 18 8 2
Valence	2+
Ionic radius (A)	1.35
Boiling point, °C	1140(?)
Melting point, °C	850(?)
Density	3.75 g/cm^3 at 20°C
Latent heat of vaporization at boiling point, kj/g-atom	374

gray-white appearance, and the metal is both ductile and malleable. The physical properties of the elementary form are given in the table.

For the manufacture of barium compounds, soft (easily crushable) barite is preferred, but crystalline varieties may be used. Crude barite is crushed and then mixed with pulverized coal. The mixture is roasted in a rotary reduction furnace, and the barium sulfate is thus reduced to barium sulfide or black ash. Black ash is roughly 70% barium sulfide and is treated with hot water to make a solution used as the starting material for the manufacture of many compounds.

Lithopone, a white powder consisting of 20% barium sulfate, 30% zinc sulfide, and less than 3% zinc oxide, is widely used as a pigment in white paints. Blanc fixe is used in the manufacture of brilliant coloring compounds. It is the best grade of barium sulfate for paint pigments. Because of the large absorption of x-rays by barium, the sulfate is used to coat the alimentary tract for x-ray photographs in order to increase the contrast. Barium carbonate is useful in the ceramic industry to prevent efflorescence on claywares. It is used also as a pottery glaze, in optical glass, and in rat poisons. Barium chloride is used in purifying salt brines, in chlorine and sodium hydroxide manufacture, as a flux for magnesium alloys, as a water softener in boiler compounds, and in medicinal preparations. Barium nitrate, or the so-called baryta saltpeter, finds use in pyrotechnics and signal flares (to produce a green color), and to a small extent in medicinal preparations. Barium oxide, known as baryta or calcined baryta, finds use both as an industrial drying agent and in the case-hardening of steels. Barium peroxide is sometimes used as a bleaching agent. Barium chromate, lemon chrome or chrome yellow, is used in yellow pigments and safety matches. Barium chlorate finds use in the manufacture of pyrotechnics. Barium acetate and cyanide are used industrially as a chemical reagent and in metallurgy, respectively. [R.F.R.]

Bark A word generally referring to the surface region of a stem or a root. Sometimes part or all of the bark is called rind. Occasionally the word bark is used as a substitute for periderm or for cork only. Most commonly, however, it refers to all tissues external to the cambium. If this definition is applied to stems having only primary tissues, it includes phloem, cortex, and epidermis; the bark of roots of corresponding age would contain cortex and epidermis. In the more general usage the term bark is restricted to woody plants with secondary growth.

In most roots with secondary growth, the bark consists of phloem and periderm since the cortex and epidermis are sloughed off with the first cork formation in the pericycle that is beneath the cortex. In stems, the first cork cambium may be formed in any living tissue outside the vascular cambium, and the young bark may include any or all of the cortex in addition to the phloem and periderm. The region composed of the successive layers of periderm and the enclosed dead tissues is called outer bark. The outer bark composed of dead phloem alternating with bands of cork is called, technically, rhytidome. Both stems and roots may have rhytidome. The inner bark is living, and consists of phloem only. *See* CORTEX (PLANT); EPIDERMIS (PLANT); PARENCHYMA; PERICYCLE; PERIDERM; PHLOEM; ROOT (BOTANY); STEM. [H.W.Bl.]

Barkhausen effect An effect, due to discontinuities in size or orientation of magnetic domains as a body of ferromagnetic material is magnetized, whereby the magnetization proceeds in a series of minute jumps. *See* FERROMAGNETISM; MAGNETIZATION.

Ferromagnetic materials are characterized by the presence of microscopic domains of some 10^{12} to 10^{15} atoms within which the magnetic moments of the spinning electrons are all parallel. In an unmagnetized specimen, there is random orientation of the various domains. When a magnetic field is applied to the specimen, the domains turn into an orientation parallel to the field, or if parallel to the field, the domains increase in size. During the steep part of the magnetization curve, whole domains suddenly change in size or orientation, giving a discontinuous increase in magnetization. If the specimen being magnetized is within a coil connected to an amplifier and loudspeaker, the sudden changes give rise to a series of clicks or, when there is a rapid change, a hissing sound. This is called the Barkhausen effect; it is an important piece of evidence in support of a domain theory of magnetism. [K.V.M.]

Barley A cereal grass plant whose seeds are useful to humans. It is grown in nearly all cultivated areas of the temperate

Barley spikes: (*a*) six-rowed *Hordeum vulgare*; (*b*) two-rowed *H. distichum* (*USDA*).

parts of the world, and is an important crop in Europe, North and South America, North Africa, much of Asia, and Australia. Barley is the most dependable cereal crop where drought, summer frost, and alkali soils are encountered. In the United States, barley is grown to some extent in 49 states, with the most important production areas in North Dakota, Montana, and California. Principal uses of barley grain are as livestock feed, for the production of barley malt, and as human food. It is also used in some areas for hay and silage.

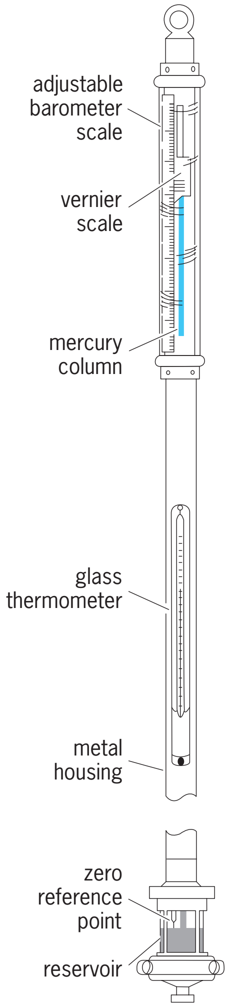
Taxonomically barley belongs to the family Gramineae, subfamily Festucoideae, tribe Hordeae, and genus *Hordeum*. Most of the modern cultivated barleys are *H. vulgare* (six-rowed) or *H. distichum*. (two-rowed; see illustration). All cultivated barleys are annuals and are naturally self-pollinated. In the cultivated varieties, a wide diversity of morphological, physiological, and anatomical types are known. There are spring, facultative, and winter growth habits; hulled and naked grain; awned, awnless, and hooded lemmas; black, purple, and white kernels; and also a wide range of plant heights, spike densities, and resistances to a wide range of diseases and insects. There are in excess of 150 cultivars presently commercially grown in the United States and Canada alone, and many additional cultivars are grown in other parts of the world. New and improved varieties produced by barley breeders are constantly replacing older varieties. Several barley collections are being maintained in different countries as germplasm sources for breeding and research. These include both collections made by direct exploration in many barley-growing areas of the world and lines from barley-breeding programs. Among the largest of these collections is one maintained by the U.S. Department of Agriculture, which includes more than 17,000 individual strains. *See* CYPERALES. [D.A.R.]

Barnacle The name popularly applied to two types of Crustacea, subclass Cirripedia, the goose barnacles and acorn barnacles. Both were formerly of importance to seafarers (and acorn barnacles are still so) because of their habit of adhering to ships hulls. Four orders of barnacles are recognized, of which one only, the Thoracica, fits the popular conception of barnacles. *See* CIRRIPEDIA; THORACICA. [H.G.St.]

Baroclinic field A distribution of atmospheric pressure and mass such that the specific volume, or density, of air is a function of both pressure and temperature, but not either alone. When the field is baroclinic, solenoids are present, there is a gradient of air temperature on a surface of constant pressure, and there is a vertical shear of the geostrophic wind. Significant development of cyclonic and anticyclonic wind circulations typically occurs only in strongly baroclinic fields. Fronts represent baroclinic fields which are locally very intense. *See* AIR PRESSURE; FRONT; GEOSTROPHIC WIND; SOLENOID (METEOROLOGY); STORM; WIND. [F.S.; H.B.B.]

Barometer An absolute pressure gage specifically designed to measure atmospheric pressure. This instrument is a type of manometer with one leg at zero pressure absolute. *See* MANOMETER.

The common meteorological barometer (see illustration) is a liquid-column gage filled with mercury. The top of the column is sealed, and the bottom is open and submerged below the surface of a reservoir of mercury. The atmospheric pressure on the reservoir keeps the mercury at a height proportional to that pressure. An adjustable scale, with a vernier scale, allows a reading of column height. Aneroid barometers using metallic diaphragm elements are usually less accurate, though often more sensitive, devices, and not only indicate pressure but may be used to record it. *See* PRESSURE MEASUREMENT. [J.H.Z.]



Mercury barometer.

Barotropic field A distribution of atmospheric pressure and mass such that the specific volume, or density, of air is a function solely of pressure. When the field is barotropic, there are no solenoids, air temperature is constant on a surface of constant pressure, and there is no vertical shear of the geostrophic wind. Significant cyclonic and anticyclonic circulations typically do not develop in barotropic fields. Considerable success has been achieved, paradoxically, in prediction of the flow pattern at middle-tropospheric elevations by methods which are strictly applicable only to barotropic fields, despite the fact that the field in this region is definitely not barotropic. The subtropics, however, are to a large extent barotropic. *See* AIR PRESSURE; BAROCLINIC FIELD; GEOSTROPHIC WIND; SOLENOID (METEOROLOGY); WEATHER FORECASTING AND PREDICTION; WIND. [F.S.; H.B.B.]

Barracuda The name for about 20 species of fish found in warm seas throughout the world. All species belong to the genus *Sphyraena* and are members of the order Perciformes. The larger species, such as the great barracuda (*Sphyraena barracuda*), are solitary and not found in schools. Generally, all species are good food fish.

The teeth, which occur both in the jaws and on the roof of the large mouth, are strong and pointed, resembling canine teeth. The jaws are long, with the lower projecting beyond the upper, and the upper incapable of being protracted. The head is large and pointed, and the body is compressed and long, somewhat like the pike. The body is covered with cycloid scales, and the lateral line is well developed. Many of these fish weigh over 100 lb (45 kg) and reach a length of 10 ft (3 m). *See* Perciformes. [C.B.C.]

Barretter A bolometer element with a positive temperature coefficient of resistance, used to detect and measure power at radio, microwave, infrared, and optical frequencies. The temperature of the barretter increases when electromagnetic energy is absorbed. Barretters are made of metal; therefore, the electrical resistance increases when the temperature increases. The resulting resistance change of the barretter is measured by using direct-current or low-frequency instruments. *See* Bolometer.

The barretter resistance is selected to absorb most of the power when the barretter is mounted as a termination in a waveguide or coaxial transmission line. A barretter can be made to detect power at optical and infrared frequencies by using a very thin metal ribbon blackened to absorb light. *See* Transmission lines; Waveguide.

Barretters with less sensitivity and accuracy for use at radio frequencies can be made by using low-current fuses made with fine wires. *See* Fuse (electricity); Incandescent lamp.

A meter can be made to measure high-frequency signal amplitudes using a barretter. The temperature and hence the resistance of a barretter can change at audio-frequency rates, but the time constant of a barretter is too great for the resistance to vary at radio-frequency rates. A radio- or microwave-frequency current modulated at a low frequency will cause the barretter resistance to follow the low-frequency signal. If a direct-current voltage is applied to the barretter while the modulated radio-frequency current is also applied, the varying resistance will produce a current which follows the modulation. The low-frequency current can be coupled to the input of an audio amplifier tuned to the modulation frequency by using an audio transformer. The output of the audio amplifier may be rectified to drive a direct-current meter. The meter then indicates the relative amplitude of the radio-frequency or microwave signal. [R.C.Po.]

Barrier islands Elongate, narrow accumulations of sediment which have formed in the shallow coastal zone and are separated from the mainland by some combination of coastal bays and marshes. They are typically several times longer than their width and are interrupted by tidal inlets. Although their origin has been widely discussed, at least three possibilities exist: longshore spit development and subsequent cutting of inlets; drowning of old coastal ridges; and upward shoaling of subtidal sediment accumulations. All three may have occurred; however, the last seems most likely and most prevalent.

Barrier islands must be considered in terms of the adjacent and closely related environments within the coastal system. Beginning offshore and proceeding landward, the sequence of environments crossed is shoreface, beach, dunes, back-island flats or marsh, coastal bay, marsh, and mainland. The barrier island proper consists of the beach, dunes, and back-island flats or marsh; however, of the remaining environments, at least the shoreface is closely integrated with the barrier island in terms of morphology, processes, and sediments. *See* Dune.

A variety of physical processes exists along the coast. These processes act to shape and maintain the barrier-island system and also to enable the barrier to migrate landward as sea level continues to rise. The most important process in the barrier-island system is the waves, which also give rise to longshore currents. Waves and longshore currents dominate the outer portion of the barrier system, whereas tidal currents are dominant landward of the barrier, although small waves may also be present. Tidal currents are most prominent in and adjacent to the inlets. On the supratidal portion of the barrier island, the wind is the most dominant physical process.

Barrier-island sands represent one of the best sources of oil and gas, with the tight organic-rich source rocks being in the form of the bay and shelf muds and the barrier itself being the reservoir rock. These elongate sand bodies have been sought by exploration geologists for decades. The Tertiary sequences of the Texas Gulf coasts are an example of such barrier systems which have been very productive. *See* Coastal landforms. [R.A.D.]

Baryon The generic name for any hadronic particle with baryon number $B = +1$. By far the most common baryons are the proton and neutron, the two states of the nucleon doublet $N = (p, n)$ [Table 1]. The baryon number of any particular state may be deduced from its production or decay processes, or both, since the total baryon number is conserved (with possible rare exceptions discussed below) and $B = 0$ holds for all mesons and leptons. *See* Lepton; Meson; Neutron; Nucleon; Proton.

It is now generally accepted that hadrons are composite, consisting of spin-$^1/_2$ quarks (q), corresponding antiquarks (q), and some number of gluons, the last being the quanta of the intermediate field which binds the quarks and antiquarks to form hadrons. $B = +\frac{1}{3}$ holds for a quark q, $B = -\frac{1}{3}$ for an antiquark q, while $B = 0$ holds for a gluon. Thus, a baryon consists of three ("valence") quarks, together with some number of quark-antiquark (qq) pairs (called the quark-antiquark sea) and of gluons. The quarks must be assigned fractional charge values, relative to the proton charge (Table 2). *See* Gluons; Hadron; Quarks.

Color and quantum chromodynamics. This quark theory of the hadrons has been proposed in a quite specific form, known as quantum chromodynamics (QCD). It is a gauge theory based on a symmetry hypothesized for the hadronic interactions of the quarks, which says that these interactions are invariant with respect to a local (gauge) group of unitary transformations with modulus unity, $\mathrm{SU}(3)_C$, acting in an abstract complex three-dimensional space known as color space. Each quark type then has three color states, usually labeled by the suffixes r (red), g (green), and b (blue), corresponding to the three axes of this space. The gauge particle of this symmetry theory is the gluon, a neutral vector particle coupled universally with the currents of color, just as the photon, the gauge particle of quantum electrodynamics (QED), is coupled universally with the electromagnetic current. However, whereas the photon has no charge, the gluon has eight color components, so that it is a color octet. Consequently, there is a gluon contribution to the color currents, and so the gluon field must interact with itself, introducing a nonlinearity into quantum chromodynamics which has no parallel in quantum electrodynamics. This nonlinearity has important implications for quantum chromodynamics, leading to its asymptotic freedom, the property that the coupling of gluon to the color current approaches zero at short distances, which is essential for even qualitative agreement between quantum chromodynamics predictions and the empirical data on high-energy collision processes. *See* Color (quantum mechanics); Gauge theory; Quantum chromodynamics; Quantum electrodynamics; Symmetry laws (physics).

An important element in quantum chromodynamics is the confinement dogma, the assertion that only color singlet states have finite energy. This assertion implies that neither a quark nor a gluon can exist in a free state, since the former is a color triplet and the latter a color octet, and indeed no observations of free gluons or quarks have yet been confirmed. However, no rigorous proof that the dogma follows from quantum chromodynamics has yet been given.

Quantitative predictions of the properties of baryonic states are currently made by using a simplified quark-quark (q-q) potential with the following features: (1) an attractive long-range potential, increasing with separation to ensure confinement, and (2) a spin-dependent potential representing one-gluon exchange, effective at small separation, where the regime of

†Σ_c is included here, although hadronically unstable, because Λ_c, Σ_c, Ξ_c, and Ω_c belong to a common SU(3)$_f$ multiple t; see Fig. 2*a*.

asymptotic freedom holds and perturbation theory is valid. Such predictions have had a great deal of success.

The quark content of the nucleons is given by Eqs. (1).

$$p = (uud) \qquad n = (udd) \tag{1}$$

The replacement of a d quark in the nucleon by an s quark produces a baryon state with spin parity $\frac{1}{2}^+$ and strangeness number $s = -1$, the latter being given by $[n(s) - n(\bar{s})]$, where $n(q)$ denotes the number of quarks of type q in the system considered. The states thus reached have the flavor structures of Eqs. (2), the

$$(\Sigma^+, \Sigma^0, \Sigma^-) = (uus, (ud + du)s/\sqrt{2}, dds) \tag{2a}$$

$$\Lambda = (ud - du)s/\sqrt{2} \tag{2b}$$

other factors in their wave functions being identical with those for the nucleons; thus the isotriplet Σ and isosinglet Λ states are obtained. If a u quark and a d quark are each replaced by an s quark in Eqs. (1), the isodoublet Ξ states of Eq. (3) are

$$(\Xi^0, \Xi^-) = (uss, dss) \tag{3}$$

obtained. The quark has $I = 0$, being unaffected by the SU(2)τ transformations in the (u, d) space. The flavor wave function (sss) is necessarily symmetric and cannot occur with total spin $S = \frac{1}{2}$. Baryonic states with $s \neq 0$ are collectively termed hyperons. *See* HYPERON; STRANGE PARTICLES.

Flavor	$I_3 = -\frac{1}{2}$	$I_3 = +\frac{1}{2}$	$s = -1$	$c = +1$	$b = -1$	$t = +1$
Lepton type	ν_e	e^+	μ^+	ν_μ	τ^+	ν_τ

*To each quark and lepton, there exists an antiquark and antilepton with opposite flavor values and with opposite intrinsic parity.
†Quark masses are rough estimates of the "effective mass" of each quark in a hadron.

These eight baryon states (p, n, Σ^+, Σ^0, Σ^-, Λ, Ξ^0, Ξ^-) all have the spin parity $\frac{1}{2}^+$ and the same internal wave functions. It is helpful to use the quantum number $Y = (B + s)$, named hypercharge. Then, if the states are arrayed in the $I_3 - Y$ plane (Fig. 1), the symmetry of their relationship is evident.

The mass difference $\delta m = [m(s) - m(u, d)]$ is quite large, and so SU(3)$_f$ symmetry is much more strongly violated than SU(2)$_\tau$ symmetry. The baryon mass values vary widely over the octet; the leading variation is that proportional to the strangeness s, which counts the s-quark content of each baryon. The approximately 75-MeV difference between the mean Σ mass $m(\Sigma)$ and $m(\Lambda)$ has a more subtle origin, but is well accounted for on the basis of the quark-quark (qq) potential from quantum chromodynamics, described above. The small mass differences within each isospin multiplet are believed to be due to the intrinsic (u, d) mass difference and to electromagnetic effects.

The baryon-baryon interactions are of particular interest. That

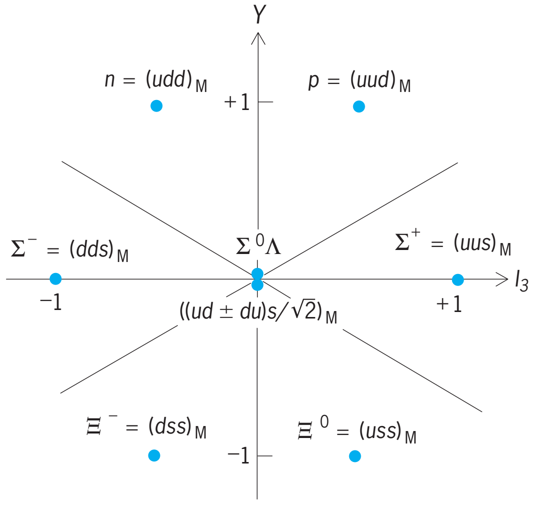

Fig. 1. Baryon octet states, arrayed with respect to I_3 as ordinate and $Y = (B + s)$ as abscissa. The charge number Q is given by $Q = I_3 + Y/2$. There are three axes of symmetry.

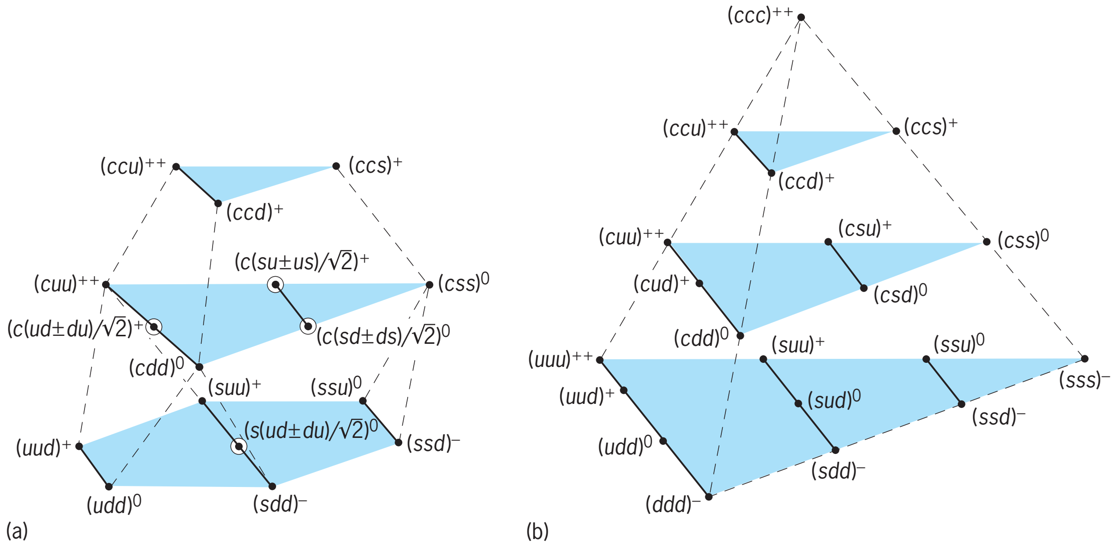

Fig. 2. Arrays of the states of baryons made from three quarks of the types *u, d, s,* and *c*, with no internal orbital angular momentum. The quark content and charge of each state is specified. The vertical axis specifies the number of *c* quarks. (*a*) $^1/_2{}^+$ baryons. (*b*) $^3/_2{}^+$ baryons. The former have flavor symmetry M; the latter have symmetry S.

between nucleons gives rise to the existence of atomic nuclei, and has been particularly well studied, both empirically and theoretically. For large separations (greater than 0.8 femtometer), the *NN* force is due to the exchange of pions and of other known mesons with masses less than about 1 GeV; for small separations (less than 0.4 fm), a strong short-range repulsion is observed, possibly arising from the suppressive effects of the Pauli principle for quarks when the quark structures of the two nucleons overlap. At low energies, the outstanding feature of the *NN* interaction is its strong noncentral tensor component, which is due to one-pion exchange and is a direct consequence of the pseudoscalar nature of the pion. It also has a strong spin-orbit interaction, observed in *NN* interactions at higher energy and of much importance for the shell structure of nuclei. *See* Nuclear structure.

Many further particle-unstable baryon states, with lifetimes in the range 10^{-22} to 10^{-23} s, have become established, up to mass values of order 2500 MeV, all consistent with the limitations of the three-quark model.

Further baryon states can be formed by replacing one or more of the *u*, *d*, and *s* quarks of the states discussed above by a *c* quark. If the *s* and *c* quarks both had the same mass as the (*u, d*) quarks, the states formed would correspond to an SU(4)$_f$ symmetry. Extensions of the $^1/_2{}^+$ baryon octet (Fig. 2*a*) and the $^3/_2{}^+$ baryon decuplet (Fig. 2*b*) to arrays in three dimensions are obtained in this way. The lowest plane of each such array consists of the charmless baryon states, in accord with the original octet or decuplet. In reality, the *c*-quark mass is so large that little quantitative detail of SU(4)$_f$ symmetry can survive in the physical situation, and these arrays have value mainly for general comprehension and for the counting of states.

The fifth quark, named "bottom" (symbol *b*), was discovered in 1978. The baryon $\Lambda_b{}^0$ is well established, with decay mode $\pi^-\Lambda_c{}^+$ and mass 5624 ± 9 MeV. *See* Upsilon particles.

The sixth quark, named "top" (symbol *t*), became established in 1994 through top-antitop pair production in proton-antiproton collisions at center-of-mass energy 1800 GeV. Its mass, 174 ± 5 GeV, is remarkably large, far above the bW^+ threshold at ≈85 GeV. The decay $t \to bW^+$ is very rapid, its lifetime being 4×10^{-25} s and its decay width $\Gamma_t \approx 1.5$ GeV. This decay is so much faster than hadronization that there is almost no time for top baryons to form.

No further quark-lepton families are expected. This conclusion comes from counting the number of neutrino species in Z^0 decays, and from astrophysical arguments about light-nucleus formation in the early universe.

For every baryonic state mentioned above, there will exist an antibaryon state with opposite flavor quantum numbers, in particular with $B = -1$. The antiproton $\bar{p}$ was first identified in 1954, and antiproton beams at high-energy proton accelerators are a basic tool in elementary particle research. Most of the expected antibaryon states have been detected and studied in some detail.

In grand unification theories (GUT), which attempt to account for both quarks and leptons, together with their strong, electromagnetic, and weak interactions, quark → lepton transitions generally exist, at some level, since such theories assign leptons and quarks to common multiplets. This violation of baryon conservation opens the possibility that the lightest baryon, the proton, might not be absolutely stable but may undergo decay processes such as $p \to e^+ \pi^0$ at a very low rate. Indeed, cosmology appears to require the existence of nucleon decay processes in order to account for the baryon-antibaryon asymmetry of the universe. Empirically, the partial decay rate $\Gamma(p \to e^+\pi^0)$ is less than 0.58×10^{-40} s^{-1} with 90% probability. In the simplest GUT [known as SU(5)], this leads to a proton lifetime greater than 1.7×10^{32} years. Other GUTs may predict smaller decay rates, even zero. Since proton decay offers the possibility of discriminating between various GUTs, the detection of proton decay (and neutron decay involving baryon nonconservation, for example, when bound in a deuteron or alpha particle), or at least the improvement of the present empirical limits on its rate, is an important subject of investigation. *See* Cosmology; Elementary particle; Fundamental interactions; Grand unification theories. [R.H.D.]

Basalt An igneous rock characterized by small grain size (less than about 0.2 in. or 5 mm) and approximately equal proportions of calcium-rich plagioclase feldspar and calcium-rich pyroxene, with less than about 20% by volume of other minerals. Olivine, calcium-poor pyroxene, and iron-titanium oxide minerals are the most prevalent other minerals. Most basalts are dark gray or black, but some are light gray. Various structures and textures of basalts are useful in inferring both their igneous origin and their environment of emplacement. Basalts are the predominant surficial igneous rocks on the Earth, Moon, and probably other bodies in the solar system. Several chemical-mineralogical types of basalts are recognized. The nature of basaltic rocks provides helpful clues about the composition and temperature within the Earth and Moon. The magnetic properties of basalts are responsible in large part for present knowledge of the past behavior of the Earth's magnetic field and of the rate of sea-floor spreading. Some meteorites are basaltic rocks. They differ significantly from lunar basalts and appear to have originated elsewhere in the solar system at a time close to the initial condensation of the solar nebula. *See* Igneous rocks; Meteorite.

Basalt erupts out of fissures and cylindrical vents. Repeated or continued extrusion of basalt from cylindrical vents generally builds up a volcano of accumulated lava and tephra around the vent. Fissure eruptions commonly do not build volcanoes, but small cones of tephra may accumulate along the fissures. *See* Volcano; Volcanology.

Basalts display a variety of structures mostly related to their environments of consolidation. On land, basalt flows form pahoehoe, aa, and block lava, while under water, pillow lava is formed. Basalt also occurs as pumice and bombs. Commonly, basaltic pumice is called scoria to distinguish it from the lighter-colored, more siliceous rhyolitic pumice.

The mineralogy and texture of basalts vary with cooling history and with chemical composition. As basalt crystallizes, both the minerals and the residual melt change in composition because of differences between the composition of the melt and the crystals forming from it. In basalts, because of the rapid cooling, there is little chance for crystals to react with the residual melt after the crystals have formed. Completely solid basalts generally preserve a record of their crystallization in the zoned crystals and residual glass.

Most basalts contain minor amounts of chromite, magnetite, ilmenite, apatite, and sulfides in addition to the minerals mentioned above. Magnetite in basalts contains a history of the strength and orientation of the Earth's magnetic field at the time of cooling. Therefore, although magnetite is minor in amount, it is probably the most important mineral in terrestrial basalts, because it enables earth scientists to infer both the magnetic history of the Earth and the rate of the production of basaltic ocean floor at the oceanic ridges.

Basalts occur in all four major tectonic environments: ridges in the sea floor, islands in ocean basins, island arcs and mountainous continental margins, and interiors of continents. The principal environment is the deep sea floor. Significant differences exist in the composition of basalt which relate to different tectonic environments (see table). Chemical analyses of basalts are now used instead of, or together with, the textural criteria as a basis of classification. Geologists customarily recast the chemical analysis into a set of ideal minerals according to a set of rules. The result is called the norm of the rock. In general there is rather close correspondence between the normative minerals and the observed minerals in basaltic rocks. *See* Petrology; Magma. [A.T.A.]

Base (chemistry)

In the Brønsted-Lowry classification, any chemical species, ionic or molecular, capable of accepting or receiving a proton (hydrogen ion) from another substance. The other substance acts as an acid in giving up the proton. A substance may act as a base, then, only in the presence of an acid. The greater the tendency to accept a proton, the stronger the base. The hydroxyl ion acts as a strong base. Substances that ionize in aqueous solutions to produce the hydroxyl ion (OH), such as potassium hydroxide (KOH) and barium hydroxide [$Ba(OH)_2$], are also conventionally called bases.

Anions of weak acids such as acetic and formic, act as bases in reacting with solvent water to form the molecular acid and hydroxyl ion, for example, the acetate ion (CH_3COO^-). Ammonia (NH_3) and amines react similarly in aqueous solutions. In these examples, the acetate ion and acetic acid (CH_3COOH) and NH_3 and the ammonium ion are conjugate base-acid pairs. The basicity constant, K_b, is the equilibrium constant for the proton transfer reaction, and it is a quantitative measure of base strength.

The Lewis classification involves the concept of a base as a substance that donates an electron pair to an acid aceptor. In the gas phase, NH_3 acts as a base contributing an electron pair to the formation of a convalent bond with the boron trifluoride (BF_3) molecule. *See* Acid and base. [F.J.J.]

Basidiomycota

A phylum in the kingdom fungi; commonly known as basidiomycetes. Basidiomycetes traditionally included four artificial classes: Hymenomycetes, Gasteromycetes, Urediniomycetes, and Ustilaginomycetes. They are mostly filamentous fungi characterized by the production of basidia. These are microscopic, often club-shaped end cells in which nuclear fusion and meiosis usually take place prior to the maturation of external, typically haploid basidiospores, which are then disseminated. Common basidiomycetes are the rusts and smuts, which cause severe plant diseases, mushrooms (edible and poisonous), boletes, puffballs, stinkhorns, chanterelles, false truffles, jelly fungi, bird's-nest fungi, and conk or bracket fungi. Basidiomycetes are the most important decayers of wood, living or dead, in forests or buildings, causing either brown rot (for example, dry rot) or white rot. Many, especially mushrooms and boletes, are the primary fungal partners in symbiotic ectomycorrhizal associations with tree roots. Plant litter and soil are other major habitats. A few basidiomycetes are cultivated for food. Some are luminescent, hallucinogenic, lichenized, nematophagous, or aquatic. Some are cultivated by ants or termites, or are symbiotic with captured scale insects. Some can convert to a yeast (or single-cell) phase, one of which causes cryptococcosis in humans and animals. *See* Mushroom; Mycorrhizae; Rust (microbiology); Wood degradation. [S.A.R.]

Basil

An annual herb (*Ocimum basilicum*) of the mint family (Labiatae), grown from seed for its highly scented leaves. It is sold fresh or dried, and its essential oil is used in pharmaceuticals and flavoring. The genus *Ocimum* has approximately 150 species, many of which are also grown as “basil.” *See* Lamiales.

Growth habit varies with type, but it is usually upright and branching from a square central stem up to 24 in. (61 cm) in height. Leaf shape and odor vary considerably from type to type, with “sweet basil,” the most popular, having broad, flat, shiny green leaves to 3 in. (75 cm) long. Wild forms of basil are found in South America, Africa, India, and Europe. Cultivated basil differs little from its wild forms, although breeding and selection work have been performed on some of the varieties grown for essential oil production. Some of the more popular cultivated types are: sweet basil (used fresh or dehydrated), lemon-scented basil, opal basil (a purple-leaved type), and large- or lettuce-leaf basil. Many unusual types can be obtained which have a scent similar to camphor, lemon, licorice, or nutmeg. *See* SPICE AND FLAVORING. [S.Kir.]

Basin A low-lying area which is wholly or largely surrounded by higher land. An example is Hudson Bay in northeastern Canada, which was formed by depression beneath the center of a continental ice sheet 18,000 years ago. Another example, the Qattara depression, is 150 mi (240 km) long and the largest of several wind-excavated basins of northern Egypt. Depressions in the ocean floor are also basins, such as the Canary Basin, west of northern Africa, or the Argentine Basin, east of Argentina. These basins occur in regions where cold, dense oceanic crust lies between the topographically elevated ocean ridges and the continental margins. *See* CONTINENTAL MARGIN; MARINE GEOLOGY.

A drainage basin is the entire area drained by a river and its tributaries. Thus, the Mississippi Basin occupies most of the United States between the Rocky Mountains and the Appalachians. Interior drainage basins consist of depressions that drain entirely inward, without outlet to the sea. Examples may be quite small, such as the Salton Sea of southern California or the Dead Sea of central Asia. One of the most remarkable examples of an interior drainage basin is the Chad Basin in northern Africa, the center of which is occupied by Lake Chad. The fresh waters of the lake drain underground to feed oases in the lowlands 450 mi (720 km) to the northeast.

In the geologic sense, a basin is an area in which the continental crust has subsided and the depression has been filled with sediments. Such basins were interior drainage basins at the time of sediment deposition but need not be so today. As these basins subside, the layers of sediment are tilted toward the axis of maximum subsidence. Consequently, when the sedimentary layers are observed in cross section, their geometry is a record of the subsidence of the basin through time and contains clues about the origin of the basin.

The origin of geologic basins is a topic of continuing interest in both applied and basic geological studies. They contain most of the world's hydrocarbon reserves, and they are regarded as some of the best natural laboratories in which to understand the thermal and mechanical processes that operate deep in the interior of the Earth and that shape the Earth's surface. [G.Bo.; M.Ko.]

Basommatophora A superorder of the molluscan subclass Pulmonata containing about 2500 species that are grouped into 11–15 families. Only a few members of the family Ellobiidae are terrestrial, with the other species today being tidal to supratidal or estuarine in habitat. The families Siphonatiidae and Trimusculidae are marine limpets with cap-like shells. The families Otinidae and Amphibolidae also are marine taxa. The remaining families inhabit a great variety of fresh-water situations and are quite varied in shell structure and shape. Because of this great variation in habitat and form, it is difficult to find structures that are common to all taxa and thus diagnostic of the group, which indeed may not have a common origin. The most easily observable characters are having the eyespots normally located at the base of two slender tentacles that are neither contractile nor retractile, and usually having two external genital orifices. Most features of the anatomy are shared with other pulmonate superorders, or are specializations related to major changes in habitat or body form. *See* PULMONATA. [G.A.S.]

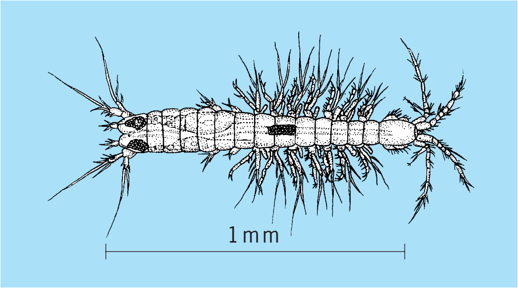
Bass The name for a number of fishes assigned to two families in the order Perciformes. Both marine and fresh-water species are included under this common name, and all are highly prized as game fish as well as for food. Members of the family Centrarchidae are commonly referred to as the freshwater or black basses, while the Serranidae are designated as the sea basses. *See* PERCIFORMES. [C.B.C.]

Basswood A member of the linden family in the order Malvales. One species, known as the American linden (*Tilia americana*), is a timber tree of the northeastern quarter of the United States and the adjacent area of Canada. *Tilia* is also an ornamental tree. *Tilia europea*, or lime tree of Europe, is often cultivated along the streets. The lindens are also important as bee trees. The leaves are heart-shaped, coarsely toothed, long, pointed, and alternate. All species of *Tilia* can be recognized by the winter buds, which have a large outer scale that gives the bud a humped, asymmetrical appearance, and by the small, spherical, nutlike fruits borne in clusters.

The wood of basswood, also known as whitewood, is white and soft and is used for boxes, venetian blinds, millwork, furniture, and woodenware. There are about 30 species in the temperate regions of the Northern Hemisphere in North America south to Mexico, but none in the western part. In Asia lindens grow south to central China and southern Japan. *See* MALVALES. [A.H.G./K.P.D.]

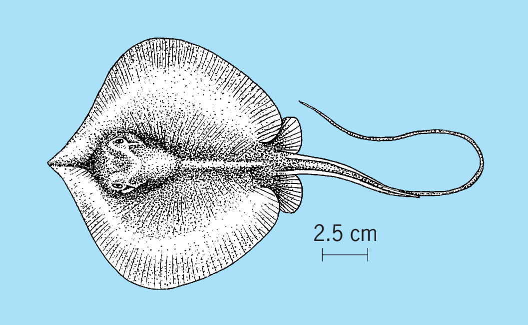
Batales A small order of flowering plants, division Magnoliophyta (Angiospermae), in the subclass Dilleniidae of the class Magnoliopsida (dicotyledons). It consists of two small families and fewer than 20 species, of no economic significance. The plants are trees, shrubs, or subshrubs with simple, entire leaves and small, unisexual flowers. The perianth consists of small, separate or fused sepals with no petals. The stamens are four to numerous; the pistil has (1)2-many carpels, fused to form a plurilocular, superior ovary. The fruit is a dry, dehiscent nutlet or a drupe. The taxonomic disposition of the Batales has long been disputed, and it is often included in the Caryophyllidae. However, the presence of mustard oils as well as certain morphological features suggest that the order is best included near the Capparales in the Dilleniidae. *See* CAPPARALES; DILLENIIDAE; MAGNOLIOPHYTA; PLANT KINGDOM. [T.M.Ba.]

Bathynellacea An order of syncarid crustaceans found in subterranean waters in central Europe and England. The body is elongate and segmented. Organs and limbs are primitive. Each of the thoracic limbs has two epipodites which function as gills. The thorax and abdomen have a similar form (see illustration). These animals have no metamorphosis. *See* SYNCARIDA. [H.J.]



***Bathynelia natans*, female.**

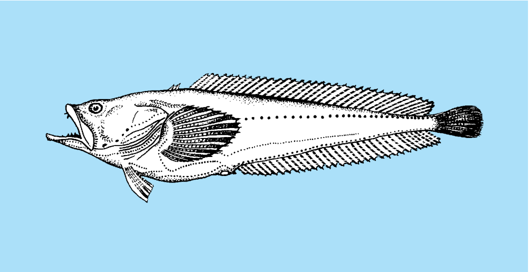
Batoidea Skates and rays, one of the two Recent orders of the subclass Elasmobranchii. The order is also known as Rajiformes. The skates and rays differ from the sharks (order Selachii) in having ventral gill slits, the edge of the pectoral fin attached to the side of the head anterior to the gill clefts, and the upper margin of the orbit not free from the eyeball (see illustration). Guitarfishes, the most generalized rays, appeared in the Upper Jurassic, but most major groups of rays date from the Cretaceous.



Atlantic stingray (*Dasyatis sabina*). (*After G. B. Goode, Fishery Industries of the United States, 1884*)

Rays have been classified in 5 suborders, 16 families, 47 genera, and 300–350 species. They occur in all oceans, and most are sluggish bottom inhabitants, although the mantas commonly swim at the surface. A few, especially stingrays and sawfishes, penetrate estuaries of tropical rivers or even live far upstream. Rays vary in size from less than 1 ft (0.3 m) in length as adults to a width of over 20 ft (6 m) in the giant mantas. There are some bizarre skates that live at depths of as much as 9000 ft (2750 m); however, none of these is luminescent. The torpedoes have a pair of enlarged electric organs located lateral to the eyes on the expansive pectoral fins; these can deliver a strong and temporarily disabling shock to bathers. More to be feared, however, are the stingrays, which lie in shallow water and if stepped on are able to inflict a dangerous or fatal wound with the serrated tail spine and its venom gland. Rays are carnivorous, feeding on a wide variety of marine worms, mollusks, crustaceans, and other invertebrates, as well as small fishes. Although rays are abundant in many seas, they are of minor commercial importance. *See* ELASMOBRANCHII. [R.M.B.]

Batrachoidiformes The toadfishes, which make up an order (or suborder) of actinopterygian fishes. This group is also known as the Haplodoci. The first vertebra of Batrachoidiformes is rigidly fused with the broad, flattened cranium; the short posttemporal is not forked and is suturally attached to the skull. There are no epiotics, intercalars, or ribs, and the four or five pectoral radials are elongate. There are only three gill arches, and the gill openings are reduced in size. The pelvic fins are on the throat; the spinous dorsal fin is short, and the soft dorsal and anal fins are long (see illustration).



Atlantic midshipman (*Porichthys porosissimus*). (*After D. S. Jordan and B. W. Evermann*)

The single family, Batrachoididae, known from Miocene to Recent lime, includes 10 genera and about 35 species. Most live in tropical and temperate oceanic shore waters or in moderate depths, but a few ascend tropical rivers. Some species are luminescent; some have hollow opercular and dorsal spines associated with venom glands. Toadfishes have powerfully muscled jaws and strong teeth and are predacious. *See* ACTINOPTERYGII; BIOLUMINESCENCE; OSTEICHTHYES. [R.M.B.]

Battery An electrochemical device that stores chemical energy which can be converted into electrical energy, thereby providing a direct-current voltage source. Although the term “battery” is properly applied to a group of two or more electrochemical cells connected together electrically, both single-cell and multicell devices are called battery. *See* ELECTROCHEMISTRY; ELECTROMOTIVE FORCE (CELLS).

The two general types are the primary battery and the secondary battery. The primary battery delivers current as the result of a chemical reaction that is not efficiently reversible. Practically, this makes the primary battery nonrechargeable. Only one intermittent or continuous discharge can be obtained before the chemicals placed in it during manufacture are consumed. Then the discharged primary battery must be replaced. The secondary or storage battery is rechargeable because it delivers current as the result of a chemical reaction that is easily reversible. When a charging current flows through its terminals in the direction opposite to the current flow during discharge, the active materials in the secondary battery return to approximately their original charged condition.

The cell is the basic electrochemical unit. It has three essential parts: (1) a negative electrode (the anode) and (2) a positive electrode (the cathode) that are in contact with (3) an electrolyte solution. The electrodes are metal rods, sheets, or plates that are used to receive electrical energy (in secondary cells), store electrical energy chemically, and deliver electrical energy as the result of the reactions that occur at the electrode-solution surfaces. Solid polymer or plastic active materials have been developed that can serve as the cathode in rechargeable batteries. The electrolyte is a chemical compound (salt, acid, or base) that when dissolved in a solvent forms a solution that becomes an ionic conductor of electricity, but essentially insulating toward electrons—properties that are prerequisites for any electrolyte. In the cell or battery, this electrolyte solution is the conducting medium in which the flow of electric current between electrodes takes place by the migration of ions. When water is the solvent, an aqueous solution is formed. Some cells have a nonaqueous electrolyte, for example, when alcohol is used as the solvent. Other cells have a solid electrolyte that when used with solid electrodes can form a leak-free solid-state cell or battery.

During charging of a secondary cell, the negative electrode becomes the cathode and the positive electrode becomes the

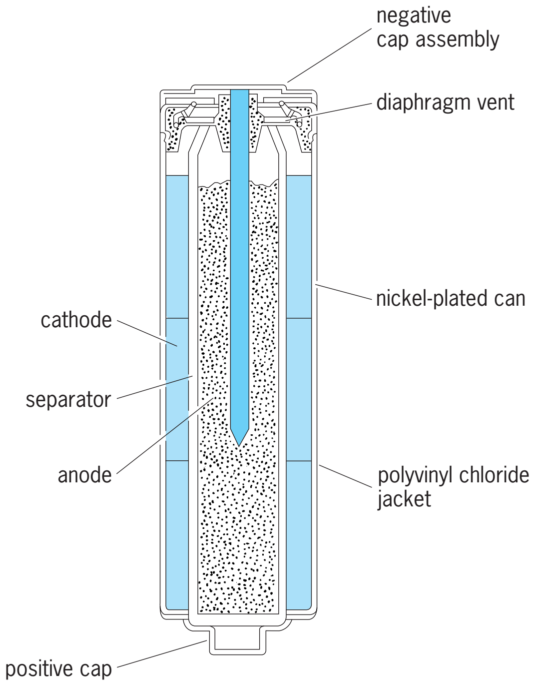


Diagram of a zinc-alkaline-manganese dioxide cylindrical cell.

anode. However, electrode designation as positive or negative is unaffected by the operating mode of the cell or battery. Two or more cells internally connected together electrically, in series or parallel, form a battery of a given voltage. Typical are the rectangular 9-V primary battery, which has six flat 1.5-V zinc-carbon or alkaline "dry" cells connected in series, and the 12-V automotive or secondary battery, which has six 2.1-V lead-acid "wet" cells connected in series.

A primary cell or battery is not intended to be recharged and is discarded when it has delivered all its electrical energy (see illustration). Several kinds of primary cell are widely used, particularly in portable devices and equipment, providing freedom from the dependence on alternating-current line power. They are convenient, lightweight, and usually relatively inexpensive sources of electrical energy that provide high energy density (long service life) at low-to-moderate or intermittent discharge rates, good shelf life, and ease of use while requiring little or no maintenance.

Primary cells are classified by their electrolyte, which may be described as aqueous, nonaqueous, aprotic, or solid. In most primary cells the electrolyte is immobilized by a gelling agent or mixed as a paste, with the term "dry cell" commonly applied to the zinc-carbon Leclanche cell and sometimes to other types. An aqueous electrolyte or electrolyte system is used in zinc-carbon, magnesium, alkaline-manganese dioxide, mercuric oxide, silver oxide, and zinc-air cells. Nonaqueous electrolyte systems are used in lithium cells and batteries. *See* ELECTROLYTE. [D.L.An.]

Secondary batteries (also known as accumulators) are rechargeable. This means that the electrochemical reactions in the cell must be reversible so that if the load in the external circuit is replaced by a power supply, the reactions in the cell can be forced to run in reverse, thereby restoring the driving force for reaction and hence recharging the cell. The paradigm of battery design is to identify a chemical reaction with a strong driving force and then to fashion a cell that requires the reaction to proceed by a mechanism involving electron transfer, thereby making electrons available to a load in the external circuit. The magnitude of the driving force will determine cell voltage; the kinetics of reaction will determine cell current.

Most batteries have solid electrodes and a liquid electrolyte. However, there are examples of batteries in which the anode and cathode are both liquid, and the electrolyte is solid.

The lead-acid battery is the dominant secondary battery, used in a wide variety of applications, including automotive SLI (starting, lighting, ignition), traction for industrial trucks, emergency power, and UPS (uninterruptible power supplies). The attributes of lead-acid batteries include low cost, high discharge rate, and good performance at subambient temperatures. The anode is metallic lead. The cathode active material is lead dioxide, which is incorporated into a composite electrode also containing lead sulfate and metallic lead. The electrolyte is an aqueous solution of sulfuric acid, 37% by weight when the battery is fully charged.

Other secondary types include the nickel-cadmium, nickel-metal hydride, silver-zinc, sodium-sulfur, zinc-air, lithium-ion, and lithium-solid polymer electrolyte battery. [D.R.Sa.]

Bauxite A rock mainly comprising minerals that are hydrous aluminum oxides. These minerals are gibbsite, boehmite, and diaspore. The major impurities in bauxite are clay minerals and iron oxides. Bauxite is a weathering product of aluminous rock that results from intense leaching in tropical and subtropical areas, a process called laterization. Bauxite deposits are generally found on plateaus in stable areas where they had sufficient geologic time to form and were protected from erosion. *See* ALUMINUM.

Bauxite is the primary ore of aluminum. The two types of bauxites that are used commercially as aluminum ores are laterite and karst. Lateritic bauxites constitute more than three-fourths of the world's bauxite resources. Karstic bauxites are formed on a carbonate terrain and are concentrated in sinkholes and solution depressions on the surface of carbonate rocks. *See* LATERITE.

Bauxite used to produce alumina is called metallurgical grade; approximately 90% of the world's production is for this purpose. Other major uses are in refractories, abrasives, chemicals, and aluminous cements. The compositional requirements are much more rigid for these uses. The alumina content must be higher, and the iron, silica, and titanium contents significantly lower, than for metallurgical-grade bauxite. World resources of bauxite are many tens of billions of tons, so an adequate supply is assured for hundreds of years. [H.H.Mu.]

Bayesian statistics An approach to statistics in which estimates are based on a synthesis of a prior distribution and current sample data. Bayesian statistics is not a branch of statistics in the way that, say, nonparametric statistics is. It is, in fact, a self-contained paradigm providing tools and techniques for all statistical problems. In the classical frequentist viewpoint of statistical theory, a statistical procedure is judged by averaging its performance over all possible data. However, the bayesian approach gives prime importance to how a given procedure performs for the actual data observed in a given situation. Further, in contrast to the classical procedures, the bayesian procedures formally utilize information available from sources other than the statistical investigation. Such information, available through expert judgment, past experience, or prior belief, is described by a probability distribution on the set of all possible values of the unknown parameter of the statistical model at hand. This probability distribution is called the prior distribution. The crux of the bayesian approach is the synthesis of the prior distribution and the current sample data into a posterior probability distribution from which all decisions and inferences are made. This synthesis is achieved by using a theorem proved by Thomas Bayes in the eighteenth century.

The posterior distribution combines the prior information about the unknown parameter θ with the information contained in the observed data to give a composite picture of the final judgments about θ. In order to arrive at a single number as the estimate of θ, it may be necessary to bring in the notion of the loss suffered by the decision maker as a result of estimating the true value θ by the number θ. Depending on the choice of the loss function, the mode, the mean, and the median of the posterior distribution are all reasonable estimates of θ.

The choice of the prior distribution for the unknown parameter θ is of crucial importance in bayesian statistics. The selected prior distribution for θ must be at least a reasonable approximation to the true beliefs about θ. In addition, the prior distribution must be such that the posterior distribution is tractable.

Noninformative and improper priors. The bayesian approach remains applicable even when little or no prior information is available. Such situations can be handled by choosing a prior density giving equal weight to all possible values of θ. Priors that seemingly impart no prior preference, the so-called noninformative priors, also arise when the prior is required to be invariant under certain transformations. Frequently, the desire to treat all possible values of θ equitably leads to priors with infinite mass. Such noninformative priors are called improper priors.

Criticism. Proponents of the bayesian paradigm claim a number of significant and fairly convincing advantages over the classical non-bayesian approach. However, bayesian statistics is itself criticized for its apparent lack of objectivity. The use of a prior distribution introduces subjectivity into a bayesian analysis so that decision makers having different priors may come to different conclusions even when working on the same problem with the same observed data. This, however, is the price that must be paid in order to incorporate prior information or expert judgment. Moreover, the bayesian approach seems to be the most logical approach if the performance of a statistical procedure for the actual observed data is of interest, rather than its average performance over all possible data. *See* ESTIMATION THEORY; PROBABILITY; STATISTICS. [S.N.U.A.K.]

Bdelloidea A class (formerly order) of the phylum Rotifera. Bdelloid rotifers have a very characteristic appearance; the agile elongate body consists of several (typically 16) false segments or annuli which do not correspond to the true segmentation of the body. Of these, the shorter and smaller head, neck, and foot segments are telescopically retractile into the larger and longer trunk joints. In typical species the corona has the characteristic form of two trochal disks, raised on pedicels, and a single cingulum of smaller cilia. The corona can be completely withdrawn, to reveal the true anterior end of the body. The mouth is large and funnel-shaped, and leads via a ciliated buccal tube into the mastax (a gizzardlike structure) whose ramate trophi are in constant motion. The intestine is syncytial, often colored brown or red by its contents, and digestion appears to be extracellular, rapid, and occurring in an alkaline medium. No males are known, and reproduction is believed to be parthenogenetic. A few genera are viviparous, but most are oviparous.

The Bdelloidea are typically bottom dwellers and crawl over the substratum leech-fashion. They are the most common inhabitants of standing fresh waters throughout the world, occurring in the smallest pools, in the littoral zones of large lakes, and also in mosses, liverworts, and lichens, some of which may be wetted only intermittently. *See* ROTIFERA. [J.B.J.]

Bdellonemertini An order of the class Enopla in the phylum Rhynchocoela. The proboscis is unarmed. The alimentary system comprises the mouth, papillate foregut, sinuous intestine without diverticula, and anus. Members are characterized by the presence of a posterior adhesive disk and dorsoventral flattening of the body, which lacks eyes, cephalic slits, and cerebral organs. The order contains the single genus *Malacobdella*, with three species ectocommensal in the mantle cavity of marine bivalves and one in the pulmonary sac of a freshwater gastropod. *See* ENOPLA; RHYNCHOCOELA. [J.B.J.]

Beam A structural member that is fabricated from metal, reinforced or prestressed concrete, wood, fiber-reinforced plastic, or other construction materials and that resists loads perpendicular to its longitudinal axis. Its length is usually much larger than its depth or width. Usually beams are of symmetric cross section; they are designed to bend in this plane of symmetry, which is also the plane of their greatest strength and stiffness. This plane coincides with the plane of the applied loads. Beams are used as primary load-carrying members in bridges and buildings. [T.V.G.]

Beam column A structural member that is subjected to axial compression and transverse bending at the same time. A beam column differs from a column only by the presence of the eccentricity of the load application, end moment, or transverse load. Beam columns are found in frame-type structures where the columns are subjected to other than pure concentric axial loads and axial deformations, and where the beams are subjected to axial loads in addition to transverse loads and flexural deformations. *See* BEAM; COLUMN. [R.T.R.]

Beam-foil spectroscopy A technique used in atomic physics to study the structure and dynamics of atomic ions of any element in any state of ionization. For this purpose, a beam of fast ions is sent through a very thin foil. The ion-foil interaction shakes up the electronic shells of the projectile and, after leaving the foil, the ions shed surplus energy by emitting photons, and sometimes electrons. The energies and intensities of these particles yield spectral information on the projectile. *See* PARTICLE ACCELERATOR.

The multitude of collisions inside the foil changes the complement of electrons that travel with the projectile ion; some are ejected and others are captured from the target atoms. The ion beam therefore has a different charge-state composition after passage through the foil. (Higher exit charge states are produced at higher incident beam energies.) The beam-foil interaction efficiently populates atomic levels with a high degree of excitation such as multiply excited and core-excited levels. The richness of the resulting spectra yields a great deal of information on atoms and ions, although it is often difficult to resolve the details of line-rich spectra that reflect the complexity of multiply excited systems.

The ion beam travels in a high vacuum before and after transiting the target foil. This environment minimizes collisional perturbation of the ions. The sudden termination of the ion-foil interaction provides an inherently good time resolution to beam-foil spectroscopy. This property of the source permits lifetime measurements as well as the observation of coherent-excitation phenomena such as quantum beats. Because the ion velocity is constant and measurable, it is sufficient to trace the change in intensity of the fluorescence from the ion beam as a function of distance from the foil in order to determine atomic level lifetimes. *See* FLUORESCENCE.

Beam-foil spectroscopy has developed into many variants which now go under the name of fast-beam spectroscopy. For example, a gas target may be used, a laser, a combination of gas or foil and laser, or a target of free electrons in a heavy-ion storage ring. The ion-foil interaction is capable of producing all ionization stages of all elements from negative ions to U^{91+}. The production of the highest ionization stages, however, requires a beam energy of about 500 MeV/nucleon, which can be reached only at the most energetic accelerators. However, since only the relative motion of electrons and ions is important, the same degree of ionization can be reached by use of 250-keV electrons in an electron-beam ion trap (EBIT). The device offers easier ways to attain high spectroscopic precision because the ions are practically at rest. In beam-foil spectroscopy the ions are rapidly moving, which shifts and broadens the spectral lines. This, in turn, causes problems in wavelength calibration and spectral resolution. However, the inherent time resolution of the foil-excited fast-ion-beam source is unique and remains a great asset in time-resolved spectroscopic measurements. *See* ATOMIC STRUCTURE AND SPECTRA; ION SOURCES; SPECTROSCOPY. [E.Tr.]

Bean Any of several leguminous plants, or their seeds, long utilized as food by humans or livestock. Some 14 genera of the legume family contain species producing seeds termed "beans" which are useful to humans. Twenty-eight species in 7 genera produce beans of commercial importance, which implies that the bean can be found in trade at the village level or up to and including transoceanic commerce.

The principal Asiatic beans include the edible soybeans, *Glycine* sp., and several species of the genus *Vigna*, such as the cowpea and mung, grams, rice, and adzuki beans. The broad bean (*Vicia faba*) is found in Europe, the Middle East, and Mediterranean region, including the North African fringe. Farther south in Africa occur *Phaseolus* beans, of the *vulgaris* (common bean) and *coccineus* (scarlet runner) species. Some *Phaseolus* beans occur in Europe also. The cowpea, used as a dry bean, is also found abundantly in Nigeria. *See* COWPEA; SOYBEAN.

In the Americas, the *Phaseolus* beans, *P. vulgaris* and *P. lunatus* (lima bean), are the principal edible beans, although the blackeye cowpea, mung bean, and chick pea or garbanzo (*Cicer arietinum*) are grown to some extent. *Phaseolus coccineus* is often grown in higher elevations in Central and South America, as is *Vicia faba*. The tepary bean (*P. acutifolius*) is found in the drier southwestern United States and northern Mexico. *See* ROSALES.

Bean plants may be either bush or vining types, with white, yellow, red, or purple flowers. The seed itself is the most differentiating characteristic of bean plants. It may be white, yellow, black, red, tan, cream-colored, or mottled, and range in weight from 0.0044 to over 0.025 oz (125 to over 700 mg) per seed. Seeds are grown in straight or curved pods (fruit), with 2–3 seeds per pod in *Glycine* to 18–20 in some *Vigna*.

Beans are consumed as food in several forms. Lima beans and snap beans are used as fresh vegetables, or they may be processed by canning or freezing. Limas are also used as a dry bean.

Mung beans are utilized as sprouts. Usage of dry beans (*P. vulgaris*) for food is highly dependent upon seed size, shape, color, and flavor characteristics, and is often associated with particular social or ethnic groups. *See* LEGUME. [M.W.A.]

Bear The name for a number of species of carnivorous mammals in the family Ursidae (see table). Bears are large and heavy bodied, with short, strong legs and short tails. They are completely plantigrade, walking with their metatarsal and metacarpal regions touching the ground, but are able to stand upright. The foot has five toes which terminate in nonretractile claws. The toes are separate with no membranes between them. The foot soles of the polar bear are covered with hair, lacking in other species, which aids in walking on ice. The eyes of bears are relatively small and vision is rather poor; however, hearing and smell are acute. The rounded ears are small, and the muzzle is elongate.

Depending upon the species, the female produces one to three young per lifter; gestation varies from 180 to 250 days. The small, blind, toothless offspring weigh less than 1 lb (0.5 kg). The female cares for the cubs since the male usually does not remain with her.

Common name and geographic distribution of some Ursidae species

Scientific name	Common name	Distribution
Tremarctos ornatus	Spectacled bear, Andean bear	Pacific slopes of Andes from northern Chili to Colombia
Selenarctos thibetanus	Asiatic black bear, moon bear, Himalayan bear	Iran, China, Japan, Himalayas
Ursus arctos	Brown bear, many varietal names	Eastern Europe, Asia, North America, Pyrenees
Ursus americanus	American black bear	North American forested areas
Thalarctos maritimus	Polar bear	Arctic regions of Northern Hemisphere
Helarctos malayanus	Sun bear, honey bear, bruang, Malay bear	Sumatra, Borneo, southeastern Asia
Melursus ursinus	Sloth bear	Ceylon, southern India

Bears originated in the Northern Hemisphere and are now widely distributed throughout the world. The brown bear (*Ursus arctos*) is the commonest species, in North America as well as in other areas of the world. The grizzly bear is an example of a species that is on the verge of extinction. It is found in national park areas, Alaska, and the Yukon region. The spectacled bear (*Tremarctos ornatus*) is the only native bear in the Southern Hemisphere, where it is found in the forested foothills of the western slopes of the Andes. The Himalayan bear (*Selenarctos thibetanus*) occurs in China, Japan, Iran, and the Himalayas. The black bear (*Ursus americanus*) is still numerous across North America in forested areas. It is hunted for its fur and as a game animal in many parts of the United States. The sun bear (*Helarctos malayanus*) is found in the tropical forested areas of southern Asia, and thus differs from other bears in its habitat preference. It is the smallest of all bears. The polar bear (*Thalarctos maritimus*) occurs in the polar regions of the Northern Hemisphere. *See* CARNIVORA; HIBERNATION. [C.B.C.]

Beat A variation in the intensity of a composite wave which is formed from two distinct waves with different frequencies. Beats were first observed in sound waves, such as those produced by two tuning forks with different frequencies. Beats also can be produced by other waves. They can occur in the motion of two pendulums of different lengths and have been observed among the different-frequency phonons in a crystal lattice.

One important application of beat phenomena is to use one object with an accurately known frequency to determine the unknown frequency of another such object. The beat-frequency or heterodyne oscillator also operates by producing beats from two frequencies. *See* OSCILLATOR. [B.DeF.]

Beaver The common name for two different and unrelated species of rodents—*Aplodontia rufa*, the mountain beaver, and *Castor canadensis*, the common or true beaver.

The mountain beaver is the only living species of the family Aplodontidae. It is a medium-sized animal and resembles a muskrat. The eyes are small as are the external ears, an adaptation to its fossorial (digging) habits. The tail is a short stump, the body is short and stout, and the limbs are short and terminate in broad feet with five toes and long claws. The mountain beaver is a vegetarian. Although not strictly nocturnal, it is more active at night. The animals form colonies with a single family inhabiting a series of runways. The mountain beaver is found along the Pacific Coast and ranges from British Columbia, Canada, to California.

The common beaver, a member of the family Castoridae, is a large rodent (weighing up to 50 lb or 23 kg). It occurs across Europe, North America from Labrador southward, and Asia, and is a valuable fur-bearing animal. The tail is broad and spatulate and is used, together with the webbed hindfeet, for swimming. The beaver is aquatic and builds its lodge in water by using mud, sticks, and branches interwoven. These beavers are vegetarians. Mating occurs in February, and the average litter of four young is born in May. These beavers appear to be monogamous and mate for life. *See* RODENTIA. [C.B.C.]

Bee Insects of the superfamily Apoidea in the order Hymenoptera. There are some 3000 species of bees divided into 19 families. Present-day bees subsist almost entirely on pollen as a source of protein, and on the sugar in nectar as an energy source. They are now obligately dependent on flowers, although a few species can sometimes feed on "honeydew" secretions from aphids and scale insects. In turn, many plants have become obligately dependent on bees for pollination. *See* HYMENOPTERA.

Most of the world's bee species are solitary. That is, a female builds a nest cell, provisions the cell with a nectar-pollen mixture, lays an egg on this food, and seals the nest cell, allowing the larva to develop and emerge as much as a year later. In primitively social bees such as some of the sweat bees (family Halictidae) and bumblebees (family Bombidae), an overwintered female (queen) that has mated the previous fall emerges from her underground hibernacula in the spring and attempts to start her own colony. A colony consists initially of sterile female offspring, who are her workers. Near the end of the colony cycle, in late summer or fall, the workers aid the queen in producing large numbers of sexuals, the drones and new queens. Colonies generally consist of several dozen and up to several hundred individuals at the height of the colony cycle in the summer. The workers, drones, and old queens all die off in the fall, and the new queens disperse and hibernate.

In the highly social bees, the honeybee (*Apis mellifera*) and stingless (*Trigona*) species, as many as 50,000 and 150,000 individuals, respectively, may be present in the colonies. In these bees the old queen lives several years, and the colonies are perennial rather than annual. The queens are nearly exclusively concerned with egg laying, and the workers are produced not only during times of food availability in the field, but also before major times of flowering by relying on large stores of pollen and honey. These bees reproduce by swarming, when the old queen leaves the hive accompanied by about half of the workers, which help her to initiate a new colony. *See* SOCIAL INSECTS.

The highly social organization of honeybees and stingless bees is orchestrated by scent, sound, and "dance" signals. The queen emits a chemical (pheromone) which inhibits the workers from developing and laying eggs. Absence or low concentrations of the queen pheromone cause the workers to rear a new queen. The workers also produce pheromones that act as signals to other workers. Honeybees indicate the direction, distance, and quality of rewarding food sources to hive mates by a symbolic dance language. Honeybees also buzz during the dance, which may serve to alert potential followers that then attempt to "read" the dancer's message. Stingless bees also alert hive mates by buzzing. The hive mates follow the scout bee (that has discovered the food) out of the hive; the scout then deposits a trail of scent droplets onto vegetation that aid the recruit to find the food. Bumblebees do not seem to have any way of communicating food found by successful hive mates.

By visiting flowers, bees serve as agents of cross-pollination. They are of inestimable importance in the pollination of crops and in pollination of the natural flora. Their activity is thus vital, not only directly for the human food supply, but also for land, water, and animal resources. *See* BEEKEEPING; POLLINATION. [B.He.]

Beech A genus, *Fagus*, of deciduous trees of the beech family Fagaceae, order Fagales. They can best be distinguished by their long (often more than 1 in. or 2.5 cm), slender, scaly winter buds; their thin, gray bark, smooth even in old trees; and their simple, toothed, ovate or ovate-oblong, deciduous leaves.

The American beech (*F. grandifolia*) is native in the United States east of the Mississippi River and in the lower Mississippi Valley. The hard, strong wood is used for furniture, handles, woodenware, cooperage, and veneer. The small, edible, three-sided nuts, called beechnuts, are valuable food for wildlife. The European beech (*F. sylvatica*) is more popular as an ornamental tree than the American species. Its leaves are smaller, with 5–9 pairs of primary veins compared with 9–14 pairs in the American beech. The leaf teeth are also shorter. Important ornamental varieties are *F. sylvatica purpurea*, the copper or purple beech; var. *incisa*, the cut-leaved or fern-leaved beech; and *F. pendula*, the weeping European beech. *See* FAGALES. [A.H.G./K.P.D.]

Beekeeping The management and maintenance of colonies of honeybees. Although the commonly known honeybee species is native to Europe and Africa only, humans have transported them to other continents, and in most places they have flourished. The natural home for a honeybee colony is a hollow tree, log, or cave. European strains of the honeybee build a nest only in locations which are dry and protected from the wind and sunlight. African bees are less selective and may nest in hollowed-out termite mounds, rock piles, and locations which are less well protected. *See* BEE.

The honey which beekeepers harvest is made from nectar, a sweet sap or sugar syrup produced by special glands in flowers, collected from both wild and cultivated plants. Nectar, the honeybees' source of sugar or carbohydrate, and pollen, their source of protein and fat, make up their entire diet. Nectar contains 50–90% water, 10–50% sugar (predominantly sucrose), and 1–4% aromatic substances, coloring material, and minerals. To transform nectar into honey, bees reduce its moisture content, so that the final honey produced contains between 14 and 19% water, and also add two enzymes which they produce in their bodies.

Scientific beekeeping started in 1851 when an American, L. L. Langstroth, discovered bee space and the movable frame hive. Bee space is the open space which is about 0.4 in. (1 cm) wide and maintained around and between the combs in any hive or natural nest and in which the bees walk. If this space is smaller or larger than 0.4 in. (1 cm), the bees will join the combs. When the combs are stuck together, the hive is not movable, and it is not possible for beekeepers to manipulate a colony or to examine a brood nest. It was found, in 1857, that bees could be forced to build a straight comb in a wooden frame by giving them a piece of wax, called foundation, on which the bases of the cells were already embossed. Bees use these bases to build honeycomb, the cells of which are used for both rearing brood and for storing honey. When a hive of bees is given a frame of foundation, they are forced to build the comb where the beekeeper wants it and not where they might otherwise be inclined to build it. Another discovery, made in 1865, was that honey can be removed from the comb by placing a comb full of honey in a centrifugal force machine, called an extractor. If the beekeeper can return an intact comb to a hive after removing the honey from it, the bees are saved the time and trouble of building a new comb, and the honey harvest is increased. The next discovery, in 1873, was the modern smoker. When bees are smoked, they engorge with honey and become gentle. Without smoke to calm a hive, normal manipulation of the frames would not be possible. By 1880, honey, which had once been a scarce commodity, became abundant.

All beehives used in the industry today are made of wooden boxes with removable frames of comb. Beekeepers have standardized their equipment so that parts will be interchangeable within an apiary and from one commercial operation to another. To be successful in commercial beekeeping, beekeepers must locate in those areas where nectar-producing plants abound. The best-known honey in the United States is clover honey. Alfalfa and oranges are also good nectar-producing plants and are major sources of honey. Bees collect nectar from hundreds of kinds of flowers, and thus there are a great variety of honey flavors. Thousands of colonies of honeybees are rented each year by growers of crops needing cross pollination. As the plants come into bloom, the beekeeper moves the bees, usually at night when all the bees are in the hive, and places them in groups in groves, orchards, and fields. While beekeepers make most of their living producing honey, the real importance of their bees in the agricultural economy is as cross pollinators. Without cross pollination the abundance and variety of food and flowers would not exist. Commercial beekeepers feel they need to own 500 to 2000 colonies to make a living, depending on how they market their honey. Some beekeepers sell their honey on the wholesale market only, while others pack their honey themselves and devote a great deal of time to sales. [R.A.Mo.]

Beet The red or garden beet (*Beta vulgaris*), a cool-season biennial of Mediterranean origin belonging to the plant order Caryophyllales (Centrospermales). This beet is grown primarily for its fleshy root, but also for its leaves, both of which are cooked fresh or canned as a vegetable. Detroit Dark Red strains predominate. Cool weather favors high yields of dark red roots. Wisconsin, New York, and Texas are important beet producing states. *See* CARYOPHYLLALES; SUGARBEET. [H.J.C.]

Behavior genetics The study of the hereditary factors of behavior. Charles Darwin, who originated the theory that natural selection is the basis of biological evolution, was persuaded by Francis Galton that the principles of natural selection applied to behavior as well as physical characteristics. Members of a species vary in the expression of certain behaviors because of variations in their genes, and these behaviors have survival value in some environments. One example of such a behavior is curiosity—some organisms are more curious than others, and in some settings curiosity is advantageous for survival. The science of behavior genetics is an extension of these ideas and seeks (1) to determine to what extent the variation of a trait in a population (the extent of individual differences) is due to genetic processes, to what extent it is due to environmental variation, and to what extent it is due to joint functions of these factors (heredity-environment interactions and correlations); and (2) to identify the genetic architecture (genotypes) that underlies behavior.

Traditionally, some of the clearest and most indisputable evidence for a hereditary influence on behavior comes from selective-breeding experiments with animals. Behavior genetic research has utilized bacteria, paramecia, nematodes, fruit flies, moths, houseflies, mosquitoes, wasps, bees, crickets, fishes, geese, cows, dogs, and numerous other organisms. Breeding of these organisms allows genetically useful types of relationships, such as half-sibs, to be produced easily. Artificial selection (selective breeding) can be used to obtain a population that scores high or low on specific traits. Inbred strains of many animals, particularly rodents, are readily available, and the study of various types of crosses among them can provide a wealth of information. An experimental design using the recombinant inbred-strain method shows great promise for isolating single-gene effects. This procedure derives several inbred strains from the F_2 generation (grandchildren) produced by a cross between two initial inbred strains. Since it is possible to exert a great deal of control over the rearing environments, the experimenter can manipulate both heredity and environment.

Other work has focused on the effects of the environment and genotype-environment interactions. For example, experiments with mice have shown that, with respect to several learning tasks, early environmental-enrichment effects and maternal effects were quite small, relative to the amount of normal genetic variation found in the strains of mice tested. Only a few genotype-environment interactions were found. Still other work has shown that early experiences affect later behavior patterns for some strains but not others (a genotype-environment interaction).

An increasing role for animals in genetic research is to provide models of human genetic diseases, many of which have behavioral features. Such animal models may occur naturally or may be engineered in the laboratory. Animal models are available for many neurobehavioral disorders, including narcolepsy, various epilepsies, and alcoholism. The availability of animal models allows researchers to obtain information about the development of genetic disorders and the effects of different environments on this development, as well as to explore treatment options. While it is not always prudent or desirable to generalize from animal results to humans, it is assumed that basic genetic systems work in similar ways across organisms, and it is likely that these types of animal studies will play a key role in elucidating the ways in which environment influences phenotypic variation. With advances in genetic technology, it is possible to observe genetic variation more directly by locating, identifying, and characterizing genes themselves.

The effects of a single gene on behavior have been most extensively studied in the domain of mental retardation. Research has shown that there are a large number of metabolic pathways which have defects due to a single gene. Over 100 of these defects influence mental ability. One such single-gene defect is classic phenylketonuria (PKU), an autosomal recessive disorder, which also illustrates the role that environment can play in the expression of a trait. Individuals who are homozygous (having two copies of the PKU allele) are unable to make the enzyme phenylalanine hydroxylase, which converts the essential amino acid phenylalanine to tyrosine, a nonessential amino acid. Instead, the excess phenylalanine builds up in the blood and is converted into phenylpyruvic acid, which is toxic to the developing nervous system in large amounts. The main effect of untreated PKU is severe mental retardation, along with a distinctive odor, light pigmentation, unusual gait and posture, and seizures. Many untreated individuals with PKU show fearfulness, irritability, and violent outbursts of temper. *See* MENTAL RETARDATION; PHENYLKETONURIA.

Every organism develops in a particular environment, and both genes and environment control development. It is, therefore, not possible to state that a particular behavioral trait is either genetic or environmental in origin. It is possible, however, to investigate the relative contributions of heredity and environment to the variation among individuals in a population. With humans, it is possible to obtain approximate results by measuring the similarity among relatives on the trait of interest. Twins are often used in such studies. One method compares the similarity within pairs of both identical twins and fraternal twins reared together. Identical twins have all their genes in common by descent, since they arise from a single fertilized egg. Fraternal twins arise from two fertilized eggs and so share on average one-half of their genes. If it is assumed that the effects of the shared environments of the two types of twins are equal (a testable assumption), greater resemblance between identical twins than fraternal twins should reflect the proportion of genes they share, and the difference between the correlations of the two twin types should represent about one-half the genetic effect.

A second type of twin study compares not only twins reared together but twins who have been reared apart. The degree of similarity between identical twins reared in the same home would reflect the fact that all their genes are identical and that they share a common family environment. On the other hand, if identical twins can be located who had been adopted by different families chosen at random (an unlikely event, since adopted children tend to be selectively placed), a measure of their degree of similarity would reflect only the effect of their common genes. If it were true that an individual's level on a measure (for example, extroversion) is determined in large part by the characteristics of his or her family and the opportunities that the family makes available to him or her, reared-apart identical twins should be no more alike than pairs of individuals chosen at random. If they do exhibit some degree of similarity, it would reflect genetic effects alone. The existence of even very large genetic effects, however, would in no way imply that the environment was unimportant in the development of the trait; it would simply imply that environment was less important than genes in determining the variation among individuals on the trait in question at the time of measurement. That is, the individuals would differ more because of the genes they carry than because of the particular environments to which they were exposed. In another range of environments, the results might be different. *See* TWINS (HUMAN).

Developmental psychologists are finding that differences in children's behavioral phenotypes are due more to their different genotypes than to their different rearing environments, as long as those environments are within a normal range of experiences. Identifying environmental variables from this normal range that have an important effect on the behavioral phenotype may be even more difficult than identifying contributing genes. Advances in theory and new technologies, combined with information from more traditional methodologies, will continue to provide insight into the contributions of genes and environment to behavior. [K.J.W.; T.J.B.]

Behavioral ecology The branch of ecology that focuses on the evolutionary causes of variation in behavior among populations and species. Thus it is concerned with the adaptiveness of behavior, the ultimate questions of why animals behave as they do, rather than the proximate questions of how they behave. The principles of natural selection are applied to behavior with the underlying assumption that, within the constraints of their evolutionary histories, animals behave optimally by maximizing their genetic contribution to future generations. For example, animals must maintain their internal physiological conditions within certain limits in order to function properly, and often they do this by behavior. Small organisms may avoid desiccation by living under logs or by burrowing. Many insects must raise body temperatures to 86–95°F (30–35°C) for effective flight, and achieve this by muscular activity such as the shivering of butterflies in the early morning or by orienting to the Sun. Other adaptive behaviors that are studied may fall in the categories of habitat selection, foraging, territoriality, and reproduction. *See* BEHAVIOR GENETICS; ETHOLOGY; MIGRATORY BEHAVIOR; REPRODUCTIVE BEHAVIOR. [H.Di.; P.Fr.]

Behavioral psychophysics The use of behavioral methods to measure the sensory capacities of animals and nonverbal humans such as infants. The observations are analogous to those obtained from adult human subjects who are asked to observe appropriate stimuli and report what they see. The behavioral methods differ primarily in that stimulus-response associations are established by means other than verbal instructions, either as unlearned reflexes or through conditioning. Any sense or species may be studied, but most work has been done on the vision and hearing of primates, cats, pigeons, and rats. Typical investigations determine (1) the absolute threshold (the minimum intensity needed to elicit a standard response); (2) the difference threshold (the minimum change in a stimulus needed to elicit a standard response); and (3) points of apparent equality (values of stimuli that elicit no response because a change in one aspect compensates for a change in another). A few investigations have determined stimulus scales that express quantitative relations between the physical stimulus and the perceptual effect over a range of stimulus values. These various measures provide a picture of the sensory function, such as visual acuity, color sensitivity, loudness or pitch perception, and odor discrimination. Efficiency and sensitivity to the sensory function of interest are the major factors that govern the choice of method in behavioral psychophysics.

Reflex methods are the most convenient since no training is required. An example is the preferential looking response in infants. Without training, infants spend more time looking at patterned stimuli than at blank fields. Two stimulus fields are placed before the infant, and the relative time spent looking at each is determined. A preference for one pattern according to this measure indicates that the infant can detect a difference between the two.

Unconditioned reflex methods are limited to sensory functions for which appropriate reflexes may be found; also, they usually impose severe limits on the specific stimulus conditions that may be used. Conditioning methods add considerable flexibility. In Pavlovian conditioning, the stimulus of interest becomes the conditioned stimulus through its association with a stimulus that elicits a clear-cut reflexive response (the unconditioned stimulus).

Operant conditioning offers still more flexibility. Typically the subject is rewarded for making an indicator response in the presence of one stimulus value; reward is withheld (or another response rewarded) in the presence of other stimulus values. The responses are selected to suit the species and the stimulus under study.

Interest in the development of sensory function has spurred the use of behavioral methods in infants and young children, while the effects of controlled sensory input during development have been extensively monitored in nonhuman subjects. Applications to the prevention and control of sensory disorders also are increasing. For example, a number of toxicants, drugs, and environmental stressors have been related to sensory disorders; the methods of behavioral psychophysics are used to follow the development of these disorders under controlled conditions, and to uncover potential preventive and therapeutic measures. *See* Psychology; Sensation. [D.Bl.]

Behavioral toxicology The study of behavioral abnormalities induced by exogenous agents such as drugs, chemicals in the general environment, and chemicals encountered in the workplace. Just as some substances are hazardous to the skin or liver, some are hazardous to the function of the nervous system. In the case of permanent effects, changes in sensation, mood, intellectual function, or motor coordination would obviously be undesirable, but even transient alterations of behavior are considered toxic in some situations. For example, operating room personnel accidentally exposed to very small doses of anesthetic do not exhibit altered performance on an intelligence test, a dexterity test, or a vigilance task. However, significant decrements in performance occur in recognizing and recording visual displays, detecting changes in audiovisual displays, and recalling series of digits.

By comparing the behavior of exposed subjects and control subjects, behavioral toxicologists seek to identify agents capable of altering behavior and to determine the level of exposure at which undesirable effects occur. When the agent under study is one in common use, and there is no evidence of its being hazardous to health, experiments may be carried out on human volunteers, or comparisons may be made from epidemiologic data. More frequently, safety considerations dictate the use of laboratory animals in toxicology research.

Perhaps the best-known example of toxicity in humans is methyl mercury poisoning (Minimata disease), which occurred in epidemic proportions in a Japanese coastal town where the inhabitants ate fish contaminated with mercury from industrial pollution. Although mercury affects a variety of behaviors, the most obvious symptoms are tremors and involuntary movements.

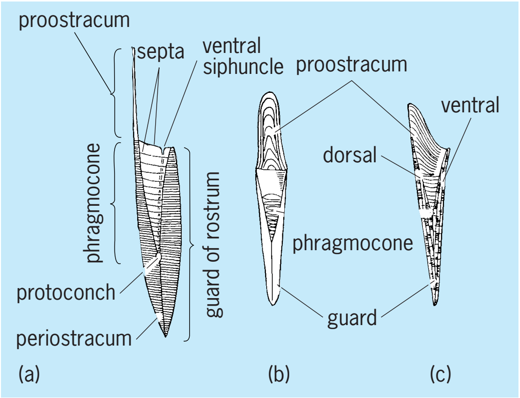
A different set of functional problems is exemplified by the effects of ethyl alcohol, a single agent with direct and indirect, short- and long-term consequences. The short-term, low-dose effects of alcohol include sensory disturbances, motor problems, and difficulties with processing information. Neurologically, alcohol is usually described as a central nervous system depressant which is general, in the sense that it disrupts many functions.

In some individuals, large quantities of alcohol consumed over a long period lead to permanent damage to the nervous system. Behaviorally, individuals with Korsakoff's syndrome exhibit severe memory deficits. Anatomically, their brains are found to have degenerative changes in the thalamus. This syndrome is not just an extension of the short-term effects. In fact, it is thought to arise from alcohol-induced malnutrition rather than as a direct effect of alcohol itself.

Lasting injuries to the nervous system have been reported to occur in children exposed to alcohol before birth. The behavioral problems associated with fetal alcohol syndrome do not appear to be related to either Korsakoff's syndrome or the immediate effects of alcohol. Rather, they constitute a third set of effects, including learning deficits, problems with inhibiting inappropriate behavior, and fine motor dysfunction, along with some visible physical abnormalities. While malnutrition may play a role in this congenital syndrome, the mechanism and locus of damage are not known. *See* Alcoholism; Congenital anomalies; Fetal alcohol syndrome.

When toxicity is considered only in terms of direct risk to survival, behavioral toxicity may seem to be of minor importance. However, survival is not the only criterion of good health. In a complex society that places heavy demands on an individual's educability, alertness, and emotional stability, even small deviations in behavior are potentially hazardous. Severe disabilities, as in the gross motor malfunctions of Minimata disease, have drawn attention to behavioral toxicology. Such incidents represent failures of control of toxic substances. Successes are difficult to measure, for they can be seen only in reduction of risk—the ultimate goal of toxicology. *See* Toxicology. [P.M.R.]

Belemnoidea An order of extinct dibranchiate cephalopods. These mollusks ranged from the Upper Mississippian through the Cretaceous. The oldest known representative is highly specialized, although the belemnoids are considered to be the most primitive of the dibranchiates. Belemnoids have a chambered shell or phragmocone which fits into a guard or rostrum, the apical portion of the shell (see illustration).



Belemnoidea. (*a*) Diagram of a belemnitid shell. (*b*) Ventral aspect and (*c*) lateral aspect of a belemnite. (*After R. R. Shrock and W. H. Twenhofel, Principles of Invertebrate Paleontology, 2d ed., McGraw-Hill, 1953*)

Belemnites is an important index fossil. *See* Cephalopoda; Index fossil. [C.B.C.]

Bell A hollow metallic cylinder closed at one end and flared at the other. A bell is used as a fixed-pitch musical instrument or a signaling device, frequently in clocks. A bell is set vibrating by a clapper or tongue which strikes the lip. The bell has two tones, the strike note or key, and the hum tone, which is a major sixth below the strike note. Both tones are rich in harmonics. The finer bells are made for carillons. Small carillons have two full chromatic octaves and large ones have four or more chromatic octaves, the bell with the lowest tone being called the bourdon. All bells of a carillon are shaped for homogeneity of timbre.

Bell metal is approximately four parts copper and one part tin, although zinc, lead, or silver may be used. The shape of a bell—its curves and full trumpet mouth—evolved from experience. A bell can be pitched slightly. The tone is raised by grinding the outer surface, effectively decreasing the diameter, or lowered by grinding the inner surface. Too much tuning of a well-shaped bell is apt to degrade its voice or timbre. [F.H.R.]

Belladonna The drug and also the plant known as the deadly nightshade, *Atropa belladonna*, which belongs to the nightshade family (Solanaceae). This is a coarse, perennial herb native to the Mediterranean regions of Europe and Asia Minor, but now grown extensively in the United States, Europe, and India. During the blooming period, the leaves, flowering tops, and roots are collected and dried for use. The plant contains several important medicinal alkaloids, the chief one being atropine, which is much used to dilate the pupil of the eye. *See* Atropine; Solanales. [P.D.St./E.L.C.]

Belt drive The lowest-cost means for transmitting power between shafts that are not necessarily parallel. Belts run smoothly and quietly, and they cushion motor and bearings against load fluctuations. Belts typically are not as strong or durable as gears or chains. However, improvements in belt construction and materials are making it possible to use belts where formerly only chains or gears would do.

Advantages of belt drive are: They are simple. They are economical. Parallel shafts are not required. Overload and jam protection are provided. Noise and vibration are damped out. Machinery life is prolonged because load fluctuations are cushioned (shock-absorbed). They are lubrication-free. They require only low maintenance. They are highly efficient (90–98%, usually 95%). Some misalignment is tolerable. They are very economical when shafts are separated by large distances. Clutch action may be obtained by relieving belt tension. Variable speeds may be economically obtained by step or tapered pulleys.

Disadvantages include: The angular-velocity ratio is not necessarily constant or equal to the ratio of pulley diameters, because of belt slip and stretch. Heat buildup occurs. Speed is limited to usually 7000 feet per minute (35 meters per second). Power transmission is limited to 370 kilowatts (500 horsepower). Operating temperatures are usually restricted to –31 to 185°F (–35 to 85°C). Some adjustment of center distance or use of an idler pulley is necessary for wear and stretch compensation. A means of disassembly must be provided to install endless belts.

There are four general types of belts: flat belts, V-belts, film belts, and timing belts. Each has its own special characteristics, limitations, advantages, and special-purpose variations for different applications.

Flat belts, in the form of leather belting, served as the basic belt drive from the beginning of the Industrial Revolution. They can transmit large amounts of power at high speeds. Flat belts find their widest application where high-speed motion, rather than power, is the main concern. Flat belts are very useful where large center distances and small pulleys are involved. They can engage pulleys on both inside and outside surfaces, and both endless and jointed construction are available.

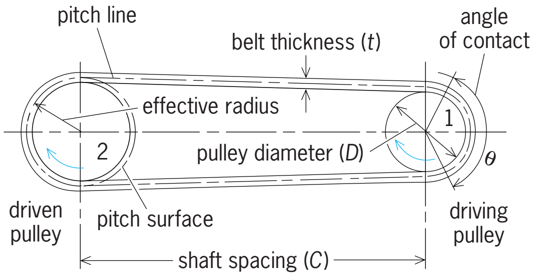


Fig. 1. Open belt drive.

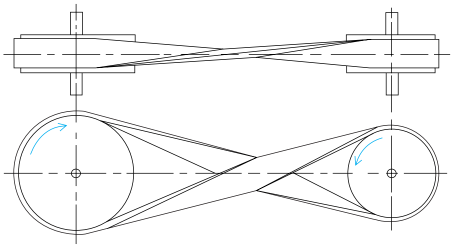

Fig. 2. Cross belt drive.

V-belts are the basic power-transmission belt, providing the best combination of traction, operating speed, bearing load, and service life. The belts are typically endless, with a trapezoidal cross section which runs in a pulley with a V-shaped groove. The wedging action of the belt in the pulley groove allows V-belts to transmit higher torque at less width and tension than flat belts. V-belts are far superior to flat belts at small center distances and high reduction ratios. V-belts require larger pulleys than flat belts because of their greater thickness. Several individual belts running on the same pulley in separate grooves are often used when the power to be transmitted exceeds that of a single belt. These are called multiple-belt drives.

Film belts are often classified as a variety of flat belt, but actually they are a separate type. Consisting of a very thin strip of material, usually plastic but sometimes rubber, their widest application is in business machines, tape recorders, and other light-duty service.

Timing belts have evenly spaced teeth on their bottom side which mesh with grooves cut on the periphery of the pulleys to produce a positive, no-slip, constant-speed drive. They are often used to replace chains or gears, reducing noise and avoiding the lubrication bath or oiling system requirement. They have also found widespread application in miniature timing applications. Timing belts, known also as synchronous or cogged belts, require the least tension of all belt drives and are among the most efficient.

The most common belt-pulley arrangement, by far, is the open belt drive (Fig. 1). Here both shafts are parallel and rotate in the same direction. The cross-belt drive of Fig. 2 shows parallel shafts rotating in opposite directions. Timing and standard V-belts are not suitable for cross-belt drives because the pulleys contact both the inside and outside belt surfaces.

Industrial belts are usually reinforced rubber or leather, the rubber type being predominant. Nonreinforced types, other than leather, are limited to light-duty applications.

Belts probably fail by fatigue more often than by abrasion. The fatigue is caused by the cyclic stress applied to the belt as it bends around the pulleys. Belt failure is accelerated when the following conditions are present: high belt tension; excessive slippage; adverse environmental conditions; and momentary overloads caused by shock, vibration, or belt slapping. *See* Chain drive; Gear drive; Pulley. [A.Erd.; R.G.]

Bentonite The term first applied to a particular, highly colloidal plastic clay found near Fort Benton in the Cretaceous beds of Wyoming. This clay swells to several times its original volume when placed in water and forms thixotropic gels when small amounts are added to water. Later investigations showed that this clay was formed by the alteration of volcanic ash in place; thus, the term bentonite was redefined by geologists to limit it to highly colloidal and plastic clay materials composed largely of montmorillonite clay minerals, and produced by the alteration of volcanic ash in place. The term has been used commercially for any plastic, colloidal, and swelling clays without reference to a particular mode of origin. *See* Clay; Gel; Montmorillonite.

Bentonites have been found in almost all countries and in rocks of a wide variety of ages. They appear to be most abundant in rocks of Cretaceous age and younger. In the United States, bentonites are mined extensively in Wyoming, Arizona, and Mississippi. England, Germany, Yugoslavia, Russia, Algeria, Japan, and Argentina also produce large tonnages of bentonite. Many bentonites are of great commercial value. They are used in decolorizing oils, in bonding molding sands, in the manufacture of catalysts, in the preparation of oil well drilling muds, and in numerous other relatively minor ways. The properties of a particular bentonite determine its economic use. [R.E.Gr.; F.M.W.]

Benzene A colorless, liquid, inflammable, aromatic hydrocarbon of chemical formula C_6H_6 which boils at 80.1°C (176.2°F) and freezes at 5.4–5.5°C (41.7–41.9°F). In the older American and British technical literature benzene is designated by the German name benzol. In current usage the term benzol is commonly reserved for the less pure grades of benzene.

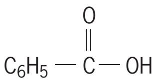
Benzene is used as a solvent and particularly in Europe as a constituent of motor fuel. In the United States the largest uses of benzene are for the manufacture of styrene and phenol. Other important outlets are in the production of dodecylbenzene, aniline, maleic anhydride, chlorinated benzenes (used in making DDT and as moth flakes), and benzene hexachloride, an insecticide.

The six carbon atoms of benzene, each with a hydrogen atom attached, are arranged symmetrically in a plane, forming a regular hexagon. The hexagon symbol, commonly used to represent the structural formula for benzene, implies the presence of a carbon atom at each of the six angles and, unless substituents are attached, a hydrogen at each carbon atom. Whereas the three double bonds usually included in the formula are convenient in accounting for the addition reactions of benzene, present evidence is that all the carbon-to-carbon bonds are identical.

Nearly all commercial benzene is a product of petroleum technology. The gasoline fractions obtained by reforming or steam cracking of feedstocks from petroleum contain benzene and toluene which can be separated economically. Benzene may also be produced by the dealkylation of toluene.

Benzene is a toxic substance, and prolonged exposure to concentrations in excess of 35–100 parts per million in air may lead to symptoms ranging from nausea and excess fatigue to anemia and leukopenia. *See* Aromatic hydrocarbon. [C.K.B.]

Benzoic acid An organic acid, also known as benzene carboxylic acid, with the formula below. Melting point is 250.2°F (121.2°C), and the acid sublimes at 212°F (100°C). Benzoic acid is only slightly soluble in water but is soluble in most organic solvents, and reacts with bases to form the corresponding benzoate salts. Benzoic acid was first obtained by sublimation from gum benzoin. It occurs both free and combined in nature, being found in many berries (cranberries, prunes, cloves) and as the end product of phenylalanine metabolism.



$$C_6H_5-\overset{\overset{O}{\|}}{C}-OH$$

Benzoic acid is prepared in the laboratory by the Grignard reaction, hydrolysis of benzonitrile (C_6H_5CN), or prolonged oxidation of alkyl benzenes with potassium permanganate regardless of the length of the alkyl group. Commercially it was previously prepared by the chlorination of toluene ($C_6H_5CH_3$) with the subsequent hydrolysis of the benzotrichloride ($C_6H_5CCl_3$), and by the monodecarboxylation of phthalic anhydride (from naphthalene). Modern preparation is by the catalytic oxidation of toluene at elevated temperatures with a cobalt catalyst, and purification by sublimation. *See* Grignard reaction.

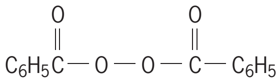
Benzoic acid undergoes the normal reactions of the aromatic ring (nitration, sulfonation, halogenation, alkylation). Groups are inserted in the meta position due to the directive influence of the carboxyl group. Substitution occurs less readily than with ortho- or para-directing groups due to the deactivating effect of the meta-directing group. Ortho or para derivatives can be obtained with some starting materials other than the acid. Benzoic acid also undergoes the usual reactions of the carboxyl group, forming acyl halides, anhydrides, amides, esters, and salts. *See* Halogenation; Nitration; Substitution reaction.

Sodium benzoate is the only salt of importance. It is water-soluble, has antipyretic and antiseptic properties, is useful as a corrosion inhibitor with sodium nitrite if used for iron, and is also used to modify alkyd resins by increasing hardness, adhesion, and gloss.

Esters of benzoic acid are also found in nature. They are almost universally fragrant. Methyl benzoate is the fragrant principle in tuberose. Some esters of benzoic acid are used in the perfume industry, for example, benzyl ester as a fixative. The butyl ester is used as a dye carrier because of its desirable biodegradable properties; and glycol esters are used as plasticizers. *See* Ester.

Uses for both benzoic acid and its derivatives include the pharmaceuticals and synthetic polymers. Benzoic acid is used in preservatives and many cosmetics. The derivatives are used in the dyeing industry, with some applications in the cosmetic industry. Pure benzoic acid is a standard for bomb calorimetry because of its ease of purification by sublimation. *See* Calorimetry. [E.H.H.]

Benzoyl peroxide A chemical compound, sometimes called dibenzoyl peroxide, with the formula below. It is a colorless, crystalline solid, melting point 106–108°C (223–226°F), that is virtually insoluble in water but very soluble in most organic solvents. Benzoyl peroxide is an initiator, a type of material that decomposes at a controlled rate at moderate temperatures to give free radicals. *See* Free radical.



$$C_6H_5\overset{\overset{O}{\|}}{C}-O-O-\overset{\overset{O}{\|}}{C}-C_6H_5$$

Benzoyl peroxide has a half-life (10 h at 73°C or 163°F in benzene) for decomposition that is very convenient for many laboratory and commercial processes. This, plus its relative stability among peroxides, makes it one of the most frequently used initiators. Its primary use is as an initiator of vinyl polymerization. It also is the preferred bleaching agent for flour; is used to bleach many commercial waxes and oils; and is the active ingredient in commercial acne preparations. *See* Bleaching; Polymerization.

Benzoyl peroxide itself is neither a carcinogen nor a mutagen. However, when coapplied with carcinogens to mouse skin it is a potent promoter of tumor development. All peroxides should be treated as potentially explosive, but benzoyl peroxide is one of the least prone to detonate. *See* Mutagens and carcinogens. [Wi.A.P.]

Bering Sea A water body north of the Pacific Ocean, 875,000 mi^2 (2,268,000 km^2) in area, bounded by Siberia, Alaska, and the Aleutian Islands. The Bering Sea is a biologically productive area, with large populations of marine birds and mammals. An active pollock fishery and a developing bottomfish industry are evidence of its rich biological resources.

The Bering Sea consists of a large, deep basin in the southwest portion, where depths as great as 9900 ft (3000 m) are encountered. To the north and east, an extremely wide, shallow continental shelf extends north to the Bering Strait. The two major regions are separated by a shelf break, the position of which coincides with the southernmost extent of sea ice in a cold season. Ice is a prominent feature of the Bering Sea shelf during the cold months. Coastal ice begins to form in late October, and by February coastal ice is found in the Aleutians. The sea ice may extend as far south as 58°N. Thus, the ice edge in the eastern Bering Sea advances and retreats seasonally over a distance as great as 600 mi (1000 km). Ice-free conditions can be expected throughout the entire region by early July. *See* SEA ICE.

The main water connections with the Pacific are in the west of the Aleutian Islands, the 6600-ft-deep (2000-m) pass between Attu and Komandorskiye Islands and the 14,000-ft-deep (4400-m) pass between the Komandorskiyes and Kamchatka. Aleutian passes also serve to exchange water. The Bering Sea connection with the Arctic Ocean (Chukchi Sea) is the Bering Strait, 53 mi (85 km) wide and 30 mi (45 m) deep.

Tides in the Bering Sea are semidiurnal, with a strong diurnal inequality typical of North Pacific tides. Three water masses are associated with Bering sea water—Western Subarctic, Bering Sea, and the Alaskan Stream. The general circulation of the Bering Sea is counterclockwise, with many small eddies superimposed on the large-scale pattern. The currents in the Bering Sea are generally a few centimeters per second except along the continental slope, the coast of Kamchatka, and in certain eddies, where somewhat higher values have been found. *See* OCEAN CIRCULATION; TIDE. [V.A.]

Berkelium Element number 97, symbol Bk, the eighth member of the actinide series of elements. In this series the 5*f* electron shell is being filled, just as the 4*f* shell is being filled in the lanthanide (rare-earth) elements. These two series of elements are very similar in their chemical properties, and berkelium, aside from small differences in ionic radius, is especially similar to its homolog terbium. *See* PERIODIC TABLE; RARE-EARTH ELEMENTS; TERBIUM.

Berkelium does not occur in the Earth's crust because it has no stable isotopes. It must be prepared by means of nuclear reactions using more abundant target elements. These reactions usually involve bombardments with charged particles, irradiations with neutrons from high-flux reactors, or production in a thermonuclear device.

Berkelium metal is chemically reactive, exists in two crystal modifications, and melts at 986°C (1806°F). Berkelium was discovered in 1949 by S. G. Thompson, A. Ghiorso, and G. T. Seaborg at the University of California in Berkeley and was named in honor of that city. Nine isotopes of berkelium are known, ranging in mass from 243 to 251 and in half-life from 1 hour to 1380 years. The most easily produced isotope is ^{249}Bk, which undergoes beta decay with a half-life of 314 days and is therefore a valuable source for the preparation of the isotope ^{249}Cf. The berkelium isotope with the longest half-life is ^{247}Bk (1380 years), but it is difficult to produce in sufficient amounts to be applied to berkelium chemistry studies. *See* ACTINIDE ELEMENTS; TRANSURANIUM ELEMENTS. [G.T.S.]

Bermuda grass A long-lived perennial (*Cynodon* spp.) that originated in Africa. It is believed that in the early 1500s Spanish explorers unintentionally brought the first common Bermuda grass seeds to the Western Hemisphere with the hay that fed their horses. The weedy common type, *C. dactylon* (the type species), can now be found throughout the tropical and subtropical regions of the world. *Cynodon dactylon* is an extensively creeping grass with both stolons and rhizomes. It has short leaves borne on 8–12-in. (20–30-cm) upright culms with several slender seed-bearing spikes digitate at their summit. It is propagated by planting seed, stolons, rhizomes, or green stems cut at an advanced hay stage. It is well adapted to a wide range of soil types, tolerates a pH range from 4.0 to over 8.0, prefers well-drained soils, is very drought-tolerant, and responds well to fertilization. It grows best during high summer temperatures, grows little at temperatures below 65°F (18°C), and goes dormant when temperatures drop below 30°F (−1°C). Although a weed in cultivated fields, it controls erosion, makes excellent turf, and supplies good grazing for all classes of livestock. *See* CYPERALES; LAWN AND TURF GRASSES.

Bermuda grass is a highly variable, heterozygous, cross-pollinated species. Breeding work, begun in 1936, has produced a number of superior F_1 hybrids that are sterile and must be propagated vegetatively. Vegetative propagation is facilitated by the rapid spread of the aboveground stolons of the new hybrids. The top turf Bermuda grasses, Tifgreen, Tifway, and Tifdwarf, are the best of a number of F_1 hybrids between selected plants of *C. dactylon* and *C. transvaalensis*. Tifdwarf, tolerant of daily mowing at 3/16 in. (0.5 cm), is unsurpassed for use as top-quality turf for golf greens and bowling greens. Tifgreen, also bred for golf greens, must be mowed at a higher cut. Tifway, more resistant to pests, weeds, and frost, is the best Bermuda grass for golf fairways and tees, lawns, and athletic fields. People suffering from asthma and hay fever find Bermuda grass pollen to be one of the worst offenders. The sterile turf Bermuda grass hybrids solve this problem by producing no pollen. *See* ASTHMA; GRASS CROPS; POLLEN. [G.M.Bu.]

Bernoulli's theorem An idealized algebraic relation between pressure, velocity, and elevation for flow of an inviscid fluid. Its most commonly used form is for steady flow of an incompressible fluid, and is given by the equation below, where p is

$$\frac{p}{\rho} + \frac{V^2}{2} + gz = \text{constant}$$

pressure, ρ is fluid density (assumed constant), V is flow velocity, g is the acceleration of gravity, and z is the elevation of the fluid particle. The relation applies along any particular streamline of the flow. The constant may vary across streamlines unless it can be further shown that the fluid has zero local angular velocity.

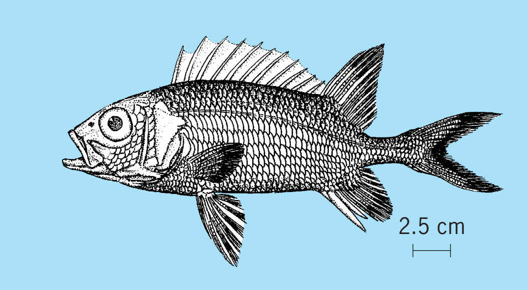
The above equation may be extended to steady compressible flow (where changes in ρ are important) by adding the internal energy per unit mass, e, to the left-hand side. *See* COMPRESSIBLE FLOW.

The equation is limited to inviscid flows with no heat transfer, shaft work, or shear work. Although no real fluid truly meets these conditions, the relation is quite accurate in free-flow or "core" regions away from solid boundaries or wavy interfaces, especially for gases and light liquids. Thus Bernoulli's theorem is commonly used to analyze flow outside the boundary layer, flow in supersonic nozzles, flow over airfoils, and many other practical problems. *See* AERODYNAMICS; BOUNDARY-LAYER FLOW. [F.M.Wh.]

Beroida An order of the phylum Ctenophora comprising two genera, *Beroë* and *Neis*. These are the only ctenophores that lack tentacles throughout their life, and their origin relative to other ctenophores is uncertain. The conical or cylindrical body ranges in size from a few millimeters to about 40 cm (16 in.) and is strongly flattened in the tentacular plane. Beroids range from clear to bluish, orange, pink, and red in color. Comb rows are well developed in all, and run the entire body length in some species. The mouth is large and extensile, lined with bundles of macrocilia that help to grip and swallow prey.

Beroids are actively swimming predators that feed mainly on other ctenophores. On contact, they rapidly engulf the entire prey or bite off large pieces with the macrocilia. The single species of *Neis* is known only from Australia. Numerous species of *Beroë* have been described from all over the world. Many of these are simply variations in color, and there may be only about a dozen valid species. *See* CTENOPHORA. [L.P.M.]

Beryciformes An order of somewhat intermediate position among actinopterygian fishes. Beryciformes, or Berycomorphi, have fin spines (see illustration) and ctenoid scales, an



Squirrelfish (*Holocentrus ascensionis*). (*After G. B. Goode, Fishery Industries of the United States, 1884*)

upper jaw that is bordered by the premaxillae, and a ductless swim bladder and lack a mesocoracoid.

Beryciformes have a rich fossil history extending back to the Upper Cretaceous. Recent representatives are classified in 3 suborders, 12 families, some 30 genera, and about 135 species. They are cosmopolitan in tropical and temperate seas; many are restricted to deep water but some are pelagic and others live in shore waters. Most familiar of the beryciforms are the squirrelfishes and soldierfishes, family Holocentridae, nocturnal animals found in shallow tropical and subtropical reefs. Most are reddish in color. *See* ACTINOPTERYGII; OSTEICHTHYES; TELEOSTEI. [R.M.B.]

Beryl The most common beryllium mineral. Beryl, $Al_2[Be_3Si_6O_{18}]$, crystallizes in the hexagonal system. The crystal structure consists of six-membered rings of corner-sharing silicon-oxygen (SiO_4) tetrahedra cross-linked by corner-sharing beryllium-oxygen (BeO_4) tetrahedra to make a three-dimensional honeycomb structure; aluminum-oxygen (AlO_6) octahedra lie between the Si_6O_{18} rings. Beryl has a vitreous luster and is typically white to bluish- or yellowish-green, but it can also be shades of yellow, blue, and pink. Its hardness is 7.5–8 on Mohs scale; it has an imperfect basal cleavage and a specific gravity of 2.7–2.9 (increasing with alkali content). Weakly colored varieties can be confused with quartz or apatite. *See* CRYSTAL STRUCTURE; HARDNESS SCALES.

Beryl is a minor accessory mineral in many natural environments, most commonly in granites and associated hydrothermally altered rocks. Granitic pegmatites constitute the major source of beryl (used for beryllium and gemstones); rarely, single crystals weigh many tons. Alkali-rich beryl occurs in complex pegmatites which contain abundant rare-element minerals such as spodumene, lepidolite, and tourmaline. Alkali-poor beryl occurs in mineralogically simple pegmatites, tin and tungsten deposits, and hydrothermal veins. The gem varieties of beryl, aquamarine (blue), emerald (deep green), and morganite (pink to red), are produced from pegmatites (aquamarine, morganite, some emerald), veins (some aquamarine, most emerald), and, rarely, rhyolites (ruby-red morganite). *See* BERYLLIUM; BERYLLIUM MINERALS; PEGMATITE; SILICATE MINERALS. [M.D.B.]

Beryllium A chemical element, Be, atomic number 4, with an atomic weight of 9.0122. Beryllium, a rare metal, is one of the lightest structural metals, having a density about one-third that of aluminum. Some of the important physical and chemical properties of beryllium are given in the table. Beryllium has a number of unusual and even unique properties. *See* PERIODIC TABLE.

The largest volume uses of beryllium metal are in the manufacture of beryllium-copper alloys and in the development of beryllium-containing moderator and reflector materials for nuclear reactors. Addition of 2% beryllium to copper forms a nonmagnetic alloy which is six times stronger than copper. These beryllium-copper alloys find numerous applications in industry as nonsparking tools, as critical moving parts in aircraft engines, and in the key components of precision instruments, mechanical computers, electrical relays, and camera shutters. Beryllium-copper hammers, wrenches, and other tools are employed in petroleum refineries and other plants in which a spark from steel against steel might lead to an explosion or fire. *See* ALKALINE-EARTH METALS; BERYLLIUM ALLOYS.

Physical and chemical properties of beryllium

Atomic and mass properties	
Mass number of stable isotopes	9
Atomic number	4
Outer electronic configuration	$1s^22s^2$
Atomic weight	9.0122
Atomic diameter	0.221 nm
Atomic volume	4.96 cm^3/mole
Crystal structure	Hexagonal close-packed
Lattice parameters	$a = 0.2285$ nm $c = 0.3583$ nm
Axial ratio	$c/a = 1.568$
Field of cation (charge/radius^2)	17
Density*, 25°, x-ray (theoretical)	1.8477 ± 0.0007 g/cm^3
Density, 1000°, x-ray	1.756 g/cm^3
Radius of atom (Be^0)	0.111 nm
Radius of ion, Be^{2+}	0.034 nm
Ionization energy ($Be^0 \rightarrow Be^{2+}$)	27.4 eV
Thermal properties	
Melting point	1285°C (2345°F)
Boiling point†	2970°C (5378°F)
Vapor pressure ($T = K^\circ$)	$\log P$ (atm) $= 6.186 + 1.454 \times 10^{-4}T - (16{,}700/T)$
Heat of fusion	250–275 cal/g
Heat of vaporization	53,490 cal/mole
Specific heat (20–100°)	0.43–0.52 cal/(g)(°C)
Thermal conductivity (20°)	0.355 cal/(cm^2)(cm)(s)(°C) (42% of copper)
Heat of oxidation	140.15 cal
Electrical properties	
Electrical conductivity	40–44% of copper
Electrical resistivity	4 microhms/cm (0°C) 6 microhms/cm (100°C)
Electrolytic solution potential, Be/Be†	$E^0 = -1.69$ volts
Electrochemical equivalent	0.04674 mg/coulomb

*Measured values vary from 1.79 to 1.86, depending on purity and method of fabrication.

†Obtained by extrapolation of vapor pressure data, not considered very reliable.

Beryllium has found many special uses in nuclear energy because it is one of the most efficient materials for slowing down the speed of neutrons and acting as a neutron reflector. Consequently, much beryllium is used in the construction of nuclear reactors as a moderator and as a support or alloy with the fuel elements. *See* NUCLEAR REACTOR.

The following list shows some of the principal compounds of beryllium. Many of the compounds listed are useful as intermediates in the processes for the preparation of ceramics, beryllium oxide, and beryllium metal. Other compounds are useful in analysis and organic synthesis.

Acetylacetonate
Ammonium beryllium fluoride
Aurintricarboxylate
Basic acetate,
  $BeO \cdot Be_3(CH_3COO)_6$
Basic beryllium carbonate
Beryllate, $BeO_2{}^{2-}$
Beryllium ammonium
  phosphate
Bromide, BeB_2
Carbide, Be_2C
Chloride, $BeCl_2$
Dimethyl, $Be(CH_3)_2$
Fluoride, BeF_2
Hydroxide
Nitrate,
  $Be(NO_3)_2 \cdot 4H_2O$
Nitride, Be_3N_2
Perchlorate,
  $Be(ClO_4)_2 \cdot 4H_2O$
Oxide, BeO
Plutonium-beryllium, $PuBe_{13}$
Salicylate
Silicates (emerald)
Sulfate, $BeSO_4 \cdot 4H_2O$
Uranium-beryllium, UBe_{13}

Beryllium is surprisingly rare for a light element, constituting about 0.005% of the Earth's crust. It is about thirty-second in order of abundance, occurring in concentrations approximating those of cesium, scandium, and arsenic. Actually, the abundances of beryllium and its neighbors, lithium and boron, are about 10^{-5} times those of the next heavier elements, carbon, nitrogen, and oxygen. At least 50 different beryllium-bearing minerals are known, but in only about 30 is beryllium a regular constituent. The only beryllium-bearing mineral of industrial importance is beryl. Bertrandite substitutes for beryl as a domestic source in the United States. *See* BERYL. [J.Sch.]

Beryllium alloys Dilute alloys of base metals which contain a few percent of beryllium in a precipitation-hardening system. Although beryllium has some solid solubility in copper, silver, gold, nickel, cobalt, platinum, palladium, and iron and forms precipitation-hardening alloys with these metals, the copper-beryllium system and, to a considerably lesser degree, the nickel-beryllium alloys are the only ones used commercially. *See* BERYLLIUM.

In addition to these precipitation-hardening systems, small amounts of beryllium are used in alloys of the dispersion type wherein there is little solid solubility (Al and Mg). Various amounts of beryllium combine with most elements to form intermetallic compounds. Development of beryllium-rich alloys has been chiefly confined to the ductile matrix Be-Al, Be-Cu solid solution alloy with up to 4% Cu, and dispersed-phase-type alloys having relatively small amounts of compounds (0.25–6%), chiefly as BeO or intermetallics, for dimensional stability, elevated temperature strength, and elastic limit control. *See* ALLOY.

Primary applications of beryllium-copper alloys are found in the electronics, automotive, appliance, instrument, and temperature-control industries for electric current–carrying springs, diaphragms, electrical switch blades, and other devices. Applications in structural aerospace and nuclear fields are submarine repeater cable housings for transoceanic cable systems, wind tunnel throats, liners for magnetohydrodynamic generators for gas ionization, and scavenger tanks for propane-Freon bubble chambers in high-energy physics research.

Beryllium intermetallic compounds (beryllides) have high strength at high temperature, good thermal conductivity, high specific heat, and good oxidation resistance. Beryllides are formed with actinide and rare metals, as well as with the transition metals. They are of interest to the nuclear field, to power generation, and to aerospace applications. Evaluation of the intermetallics as refractory coatings, reactor hardware, fuel elements, turbine buckets, and high-temperature bearings has been carried out. [W.W.Be./W.D.T.]

Beryllium metallurgy Beryllium metallurgy involves two processes for the extraction of beryllium oxide or hydroxide from beryl ore. There are also two methods employed to reduce BeO to beryllium metal. The two extraction methods are based on dissolving beryl as either a fluoride or a sulfate. Reduction is accomplished thermally by means of magnesium with beryllium fluoride, and electrolytically with beryllium chloride. Over 90% of the metal is made from the thermal process.

Vacuum-cast beryllium ingots either are produced as raw material for the powder-metal process, which accounts for over 90% of the material being used, or are cast directly for fabrication. Machined parts are usually made from powder-metal products, while ingot beryllium is usually rolled or otherwise worked. *See* BERYLLIUM.

Beryllium can be welded, soldered, brazed, or plastically bonded, with brazing and plastic bonding, as well as mechanical fasteners, being the usual production methods. Surface protection of finished beryllium surfaces can be provided by anodizing, plating, optical polishing, or using conversion coatings. Chemical machining and chemical milling are used to provide patterned and low-damage surfaces.
